The **Measure** is the unit of information in the *Energy Efficiency Manual*. Each Measure is a self-contained, hands-on guide to one specific method of saving energy and reducing utility costs.

the **Measure number** locates this Measure within the 400 Measures of the *Manual*.

the **Section** tells you the major subject area, such as boilers, water systems, or lighting.

the **Subsection** tells you the specific type of energy system, such as boiler fuel systems. Or, it tells you a specific area of efficiency, such as reducing solar cooling load.

the **sequence number** within the Subsection. The Measures are grouped logically.

the **subsidiary sequence number**. Only "subsidiary" Measures have this.

NOTE: In the text, "ff" after a Measure number means "the Measure and every Measure that is subsidiary to it."

SUMMARY

A convenient and accurate method of matching lighting to changing requirements. Vulnerable to poor user instructions.

Ease of Retrofit	☺ ☺ ☺

Programmable lighting controls allow you to change instantly from one pattern of lighting to another by selecting different groups of fixtures. A programmable lighting controller is simply a multi-pole, multi-position switch that activates relays in patterns. The controller can store a variety of patterns for instant recall. The patterns are selected by the installer or by the facility staff. Modern programmable switches are solid state devices.

Programmable switching requires relay lighting control, which is explained in Measure 9.6.4, above. As with all relay-controlled lighting, the degree of control flexibility depends of the number and arrangement of lighting relays.

A typical application for programmable switching is in a multipurpose space, such as a school cafeteria. The controller turns on all the lights except those near the windows. For evening functions, the controller turns on all the lights except those in the cafeteria.

Programmable switching is convenient, particularly in preparation hours, only when the lights are needed. And so for each fixture, although the controller is somewhat awkward to use in a space with many fixtures. Programmable controllers improve the control of lighting relays.

the extent that they increase the likelihood that users will use the controller for lighting to the activities.

User Instructions

• how to program lighting controls. They have been the desired selection. They are often installed in a convenient location. If the controller does not have clear instructions, you have to create them. Programmable controllers are available for guidance on how to do this.

ECONOMICS

SAVINGS POTENTIAL: 10 to 70 percent of the energy of controlled lighting, depending on fixture and activity layout. Lamp and replacement labor costs may be reduced by similar amounts.

COST: Several hundred to several thousand dollars, for the programmable controller itself and \$50 to \$200 per fixture to install relay lighting control.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: All models are probably reliable. Select equipment to be as user-friendly as possible. Try out the models you are considering before you buy.

INSTALLATION: Install the equipment in an obvious, easily accessible location. Invest the effort to produce clear instructions.

MONITOR PERFORMANCE: Check periodically to see whether the programmable switches are being used appropriately.

Economics rates the Measure in terms of three primary financial criteria. You must make detailed estimates for your individual applications.

Savings Potential states the amount of savings you can expect, usually expressed as a fraction of the system's operating cost.

Cost indicates the amount of money required. Gives you specific equipment and labor costs where possible.

Payback Period estimates the length of time needed to pay off the investment.

Traps & Tricks alert you to factors that threaten success. Gives you hints for getting it right the first time and for keeping the Measure effective in the long term.

the **Measure title** says what to do.

the **Summary** highlights aspects of the Measure that place it in perspective within your overall efficiency program.

the **text** of the Measure explains **who, what, where, when, how, and why**. It focuses on issues that are directly related to accomplishing the Measure. (Important background information for the Measures is in the **Reference Notes**, Section 11.)

the **Ratings** suggest the priority that this Measure deserves in your overall energy conservation program, in typical situations.

 - ☺ **VERY CHALLENGING.** Can be unpleasant, likely to be resisted. Or, installation is difficult and expensive. Or, requires major experimentation.

How to Use the *Energy Efficiency Manual*

The *Energy Efficiency Manual* is your primary tool for improving energy efficiency and reducing your utility costs. It is a comprehensive, step-by-step guide that is designed to help you manage your activities effectively and with confidence.

The core of the *Energy Efficiency Manual* is 400 energy efficiency “Measures.” The Measures have a standard format that makes it easy to organize them into an optimum efficiency program for your facility. Refer to the inside of the front cover to learn how to exploit the Measures.

The Measures are grouped into Sections and Subsections. These correspond to *types of energy systems* (for example, boilers, chillers, or lighting) or to *energy waste in specific components* (for example, air leakage through doors, or solar heat gain through windows). This arrangement lets you quickly identify whole groups of Measures that may or may not apply to your facility. For example, if your boilers are fueled by natural gas, you can bypass the Subsection that deals with fuel oil systems. Use the Table of Contents to find the Sections and Subsections that apply to your situation.

The Reference Notes, the last Section of the book, serve you in two important ways. They support the Measures with additional explanation, which may be more basic or more advanced than the “working” information in the Measures. Also, you can read each Reference Note by itself for a concise overview of an important energy conservation topic.

Use the Index to find specific topics that interest you, or to find definitions of terms.

- ❑ **If you are involved in new construction** — if you are an architect, an engineer, a construction manager, a contractor, or a code official — use the *Energy Efficiency Manual* as a design review guide. As you develop your design, continually check the *Manual* for efficiency features that you can exploit. Use it to find where the design wastes energy, and to find better ways of saving energy.
- ❑ **If you own, manage, or operate facilities** — anything from a private house to an office complex or hospital or paper mill — use the *Energy Efficiency Manual* to find all your opportunities for savings. Then, use it to prioritize your activities. Finally, let it guide you in accomplishing and preserving your improvements.
- ❑ **If you are a specialist in energy efficiency**, use the *Energy Efficiency Manual* as a designer or facility manager would, depending on whether you deal with new or existing facilities. It will improve the quality of your work and reduce the time you need to provide the best service to your clients.
- ❑ **If you are a student or teacher**, start with the Reference Notes to learn fundamental principles. With each Reference Note, use the related Measures as examples of practical applications.
- ❑ **If you are an advocate for efficiency or the environment**, use the *Energy Efficiency Manual* to learn the real-world aspects of the conservation activities that interest you. The *Manual* will help you to promote resource conservation that produces credible results.

Now, please read “A Personal Note: the Right Way to Do Energy Conservation.”

A PERSONAL NOTE: THE RIGHT WAY TO DO ENERGY CONSERVATION

Improving energy efficiency may be the most profitable thing that you can do in the short term. How much you will actually benefit from this opportunity depends on how you approach it. Please take a few minutes to read the following suggestions about using the *Energy Efficiency Manual* and about your role in energy conservation. Invest a little time in learning how to use the *Manual*, and it will reward you with years of savings and achievement.

If you are involved in new construction — if you are an architect, an engineer, a construction manager, a contractor, or a code official — use the *Energy Efficiency Manual* as a design review guide. As you develop your design, continually check the *Manual* for efficiency features that you can exploit. Use it to find where the design wastes energy, and to find new ways of saving energy.

If you own, manage, or operate facilities — anything from a private house to an office complex or hospital or steel mill — use the *Energy Efficiency Manual* first to find all your opportunities for savings. Then, use it to prioritize your activities. Finally, let it guide you in accomplishing and preserving your improvements.

If you are a specialist in energy efficiency — if you are an energy consultant, a utility energy specialist, or an energy services provider — use the *Energy Efficiency Manual* in the same way, depending on whether you deal with new or existing facilities. You will find that it greatly improves the quality of your work and reduces the time you need to provide service of top quality to your clients.

If you are a student preparing to enter any of these important fields, or if you are a teacher, you will use the *Energy Efficiency Manual* in a different way. Start with the Reference Notes to learn fundamental principles. With each Reference Note, use the related Measures as examples of practical applications.

If your job or your vocation is to advocate efficiency — for example, if you are a government energy official or an environmental advocate — use the *Energy Efficiency Manual* to learn the real-world aspects of the conservation activities that interest you. Both governments and advocacy groups have played an invaluable role in promoting efficiency. At the same time, naive enthusiasm sets the stage for failures,

which undermine public confidence in energy conservation and actually waste energy. The *Energy Efficiency Manual* will help you to promote resource conservation that produces credible results.

How to Use the Energy Efficiency Manual

The *Energy Efficiency Manual* is designed to be your primary tool for improving energy efficiency and reducing your utility costs. It is a comprehensive, step-by-step technical guide, and it also helps you manage your activities efficiently. Learning to use this tool proficiently will take only a few moments.

The core of the *Energy Efficiency Manual* consists of four hundred energy efficiency “Measures.” Each Measure is a specific energy efficiency improvement or cost saving activity. Each Measure gives you the information you need to plan the activity efficiently and accomplish it successfully.

All the Measures have a standard format. This includes special features, Ratings and a Selection Scorecard, that help you to quickly judge the value of each Measure for your applications. Other features, the Summary, Economics, and Traps & Tricks, give you the main features of each Measure. To become familiar with these features, refer to the key to the Measures, inside the front cover, as you browse through the Measures.

The Measures are grouped into Sections and Subsections. These correspond to *types of energy systems* (e.g., boilers, chillers, lighting) or to *energy waste in specific components* (e.g., air leakage through doors, solar heat gain through windows). This lets you quickly identify whole groups of Measures that may or may not apply to your facility. For example, if your boilers are fueled by natural gas, you can bypass the Subsection that deals with fuel oil systems. Use the Table of Contents to select the Sections and Subsections that apply to your facility.

First, find all your opportunities.

Resist the temptation to rush into energy conservation projects without considering all your opportunities first. You may be eager to get started after attending a seminar, or reading an article, or getting a sales pitch. Those are good ways to get an introduction to new concepts, but they are no substitute for knowing all your opportunities.

If you grab at opportunities randomly, you will miss many good ones and waste money. In a facility of any size, there will be many things that you can do to reduce your utility costs. Every building and plant wastes energy in hundreds or thousands of places. Find them all.

There is no way to find the best opportunities first. It is like an Easter egg hunt. You can't tell how big the prizes are until you have searched everywhere and found all the eggs. By the same token, don't expect to find a "short list" of improvements that are best for your facility. Each building and plant wastes energy in different ways.

Your search for efficiency improvements will be time-consuming. (In existing facilities, this search is often called an "energy audit.") Typically, it requires weeks or months. In a large, diverse facility, it may require more than a year. Demand the time to do it right.

A false concept that came out of the popular energy conservation movement of the 1970's is the "walk-through" or "one-day" energy audit. According to this notion, whizzing through a facility reveals energy conservation opportunities by a mystical kind of inspiration. Reject this ouija board approach, even as a starting point. Quickie surveys fool you into believing that you know your options when you really don't.

Budget your time as wisely as your money.

When you complete your list of potential efficiency improvements, your next job is to decide the most effective sequence for accomplishing them. You want to produce the greatest payoff in the shortest time. Be shrewd about managing your program's two most important resources, money and personal capabilities.

The *Energy Efficiency Manual* helps you make the best use of both these resources. The Ratings in each Measure suggest its overall priority, taking into account the economics of the Measure, the difficulty of accomplishing it, and the degree of risk. To refine your ranking, the Selection Scorecard, just below the title, rates these factors individually. At the end of each Measure, the Economics gives you general estimates of the potential savings, the cost, and the rate of return.

Recognize that your time is a more precious resource than the money needed to make the

improvements. Energy efficiency is a profit maker. So, you could borrow money to fund any project that you know will pay off. The skills and effort of the people involved are the real limiting factors. Traps & Tricks, located right after Economics, alert you to aspects of the Measure that will challenge the people involved.

Give priority to the Measures, or groups of Measures, that will produce the largest savings, even though they may not pay off most quickly. Don't divert your time to minor activities while there are more important things to be done. On the other hand, if you see that you can accomplish a Measure quickly and reliably, go ahead and do it. Don't waste time analyzing small improvements in detail.

Try to accomplish groups of related Measures together. For example, make all the control improvements to your air handling systems as a single activity. This avoids duplication of effort, saves money in contracting, and produces a better overall system. The *Energy Efficiency Manual* is organized to make this easy for you.

Most important, don't get in over your head at the beginning with a large project that demands all your attention. If a Measure seems overwhelming, defer it until you have more time to study it. Don't start any Measure until you are ready to complete it *successfully*.

Don't expect instant gratification.

The desire for quick and effortless results has ruined more energy conservation projects than any other cause. Rushing into a project blindly is unprofessional. You would not want your surgeon to rush through your operation just to prove how quickly he can do it.

You have heard expressions like "no-cost energy conservation measure," "pick the low fruit," and so forth, to describe retrofit projects that are supposed to be "easy" or "simple." These notions are illusions that lure you into being too hasty. Every opportunity for saving energy requires significant effort, if it is going to work and to endure.

Your willingness to invest the needed effort and time is what guarantees the success of your projects. The *Energy Efficiency Manual* will show you how to make your improvements as quickly and easily as possible.

Rely on proven equipment and methods.

Energy conservation is not a license to use the owner as a guinea pig. In most cases, rely on conventional equipment and methods. Contrary to popular opinion, energy efficiency does not require exotic technology. That's good news. The bad news is that fads in energy conservation have strong appeal, distracting people from proven profit makers. The only good reason to do energy conservation is to produce predictable, certain savings.

Everyone is fascinated by innovation. Innovation drives progress. But, the price of innovation is a big chance of failure. Most owners can't afford that risk. Leave unproven equipment and methods to those who develop new products and have a laboratory budget.

On the other hand, if you are in a position to work at the frontiers of energy efficiency, the *Energy Efficiency Manual* will help you survive as a pioneer. You will find many Measures at the leading edge of energy efficiency (and a few that are just on the outer fringe). These too can be profitable if you give them the attention they need. Riskier Measures have a Rating of "C" or "D", and their Traps & Tricks warn you of the dangers of unexplored territory.

Why is there so much stress on reliability?

The *Energy Efficiency Manual* devotes a lot of attention to the details that make the difference between a reliable system and one that is riddled with problems. This emphasis on avoiding pitfalls and dealing with tricky factors is intended to alert you, not to frighten you. Energy conservation is still a new subject. The blunt truth is that many energy conservation projects have failed, almost always because people ignored vital issues at the outset. These issues are often simple. For example, a common cause of energy waste is failing to mark controls so that people know how to use them.

Only successful projects pay off. We want you to contribute to the successes, not to the failures. The Measures spell out the issues that you need to consider. It's like driving around potholes. Keep your eyes open and don't rush.

Why all the explanations?

A large part of the *Energy Efficiency Manual* is devoted to explaining how things work. There are several important reasons for this. If you understand the principles, you are much less likely to make mistakes. Knowing the principles also enables you

to keep up with changes in technology. And, knowing what you are doing at a basic level turns the work into fun.

The "theory" is located in two places. Each Measure offers the basic information that you need, and if necessary, it suggests where to get more information. Often, a Measure will refer you to one or more Reference Notes. Each Reference Note is a self-contained explanation of a specific topic.

Don't let mere words get in your way.

Each area of design, construction, and facility operation has a separate vocabulary. Architects have one set of jargon, mechanical engineers have another, electrical contractors still another, and so forth. Don't let this deter you from making efficiency improvements in each of these areas. The principles are important, not knowing particular words.

The *Energy Efficiency Manual* keeps the language as simple as possible. For example, we say "lamp" or "light fixture" instead of "luminaire." We say "window" or "skylight" instead of "fenestration." To help you communicate with specialists who may be fussy about language, the *Manual* explains specialized terms in the places where you need to know them.

Fortunately, each area has only a few specialized terms that are important. If you find a word that is unfamiliar, the Index will steer you to a concise, practical explanation.

You don't need much math, but be comfortable with numbers.

You will probably be happy to see that the *Energy Efficiency Manual* uses little mathematics. There are only a few simple formulas, and you need only arithmetic to use them.

Even so, energy efficiency is all about numbers. In most cases, you are not doing something that is fundamentally new. Instead, you are doing something *better*. To judge whether the improvement is worth the cost, you have to be able estimate the benefit in terms of numbers. If you are not comfortable doing the math, or if you need a calculation that requires specialized knowledge, get a specialist to make the calculations for you.

Recognize that energy savings are uncertain to some extent. They are subject to conditions that you cannot predict, including future energy costs,

operating schedules, weather, and human behavior. Make your estimates of savings for a reasonable range of conditions.

Keep your facility efficient for its entire life.

When energy conservation became a public issue during the 1970's, it was promoted by many well-intentioned people who lacked experience in keeping things working. Energy conservation was treated as a magic pill that would cure the disease of energy waste once and for all. In reality, energy waste is a degenerative condition that keeps trying to return.

Maintaining efficiency is like maintaining your physical fitness. You have to keep it up. Design your efficiency improvements to survive as long as the facility. Each Measure that requires maintenance tells you how to keep it profitable.

Let all your information sources work for you.

Capable professionals depend primarily on a few well-worn references. But, they also know how to get information from other sources quickly. Whether you are a professional or not, the *Energy Efficiency Manual* is your primary reference for energy efficiency. However, no single book can tell you everything you need to know. To do battle with energy waste, assemble an armory of information that is appropriate for the level of improvements that you plan to make.

You will see that the *Energy Efficiency Manual* is not cluttered with formulas and tables. When you need detailed engineering data, get it from the appropriate reference books. Fortunately, you need only a few of these. If you are involved at a professional level with heating, air conditioning, refrigeration, or designing a building's skin, you should have the four-volume *ASHRAE Handbook* on your shelf. For electric lighting, the prime reference source is the *IESNA Handbook*.

Many books are available on specialized aspects of energy conservation, such as solar energy, cogeneration, and residential insulation. Don't hesitate to get another book to expand your knowledge about a subject. There is no better bargain. A good book costs almost nothing in comparison with your utility expenses, and it protects your most valuable assets, which are your time and your professional reputation.

Once you decide to use a particular type of equipment, study the catalogs and equipment manuals of different manufacturers. These are a treasure of important details, and they are your most current source of information. But, beware. The big weakness of manufacturers' literature is a selective rendition of the truth. Knowing potential problems beforehand is critical to success, but manufacturers tend to omit or minimize this vital information.

Talk to others.

Two heads are better than one. Seek other people's opinions before you get involved with unfamiliar equipment or procedures. You can get practical advice from books, trade magazines, professional organizations, consultants, colleagues, and vendors. Talk to facility operators for their opinions about how well something really works.

As you do this, take everything with a grain of salt. People's perceptions are distorted by wishful thinking, embarrassment about disappointing outcomes, and inability to measure actual performance. I have listened to experienced plant operators brag about big efficiency improvements that they were convinced they had achieved with gadgets that were purely bogus.

Don't try to do everything yourself.

If you have a big facility, you will not live long enough to make it efficient by yourself. If you try, energy and money will bleed away while valuable efficiency improvements wait to be made.

Spread the work effectively. In a big facility, your main job is to decide which Measures to accomplish, and to make sure that they get done correctly. Use engineers, architects, contractors, specialized consultants, along with the facility staff. As your program gains momentum, you will have your hands full making sure that others do their work correctly.

Many Measures straddle the boundaries of the established design and construction disciplines. For example, successful daylighting requires close coordination between the architect, the lighting designer, the electrical engineer, and the mechanical engineer. You have to bring all these people together and require them to address all the issues that are critical for success. This is not always easy. Select your people for their willingness to listen and learn.

Seize the opportunity!

The most important point is to get started. At every moment, motors and fans are running, lights are turned on, boilers are burning fuel, and other equipment is consuming energy. Some of this energy is being wasted, and it is probably more expensive than you realize. Remember that cost savings are pure profit. You would have to sell a lot more of your product or service to make as much profit as you can from energy efficiency. Start tapping this resource.

On an industry-wide basis, the efficiency of your facilities will increasingly determine whether your organization can continue to survive and compete. On a global scale, improving efficiency is the most satisfactory way for civilization to adapt to declining energy resources and to minimize harm to the environment.

Enjoy yourself.

At this point, you may feel that you got into more than you bargained for. Don't worry. Energy conservation is a bigger challenge than most people expect, but the *Energy Efficiency Manual* breaks it down into easy steps. Set a comfortable pace, and stick with it. Your energy savings will soon show up on your utility bills, and those savings will continue to grow and accumulate.

Your energy efficiency program can be the most interesting and rewarding part of your career. It will give you an opportunity to become involved in every aspect of your industry. There is probably no other way that you can have as much fun while doing something of fundamental importance.

Expression of Gratitude

This book aspires to bring order and understanding to the vast field of energy efficiency. It organizes what I have learned about the subject during a career that has spanned the most exciting years of energy conservation in the United States and the world. Almost everything that I know was learned from others in one way or another. I would like to begin the book by recognizing those who contributed generously and specifically to the book, and also to recognize several persons and organizations who contributed more generally to my education in energy efficiency. This book is largely their achievement. The following brief acknowledgments cannot adequately recognize the individuals who made important contributions. However, I hope that these mentions will be accepted as a token of my deep gratitude.

Clinton W. Phillips, a figure revered in the air conditioning industry for his limitless contributions, erudition, and charm, meticulously reviewed two separate drafts of the material that deals with cooling systems. In addition to checking the text, he made important comments on both the theory of refrigeration and the lore of practical applications.

Henry Borger, a leader in construction research as well as a talented writer on diverse subjects, reviewed the entire book, suggesting improvements in structure and content.

Charles Wood reviewed the text that deals with boiler systems, providing valuable comments on this technical area and on the editorial approach.

Jim Crawford of the Trane Company contributed extensive and detailed information about the fast-changing world of refrigerants. Dave Molin of the Trane Company reviewed the Reference Note on energy analysis computer programs.

Richard Ertinger and Edward Huenniger of Carrier Corporation provided valuable information about the most recent advances in cooling technology.

Ken Fonstad, of the Graham Division of Danfoss, Inc., wrote lucid explanations of the electrical subtleties of variable-frequency motor drives, accompanied by extensive oscilloscope traces that he made. He also contributed a number of illustrations.

Sean Gallagher shared his experience with the practical aspects of lighting retrofits and with utility purchasing in this era of rapid change in the utility industry.

Don Warfield of Solarex provided information about the current state of photovoltaic technology, and made several illustrations available.

Many others contributed information during the twenty years of the book's preparation. It is impossible now to recall all the valuable discussions and presentations. I hope that the individuals will approve of the way that the book reflects their expertise.

Many organizations contributed illustrations that help to achieve the book's goal of bringing to life many unfamiliar and subtle concepts. These organizations are listed in the back of the book. The individuals who were especially helpful in providing the illustrations include Pat McDermott and Claudia Urmoneit of Osram Sylvania; Eric Johnson, Dave McDevitt, and Pat Barbagallo of Carrier Corporation; Jake Delwiche and Dick Figgie of the Trane Company; Thomas Henry and Pam Blasius of Armstrong International; Andrew Olson and Jim Baker of Rite-Hite Corporation; Tania Davero of Advance Transformer Company; Leight Murray and Diane Iaderosa of the Airolite Company; Doby Byers of American Mill Sales; Peter DeMarco of American Standard; John Figan of Bacharach; William McCloskey of Baltimore Aircoil Company; Steve Hill of Blender Products; Roy Nathan of Calmac Manufacturing Corporation; Bob Agnew of Celotex Corporation; Sharon Quint and Bill Garratt of Cleaver-Brooks; Paul Moulton of Construction Specialties, Inc.; Dewey Boggs of Coyote Electronics; Sherri Snow of Danfoss Automatic Controls; Lynn Hamrick of Donlee Technologies; Trish Steele of Dow Chemical Company; Linda Byam of Duo-Gard Industries; Herman Knapp and Keith Knapp of Fuel Efficiency, Inc.; Chris Van Name of Goodway

Tools Corporation; William Bakalich of Hi-Fold Door Corporation; Eric Huffman of Huvco, LLC; Joachim Harasko of IMR Environmental Equipment; Rob Carter of Industrial Combustion; Bruce Keller of Kalwall Corporation; Bob Hanson of Kentube; Judy Kuczynski of Leeson Electric Corporation; Jennifer Vizvary of Lennox Industries; Lee Webster of LightScience Corporation; Don Betts of Ludell Manufacturing Company; Dipti Datta of M&I Heat Transfer Products; Wayne Toenjes and Susie Toenjes of Major Industries; Bob Rank of Paragon Electric Company; Mike Leeming of Parker Boiler Company; Daniel Manna and Juli Stovall of Paul Mueller Company; Steve McNeil of Pennsylvania Separator Company; Larry Wilton of Philips Lighting; Ken Brooks of Preferred Utilities Manufacturing Corporation; Leon Siwek of Pure Water/Clean Air Group; Tom Hilty of Reliance Electric; Eileen Moran of Resources Conservation Inc.; Rick Wirth of Robicon; Henry Warner and Deb Jamour of Ruud Lighting; Mike Schweiss of Schweiss Distributing; Jean Posbic and Cindy Axline of Solarex; Jeff Sommer of Spirax Sarco; Brian Edwards of Sun Tunnel Skylights; James Satterwhite and Cindy Selig of Super Sky Products; Mike Williams of Todd Combustion; Gerry Denza of Unenco Electronics; Jim Carney of Vaughn Manufacturing; Michael Boyd of Vistawall Architectural Products; Jochen Schiwietz of Water Technology of Pensacola; Dorothea Rynearson of WaterFurnace International, and Klaus Reichardt of the Waterless Company.

The archives of Wulfinghoff Energy Services, Inc. yielded many of the figures, found among thousands of photographs that were originally taken as field notes in energy efficiency projects, and among illustrations made for courses and seminars.

Like all who are involved with energy efficiency, I owe a great debt to the American Society of Heating, Refrigerating, and Air Conditioning Engineers, known to the world as ASHRAE. This book's many referrals to the *ASHRAE Handbook* attest to its role as the primary reference for the practice of refrigeration and building design. The Society gave me the opportunity to serve with several committees that defined the course of energy conservation in response to energy crises of the 1970's. Among these responsibilities were helping to organize and to serve as a judge of the ASHRAE Energy Awards, which provided exposure to the energy conservation philosophies of the most innovative engineers of that era. ASHRAE also provided the impetus to write *Managing Your Energy*, the tutorial on the management aspects of energy conservation that became the basis of the Energy Management chapter of the *ASHRAE Handbook*. Another committee assignment gave me the opportunity to investigate how the different types of buildings use energy, then and now a topic that is rife with misconceptions.

I am particularly indebted to the National Capital Chapter of ASHRAE. During the years that I have been a member, the Chapter presented several hundred technical presentations, from each of which I learned something new and valuable. Two individuals stand out for their accomplishments in the Chapter. Jim Wolf, the president when I first began to serve in its offices, created the model of disciplined organization that keeps the Chapter effective to this day. Jim also facilitated technical reviews and illustrations from the Trane Company and American Standard. Jose Reig was the mainstay of the Energy Management Committee when I served as its early chairman, and later supported me when I became responsible for ASHRAE's energy conservation programs in the mid-Atlantic States. His intense dedication to everything he undertakes has been rewarded by the success of the engineering firm that he built.

The George Washington University provided my first platform for teaching energy efficiency to professionals, starting during the late 1970's. This gave me the occasion to consolidate the lessons that were being learned in those heady days of intense interest in energy conservation. The notes of those courses became the early structure of the *Energy Efficiency Manual*.

The U.S. Navy Engineer Officers School, San Diego, provided my first serious introduction to the machinery of energy systems. The School was a model of effective instruction that should be copied by all engineering schools.

My education in energy efficiency would have been inadequate for this task without the practical experience gained while working for the clients of my energy efficiency firm. Improving their facilities taught me the lessons of energy efficiency in the real world, including the diversity of ways that energy is wasted, the importance of details at every step, and the need for relentless maintenance and management attention. I always tried to spare our clients from the fads that were rampant during the infancy of the energy conservation movement. Still, those forward looking managers were the experimental subjects who made progress possible. And, they provided the living that financed the long years of writing.

Among our clients who became good friends, Michael Whitcomb deserves special mention as an extraordinary facility energy manager who aggressively and successfully pioneers important areas of energy efficiency. Our discussions about the practical realities of managing energy systems continue to be instructive.

The *Energy Efficiency Manual* benefited immensely from the editorial review of two extraordinary individuals. Nancy Dashiell, the original and veteran writer and technical editor of U.S. Pharmacopeia *Drug Information* (published by Consumers Union under the title *Complete Drug Reference*), edited the crucial final manuscript of the book and made valuable suggestions about earlier versions. Felicity Evans, whose experience includes service as a government energy official, insisted on essential changes to the early structure and style of the book. Among other important improvements, her suggestions led to the creation of the Reference Notes.

Dan Poynter, renowned parachutist and publishing mentor, made penetrating comments on an early draft that led to a complete rewrite to make the book easy to use by a broad audience.

In the production of the book, one individual stands out. Mark Dorbert, the proprietor of Wet Ink Printing & Graphics, shepherded the book from manuscript to press, rendering the interior design, accomplishing the composition and typesetting, and electronically processing the illustrations. An inspired artist, he also designed the end material. He did an enormous amount of work that would normally require a large team of individuals, mastering the range of prepress skills during a period in which the technology of publishing is changing from month to month. Nothing daunts him, he never slackens the pace, and his humor keeps the work enjoyable.

Cindy Fowler, of Graves Fowler Associates, rendered the cover design flawlessly and quickly, patiently dealing with many details.

Steve Dolan, of Scanners LLC, made the electronic renderings of the author's drawings, putting in many hours of work to meet a short deadline.

<i>How to Use the Energy Efficiency Manual</i>	5
A Personal Note: The Right Way to Do Energy Conservation	7
Expression of Gratitude	13
Section 1: Boiler Plant	17
1.1 Equipment Scheduling and Operating Practices	19
1.1.1 Minimize the Duration of Boiler Plant Operation	20
1.1.1.1 For Applications with Regular Schedules, Install Clock Controls to Start and Stop Boilers	22
1.1.1.2 In Applications That Require a Warm-Up Period, Control Boiler Operation Using an Optimum-Start Controller	23
1.1.1.3 If the Boiler Plant Is Used Only for Comfort Heating, Limit the Operation of the Boiler Plant Based on the Outside Air Temperature	25
1.1.1.4 In Applications Where Automatic Starting and Stopping of Boilers Is Not Desirable, Use Automatic Controls to Signal the Starting and Shutdown Sequence to Operators	27
1.1.2 With Multi-Fuel Boilers, Select the Most Economical Fuel on a Moment-to-Moment Basis	28
1.1.2.1 Install Automatic Fuel Changeover	30
1.1.3 Operate Boiler Auxiliary Equipment Consistent with Boiler Operation and Load	31
1.1.3.1 Interlock Auxiliary Equipment with the Boilers It Serves	33
1.1.3.2 Install Power Switching That Prevents Unnecessary Operation of Spare Pumps	34
1.1.4 Distribute the Heating Load Among Boilers in the Manner That Minimizes Total Plant Operating Cost	34
1.1.4.1 Install an Automatic Boiler Scheduling Controller	38
1.1.5 In Steam Systems, Keep Steam Pressure at the Minimum That Satisfies Equipment and Distribution Requirements	40
1.2 Boiler Plant Efficiency Measurement	43
1.2.1 Test Boiler Efficiency on a Continuing Basis	44
1.2.2 Install Efficiency Instrumentation Appropriate for the Boiler Plant	54
1.2.3 Calibrate Boiler Plant Instruments at Appropriate Intervals	57
1.2.4 Keep Operators Proficient in Using Instrumentation to Maximize Boiler Plant Efficiency	58
1.3 Air-Fuel Ratio	59
1.3.1 Optimize the Air-Fuel Ratio	60
1.3.2 Install Automatic Air-Fuel Mixture Controls	65
1.3.3 Adjust and Repair Air-Fuel Ratio Controls	69

1.4	Burner and Fan Systems	71
1.4.1	Clean, Adjust, and Repair Burner Assemblies at Appropriate Intervals	72
1.4.2	Eliminate Air Leaks in Air Casings, Blower Housings, and Connecting Ducts	74
1.4.3	In Boilers That Are Fired at Inefficiently High Output, Reduce the Maximum Firing Rate	75
1.4.4	Install Burner Systems That Provide the Best Efficiency and Other Features	78
1.4.5	Replace the Motors in Burners and Fans with Models Having the Highest Economical Efficiency	89
1.4.6	Replace Continuous Pilot Flames with Electrical Ignition	89
1.4.7	Install Variable-Output Fan Drives on Large Forced-Draft and Induced-Draft Fans	90
1.5	Draft Control	93
1.5.1	Adjust Draft for Maximum Efficiency	94
1.5.2	Correct Defects in Flue Systems and Boiler Room Ventilation That Cause Draft Problems	99
1.5.3	Minimize Standby Losses	102
1.5.3.1	Control All Fans in the Combustion Air Path to Stop, and All Dampers to Close, When the Burner Is Not Firing	103
1.5.3.2	Install an Automatic Flue Damper	104
1.5.3.3	Install a Burner Assembly or Boiler That Minimizes Standby Losses	106
1.5.3.4	With Cycling Burners, Adjust the Controls to Minimize the Frequency of Firing Cycles	106
1.6	Firesides and Watersides	109
1.6.1	Clean Firesides at Appropriate Intervals	110
1.6.2	Install Soot Blowers in Boilers That Burn Sooting Fuels	112
1.6.3	Optimize Soot Blower Operation	115
1.6.4	Clean Watersides at Appropriate Intervals	116
1.6.5	Avoid Leaving Waterside Deposits When Deactivating Boilers	118
1.7	Combustion Gas Heat Transfer and Heat Recovery	119
1.7.1	Install a Flue Gas Heat Exchanger to Recover Additional Heat	120
1.7.1.1	Install a Conventional (Non-Condensing) Economizer	121
1.7.1.2	Install a Heat Recovery Air Preheater	126
1.7.1.3	Install a Condensing Economizer	129
1.7.1.4	Install a Water Spray Heat Recovery Unit	131
1.7.2	In Firetube Boilers, Install Turbulators	133
1.8	Condensate, Feedwater, and Water Treatment	137
1.8.1	Test and Treat Boiler Water on a Continuing Basis	142
1.8.1.1	Hire a Qualified Consultant and Contractor to Perform Water Treatment	150
1.8.1.2	Install Automatic Water Treatment Equipment	152
1.8.2	Control Top and Bottom Blowdown to Maintain Required Water Quality and Minimize Waste of Boiler Water	153
1.8.2.1	Install Automatic Blowdown Control	157
1.8.3	Install Blowdown Heat Recovery	158
1.8.4	Maximize Condensate Return	163
1.8.4.1	Recover the Heat from Condensate That Must Be Discarded	166

1.8.4.2	Recover the Energy of Hightemperature Condensate That Would Be Lost by Flashing	167
1.8.5	Keep Vacuum Condensate Systems Operating Properly	169
1.8.6	Replace Pump Motors with Models Having the Highest Economical Efficiency	171
1.9	Fuel Oil Systems	173
1.9.1	Adjust Fuel Oil Temperature to Provide the Optimum Viscosity for Burner Efficiency	174
1.9.1.1	Install Automatic Fuel Oil Viscosity Control Equipment	176
1.9.2	Use the Most Economical Heat Source for Fuel Oil Heating	177
1.9.3	Use Fuel Oil Additives to Improve Combustion Efficiency and/or Improve Other Fuel Oil Properties	178
1.9.4	Replace Pump Motors with Models Having the Highest Economical Efficiency	180
1.10	Steam and Water Leakage	181
1.10.1	Monitor Boiler System Water Loss	182
1.10.2	Locate and Repair Steam and Water Leaks at Appropriate Intervals	183
1.10.3	Use the Most Efficient Type of Steam Trap for Each Application	187
1.10.4	Test and Repair Steam Traps on a Continuing Basis	198
1.10.4.1	Install Accessory Devices to Assist in Steam Trap Diagnosis	203
1.10.4.2	Hire Specialists to Perform Periodic Steam Trap Inspections	207
1.10.5	Recover Heat and Water from Steam Vents	208
1.11	Conduction and Radiation Losses	211
1.11.1	Locate and Repair Defective Insulation on All Heating Plant Equipment and Piping	212
1.11.2	Minimize Cooling or Ventilation of Pipe Tunnels and Other Unoccupied Spaces Surrounding Hot Distribution Equipment	216
1.11.3	Route Combustion Air to the Boiler by a Path That Recovers Heat From the Boiler Room	218
1.12	System Design for Efficient Low-Load Heating	225
1.12.1	In Facilities That Operate for Extended Periods with Low Heating Loads, Install a Small, Efficient Lead Boiler	226
1.12.2	Install Localized Heating Units to Allow Shutting Down the Central Plant During Periods of Low Load	230
1.12.3	If It Is Desirable to Reduce the Boiler Operating Pressure, Eliminate High-Pressure Steam Users or Provide Separate High-Pressure Steam Boilers	232
1.12.4	If a Facility Has Several Boiler Plants, Provide Cross Connections That Allow Shutting Down the Least Efficient Boilers	233
Section 2: Chiller Plant		237
2.1	Equipment Scheduling and Operating Practices	239
2.1.1	Distribute the Cooling Load Among Chillers in the Manner That Minimizes Total Plant	240
2.1.1.1	Install an Automatic Chiller Scheduling Controller	243
2.1.2	Use Automatic Controls to Shut Down the Entire Chiller Plant When There Is No Cooling Load	245
2.1.2.1	Control Chiller Plant Operation by Sensing the End-User Cooling Load	246

2.1.2.2	Limit the Operation of the Chiller Plant Based on the Temperature or Enthalpy of the Outside Air	247
2.1.2.3	In Applications with Regular Schedules, Use Time Controls	249
2.1.2.4	In Applications Where Pre-Cooling Is Required, Use Optimum-Start Controllers	249
2.1.2.5	In Applications Where Automatic Starting of Chillers Is Undesirable, Use Automatic Controls to Alert Personnel to Start Them Manually	250
2.1.3	Turn off and Isolate Heat Rejection Equipment When the Corresponding Chiller Turns off	250
2.1.4	In Plants with Multiple Water Chillers, Minimize the Operation of Chilled Water Pumps and Isolate Idle Evaporators	253
2.1.5	Install Power Switching That Prevents Unnecessary Operation of Spare Pumps	260
2.1.6	Turn off Compressor Sump/Crankcase Heaters During Extended Shutdown Intervals	261
2.2	Optimum Operating Temperatures	263
2.2.1	Keep the Chilled Water Supply Temperature as High as Possible	264
2.2.1.1	Reset Chilled Water Temperature Manually	265
2.2.1.2	Install an Automatic Chilled Water Temperature Controller	266
2.2.2	Optimize the Condensing Temperature	267
2.2.2.1	Adjust the Condenser Temperature Manually	270
2.2.2.2	Install Automatic Condenser Temperature Reset Controls	272
2.3	Condenser and Evaporator Heat Transfer Efficiency	275
2.3.1	In Systems with Open-Loop Cooling Towers, Clean Condenser Tube Watersides Regularly	276
2.3.1.1	Install Automatic Condenser Tube Cleaners	277
2.3.2	With Water Chillers, Clean Evaporator Tube Watersides at Appropriate Intervals	279
2.3.3	With Wet Condenser Cooling Systems, Test and Treat Cooling Water on a Continuing Basis	280
2.3.3.1	Hire a Qualified Consultant and Contractor to Perform Water Treatment	282
2.3.3.2	Install and Maintain Automatic Chemical Feeders	282
2.3.4	With Wet Cooling Systems, Adjust the Bleed Rate to Maintain Proper Water Conditions with Minimum Water Consumption	283
2.3.4.1	Install and Maintain an Automatic Bleed Control	285
2.3.5	In Chilled Water Systems, Install Turbulators in the Evaporator Tubes	286
2.4	Heat Rejection Equipment	289
2.4.1	Modulate Fan Output in Heat Rejection Units to Follow the Cooling Load	291
2.4.1.1	Install Variable-Frequency Fan Drives	295
2.4.1.2	Install Variable-Pitch Propeller Fans	297
2.4.1.3	Install Dual or Multi-Speed Motors	299
2.4.2	In Multiple-Cell Cooling Units, Sequence the Fans Efficiently	301
2.4.3	Clean Heat Rejection Units at Appropriate Intervals	302
2.4.3.1	Install and Screen Heat Rejection Units to Minimize Debris Accumulation	305
2.4.4	In Gravity-Flow Cooling Towers, Ensure Proper Water Distribution	307
2.4.5	Keep Heat Rejection Unit Housings and Fittings Intact	308
2.4.6	Avoid Recirculation of Air Through the Same or Adjacent Heat Rejection Units	310
2.4.7	Install Fan and Pump Motors Having the Highest Economical Efficiency	315

2.5	Pump Energy Consumption	317
2.5.1	Adjust the Discharge of Pumps to Match System Flow and/or Pressure Requirements	318
2.5.1.1	Trim Pump Impellers	318
2.5.1.2	Throttle Pump Discharge Valves	319
2.5.2	Install Variable-Flow Chilled Water Distribution	319
2.5.3	Install Pump Motors Having the Highest Economical Efficiency	330
2.6	Compressors	331
2.6.1	If the Compressor Motor Fails, Replace It with a More Efficient Motor	332
2.6.2	Replace Inefficient Compressors with Efficient Units	333
2.6.3	In Centrifugal Chillers, Install Variable-Speed Compressor Drives	335
2.7	Refrigerant Condition	337
2.7.1	Repair Chiller System Leaks	338
2.7.2	Maintain the Proper Refrigerant Charge	342
2.7.3	Operate Purge Units Appropriately	347
2.7.3.1	Install High-Efficiency Purge Units	350
2.7.4	Install Accessories That Prevent Air Leakage into Idle Chillers	352
2.7.5	Drain the Water From the Evaporators and Condensers of Idle Chillers	354
2.8	System Design for Efficient Low-Load Cooling	355
2.8.1	Install Chillers and Auxiliary Equipment of Appropriate Size to Avoid Extended Operation at Low Load	357
2.8.2	Install Local Cooling Units to Allow Shutting Down the Central Chiller Plant During Periods of Low Load	361
2.8.3	If a Facility Has Several Chiller Plants, Provide Cross Connections That Allow Shutting Down the Least Efficient Chillers	364
2.9	Exploiting Low Ambient Temperature for Water Chilling	367
2.9.1	Install Chiller “Free Cooling.”	371
2.9.2	Cool Chilled Water with a Heat Exchanger in the Cooling Tower Circuit	373
2.9.3	Install a Strainer System to Use Cooling Tower Water Directly in the Chilled Water System	375
2.9.4	Install a “Waterside Economizer” System Using Separate Cooling Coils	379
2.9.5	Install a Closed-Loop Atmospheric Cooling Unit in the Chilled Water Circuit	382
2.10	Heat Recovery from Chillers	385
2.10.1	Use Condenser Water Directly for Heating Applications	389
2.10.2	Use an Auxiliary Condenser or Double-Bundle Condenser for Heat Recovery	391
2.10.3	To Recover Large Amounts of Heat at Elevated Condensing Temperature, Install a Heat Recovery Chiller	394
2.10.4	To Recover Small Quantities of Heat at Maximum Temperature, Install a Desuperheater	397
2.10.5	Improve the Quantity or Economics of Heat Recovery by Adding or Increasing Heat Storage	400
2.11	Cooling Thermal Storage	405
2.11.1	Install Cooling Thermal Storage	406

Section 3: Service Water Systems	437
3.1 Reducing Service Water Consumption	439
3.1.1 Repair Water Fixtures Regularly	440
3.1.2 Install Efficient Wash Basin Fixtures	443
3.1.3 Install Efficient Shower Heads	445
3.1.4 Install Shower Valves That Allow Easy Control of Temperature and Flow Rate	448
3.1.5 Provide Instructions for Efficient Use of Water in Showers and Lavatories	450
3.1.6 Install Efficient Toilets	451
3.1.7 Install Efficient Urinals or Improve Existing Urinals	453
3.2 Water Heating Systems	457
3.2.1 Minimize the Hot Water Temperature	458
3.2.1.1 Use Low-Temperature Detergents	461
3.2.2 Install a Separate High-Temperature Water Heater for High-Temperature Applications	462
3.2.3 Install Water Heaters That Have the Lowest Energy Cost and Highest Efficiency	463
3.2.4 Install Supplemental Insulation on Water Heaters	468
3.2.5 Install Automatic Flue Dampers on Fuel-Fired Water Heaters	469
3.2.6 Clean and Adjust the Combustion Systems of Fuel-Fired Water Heaters Periodically	470
3.2.7 Clean Out Scale from Water Heaters Periodically	471
3.2.8 Exploit Interruptible or Storage Rates for Electric Water Heating	473
3.2.9 Control Electric Water Heating to Reduce Demand Charges	477
3.3 Service Water Pumping	479
3.3.1 In Facilities That Have Their Own Service Water Pumps, Configure the System to Minimize Pump Energy Consumption	480
3.3.1.1 Use Multiple Pressurization Pumps	484
3.3.1.2 Install Gravity Tanks or Pressurized Storage Tanks	488
3.3.2 Design Hot Water Recirculation to Minimize Pump Energy	492
3.3.3 Trim Pump Impellers to Eliminate Excess System Pressure	495
3.3.4 Install Power Switching That Prevents Unnecessary Operation of Spare Pumps	495
3.3.5 Install Pump Motors Having the Highest Economical Efficiency	496
Section 4: Air Handling Systems	497
4.1 Minimizing Duration of Operation	505
4.1.1 Turn off Air Handling Systems When They Are Not Needed	506
4.1.1.1 Where Spaces Operate on Regular Schedules, Use Timeclocks to Start and Stop Air Handling Equipment	507
4.1.1.2 Install Optimum-Start Controllers to Adapt Starting Times to Weather Conditions	509
4.1.1.3 In Spaces with Irregular Usage, Install Rundown Timer Switches to Provide User Control of Air Handling System Operation	511
4.1.1.4 In Spaces with Irregular Usage, Install Personnel Sensors to Control Air Handling Equipment	513
4.1.1.5 Assign Responsibility for Operating Air Handling Systems to the Personnel Who Administer the Spaces	515

4.1.1.6	In Applications Where Automatic Starting and Stopping of Air Handling Units Is Undesirable and Operators Are on Duty, Use Automatic Controls to Alert Operators to Turn Systems on and off	516
4.2	Outside Air Intake and Building Pressurization	517
4.2.1	Adjust Outside Air Intake to the Minimum Needed to Satisfy Comfort, Health, and Code Requirements, and to Maintain Proper Building Pressurization	519
4.2.1.1	During Periods of Reduced Occupancy, Control Outside Air Dampers and Exhaust Fans to Reduce the Quantity of Ventilation Air Appropriately	527
4.2.1.2	Control Outside Air Intake by Sensing Air Contaminants	530
4.2.2	Provide Accurate Control of Outside Air Intake and Building Pressurization by Adding a Return Fan or Relief Fans and Improving the Damper Configuration	532
4.2.3	Where Once-Through Air Handling Systems Are Installed Unnecessarily, Modify Them to Provide Recirculation	538
4.2.4	Use Air Cleaning to Reduce the Need for Outside Air Ventilation	539
4.2.5	Provide Outside Air Economizer Cycle Operation of Air Handling Units	547
4.2.6	Install Enthalpy Control of Economizer Cycles	551
4.2.7	Install a Purge Cycle for Overnight Cooling	553
4.2.8	Install an Exhaust Air Heat Recovery System	555
4.2.9	Improve the Envelope Penetrations of Air Handling Systems to Minimize Air Quality Problems, Wind Problems, and Energy Requirements	563
4.2.10	Minimize the Use of Extra Heat for Freeze Protection	568
4.2.11	Eliminate Air Handling System Stratification That Increases Energy Consumption or Reduces Comfort	573
4.3	Single-Zone Systems	579
4.3.1	Install Placards at User Controls to Encourage Efficient Operation	581
4.3.2	If Conditioning Cannot Be Turned off during Unoccupied Hours, Install Temperature Setback	583
4.3.3	Match Fan Output To the Conditioning Load	585
4.3.3.1	Trim Fan Output	588
4.3.3.2	Cycle the Running of the Fans and Other Air Handling System Equipment with the Space Thermostat	588
4.3.3.3	Install Multi-Speed Fan Motors	591
4.3.3.4	Convert the System to VAV Operation	593
4.3.4	Install Thermostatic Controls That Allow Space Temperature to Drift Within Comfortable Limits	596
4.3.4.1	Install Thermostats That Require Manual Switching Between Heating and Cooling	597
4.3.4.2	Install Deadband Thermostats	600
4.3.4.3	Adjust or Modify the Coil Controls to Increase Deadband	603
4.4	Single-Duct Reheat Systems	605
4.4.1	Set the Cooling Coil Discharge at the Highest Temperature That Maintains Satisfactory Cooling	607
4.4.1.1	Install Automatic Chilled Air Temperature Reset Control	610
4.4.2	Turn off the Air Handling Unit Cooling Coils When Cooling Is Not Needed	612

4.4.3	Turn off Reheat Coils When Practical	613
4.4.4	In Terminal Units That Blend Supply Air with Reheated Air, Block the Reheat Passages During the Cooling Season	614
4.4.5	Trim the Fan Output	615
4.4.6	Install Multi-Speed Fan Motors	616
4.4.7	Convert the System to Variable-Air-Volume (VAV) Operation	618
4.4.8	Replace All Reheat Coils in a System with Heating/Cooling Coils and Minimize Operation of the Air Handling Unit Cooling Coil	631
4.4.9	Install Self-Contained Heating/Cooling Units, and Use the Air Handling System Only for Ventilation	634
4.5	Dual-Duct Reheat Systems	637
4.5.1	Keep the Temperature of the Cold Duct as High as Possible and the Temperature of the Hot Duct as Low as Possible	640
4.5.1.1	Install Temperature Reset Controllers for Both the Cold Duct and the Hot Duct	642
4.5.2	Turn off the Heating Coil and/or the Cooling Coil Whenever Practical	643
4.5.3	Trim the Output of the Air Handling System Fans	644
4.5.4	Install Multi-Speed Fan Motors	644
4.5.5	Convert the System to Variable-Air-Volume (VAV) Operation	644
4.6	Multizone Systems	651
4.6.1	Keep the Temperature of the Cold Deck as High as Possible and the Temperature of the Hot Deck as Low as Possible	654
4.6.1.1	Install Temperature Reset Controllers for Both the Cold Deck and the Hot Deck	654
4.6.2	Turn off the Cooling Coil or the Heating Coil Whenever Practical	654
4.6.3	Trim the Fan Output	655
4.6.4	Install Multi-Speed Fan Motors	655
4.6.5	Convert the System to Variable-Air-Volume (VAV) Operation	656
4.7	Variable-Air-Volume Single-Duct Systems	661
4.7.1	In Spaces with Shutoff VAV Terminals, Install Thermostat Placards	662
4.7.2	In Spaces with Shutoff VAV Terminals, Install Deadband Thermostats	664
4.7.3	If the Air Handling Systems Cannot Be Turned off during Unoccupied Hours, Install Temperature Setback	667
4.7.4	Turn off the Air Handling Unit Cooling Coil When Cooling Is Not Needed	669
4.7.5	Minimize the Minimum-Flow Settings of Terminal Units	670
4.7.6	Set the Cooling Coil Discharge at the Highest Temperature That Maintains Satisfactory Cooling	672
4.7.6.1	Install Automatic Chilled Air Temperature Reset Control	673
4.7.7	With Minimum-Flow Terminals, Install Heating/Cooling Changeover	674
4.7.8	Improve the Efficiency of Fan Modulation	677
4.8	Variable-Air-Volume Dual-Duct Systems	681
4.8.1	In Spaces with Shutoff VAV Terminals, Install Temperature Setting Placards on Thermostats	683

4.8.2 In Spaces with Shutoff VAV Terminals, Modify Thermostatic Controls to Maximize Deadband 683

4.8.3 If Air Handling Equipment Cannot Be Turned off during Unoccupied Hours, Install Temperature Setback 684

4.8.4 Turn off the Heating Coil and/or the Cooling Coil Whenever Practical 684

4.8.5 Adjust Minimum-Flow Terminals to Minimize Overlap of Hot and Cold Air Flow 685

4.8.6 Keep the Cold Duct Temperature as High as Possible and the Hot Duct Temperature as Low as Possible 687

 4.8.6.1 Install Duct Temperature Reset Controllers for Both the Cold Duct and the Hot Duct 688

4.8.7 Improve the Efficiency of Fan Modulation 688

4.8.8 Install an Outside Air Economizer Cycle with Separate Hot and Cold Duct Fans 689

4.9 Induction Systems 691

 4.9.1 Maximize the Primary Air Temperature 693

 4.9.1.1 Install Automatic Temperature Reset Control for the Primary Air 694

 4.9.2 Turn off the Air Handling Unit Cooling Coil When Cooling Is Not Needed 695

 4.9.3 Install Temperature Setback 696

 4.9.4 Clean, Adjust, and Repair Induction Terminal Units at Appropriate Intervals 698

 4.9.5 Avoid Discharging Conditioned Air on Exterior Surfaces 699

Section 1. BOILER PLANT

INTRODUCTION

A large fraction of a facility's total energy usage begins in the boiler plant. The cost of boiler fuel is typically the largest energy cost of a facility, or the second largest. For this reason, a relatively small efficiency improvement in the boiler plant may produce greater overall savings than much larger efficiency improvements in individual end users of energy. Also, most boiler plants offer significant opportunities for improving efficiency. These reasons make the boiler plant a good place to start the search for savings.

How to Use Section 1

This Section is organized primarily by the subsystems of the boiler plant. Table 1, on the next page, relates the ways that boiler plants waste energy to these subsystems. Use Table 1 as the first step in identifying the areas for improving your plant. The first two Subsections apply to all boiler plants, and you should start with them. The last Subsection applies only to larger facilities. You can ignore Subsections that do not apply to your particular type of plant.

Before Getting Started ...

Read [Reference Note 30](#), Boiler Types and Ratings, for a quick overview of boiler types and the way they are rated. Read [Reference Note 20](#), Fossil Fuels, to understand the role of boiler fuels in efficiency, operating practices, maintenance, and cost.

Equipment Scheduling and Operating Practices

This is the place to start in reducing your boiler plant's energy consumption. The Measures in this Subsection all deal with control of your boiler plant equipment. They recommend operating practices and automatic controls that limit operation of the heating plant and its major components to conform to need. These Measures may provide large savings at modest cost. Most of them are easy to accomplish.

INDEX OF MEASURES

1.1.1 Minimize the duration of boiler plant operation.

1.1.1.1 For applications with regular schedules, install clock controls to start and stop boilers.

1.1.1.2 In applications that require a warm-up period, control boiler operation using an optimum-start controller.

1.1.1.3 If the boiler plant is used only for comfort heating, limit the operation of the boiler plant based on the outside air temperature.

1.1.1.4 In applications where automatic starting and stopping of boilers is not desirable, use automatic controls to signal the starting and shutdown sequence to operators.

1.1.2 With multi-fuel boilers, select the most economical fuel on a moment-to-moment basis.

1.1.2.1 Install automatic fuel changeover.

1.1.3 Operate boiler auxiliary equipment consistent with boiler operation and load.

1.1.3.1 Interlock auxiliary equipment with the boilers it serves.

1.1.3.2 Install power switching that prevents unnecessary operation of spare pumps.

1.1.4 Distribute the heating load among boilers in the manner that minimizes total plant operating cost.

1.1.4.1 Install an automatic boiler scheduling controller.

1.1.5 In steam systems, keep steam pressure at the minimum that satisfies equipment and distribution requirements.

RELATED MEASURES

- Measures 2.1.2 ff, control of chiller plant equipment
- Measures 4.1.1 ff, control of air handling systems
- Subsection 5.1, for control of room conditioning units and self-contained HVAC equipment

MEASURE 1.1.1 Minimize the duration of boiler plant operation.

A primary principle of energy conservation is turning off equipment when it is not needed. Apply this principle to your boilers and their auxiliary equipment. The subsidiary Measures give you the basic techniques. Select from these to fit your particular situation. Combine the methods, if appropriate.

Energy Saving Potential

If you minimize the operation of the boilers and their auxiliary equipment, you will save energy in these areas:

- **plant and distribution system losses.** Conductive heat losses continue as long as the boiler plant is hot, and leaks continue as long as the boiler plant is kept under pressure. Losses are greatest in plants that are large, that have long distribution systems, and that are poorly maintained.
- **unnecessary energy consumption by boiler plant auxiliary equipment.** Even if the heat demand on a boiler is minimal, some equipment may continue to operate, such as hot water distribution pumps and feedwater pumps that serve larger boilers. The amount of such energy waste depends on the design of the boiler plant.
- **unnecessary operation of user equipment that is not separately controlled.** For example, old steam radiators with manual control valves operate as long as they are provided with steam, regardless of need. The amount of energy waste depends on the amount of user equipment that lacks individual control. (This issue is discussed below.)

Where are the Best Locations to Control Heating?

The first step is to develop a consistent plan of control for heat-using equipment throughout the facility. Decide whether to control heating operation at the plant, at the end-use equipment, or in some combination of these two. Each approach has advantages and disadvantages:

- **minimizing steam consumption by turning off the end-use equipment.** You can install shutdown controls on each item of end-use equipment. From an overall efficiency standpoint, this method is good because each piece of end-use equipment can shut down in accordance with its individual heating requirements. The major disadvantage of this method is the expense and maintenance of having separate controls at each item of end-use equipment. The boiler senses the disappearance of heating load when the end-use equipment shuts off. Boiler output falls as the end-use equipment shuts down,

and no separate boiler plant controls may be required. (Individual control of heating units is covered in [Section 5](#).) However, this method does not eliminate the energy consumed to keep the boiler system warmed up, to replace distribution system losses, and to operate boiler plant auxiliary equipment. To avoid these losses, you need additional controls to shut down the boiler plant itself.

- **minimizing steam consumption by shutting down the boiler plant.** At the other extreme, you may shut down the boiler system, which will shut down all the equipment served by the system. This method is much less expensive than installing individual shutdown controls on the end-use equipment.

This method wastes some energy unless all end-use equipment operates on the same schedule. For example, if the boiler plant serves radiators, operating a boiler to provide heat to one room keeps every radiator in the facility working.

Another disadvantage of this method is that it does not stop the energy consumption of non-heating components of end-use equipment, such as the fans in fan-coil units.

- **minimizing steam consumption when end-use equipment operates on a variety of schedules.** In situations where some end-use equipment operates on a shorter schedule than the boiler plant, you can provide separate shutdown controls just for the equipment that operates on shorter schedules. For example, you might install such controls for the administrative spaces in a hotel, while the guest rooms have heating available continuously or seasonally.

- **minimizing steam consumption using different control criteria.** You can use different methods of shutdown for the boiler plant and the end-use equipment. For example, you might shut down end-use equipment with timeclocks and shut down the boiler plant with an outside air temperature sensor.

There may be many ways to distribute shutdown control of heating within a facility. Your objective is to make the boiler plant respond efficiently to the range of conditions that may occur, including the operating schedule of heating equipment, outside temperature, etc., and to satisfy the constraints of cost, reliability, and maintenance requirements.

What is the Shortest Practical Shutdown Interval?

Shutting down a boiler causes thermal stresses in the boiler itself and in plant equipment, shortening

equipment life and hastening the formation of leaks. In steam systems, allowing the plant to cool causes the steam throughout the system to condense, creating a vacuum that draws air into the system. The degree of adverse effect varies widely, depending on the type of system.

In general, you can shut down smaller boiler plants for shorter periods of time. Starting up and shutting down large boiler plants are major operations, requiring hours to accomplish. Whether to shut down a boiler plant overnight or over a weekend is a decision that you make by comparing all the costs of leaving the system in operation to all the costs of shutting it down. These costs should include labor and maintenance, as well as energy.

Don't Forget to Limit Operation of Auxiliary Equipment

Limit the operation of boiler plant auxiliary equipment along with the operation of the boilers themselves. This equipment includes heating water distribution pumps, feedwater and condensate pumps, control air compressors, and a variety of less energy-intensive equipment. See [Measures 1.1.3 ff](#) for details.

Coordinate with Control of Chiller Plant Equipment

Most of the methods given by the subsidiary Measures for minimizing the operation of a boiler plant

can also be used to minimize the operation of a chiller plant. If the boiler plant is located near the chiller plant, consider combining the control installations. See [Measures 2.1.1 ff](#) for comparison.

Automatic Control is More Efficient than Manual Control

People are not well adapted for starting and stopping equipment at precise times. People are especially unreliable if action is needed at irregular times, and as conditions change. For this reason, use automatic controls wherever possible. The subsidiary Measures emphasize automation for starting and stopping boiler plant equipment. For situations where automatic operation is not advisable, [Measure 1.1.1.4](#) provides a hybrid approach that improves reliability while retaining manual control.

Explain It!

Make it easy for plant operators to understand the desired operating schedule and the operation of automatic controls. Install effective placards at locations that are visible to the persons responsible for controlling the operation of equipment. See [Reference Note 12, Placards](#), for details of effective placard design and installation.

Cleaver-Brooks

MEASURE 1.1.1.1 For applications with regular schedules, install clock controls to start and stop boilers.

In many facilities, the best way to minimize unnecessary boiler plant operation is to use a timeclock to limit operation of the equipment. This method is appropriate for facilities where the need for the boiler plant is limited to specific times.

This is the first of four Measures that provide methods of limiting equipment operation. Expect to use time controls in combination with other methods of control for better tailoring of boiler operation to need.

Preliminary Decisions

As a first step, inventory the heat requirements of each space and application that is served by the boiler plant. From this, decide on the best distribution of operating controls, as discussed under [Measure 1.1.1](#), above.

It is not always simple to know when operation of the boiler plant is actually needed. In addition to operating on a routine schedule, boilers need to be available during unusual periods of facility operation. If a time control prevents a boiler from operating when it is needed, somebody will eventually disable the time control or reset it to a less efficient schedule. This is why effective overrides are an essential part of time control. See [Reference Note 10](#), Clock Controls, for details of overrides.

Selecting Time Control Equipment

Fortunately, you now have a rich field of choice in time controls, and prices are modest. But, don't be hasty in making your selection. Select your time controls to provide reliability, ease of use, scheduling flexibility, and easy override. Use [Reference Note 10](#), Clock Controls and Programmable Thermostats, as a checklist for equipment features, installation practices, and operating procedures.

If your facility has old-style electro-mechanical timeclocks, consider replacing them with newer electronic models to take advantage of internal power backup, multiple schedules, and other features that are important in most timeclock applications.

If you have an energy management control system, you might use it for starting and stopping boiler plant equipment. See [Reference Note 13](#), Energy Management Control Systems, for the advantages and disadvantages of this approach.

Optimum-Start Controls

If the boiler plant needs a variable warm-up period to adapt to changes in the outside temperature, consider

RATINGS

New Facilities	Retrofit	O&M
A	B	

This is the second of a series of Measures that limit the operation of boilers and their auxiliary equipment. The first Measure covers timers that start and stop equipment at fixed times. This Measure uses time control that adapts automatically to changes in weather. This feature is called “optimum-start.”

Description

Optimum-start control is a supplemental feature of time controls that automatically adjusts the equipment start time in response to conditions. The start time usually is based on outside air temperature, and in more sophisticated models, is also based on the inside temperature.

The simplest optimum-start controllers vary the start time based on a fixed relationship to the outside air temperature (and perhaps the inside temperature). This relationship is set manually, and you have to find the optimum setting by trial-and-error. More sophisticated units have the capability to establish an optimized schedule automatically by “learning” from experience.

Time controls that offer an optimum-start feature typically offer several channels of control, each of which can be operated on a separate schedule. For example, the controller could provide different turn-on times for different boilers.

Where to Use Optimum-Start Controls

At the present time, commercially available optimum-start controls are designed for applications where the start time depends on the weather. For example, it may take several hours to warm a building that has been shut down over a cold weekend. This requires starting up the boiler plant well before occupancy of the building begins. The same building may require a much shorter warm-up period the following day. If the boilers are started using simple time controls, operators tend to set the start time for the worst conceivable condition, which wastes heating energy under less severe circumstances.

You can extend the optimum-start principle to any application where there is a definable relationship between the start time and some condition that requires the boiler plant to operate. For example, a boiler plant that provides heat for a manufacturing process might be optimized to start at a time that depends on the size of the batch of product being produced. However, you will have to do this on a custom basis, typically by using a programmable logic controller (PLC).

Low-Temperature Protection

Where freezing or other damage from low temperature is a potential problem, provide supplemental controls to start the boiler plant to avoid this risk. Usually, the best approach is to include a low-temperature override that restarts the boiler plant if the

Paragon Electric Company

temperature at some critical location in the facility falls below a set level.

Methods of Accomplishing Optimum-Start

The simplest and most reliable way to install optimum-start capability is to install an optimum-start controller for the individual items of equipment that you wish to control. Figure 1 shows typical units that have a wide range of capabilities.

You can't retrofit optimum-start capability to existing time controls. You don't need to. Timeclocks with optimum start have become so inexpensive that it is often economical to replace existing timeclocks in order to acquire optimum-start capability. If you do buy a new timeclock to take advantage of optimum start, select the unit for other desirable features. The features of time controls are covered in [Reference Note 10](#), Clock Controls and Programmable Thermostats.

Most centralized energy management control systems offer optimum-start capability. However, this approach is less reliable than using a dedicated optimum-start controller. Also, the cost of a dedicated unit may be lower than the cost of re-programming an existing centralized computer system and connecting it to the boiler plant equipment. See [Reference Note 13](#), Energy Management Control Systems, for the reasons why.

Combine with Optimum-Start for Cooling

Many models of optimum-start controls (but not all) provide optimum start for both heating and cooling. Thus, you can use a single controller for both the chiller plant and the boiler plant. You can also use it with air handling systems, and with other heating and cooling equipment. See [Measure 2.1.2.4](#) for optimum-start with chillers, and [Measure 4.1.1.2](#) for optimum-start with air handling systems.

How to Install the Outside Air Temperature Sensor

Efficient operation of an optimum-start control depends on getting true outside and inside temperature signals. The placement and shielding of the outside air temperature sensor are critical. Install the sensor so that:

- it is exposed to the prevailing outdoor air temperature
- the penetration through the envelope is sealed so that positive pressure inside the building cannot force inside air over the sensor
- sunlight does not heat the sensor, either directly or by heating surrounding surfaces
- precipitation cannot reach the sensor, either directly or by splashing
- it is protected from physical impact.

ECONOMICS

SAVINGS POTENTIAL: 0.1 to 10 percent of heating costs, the percentage being larger in colder climates.

COST: Electronic time controls with optimum-start cost from \$100 to several thousand dollars. Labor costs depend on the difficulty of making connections to the boiler and auxiliaries. The cost of programming an existing computer energy management system for optimum-start is typically several thousand dollars.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

In addition to the cautions in [Measure 1.1.1.1](#), make sure that the outside air temperature sensor is installed properly.

MEASURE 1.1.1.3 If the boiler plant is used only for comfort heating, limit the operation of the boiler plant based on the outside air temperature.

RATINGS

New Facilities	Retrofit	O&M
A	B	

This is the third of a series of Measures that prevent unnecessary operation of the boiler plant. It is limited to boilers or boiler plants that are used only to serve loads that respond to weather. Space heating is the typical application.

The technique is to control boiler plant operation simply by sensing the outside air temperature. This method is cheap, reliable, and effortless. It gives more precise response to weather than the seasonal shutdown that is commonly used for heating plants. Figures 1 and 2 show a couple of typical control installations.

Use the outside air temperature sensor to control plant auxiliary equipment as well as the boilers themselves. Refer to [Measures 1.1.3 ff](#) for this.

Where to Use This Method

The usual application for this method is a boiler plant that is used only for comfort heating. The loads of all the facilities served by the boiler plant must depend on weather in the same way.

WESINC

If a small fraction of the boiler plant load is not related to weather in the same way as the rest of the load, consider separate heating equipment for those applications. For example, you might install localized water heaters to allow you to shut down the boiler plant during warm weather. This approach is recommended by [Measure 1.12.2](#).

Energy Saving Potential

Using outside air temperature to control the operation of the boiler plant saves energy in these ways:

- *by shutting off heating to end uses that tend to waste energy during mild weather.* Common

WESINC

Fig. 2 A simple on-off control This thermostat simply turns the boiler on or off. It is connected to a temperature sensor installed outside the window. The labeling is crude but effective, at least until the next paint job.

examples are apartment complexes, military bases, and campuses where tenants do not pay directly for their utilities and may be negligent in controlling heating. Buildings with openable windows are especially vulnerable to this waste of heating energy. On the other hand, facilities with good end-user thermostatic control have little loss of this type.

- **by reducing standby and distribution losses.** A boiler system suffers heat loss even when there is no end-use heating. Large central heating systems with distribution piping in poor condition may have large losses even when there is no end-use heating load. On the other hand, typical single-building steam heating systems have little loss of this type.
- **by reducing operation of auxiliary equipment.** Heating plants continue to use pump energy, regardless of load, unless the entire plant is turned off. Steam heating systems typically have less auxiliary load during mild weather.

How to Install the Outside Air Temperature Sensor

The only critical aspect of this control method is installing the outdoor temperature sensor. Refer to [Measure 1.1.1.2](#), previous, for details.

ECONOMICS

SAVINGS POTENTIAL: 0.2 to 5 percent of annual heating energy consumption.

COST: Several hundred to several thousand dollars, depending on the existing controls and the difficulty of installing the outside air thermostat.

PAYBACK PERIOD: One year to several years.

TRAPS & TRICKS

INSTALLATION: Make sure that the outside air temperature sensor is installed as described in [Measure 1.1.1.2](#). A temperature reading error of even a few degrees can cause discomfort, leading to abandonment of the energy saving control.

MONITOR PERFORMANCE: Inspect the controls at scheduled intervals to ensure that they are working properly.

MEASURE 1.1.1.4 In applications where automatic starting and stopping of boilers is not desirable, use automatic controls to signal the starting and shutdown sequence to operators.

RATINGS

New Facilities	Retrofit	O&M
A	B	

This is the fourth of a series of Measures that prevent unnecessary operation of the boiler plant. It is useful for plants where it is not acceptable to start or stop the plant automatically. This is typical in large boiler plants where starting may require a sequence of manual operations, such as draining steam lines and preheating feedwater. From a safety standpoint, it may be necessary to have staff present to take action in the event of equipment failure at start-up. Also, it may be dangerous to turn off boilers automatically if they serve a critical function.

Unfortunately, manual starting and stopping is not reliable in terms of minimizing the operation of equipment to conserve energy. Even when operators stand watch at equipment control stations, they may not be able to judge the optimum starting times for the boilers.

A solution is to use the appropriate methods from the previous Measures to indicate when equipment should be turned on and off, rather than operating the systems directly. For example, you can use an optimum-start timeclock to flash a light on an indicator panel when the boilers should be turned on.

Similarly, you can use a series of timers to ensure that the proper auxiliaries are turned on before the boiler starts. For example, the timers can indicate the need for feedwater heating, fuel oil heating, starting of feedwater and condensate pumps, etc., at the appropriate times in advance of signalling the boiler to be lighted.

This type of control can be built into any large control panel, such as the one shown in Figure 1. The controls alert operators with indicator lights and audible signals, preferably associated with a diagram of the plant equipment being controlled. In effect, the panel serves as an automated checklist for start-up and shutdown. An elegantly executed panel invites people to use it.

This method is less expensive than connecting automatic controls to the equipment itself. The connections are simple and do not require specialized knowledge of the equipment controls.

Control Other Plant Equipment with the Same Panel

For greatest efficiency, use this same method to control chillers (see [Measure 2.1.2.5](#)), air handling units (see [Measure 4.1.1.6](#)), and other equipment that must be started and stopped manually.

ECONOMICS

SAVINGS POTENTIAL: 1 to 5 percent of system operating cost.

PAYBACK PERIOD: Less than one year, typically.

TRAPS & TRICKS

DESIGN AND INSTALLATION: Design and install the panel so that it grabs the attention of the operators, with bright indicator lights and loud audible signals. But, don't make it obnoxious, or the operators will disable it.

MAINTENANCE: Test the panel periodically to ensure that it is working properly. Replace the burned-out bulbs, etc.

MEASURE 1.1.2 With multi-fuel boilers, select the most economical fuel on a moment-to-moment basis.

RATINGS

New Facilities	Retrofit	O&M
		B

If you have the capability of using more than one type of fuel or energy source, use the most economical source at all times. This may provide significant savings with minimal effort. It is not uncommon for one of the fuels to be more economical at some times, and less economical at others. For example, a common dual-fuel combination is oil and natural gas. Natural gas may be less expensive than oil in summer, but more expensive in winter.

You expect plant operators to be competent in the technical aspects of plant operation, but don't expect them to know the details of energy pricing. You have to translate your energy pricing and other costs into specific instructions for fuel changeover that the plant operators

Cleaver-Brooks

can follow. See Figure 1. Do this in the four steps explained here.

This Measure shows you how to decide when to change from one energy source to another. The subsidiary Measure recommends automatic changeover, which is possible only under certain conditions.

Step 1: Determine Your Instantaneous Energy Costs

Calculate the cost of all your fuels on a common baseline, such as dollars per million BTU. To do this, get out every one of your boiler fuel contracts and rate schedules. Study them until you understand them completely.

Fuels that you purchase in batches and store on your premises, such as oil and propane, have the simplest pricing. Base your fuel switching decision on how much your fuel is worth at the time. This is not what you paid for the fuel, but what you will have to pay when the time comes to buy the next batch. You will have to use some judgement in deciding this.

Rates for pipeline gas are usually constant over long periods of time, but check your rate schedule to make sure.

Electricity pricing can be complex. See [Reference Note 21](#), Electricity Pricing, to help you understand your electricity rate schedule. Don't be reluctant to call your utility for clarification.

By the time you finish this step, you may learn ways to buy your energy sources more economically.

Step 2: Calculate Your Other Fuel-Related Costs

Your choice of fuel will have cost effects other than the cost of the fuel itself. Take into account:

- **maintenance costs.** For example, burning oil instead of gas increases the need for cleaning firesides, burners, fuel oil heaters, etc.

- **effect on boiler efficiency.** Different fuels have different combustion efficiencies in a particular boiler. Measure the efficiencies using the methods explained in [Measure 1.2.1](#).
- **auxiliary equipment operation.** For example, burning heavy fuel oil instead of light oil increases the cost of soot blowing and fuel tank heating. Burning fuel oil instead of gas requires the operation of fuel oil pumps.

Do not include amortization of equipment that is not affected by your choice of fuel. For example, fuel oil requires storage tanks, but since they already exist, their cost is not a factor in your fuel selection. (Costs of this type are called “sunk costs”, which means that they should have no effect on future economic decisions.)

Express these costs in the same way that you calculated your fuel costs, for example, dollars per million BTU.

Step 3: Decide on the Changeover Conditions

In most cases, you want to change to each of the available fuels as soon as it becomes the least expensive choice, considering the cost factors that you calculated in Steps 1 and 2. Now, you have to decide how and when to decide to change fuels.

If all your fuel prices remain constant for long intervals, review your fuel selection whenever the price of one of the fuels changes. For example, if you can burn light oil or natural gas, you might shift to fuel oil when its price drops to \$0.50 per million BTU less than the price of natural gas. The differential accounts for differences in efficiency, maintenance costs, and auxiliary equipment. You should review the relative prices whenever you buy a new batch of fuel oil or whenever the price of gas changes.

If a fuel price depends on conditions, such as the time of day or the month of the year, you need to take action whenever these conditions change. For example,

if electricity is your least expensive energy source during off-peak hours, switch to the electric boiler during these hours. For predictable changeovers like this, consider automatic changeover, which is recommended by the subsidiary [Measure 1.1.2.1](#).

Step 4: Give the Instructions

The fourth step is effective writing. Compose clear and specific instructions that explain when to switch from one energy source to another. If necessary, include a worksheet for any calculations that need to be done.

If you assign responsibility for deciding changeover to the boiler operators, recognize that they have a strong bias in favor of fuels that require the least equipment maintenance, regardless of cost. Operators prefer to burn gas over oil, and light oil over heavy oil. Unfortunately, the fuels preferred for low maintenance are usually the more expensive. Explain the economic consequences to the operators.

Review the procedure periodically to make sure that it is staying abreast of the latest energy price structures. Make this a permanent item in your operations calendar.

MEASURE 1.1.2.1 Install automatic fuel changeover.

RATINGS

New Facilities	Retrofit	O&M
A	B	

This subsidiary Measure recommends switching fuels automatically in multi-fuel installations. The previous Measure showed you how to decide when to switch.

Automatic fuel changeover is most important when it is desirable to switch fuels frequently or unexpectedly. For example, some gas suppliers offer a discount if gas service can be terminated whenever the outside temperature falls to a certain level. To exploit such opportunities, you need to be able to respond quickly and with certainty. Manual changeover may be unreliable, especially if the boiler plant is unattended.

If electricity is used as an alternate energy source, it is especially important to stop using electricity during the times specified in the electric rate schedule. Failure to do so even one time typically voids the discount that applies to off-peak electricity.

How to Install the Equipment

To switch fuels automatically, you need the right controls to shut down the burner for one fuel safely and start the burner for the other fuel. Dual-fuel boilers almost always have such controls.

To make the changeover automatic, the controls must be able to sense the conditions that determine when to change fuels. For example, if the changeover is based on the time of day, install a timeclock to provide the changeover signal to the burner controls. Similarly, the control signal might be based on outside air temperature or the facility’s total electric demand. Or, the signal might be transmitted by a fuel supplier.

Boiler controls have major safety considerations, so have the work done by a boiler controls specialist.

SUMMARY

A way of ensuring that the most economical fuel is used without relying on continuous operator attention. Still requires periodic management review. Feasible only if fuel changeover relates to a condition that can be sensed automatically.

MEASURE 1.1.3 Operate boiler auxiliary equipment consistent with boiler operation and load.

RATINGS

New Facilities	Retrofit	O&M
□	□	B

In many boiler plants, you can save energy just by being careful how you operate your plant auxiliary equipment. For example, see Figures 1 and 2.

Auxiliary equipment wastes energy when it consumes more energy than is needed to handle the existing level of boiler output. There are two main causes of this waste:

- **operating unnecessary equipment.** A boiler plant typically has duplicate pumps, as in Figure 1, and it may have other duplicate equipment. These units are installed to provide increased reliability, or to accommodate different boiler loads. The plant staff may operate more of the units than are necessary. You can correct this cause of energy waste by improving operating procedures and by installing automatic controls.
- **throttling control of equipment output.** Some auxiliary units are driven at constant speed under all conditions, with their output throttled to follow the boiler load. For example, this is the mode of

operation for combustion air fans on smaller boilers, and for feedwater pumps on many larger boilers. To correct this kind of energy waste, you need to modify the auxiliary equipment or get different kinds.

This Measure and the two subsidiary Measures reduce energy waste from the first of these two causes. This Measure suggests general procedures and the subsidiary Measures recommend control improvements.

Energy waste from the second cause is covered by Measures in [Subsection 1.5](#) (for combustion air fans),

Fig. 2 Stack draft inducer This retrofitted unit, intended to solve a draft problem, was found running continuously. It should be controlled to turn off when the boiler is not firing. Otherwise, it increases standby losses and cools the flue, which kills the draft and causes flue corrosion.

[Subsection 1.8](#) (for water pumps and water treatment equipment), and [Subsection 1.9](#) (for fuel oil pumps).

Energy Saving Potential

The amount of energy you can save, and the potential for wasting energy, varies widely between boiler plants. These factors depend on the amount of energy that is consumed by auxiliary equipment and on how effectively the auxiliary equipment is controlled.

For example, a large boiler plant burning heavy oil may expend five to ten percent of its total energy input to operate auxiliary equipment, and even more under certain load conditions. At the other extreme, a gas-fired boiler with atmospheric burners has virtually no auxiliary energy consumption.

As a rule, energy waste usually does not occur with auxiliary equipment that is controlled in an on-off manner in response to the boiler load. For example, there is no unnecessary operation of an on-off feedwater pump that operates in response to a boiler water level control. If the boiler is not operating, the boiler water level remains constant, and the feedwater pump remains off.

In contrast, one feedwater pump may be used to serve several boilers through solenoid valves. In most such installations, the pump runs continuously, regardless of the needs of the boilers. It is easy to overlook the fact that the pump keeps running even when all the boilers are turned off.

Decide How to Control the Equipment

Start by identifying all the auxiliary equipment in the boiler plant, including:

- heating water circulating pumps
- feedwater pumps
- condensate pumps
- fuel oil pumps
- fuel oil heaters
- equipment for handling solid fuels
- forced draft fans

- induced draft fans
- air compressors for soot blowing
- air compressors for control air
- water treatment chemical feeders
- and, other specialized equipment.

Determine the conditions under which each item is needed. See how each item is controlled to respond to boiler load.

In cases where an item of auxiliary equipment can operate unnecessarily, decide whether you want to control the auxiliary equipment manually or automatically. Manual control is satisfactory in facilities where you can maintain adequate operator training and discipline, but manual control is likely to fail in other environments. If you decide to use automatic control, refer to the subsidiary Measures.

Give the Instructions

Where you decide to retain manual control, give appropriate instructions for operating each unit of auxiliary equipment that has the potential of being operated unnecessarily. Make your instructions clear and permanent. To make the instructions permanent, install an effective placard that explains the relationship between boiler operation and auxiliary equipment operation. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

MEASURE 1.1.3.1 Interlock auxiliary equipment with the boilers it serves.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
A	B	

Measure 1.1.3 recommended minimizing the operation of auxiliary equipment. This is the first of two subsidiary Measures that provide control techniques to make this foolproof.

The most effective method of minimizing the operation of auxiliary equipment is to interlock it with the operation of the boiler. To do this, provide power to the auxiliary equipment through the boiler itself.

This simple technique works even if a particular item of equipment serves several boilers. For example, consider a boiler plant where a single feedwater pump that runs continuously serves several boilers through solenoid valves. There may be long periods when none of the boilers is firing. To shut down the feedwater pump whenever possible, provide power to the feedwater pump through the solenoid valves, using relays. In this way, the feedwater pumps remain off unless any one of the boilers calls for feedwater.

How Much Cycling Can Equipment Tolerate?

This technique may cause some auxiliary equipment to cycle, rather than running continuously. Cycling equipment too often increases maintenance cost and reduces reliability. For example, the life of a motor is shortened if it is turned on and off frequently, say, every minute or two. This effect may negate the value of the energy saving. Therefore, when interlocking auxiliary equipment to boilers, avoid situations in which the equipment is cycled too frequently.

This is a judgement call. For example, the fan in a power burner cycles along with the flame, and service life is satisfactory. By the same token, you should be able to cycle a feedwater pump of modest size. Most pumps and smaller fans tolerate cycling because they do not have much inertia to resist starting. In general, it is practical to cycle smaller equipment more frequently than larger equipment.

Excessively short cycles are likely to be caused by setting the burners to fire over too small a range of temperature or pressure. (See Measure 1.5.3.4 about increasing this range.)

Operation Through Boiler Sequencing Controls

Measure 1.1.4.1 recommends automatic controls to sequence boilers efficiently in multi-boiler installations. Boiler sequencing controls may be able to limit the operation of auxiliary equipment as well. However, you would not install a sequencing controller primarily for this purpose. The method given here is simple, obvious, reliable, and inexpensive. Not every function has to be performed by a microprocessor.

This is the second of two subsidiary Measures that eliminate unnecessary operation of auxiliary equipment. This technique avoids unnecessary operation of duplicate units.

A boiler plant typically has equipment that is installed in pairs for the sake of reliability. Common

examples are pumps for heating water, condensate, feedwater, fuel oil transfer, and fuel oil pressurization. You can avoid unnecessary operation of this equipment simply by installing a transfer switch in the equipment’s power circuits. See [Measure 10.4.1](#) for the details.

MEASURE 1.1.4 Distribute the heating load among boilers in the manner that minimizes total plant operating cost.

RATINGS

New Facilities	Retrofit	O&M
		B

If you have more than one boiler, you may be able to reduce your operating costs by paying attention to the sequence in which you start the boilers, and by the way you distribute the load among them. Here is why:

- boilers of different types, models, and sizes may differ in efficiency by as much as 30%.
- the efficiency of a given boiler may vary significantly at different levels of load. For example, consider a pair of identical boilers whose peak efficiency occurs at 60%, and whose efficiency drops off at higher and lower loads. If the total plant load equals 120% of the full load of one boiler, the two boilers handle the plant load with best efficiency if each operates at 60% load. In contrast, if one boiler were operated at 100% load and the other boiler were operated at 20%, both would be operating well away from their points of maximum efficiency.
- boilers may differ in maintenance cost and in the cost of operating their auxiliary equipment
- different boilers may use different fuels. (This issue was covered by [Measures 1.1.2 ff.](#))

In a nutshell, you want to operate the cheapest combination of boilers and boiler load under all conditions. Doing this involves three steps: (1) calculate the total operating cost of each boiler at all of its firing levels, (2) determine the optimum combination of boilers and boiler loading for each level of overall heating load, and (3) issue effective instructions to operate the boilers at the optimum loading.

The subsidiary Measure changes the third step by recommending boiler sequencing controls that distribute the boiler load automatically.

Boiler Efficiency Characteristics and Energy Saving Potential

To provide background for accomplishing this Measure, let’s quickly review the efficiency characteristics of boilers. This will give you an idea of the benefit that you can expect from sequencing your boilers most efficiently.

There is a distinct difference in efficiency between modern boilers and many older boilers. Some older boilers may have efficiencies as low as 70%, or even lower. When an older boiler is inefficient, the major cause usually is insufficient heat transfer. In such boilers, efficiency drops substantially as load is increased. Also, there is a drop in efficiency at the low end of the load range.

Standby losses may be the most important source of inefficiency in some boilers. The most vulnerable type, boilers with open atmospheric combustion chambers, may average standby losses of 10% over the

course of a year. Standby losses are explained in [Measure 1.5.3](#). There are large differences in the standby losses of different types of boilers. In summary, (1) boilers with open combustion chambers have much higher standby loss than boilers with closed combustion chambers, (2) single-stage burners have more standby loss than staged burners, and (3) burners that modulate over a wide range have little standby loss. In a given boiler, standby losses increase as the load is reduced.

Among the best available industrial-sized boilers, there is little difference in efficiency, for a given fuel. The best modern boilers commonly approach the theoretical maximum efficiency that is practical. Good oil-fired boilers have peak combustion efficiencies ranging from 82% to 85%, depending on the grade of oil for which the boiler is designed. Good gas-fired boilers have peak combustion efficiencies around 81%.

In boilers that are designed for high efficiency, the efficiency does not vary much across the load range. Typically, the efficiency of such boilers is almost constant in the upper half of their load range, falling off a few percent at low loads. The reason for the drop at low load is that losses from such boilers (such as surface radiation) remain constant, so that they assume greater relative significance at lower loads.

There is one significant efficiency difference among modern boilers. Some boilers recover the heat of flue gas condensation, which gives them substantially higher efficiencies than other boilers. These boilers typically have total efficiencies exceeding 90%. They are usually fired by gas.

In general, boilers with low peak efficiency also tend to lose more efficiency if they are not maintained well. For example, if a boiler has inadequate heat transfer surface, it loses efficiency rapidly as fireside and waterside fouling accumulate.

■ How Burner Modulation Affects Efficiency

The ability of a boiler to vary its output is determined by the burner design. Most burners are either single-stage, two-stage, or modulating. A boiler's efficiency changes with output, so the way the burner changes its output determines the boiler's average efficiency.

If the boiler has a single-stage burner, the only boiler efficiency that matters is the efficiency at full output, i.e., with the burner operating. Standby losses are the only influence that can vary the boiler's average efficiency.

With two-stage burners, you are interested in the efficiency at both firing rates. The "low-fire" output is typically about 60% of the "high-fire" (maximum) output, although this may vary. In an efficient boiler, the efficiency at both stages is about the same, since modern boilers are typically designed for peak efficiency at about 80% of full load. In boilers with inadequate

heat transfer, the first stage may be significantly more efficient than the second stage.

Modulating burners can adjust output over a continuous range, extending from full load down to a minimum output. Boilers with multiple burners may have a minimum output close to zero. Single modulating burners typically have a minimum output between 25% and 50% of full load.

If a boiler has an inefficient load range, a modulating burner will allow the boiler to operate in that range. The amount of energy waste depends on the length of time that the boiler is fired in the inefficient load range. This depends on the load profile, on the size distribution of the boilers, and on the way the load is shifted between boilers.

Step 1: Calculate Operating Cost vs. Load for Each Boiler

You need to work with hard numbers, not with assumptions. For example, it is not always true that a load is served most efficiently with the smallest number of boilers, or that a smaller boiler should be shut down when a larger one is started.

The starting point is to find out your actual boiler efficiencies at all their firing rates. Do this by performing combustion efficiency tests, using the methods spelled out in [Subsection 1.2](#).

Combustion efficiency tests do not reveal standby losses. You have to estimate your standby losses from the type of boiler and its typical load profile.

After you have collected your efficiency figures, calculate the fuel cost per unit of output energy for each boiler, at each firing rate.

If your boilers have separate auxiliary equipment, calculate the costs of operating the equipment as a function of load.

If your boilers differ in maintenance cost, calculate the maintenance cost as a function of load.

Now, add all these costs together. This gives you the total operating cost of each of your boilers as a function of load.

(This procedure is similar to the one in [Measure 1.1.2](#) for selecting the most economical fuel in multi-fuel installations. If you have multi-fuel boilers, save effort by doing both sets of calculations at the same time.)

Step 2: Decide the Start-Stop Sequence and Load Sharing

Now that you know the individual cost characteristics of your boilers, you have to figure out how to combine the boilers most economically for each level of overall load. In some cases, this is simple. In other cases, it requires a few hours of time with graph

paper and a calculator. You have to do the most figuring if your boilers are not identical, and especially if their efficiencies overlap in different parts of their load ranges.

The optimum method of distributing the load depends on the type of burner modulation. To avoid confusion, we will discuss the load distribution procedures separately for each type burner.

■ Distributing the Load with Single-Stage Burners

If all the boilers have single-stage burners, the only step necessary is to sequence the boilers in the order of their operating costs.

In normal operation, this requires no special controls and no special effort. The firing of a steam boiler normally is controlled by the steam pressure in the discharge header, and the firing of a hot water boiler normally is controlled by its discharge water temperature. To get the most efficient boiler to operate first, adjust the burner control to start at the highest pressure or temperature, with the other boilers adjusted to start at successively lower pressures or temperatures, in order of their increasing operating cost.

Starting a cold plant needs special attention. Simple firing controls try to start all the boilers together. Ordinarily, you want to warm up the plant using only the most efficient boiler or boilers. Therefore, you have to lock out all the boilers except the most efficient during the warm-up phase.

However, if there is a heavy heating load, the most efficient boilers may not be able to satisfy the load alone, or they may take too long to warm up the system. In this case, the operators must decide which boilers to operate, based on the expected load.

Alternatively, you can use an automatic controller for this purpose. The controller must be able to determine the load, or to predict the load. If the boiler plant is used primarily for comfort heating, you can use an optimum-start controller that responds to changes in the outside temperature. See [Measure 1.1.1.2](#) for details of this equipment.

Don't worry about the efficiency of starting a cold plant if the plant runs continuously, or for an entire season. On the other hand, if a plant is started every day, this can be a major factor.

■ Distributing the Load with Two-Stage Burners

Setting the most efficient firing sequence for boilers with multi-stage burners is only slightly more complex. The trick is to think of each stage of firing as a separate boiler to be sequenced efficiently.

For example, consider a boiler with a two-stage burner that is firing its first stage. As the load increases, should the boiler fire on its second stage, or should a second boiler be started on its first stage? In the form of a table, here are the two choices:

<u>Cut-In Pressure</u>	<u>Boiler Stage</u>			<u>Boiler Stage</u>	
13 PSI	#1	1st		#1	1st
12 PSI	#2	1st	OR	#1	2nd
11 PSI	#1	2nd		#2	1st
10 PSI	#2	2nd		#2	2nd

If both boilers have the same efficiency characteristics, the answer depends on the efficiency of each stage of firing. For example, if both boilers are 80% efficient in the first stage and 76% efficient in the second stage, then start both boilers at the first stage before firing any boiler at second stage.

Conversely, if the first boiler is 80% efficient at both stages, and the second boiler is 76% efficient at both stages, then fire the first boiler to full output before starting the second boiler.

In normal operation, distribute the load between firing stages by setting the turn-on pressures or temperatures for each stage, as with single-stage boilers.

Starting a cold plant that has multi-stage boilers may be somewhat more complex than with single-stage boilers. Virtually all multi-stage boilers are controlled to start at high fire. You will probably need a boiler scheduling controller to let you select the firing sequence of boiler stages between different boilers.

In other respects, starting a cold plant involves the same considerations as with single-stage boilers.

■ Distributing the Load with Modulating Burners

If your boilers have similar cost-vs.-load characteristics, operate all the boilers at equal percentages of load. This general rule applies even if the boilers are different sizes. (For those who are interested in mathematical proof of this, it derives from the fact that the efficiency curves of most boilers are convex upward at all points. The same is likely to be true of the cost curves.)

If your boilers fit this description, how many should you operate? The answer: operate the number that keeps the cost per unit of output as low as possible. For example, if the boilers have the lowest operating cost at 70% load, operate the number that keeps the load on each boiler nearest to this percentage.

With modulating burners, it is easy to keep all the operating boilers near the same percentage of load. Simply set the firing controller of each boiler to the same steam pressure or water temperature.

The situation is more complex if the boilers have different efficiency profiles. For example, if the first boiler is very efficient, do not start the second boiler until the first boiler reaches full load. Conversely, if the first boiler has a serious drop in efficiency at higher

loads, it might be more economical to start the second boiler before the first boiler reaches full load.

If the boilers do not have identical efficiency profiles, you will have to install a specialized controller that modulates the output of each boiler according to a schedule that is programmed into the controller. Each installation must be customized to the characteristics of the boilers. See subsidiary [Measure 1.1.4.1](#) for details.

Warming up a cold plant efficiently involves the same considerations as for single-stage and multi-stage burners, discussed previously.

Step 3: Instruct or Automate

The final challenge is to educate the boiler operators about the operating schedule and to make sure that the procedure is followed. If the boiler load changes continuously, this activity can be tedious. People are involved, so the process may be unreliable. Except in the simplest cases, it is far more reliable to automate this process, as recommended in the subsidiary Measure.

Related Boiler Efficiency Improvements

Some of the other Measures may affect the way you shift load between boilers. For example, if you have multi-stage boilers that suffer low efficiency at high fire, you may eliminate the high-fire setting in one or more of the boilers. ([Measure 1.4.3](#) recommends this.) That

modification converts the boiler to a single-stage boiler of lower capacity, which is easier to coordinate with other boilers.

Keep in mind that the energy consumption of boiler auxiliary equipment may be an important cost factor. See [Measures 1.1.3 ff](#), above, to coordinate auxiliary equipment operation efficiently with boiler operation.

ECONOMICS

SAVINGS POTENTIAL: Typically, 1 to 10 percent of the cost of boiler operation, depending on the relative efficiency characteristics of the boilers that are installed.

COST: Small. The main cost is for the analysis required to create the optimum operating schedule, including boiler efficiency testing.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

CALCULATIONS AND EFFICIENCY MEASUREMENTS: Don't make any assumptions about boiler efficiency. To distribute the load efficiently, you need to know the real efficiencies of all your boilers at all firing levels. Measure these efficiencies yourself.

TRAINING AND COMMUNICATION: The big challenge is keeping the plant operators on top of the procedure. This requires effective training and supervision.

RATINGS

New Facilities	Retrofit	O&M

The manual control procedure recommended by Measure 1.1.4 has a number of weaknesses in all but the simplest boiler installations: it requires operators to be present in the boiler plant whenever boilers are operating, it requires constant attention by the operators, and it requires resetting the boiler firing response whenever an additional boiler is started or stopped.

This subsidiary Measure avoids these shortcomings by using a boiler scheduling controller to automatically sequence boiler firing and to distribute the load among the boilers.

Where to Install a Boiler Scheduling Controller

The additional benefit provided by a scheduling controller depends on the type of burner modulation, on the relative efficiencies of the boilers, and on how often you start a cold plant.

Boilers with single-stage burners can be sequenced satisfactorily simply by sensing the system temperature or pressure, for the reasons discussed in Measure 1.1.4. If all your boilers are single-stage, a sequencing controller is not likely to be useful except when starting a cold plant. In the latter case, a sequencing controller is most valuable if the boilers differ in efficiency.

The same is usually true of boilers with multi-stage burners. Make sure that the burner staging controls can

stagger the firing of different boilers in an efficient sequence. This should not be a problem if the boilers are similar in efficiency characteristics. However, if there are more than two or three boilers with multi-stage burners, conventional staging controls that sense system temperature or pressure independently may cause unstable cycling. In this case, get a sequencing controller.

A controller is usually necessary for optimum automatic sequencing if the boilers have modulating controls, especially if the boilers start and stop automatically.

Fig. 1 Typical control system for optimizing boiler load

How to Select the Controller

A boiler scheduling controller is a simple computer that senses the water temperature or steam pressure and sends the appropriate firing instructions to the burners. Various models are available that differ in sophistication and cost. Figure 1 shows a typical system installation.

Select a controller that has sufficient capability to accommodate differences between the boilers. If modulating burners are used in boilers with different efficiency characteristics, the controller should be able to shift load between the boilers based on the individual control response of each burner.

If the boiler plant is shut down frequently, be sure that the controller can warm up a cold system efficiently.

These functions could be performed with an energy management computer system, or with a general purpose computer that is properly interfaced to the boiler firing controls. However, both approaches require a substantial amount of custom work. Unless the control requirements are unusual, it is quickest and most economical to use a controller that is packaged for this purpose.

■ Combination with Other Functions

The functions of this equipment are sometimes combined with combustion controls and combustion trim systems (Measure 1.3.2). When selecting a controller, determine whether it also makes sense to use it for fuel changeover in multi-fuel systems (Measure 1.1.2.1) or for control of auxiliary equipment (Measures 1.1.3 ff).

Programming the Controller

As with any computer, the accuracy of the control signals sent to the burners depends on the accuracy of the input information. You have to input the burner firing sequences you want. With modulating burners, you have to input the burner firing rates at each pressure or temperature. To determine what these inputs should be,

make the same analysis that is outlined in Measure 1.1.4. Do this before you select the controller. It will help you to decide which controller to buy.

ECONOMICS

SAVINGS POTENTIAL: Typically, 1 to 10 percent of the cost of boiler operation, depending on the relative efficiency characteristics of the boilers that are installed.

COST: A specialized boiler load controller typically costs \$8,000 to \$30,000, depending on the size and complexity of the boiler plant. You may be able to do the job with a programmable logic controller (PLC), which typically costs \$1,000 to \$5,000, but then you have to program the controller. Also, include the cost of boiler efficiency testing.

PAYBACK PERIOD: Several years or longer.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Make sure to select a controller with enough flexibility to handle your combination of boilers. If the plant has boilers of different types, a relatively complex and expensive controller may be needed.

Resist the temptation to perform this function with a general-purpose energy management computer unless you really understand how to program the computer system. Also, such a computer is likely to become obsolete long before the boilers wear out.

PROGRAMMING: Selecting the optimum schedule is not as easy as it may seem, especially if the boilers are of mixed types. Be sure to account for all load conditions.

MONITOR PERFORMANCE: Schedule periodic checks to ensure that the controller is doing what you want, and that no one has tampered with the scheduling sequence.

MEASURE 1.1.5 In steam systems, keep steam pressure at the minimum that satisfies equipment and distribution requirements.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

You can save energy and gain other benefits by keeping the boiler and steam distribution pressures to a minimum as the steam load varies. The greatest energy savings occur in extended distribution systems, especially if the system has developed a significant amount of leakage.

You have the greatest ability for reducing pressure at low loads in steam systems that have long pipe runs. This is because a substantial part of the boiler pressure is needed to overcome flow resistance. The resistance is proportional to the square of the flow rate, so it drops considerably at low flow rates.

In steam systems that operate at lower pressures, minimizing steam pressure may allow boilers to operate unattended that otherwise require continuous operator presence, or the boilers may be tended by operators with a lower class of license. This may save labor cost if you can reliably predict the times when steam pressure can be reduced.

Energy Saving Potential and Other Benefits

The benefits of minimizing pressure in a steam system are:

- **reduced leakage throughout the system.** In larger steam systems, leakage can steal a large fraction of the steam produced by the boiler plant. Leakage wastes the heat carried by the steam, increases water consumption, and incurs the cost of treating the replaced water. The extent of the saving is related to the size and condition of the distribution system. By the same token, reducing pressure also significantly reduces the growth of leaks, a relentless process responsible for major maintenance and replacement costs.
- **reduced conductive heat loss throughout the system.** If the steam is distributed in a saturated state (that is, without superheat), the temperature of the steam is proportional to its pressure. Conductive heat loss is directly proportional to the temperature, so reducing the pressure reduces the heat loss. The potential saving is related to the effectiveness of the system’s insulation.
- **improved boiler efficiency.** Reducing the steam temperature increases the temperature differential between the combustion gases and the water, which increases heat transfer and efficiency. The maximum boiler efficiency improvement is in the range of 1 or 2 percent.
- **reduced scaling and oxygen corrosion.** Scale formation and oxygen corrosion rise dramatically

SUMMARY

An easy adjustment that may save a significant amount of energy, especially in steam systems that are large or leaky. Requires continuous operator attention. In some cases, may allow unattended firing of boilers or reduced operator licensing requirements. May cause problems if overdone.

with boiler pressure. Scale reduces heat transfer and efficiency, and it is difficult to remove. Oxygen corrosion in high-pressure systems causes pitting of the boiler tubes, which ultimately leads to pinhole leaks. Reducing steam pressure is no substitute for scrupulous water treatment, but it does provide additional protection. (See [Subsection 1.8](#) about water treatment.)

- **reduced control valve erosion.** Control valves on steam equipment suffer accelerated erosion of the disk and seat surfaces when the valves are almost closed. Fluid passing through valves that are barely open achieves high velocity and turbulent flow because of the pressure difference across the valve. Abrasion by the steam erodes the valve surfaces. Reducing the system pressure lessens this problem in two ways. First, there is less pressure to be converted to steam velocity. Second, the valve is opened wider for a given load, reducing the pressure differential across the valve itself.
- **improved control valve stability at low loads.** Steam control valves tend to chatter or cycle when they are barely open. Reducing the steam pressure causes control valves to open wider, reducing this effect.

The last two benefits occur with pressure reducing valves and with equipment inlet valves that operate directly from the main steam line. They do not occur with valves that are installed downstream of a pressure reducing valve, because the latter holds the downstream pressure constant.

How Low Can You Reduce the Pressure?

A steam system is designed to operate at a certain pressure in order to provide sufficient delivery of steam, sufficient pressure at the user equipment, and sufficient temperature at the user equipment. Do not reduce steam pressure to the point that any of these requirements are violated. For example, steam equipment such as sterilizers and cookers requires a minimum steam temperature, regardless of load.

On the other hand, in a steam system designed for space heating, space heating equipment may require only a fraction of the equipment's design pressure during mild weather. This allows the pressure at the boiler to be reduced more than if distribution pressure losses were the only factor.

Develop a Schedule of Pressure vs. Load

Your objective is to operate the boilers at the lowest acceptable pressure under all load conditions. As the steam output of the plant is reduced, reduce steam pressure correspondingly. To do this rationally, develop a schedule of boiler steam pressure as a function of steam output.

Do this by observing the performance of the user equipment as the pressure at the plant is reduced, to determine the minimum acceptable boiler pressure. Repeat this over the range of plant load conditions, as the boiler goes from low output to high output. If the plant output is related to weather, it may take a period of months to accurately determine the minimum steam pressure that is acceptable under different load conditions.

Different boiler pressures may be required for a given rate of steam output, depending on which loads are being served. For example, a campus may have dormitories that need a large amount of steam at night for heating, and a cafeteria that needs a smaller amount of steam during the daytime for cooking. Even so, the daytime pressure may need to be higher to accommodate the higher pressure requirements of the cafeteria cooking equipment. Similarly, a part of a facility that operates on a distinct schedule may require higher pressure because its distribution system has higher losses.

Modify Steam Users to Lower System Pressure Requirements

If a relatively minor steam user has a larger pressure requirement than the rest of the system, it forces the entire system to operate at higher pressure. In such cases, consider separating this steam user from the rest of the system, or modifying it to operate at lower pressure. See [Measure 1.12.3](#) for details.

Possible Boiler Damage at Reduced Pressure

A boiler is designed to operate within a certain range of pressures. Odd as it may seem, a boiler may have a

minimum safe pressure as well as a maximum safe pressure. In case of doubt, contact the boiler manufacturer to find out whether this may be a problem.

Your primary concern is excessive formation of steam bubbles within the boiler. The boiler water cools the steel parts of the boiler against damage from the higher temperature of the combustion gases. Steam does not provide this protection. When pressure is reduced, the steam bubbles in the water expand to take up more volume. This leaves metal surfaces with less cooling. This is most likely to be a problem in watertube boilers, where the enlarged steam bubbles may drive water out of the tubes.

If you reduce pressure only when boiler load is low, this problem becomes less critical because there is less steam formation and less heat transfer through the boiler tubes. However, it is not prudent to depend on this. It is likely that the boiler will sometimes be fired at a high rate even when the pressure is low. For example, this might happen when starting a cold system, or when shutting down one of two boilers.

Another possible problem is that the larger bubbles formed at lower pressure may cause increased carryover of liquid into the steam, along with the impurities and chemicals in the boiler water. This problem is also less likely to occur at low load.

Possible Steam Metering Error

Changing steam pressure may cause steam meters to read erroneously. Error occurs in both orifice meters and pitot tubes, which are calibrated for a given steam density. If metering is critical, you can compensate for pressure changes by using more complex metering equipment. Microcomputers in some steam metering systems can adjust for pressure changes.

Safety Issues if Staffing is Reduced

It is never prudent to skimp on safety, so consider whether it is appropriate to reduce the level of staffing when reducing pressure, even though this may be allowed by local laws. Consider the general condition of the boiler, the nature of the control system, the effectiveness of installed safety devices, and the vulnerability of the facility to the types of boiler failures that might occur.

ECONOMICS

SAVINGS POTENTIAL: *If the distribution system is large and in poor condition, minimizing pressure may save 5 to 20 percent of steam energy. In facilities that have short, well maintained distribution systems operating at low pressures, the benefit of reducing pressure is minimal.*

COST: *Minimal. The main cost is the manpower required to develop the steam pressure schedule.*

PAYBACK PERIOD: *Less than one year.*

TRAPS & TRICKS

PREPARATION: Check to be sure that reducing pressure will not cause boiler problems. Have the patience to refine your steam pressure schedule until it is optimum. You may need a year of observations to determine the minimum acceptable steam pressures under all conditions of steam demand and weather.

OPERATION: You need to stay on top of this activity. Schedule periodic checks to verify that the procedure is being followed and that it is not causing problems. This is a training and communication challenge.

METERING ACCURACY: If you need accurate steam metering, get steam meters that can compensate for changes in supply pressure.

Boiler Plant Efficiency Measurement

Measure the efficiency of your boilers on a regular basis. This is the first step in keeping them efficient. Efficiency testing is important for two reasons. First, a large fraction of the total energy consumed by a facility passes through its boilers, so even a small drop in boiler efficiency represents a large loss of energy. Second, boiler efficiency declines continuously over time, so you need to test efficiency regularly to know when to perform maintenance.

Fortunately, boiler efficiency testing is easy. The Measures in this Subsection show you how to do it, and how to keep your testing program effective.

RATINGS

New Facilities	Retrofit	O&M

Periodic efficiency testing is an important part of the management of any boiler plant, for these reasons:

- a large fraction of a facility’s total energy consumption flows through its boilers, so even a small drop in efficiency represents a large amount of energy and cost in absolute terms. In facilities where boilers have operated for long periods of time without being tested, it is not uncommon to find that efficiency has fallen by five or ten percent, which may represent a very large cost.
- efficiency testing is the most accurate indicator for adjusting the boiler and its auxiliary equipment, such as adjusting the air-fuel ratio (covered in [Subsection 1.3](#)). Efficiency testing tells you the “bottom line” economic performance of the boiler, unlike indirect clues, such as flame color.
- you can localize most boiler problems by knowing how to exploit the full range of efficiency test methods. Efficiency tests are to boilers what blood tests are to human beings.
- efficiency testing is the first step in estimating the benefit of potential boiler improvements, such as adding an economizer or an air-fuel control system.

Boilers are vulnerable to conditions, such as tube fouling, that may reduce their efficiency over relatively short periods of time. Therefore, you should test boiler efficiency on a regular basis. Fortunately, boiler testing is easy. It is practical for most facilities to have at least one person who is proficient in testing. This individual need not be a boiler operator, or even a member of the physical plant staff.

You may need several types of efficiency tests to get a complete picture of boiler performance. There is one main type of test, called a “combustion efficiency” test. You may have to supplement this with one or two specialized tests, such as a test for carbon monoxide, to get a complete picture of your boilers’ performance. This Measure tells you how to select the appropriate tests for your boilers, how to do them, and the weaknesses of each method. In a short time, you can be testing your boiler efficiency with confidence.

What “Efficiency Testing” Means in Boilers

Efficiency is defined as the ratio of the useful output energy produced by a system to the raw energy input into the system. In principle, it is possible to test the overall efficiency of a boiler plant. You could do this by measuring the energy content of the steam or hot water that is exported by the boiler plant and the total quantity of energy that is input to the boiler plant,

including fuel for the boilers and other energy for the auxiliary equipment.

In actual boiler plants, such a comprehensive test is impractical. Measuring steam or hot water energy with reasonable accuracy, say within one percent, is possible only under laboratory conditions. Field measurements of flow are vulnerable to error, even if they are done by expensive consultants. Measuring input energy is also subject to error. You would have to analyze the energy content of your fuels, make corrections for ambient conditions, and create very stable test conditions. This is not possible under realistic conditions.

Fortunately, you don’t need to measure the total efficiency of a boiler plant if your objective is to tune up the plant’s efficiency, rather than running a testing laboratory. You can use an easy procedure, called a “combustion efficiency” test, to measure the aspects of boiler efficiency that cause most losses in normal operation. The “combustion efficiency” test determines how completely the fuel is burned, and how effectively the heat of the combustion products is transferred to the steam or water.

The efficiency of the other boiler plant components, such as pumps, fans, and motors, tends to remain constant, so you don’t need to test their efficiency on a continuing basis.

Limitations of the Combustion Efficiency Test

The combustion efficiency test is your primary tool for monitoring boiler efficiency. You can achieve accuracy in the range of one percent of efficiency if you do the testing carefully and use equipment of good quality. However, be sure that you understand what the test is telling you. The combustion efficiency test does not account for:

- **standby losses.** You perform a combustion efficiency test when the boiler is operating under a steady load. Therefore, the combustion efficiency test does not reveal standby losses, which occur between firing intervals. You cannot measure standby losses directly. You have to estimate them from the type of boiler and the firing schedule. See [Measure 1.5.3](#) for an explanation of standby losses.
- **heat loss from the surface of the boiler to the surrounding space.** As a practical matter, you cannot measure this loss. Typical estimates state that the loss from surface radiation is about two percent of the boiler’s full load energy consumption. ([Subsection 1.11](#) shows you how to reduce surface heat loss and recover the heat.)
- **blowdown loss.** The amount of energy wasted by blowdown varies over a wide range. ([Subsection 1.8](#) shows you how to minimize blowdown loss and how to recover heat from blowdown.)
- **soot blower steam.** The amount of steam used by soot blowers is a variable that depends on the type of fuel and the judgement of the staff. ([Subsection](#)

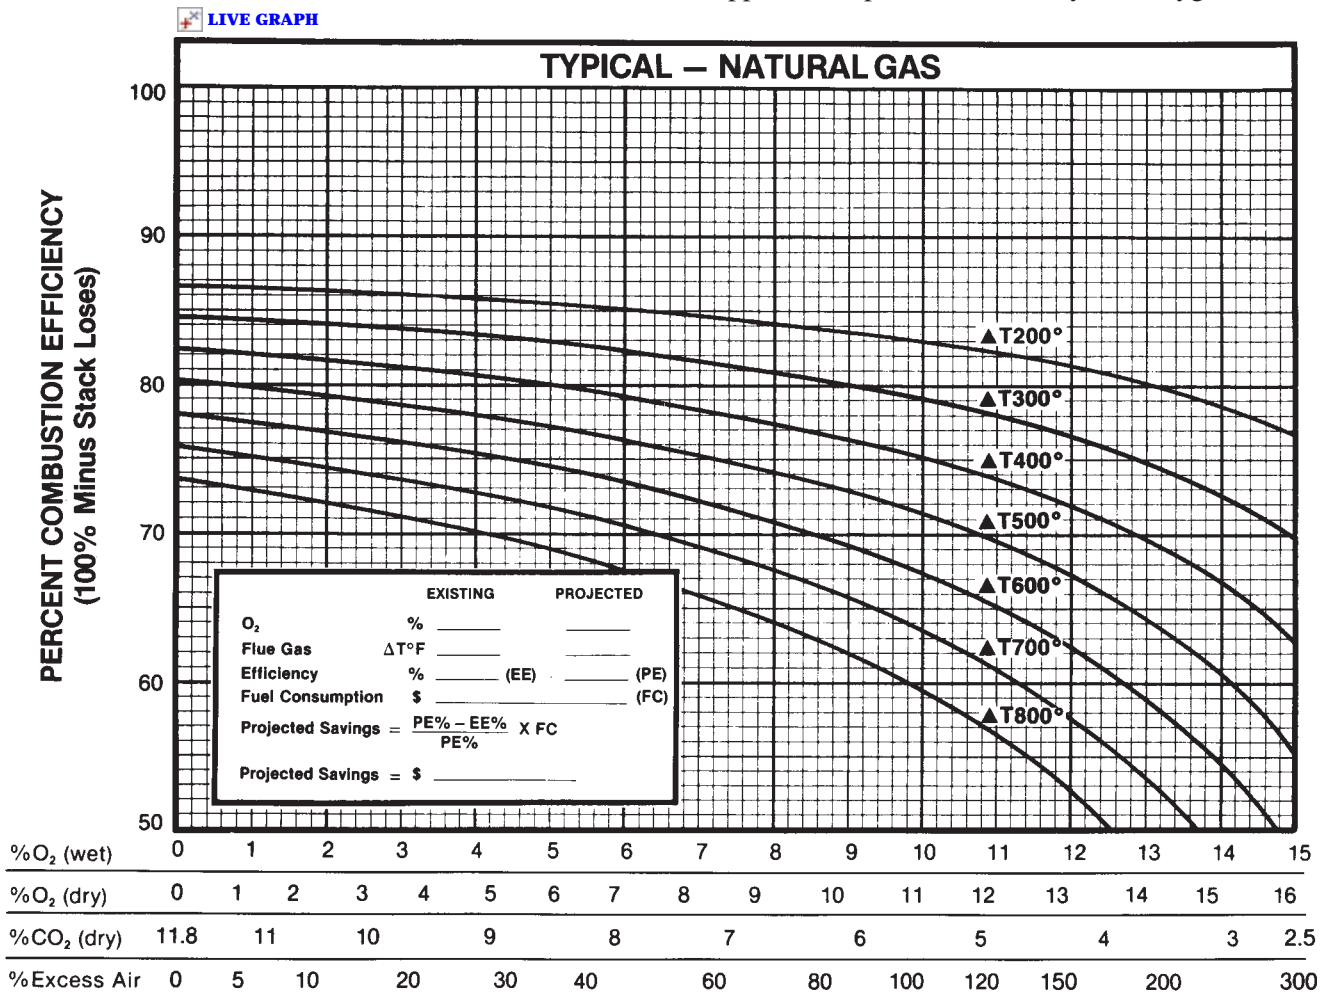

1.6 shows you how to minimize soot blower steam consumption.)

- **auxiliary equipment energy consumption.** The combustion efficiency test does not account for the energy use by auxiliary equipment, such as burners, fans, and fuel pumps. (To minimize this energy consumption, see the Subsections that cover the specific types of auxiliary equipment.)

While the combustion efficiency test does not give the overall efficiency of the boiler plant, it is by far the easiest method of tracking moment-to-moment, day-to-day, and season-to-season variations of boiler efficiency. Combustion efficiency testing tells you how far boiler efficiency drifts away from the best efficiency that you can achieve when the boiler is fully tuned up.

How to Do a Combustion Efficiency Test

You test combustion efficiency by measuring either the oxygen content or the carbon dioxide content in the flue gases. The oxygen test can provide much better accuracy in the range of air-fuel ratio where the boiler is supposed to operate. In recent years, oxygen testers

Preferred Utilities Manufacturing Corp.

Fig. 1 Form for calculating combustion efficiency This form works with either oxygen or carbon dioxide measurements. You don’t need this if you have an electronic efficiency tester that calculates efficiency automatically. The graph nicely illustrates the fixed relationships between the amounts of oxygen, carbon dioxide, and excess air in the flue gas, for a particular type of fuel.

of good quality have become available at modest prices. Therefore, use the oxygen test as your fundamental test for combustion efficiency.

Testing for combustion efficiency using the oxygen method consists of three easy measurements:

- the percentage of oxygen in the flue gases
- the temperature of the flue gases
- the temperature of the air going into the boiler

Make the oxygen measurement with a specialized tester that is described below. Make the two temperature measurements with ordinary thermometers. To make the flue gas measurement, you may have to drill a small hole in the flue or breeching, as close to the outlet of the boiler as possible. (Check first. Unless the facility is brand new, somebody probably made a hole already.)

Some combustion efficiency testers have an internal computer that calculates the efficiency directly from these measurements. If you don't have such a unit, use the three measurements with an efficiency table or graph for the specific type of fuel. These are provided with the test equipment, or you can find them in reference books. A typical graph for calculating combustion efficiency is reproduced in Figure 1.

For example, using the graph in Figure 1, say that the oxygen tester gives a reading of 5% oxygen in the flue gases. (This is the "wet" value, which means that the water vapor has not been removed from the flue gas sample.) If the flue thermometer reads 480°F and the air going into the boiler has a temperature of 80°F, the flue-to-inlet temperature difference is 400°F. Entering the table with these numbers gives a combustion efficiency of 80%.

It's that easy. The carbon dioxide test is done in the same way, except that a different tester is used to measure carbon dioxide instead of oxygen, and the efficiency table or graph is based on carbon dioxide percentage.

You may do other tests, explained below, to supplement the combustion efficiency test or to measure pollutants. These tests are even simpler.

The Logic of Combustion Efficiency Tests

Your boiler burns fuel efficiently if it satisfies these conditions:

- it burns the fuel completely
- it uses as little excess air as possible to do it
- it extracts as much heat as possible from the combustion gases.

The combustion efficiency test analyzes the flue gases to tell how well the boiler meets these conditions. The test is essentially a test for excess air, combined with a flue gas temperature measurement. The only purpose of bringing air into the boiler is to provide oxygen for combustion. Bringing in too much air reduces efficiency because the excess air absorbs some of the heat of combustion, and because it reduces the

temperature of the combustion gases, which reduces heat transfer. The temperature of the flue gas indicates how much energy is being thrown away to the atmosphere.

All the calculations needed to perform the efficiency test are contained in the efficiency table, so no mathematics is needed. The efficiency table uses this logic:

- The amount of oxygen in the flue gas indicates directly the amount of excess air that is flowing through the boiler. The atmosphere contains about 21% oxygen. All this oxygen would be consumed if combustion were perfect. Therefore, the presence of oxygen in the flue gas indicates that more air is being used than is necessary for perfect combustion.
- The efficiency table is based on a certain heat content for the fuel. This is why there are different tables for different fuels. The tables also assume that the fuel is burned completely. These assumptions provide the amount of heat released in combustion.
- The volume of flue gas is known from the assumed chemical composition of the fuel and the amount of excess air. Knowing the volume of the flue gas and its temperature indicates how much energy is contained in the flue gas. This energy is wasted.
- Knowing how much energy is being produced and how much is being lost gives the combustion efficiency.

If your efficiency tester has a built-in efficiency computer, it follows the same logic, and you don't even have to look up numbers in the table.

You can also test combustion efficiency by measuring the carbon dioxide content of the flue gases instead of measuring the oxygen content. Although the test procedure is the same as for oxygen testing, the principles of the carbon dioxide test are different. Carbon dioxide content indicates both the amount of fuel burned and the amount of energy released because it is a principal residue of fuel combustion. (The other major residue is water vapor.) If there were no excess air, the amount of carbon dioxide in the flue gases would be a certain amount, determined by the chemical composition of the fuel. A lower concentration of carbon dioxide therefore indicates excess air.

In other words, the oxygen test indicates the amount of excess air directly, whereas the carbon dioxide test indicates excess air indirectly, based on an assumption about the chemical composition of the fuel.

■ Assumptions of Combustion Efficiency Testing

Be aware that the efficiency tables used in combustion efficiency testing make some assumptions. Most importantly, they assume a certain average chemical composition of the fuel. This makes it important to use the specific table for the fuel being burned. If you use a tester that calculates the efficiency, you have to set the type of fuel in the tester.

Bacharach, Inc.

Fig. 2 Why flue gas oxygen indicates combustion efficiency more accurately than carbon dioxide First, the oxygen content changes radically with excess air. Second, the relationship between oxygen and excess air is almost independent of the fuel type.

The chemical composition of a fuel varies considerably even within a given type (such as “No. 2 oil”). However, the effect of such differences is small enough to ignore for most practical purposes.

Another assumption of the tables is that the fuel is burned completely. As long as the burners are operating properly and the air-fuel ratio is not grossly out of range, this is a reasonable assumption. However, burner malfunctions and insufficient air cause incomplete combustion. These conditions cause fuel to be thrown into the boiler without producing heat. The unburned fuel is not detected by the oxygen or carbon dioxide tests, so these tests yield artificially high efficiency figures if combustion is incomplete. This is one reason why you need an additional test to check for incomplete combustion.

To be extremely accurate, you would have to measure the temperature of the fuel, to take into account the sensible heat carried by the fuel. As a practical matter, this energy is minor in comparison with the chemical energy of the fuel. Furthermore, the temperature of the fuel that is delivered to the boiler usually varies little from one time to another. So, you can forget about fuel temperature in most cases. (The temperature of heavy fuel oil is important for viscosity control. That aspect is covered in [Subsection 1.9.](#))

Why the Oxygen Test is Better than the Carbon Dioxide Test

For any given fuel, there is a fixed relationship between the amounts of oxygen and carbon dioxide in the flue gas. This is why you can measure either one to determine combustion efficiency. The fixed relationship between oxygen, carbon dioxide, and excess air is shown in Figure 1.

The oxygen test is more accurate than the carbon dioxide test. The reason is apparent from the graph in Figure 2. When you approach the optimum excess air setting, the relative change in oxygen is much greater than the relative change in carbon dioxide for a given change in excess air. For example, with No. 2 oil, an increase in excess air from 2% to 10% causes oxygen in the flue gas to increase by a factor of five, a change that you can measure easily. On the other hand, the same increase in excess air causes carbon dioxide to drop by only 10%, a difference that is more difficult to measure accurately.

Another advantage of the oxygen test is that the results are much less sensitive to variations in the chemical composition of the fuel. Figure 2 shows this dramatically. The amount of carbon dioxide in the flue gas depends on the amount of carbon in the fuel, and the amount of excess air is calculated from this carbon dioxide value. There are large differences in the chemical composition of some fuels, such as industrial by-product gases. All liquid and gas fuels have some variation.

In contrast, the oxygen test provides a direct indication of excess air. Variations in carbon content do not affect the results of the oxygen test at all, and variations in the total energy content of the fuel affect the oxygen content much less than they affect the carbon dioxide content.

Unlike the carbon dioxide test, the oxygen test works only in the region of excess air. There is no oxygen to measure when there is no excess air. This is not a problem in normal testing, because you should always operate boilers with a small amount of excess air.

Check the Oxygen Test with the Carbon Dioxide Test

Boiler efficiency testing is so important that it is worth a small additional effort to check the oxygen test with a carbon dioxide test. Test equipment for both tests is readily available. The cost in time and money for the additional test is minor. If continuous-reading oxygen test equipment is installed in your boiler plant, check this equipment occasionally with portable test equipment that checks for both oxygen and carbon dioxide.

If the carbon dioxide test does not give the same results as the oxygen test, something is wrong. One (or both) of the tests could be erroneous, perhaps because of stale chemicals or drifting instrument calibration.

Another possibility is that outside air is being picked up along with the flue gas. This occurs if the combustion gas area operates under negative pressure and there are leaks in the boiler casing. Watch out for this problem in boilers with induced draft fans and in boilers that have atmospheric burners.

A discrepancy between the two tests could also be caused by a defect in the burner assembly, such as a clogged nozzle. Remember that *combustion efficiency testers assume complete combustion of the fuel*. Any condition that interferes with complete combustion renders the tests invalid, and also breaks the correlation between oxygen content and carbon dioxide content.

Beware of electronic efficiency testers that claim to “measure” both oxygen and carbon dioxide. Many such units really measure only the oxygen percentage. They calculate the carbon dioxide percentage from the oxygen percentage, using assumptions about the fuel composition. *The carbon dioxide indications of such units are meaningless, and you cannot use them for cross checking purposes.*

Tests for Incomplete Combustion

No boiler is capable of burning fuel without some amount of excess air, although the percentage of excess air may be small. As the excess air is reduced toward zero, there is some fuel that is not burned completely. This partially burned fuel creates smoke, leaves deposits on firesides, and creates environmental problems.

Unburned fuel may also represent a significant waste of energy. The amount of waste depends on the energy content of the unburned fuel components. For example, the unburned components of heavy oil are mostly organic compounds that have a high energy content. On the other hand, the unburned components of coal may consist largely of foreign matter that has much lower energy content than coal itself. One source estimates that each 0.1 percent of unburned combustibles in flue gas typically represents between 0.3 and 0.6 percent of the energy content of the fuel. *This waste of energy is not measured by the combustion efficiency test.*

Therefore, optimum efficiency requires some positive amount of excess air, even though the combustion efficiency test indicates maximum efficiency with no excess air. If the boiler is working properly, the optimum amount of excess air is small.

To fine-tune the excess air, you may need an additional test that detects small amounts of incompletely burned combustion products. Two common tests for this purpose are smoke density and carbon monoxide in the flue gas.

■ Smoke Opacity Test

Before combustion efficiency test equipment became available, the amount of air was adjusted by observing the smoke emerging from the stack. For example, boilers burning heavy oil used the rule that

the flue gases should be a “light brown haze.” This is no longer satisfactory as a primary test, but it continues to be a useful check. If there is too much smoke when the excess air is set to a reasonably low figure, something is wrong. Therefore, measuring smoke density (“opacity,” to be precise) continues to be a valuable diagnostic test.

You can use the smoke density test with heavier grades of oil and with solid fuels. Smoke density is not a reliable indicator with gaseous fuels and with light oils. The unburned residue of these fuels is not visible unless air is very deficient.

■ Carbon Monoxide Test

The carbon monoxide content of flue gas is a good indicator of incomplete combustion with all types of fuels, as long as they contain carbon. Carbon monoxide in the flue is minimal with ordinary amounts of excess air, but it rises abruptly as soon as fuel combustion starts to be incomplete. This makes it an excellent indicator when making your final adjustments of the air-fuel ratio.

An excessive level of carbon monoxide that occurs in the normal region of the air-fuel ratio indicates trouble within the boiler. Carbon monoxide rises excessively if any defect in the boiler causes incomplete combustion, even with excess air. This makes carbon monoxide testing an excellent tool for discovering combustion problems, especially if it is used in combination with oxygen testing. For example, the carbon monoxide test might reveal a fouled burner. It might also point toward a more subtle problem, such as a poor match of the burner assembly to the firebox, causing a portion of the flame to strike a surrounding surface. (Cooling the flame interrupts the combustion process, leaving carbon monoxide and other intermediate products of combustion in the flue gases.)

Carbon monoxide also forms if there is a great excess of air. This is not a matter of practical significance. Once you set the air-fuel ratio properly, the carbon monoxide content falls into the proper range if there are no other problems.

Flame Appearance

The practice of adjusting burners on the basis of the color and shape of the flame is no longer acceptable, now that more accurate tests are readily available. However, you should still check the color and shape of the flame periodically to verify that there are no combustion problems, such as a clogged burner or water in the fuel.

Tests for Specific Environmental Pollutants

Environmental regulations may require you to test flue gases to ensure that emission of certain pollutants, such as nitrogen oxides, sulfur oxides, hydrogen sulfide, and chlorine, does not exceed specified limits. These tests are usually simple, requiring nothing more than

sucking a flue gas sample into a specialized chemical or electronic tester.

Controlling pollutants requires specialized procedures, such as recirculating the flue gases, increasing air flow, or adjusting the burner flame. These procedures are likely to affect efficiency. Do efficiency testing as part of any change you make to control pollutants. Keep your pollutants within limits by using methods that reduce efficiency the least.

How to Select Test Equipment

Efficiency test equipment must be accurate. The objective is to measure efficiency within a fraction of a percent, because a difference this small can correspond to a large amount of energy. The entire range of possible boiler efficiencies corresponds to a range of flue gas oxygen content from zero to twenty percent. At the high end of the efficiency range, an error of two percent in flue gas oxygen results in a half percent error in combustion efficiency.

You don't need the skill of a surgeon to do combustion efficiency testing, but you do have to be careful. Some types of test equipment require more finesse than others. Let's look at what is available.

■ Oxygen and Carbon Dioxide Testers

The pioneer of combustion efficiency testers is the Orsat analyzer, a chemical testing apparatus in which flue gases are mixed with a liquid reagent that changes volume as a result of the reaction. The apparatus displays the volume change accurately, providing an accurate

indication of combustion efficiency. Oxygen, carbon dioxide, carbon monoxide, and other gases can be analyzed.

The Orsat analyzer is simple and accurate. A portable version is available at moderate price. However, the apparatus is built of delicate glass tubing and requires a fine touch. Modern testers are much more rugged and much easier to use, so the Orsat analyzer is now a museum piece.

A similar chemical approach is used by the vintage Bacharach "Fyrite" tester, which is compact and made of plastic. One version of this unit tests for oxygen, and a different version tests for carbon dioxide. They are shown in Figure 3. The "Fyrite" is less accurate than the Orsat, but it is rugged and fairly easy to operate. It is the least inexpensive of all combustion gas analyzers. You need to read a table to use this device.

These testers require replacing their chemicals after a certain number of tests, and the chemicals have a limited storage life.

In recent years, electronic testers have become available for analyzing flue gases. Some typical units are shown in Figure 4. Most electronic testers use an electro-chemical cell as the gas sensing element. A different cell is required for each gas being measured.

The most common sensor used in oxygen testers is a zirconium oxide element that develops a voltage difference across two sides if there is a difference in oxygen concentration. The zirconium oxide element has the advantage that it can be exposed to flue gases for thousands of hours.

Bacharach, Inc.

Fig. 5 Chemical carbon monoxide tester The simple device on the right draws a flue gas sample through a glass tube containing a chemical that reacts with carbon monoxide to change color. Each tube is used one time. By using different chemicals, the device can test for other flue gases.

The overwhelming advantage of electronic testers is that they provide an immediate and continuous readout simply by inserting a probe into the flue gases. This allows you to see the effect your of boiler adjustments immediately.

Some combustion efficiency testers avoid the need to use a table to calculate efficiency. They perform the efficiency calculation with a microcomputer and read out combustion efficiency directly. There is a potential for error with such testers because efficiency depends on the temperature of the inlet air as well as the temperature of the flue gas. Some testers use the temperature of the air surrounding the tester as the inlet

Fig. 6 Smoke density tester This device, similar to a bicycle tire pump, sucks a flue gas sample through a piece of filter paper. The resulting smoke spot is compared with the chart behind the pump.

air temperature. This introduces error because the air near the flue may be much warmer than the air entering the boiler. Better testers provide a separate remote thermometer for measuring the air inlet temperature while you take the flue gas sample.

Electronic testers of good quality are substantially more expensive than chemical testers. Still, the price is small compared to the benefit of keeping boiler efficiency optimized (unless your boilers are very small).

As with most electronic equipment, the quality of electronic flue gas analyzers varies widely. The best of the lot may be capable of better accuracy than the inexpensive chemical testers. The worst of the lot are incapable of providing useful accuracy.

A weakness of all electronic gas analyzers is that they must be re-calibrated frequently because the sensor output drifts. Fortunately, oxygen testers may be self-calibrating by using the oxygen content of the atmosphere as a calibration point. Testers for other gases require calibration using pre-mixed gases. Since the inner workings of these instruments are invisible, calibration is an act of faith in the calibration gases.

Most inexpensive electronic combustion analyzers do not measure carbon dioxide directly. Some units provide a carbon dioxide reading, but this is derived by internal calculation from the oxygen measurement. If you want to use a carbon dioxide test to check the oxygen test, a value that is calculated from the oxygen measurement is useless. Measure carbon dioxide with a separate instrument designed for that purpose.

■ Testers for Carbon Monoxide and Specialized Gases

You can find electronic testers for gases other than oxygen or carbon dioxide, but these tend to be expensive and specialized. The most economical testers for carbon monoxide and specific pollutant gases use disposable chemical capsules for each type of gas. These units are reliable and easy to use. See Figure 5.

For example, one type of tester uses disposable chemical capsules in the form of slender tubes. The tester consists of a holder for the capsule that is equipped with a pump that draws the gas sample through the capsule. The gas concentration is indicated by the length of a color change inside the capsule.

■ Smoke Testers

You can measure smoke density cheaply and reliably with a tester that is constructed like a bicycle pump. It pulls a measured amount of flue gas through a piece of filter paper. You compare the blackness of the smoke spot on the filter paper to a chart that comes with the tester. See Figure 6.

Another method of testing smoke density is to install an optical densitometer in the flue. This is a simple device that shines a light beam across the flue. The amount of light that is absorbed by the smoke is

Bacharach, Inc.

measured by a photocell. This device provides a continuous reading. In fact, some older oil-fired boilers use this device as the primary means of adjusting air-fuel ratio.

■ Thermometers

The thermometer that you use for flue temperature measurements must be accurate. An error of 40°F in the flue temperature measurement can result in a one percent error in boiler efficiency. Combustion efficiency testing is no place for a shirt pocket thermometer. Use a laboratory grade liquid-in-glass thermometer. Mercury-in-glass thermometers are available with maximum temperatures up to 1,200°F. To read the thermometer most accurately, get one that has a maximum temperature close to the maximum temperature of the flue gases. A 500°F (or 300°C) thermometer is appropriate for efficient boilers. A 750°F (or 400°C) thermometer is adequate for most others.

Good mercury thermometers are inexpensive, but they are fragile and difficult to read. Buy a couple of spares, along with a protective storage case.

Dial thermometers use a bimetallic sensing element that may drift with time. The only merit of dial thermometers is that they are easy to read. In a pinch, you can calibrate or check the low temperature end of a bimetallic thermometer by placing it in boiling water, which provides a reliable standard of 212°F (100°C) at sea level. If you use this method, correct for your

altitude, because water boils at lower temperature at higher altitudes.

Electronic thermometers have high-tech appeal, but they may be inaccurate, just a toy dressed up with a digital output. Electronic temperature sensing elements are inherently non-linear. Most of the cost of the electronic thermometer goes to compensating for the weaknesses of the sensing element. Some electronic thermometers are accurate, but you typically have no way of distinguishing these units from the toys. Even with an electronic unit of high quality, be aware of the guaranteed accuracy range. For example, a one percent error in absolute temperature corresponds to an error of about 10°F at typical flue temperatures.

Avoid Error Due to Extraneous Air

The combustion efficiency test involves measuring a small quantity of residual oxygen in the combustion gases. In a well tuned boiler, the gases contain less than one percent of free oxygen. Therefore, the test is seriously falsified by any outside air that enters the test probe.

Be careful to avoid getting outside air into the probe at the probe hole. Sloppy technique may allow outside air to travel along the shaft of the probe and enter the tip. To avoid this, aim the probe toward the boiler, preferably by bending the probe to that it faces into the flue gas stream well inside the flue. Wrap a piece of cloth around the probe to act as a gasket between the probe and the edge of the hole. It's the same general idea as safe sex. See Figures 7 and 8.

IMR Environmental Equipment, Inc.

Fig. 8 Large boiler, small tester Combustion efficiency testing is done the same way on all boilers and furnaces. Here, a test is conducted high on a large stack. The probe is located at the arrow, the tester is in the foreground. All these people are relaxing. It takes only one person to run the test.

If the flue contains a draft hood or atmospheric damper, tap the gas sample well below the point of entry of outside air. Turbulence in the flue may cause ambient air to backflow to the probe. Such backflow is especially likely to occur near bends in the ductwork.

Leakage of extraneous air into the flue is likely to occur if the boiler has an induced-draft fan, i.e., a fan that sucks combustion gases through the boiler rather than blowing them through. If you insert the probe at a point between the boiler outlet and the induced-draft fan, the induced-draft fan will draw outside air into the test hole. Air will enter at any leaks that exist in the flue ahead of the test probe. To avoid this problem, examine the boiler breeching ahead of the test hole, and plug any leaks. Drill the test hole as close to the boiler or economizer outlet as possible.

Errors from Sensing the Wrong Gases

A particular type of sensor may respond to more than one substance in the flue gas. This leads to a false reading if you are expecting to test for one substance but your tester registers another. The most common problem is that hydrogen and hydrogen sulfide register as carbon monoxide with some electrochemical carbon monoxide sensors. This is not a problem with clean fuels, which produce only carbon dioxide and water vapor as their principal end products. Beware of false readings when burning fuels, such as high-sulfur oil and coal, which produce gases other than carbon dioxide and water.

Errors Due to Internal Steam Leaks

If a boiler has an internal steam leak, the steam mixes with the flue gases. The steam is cooler than the combustion gases and lowers the temperature at the test point, giving an erroneously high efficiency calculation. If the steam leak is large, it may become apparent from an efficiency reading that seems abnormally high, especially at low loads. The rate of steam leakage remains constant at all firing rates, as long as the boiler pressure remains constant. Therefore, the error caused by the escaping steam is larger at low firing rates. If a boiler has a steam leak large enough to be detected by an efficiency test, it should be shut down immediately and repaired.

How to Test Boilers with Flue Gas Recirculation

To reduce the production of nitrogen oxides during the combustion process, many boilers now recirculate a portion of the flue gas. Exhaust gas is drawn from the flue with a fan and it is injected back into the boiler at the burner. The flue gas contains little oxygen and it is relatively cool. The purpose of this is to reduce the peak combustion temperature, since nitrogen oxides are formed mainly at high combustion temperatures.

Flue gas recirculation does not cause any problems with combustion efficiency testing. Efficiency testing works by measuring what goes into the boiler and what comes out. Recirculation is a process that occurs entirely within the boiler. Therefore, any effect that recirculation may have on efficiency is included in the flue gas analysis. Recirculation does not affect where you should tap your flue gas sample.

How to Test Boilers with Economizers and Air Preheaters

Economizers and air preheaters (covered in [Subsection 1.7](#)) are devices for capturing additional heat from the flue gases after they leave the boiler. The recovered heat typically is used to heat feedwater or combustion air, respectively. These devices lower the flue gas temperature, so they affect the efficiency test.

With both types of units, the proper place to measure the flue gas temperature is at the outlet of the heat recovery device, rather than at the outlet of the boiler.

With a combustion air preheater, the place to measure inlet air temperature is at the inlet to the air preheater, not the inlet to the burner. In other words, do not measure the temperature of the heated air produced by the preheater.

With a combustion air preheater of the heat wheel type, the flue gas test may yield an erroneously high efficiency. This is because the rotation of the wheel carries a certain amount of cool ambient air into the exhaust stream. Some types of heat wheels have purge sections that deliberately recirculate a portion of the incoming air into the exhaust from the heat wheel. Furthermore, different portions of the heat wheel are at different temperatures, so the flue gas temperature leaving the heat wheel is non-uniform. There is no practical way to make an accurate correction for these factors.

Preparation and Testing Conditions

When you first start your efficiency testing program, do a test under optimum conditions to establish a baseline for future tests. Do the baseline test with the boiler in peak condition, and across the entire load range of the boiler. Compare later tests to this baseline. When the boiler efficiency falls too far below your measured baseline, it is time to take corrective action.

For this baseline test, expect to spend considerably more effort and time inspecting the boiler plant and correcting deficiencies than in doing the testing itself. Adjust, clean, and repair all parts of the boiler that affect efficiency. Clean firesides and watersides. Clean and adjust burners. Remove all looseness from air and fuel control linkages. Check the combustion air supply. Adjust flue draft. And so forth. Refer to the other Subsections for the Measures that optimize the efficiency of your particular types of boilers.

Do the tests while the boiler has a steady load. If the system is used primarily for comfort heating, you may not have enough load to test your boilers during warm weather. It is easier to conduct tests in a plant that has more than one boiler, so the boiler being tested can shift load to and from the other boilers.

Do not attempt to create a load on the boiler by warming it from a cold state. This produces an efficiency reading that is artificially high, because the flue gases are being cooled by the mass of the boiler and water.

You have to make certain adjustments to the boiler plant while the boiler is operating. For example, determine the optimum fuel oil heater temperature by adjusting the fuel oil temperature for peak boiler efficiency. Make these adjustments as the test progresses.

How Often to Repeat Efficiency Tests

The most common reason for a decline in efficiency is accumulation of fouling on firesides, watersides, and burners. Fouling accumulates at a fairly predictable rate, if the boiler has no defects. The appropriate interval for combustion efficiency testing depends on the type of boiler and the type of fuel. A simple gas-fired boiler with atmospheric burners may hold its efficiency for years without adjustment, and with minimal maintenance. On the other hand, a large pressure-fired boiler burning a variety of fuels may have a noticeable drift in efficiency over a period of days or weeks.

Even if the boiler has recently been cleaned, test for efficiency and make adjustments whenever anything changes that can reduce efficiency. For example, test efficiency when changing from one type of fuel to another, when changing batches of fuel, and when slack in the linkages controlling air-fuel ratio becomes apparent. If controls are subject to drift, determine the length of time that it takes a significant error to

accumulate. (If drift is serious, improve the control system as recommended by [Measures 1.3.2](#) and [1.3.3](#).)

ECONOMICS

SAVINGS POTENTIAL: 2 to 10 percent of fuel cost, typically. Credit the savings to the specific actions that you take to improve efficiency, such as optimizing the air-fuel ratio, optimizing fuel oil viscosity, etc.

COST: You can purchase a good chemical combustion efficiency test kit that measures oxygen, carbon dioxide, and smoke for less than \$500. A chemical carbon monoxide tester costs less than \$300. Electronic testers of reasonable quality cost from \$1,000 to several thousand dollars. Also, consider the cost of the actions that you take to improve efficiency.

PAYBACK PERIOD: Very short, to several years, depending on the amount of fuel consumed by the boiler and its tendency to lose efficiency.

TRAPS & TRICKS

TRAINING AND ADMINISTRATION: Efficiency testing does not require a high level of skill, but it does require practice and strict adherence to the instructions. If you delegate this responsibility to others, make sure that they are well trained.

SELECTING THE EQUIPMENT: Don't skimp on the quality of the test equipment. If your budget is limited, get a proven chemical test kit. The quality of electronic test equipment varies. Higher price does not necessarily mean better accuracy. High-quality electronic testers are easy to use and reduce the opportunity for mistakes.

KEEP IT UP: Efficiency testing is easy to forget. Schedule periodic review of testing procedures. Verify that testing is done properly, that results are recorded, and that appropriate action is taken.

MEASURE 1.2.2 Install efficiency instrumentation appropriate for the boiler plant.

You can do a good job of testing boiler efficiency with portable instruments that are relatively inexpensive. However, it may be a good idea to install some efficiency-related instruments permanently. This can make it easier to monitor efficiency and energy consumption.

Permanently Installed or Portable?

To decide whether to install permanent instruments, and which to install, consider these factors:

- **the amount of money at stake.** Portable instruments are less expensive, it is easier to service and calibrate them, and you can use them for any number of boilers. It may not be economical to install and maintain fixed instruments in a small boiler plant. In contrast, the cost of instruments for a large boiler plant is almost trivial compared to fuel cost.
- **the types of boiler plant equipment.** For example, simple gas boilers with atmospheric burners, serving a single customer, may require no fixed instrumentation, except for a boiler gas meter and a flue thermometer. With such boilers, efficiency does not deteriorate over short periods of time, and there are few things to can go wrong in a way that affects efficiency. At the other extreme, a large, complex boiler plant serving multiple customers deserves an extensive array of instruments and data recording devices.
- **the sophistication of the boiler operators.** If there are no operators on duty in the plant, or if the boiler operators do not have the skills to exploit the instrumentation, there is no use in installing it. (See Measure 1.2.4 about training.) If you hire someone to test the boilers periodically, that person will bring his own instruments.
- **the improvement in ease of use.** Permanent instruments may be much easier to use, and this may motivate people to monitor conditions better. For example, nobody likes to clamber up a ladder to stick a sampling tube into hot boiler breeching. Portable instruments tell you nothing as long as they are locked up in the chief engineer’s office.
- **instrument accuracy and longevity.** Exposing sensors to flue gases on a continuous basis causes calibration to drift and requires periodic replacement of sensor elements. Instruments that are kept inside a padded box most of the time may last much longer. However, well designed permanent instruments make it easy to replace elements, and the newer types of sensors have greatly improved longevity.

Types of Instruments to Consider

The main types of efficiency-related instrumentation to consider for permanent installation in the boiler plant are:

- **combustion efficiency indicators.** These days, permanently installed efficiency instruments are electronic. They operate on the principles explained in Measure 1.2.1.
- **stack thermometers.** A glance at a stack thermometer can reveal that efficiency is dropping, provided that the operators have a table indicating the desired stack temperature at each level of load. The thermometer must be accurate. The typical cheap units that have bimetallic elements are not stable, so they must be checked and re-calibrated periodically. Newer electronic thermometers designed specifically for this purpose may be much more accurate.
- **smoke opacity sensors.** Boilers that burn heavy liquid fuels and solid fuels should have a smoke opacity indicator. Excess smoke density is an immediate indication of trouble that causes rapid fireside fouling. Also, smoke density is related to pollution emissions that are regulated in many jurisdictions. Figures 1 and 2 show the elements of permanently installed smoke opacity indicators.
- **pollutant sensors.** Special sensors for nitrogen oxides, sulfur oxides, chlorine, mercury, and other pollutants may be required to satisfy regulatory limits on emissions.
- **fuel flowmeters** are the most accurate way of measuring energy input. Flowmeters for individual boilers are important for making efficiency measurements, and for shifting load among boilers of different sizes. Measuring the total facility fuel

WESINC

Fig. 1 Smoke opacity monitor This is simply a bright lamp that shines across the flue toward a light sensor on the other side.

flow rate gives you an instantaneous indication of facility energy consumption.

- **fuel quantity meters** are needed to indicate total fuel consumption over periods of time. Mechanical fuel meters measure consumption accurately. See Figure 3. Alternatively, you can use the same electronic instrument to measure fuel flow rate and total consumption. Metering individual boilers is not necessary unless they serve separate functions.
- **steam or BTU meters** are installed if the plant is serving multiple customers who are separately accountable for energy usage. Steam and BTU meters are limited in accuracy and reliability. Don't expect that you can use them to determine the overall efficiency of your boilers. However, you will find it informative to compare your combustion efficiency tests to the efficiency you calculate using the steam or BTU meters. True combustion efficiency is somewhat higher than true overall efficiency. This is because combustion efficiency testing does not measure all losses.
- **fuel oil thermometers.** Fuel oil temperature is a factor in burner efficiency, as discussed in [Measure 1.9.1](#).
- **fuel oil and gas pressure gauges.** Fuel pressure is a factor in burner efficiency.
- **air casing pressure gauges.** Monitor air casing pressure when the flow of air into the casing from the forced-draft fans is adjustable. You can use this information to minimize the energy consumption of variable-flow fans, as recommended by [Measure 1.4.7](#).

Data Displays and Recorders

Chart recorders provide a valuable display of trends in measurements. For example, a strip chart recording of oxygen in the flue gases indicates how well the air-fuel controls are working. Even if the oxygen content stays within acceptable limits, a recording might show

WESINC

Fig. 3 Fuel meter This accurate, inexpensive device, installed in the fuel oil line to the burner, tells you how much energy is going into your boiler. If combined with an accurate measurement of heat output, it also tells you the average efficiency of the boiler.

that the controls are starting to behave erratically, suggesting loose control linkages, a failing sensor, etc.

This does not mean that you should attach a chart recorder to every gauge in the boiler plant. Use recording instruments where it is useful to see the long-term trends or the short-term stability of measurements.

Multiple-channel recorders are valuable for seeing the relationship between different measurements. For example, there is no point in recording stack temperature alone because it fluctuates with load. But, using a two-channel recorder that records the stack temperature and the fuel flow rate simultaneously makes it possible to track relative efficiency.

The latest development in data recording is digital logging. This is much more convenient than using messy paper charts (no more ink pens!), and it gives you much more capability to analyze the data and produce reports. With a digital recording system, the sensor output is converted to a digital record. You can save virtually unlimited amounts of data on tiny digital storage media. You can perform any kind of calculation with the data, and display the output in any form that is convenient (a computer monitor, a printer, etc.). Software that allows you to take advantage of this capability is now becoming available at modest cost.

Be aware that collecting data in digital form does not improve its accuracy. Accuracy depends mainly on the sensors. Digital recording adds an extra step of conversion from the sensor output to a digital signal, which may increase the measurement error. On the other hand, digital data collection allows more accurate calculations from the data, such as totalling the steam flow that is measured by steam meters.

Coordinate with Your Other Efficiency Instrumentation

Take a broad view as you plan your permanent efficiency instruments. You will also want appropriate instruments to optimize the efficiency of your chiller

plant, air handling systems, industrial processes, and other equipment. You need different types of instruments for each of those other purposes, but consider the ways that you can save effort and cost by planning them all together. As a minimum, you will probably want all your fixed instruments to provide uniform formats for collecting and analyzing data for energy management purposes.

ECONOMICS

SAVINGS POTENTIAL: *In the most favorable cases, using installed efficiency instrumentation to keep a boiler tuned may save several percent of efficiency, compared to testing and adjustment at long intervals. Credit these savings to the specific actions you take to improve efficiency.*

COST: *Less than one hundred dollars (for a good quality stack thermometer, for example) to tens of thousands of dollars for elaborate data logging equipment. The cost of appropriate instrumentation is roughly proportional to the size and complexity of the plant. The cost is minor compared to overall plant operating costs.*

MAINTENANCE: *Most instrumentation related to boiler efficiency requires periodic calibration and/or maintenance to maintain accuracy. See [Measure 1.2.3](#).*

MEASURE 1.2.3 Calibrate boiler plant instruments at appropriate intervals.

RATINGS

New Facilities	Retrofit	O&M

Boiler plant instruments must be accurate in order to be useful. An instrument may have to be calibrated when it is first installed, or it may have to be re-calibrated periodically, or both. Re-calibrate your instruments often enough to keep them within the range of accuracy that you need to maintain efficiency.

Each type of instrument requires different calibration procedures, and some are more difficult to calibrate than others. For example, you need to test and/or calibrate temperature sensors against a reliable standard thermometer, or by testing them in boiling water.

Some instruments cannot be re-calibrated. Sealed units, such as liquid and capillary thermometers, must be replaced if they are inaccurate.

Some instruments cannot be tested for accuracy once they are installed. For example, there is no way of checking the accuracy of flow measuring devices without setting up a virtual test laboratory. Such equipment depends on factory calibration, which must be taken on faith. This is also true of some control elements, e.g., square root extractors for pitot tubes.

Many boiler plants are beautifully equipped with instruments to measure virtually every parameter of the plant’s operation. But in many such plants, you can see that the instruments are out of calibration and no one is paying any attention to them. Or, someone takes readings every hour, and no one ever reviews the log sheets. Is this happening in Figure 1?

Instrumentation is useless unless the operating staff have the ability and the instructions to exploit it properly. Provide formal training for your boiler personnel in using efficiency instrumentation. The key elements in doing this are an effective instructor, effective training procedures, and an operating staff that is capable and motivated.

In large plants, operators may be specialized. For example, only a single individual may be trained and authorized to adjust the combustion controls. On the other hand, all operators should know how to use

Air-Fuel Ratio

The ratio of combustion air to fuel is the most important adjustment on a boiler. You can often improve efficiency significantly by keeping the air-fuel ratio optimized. The Measures in this Subsection optimize the air-fuel ratio, improve air-fuel controls, and correct defects in the controls.

MEASURE 1.3.1 Optimize the air-fuel ratio.

Air-fuel ratio is by far the most important routine adjustment that is made to boilers. Of all the adjustments that plant operators can make, it has the greatest influence on efficiency. Furthermore, failure to set the air-fuel ratio properly can create serious maintenance and environmental problems.

If you have automatic combustion controls, adjusting the air-fuel ratio is easy. Using the methods explained in [Measure 1.2.1](#), measure combustion efficiency while setting the combustion controls to the optimum air-fuel ratio. The combustion controls will then maintain this ratio under all load conditions.

Adjusting the air-fuel ratio is not much more difficult if you have burners that fire at one or more fixed firing rates. On the other hand, adjusting modulating burners can be tedious.

The basic steps are described here. See the burner maintenance manual for details of how to adjust your particular model of burner.

The Optimum Air-Fuel Ratio

A perfect boiler would use just enough air to burn all the fuel completely, with no oxygen left over in the flue gas. (The ratio of air to fuel that achieves this ideal result is called a “stoichiometric mixture” by chemists and advanced boiler people.) With real boilers, achieving reasonably complete combustion requires a certain amount of air in excess of the stoichiometric ratio. The excess air is needed to ensure that all the fuel comes in contact with sufficient oxygen for complete combustion within the flame area.

The minimum amount of excess air that is necessary for clean combustion depends on the type of fuel and on the type of burner. Table 1 in [Measure 1.4.4](#) lists typical ranges of excess air for different fuels and burner types. More excess air is needed for fuels that are heavier and dirtier. Also, burners in smaller equipment tend to have substantially higher excess air requirements. Modern, high-efficiency burners minimize the amount of excess air required. The best modern burners do a much better job of preparing the fuel for combustion and of bringing the proper amount of air into the combustion zone.

The design of the boiler’s combustion chamber may also affect the excess air requirement. The design of the combustion chamber becomes an issue in existing boilers if you plan to retrofit a new burner.

Determine the optimum air-fuel ratio for each of your boilers individually, using the tests recommended below.

SUMMARY

The most important routine adjustment for boilers. Has a major effect on efficiency, maintenance, and pollution. The trick is to set the air-fuel ratio as close to optimum as possible, while avoiding insufficient air.

Efficiency Loss from Incorrect Air-Fuel Ratio

Efficiency suffers from too much air, and from too little. Efficiency declines rapidly as the amount of air is reduced below the point of best efficiency. Efficiency declines much more slowly above the point of best efficiency. This is because insufficient air and excess air waste energy in two different ways.

With insufficient air, efficiency falls primarily because combustion is incomplete. The incompletely burned portion of the fuel is being thrown away through the flue, taking along its unused energy.

With excess air, the fuel is being burned almost completely, but a portion of the combustion energy is wasted in heating the excess air. The heated excess air is carried through the boiler as useless baggage. Also, mixing the combustion gases with excess air lowers the temperature of the gases, which reduces heat transfer. See the effect in the graph of Figure 1 in [Measure 1.2.1](#).

If the amount of excess air is extreme, the large volume of cool air can quench the combustion process, causing fuel to be burned incompletely. However, this effect does not become significant until efficiency has already been lowered drastically by the previous effect.

Other Problems Caused by Insufficient Air

To repeat, insufficient air wastes much more energy than an equal percentage of excess air. In addition, insufficient air causes these problems:

- **air pollution.** For any hydrocarbon fuel (gas, oil, coal, wood, peat, etc.), the end products of complete combustion are carbon dioxide and water, along with a small amount of additional compounds that may be formed from other substances in the fuel.

The combustion process is complex, and includes a myriad of intermediate organic compounds, especially with oil and solid fuels. Many of these partially burned combustion products are noxious compounds that comprise an air pollution problem if they escape unburned. If the air-fuel ratio is too low, the chain of combustion reactions is incomplete, greatly increasing the emission of pollutants.

- **fireside fouling.** With insufficient air, some of the products of incomplete combustion adhere to the heat transfer surfaces in the form of soot. Soot is a porous material that is mostly carbon, combined with other products of incomplete combustion that tend to be sticky. Its porous nature makes it an effective insulator, resisting the flow of heat from the combustion gases to the boiler water. Even small amounts of soot can significantly reduce efficiency. Soot accumulates rapidly when there is too little air for complete combustion.
- **explosion hazard.** When combustion is incomplete, the unburned fuel components make the flue gas potentially explosive. If the gases reach a part of the boiler or flue where they can be mixed with additional air (for example, above an atmospheric flue damper), they could explode if ignited.
- **flame instability.** Flame stability can be a problem when pushing the limits of low excess air with conventional burners. Minimizing excess air can produce noticeable pulsations in the flame. This can become dangerous if the flame is briefly extinguished and then re-ignites. This problem can occur with some burners even though the amount of air still exceeds the stoichiometric ratio. With such burners, the most direct solution is to replace them with burners that are designed to operate with low excess air. See [Measure 1.4.2](#) for this Measure.

Insufficient air creates highly visible smoke and it deposits soot that requires hard work to remove, so boiler operators tend to avoid insufficient air. They may carry this to the extreme of carrying far too much excess air.

Incomplete Combustion Caused by Extreme Excess Air

When excess air is carried to an extreme, it cools the gases enough to prevent complete combustion. The amount of excess air that will cause incomplete combustion depends on the type of fuel, the burner design, and the firebox conditions. The main problems caused by having too much excess air are inefficiency, air pollution, and fireside fouling.

The compounds that form in excess air are different from the compounds that form when there is insufficient air. You can see this easily by observing the smoke.

For example, burning petroleum with insufficient air produces dense black smoke, while an extreme amount of excess air produces dense white smoke.

General Procedure for Adjusting Air-Fuel Ratio

Adjusting the air-fuel ratio consists of testing the combustion efficiency of the boiler and adjusting the air-fuel ratio until you find the optimum air-fuel ratio. [Measure 1.2.1](#) gives the details of the tools you need to measure the air-fuel ratio. In summary, the test sequence is:

- **Set the air-fuel ratio by using the oxygen test.**
- **Refine the adjustment by setting carbon monoxide.** As you reduce excess air and get close to the point of optimum efficiency, the carbon monoxide in the flue gas will start to rise rapidly. This rapid increase occurs at about 200 to 400 parts per million carbon monoxide, with most fuels. Set the air-fuel ratio just short of this rapid rise. You will not be able to set the carbon monoxide level properly if there is a defect in the boiler that causes incomplete combustion. In such cases, the amount of carbon monoxide remains high near the optimum air-fuel ratio. In fact, this condition is a reliable indication of trouble. Typical causes of high carbon monoxide are a fouled burner or an improper flame pattern that allows the flame to contact a combustion chamber surface.
- **With dirty fuels, conduct a smoke test.** Add air as necessary to reduce soot and smoke to acceptable levels. Use a smoke test if the fuels used produce too much soot and smoke even at low carbon monoxide concentrations. Dirty fuels require additional excess air to burn up combustible material that is embedded in inorganic particles that are released when the fuel is burned.
- **Repeat the oxygen test and check it with a separate carbon dioxide test.** The oxygen test is based on some assumptions (spelled out in [Measure 1.2.1](#)) that break down under certain conditions, so it is a good idea to check it with a test of a different type. If the carbon dioxide test does not correlate to the oxygen test, there is something wrong with either the test or the boiler. If you find that you cannot reduce excess air without producing excessive smoke or carbon monoxide, the problem is probably in the boiler. Either the burners need cleaning or there is an equipment defect in the boiler, the flue, or the air delivery system.

The procedure for adjusting the burner assembly or the air-fuel controls differs from one unit to another. The only reliable guide is the burner manufacturer's instructions. Follow the instructions exactly.

WESINC

Fig. 1 Atmospheric gas burner The primary air to each venturi is adjusted on this furnace by rotating a plate with holes in it. As you can see, the settings are random, wasting energy and increasing air pollution.

WESINC

Fig. 2 Another atmospheric gas burner On this furnace, the primary air for each venturi is adjusted by a disk that moves along a threaded rod, providing fine adjustment.

Use a Little Additional Excess Air to Allow for Changing Conditions

You can set the air-fuel ratio with almost perfect precision by using the methods just described. However, the air-fuel ratio can wander after it is set, from these causes:

- changes in atmospheric conditions
- imperfect calibration of throttling burners across the load range
- wear of mechanical linkages
- friction in pneumatic actuators
- fouling of sensors in automatic combustion controls
- burner fouling
- differences in fuel composition between batches
- changes in fuel oil or gas pressure
- changes in fuel oil temperature.

With mechanical air-fuel controls, these factors make it advisable to provide an additional margin of excess air to avoid the problems caused by insufficient

air. If the maintenance of the plant is competent and energetic, it is probably not necessary to add more than a few percent of excess air to account for these factors. In plants with less sophisticated controls, and in plants that are not monitored closely, you may have to widen the margin of excess air. But don't overdo it.

Even with automatic air-fuel controls, it may be desirable to add a small margin of excess air. The amount depends on the accuracy of the controls. You will get a feeling for the right amount of excess air from regular combustion efficiency testing and from monitoring the trend of fireside fouling.

How to Adjust the Air-Fuel Ratio Mechanically

If you do not have automatic combustion controls, you need to set the air-fuel ratio by making mechanical adjustments to the burners or the control linkages. You need the burner manufacturer's maintenance manual and the latest service bulletins to show you precisely what to do. There may be critical adjustments that do not seem important from their appearance. If you are not sure that you have all the information you need, call the factory. Details matter, so don't try to fake it.

Also, you should have a combustion efficiency tester for this job that provides a continuous, instantaneous readout. (See [Measure 1.2.1](#) for tips on selecting the equipment.)

It helps to have two persons doing this work, especially if the burner adjustments are not close to the point where the flue gas sample is taken for the combustion efficiency tests. One person stays at the boiler breeching with the test equipment and calls out the readings, while the other person adjusts the burner.

Try to hold the boiler load as steady as possible during the adjustments. If the burner operates at different firing rates, you may have to set the air-fuel ratio for each firing rate at different times, as the load changes. If the load on the boiler plant is light, it is practically impossible to set the fuel-air ratio for high firing rates. Do not create a load by warming up a cold boiler, because this would produce erroneous efficiency readings and air-fuel settings.

■ Atmospheric Gas Burners

Most atmospheric gas burners have two sources of air, "primary" air and "secondary" air. Primary air enters the venturi and mixes with the fuel there. Secondary air enters around the outside of the burner, and mixes with the flame at the burner.

In packaged boilers where the burner is an integral part of the boiler, there is usually no adjustment for secondary air. In such boilers, setting the air-fuel ratio involves little more than changing the position of a shutter that controls the flow of primary air. Figures 1 and 2 show two examples.

In contrast, generic burners designed for retrofit installations have a separate adjustment for secondary

air, and the proper secondary air setting is important in such installations. See [Measure 1.4.2](#) for more about atmospheric burners.

You may find that the primary air setting has little effect on boiler efficiency or on the excess air requirement. But, the primary air setting may seriously affect the carbon monoxide concentration in the flue gas. Therefore, test for carbon monoxide when setting atmospheric burners.

■ Modulating Burners

Modulating burners with mechanical air-fuel controls typically have a single control motor that moves in response to the boiler's output pressure or temperature. The control motor has a linkage connected to an air control, which typically is a damper. The motor also has linkage to the fuel control, which is a valve of some kind. If the burner can burn more than one type of fuel, there is a separate linkage for each type of fuel.

The control linkages are non-linear, which means that a certain amount of motion in the air control linkage does not produce the same relative change as the motion in the fuel linkage. To compensate for this, the fuel linkage typically has an adjustable cam, which makes the fuel flow proportional to the air flow.

Boilers with mechanically modulating burners commonly link the air and fuel controls with a common shaft, called a "jackshaft." The load control motor drives the jackshaft. The jackshaft typically has an arm that drives a linkage to the air damper, and it has one or

WESINC

Fig. 3 Typical jackshaft air-fuel control The jackshaft is mounted horizontally, moved by the control motor on the upper left. A cam on the left end of the jackshaft controls a fuel oil valve, and a cam on the right end of the shaft controls a gas valve. An arm to the left of the shaft's center support moves the combustion air damper. The air-fuel ratio depends on the relative positions of these mechanical linkages.

more cams to depress plunger-type fuel valves. Figure 3 shows a typical jackshaft arrangement for a dual-fuel boiler, and Figure 4 shows a detail of a typical cam.

The air-fuel linkages are normally adjusted at the factory, with little provision to make it easy to adjust them in the field. For example, the typical fuel adjustment cam has a shape that is set by adjusting a large number of screws. This makes it tedious to adjust the air-fuel ratio.

WESINC

Fig. 4 Typical cam on jackshaft air-fuel linkage The shape of the cam determines the air-fuel ratio at all boiler loads. The shape can be adjusted by turning the screws that you see between the cam body and the curved spring that rides on the plunger. This is a tedious job.

The procedure consists of holding the firing rate steady, measuring the efficiency, performing the necessary adjustment to the air-fuel ratio, and repeating the sequence until the point of best efficiency is found. Then, repeat this process for the next increment of load. The number of adjustments depends on the design of the mechanism that controls air and fuel. With a variable cam, you have to change the boiler loading in small increments that allow you to set each of the adjustment screws. Regardless of the linkage design, make the adjustments at sufficiently close intervals to keep the boiler efficient at all loads.

It may be difficult to hold the boiler output steady at each percentage of load as you make the adjustments. If you have more than one boiler, you can shift the load between boilers by changing the relative pressure or temperature settings of the boilers. You can use three people for this job. One adjusts the boiler load, another performs the combustion efficiency tests and calls out the readings, and the third adjusts the air-fuel controls.

After you go through this exercise, you will understand the advantages of combustion air “trim” systems, which adjust the air-fuel ratio automatically and continuously. See [Measure 1.3.2](#) for details.

■ How Often Should You Adjust the Air-Fuel Ratio?

Inspect the air-fuel ratio on a periodic basis. With mechanical air-fuel controls, the ratio drifts because of the factors discussed previously. You need less excess air as a safety factor if you test and adjust the air-fuel ratio more often.

The appropriate interval between settings depends on the type of boiler and the type of fuel. A simple gas-fired boiler with atmospheric burners may hold its efficiency for years without adjustment and with minimal maintenance. On the other hand, a large

pressure-fired boiler burning a variety of fuels may have a noticeable drift in air-fuel ratio over a period of days or weeks.

Adjust Flue Draft First

Adjust the flue draft before you set the air-fuel ratio. The principles of flue draft and the methods of adjusting it are explained in [Measure 1.5.3](#).

ECONOMICS

SAVINGS POTENTIAL: 1 to 10 percent of fuel cost, typically.

COST: The cost of efficiency test equipment is covered in [Measure 1.2.1](#). The amount of labor required to set air-fuel ratio can be less than one man-hour for a boiler with a single-stage burner, to several man-days for a boiler with throttling burners and difficulty in maintaining a steady load.

PAYBACK PERIOD: Immediate, to one year.

TRAPS & TRICKS

SKILLS: Adjusting air-fuel ratio requires two skills, efficiency testing and setting the boiler's air-fuel controls. See [Measure 1.2.4](#) about the former. Make sure that the person adjusting the boiler knows how to do it correctly.

TEST EQUIPMENT: The right test equipment makes the work much easier. See [Measure 1.2.1](#) about selecting test equipment.

BOILER CONDITION: You can't set the air-fuel ratio properly if the boiler's controls are sloppy or defective. See [Measure 1.3.3](#) about maintenance.

SCHEDULING: Repeat the procedure periodically. Make sure that you have an effective method of scheduling it.

RATINGS

New Facilities	Retrofit	O&M
A	C	

Automatic air-fuel controls provide the ultimate in efficiency by continuously monitoring the flue gas composition and readjusting the air-fuel ratio. These controls are common on larger boilers. You can retrofit them to existing boilers.

Environmental regulation of boiler operation has expanded enormously in recent years, and continues to expand. If you decide to install automatic air-fuel controls, consider the effect of regulation on the capabilities that the controls should have. Try to satisfy foreseeable environmental regulations as well as maximizing efficiency.

The simplest type of automatic air-fuel control is an “oxygen trim” system. Oxygen trim systems typically sense only oxygen in the flue gases. The output of the oxygen trim system is a small adjustment in the air-fuel ratio to move the measured oxygen content in the desired direction. Figure 1 shows the control box for a typical oxygen trim system.

At the other extreme are complex air-fuel control systems for large boilers that measure a variety of flue gases and combustion conditions. Virtually all of these use flue gas oxygen as the primary measurement. They may also sense carbon monoxide, nitrogen oxides, other gases, and smoke. Such systems provide accurate control of boiler output, precise control of air-fuel ratio, and control of various functions related to plant emissions, such as stack gas recirculation and scrubbing.

Potential Savings

The improvement in efficiency that you can expect from automatic air-fuel control system varies widely from one boiler plant to another. As an example, a boiler burning heavy oil might have an optimum excess air of 15%. In this boiler, increasing the excess air to 30% would cause an efficiency loss of one percent. In some plants, excess air may drift from 15% to 30% under realistic operating conditions. Therefore, you may be able to save about one percent of fuel energy percent in such a plant. In plants where maintenance has been neglected, the saving may be as high as several percent of the fuel input.

On the other hand, a well maintained boiler that burns natural gas of stable characteristics may benefit little from automatic air-fuel adjustment. In this case, a simple mechanical linkage that regulates the air-fuel ratio may keep efficiency optimized within close tolerances. With such a boiler, the efficiency improvement would typically be only a fraction of one percent.

Take the claims of efficiency improvements made by combustion control manufacturers with a grain of salt. Before-and-after comparisons, even if they are monitored by a disinterested party, may be misleading. Much of the improvement that is measured when a trim system is installed may actually result from the cleaning and tune-up that occurs along with the installation.

Most Favorable Applications

Larger boilers are candidates for automatic air-fuel controls because small differences in efficiency can produce large differences in absolute energy consumption. For example, a boiler that produces 100

million BTU's per hour of steam for 3,000 hours per year while burning heavy oil at \$1.00 per gallon has an annual fuel cost of approximately \$2,500,000. Improving efficiency by one half of one percent would save approximately \$12,000 per year.

An automatic air-fuel control system is more valuable if the factors that affect the air-fuel ratio are subject to change. Some of the conditions that can cause the air-fuel ratio to drift are listed in [Measure 1.3.1](#), above.

Boilers that burn solid fuels or heavy oils need to adjust the air-fuel ratio continually to account for changes in fuel characteristics, such as the content of carbon, hydrogen, oxygen, sulfur, moisture, and dirt. With coal, these factors can change as fuel is brought in from different parts of the coal pile. With oil, they can change as different strata of oil are tapped from the tanks.

Automatic air-fuel controls correct for drift, hysteresis, and non-linearity in control linkages. For example, where pneumatic actuators are used to control the fuel valves and/or fan dampers, friction in the actuators and linkages can cause errors in the air-fuel ratio. Linkage geometry in modulating burners is typically non-linear, and requires tedious adjustments of cams to compensate. Automatic controls can eliminate the need to adjust for these factors.

Staff Skill and Control Reliability

To a certain extent, automatic air-fuel controls can compensate for deficient maintenance. In particular, it can compensate for lack of tuning and for looseness in the controls. However, automatic combustion controls are not a proper substitute for skills, salary, and supervision. Installing a complex control system in an environment with poor maintenance trades continuing poor efficiency for the possibility of much worse efficiency if the control system fails.

By the same token, you need controls that are especially reliable in plants that are not continuously monitored by skilled operators. This situation is common in non-industrial facilities, where the boiler plant is often treated as an inscrutable nuisance.

Any automatic combustion control should continuously self-test, and it should sound an alarm if it senses failure or an out-of-range condition.

System Components and Installation Issues

Automatic air-fuel mixture controls vary in complexity, control accuracy, and versatility. Their performance depends on their installation as well as their components. These are the basic components, and some important issues to consider in installing them:

- **flue gas probe(s) or sensor(s).** The mechanics of installing sensors is usually easy. Be sure that the location where you install the sensor(s) provides a representative sampling of flue gases, and that it

provides a reliable average flue gas temperature. Be careful to prevent outside air from mixing with the flue gas sample. See [Measure 1.2.1](#) for more about this.

- **analysis hardware and logic circuitry.** This usually comes in a single box. If the sensor output is electrical (for example, from a zirconium oxide oxygen sensor), the box can be installed almost anywhere. If gas samples are conveyed to the box through tubing, install the box within a specified distance from the sampling point.
- **displays.** You should install gauges or recorders that display gas content, efficiency, etc. Install them where they are mostly likely to be monitored by the operators.
- **actuators.** Actuators translate the output signal of the combustion control system to motion of the fuel valves and air dampers. Retrofitting actuators on a preexisting control system can be challenging, unless the retrofit system is custom designed for the particular boiler.

With boilers that use a common mechanical linkage to control both air and fuel, the usual practice is to insert a variable-length link in a part of the original linkage that controls either the air or the fuel. The trim system works by controlling the length of the variable link.

Larger boilers typically use pneumatic, electric analog, or digital signals to control the motion of separate actuators on the fuel valve and fan control. With such controls, you have to match the output signals of the combustion control system with the signals needed by the actuators. For example, if the original controls move the fuel and air actuators with 3-to-15 PSI air pressure, the trim system must have pneumatic outputs in this range. Alternatively, you can change the actuators.

- **failure alarms.** To repeat, the control system should test itself continuously. If a failure occurs, or if the air-fuel ratio gets out of the designated range, the controls should indicate an alarm. Make the alarm able to get attention, in a manner appropriate to the staffing. For example, if the boiler plant is not staffed continuously, have the alarm trigger a loud horn, or automatically dial the telephone of the appropriate manager, or whatever is needed to initiate immediate repairs.

How to Select Air-Fuel Controls

Air-fuel control systems differ widely in cost and in the range of features that they offer. Here are the main features to consider when shopping for a system.

■ What is Sensed

Sensing the oxygen content of the flue gas provides the most direct and accurate indication of combustion

efficiency. The least sophisticated combustion air trim systems measure only oxygen, and these systems are called “oxygen trim” systems.

More sophisticated combustion air trim systems adjust the oxygen concentration by sensing unburned combustibles. These systems typically sense carbon monoxide as an indicator of unburned combustibles. Carbon monoxide plays this role because it is the second from the last combustion product in the long chain of reactions by which the carbon in petroleum or other complex fuels is converted to carbon dioxide. Hydrogen is sometimes used as an indicator of unburned combustibles, but this practice is limited to specialized applications.

Smoke density, or opacity, is commonly used as a separate indicator of unburned combustibles when burning dirty fuels, like heavy oil or coal. A separate indicator is desirable because carbon monoxide does not correlate well to the concentration of large unburned particulate matter in the flue gases. Monitoring smoke opacity is necessary in its own right because visible smoke may be an environmental or public relations issue.

Still another approach is measuring total unburned combustibles, using one of the sensor types described below. At the present time, this approach is uncommon in smaller boilers.

The combustion air trim system may also have to control other gases not directly related to efficiency. Environmental laws restrict emission of nitrogen oxides and sulfur oxides from larger boilers. Specialized boilers, such as refuse burners, may have to control other flue gas constituents, such as chlorine and mercury. Such gases are controlled by boiler design and by the addition of specialized equipment, such as flue gas scrubbers and flue gas recirculators. The operation of such equipment affects combustion air control.

■ Sensor Types

Oxygen is commonly measured with a zirconium oxide sensor. This is a solid state device that develops a voltage in response to a difference in oxygen concentration across two sides.

Carbon monoxide is measured with a variety of devices, including:

- electrochemical cells, which produce electric current when carbon monoxide is involved in specific chemical reactions
- infrared absorption detectors, which send a beam of infrared light through the flue gas. The light is tuned to an oscillation frequency of the carbon monoxide molecule, which causes carbon monoxide to absorb and scatter the light.
- polarization detectors, which function by sending a beam of polarized light through the flue gas, and measuring rotation of the direction of polarization

by the gas. This is done with polarizing filters similar to polarized sunglasses.

Unburned combustibles can be measured directly with catalytic units that work by burning up the combustibles and measuring the heat produced. In order for this type of sensor to work, there must be some oxygen in the flue gas. Unburned combustibles can also be measured with flame ionization detectors.

Smoke opacity, which may indicate both combustible and non-combustible particulate matter, is usually sensed by measuring the absorption of a beam of light in the flue.

Flue gases that are not directly related to combustion efficiency, such as nitrogen and sulfur oxides, are measured with a variety of technologies. For example, oxides of nitrogen can be sensed by chemiluminescence, which is the emission of certain wavelengths of light when nitrogen oxides undergo specific chemical reactions. Sulfur oxides and chlorine can be detected with polarized light sensing. And so forth.

With some types of sensors, one type of gas may register as another. For example, hydrogen and hydrogen sulfide register as carbon monoxide on some electrochemical carbon monoxide sensors. Guard against such cross readings if the flue gases contain large concentrations of combustion products other than carbon dioxide and water vapor.

Sensor technology is a rich and growing field. Check the latest offerings when selecting a system. The best types for air-fuel control will probably change with time as existing sensor types evolve and new types are discovered.

■ Sensor Calibration

The sensors used in combustion air controls are exposed continuously to the harsh environment of the flue. This causes the output of the sensors to drift. If not corrected, sensor drift causes serious inaccuracy in control. The only solution to drift is recalibrating the sensors at appropriate intervals. Some types of sensors can be recalibrated with the boiler in operation, and others cannot be. Sensor accuracy is important, so get sensors that can be recalibrated while the boiler is operating.

Even if the sensors can be calibrated during boiler operation, you may have to manually initiate a calibration cycle. This has the disadvantage that the procedure can be neglected, but it has the advantage of reminding operators of the need for checking the condition of sensors. Automatic recalibration cannot repair a sensor that becomes defective.

Oxygen sensors have the important advantage that they can be calibrated using ambient air. The atmosphere contains a fixed percentage of oxygen, so the sensor can be calibrated by diverting boiler room air into the sensor while it remains in place. Most zirconium oxide

sensors used in combustion control systems include this feature.

Carbon monoxide sensors that use the principles of infrared absorption or polarization can be calibrated continuously by using reference beams of light. Sensors that use electrochemical cells must be recalibrated periodically by passing calibration gases through the sensor.

Instruments that need calibration gases require you to keep a stock of the appropriate gases on hand. Also, using calibration gases requires more skill.

Smoke opacity sensors can be recalibrated continuously by using a reference light beam.

Sensors for gases that are not directly related to combustion efficiency operate on a variety of principles. Some of them can be continuously recalibrated, and some cannot be.

■ Ability to Change the Air-Fuel Ratio with Load

The simplest oxygen trim systems establish a constant percentage of oxygen at all boiler loads. A constant oxygen percentage is less than optimum because it allows the percentage of unburned fuel products to rise at lower loads. (This occurs because the combustion zone is smaller and cooler at low loads, requiring more oxygen to ensure complete combustion.)

The appropriate variation in oxygen content with load depends on the fuel and the boiler design. For this reason, most oxygen trim systems include provision to manually adjust the amount of excess oxygen at different boiler loads. This is called “characterization” of the controls. Do it when the controls are installed, and when sensor elements are replaced.

More sophisticated combustion air trim systems eliminate the need for manual characterization of excess air by sensing unburned fuel components in addition to sensing oxygen. Even so, complex systems may still have a manual characterization capability to allow for control of smoke or environmental pollutants.

■ Multi-Fuel Capability

In boilers that burn more than one type of fuel, account for the fact that the optimum air-fuel ratio differs from one fuel to another. Heavier and dirtier fuels require more excess air than gaseous or light fuels. Therefore, get automatic air-fuel controls that provide separate characterization for each fuel burned.

■ Failure Modes and Overrides

Combustion controls will fail occasionally. For this reason, the system should have a reliable self-test feature, and it should respond to failures by reverting to a fail-safe setting. Typically, the fail-safe setting is a fixed percentage of excess oxygen.

A particularly reliable method of fail-safe control is to have mechanical stops in the control linkages so that high and low limits in the air-fuel ratio cannot be exceeded. Such stops are possible only if the air damper

and the fuel valve are connected by a common mechanical linkage. This type of fail-safe limit is not possible with control systems in which the air and fuel are controlled separately by pneumatic, electrical, or electronic signals.

■ Alarms

The controls should have effective alarms to alert operators of any undesirable condition, especially a failure of the combustion control system or an excess of undesirable gases in the flue.

■ Displays and Data Logging

The control system should include convenient displays of all the measurements being taken, such as percentage of gas concentration and flue temperature. If you can afford it, get data logging equipment to record and analyze long-term trends in the measurements.

Some systems display derived values, such as percent efficiency and boiler load. Understand which outputs are being measured directly, and which are derived. For example, percent carbon dioxide may be calculated from the measured percent oxygen and the flue temperature. Such a derived value is dubious and can be misleading. Boiler load indications may be derived from stack temperature. Such a load indication is only approximate, because other factors can affect flue temperature.

The output of the combustion control system must be matched to the input of the recording and analysis equipment. There are a variety of signal conventions, such as 4-to-20 milliamperes or 0-to-100 millivolts. If the combustion control system includes integral data logging, you don't have to worry about this.

■ Actuator Connections

It can be tricky to make the mechanical connections to the existing air-fuel control system. Select a system that makes this job as easy as possible.

■ PID Control Characteristics

It is difficult to maintain control of the air-fuel ratio when the boiler load fluctuates rapidly, as occurs in many applications. To achieve accurate tracking, sophisticated control systems have special features to reduce error, eliminate overshoot, and prevent oscillations. These are usually called “proportional-integral-derivative” (PID) control characteristics. See [Reference Note 37](#), Control Characteristics, for details.

RATINGS

New Facilities	Retrofit	O&M
		A

The air-fuel control system needs maintenance on a regular basis. The mechanical components that control air and fuel are continually moving in response to load changes. Something as simple as a loose connection can cause a major error in the air-fuel ratio. Combustion control systems have sensors that are exposed to hot flue gases, so they require periodic calibration and replacement.

Looseness in Mechanical Linkages

The air and fuel controls of most boilers have some mechanical linkages. Most small and medium sized boilers control the air-fuel ratio entirely with mechanical linkages, which may include a rotating shaft, one or more bellcranks, pushrods, and an adjustable cam. These linkages are simple, accessible, and easy to understand. Figure 1 shows a typical example.

This is fortunate, because the adjustment of the linkages is critical. Even a small amount of play may cause significant inefficiency because fuel and air controls typically have a small range of movement. Fuel valves are usually the most sensitive element. For example, movement of a millimeter in a plunger-type fuel valve may cause a significant change in fuel flow.

Air-fuel linkages have a number of wear points and opportunities for components to come loose. To discover play in a control linkage, hold one end of the linkage in a fixed position. Then, grasp the linkage at various places and attempt to move it while feeling for looseness. Inspect each bearing and joint in the linkage as you do this. If there is enough play in the linkage to allow any significant amount of motion, repair the linkage or tighten it. Replace all worn components.

Unfortunately, many burners have air-fuel linkages made of cheap stamped parts, so they are vulnerable to wear and working loose. Some common components,

such as slotted sheetmetal control arms, are unbelievably flimsy. Linkages are often adjusted with ordinary nuts, which are virtually certain to work loose in time. Improve such features wherever you can. For example, if your linkages have slotted control arms, install friction washers on each side of the slot, and use an all-metal stop nut.

Industrial Combustion

Fig. 1 Typical dual-fuel burner assembly All the linkages that control the air-fuel ratio of this burner are easily accessible for inspection, adjustment, and repair.

■ Mechanical Components of Combustion Air Trim Controls

In air-fuel controls that have combustion air trim systems (covered in [Measure 1.3.2](#)), the trim system can compensate for wear in the mechanical components up to a point. But don't rely on this. When the movement of the linkage reverses direction, the slack in the control linkage must be taken up in the reverse direction to get the air-fuel ratio back within limits. Such control reversals may occur frequently, and the hammering that they produce in the linkage aggravates the looseness. Beyond a certain point, looseness in the control system can trigger major control oscillations so that the air-fuel ratio never stabilizes. For this reason, keep your combustion control systems just as tight as mechanical air-fuel controls.

Sensors in Combustion Control Systems

Combustion control systems continuously readjust the air-fuel ratio by sensing the combustion products in the flue gases. When they function properly, automatic combustion controls provide the ultimate in efficiency. However, their accuracy depends on proper operation and calibration of their gas sensors and associated circuitry.

The combustion gas sensors are the most vulnerable element of automatic air-fuel control systems. Most combustion control systems operate by sensing oxygen with a zirconium oxide element. Zirconium oxide elements are more tolerant of the flue environment than other types of sensors, but they eventually foul. The sensor typically must be replaced every year or two. Between replacements, the sensor and associated instrumentation require periodic recalibration. This may be done automatically by the control system, or an operator may have to initiate a recalibration cycle. Oxygen sensors typically are recalibrated with ambient air, which contains a known quantity of oxygen.

More sophisticated combustion control systems operate by sensing other flue gases in addition to oxygen, such as carbon monoxide. Sensors for other gases typically require frequent replacement. Also, calibration of the sensors may require more elaborate procedures than for calibrating oxygen sensors. Some types of sensors require calibration gases for recalibration. These are gases that have a known percentage of the type of gas that is being measured in the flue.

Test, maintain, and calibrate sensors using the manufacturer's procedures. Calibrate often enough to avoid substantial drift in control accuracy.

Upgrading

The technology of air-fuel controls has been advancing rapidly. Newer equipment may be significantly superior to older combustion control installations, justifying upgrading. See [Measure 1.3.2](#) for the features of newer equipment.

Burner and Fan Systems

A burner assembly prepares the fuel for burning and mixes the fuel efficiently with combustion air. The fans that move the air and flue gases are an integral part of the system.

Modern burner systems are capable of burning fuel almost completely. Even so, you can save energy in the burner system by reducing the amount of excess air, by reducing the amount of energy needed to operate the burner system, by improving the efficiency of heat transfer, by avoiding standby losses, and by burning the most economical fuels. At the same time, you want to minimize pollution, minimize maintenance, and avoid damage to the boiler.

The Measures in this Subsection exploit all these opportunities. Some are routine maintenance activities, some are simple adjustments, and some are equipment changes.

MEASURE 1.4.1 Clean, adjust, and repair burner assemblies at appropriate intervals.

Lack of routine maintenance is the most common cause of inefficiency in burners. Fortunately, most burners are relatively simple devices, and most routine maintenance is fairly easy. Just make sure that the maintenance gets done.

Maintenance Procedures

Use the manufacturer's operating manual as your primary guide in maintaining your burners. The instructions for most burners include an exploded diagram of the burner, showing all its components. Use it as a guide.

If you cannot find adequate maintenance instructions (usually because the manufacturer has gone out of business), or if the instructions are inadequate, concentrate on these items:

- **Keep all the fuel passages scrupulously clean.**

Virtually all types of burners for gas or liquid fuels prepare the fuel for combustion by dispersing it through small orifices or an array of small orifices. (The rotary cup burner is the single significant exception.) In many burners, a swirling motion of the fuel created by small vanes or flutes in the burner head helps to atomize the fuel. Recirculating oil burners contain narrow passages to control return of oil to the pump.

Burners for light oil tend to be kept clear by the solvent properties of the oil, but the parts exposed to high temperature may form coke and clog. Furthermore, particles in the oil may clog the burner.

With heavy fuel oil, distillation and coking of the fuel may leave residues that clog narrow passages and bake on to hot metal of the burner head. As a result, burners for heavy oil require periodic disassembly and cleaning. Cleaning is done with strong solvents and mechanical removal of deposits. Take care to avoid reaming or scoring the components when cleaning them mechanically. Cleaning tools should be softer than the burner materials. Copper wire and toothpicks are used for cleaning nozzles and burner head components. A dental pick is handy for getting carbon residue out of grooves, but be careful because the steel is hard.

Gas burners tend to stay clean because gas combustion does not produce products that can clog the burner. As a result, gas burners may operate for years without losing efficiency. But, don't ignore them. Check and clean gas burners

periodically. Burner manifolds are made of iron, and rust may clog the nozzles over time. Atmospheric gas burners have been clogged by spider cocoons in the primary air passages.

- **Replace worn orifices.** The atomizing orifices in oil burners enlarge by erosion. Some manufacturers recommend replacing nozzles every year or two.

- **Repair leaking seals.** Inspect the burner for leaks while it is under pressure, but with the fuel valve or solenoid valve turned off. Fuel leakage may be caused by leaking fuel valves, leaking recirculation valves, or defective seals, depending on the burner design. Unfortunately, this does not reveal any leaks downstream of the fuel valve, so you have to carefully check the discharge end of the burner assembly.

Seals and sealing surfaces are vulnerable when burner tips are removed and replaced. With the high pressures that are used in oil burners, a small scratch on a sealing surface or on a copper gasket can cause a significant leak. Cross threading also causes serious leaks.

- **Keep moving parts operating freely and without play.** Lubricate linkages, damper blades, and other components that need it. Inspect thoroughly to find any points of wear. Correct for wear by adjusting or replacing the worn part.

- **Make sure that air shutters close tightly.** This is important for minimizing standby losses, which occur when the burners are not firing.

- **Keep remote forced-draft and induced-draft fans operating properly.** The maintenance required for combustion air fans is generally the same as for any centrifugal fan. The main items are keeping the impeller blades clean and the bearings lubricated.

Diagnosing Burner Problems

Burners are subject to a variety of problems that may develop quickly and reduce burner efficiency. Make sure that all boiler operators know how to spot problems.

Burner problem diagnosis charts that are provided by some manufacturers are valuable for diagnosing problems that are peculiar to a specific model of burner. However, operators must first notice that a problem exists. These are common indications of trouble:

- **smoke indicates incomplete combustion.** Check for smoke continuously. However, don't depend on smoke to indicate a problem. Not all burner defects produce smoke. A partially clogged burner results in a high air-fuel ratio that may burn off smoke before it leaves the combustion chamber. With gas fuels, incomplete combustion may not generate enough smoke to be noticeable.
- **a drop in measured combustion efficiency** could be due to many causes. You should be testing combustion efficiency on a regular basis, as recommended by [Measure 1.2.1](#). A defect in the burner is likely if carbon monoxide and/or smoke are higher than normal in relation to the oxygen content.
- **irregular flame appearance**, including a change in the color, shape, intensity, or other appearance characteristics of the flame. Check the appearance of the flame regularly. Sparks or flashes may indicate incomplete combustion, or they may be caused by water or other contaminants in the fuel. It takes experience and a practiced eye to know what a change in flame appearance means, but any change should prompt further inspection.
- **unusual sound and vibration.** A burner defect may change the sound of the flame enough to be noticeable to an experienced operator. However, this clue is too subtle to be useful to most operators. A burner defect that causes non-uniform mixing of air and fuel may cause instability of the flame, creating a noticeable sound or even severe pulsing of the boiler. The flame may also become unstable if you attempt to minimize excess air with a burner that is not designed for low excess air. An unstable flame is dangerous. If it causes the flame to blow out, it can cause a firebox fuel explosion.
- **low flue temperature.** With non-modulating burners, you may be able to detect a drop in flue temperature that indicates a reduction in burner output. This could be caused by a clogged burner. However, a burner may be partially fouled without a noticeable drop in flue temperature. Also, a drop in flue temperature caused by a fouled burner could be masked by a rise in temperature due to soot accumulation on the tubes.

- **dirty burner appearance.** Inspect your burners regularly. Larger boilers may have multiple burner barrels that can be removed individually for inspection and cleaning while the boiler is operating. Other types of burners can be inspected only when the boiler is cold.

Burner assemblies should look clean and be tight. The critical factor in atomizing is the cleanliness of the small passages through which the fuel passes. The only way to find an obstruction in this area is to disassemble the burner.

- **soot accumulation.** Soot anywhere within the boiler, whether on the tubes, the refractories, or the burner itself, is an indication of incomplete combustion. Gas that is burned properly produces virtually no soot. Light oil should produce only a light accumulation of soot over a long period of time. Heavy oil produces a normal accumulation of soot that must be cleaned away periodically.

A change in the way soot accumulates indicates trouble. If abnormal sooting occurs within a boiler, the pattern of accumulation usually indicates whether the problem is due to the burner or to another cause. Opening the boiler to check for soot and other conditions is dirty work, but it needs to be done regularly.

- **irregular appearance of refractories.** Irregular appearance of the fire brick and other refractories usually indicates that the flame is coming too close to the refractory or that material is being thrown on the refractory by the burner. The symptoms are localized discoloration, melting, and spalling. A partially clogged burner could distort the flame shape enough to cause these symptoms. However, these symptoms are more likely to be caused by a burner that is mismatched to the boiler or is being operated at the wrong pressure. Fuel contaminants sometimes cause unusual deposits on refractories.

- **loose control linkages** can cause radically improper air-fuel mixtures. This is a common problem. For example, a jam nut may come loose on a jackshaft assembly. Such defects are usually easy to spot.

Check and Adjust the Air-Fuel Ratio

Whenever you work on a burner or burner assembly, adjust the air-fuel ratio. [Measure 1.3.1](#) explains the procedures.

ECONOMICS

SAVINGS POTENTIAL: 0.5 to 10 percent of fuel cost.

COST: Usually minor. Facilities that have a boiler staff should be able to accomplish burner maintenance as part of the normal operating routine.

PAYBACK PERIOD: Immediate. Appropriate maintenance is always cheaper than neglecting it.

TRAPS & TRICKS

TRAINING AND SKILLS: For routine maintenance, follow the recommendations of the boiler and burner manufacturer. Diagnosing and repairing defects may require a great deal of experience and skill. If necessary, bring in a specialist at appropriate intervals to inspect your boilers.

EXPLAIN IT: Write explicit instructions and checklists for the maintenance to be accomplished by the in-house staff.

MONITOR PERFORMANCE: Maintenance is everyone's lowest priority, and nobody likes to do boiler maintenance. So, stay on top of it.

MEASURE 1.4.2 Eliminate air leaks in air casings, blower housings, and connecting ducts.

RATINGS

New Facilities	Retrofit	O&M
		A

The boiler system's fans expend energy to move air into the boiler and to move flue gas out of the boiler. The potential energy waste is greatest if a fan is separated from the boiler by a length of ducting or flue, and if the boiler is surrounded by an air casing. The energy waste typically is small, but you can prevent it easily.

If the boiler has an induced-draft fan, air leaks into the flue may cause errors in combustion controls and combustion efficiency tests that can lead to serious problems.

Leakage typically occurs as a result of flexible duct couplings that break from vibration, sloppy joints in casings, and cover plates being left off. Repairs usually are obvious and cheap.

Finding leaks is simply a matter of careful inspection. In parts of the system that are under positive pressure, you can find leaks by running a hand around areas where it may be occurring. Finding leaks in parts of the boiler that are under negative pressure is more difficult. A smoke pencil is a good tool for finding leaks into a duct or flue.

Waste of Fan Energy

The amount of fan energy that is wasted is small in relation to other boiler plant losses. For a given amount of leak area in the duct system, the amount of air leakage depends on how the flow of air into the boiler is regulated. The loss is highest if air flow is throttled at the point where the air enters the firebox, so that the entire air passage is kept under maximum pressure by the fan. The loss is lowest if air flow is regulated at the fan, because there is less pressure in the air passage.

In boilers that have induced-draft fans, the air passages are under a slightly negative pressure. The pressure difference usually is less than with forced-draft

fans. Again, the amount of air leakage depends on how the flue draft is regulated.

Adverse Effects of Air Leakage into the Flue

With induced-draft fans, air may leak into the flue. This air, which is not involved in combustion, cools the flue gas. This gives a false reading of higher efficiency. It also falsely indicates high excess air, which may motivate operators to set the air-fuel ratio too rich. This causes rapid fireside fouling, a significant drop in efficiency, and other problems, which are covered in [Measure 1.3.1](#).

Leakage in a forced-draft system usually has no ill effects other than the waste of fan energy. Air leakage may upset the air-fuel ratio in some boilers, but this problem is uncommon. Boilers large enough to have separate forced-draft fans usually have combustion controls that continuously adjust the air-fuel ratio.

ECONOMICS

SAVINGS POTENTIAL: Perhaps a maximum of several hundred dollars per year, for typical small leaks in a large

boiler system. A major leak in an induced-draft system may lead to incorrect air-fuel ratio settings that waste much more energy than the leak itself and that cause other problems.

COST: Usually minor.

PAYBACK PERIOD: Usually short.

TRAPS & TRICKS

SCHEDULING: Air leaks grow over long periods of time. Schedule inspections at appropriate intervals, such as yearly.

MEASURE 1.4.3 In boilers that are fired at inefficiently high output, reduce the maximum firing rate.

RATINGS

New Facilities	Retrofit	O&M
	B	

The flue gas temperature increases with firing rate, for a given boiler. Efficiency falls as the flue gas temperature rises. In a boiler that has a high firing rate in relation to the amount of heat transfer, the flue gas temperature rises rapidly near full load, wasting energy.

If you have a boiler that fits this description, you can improve average operating efficiency by limiting the maximum firing rate of the boiler. You may have to reduce the maximum output by 20% to 40% to achieve much efficiency improvement. The question is whether you can afford to sacrifice this much capacity. You may be able to do this if you have plenty of reserve capacity, or if you take other steps to reduce your peak heating load.

Why would a boiler lack sufficient heat transfer? The reason is usually economic. The cost of a boiler is proportional to its heat transfer surface area, so the facility may have tried to save money by purchasing a smaller boiler and using a larger burner in it. The traditional rules that relate the heating surface area of a boiler to its output are somewhat arbitrary, so capacity may be stretched at the expense of efficiency.

Many older boilers would benefit from a reduction of burner output even if they are not burdened with an oversized burner. Older boilers may have less sophisticated heat transfer design, so their efficiency tapers off at higher loads, even though they may be adequate in terms of tube surface area.

There is another source of energy waste to suspect in boilers that are driven too hard. Combustion may be incomplete because the flame is being pushed too close to the surfaces of the combustion chamber. You can detect this condition by inspecting the inside of the boiler, and by finding a high level of carbon monoxide in the flue gas.

SUMMARY

May save energy in older boilers, and perhaps in newer boilers with oversized burners. To do this, you need enough reserve capacity to tolerate the reduction in output.

Energy Saving Potential

To decide whether to limit the firing rate, consider the boiler’s efficiency characteristics, the turndown characteristics of the burners, and the reserve capacity of the boiler plant.

The greatest energy waste from overdriving a boiler occurs if the burner has only a single firing level. In this case, the boiler is operating at reduced efficiency whenever it is firing. If an inefficient boiler is being overdriven by a single-stage burner, the efficiency loss may be as high as 10 percent, compared to the boiler’s peak efficiency.

The least energy waste occurs with a modulating burner that has a turndown ratio that is large enough to follow variations in the boiler load. In typical applications, the boiler spends only a small amount of time near full load, typically when warming up the facility after a period of shutdown.

Staged burners are an intermediate case. The improvement that a 2-stage burner offers compared to a single-stage burner depends on the load profile of the

boiler, the ratio between the high-fire and low-fire outputs, and the sequence of firing stages.

Test the Potential Benefit

By this point, you should have tested the efficiency of your boilers at all their firing rates. If not, see [Measure 1.2.1](#) for an explanation of combustion efficiency testing. In short, if the efficiency of a boiler is substantially lower at higher firing rates, you can save energy by limiting the firing rate. For example, if the boiler has a two-stage burner, reducing the firing rate is desirable if the high-fire efficiency is substantially lower than the low-fire efficiency.

Even if you do not have an efficiency tester handy, you can tell that the boiler is losing efficiency at higher firing rates if the flue temperature rises dramatically. If your boiler fires only at a single rate, calculate the difference between the flue temperature and the acid dew-point temperature for the fuel you are using. (See [Measure 1.7.1.1](#) for an explanation of acid dew point.) If the difference is greater than necessary to protect the boiler, reducing the firing rate will probably improve efficiency.

An increasing carbon monoxide reading at higher firing rates suggests that the combustion chamber is being fired beyond its capacity. However, rising carbon monoxide could also be caused by burner defects.

Can You Afford to Lose the Boiler Capacity?

If you limit the firing rate of a boiler, and then discover that you miss the capacity, you can restore the higher firing rate. However, you may not be able to do so quickly. Therefore, calculate how much spare capacity your boiler plant presently has, including reserve capacity needed to deal with maintenance and unplanned outages. Spare capacity is common in boiler plants because design engineers tend to specify large amounts of reserve capacity to compensate for uncertainties and changing conditions. Also, the load may have been reduced by energy conservation measures, abandoning some facilities, etc.

Before reducing burner output, make note of the average boiler load under peak load conditions. Also, note how long the boiler must operate at high fire after a long period of shutdown, such as a cold Monday morning after a weekend shutdown. Then, estimate how much reduction in capacity you can tolerate, considering the amount of reserve capacity you want to keep.

Plants with Boilers of Different Efficiencies

[Measure 1.1.4](#) recommends that you operate your most efficient boilers first. If you have boilers of different types, do not reduce the firing rate of your most efficient boilers if doing so would force less efficient boilers to operate for longer periods of time.

Methods of Reducing the Maximum Firing Rate

First of all, do not reduce the firing rate to an extent that risks acid condensation. You have to maintain a certain margin of temperature between the flue gas temperature in the coldest part of the boiler and the acid dew-point temperature of the fuel. If you are not clear about this point, review [Measure 1.7.1.1](#).

The best method of reducing the maximum firing rate depends on the type of burner and burner controls. You may be able to use more than one of the following methods.

■ Reduce the Size of the Fuel Nozzle

You can reduce the maximum firing rate of most types of burners by replacing the existing fuel nozzle with a smaller nozzle, and adjusting the air flow accordingly. Check the manufacturer's literature or contact the manufacturer to determine the appropriate procedure. This modification is usually inexpensive.

■ Deactivate the "High Fire" Setting of Staged Burners

Most staged burners have two levels of firing, "high fire" and "low fire". The conventional method of control has the burner go immediately to high fire after starting. This provides the fastest warm-up when starting from a cold state. Also, this sequence ensures that the burner will satisfy the load.

After the set pressure or temperature is reached, the burner goes to low fire. If the load is greater than the low-fire setting is able to satisfy, the burner cycles between high fire and low fire. If the load is low, firing eventually turns off, and the cycle starts again with high fire. This is because the temperature or pressure is allowed to drop so far between firing cycles that the burner restarts at high fire. This reduces cycling, and thereby reduces standby losses.

As a result of this method of control, staged burners typically spend a large fraction of the time at high fire. One way to deal with this is to modify the burner controls to lock out the high-fire setting. The low-fire output typically is about 60% of the high-fire output. This makes the low-fire setting a good firing rate for improved efficiency in many applications.

Measure the boiler output at high and low fire before proceeding, so you won't be surprised by losing more capacity than you expected. The easiest way to estimate the boiler output is to take readings from the fuel meter.

If you want to retain the high-fire setting for warm-ups periods or during extreme loads, you might use a timeclock or an outdoor temperature sensor to allow high fire under these conditions.

The burner control sequence is built into the firing controls. Only a qualified specialist should modify these controls to bypass the high-fire setting. Contact the burner manufacturer to discuss whether this is practical.

■ Lower the High Limit of Modulating Burners

Modulating burners follow the boiler load, so they do not suffer from excessive firing during normal operation. However, modulating burners normally operate at full output during a warm-up period. If the boiler has electronic controls, you may be able to limit the maximum firing rate with a control setting. Another method is to limit the mechanical motion of the air-fuel actuators. Or, install a smaller burner nozzle, as suggested previously. Check the manufacturer's literature or contact the manufacturer to determine the appropriate procedure to limit the maximum burner output.

Limiting the maximum firing rate may also be beneficial when several boilers are operating together. This prevents one boiler from firing at an excessive level while the others are at low load. See [Measures 1.1.4 ff](#) about distributing the boiler load in the most efficient manner.

Reduce Auxiliary Energy Consumption at the Same Time

If you reduce the output of a boiler permanently, reduce the output of the boiler's auxiliaries in an efficient manner also. This is not necessary if the auxiliaries have the capability to turn down efficiently. See [Measures 1.1.3 ff](#) for efficient control of auxiliary equipment.

Leave a Record of the Change

Label or tag the burner control housing permanently to indicate the changes. See [Reference Note 12, Placards](#), about placard materials and installation. Keep your notes about the change with the rest of the reference material for the boiler.

Alternative Methods

Increasing the heat transfer of the boiler is an alternative to reducing burner output. Methods of increasing heat transfer are covered in [Subsection 1.7](#).

If you measure low combustion efficiencies at all firing rates, your boiler is an energy hog. In that case, consider replacing the boiler. See [Subsection 1.12](#) about your options.

MEASURE 1.4.4 Install burner systems that provide the best efficiency and other features.

A burner costs much less than the fuel that it burns during its service life. Therefore, even a small improvement in burner efficiency is usually worth the additional cost when buying a new boiler. With existing boilers, the efficiency improvement may justify upgrading the existing burners.

Some burners are inherently less efficient than others, mainly because they require more excess air. Also, some types of burners that have high efficiency on paper may tend to be inefficient in practice because they are sensitive to lack of maintenance.

Another reason to upgrade burners is to comply with increasingly stringent pollution abatement requirements, especially those requiring reduced emission of nitrogen oxides. If you have to upgrade burners to satisfy environmental regulations, exploit the opportunity to select burners that also maximize efficiency. A low-emissions burner is not necessarily a highly efficient burner.

In selecting a replacement burner assembly, do not be satisfied just with a claimed high efficiency, or with efficiency that is measured by testing under laboratory conditions. In addition to having a good peak efficiency, the burner should remain efficient by resisting fouling and being easy to maintain.

Burner Characteristics

A burner assembly has two main functions: to prepare the fuel for burning, and to mix air with the prepared fuel. The ideal burner would completely burn all the fuel, require no excess air, and require no energy to operate. No burner system achieves this ideal, but some come close. The goal of designing the ideal burner has led to a great variety of types, each with advantages and disadvantages, and each best adapted to a particular class of boilers. The overall efficiency of a boiler depends on a number of burner characteristics. As a result, you can't select a burner on the basis of a single efficiency figure. Furthermore, there are issues other than efficiency, especially air pollution, that you have to consider. Make your choice based on an understanding of the following burner characteristics.

■ **Fuel Burning Efficiency**

Historically, high fuel burning efficiency was one of the first goals of boiler design, and almost complete success has been achieved. With all conventional fuels, a properly functioning burner burns more than 99% of the fuel. If incomplete burning occurs, the cause is a defect in the burner or improper matching of the burner to the boiler.

SUMMARY

In new construction, this is just a matter of smart shopping. As a retrofit, this is a major modification that requires a thorough knowledge of how burners are matched to boilers. Advisable if the boiler has an efficiency limitation related to its present burners, or if the modification provides other benefits, such as reduced maintenance or multi-fuel capability.

■ **Excess Air Requirement**

Among modern burners, the main characteristic that makes one burner more efficient than another is the amount of excess air that the burner requires. Excess air absorbs heat, reduces heat transfer, and increases fan power. With current technology, all burners require some excess air, but some types require considerably less than others.

Efficient burners limit excess air by careful metering of fuel and air, and by aggressive mixing of the two. In addition, burners for liquid fuels must prepare the fuel for burning by atomizing it, which is a process of breaking the fuel into tiny droplets. Atomizing enormously increases the fuel's surface area, so that the fuel vaporizes quickly and can be mixed with air while it is still within the controlled environment of the burner.

The flame tends to become unstable when pushing the lower limits of excess air, so the design of low-excess-air burners must provide for exceptional flame stability.

■ **Flame Pattern**

The burner assembly should produce a flame shape that fits properly within the firebox. The burner should also distribute the hot gas efficiently through the heat transfer surfaces. An improper flame pattern may cause incomplete combustion and damage the boiler. This is explained in greater detail below. Good retrofit burners typically are designed to provide a range of flame shapes.

■ Combustion Chamber Insulation Requirements

If an oil burner projects the oil spray into the combustion chamber, the area of the spray must be kept hot enough to complete the vaporization of the oil. Some types of burners start the flame well inside the head of the burner, and these are relatively insensitive to combustion chamber temperature. These are called “retention head” or “flame retention” burners.

Other types, such as rotary cup burners, require that the front of the boiler combustion chamber be well insulated to create a hot zone around the burner. Most modern replacement burners are less sensitive to combustion chamber insulation than older types.

■ Standby Losses

Standby losses are explained in [Measure 1.5.3](#). They occur only if the boiler cycles on and off. Modulating burners create much less standby loss than on-off burners because they spend more time firing continuously. A burner reduces standby losses by using an air register that closes tightly when the burner is not firing. Most larger power burners use air registers, but atmospheric burners do not. Even an air register cannot avoid the large standby losses that occur with purge cycles. Standby losses can be reduced by other means, such as installing a damper in the flue, but the other methods are less effective.

■ Turndown Ratio

Turndown ratio is the ratio of the maximum heat output of a burner to the minimum heat output. With boilers that operate unattended, the turndown ratio is assumed to mean the ratio that can be achieved without operator action.

Having multiple burners provides a large increase in turndown ratio. For example, if a boiler has three burners, each of which has a 4:1 turndown ratio, the overall turndown ratio is 12:1. Even greater turndown ratios are possible in boilers with multiple burners if the burner orifices can be changed while the boiler is in operation. Such boilers have essentially unlimited turndown.

A large turndown ratio minimizes standby losses by allowing the boiler to fire continuously. It also reduces the thermal stresses that occur when firing begins and ends. The importance of a large turndown ratio depends on the application. It is especially important in boilers that operate over a wide range of loads, for example, in boilers that provide comfort heating.

Turndown is achieved by using either staged burners or modulating burners. Staged burners are simpler and easier to adjust, but they have a much smaller turndown ratio than modulating burners. Staged burners eliminate standby losses within their turndown range, but they create more thermal stress because of their sudden change of firing rate.

A large turndown ratio involves design compromises. It may not be prudent to operate a modulating burner near the low end of its advertised turndown range because it may not be able to provide accurate control of the air-fuel ratio in that region. Also, it is more difficult to adjust the air-fuel ratio of a modulating burner throughout its turndown range than to adjust a staged burner at its fixed firing rates. However, these limitations can be avoided if the boiler has automatic air-fuel ratio controls.

■ Auxiliary Energy Requirements

Burner assemblies require varying amounts of energy to operate. Oil burners require pump energy. All power burners require fan energy, whether the fan is an integral part of the burner assembly or is installed remotely. Atomizing with compressed air requires compressor energy, and atomizing with steam requires additional fuel to make the steam. Only atmospheric burners do not require extra energy to operate.

■ Pollutant Emissions

Even high-efficiency burners may emit an objectionable amount of pollutants. Currently, there is emphasis on reducing the production of nitrogen oxides, which are formed when high combustion temperatures allow the oxygen in the air to react with the nitrogen in the air. Therefore, low-emission burners attempt to reduce combustion temperature, or to accomplish part of the combustion in an oxygen-poor environment, or both.

Some burners achieve these objectives by recycling combustion gases inside the burner. Other burner systems recirculate a portion of the exhaust gas from the flue back to the burner. Figure 9 shows the latter approach.

Any burner can reduce smoke and particulate emissions by using excess air, but this approach has an efficiency penalty. As with automobile engines, reconciling high efficiency with low pollutant emission involves compromises.

■ Draft Requirements

[Measure 1.5.1](#) explains the role of draft. Burners that use forced-draft and/or induced-draft fans control draft inside the boiler by overwhelming fan power, although a stack is still required for removal of exhaust gases. At the other extreme, atmospheric burners are entirely dependent on convective draft. Small gun-type burners provide only enough draft for proportioning the air with the fuel, and they require either stack draft or a flue gas fan to move the combustion gases through the boiler.

■ Maintenance Requirements and Ease of Maintenance

Lack of maintenance may seriously reduce burner efficiency. Select burners for which maintenance is less critical, and which need maintenance less often. Burners

for gas typically need little maintenance. Oil burners vary in their maintenance requirements, especially for cleaning parts exposed to the flame. For example, rotary cup burners became notorious because of their tendency to lose efficiency if they are not cleaned frequently.

Ease of maintenance is important with burner assemblies that require periodic servicing. Needed maintenance is more likely to occur if it is easy to accomplish. Select a burner assembly that allows maintenance people to reach all the components easily. Look for burners that swing out on hinges, or that slide out on rails. At the same time, consider ease of access to the interior of the boiler.

■ Initial Cost

In all but the smallest boilers, the cost of the burner is almost trivial compared to the cost of the fuel that it burns. A small loss of efficiency costs much more in additional fuel cost than the premium for a more efficient burner.

Multi-Fuel Capability

Consider adding multi-fuel capability. Having the ability to burn more than one type of fuel allows the

facility to exploit price differences in fuels. Similarly, multi-fuel capability provides protection against shortages of individual types of fuels. In many facilities, these advantages may be even more important than the efficiency improvement.

Installing multi-fuel capability involves costs that may be much larger than the costs of the burners themselves. If you add the ability to use stored fuels, such as oil or compressed gas, you will need equipment for receiving the fuel, storing it, and conveying it to the boilers. If pipeline fuels are added, installing the pipelines may be a major undertaking. Selecting alternative fuels requires careful analysis of pricing policies, and shrewd guessing about how the energy market will change in the future. If you go this far, extend your analysis to cover all the fuels that may be used throughout the facility.

Especially in unattended boiler plants, a multi-fuel burner should provide the capability of switching fuels automatically, in response to a remote signal. (See [Measure 1.1.2.1](#) about this.) This is not possible with all multi-fuel burners, because some types must be manually retracted when they are turned off to protect them from the flame in the firebox.

Fig. 1 Atmospheric gas burner In this type of burner, air is mixed with the fuel gas in two stages. Both the primary and secondary air paths remain open, allowing serious standby losses when the burner is not firing.

Types of Burners

Attempts to combine desirable burner characteristics have given rise to a rich variety of burner designs. You have to sift through this wealth of choices. There is no formal system of classification for burners. The following groupings cover the most common types. Once you narrow the choice to a particular type, shop the market to find the best models that are currently available. Table 1 lists each of these types and their related characteristics.

■ Atmospheric Gas Burners

Atmospheric gas burners are used on the smallest gas-fired boilers, and also on some surprisingly large ones. Figure 1 shows a cross section of this type of burner. Figures 1 and 2, in [Measure 1.3.1](#), show typical atmospheric burners in small boilers..

Atmospheric burners have two major efficiency weaknesses: (1) a relatively large amount of excess air, which reduces combustion efficiency, and (2) large standby losses, which result from the fact that the combustion chamber is open to the surrounding atmosphere. The need for excess air results from a lack of vigorous mixing of the air and fuel, and from lack of control of combustion air. The burner is surrounded by ambient air, and a large amount of non-combustion air is heated and carried through the boiler.

Industrial Combustion

Fig. 2 Typical single-stage gas power burner This unit has a damper that closes the combustion air path when the burner is not firing.

To make the air mixing as efficient as possible, most atmospheric burners pre-mix a certain amount of air with the fuel before it is ignited. This air is called “primary” air. Burners usually mix gas with air by venturi action. The gas, under pressure, is injected into the throat of one or more venturis, and this creates a suction that draws air into the venturis from the surrounding space. The mixture of gas and primary air is then passed through an array of small burner orifices that are open to the combustion chamber, where the gas is ignited. Enough additional, or “secondary,” air is drawn from the combustion chamber to complete burning.

Primary air is controlled with a shutter at the inlet of the venturi or other mixing device. With burners that are designed for a specific boiler or furnace, the flow of secondary air to the burner is controlled by the design of openings in the boiler casing. Atmospheric burners designed for retrofit applications may have enclosures that provide a separate adjustment for secondary air.

Openings for secondary air need to be large. This makes it impossible to accurately control secondary air if there are pressure fluctuations of any magnitude in the boiler room air supply.

Fig. 4 A large modulating gas burner assembly

Atmospheric burners cannot adapt to changes in fuel flow. For this reason, they are controlled in an on-off mode. Multiple levels of firing can be provided by installing more than one burner assembly in the boiler.

This family of burners is called “atmospheric” because they must be kept at atmospheric pressure to function properly. The air and fuel are metered only by the low gas pressure and weak convective forces, so the air-fuel ratio is sensitive to small pressure differences in the combustion chamber and in the surrounding space. This makes it necessary to have reliable draft control,

typically provided by a draft hood or barometric damper that is installed at the flue gas outlet from the boiler. By the same token, flaws in boiler room ventilation or flue draft can alter the pressure at the burners enough to disrupt proper mixing of air and fuel.

Atmospheric burners usually do not have air inlet registers. (There is no inherent reason for this. The practical reason is that units with atmospheric burners are designed to be cheap, and adding a damper would increase cost and complication.) As a result, atmospheric burners have large standby losses. A possible remedy is to install a damper in the flue that closes when the burner is not operating. This is recommended by

Fig. 6 Diagram of the burner shown in Figure 5

Parker Boiler Co.

Measure 1.5.3.2. However, flue dampers do not close tightly, so they do not eliminate standby losses completely.

Don't expect to retrofit a power burner in a boiler that is designed for atmospheric burners. Atmospheric burners discharge their gases upward at low velocity over a large surface area. In contrast, power burners discharge their gases at high velocity in a compact flame, and usually in a horizontal direction.

■ Single-Stage Gas Power Burners

This type of burner consists of one or more gas orifices installed in a diffuser assembly. An integral fan forces air through the assembly, which provides vigorous mixing. The fan meters the amount of combustion air, providing more positive control of air-fuel ratio than is possible with an atmospheric burner. Most units have a damper that closes when the burner is not firing. Figure 2 shows a typical unit.

■ Staged Gas Power Burners

The firing rate in a gas power burner can be varied in several ways. One type of burner has two or three separate gas nozzles, with a solenoid valve controlling each nozzle. The air flow is adjusted correspondingly by changing the damper setting of the fan, or by operating the fan at different speeds. This type has a fairly good turndown ratio because each nozzle can be optimized for its own gas flow rate. Figure 3 shows a boiler with a three-stage gas burner.

Another type has a single nozzle, typically with two settings, "high fire" and "low fire." The firing rate is changed with a two-position controller that partially closes the gas valve and the air register.

■ Modulating Gas Power Burners

This type typically has an array of gas orifices installed in a diffuser assembly. To provide modulation, a gas valve is installed to control the fuel flow and a damper is installed to control the air flow. The fan may be integral with the burner assembly, or in large boilers that have an air casing, the fan is installed remotely. Figure 4 shows a large modulating gas burner assembly.

Figure 5 shows a less common type of modulating gas burner, which uses an array of burner heads similar to those found in atmospheric burners. Figure 6 shows a cross section of the burner.

A problem with all modulating burners is maintaining the correct air-fuel ratio at all loads. Smaller boilers usually accomplish this with a mechanical linkage between the fuel valve and the air damper. Unfortunately, fuel valves and air dampers are non-linear in flow, so the two cannot be coordinated with a simple mechanical connection. A common solution is to include an adjustable mechanical cam in the linkage to control the fuel valve. The cam is set at the factory based on average conditions. Adjusting the air-fuel ratio in the field requires a tedious setting of the cam across the

entire load range, which may be impossible to accomplish accurately under realistic conditions.

The limitations of a mechanical linkage are avoided in larger boilers by controlling fuel and air separately with a control system that senses the excess air in the flue gases. "Oxygen trim" systems can be retrofitted to boilers that have mechanical air-fuel linkages, and these systems compensate for errors in the linkage. See [Measure 1.3.2](#) for details.

■ Single-Stage Pressure-Atomizing Oil Burners

This type is used with light grades of fuel oil. All pressure-atomizing burners operate by forcing the oil through a small orifice under high pressure. The abrupt change in pressure as the oil passes through the orifice creates shearing forces in the oil that break it up into small droplets. The smallest single-stage atomizing burners are called "gun" burners because they have a barrel that "shoots" into the firebox. Actually, they look more like hair dryers than guns.

■ Multi-Stage Pressure-Atomizing Oil Burners

This type has a "high fire" and a "low fire" setting. To change from high fire to low fire, the oil pressure is reduced and the damper is partially closed. These burners are used on small and medium sized boilers, and may burn oil of various weights.

The turndown of common 2-stage oil burners is limited to a ratio of about 1.6 to 1. The reason is that the simple nozzles used in these burners cannot maintain proper atomizing if the pressure is changed over a wide range.

■ Modulating Pressure-Atomizing Oil Burners

This broad category of burner types may modulate output by varying oil pressure, or by recirculation, or both. With recirculating burners, the pressurized oil at the burner nozzle has two paths to follow, either out the burner orifice or back into the recirculation line. Burner

Preferred Utilities Manufacturing Corp.

output is controlled by a valve in the recirculation line that dumps unburned fuel back into the fuel tank. Figure 7 shows a burner of this type. Another type of atomizing burner modulates by changing the orifice area, for example, by inserting a tapered needle into the orifice.

The turndown ratio of a typical modulating oil burner with a fixed nozzle orifice is about 4:1. With larger boilers that have several burners, the orifice sizes of individual burners can be changed while the boiler is in operation, providing an almost unlimited modulation range.

The problems of setting the air-fuel ratio accurately in a modulating oil burner are the same as for modulating gas burners, discussed previously.

■ Air-Atomizing Oil Burners

Air-atomizing burners are used with all grades of fuel oil. Within the nozzle tip, high-pressure air is aimed at a thin stream of oil. The force of the collision breaks up the oil into droplets. Modulation is accomplished by recirculation. Turndown ratios range from about 3:1 to about 7:1.

Air-atomizing systems require a hefty air compressor and a big air storage tank. The power consumed by the compressor is typically a fraction of one percent of the energy flow through the boiler plant.

■ Steam-Atomizing Oil Burners

Steam-atomizing burners are used with heavy grades of oil. Their action is similar to that of air-atomizing burners except that steam is used instead of compressed air. The high temperature of the steam helps to break up and vaporize the oil. Modulation is accomplished by recirculation. Turndown ratios of up to 8:1 are claimed. An older type of steam-atomizing burner uses a venturi to draw oil into a steam jet, which discharges into the boiler through a nozzle.

The steam requirement of modern steam-atomizing burners is approximately one percent of boiler output. The heat of the steam is not recovered because the steam starts at the same temperature as the water in the boiler and then cools by expansion. In a steam system that has little water loss, the steam required for atomizing may add noticeably to the makeup water requirement.

■ Rotary Cup Oil Burners

This is an older type that is used with light and heavy oils. Oil is atomized by a combination of centrifugal force and collision with an air stream. The atomizing element is a rapidly rotating cylinder or cup. Oil is fed into the interior of the cup, and is thrown outward when it reaches the edge. High-velocity air flows around the outside of the cup, breaking up the oil film that is being thrown off by centrifugal force. The fan that creates the

Fig. 8 Modulating dual-fuel burner This compact unit burns oil and gas through separate nozzles.

Industrial Combustion

high-velocity air stream may be integral with the burner assembly, or it may be installed remotely, blowing air around the burner. The turndown ratio of rotary cup burners is the lowest of the modulating types, with a maximum of about 4:1.

The fuel oil is not vaporized until it has been flung beyond the cup assembly, so a high-temperature combustion zone must be maintained around the burner. This requires insulating the entry portion of the combustion chamber with refractory material. Also, matching the burner to the geometry of the combustion chamber is critical, as explained below.

Efficient atomizing depends on smooth flow of oil over the cup. Unfortunately, the cup has a large surface area within the combustion chamber, which leads to carbonizing and sludging of oil on the cup. Therefore, the burner assembly requires frequent and scrupulous cleaning. Rotary cup burners became notorious for their inefficiency when they are dirty or improperly matched to the boiler. This even led some government agencies to initiate witch hunts against rotary cup burners during the 1970's.

■ Dual-Fuel Burners

Dual-fuel burners for gas and oil have entirely separate burners for the different fuels, along with a common fan system. In oil-gas assemblies, the gas is

discharged through a relatively large cylindrical array of nozzles, and the oil is discharged through a nozzle at the end of a barrel that is inserted through the center of the gas burner. Figure 8 shows a typical unit of this type.

■ Pulverized Coal Burners

These burners are used only in large boilers. The coal is pulverized into fine particles outside the boiler and is then carried through the burner barrel suspended in a high-velocity air stream. The inside end of the burner has an impeller that distributes the coal into the combustion chamber. Combustion air is provided through the space surrounding the burner by a separate fan. The particles of coal burn as they travel through the combustion chamber, so the boiler must be designed specifically for this type of burner.

Compared to other types of coal burners, pulverized coal burners have the ability to change load quickly, like oil and gas burners. Moving the air at relatively high pressure for conveying the coal is a major cost factor, because it takes about two pounds of air to carry a pound of coal. Pulverizing and other coal preparation adds considerably to the cost of boiler operation.

■ Stokers for Solid Fuels

Stokers for coal and other solid fuels, such as refuse, consist of a grate on which the solid fuel sits while air is

Industrial Combustion

fed from underneath. There are many variations of stokers. The boiler is built around the stoker, so it is not possible to retrofit a stoker to an existing boiler. On the other hand, stoker boilers have been successfully converted to burn oil and/or gas by installing conventional oil and gas burners.

■ Fluidized Bed Combustion

Fluidized-bed burning is used primarily for coal. Every aspect of the boiler is built around this method of firing, so it is not adaptable to other existing boilers. Fluidized bed boilers emerged during the 1980's in response to concern about air pollution.

Crushed coal is fed into the boiler along with granulated limestone. The "bed" of coal and limestone is suspended by air fed from underneath. This requires large amounts of fan energy. Boiler tubes are located within the bed, providing good heat transfer by physical contact between the tubes and the heated particles. The abrasion of the particles keeps the tubes clean.

Sulfur dioxide formed in the process of combustion is immediately converted to calcium sulfate, or gypsum, by reaction with the limestone. This reduces sulfur dioxide emissions, at the expense of having to dispose of the calcium sulfate, which is dry and inert. Nitrogen oxide emissions also are low because combustion occurs at lower temperature than in conventional boilers.

Match the Burner to the Combustion Chamber

The term "combustion chamber" means the region surrounding the burner where the fuel is burned. One function of the combustion chamber is to serve as a region of high temperature to sustain combustion until it is complete. With liquid and solid fuels, the combustion chamber provides for evaporation of the fuel prior to combustion. All combustion must be completed within the combustion chamber. Beyond the combustion chamber, the gas temperature falls rapidly as heat is given up to the heat transfer surfaces, stopping combustion.

Retrofit burners for gas and oil are available that provide complete combustion in a wide variety of boilers. These burners mix fuel and air inside the burner assembly to avoid external effects. The sensitivity of burner efficiency to combustion chamber temperature is reduced by using a "flame retention" head, which is basically a small combustion chamber enclosed by the burner housing to ensure that combustion is initiated properly.

A replacement burner must have a flame pattern that keeps the flame away from any of the surfaces of the combustion chamber. Flame that touches any surface is quenched by the lower temperature of the surface, with the result that combustion stops and unburned fuel,

WESINC

Fig. 10 A modern burner retrofitted to an old brick-set watertube boiler Whether this is a prudent upgrade depends on the efficiency and condition of the boiler. Matching a modern burner to an old boiler involves a number of issues that affect efficiency and reliability.

mixed with incombustible impurities, is deposited as soot. Flame contact with refractory materials also damages the refractories. Many retrofit burners, especially larger models, allow the flame shape to be tailored to the combustion chamber by changing nozzles and diffusers.

Keeping the flame away from surfaces requires a minimum combustion chamber volume that is related to the burner output. Empirical rules for combustion chamber volume have evolved over the years. If the combustion chamber volume is not large enough for the intended burner output, efficiency suffers and damage occurs. See [Measure 1.4.3](#) for more about this.

Another function of the combustion chamber is to feed the hot combustion gases into the heat exchange surfaces in the proper direction. Fan-forced burners give the combustion gases a significant amount of inertia. This makes the discharge pattern of the burner a dominant factor in gas distribution from the combustion chamber. For example, if an upflow atmospheric burner is being replaced with a horizontal-flow power burner, it may be difficult or impossible to keep the combustion gases from bypassing a portion of the heat exchange surfaces, or backing up in one end of the combustion chamber. A bad gas flow pattern can negate the intended benefit of installing a more efficient burner.

Especially in large boilers, burner openings may be lined with refractory to maintain high temperature adjacent to the burner. The refractory is cooled by embedded waterwall tubes to prevent it from melting. Make sure that your retrofit burner adapts properly to such features.

You may have to be inventive if your burner mounting locations are awkward. For example, if you have to install the burner through an existing door at one side of the combustion chamber, you can aim the burner toward the center of the combustion chamber by using an angled mounting plate.

How to Decide Whether to Upgrade Burners

Every boiler deserves a look to determine whether you should improve the burner efficiency. Figure 10 shows how a modern burner assembly has been retrofitted to an old boiler.

Use Table 1 to compare your existing burners to others that are available. This sequence of steps will help you decide whether to replace your burners.

(1) Consider the type and age of the boiler.

Most boilers of modern design have high efficiency. Inefficient burners tend to be found in older boilers and in newer boilers of old design. If testing shows that the boiler is not efficient, the next question is whether the problem is high excess air or high stack temperature.

High excess air is a burner problem. High stack temperature indicates a lack of heat transfer capability,

which cannot be cured by a new burner. To correct high stack temperature, you need to reduce the maximum firing rate (see [Measure 1.4.3](#)), or increase the heat transfer of the existing boiler (see [Subsection 1.7](#)), or install a more efficient boiler (see [Subsection 1.12](#)).

Age is a major factor in the economic decision. It is risky to spend a lot of money converting a boiler that may be near the end of its service life.

(2) Observe whether the boiler cycles on and off frequently.

Even if the measured combustion efficiency of a boiler is high, the boiler may suffer from efficiency loss when the burner cycles on and off. One adverse effect of cycling is standby loss. Another is inefficient air-fuel ratio during the period of time that the boiler is stabilizing after it starts firing. Cycling also places stress on a boiler that causes leakage, metal fracturing, and crumbling of refractories.

Standby loss is greatly reduced if the burner has a damper that closes tightly when the burner is off. Most on-off burners have a damper, except for atmospheric burners and the smallest power burners. If the boiler does not have a combustion air damper, installing a flue damper ([Measure 1.5.3.2](#)) is an alternative. Dampers do not reduce standby loss that occurs during the purge cycles, when all dampers must be open.

You can minimize cycling by installing a modulating burner that has a high turndown ratio. A less effective solution is installing a 2-stage burner. Unfortunately, you cannot estimate standby losses accurately. Judge the seriousness of cycling losses by observing how often the boiler cycles under typical loads.

(3) Measure the boiler efficiency.

Tune up the boiler to its best air-fuel ratio, using the procedures of [Measure 1.3.1](#). Then, measure the minimum amount of excess air required by the burners for stable operation. Compare this to the amount of excess air that is required by other burners that could be used in the boiler. Use a combustion efficiency table to calculate how much energy you could save by installing a burner that operates with less excess air.

(4) Consider the operating energy of the burners.

If the boiler uses a large amount of fan energy, there may be room to reduce fan power, especially by selecting a burner assembly that reduces its fan power requirement in proportion to the load. An alternative is to retrofit the existing fan with a variable-speed drive, as recommended by [Measure 1.4.7](#), below.

The energy that oil burners require for atomizing may be in the form of pressure, steam, compressed air, or centrifugal force. The energy requirement for atomizing is small, the greatest being about one percent of fuel energy content, in the case of steam atomizing. Within this range, there may be an opportunity for saving energy or money.

The economic choice between air atomizing and steam atomizing depends on the relative cost of electricity and boiler fuel. One authority has pointed out that it takes about 130 BTU to produce a pound of atomizing air, while it takes about 1,300 BTU to produce a pound of steam. However, the BTU's used in air atomizing are expensive, being in the form of electricity. Steam atomizing is economically favorable only when the cost of the boiler fuel is much lower per unit of energy than the cost of electricity. This might be the case for a boiler burning refuse or wood waste.

Pressure atomizing requires less energy than steam or air atomizing. It is the most common method of atomizing light oils. Pressure atomizing has also been used extensively with heavy oils in larger boiler installations. At present, retrofit burners for heavy oils almost all use steam or air atomizing. This reflects the difficulty of atomizing heavy oil with pressure alone. However, burner technology keeps changing, so consider pressure atomizing heavy oil along with the other methods.

For solid fuels, it is usually difficult to retrofit a new type of burner because the overall design of the boiler is based on a particular method of burning. For example, a boiler with pulverized coal burners has a radically different configuration from a boiler that uses stoker firing. Modifying solid fuel burners requires case-by-case analysis.

(5) Consider how much maintenance the burners require.

Burners that require continual maintenance are likely to waste energy. Even if maintenance is good at present, it is likely that the boiler will go through periods of inadequate maintenance. It is especially important to install low-maintenance burners in boilers that are not monitored. Some types of oil burners require much more maintenance than others. The extreme example is rotary cup burners, which are notorious for becoming inefficient when they are not kept clean.

Labor cost is an economic factor if you have to hire extra people in order to accomplish adequate burner maintenance. Labor cost is not an economic factor if operators are on duty and have nothing else to do.

(6) Determine whether there are burner compatibility problems.

Start by inspecting the entire firebox environment, including the burner cones, the back wall, and all visible heat exchange surfaces. There should be no evidence of flame impingement, which causes incomplete combustion, sooting, damage to refractories, and metal stress.

Atmospheric burners and other burners that depend on convective draft are vulnerable to problems in the flue system. For example, wind descending on a stack from a tall adjacent building may upset combustion. This

problem could be controlled by installing a burner assembly that gets its draft from a powerful fan. But first, fix any air flow problems. See [Measure 1.5.2](#) about this.

Consider whether your existing burners limit opportunities to improve efficiency. For example, steam atomizing burners require high steam pressure. Using them may make it impossible to reduce system pressure to conserve energy, as recommended by [Measure 1.1.5](#).

(7) Consider whether upgrading burners can provide other advantages.

Multi-fuel burners may provide considerable savings in fuel cost. However, consider all the costs of being able to burn multiple fuels, including new piping, tanks, pumps, heaters, etc.

With existing multi-fuel boiler installations, consider installing burners that can change fuels automatically to minimize cost. Automatic changeover is especially valuable with unsupervised boilers, although the increased reliability of fuel changeover is valuable in any plant. See [Measures 1.1.2 ff](#) for control procedures to optimize the benefit of fuel switching.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely. Boiler efficiency sometimes can be improved as much as 10 percent by improving burners, but the improvement is generally much less if the original burners have been operated properly. Upgrading burners may provide additional important benefits, such as reduced maintenance, multi-fuel capability, etc.*

COST: *Gas and oil burners costs about \$5 per thousand BTUH of capacity in the smallest commercial sizes, to less than \$1 per thousand BTUH in the largest sizes. Dual oil/gas capability adds a premium of about 20% in larger sizes. The cost of coal stokers exceeds \$20 per thousand BTUH in the smallest sizes (about 1 million BTUH), to less than \$4 per thousand BTUH in the largest sizes.*

PAYBACK PERIOD: *Less than one year, to many years.*

TRAPS & TRICKS

SELECTING THE EQUIPMENT: *Consider all eligible types of burners, and understand the advantages and disadvantages of each type. Also, be sure to understand how a new burner system must interface with your boilers.*

INSTALLATION: *Unless you are an expert, have the installation done by a specialist who knows how to fit the new burners properly.*

EXPLAIN IT: *New burners have unfamiliar operating and maintenance requirements. Inform and train the people concerned. Set up an appropriate maintenance schedule.*

MEASURE 1.4.5 Replace the motors in burners and fans with models having the highest economical efficiency.

Be prepared to replace a failed motor with a model that has the highest practical efficiency. If the motor is exceptionally large and inefficient, you may even want

to replace it before it fails. See [Measure 10.1.1](#) for the details.

MEASURE 1.4.6 Replace continuous pilot flames with electrical ignition.

You can get retrofit kits to replace pilot lights with electronic igniters in many models of boilers and furnaces. Continuous flame pilot lights waste energy by consuming fuel when the boiler is not needed. They may also aggravate standby losses by enhancing convection through the boiler while the burner is not firing.

Continuous flame pilots are found only in boilers and furnaces with atmospheric natural gas burners. (A continuous pilot flame would not be safe in a boiler where fuel vapors can accumulate.) A pilot light burns fuel at a very low rate compared to the main burner, but it operates continuously. The energy waste may be significant if the pilot light continues to operate while the boiler is unused for long periods, for example, in a heating boiler that does not fire during the warm season.

Exceptions

Getting rid of the pilot light is not economical or advisable if:

- the boiler operates for a large fraction of the time
- the pilot flame is needed to maintain flue draft
- the pilot light is needed to prevent condensation on the tubes and other metal surfaces of the boiler.

Alternative: Turn off the Pilot Light Seasonally

If the heating unit is needed only on a seasonal basis, you can avoid much of the energy waste of the pilot light by turning off the pilot light at the end of the heating season.

MEASURE 1.4.7 Install variable-output fan drives on large forced-draft and induced-draft fans.

RATINGS

New Facilities	Retrofit	O&M
B	C	

If you are buying a new boiler or designing a boiler system, consider getting variable-speed fan drives to reduce fan energy consumption. You may be able to retrofit your existing boiler fans with variable-speed drives. Connecting the drive to the fan motor itself is usually straightforward. The challenge is to control the fan drive so that it maintains the proper air-fuel ratio at all loads.

Where to Install Variable-Speed Fan Drives

Variable-speed fan drives are most likely to be economical with larger boilers that have modulating burners, or perhaps staged burners. The price of variable-frequency drives per kilowatt drops rapidly with size, improving the economics of the modification for larger fans. With fans that operate continuously, the modification starts to become attractive at a fan size of about 50 KW (about 50 HP).

Combustion of hydrocarbon fuels requires about 10 to 20 pounds of air per pound of fuel, including an allowance for excess air. The low end of this range applies to coal, and the upper end to natural gas. For a fuel oil that lies in the middle of this range, burned in a boiler of average efficiency, the combustion air flow rate is roughly 250 CFM per million BTU of boiler heat output.

Assuming a typical flow resistance of 6" water gauge and fan efficiency of 60%, this translates to an average fan power requirement around 0.4 horsepower per million BTU. Thus, variable-speed fan drives start to be economical with boilers rated around 200 million

BTU per hour. This figure is approximate. As the price of electronic drives continues to fall, they will become economical in smaller sizes.

If air flow is presently controlled with an inlet vortex damper, the potential saving offered by a variable-speed fan drive is much less. Inlet vortex dampers are a moderately efficient means of reducing fan output down to about 50 percent of full flow. Replacing an inlet vortex damper would be economical only if the boiler operates for long periods at loads well below half.

■ Verify Retrofit Burner Compatibility

Check with the burner or boiler manufacturer to make sure that this modification will work with your boiler. You can skip this step only if the fan and the damper are presently remote from the boiler.

You may not be able to retrofit a variable-speed drive if the original air control damper plays a role in mixing the air with the fuel. If the damper that throttles the flow of air is an integral part of the burner assembly, the full fan pressure may be needed at all times for proper operation.

Energy Saving Potential

Forced-draft fans and induced-draft fans are typically the most energy intensive boiler accessories. Modulating or staged burner systems may waste a large fraction of the fan energy by using dampers to throttle air flow. When a damper is used to reduce air flow, the energy consumption of the fan does not drop in proportion to the reduction in flow. Instead, the fan must expend energy to force the air through the resistance of the damper.

The energy saving also depends on the load profile of the boiler. Damper control is especially wasteful in

boiler applications such as space heating, where the boiler operates at low output for much of the time.

The amount of power required to move the combustion air is approximately proportional to the third power of the boiler load. For example, if the boiler load is reduced to half, the power needed to move the combustion air is reduced to about one eighth. Fan power in excess of this amount is wasted. In applications where the boiler load varies over a wide range, the saving averages from 20 to 50 percent of full fan power.

To estimate the amount of energy your boiler fans are presently wasting, measure the power consumed by the fan under different load conditions. Use a wattmeter to measure the fan power. (You can't just measure the current and multiply by the voltage. This would neglect the changing power factor of the motor, resulting in an exaggerated estimate of power consumption.)

As you measure the fan power, you can determine the boiler load from the fuel flow rate. Estimate the total length of time that the boiler operates at each percentage of load.

Calculate the saving you would get from a variable-speed drive at each percentage of load. Request certified performance data from prospective suppliers of the variable-speed drives. The usual curves found in the glossy brochures are marketing daydreams.

How to Select and Install a Retrofit Fan Drive

Study [Reference Note 36](#), Variable-Speed Motors and Drives. In the current state of technology, the only type of drive that you need to consider is the variable-frequency electronic drive. In addition to being efficient, this type does not require any additional space at the fan itself. It does require a bulky control cabinet, but you can install the cabinet anywhere that is convenient.

Electronic variable-frequency fan drives do have some problems, especially electrical noise in the power supply system. Also, you may have to replace the present fan motor to avoid overheating. [Reference Note 36](#) covers all these issues.

Synchronizing Air and Fuel after Retrofit

Before proceeding, get a clear idea of how you intend to synchronize the air and fuel flows. This may be simple or difficult, depending on the nature of your combustion controls. Work out the details of the control design, including detailed control schematics, before purchasing equipment.

The variable-speed motor drives offered by major manufacturers have been engineered to accept a variety of input signals, including pneumatic, electric, and electronic. For example, the fan may go from minimum to maximum output based on a pneumatic input signal ranging from 3 to 15 PSI. Typically, the fan speed

responds to the input signal in a fairly linear manner, and air flow is proportional to fan speed.

The modification is simplified if the boiler has a feedback control system that adjusts the air flow independently of the fuel flow by sensing the flue gas composition. With luck, it may not be necessary to modify the existing air-fuel controls at all, except that the control signals originally sent to the fan damper actuator are now sent to the fan drive.

However, do not take this for granted. The existing control system may not have enough control range to adapt to a large difference in response characteristics between the original damper and the new fan motor controller. Discuss this with the manufacturer of the existing air-fuel control system.

The modification is more difficult if the air-fuel ratio is presently controlled by a mechanical linkage that connects the fan damper to the fuel valve. The linkage is driven in response to the boiler output (steam pressure or water temperature). The linkage typically uses a cam to move the fuel valve. The shape of the cam is set at the factory, and compensates for the fuel valve's non-linear output behavior and for the geometry of the linkage.

When installing a variable-speed motor drive in a system that uses a mechanical air-fuel linkage, disconnect the part of the linkage controlling the air damper. See [Figure 1](#), for example. Send the signal from the boiler output (steam pressure or hot water temperature) sensor to the new fan control as well as to the original mechanical positioner. Expect to make additional changes to get the air and fuel to track properly, since the variable-speed drive regulates air flow differently from a damper.

You may be able to get the air and fuel to track properly by adjusting the shape of the fuel cam. However, the adjustment range of the cam is limited, and resetting the shape of the cam over the entire load range of the boiler can be tedious, as explained in [Measure 1.3.1](#).

Another possibility is changing the response characteristic of the motor speed controller. This is a specialized feature that may be available only from certain drive manufacturers. Adjusting the air-fuel ratio properly across the entire load range requires skill and patience, regardless of the method used.

How to Control Induced-Draft Fans

Variable-output control of induced-draft fans is easier to retrofit. Induced-draft fans are usually controlled to maintain a constant draft in response to a signal from the draft sensor. This is a simple control application. Just match the input signal range of the fan control to the output signal range of the draft sensor.

Test and Adjust the Air-Fuel Ratio

After the equipment changes have been made, conduct a combustion efficiency test across the boiler's full load range. Adjust the air-fuel ratio as necessary.

ECONOMICS

SAVINGS POTENTIAL: 20 to 60 percent of fan energy, depending on the average load on the boiler. Less, if the fan presently has an inlet vortex damper.

COST: See [Reference Note 36](#), *Variable-Speed Motors and Drives*, for the costs of variable-speed drives. The additional control costs depend on the type of combustion control that is presently used.

PAYBACK PERIOD: Less than one year, to many years, depending on fan size, fuel cost, boiler loading, and duration of operation.

TRAPS & TRICKS

DESIGN: Retrofitting variable-output drives to boiler fans is still unusual. This is a major modification that cannot be done by a conventional boiler technician. Work out the details with the burner or boiler manufacturer.

SELECTING THE EQUIPMENT: Study [Reference Note 36](#), *Variable-Speed Motors and Drives*.

EXPLAIN IT: The modification is unconventional. Document the design, equipment, operating procedures, and maintenance procedures. Without a clear explanation, the maintenance staff will be baffled when the system requires adjustment or maintenance.

Subsection 1.5

Draft Control

Boiler draft is necessary for accurate mixing of air and fuel, for moving flue gases through the boiler, and for expelling exhaust gases. Draft needs to be controlled accurately for each of these purposes. Draft should be stopped when the boiler is not firing, to prevent standby losses and to minimize thermal stresses. The Measures in this Subsection control draft for these purposes and correct problems that interfere with proper control of draft.

MEASURE 1.5.1 Adjust draft for maximum efficiency.

RATINGS

Make sure that draft is regulated properly in every boiler and furnace. In some cases, draft regulation is permanently built into the system, and it requires no special attention. However, many boilers require draft adjustments to achieve optimum efficiency. The adjustments you need to make depend on the design of the boiler, the burner system, the flue, and the draft regulating devices.

What is Draft?

In the context of boilers, draft is a difference in pressure between one part of the boiler system and another. These pressure differences move air and combustion gases through the boiler system to:

- move the proper amount of air into the boiler for combustion
- mix air with fuel at the burner in the proper ratio
- move the combustion gases through the boiler at the proper rate
- expel exhaust gases to the outside, usually through a stack.

Draft for different parts of the boiler system may be provided by convection or by fans. Both sources of draft must be regulated.

Other sources of draft have been used in specialized applications. For example, the puffing of a steam locomotive is caused by exhaust steam passing through a venturi located at the base of the stack to create draft in the firebox. Draft from sources other than convection and fans is rare today.

■ Convective Draft

Convective draft is created by the buoyancy of the combustion gases. High temperature causes them to expand, and hence to become lighter. The buoyant “lifting” force is an illusion. The actual force is provided by gravity. Gravity has a greater effect on the heavier surrounding air than on the lighter combustion gases, so the combustion gases are displaced upward.

The intensity of convective draft is proportional to the height of the stack or other structure in which the heated gases are contained. The height of the boiler itself and the breeching also creates draft. A stack is necessary if the boiler is not tall enough to create sufficient draft internally, or if the internal passages of the boiler offer too much resistance to gas flow. The stack also has the more visible function of discharging the exhaust at a high elevation, so the fumes are carried away from the site.

The intensity of convective draft increases with the temperature of the combustion gases, increasing rapidly

as the boiler first warms up, and leveling off as the gas temperature increases further. The temperature of the combustion gas drops as it gives up heat to the water, but the gas temperature inside the boiler remains high enough to provide strong convection. The temperature of the gases drops slowly once they leave the heat transfer portion of the boiler, so the draft produced by a stack is essentially proportional to its height.

Convection was the original source of draft for boilers, and still plays an important role in most boiler installations. In boilers with atmospheric burners, all four of the functions of draft listed above are accomplished by convection alone. At the other extreme, boilers with forced-draft fans perform the first three functions primarily by fan power, but they rely on convection to expel exhaust out the stack. The burners used in some small and medium sized boilers have integral fans to draw combustion air into the firebox and to regulate mixing air with the fuel, but they rely on convection to move combustion gases through the boiler.

■ Fan-Induced Draft

Any or all of the four functions of draft can be accomplished with fans instead of with convective draft. Using fans allowed the development of burners with higher output and better control of air-fuel ratio than is possible with burners that operate by convection. Using fans to force combustion air through the boiler eliminates the need for a tall stack. Fans provide strong draft, so they can overpower any irregularities in gas flow caused by convection within the boiler.

Fans themselves serve as an effective draft regulator since they have stable output characteristics. However, using fans to create draft does not always eliminate the need for other forms of draft regulation. A separate stack draft regulator may be necessary if a tall stack is installed.

The fans used in a boiler may be “forced draft” or “induced draft.” Forced-draft fans blow air into the

boiler at the burner openings, and they create a positive pressure inside the combustion air ducting and the boiler. Induced-draft fans suck air out of the boiler from the outlet end of the boiler, and they create a negative pressure inside the boiler and the breeching.

Most small and medium sized boilers use forced-draft fans exclusively. Some larger boilers used induced-draft fans in addition to forced-draft fans. Induced-draft fans are usually installed in combination with forced-draft fans. An exception is older marine boilers operated with induced draft fans alone to prevent leakage of combustion gases into the confined spaces below decks.

One important class of boilers and furnaces does not rely on convection at all. These are units that use large heat transfer surfaces to reduce the flue gas temperature below the condensation temperature of water. The flue gases are too cool to create strong draft. This equipment relies entirely on one or more fans to move the combustion air and flue gases, and it operates satisfactorily without a stack.

Draft Regulators

Adjusting draft consists of adjusting a draft regulator. So, start by finding out what kind of draft regulator you have and understanding how it works. You want to make sure that the type of draft regulator you have is appropriate and that it is working properly.

In boiler systems that use convective draft, the stack is the primary source of draft. A problem is that stack draft changes with boiler loading, outside air temperature, wind, and other factors. A common

solution is to design the stack to produce more draft than necessary, and to install a draft regulator between the boiler and the stack to limit the draft at the boiler outlet.

Boilers that use fans may have no draft regulator other than the fans themselves. Fans are effective flow regulators as long as they work against constant pressure. Forced-draft fans are strong enough to overpower small fluctuations due to convection within the boiler. However, stack draft may suffer from strong fluctuations. With a tall stack, a draft regulator may be needed to compensate for the fluctuations even though the boiler has powerful fans.

A similar situation exists in boilers that have induced-draft fans that operate at constant output. A draft regulator is placed between the fan and the outlet of the boiler to throttle the draft created by the fan.

The fact that a boiler has a fan in the burner system does not necessarily mean that the fan is providing all the draft required. The fan may be intended only for proportioning the air and fuel, and it may not have the ability to move the combustion gases through the resistance of the boiler. This is typical of gun-type oil burners, for example. In such boilers, convective draft is required to overcome the resistance of the boiler, and a draft regulator is required to control the convective draft.

Parker Boiler Co.

Fig. 2 A boiler with a barometric flue damper This damper uses a delicately balanced blade to maintain a flue pressure that is slightly below the pressure in the boiler room. This boiler has atmospheric burners, but barometric dampers may also be used with power burners.

■ Types of Draft Regulators

A draft regulator is a device that is installed between the boiler and the stack to provide a controlled negative pressure at the boiler flue gas outlet. These are the types of draft regulators:

- **draft hoods.** A draft hood is essentially a missing section of flue inside the boiler room. The opening in the flue makes the pressure at that point equal to the boiler room pressure. A collecting hood is attached to the upper portion of the flue to keep the flue gases from spilling into the boiler room. Figure 1 shows typical draft hoods.

The effect of a draft hood is to isolate the boiler from the stack. The boiler draft is determined by the difference in height between the burner and the bottom of the draft hood. To increase the draft in the boiler, the draft hood can be installed at a higher point in the flue. The available boiler draft is usually small because of height limitations inside the boiler room.

At low firing rates, the stack draft is satisfied largely by air from inside the boiler room, which also acts to dilute the flue gases and reduce the stack draft. Draft hoods are cheap and foolproof, and they do not require adjustment. They have several disadvantages. They provide little negative pressure at the boiler outlet, they are not adjustable, and they

cannot prevent standby losses. Also, they cannot protect against backflow from the stack. This may occur when a boiler starts firing into a cold stack, or if wind conditions cause the stack to backflow. For these reasons, draft hoods generally are limited to boilers with atmospheric burners, or to boilers with small gun-type burners.

- **barometric dampers.** A barometric flue damper is a controlled opening installed in the side of the flue. The damper allows boiler room air to enter the flue, partially killing the stack draft. The resistance of the damper maintains a small, fixed negative pressure with respect to the surrounding space. The most common type of barometric damper has a single blade with a small balance weight. You can adjust the amount of negative pressure by moving the balance weight. Figure 2 shows a boiler with a barometric damper.

Barometric dampers are used instead of draft hoods with boilers that need greater draft to overcome internal resistance to gas flow. Barometric dampers have the advantage that they can close to prevent flue gases from flowing into the boiler room if the flue pressure becomes positive.

Barometric dampers are less reliable than draft hoods. The force moving the damper blade is too weak to overcome any tendency of the blade to stick. Cheap or improperly installed barometric dampers may not maintain a constant draft as firing levels change, and they may oscillate, upsetting the air-fuel ratio. Barometric dampers cannot prevent standby losses. They are generally limited to boilers of small and medium size.

- **motorized flue dampers** function by partially blocking the flow of flue gas from the boiler. The

damper is controlled by a draft sensor located near the burner. The damper is installed inside the boiler breeching or at some other location inside the flue close to the boiler outlet.

A significant advantage of a flue damper is that it can be controlled to close when firing is off. This reduces standby losses, as recommended by [Measures 1.5.3 ff](#), below. Motorized draft dampers generally are limited by their cost and complexity to medium and large sized boilers.

The burner controls should open the damper fully during purge cycles. The controls should open the damper partially during burner start-up. If the damper fails in any position other than fully open, combustion gases could back up, risking explosion and asphyxiation. Therefore, the burner controls should include a low-draft interlock that stops the burner if the damper fails to open fully. The boiler should also have an easily visible draft gauge that operators can use to verify proper operation.

- **variable-speed induced-draft fan.** If a boiler uses an induced-draft fan, you can regulate the draft at the boiler outlet by modulating the speed of the fan. This method is covered by [Measure 1.4.7](#).

Draft hoods and barometric dampers may draw substantial quantities of air into the flue from the boiler room. Normally, this is not a problem, because the boiler room has heat to spare. However, air loss through the draft regulator may interfere with arrangements that improve boiler efficiency by drawing combustion air from the warmest parts of the boiler room. See [Measure 1.11.3](#) for details.

How to Measure and Adjust Draft

Your primary objective is to set the draft at the burner, which is called “overfire” draft. This affects the efficiency of the burner. All burners should be operated within draft limits that are specified by the boiler or burner manufacturer. You set the overfire draft by adjusting the draft regulator.

You may also measure draft at the draft regulator and at the stack, to make sure that these two items are working properly.

Measure draft with a draft gauge, which is a sensitive pressure gauge. Insert a flexible hose from the draft gauge into the area where you want to measure the pressure. The draft gauge registers the difference in pressure between the tip of the probe and the location of the gauge housing. Draft gauges are inexpensive and readily available from heating supply houses. Figure 3 shows a typical draft gauge.

Large boilers that have air casings may have permanently installed draft gauges. An example is shown in Figure 4. The casings may be under positive or negative pressure. Maintaining the correct draft is just as important in large boilers as it is in smaller boilers.

To get correct readings, make sure that all access doors, cover plates, etc., are installed in their normal positions.

■ Overfire Draft

From the standpoint of combustion efficiency, the draft at the burner is most important. It affects the air-fuel ratio and the burner’s capacity. If the draft at the burner is correct, the combustion gases flow through the boiler properly.

Overfire draft with atmospheric burners should be slightly negative. Only a small gas pressure is feeding the burner and any positive pressure will prevent the flow of primary or secondary air into the combustion chamber. A boiler with atmospheric burners typically should have a negative pressure at the burner of about 0.02 inches of water.

Overfire draft should also be negative for many smaller burners that have built-in fans. The function of the fans in such burners is limited to proportioning the air and fuel properly. Stack draft moves the combustion gases through the boiler by convection.

Overfire draft in boilers with power burners is positive. The fans are the principal force driving the flow of gas through the boiler. This does not mean that power burners are independent of draft. The capacity of the burner, and possibly the air-fuel ratio, is affected by the firebox pressure.

Measuring overfire draft may require drilling a hole through the boiler front, since all doors and access panels should be closed. If possible, remove a bolt or screw from a flange or faceplate near the burner, and insert the probe through the bolt hole.

■ Draft at the Draft Regulator

The second draft measurement is taken at the draft hood or draft regulator. The purpose of this measurement is to verify that the draft control device is functioning and adjusted properly. The draft should be negative and steady, so that air flows inward, from the boiler room to the flue. You can also check this draft by dangling a lightweight sheet of paper near the draft regulator to see if it is drawn toward the flue.

If the boiler uses a draft hood, there is no adjustment to make. The appropriate overfire draft is created by the height difference between the burner and the draft hood.

If the boiler uses a barometric damper, you adjust the damper to provide the proper overfire draft. The damper is adjusted typically by changing the position of a balance weight.

Check a barometric damper to be sure that it moves freely but remains steady. The damper should settle down quickly when the firing level changes.

If the boiler uses a motorized damper, adjust the damper setting until the overfire draft is correct. There

is no need to measure the draft at the damper itself unless you suspect a problem.

If the boiler uses a variable-speed induced-draft fan, adjust it to maintain the desired overfire draft.

■ Stack Draft

Stack draft is determined primarily by the stack height, and it usually is not adjustable. The purpose of measuring stack draft is to verify that stack draft is adequate, i.e., that the pressure inside the bottom of the stack is negative under all operating conditions. The stack draft itself does not have to remain at a specific value, but it should be adequate to remove flue gases under all operating conditions.

The stack may be subject to wind effects, such as a downdraft from an adjacent building, that cause the flow in the stack to reverse. Measure the stack draft during periods when you suspect trouble, to find out if such problems exist. Even though the stack draft may vary over a wide range, it should not have erratic fluctuations.

You can measure stack draft at any convenient location near the base of the stack. If a draft regulator is installed, measure the stack draft above the draft regulator at a distance equal to several flue diameters. You can insert the probe through the draft regulator, if it is long enough to extend a sufficient distance above the opening. If this is not possible, drill a small hole in the stack.

When to Check Draft

Check draft, and adjust it as necessary, every time you do efficiency testing and burner maintenance.

[Measure 1.4.1](#) covers appropriate burner maintenance intervals. Also, measure draft when diagnosing burner problems.

Solving Flue Draft Problems

If you cannot adjust draft properly, or if there are problems that create erratic draft, you need to make changes to the draft system. In such cases, refer to [Measure 1.5.2](#), next.

MEASURE 1.5.2 Correct defects in flue systems and boiler room ventilation that cause draft problems.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Improper draft reduces boiler efficiency by disturbing the air-fuel ratio. It also increases maintenance by causing smoke and sooting. These problems are explained in [Measure 1.3.1](#). More severe draft problems can cause serious safety problems, especially backflow of flue gases into the boiler room. In the worst cases, this can smother the flame and cause an explosion.

This Measure explains the common causes of draft problems, and suggests appropriate remedies. Draft problems can arise anywhere in the path of combustion air or flue gases, including the entry into the building, the inside of the boiler, and the entire exhaust path. You may find serious draft defects that have persisted for years.

A draft problem may have more than one cause. Take corrective action that eliminates all the problems.

Relationship to Burners and Fans

The sensitivity of a boiler to draft depends on the design of the burner system. Burners and fans that operate at high pressure overpower fluctuations in draft, reducing their effect. At the other extreme, atmospheric burners are very vulnerable to fluctuations in draft. Other burner designs lie between these two extremes.

Problem: Defective, Improper, or Incorrectly Adjusted Draft Regulator

If the stack draft is adequate but burner draft is too weak, the problem probably is in the draft regulator. The draft regulator may be defective, or it may be improperly adjusted, or it may be the wrong type for the boiler installation. Refer to [Measure 1.5.1](#) about selecting and adjusting draft regulators. Draft regulators can limit excessive draft, but they cannot compensate for inadequate draft.

Problem: Excessive Flue Draft

The usual cause of excess draft is that the stack or flue is taller than needed. This is unavoidable in some applications, for example, with basement boiler plants in tall buildings, where the flue rises to the roof. The usual remedy is to add an appropriate draft regulator. The types of draft regulators and their characteristics are covered in [Measure 1.5.1](#).

Excessive draft can also be reduced by placing a restriction in the stack or flue. However, a fixed restriction cannot adapt well to changing boiler loads or other conditions. You may have to deal with a tall stack or flue by using both a stack restriction and a draft regulator.

SUMMARY

Draft problems are common, and they require a variety of solutions.

Problem: Insufficient Flue Draft

Insufficient stack draft may be caused by a stack that is too short, or by obstructions in the ducting leading to the stack. The ways to deal with insufficient flue draft are:

- **remove any restrictions that exist in the flue.** If the connection between the boiler and the stack has repeated bends, it can create considerable resistance to flow. Eliminate right-angle bends and use smooth, long-radius bends.
- **install a draft-inducing fan.** Small boiler systems can use an inexpensive draft inducer that fits through the side of the flue like a paddle wheel. Larger systems may require a proper induced-draft fan that moves the entire volume of flue gas. The fan should be interlocked with burner firing to conserve energy and to avoid cooling the flue between firing cycles. Control larger fans with a variable-speed drive, as recommended by [Measure 1.4.7](#).
- **install a taller stack**
- **replace the burner with a unit that operates efficiently with the existing draft.** This approach is especially desirable if you can substitute a more efficient burner. Upgrading burners is covered by [Measure 1.4.2](#).

Problem: Wind Effects on the Flue

Rapid and severe fluctuation in draft is usually caused by wind effects. A stack is not affected seriously by wind that blows horizontally, but this is an ideal condition. Adjacent buildings or terrain may cause wind to have a strong downward or upward component at the top of the stack. This is a common problem when the top of the flue is below an adjacent structure.

WESINC

Fig. 1 Blocked combustion air intake This air intake to a large boiler plant was blocked to keep the cold outside air from causing discomfort inside the plant.

A downward wind component into the stack inhibits the flow of flue gases out of the boiler. If this condition is serious, the fumes tend to smother the flame, or they spill into the boiler room through the draft regulator or other openings in the flue. A backdraft may even blow out the fire in a boiler that has atmospheric burners, posing a risk of explosion when unburned fuel is ignited by contact with the heated parts of the boiler.

Usually, the best solution is to install a broad cap at the top of the stack that blocks any vertical wind component. You can design this fixture to diffuse wind and reduce its velocity.

Don't expect a draft regulator to solve a backflow problem. It cannot even do a good job of smoothing out smaller fluctuations caused by wind, which tend to be gusty in nature. Similarly, draft inducing fans do not adequately smooth out fluctuations caused by wind.

Replacing the present burner with one that operates at higher fan pressure reduces the sensitivity of the burner to draft fluctuations. However, replacing the burner is not a substitute for fixing the draft problem.

Problem: Wind Pressure on the Boiler Room

When wind strikes a surface, it is capable of creating pressures that are high in comparison with the normal pressure differences inside a boiler system. Boiler buildings that have many ventilation openings act as a shield against wind pressure. This is because the pressure inside the boiler room is an average of the pressures on the upwind and downwind sides.

However, unbalanced boiler room pressure is likely to occur if there are ventilation openings only on one side of the building. You can minimize this problem by installing carefully designed wind deflectors over the

openings. Before making any changes, refer to [Measure 1.11.3](#), which relates to air flow through the boiler space.

Problem: Building Chimney Effect

If a boiler room is located in the basement of a tall building, the chimney effect of the building may create a negative pressure inside the boiler room. The solution to this problem is to provide a combustion air intake that leads directly to the outside of the building at grade level, and to minimize openings between the boiler room and the interior of the building. The outside air intake must be large enough to prevent drastic changes in boiler room pressure when interior doors are opened.

Problem: Inadequate Outside Air Intake Area

The space around the boiler should be at the same pressure as the air outside the building. To achieve this,

WESINC

Fig. 2 A collection of combustion air problems This air intake for a small boiler is very large. However, it has an intake fan that upsets the air-fuel ratio of the atmospheric burner. The bottom louvers of the intake have been closed, and the top is being clogged by leaves.

air must enter the boiler room through one or more openings in the boiler room enclosure. These openings must be large enough to avoid any measurable pressure drop as air enters the boiler room. Insufficient intake area causes negative pressure inside the boiler room. The pressure drop gets worse at higher firing rates.

Experience has provided rules of thumb for air intake size. A common guideline calls for one square inch of intake area for every 1,000 BTU/HR of boiler capacity. Fine mesh screens (such as insect screens, but not bird screens) over the intakes double or triple the inlet area that is advisable.

Boiler operators may reduce the inlet area to avoid discomfort from exposure to cold air during cold weather, or to protect against a perceived freezing problem. Figure 1 shows an example. To solve the combustion air problem, you must resolve the comfort problem. If necessary, relocate the outside air intake to avoid discomfort, or duct the combustion air directly to the burner area. Or, provide an enclosure for persons who work in the space. This also provides a haven from boiler room noise. However, this solution is acceptable only if plant operations permit the staff to spend most of their time inside the enclosure.

If possible, try to route outside air through the warmest parts of the boiler room to pick up heat before the air enters the boiler. This increases boiler efficiency while cooling the space. See [Measure 1.11.3](#) for details.

■ Provide Sufficient Air for Draft Hoods and Dampers

If the boilers have barometric flue dampers or draft hoods, the boiler room needs additional inlet area for the air that is drawn into these devices. Size the inlet for the possibility that much more air may flow into the draft hood or damper than is needed for combustion. Otherwise, the boiler room may develop negative pressure, and flue gas flow may become unstable.

Problem: Fans in the Boiler Room Envelope

Fans move air by creating a pressure difference. Therefore, if a fan is used to move air into or out of a boiler room, it creates a pressure change in the boiler room. Fans may be installed in the combustion air intakes by operators seeking relief from high space temperature. Also, fans are sometimes installed because of the misconception that they “help” combustion. Figure 2 shows an example.

The original design of boiler plants sometimes includes ventilation exhaust fans, especially if the space is used for other equipment, such as chillers and air handling equipment. The designer may not have recognized the disturbance of boiler draft caused in this way.

The solution in all cases is to remove fans that create irregular combustion draft. As a guideline, if a ventilation fan creates enough of a pressure differential to cause a noticeable breeze through any air inlet opening, the fan is too large or the total inlet area is too small. In principle, you can minimize the effect of fans in the boiler room envelope by making the passive openings much larger than the combined area of all the fans in the envelope. This may be impractical to achieve. Furthermore, as we have seen, plant operators tend to obstruct large openings to avoid discomfort during cold weather.

Spot cooling of personnel by using outside ventilation air is acceptable if the total volume of air is small in relation to the capacity of properly sized outside air intakes. However, in climates that have cold weather, spot cooling is uncomfortable when the outside air is too cool. As suggested previously, if operators usually stay in one area of the boiler room, you can reduce the amount of cooling ventilation by providing an enclosure for the operators.

Ventilation fans that recirculate air entirely within the boiler space do not cause a problem, regardless of their size, unless they blow on the burners or combustion fan inlets.

Problem: Soot Obstruction

In some types of boilers, especially cast iron boilers with narrow passages, sluggish burner draft could be caused by heavy soot accumulation. In most boiler designs, the amount of soot would have to be monumental to restrict gas flow noticeably.

MEASURE 1.5.3 Minimize standby losses.

Standby loss is a major cause of energy waste in many boilers. If your boilers suffer from this problem, you may be able to reduce the energy loss. The four subsidiary Measures provide a variety of ways to reduce standby losses, including equipment changes and simple adjustments.

What is “Standby Loss?”

When a boiler is firing, heat is transferred to the internal surfaces of the boiler because the combustion gases are hotter than the surfaces. Conversely, the boiler loses heat to the cold air inside the boiler when the burners are not firing. If air can circulate through the boiler when firing is off, a great deal of heat is lost this way. This loss of heat is called “standby loss.” There are two reasons why air flows through the combustion area while the boiler is not firing: convection and purging.

■ Convection Losses

Convection circulates cold ambient air through a boiler, carrying away heat up the flue. The high temperature inside a hot boiler induces a convective force through the boiler by making the air inside the boiler less dense, and therefore lighter. If a boiler does not have a damper to prevent convection when the burner is not firing, the convection continues as long as there is heat in the boiler. Standby loss from convection increases with the length of time that a boiler is not firing.

The worst convection occurs in boilers with combustion chambers that are open to the atmosphere. Such boilers have no means to restrict convection, and the flow resistance of the gas passages is low.

The least convection occurs in boilers with closed combustion chambers and fan-forced combustion. To limit convection, most larger power burners have an integral damper that closes when the burner is not operating.

Some boiler systems use dampers in the flue that close when the boiler is not firing. In boilers that do not have dampers, the amount of convection depends largely on the boilers’ internal resistance to gas flow. Boilers that use atmospheric burners typically have little internal resistance, so their convection losses tend to be high, perhaps as much as 10% of fuel consumption. At the other extreme, multi-pass firetube boilers have a high resistance to convection because of the circuitous route that the gas must follow.

Convection losses are reduced by burners that have a high turndown ratio. These allow the burner to fire

for a much larger fraction of the time, reducing the period of time during which convection loss can occur.

■ Purging Losses

Purging is a safety feature of forced-draft boilers. The purpose of purging is to ensure that nothing but air is inside the combustion space when the burners are fired. If the combustion space were filled with a mixture of air and fuel vapors, an explosion could occur. To prevent explosions, the burner controls are programmed to operate the fan for a period of time prior to firing in order to clear out the entire volume of air within the boiler. This air is replaced with cold ambient air that absorbs a considerable amount of heat from the boiler.

Some burner systems also carry out a purging cycle when firing stops. (This is called “post-purge.”) The purpose of post-purge is to blow all combustion products out of the system after firing stops. This may be necessary because the flue gases contract when firing stops, which may cause the draft to reverse and carry flue gases into boiler space. Post-purge is especially wasteful because the firesides are at maximum temperature immediately following a firing cycle.

Standby loss from purging is proportional to the rate at which a burner cycles on and off. For this reason, purging losses are reduced by burners that have a high turndown ratio. These allow the burner to satisfy low loads without turning off the flame.

Reducing Standby Losses Reduces Boiler Damage

Reducing standby losses will also reduce boiler problems, such as tube sheet leakage and refractory breakage. These problems are aggravated by abrupt changes in boiler temperature, which is associated with convection and purge cycles.

When a burner turns on or off, there is a large, abrupt change in the temperature of the boiler components. The change in temperature is increased by convection of outside air through the boiler. Boilers are designed to tolerate this abuse fairly well, but there is a correlation between certain kinds of boiler damage and the frequency of firing cycles.

Purging creates the greatest cycling stress on a boiler. The sudden flow of cold air causes rapid contraction of the boiler’s components. This temperature change is especially severe because it occurs just before firing commences, creating an abrupt reversal of temperature from cold to hot. Post-purge cycles change the temperature abruptly in the opposite direction.

Safety Considerations

Combustion air and flue gas must be able to move freely as long as the burner is firing. All fans in the combustion gas path must be operating when the burner is firing. All dampers must operate properly during

firing, and they must open fully during pre-purge and post-purge cycles. A fan or damper failure may cause combustion gases to back up, risking explosion and asphyxiation. Therefore, any modifications should be accomplished only by a technician who is competent to deal with the safety issues.

MEASURE 1.5.3.1 Control all fans in the combustion air path to stop, and all dampers to close, when the burner is not firing.

RATINGS

New Facilities	Retrofit	O&M
A	B	C

This method of reducing standby loss applies to boiler systems that have fans and/or dampers to control draft. The procedure is simply to ensure that the burner controls turn off all the fans, and close all the dampers, whenever the burners are not firing.

Control of Fans

Boiler systems may have one or more fans in the combustion gas path. If any one continues to operate when the boiler is off, it can induce a significant amount of air flow through the boiler, even if dampers are closed. Forced-draft fans and induced-draft fans normally are controlled to turn on and off as part of the firing sequence. Verify that this is true in your plant.

Draft inducers, which are small fans installed in the flue itself, may be installed to solve a stack draft problem. Letting such fans operate continuously is a mistake. If the draft inducer can draw boiler room air into the stack through the draft regulator between firing cycles, it will cool the stack. Since the stack is cold when the boiler fires, the draft has to be restarted every time the boiler fires. Also, letting the stack cool causes corrosion by allowing acids that are contained in the flue gases to condense on the flue surfaces (see [Measure 1.7.1.1](#) about acid condensation).

The solution is simple. Use the burner controls to control the operation of all fans in the boiler air system.

Control of Dampers

Dampers that are part of burner assemblies are almost always programmed to close when the burner stops firing. Verify this operation in your burners.

A motorized damper may be installed inside the flue to regulate flue draft. Such a damper may be controlled only in response to flue draft, not burner firing. If so, change the controls to close the damper when firing stops. This change has major safety implications. Therefore, equip the burner controls with a low-draft

MEASURE 1.5.3.2 Install an automatic flue damper.

RATINGS		
New Facilities	Retrofit	O&M
□	B	□

A standard method of reducing standby loss is to install an automatic damper in the flue that closes when the unit is not firing. This keeps outside air from circulating through the boiler and carrying heat out the flue.

Applications and Energy Saving Potential

Standby losses range from minimal to more than 10 percent of fuel input. It is usually not practical to measure standby loss in the field. Instead, you need to judge standby losses from the configuration of the system. This will tell you whether you need a flue damper. Consider these factors:

- **burner off time.** Standby losses are directly proportional to the time that firing is off while the boiler or furnace is still hot. Continuously operating boilers do not have standby losses.
- **the amount of heat stored in the mass of the equipment.** The convective force that causes standby losses is caused by warming of air in the idle boiler or furnace. If the unit remains hot between firing cycles, as with steam boilers, standby losses are greatest. On the other hand, a hot air furnace that fires occasionally suffers standby losses only until the furnace cools down.
- **the resistance of the system to air flow.** A tight damper in the system, either at the combustion air inlet or in the flue, prevents most standby loss.
- **the strength of the convective draft.** All other things being equal, a greater convective force increases standby loss. The greatest convective force occurs if there is a tall stack, but no draft regulator.

A flue damper is the only means of limiting standby loss if the boiler or furnace has no means of closing off the air inlet. This is characteristic of all boilers with atmospheric burners. Such boilers are wide open to convection, and the flow resistance of the gas passages is low. Also, many boilers and furnaces with smaller fan-powered burners do not have inlet dampers.

A flue damper may provide some benefit even in a boiler that has an inlet damper, although the damper is unlikely to be economical. Even with the inlet damper closed, air heated inside the boiler may pass up one side of the flue while ambient air backflows down the other side. The extent of such convection is difficult to judge. Go to the top of the stack or to the draft damper after the boiler has stopped firing for a while, and see whether there is a significant flow of hot air.

Flue dampers are not useful with high-efficiency furnaces and boilers that employ forced circulation of

combustion gases. Such units have heat exchangers with long, narrow passages that inhibit convection. Their resistance to convective flow is so high that heat loss is negligible as long as the fan is not operating.

Installation Limitations

If the boiler has a sealed flue, installing a flue damper may be relatively easy. Just remove a short section of the flue near the boiler discharge, and insert the flue damper.

WESINC

Fig. 1 A flue damper installation challenge This boiler has atmospheric burners, several flue gas outlets, and an integral draft hood. Installing a flue damper here would require a lot of sheetmetal work.

Unfortunately, installing flue dampers is most difficult on the boilers that need them the most, which are boilers with atmospheric burners. Boilers with atmospheric burners commonly have an open discharge hood at the outlet of the boiler casing, and the flue is connected to the top of this hood. An example is shown in Figure 1.

In order to block circulation of air through the boiler, the flue damper must be installed on the boiler side of any openings in the flue. If the boiler has an integral draft hood, you must remove the hood, find a way to connect the flue damper to the boiler directly, and rebuild the draft hood and the flue connections. This job may be too difficult to be practical. In this situation, think about replacing the entire boiler with one that is more efficient.

Types of Flue Dampers

Motorized, externally powered dampers are used in boilers of all sizes. For example, one major burner manufacturer offers retrofit flue damper kits in sizes ranging from 10 inches to 42 inches in diameter. Flue dampers typically are single-blade units that have the advantages of being inexpensive and closing tightly enough to block most convection. The hardware and controls are conventional. Installation is simple, provided that a suitable length of flue is accessible for mounting the damper.

Self-powered thermostatically operated flue dampers are used in smaller units. These open in response to the high temperature of flue gases. Most thermostatic dampers have a blade made of bimetallic material that changes shape when heated. After the burner lights, hot gas reaching the damper causes the bimetallic elements to warp to an open position, allowing the gas to pass to the flue. No external power or external connections are required. The advantages of thermostatic dampers are low cost, reliability, and low maintenance.

A limitation of self-powered thermostatic dampers is that they must remain partially open so that hot gas can flow quickly to the thermostatic element as soon as the burner starts firing. Partial opening is achieved by making a hole in the damper blade, or by undersizing the damper blade. This lack of tight closure undermines the effectiveness of the damper. As a result, thermostatic dampers are limited mainly to small boilers and furnaces where their lower cost is more important.

Relationship to Draft Regulators

A flue damper must be located on the boiler side of any draft hood or barometric draft damper that is installed. Otherwise, when the flue damper closes, it would force flue gases to flow into the boiler room through the draft regulator.

If a motorized draft regulation damper is already installed inside the flue, examine it to see whether it is capable of closing tightly. If so, this damper can serve to prevent convection. See [Measure 1.5.3.1](#), previous.

Okay with Pilot Lights

Older furnaces and boilers may use a continuous pilot light to ignite the burner. The amount of flue gas produced by the pilot light is small. Flue dampers generally have enough leakage to accommodate the pilot light.

Adjust the Air-Fuel Ratio

A flue damper restricts flow to a small extent even when it is open. This may affect the air-fuel ratio, especially with atmospheric burners. After installing a flue damper, adjust the air-fuel ratio as recommended in [Measure 1.3.1](#).

Safety Certification

Flue dampers involve a potential safety hazard, which is the possibility of the damper remaining in the closed position while the burner is firing. If this occurs, combustion gases will back up into the space surrounding the heating unit. Approved flue dampers include safety features that deal with this possibility. Be sure to select only approved flue dampers, and to install them in a safe manner. Standards for flue dampers are set by various agencies. For example, the American Gas Association acts as an approval agency for flue dampers that are used in gas-fired heating units. Make sure that the flue damper has the seal of the appropriate organization.

ECONOMICS

SAVINGS POTENTIAL: 2 to 10 percent of fuel consumption, if the boiler does not have an inlet damper. Less than 2 percent of fuel consumption, if the boiler has an inlet damper.

COST: Less than \$100 for small thermostatic units, to about \$1,000 for large standard motorized units, installed. Customized installations for large boilers may cost thousands of dollars.

PAYBACK PERIOD: One year to many years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Select a unit made by an experienced manufacturer. A certification label does not indicate reliability or efficient operation. Select a unit that closes as tightly as possible while satisfying safety requirements. Make sure that the unit is appropriate for your particular boiler and flue system.

INSTALLATION: Most installations are fairly easy, but some require ingenuity. Work out the details, or else the unit may not function properly.

MEASURE 1.5.3.3 Install a burner assembly or boiler that minimizes standby losses.

If the boiler has no dampers to prevent standby losses, you may be able to replace the present burner with a burner that has an integral damper. Or, you may be able to replace a cycling burner with a modulating burner. Refer to [Measure 1.4.4](#), which covers upgrading burners in general.

Select replacement burners to provide as much improvement as possible in efficiency and ease of maintenance. Replacing the burner only to prevent standby losses would rarely be economical.

If you are installing a new boiler or furnace, select a unit that has low standby losses as well as high combustion efficiency. See [Measure 1.12.1](#) for ideas.

MEASURE 1.5.3.4 With cycling burners, adjust the controls to minimize the frequency of firing cycles.

If you have boilers that control their output by cycling on and off, you can reduce standby losses and boiler deterioration by reducing the burner cycling rate. However, pushing this technique too far can cause trouble.

A Simple Solution

Heat loss from purging increases with the rate of cycling because the number of purge cycles is increased. Convective heat loss increases with the rate of cycling because the combustion chamber is kept hot for a larger percentage of the “off” time.

Therefore, you can reduce standby losses by reducing the rate of burner cycling. Burner firing normally is controlled by the outlet steam pressure or outlet water temperature. You can usually set the turn-on and turn-off pressures (or temperatures) separately. Adjust the settings so that the turn-on and turn-off points are further apart.

Limitation in Multi-Boiler Installations

In a plant with several boilers, the sequence of boiler operation may be controlled by setting each boiler to start and stop at a different steam pressure or water temperature. The sequence of boiler operation affects overall plant efficiency, as explained in [Measure 1.1.4](#). If you use this method of sequencing the boilers, you will have little opportunity for increasing the pressure or temperature range of an individual boiler.

Conflict with Minimizing Steam Pressure

In some steam systems, you can save energy by keeping steam pressure at the low end of the pressure range, as recommended by [Measure 1.1.5](#). On the other hand, to minimize cycling, the boiler needs to fire to the top of its pressure range.

Analyze your system to decide which Measure provides the greater benefit. Minimizing boiler pressure provides its greatest benefit in large steam systems, which usually do not have cycling burners.

Possible Problems with User Equipment Controls

Large swings in steam pressure or water temperature may cause control problems in user equipment. This should not be a problem if the user equipment and its controls are properly designed. However, problems may arise in some marginally designed units, or problems may be triggered in units that have incipient defects.

Large swings in steam pressure may create a nuisance in manually controlled equipment, such as old steam radiators. Widely varying steam pressure makes it difficult for occupants to find a satisfactory valve setting. Changes of pressure may create cycles of noise in steam equipment, even if they have automatic controls.

Explain It!

The benefit of extending the burner firing interval is not obvious to operating and maintenance personnel. Install a permanent placard at the firing controls to indicate the proper settings and the reason for them. See [Reference Note 12, Placards](#), for details of effective placard design and installation.

TRAPS & TRICKS

CAREFUL INITIATION: Make sure that increasing the firing interval does not interfere with boiler sequencing, cause excessive pressure or temperature fluctuations at the user equipment, or cause other problems. You may have to experiment to find the maximum desirable firing interval.

EXPLAIN IT: For the benefit of maintenance personnel who may work on the burner controls, install a permanent placard to indicate the firing interval that should be set.

Firesides and Watersides

Keeping firesides and watersides clean does more to keep boilers efficient than any other routine maintenance activity. Deposits that accumulate on these surfaces impede heat transfer, forcing more of the heat of the combustion gases to be lost to the flue. The Measures in this Subsection maintain the cleanliness of heat transfer surfaces and reduce the cost of doing so.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Deposits on fireside surfaces insulate the tubes from the combustion gases, forcing more heat energy to escape into the stack. Even modest fireside fouling can waste a significant fraction of fuel energy.

Types of Fireside Deposits

The most common fireside deposit is soot. Soot consists of unburned carbon and various dirty carbon compounds that are products of partial fuel combustion. Many of these intermediate products adhere to boiler tubes. Soot has a high insulating value because it forms as a porous layer, with a large amount of dead space. Soot can be formed by any type of fuel that contains carbon. This includes all conventional fuels and most unconventional fuels. Soot forms immediately and rapidly when combustion is not complete.

Once deposits are lodged on the tube surface, the cooling provided by the tubes keeps the deposits from burning off, even if they are combustible. The heat of the furnace may bake some of the deposits on the tubes. Some noncombustible impurities contained in the fuel, such as the mineral particulates called “fly ash,” may melt and stick to the boiler tubes.

How Often to Clean Firesides

Gas fuels can burn so cleanly in many boilers that little soot accumulates, provided that the air-fuel ratio is kept within proper limits. At the other extreme, heavy oils and coal produce soot in virtually any boiler, requiring periodic cleaning of firesides, perhaps several times per year. Boilers burning light oil accumulate fireside deposits more slowly, typically requiring cleaning about once a year.

How to Monitor Fireside Fouling

Visual inspection is the only reliable method of gauging fireside fouling. Most types of watertube and firetube boilers allow easy inspection of most of the fireside surface. Take the opportunity of inspecting the firesides whenever the boiler is shut down after an extended period of operation. Inspecting firesides does not require a great deal of analytical skill. Anything that is deposited on the tube surfaces should be removed.

You can use gas temperature to monitor soot accumulation between boiler shutdowns. A rise in temperature indicates fouling, although it does not distinguish between fireside and waterside fouling. Take the combustion air temperature into account when you take flue temperature readings.

Flue gas temperature is easy to track with on-off and two-stage burners because they always have the same heat output. Flue gas temperature is more difficult to track if the boiler has a modulating burner, because the flue temperature varies with load. To account for this, prepare a table of flue gas temperature versus load when the boiler is clean. To determine the load, use a fuel flowmeter, a steam meter, or a BTU meter. Another method is to install a position indicator on the fuel control linkage and calibrate it for load.

Cleaning Techniques

Firesides are cleaned with mechanical methods. With firetube boilers, a cylindrical brush is pushed through each tube at the end of a rotating cable. Removing heavier deposits may require a cutter head. Some machines have a vacuum cleaner attachment that disposes of the soot as it comes out of the tubes. Figure 1 shows how this type of equipment is used. Most firetube boilers allow relatively easy access to the entire fireside surface.

Cleaning watertube boilers is more tedious. Hand wire brushes and scraping tools typically are used. Access to tubes behind the first row can be a frustrating challenge. Particularly difficult cases may require air lances, sandblasting, or other messy procedures. Don't wear your Sunday clothes for this job.

Of course, you can hire contractors to clean your boilers, but you still need to monitor them. Make sure that the contractor is thorough and does not harm the boiler.

With fuels that deposit soot at a high rate, consider installing soot blowers. See [Measures 1.6.2](#) and [1.6.3](#), below, about soot blowers.

Goodway Tools Corporation

Fig. 1 Cleaning the firesides of a firetube boiler This job is dirty, but not too difficult. The vacuum cleaner attachment, at right, is the largest part of the equipment.

How to Minimize Fireside Deposits

Preventing deposits is better than removing them. The way to minimize fireside deposits is to keep the air-fuel ratio adjusted properly, as recommended by [Measure 1.3.1](#). Make sure that the boiler's air-fuel controls keep the ratio in the proper range at all times. Even a brief period of operation with insufficient air can deposit a significant amount of fouling.

The condition of burners has a major effect on fireside deposits, especially with heavier liquid fuels and with solid fuels. A partially clogged burner may cause some of the fuel to burn incompletely, creating heavy residues. For this reason, clean your burners regularly, and without fail. Follow the procedures recommended by [Measure 1.4.1](#).

Clean Firesides Upon Shutdown

Clean firesides as soon as you shut down a boiler. During shutdown, moisture may condense on the tube surfaces. Moisture reacts with the sulfur that exists in any remaining soot to form sulfuric acid, which corrodes the tubes. For this reason, cleaning at shutdown needs to be especially thorough.

Unfortunately, the areas where soot is hardest to remove are the areas where corrosion can cause the most trouble. In firetube boilers, take special care to remove any soot that collects around the outside of the tube where it projects through the tube sheet. In watertube boilers, concentrate on the areas where tubes enter the steam and mud drums. Rear rows of watertubes are especially difficult to reach.

ECONOMICS

SAVINGS POTENTIAL: 0.5 to 10 percent of fuel cost, depending mainly on the type of fuel and how well the air-fuel ratio is kept adjusted.

COST: The cost of typical rotating brush cleaning equipment for firetube boilers ranges from \$1,500 to \$4,000, depending on size and features. If you hire a cleaning service, the cost is proportional to the size of the boiler and to the difficulty of reaching all the fireside surfaces. A medium-sized firetube boiler with moderate sooting can be cleaned in one day.

PAYBACK PERIOD: Several months to several years.

TRAPS & TRICKS

DILIGENCE: Cleaning firesides is dirty, tedious, and uncomfortable, which motivates people to quit the job before it is finished. Inspect the work to make sure that all fireside surfaces are cleaned. Deposits that are not removed will cause maintenance problems later. Be careful to avoid damaging tubes and brickwork.

SELECTING THE EQUIPMENT: If you buy your own cleaning equipment, select equipment that makes the job as easy and pleasant as possible. The tools should not be so aggressive that they risk damaging the metal. Get a vacuum cleaner attachment to collect the dust.

MEASURE 1.6.2 Install soot blowers in boilers that burn sooting fuels.

RATINGS

New Facilities	Retrofit	O&M
A	C	

If you wait until shutting down the boiler to clean firesides, the deposits will reduce the boiler's efficiency for the entire time it is operating. Soot blowers allow you to remove deposits while the boiler is operating, at any interval you choose. With dirty fuels, soot blowers cannot eliminate the need for mechanical cleaning, but they may substantially reduce the drop in efficiency between cleanings.

Whether to Install Soot Blowers

A certain amount of sooting is virtually impossible to prevent. With gas and light oil, soot may deposit on firesides so slowly that it burns off before it can accumulate. With all the heavier grades of fuel oil and with all grades of coal, soot accumulates as long as the boiler is firing. Heavier grades of oil build up soot much more quickly than do lighter oils. Soot accumulation in coal-fired boilers depends on several factors, especially the grade of coal, the burner design, and the tube design.

With heavy oils and coal, significant soot accumulates within a few hours. A boiler may operate without interruption for thousands of hours, allowing

enough soot to accumulate to seriously reduce efficiency. Fortunately, soot can be kept under control while the boiler is in operation by using soot blowers. These are devices that blast soot loose with jets of steam or compressed air. Soot blowers are available for both watertube and firetube boilers.

Fuel Efficiency, Inc.

Fig. 1 Soot blower for firetube boiler This model uses compressed air. The four valves at right blow different groups of tubes in sequence.

If a boiler does not already have soot blowers, estimate the potential benefit by noting how much soot accumulates between maintenance intervals. If soot accumulates rapidly enough to reduce efficiency significantly between manual cleanings, consider soot blowers. Soot blowers do not eliminate the need for periodic manual cleaning, but they may extend the cleaning interval dramatically.

Soot blowers are especially important with economizers that have gill rings or other components that trap soot. If an economizer has aluminum gill rings, soot accumulation can cause a thermite fire, which is intense and virtually impossible to extinguish.

In calculating the economics of adding soot blowers, include the savings in fuel cost and labor. Expenses include the cost of installation and the cost of the steam or compressed air that is consumed. (Minimizing the cost of soot blowing steam or air is covered by [Measure 1.6.3](#), next.) The cost of maintaining the soot blower itself should be minimal if the unit is well designed.

Soot Blowers for Firetube Boilers

Soot blowers for firetube boilers consist of nozzles that are located just beyond the end of each tube. The nozzles are fed from manifolds that are located inside the ends of the boiler, where the combustion gases turn around to go from one pass to the next. Figure 1 shows a typical installation.

The nozzles are usually located at the burner end of the boiler. This is because the combustion gas at the end of the first pass, at the rear of the boiler, is too hot for the equipment. Therefore, the steam or compressed air will be blowing in a direction opposite the second pass (or fourth pass) of the boiler, and in the same direction as the gas in the third pass. To keep from interfering with the combustion gas flow, the nozzles are controlled in groups, so that only a fraction of the tubes in each pass are being blown at a time. This complicates the steam or air manifolds, and requires an array of valves and a sequencing controller.

The nozzles and manifolds take up a lot of space, which may interfere with gas flow. Because of the potential for problems, check on the performance of the soot blower before purchase. Compare notes with someone who has installed the same type of soot blowers in your model of boiler.

Soot blowers for firetube boilers typically are made by specialty companies.

Soot Blowers for Watertube Boilers

A typical soot blower unit for a watertube boiler consists of a pipe that extends across the width of the boiler, passing either among the tubes or in front of them. Orifices are located in the pipe to blast steam or air through the bundle so that all tubes are cleaned. The soot blower is usually rotated during operation so that

the blast reaches all the area around the blower pipe. In a typical boiler, a number of units are needed to provide complete coverage of the tubes. Figure 2 shows the typical external hardware for a steam soot blower.

Soot blowers are customized for each model of boiler. They may be made by the boiler manufacturer or by specialty companies. Each orifice or nozzle must line up properly with the adjacent tubes. Installing a soot blower assembly may be difficult or impossible in boilers that were not originally intended to have them.

Steam or Compressed Air?

High pressure is a key to soot blowing. In firetube boilers, a minimum pressure of 125 PSI is recommended, for both steam and air. Therefore, if the boiler does not produce this much steam pressure, compressed air is the only alternative. Slightly less pressure may be permissible if the soot is easily removed.

[Measure 1.1.5](#) recommends reducing the steam pressure to reduce system leakage, and for other possible benefits. In some cases, this may conflict with steam soot blowing.

With firetube boilers, the equipment that must be installed in the boiler to blow soot with steam is more

WESINC

expensive than the equipment needed to blow soot with air. However, if a separate air compressor is needed for soot blowing, the total equipment cost is about the same for steam and air.

Steam is more expensive than compressed air, unless the steam is being produced with a very cheap fuel. The loss of steam in soot blowing requires additional makeup water, but you might not notice the difference unless the steam system has low water loss.

Compressed air starts out at room temperature and it cools by expansion as it comes out of the soot blower orifices, so there is a large temperature difference between the air and the boiler steel. In firetube boilers, the air is discharged into the end of the tube, where it fits into the tube sheet. This area is sensitive to thermal stress. Whether air blowing can cause thermal damage is an issue that is not well documented.

Soot Discharge Into the Environment

Soot is dirty and corrosive, so soot blowing can create a serious problem in the vicinity of the boiler plant. For example, automobiles parked near boiler plants become covered with pinhole rust spots from soot blowing.

If soot discharge is a potential obstacle, your choice is to give up soot blowing or to install flue gas cleaning equipment.

ECONOMICS

SAVINGS POTENTIAL: 0.5 to 10 percent of fuel cost, depending on the rate of soot accumulation. Using soot blowers may substantially reduce the cost of manual fireside cleaning, and it may reduce repair costs.

COST: Compressed air soot blowers for firetube boilers cost about \$5,000 for 100 tubes, to about \$12,000 for 300 tubes. The corresponding range for steam soot blowers is about \$8,000 to \$18,000. Air compressors for soot blowing cost from \$1,000 to \$5,000, depending on the size of the boiler.

PAYBACK PERIOD: 1 to 10 years, depending primarily on the size of the boiler, the type of fuel, and fuel costs.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Retrofit installation of soot blowers is not common, so performance is not well documented. The equipment must be designed to fit the particular model of boiler, to avoid interference with gas flow, and to survive without maintenance. Ask vendors for references, and talk with purchasers who have used the equipment for several years.

INSTALLATION: As a rule, let the vendor install the equipment, because it is specialized. Do-it-yourself installation may void the warranty or weaken later damage claims.

MEASURE 1.6.3 Optimize soot blower operation.

RATINGS

New Facilities	Retrofit	O&M
		A

Soot blowing commonly is controlled on the basis of time, for example, 30 seconds every four hours. Such a rote procedure may result in unnecessary usage of steam or compressed air. On the other hand, inadequate soot blowing wastes fuel and increases the effort needed to clean firesides. Soot blowing does not use a large amount of energy, but it uses enough to make it worthwhile to optimize the procedure.

The prudent rule is to err on the side of cleanliness, but not to use more soot blower operation than is necessary to maintain a safe margin of cleaning.

How to Schedule Soot Blowing

Start with the recommendation of the soot blower manufacturer and/or the boiler manufacturer in scheduling soot blowing. Using this as a baseline, refine the schedule over the long term by inspecting the cleanliness of firesides whenever the boiler is cold.

You may hear that soot blowing should be done when a rise in flue temperature becomes apparent. This is wrong. Too much soot can accumulate before you see an increase in flue temperature. Blow soot on a firm schedule, and adjust the schedule based on experience that you gain from inspecting the firesides.

If different parts of the boiler have different soot blowing requirements, develop an appropriate soot blowing schedule for each soot blower. For example, an economizer may have different soot blowing requirements than the tubes in the firebox.

MEASURE 1.6.4 Clean watersides at appropriate intervals.

RATINGS

New Facilities	Retrofit	O&M
□	□	A

Deposits on the insides of boiler tubes reduce efficiency in the same way as deposits on the outside, by reducing heat transfer from the combustion gases to the water.

In extreme cases, waterside deposits may reduce boiler efficiency by as much as ten percent. A boiler with deposits this severe is on the verge of failure. In more typical cases of neglected waterside maintenance, a boiler suffers an efficiency loss of several percent.

Cleaning watersides is important to protect the boiler. The combustion temperature inside a boiler is high enough to destroy the steel of boiler materials. Damage does not occur in normal operation because the boiler water cools the steel enough to keep its temperature at a safe level. However, the insulating property of waterside deposits inhibits this cooling. If the deposits are not prevented from forming, or if they are not cleaned out, they can accumulate to the point that a tube will fail from overheating. Failure is most likely to occur while the boiler is under heavy load, which maximizes the damage and the hazard that results.

Characteristics of Waterside Fouling

Deposits on the watersides of tubes are mostly of a type called “scale”, because they typically are hard and

Goodway Tools Corporation

tenacious. Especially in watertube boilers, the agitation of the water washes off softer deposits, which sink to the bottom of the boiler or float to the top.

Scale and other waterside deposits conduct heat much less efficiently than boiler steel. The most common types of mineral deposits have thermal conductivities that are only two to four times higher than the conductivity of the insulating brickwork used in boilers. Silicate scale, the least conductive, has ten times the insulating value of firebrick. The causes of waterside scaling are covered in [Measure 1.8.1](#).

When Do Watersides Need Cleaning?

Visual inspection is the only accurate way to determine the thickness of waterside deposits. Unfortunately, some boilers make it difficult to see the watersides. For example, a watertube boiler with small drums may require an inspection mirror, which can provide a look only into the ends of the tubes. Scrape some of the deposit down to bare metal to see how thick it is. The thickness will suggest the cleaning methods needed.

Flue gas temperature is not a reliable indicator of waterside deposits. The deposits accumulate too slowly to be noticeable, and the resulting increase in flue gas temperature is masked by changes in boiler load. However, it is educational to note the difference in flue gas temperature immediately before and after waterside cleaning.

Cleaning Techniques

Mechanical and chemical methods are used to clean watersides. Both methods involve a lot of dirty work and both involve a risk of damaging the boiler. Unless the boiler plant operators have the skill and the equipment required, leave this activity to a specialist.

Goodway Tools Corporation

Fig. 2 Rotating brush for watertube cleaning

Large watertube boilers can be cleaned mechanically by passing a cleaning tool through each tube at the end of a rotating cable. This method is possible only if the steam drum is large enough to allow a cable to be directed into each tube. Figure 1 shows how this is done.

In order of increasing scale removing ability, the tools used are wire brushes, abrasive bead brushes, and cutter heads. Cutter heads have teeth that are hard and sharp to break up the hard scale. Even in experienced hands, it is easy for cutter heads to damage tubes. Figures 2 and 3 show typical cleaning tools.

Mechanical cleaning is difficult or impossible with many types of boilers, especially firetube boilers, because it is impossible to reach all the tube surface. Many firetube boilers have only a small handhole that exposes a small portion of the tube bundle. If deposits are soft, you may be able to remove them with a high-pressure water lance. Unfortunately, even a water lance cannot reach most of the tube surface in many boilers.

All types of boilers can be cleaned chemically. The basic technique is to use acid to eat away the mineral deposits. To keep the acid from eating away the boiler steel also, corrosion inhibitors are added to the acid. Even with inhibitors, careful control of the process is required.

Acid cleaning commonly opens up leaks at the joints between the tubes and the tube sheets, or between the tubes and the drums. This is especially likely if waterside cleaning has previously been neglected. What happens

Goodway Tools Corporation

Fig. 3 Rotating cutter for watertube cleaning

is that the acid removes mineral deposits that have plugged small leaks as they formed. The acid treatment itself may worsen the leaks once they are opened up. For this reason, be prepared to make repairs before putting the boiler back in service. You may be able to repair minor leaks by re-expanding the tube end into the tube sheet or drum. In more severe cases, the tube has to be replaced after the sealing surface is refinished.

Prevention is Better Than Cure

Preventing waterside fouling is easier, more efficient, and safer than cleaning it out. Also, it is usually cheaper, especially when considering the higher average boiler efficiency. Prevent waterside fouling with an effective water treatment program. This may radically reduce the need for waterside cleaning. See [Measure 1.8.1](#) about water treatment.

ECONOMICS

SAVINGS POTENTIAL: 0.5 to 10 percent of fuel cost.

COST: The cost of typical rotating cleaning equipment for watertube boilers ranges from \$1,500 to \$4,000, depending on size and features. The time required for cleaning is proportional to the size of the boiler and to the difficulty of reaching all the waterside surfaces. For a typical commercial-size boiler, cleaning can be accomplished in one day. Acid cleaning requires specialists. Especially with acid cleaning, set aside additional funds to repair leaks that may appear when scale is removed from leaky tube joints.

PAYBACK PERIOD: Several months to several years.

TRAPS & TRICKS

SKILL AND DILIGENCE: By any method, waterside cleaning is dirty and tedious. Skill is required to avoid boiler damage. Make sure that the people doing the work are proficient. Inspect the work to make sure that it is thorough.

MEASURE 1.6.5 Avoid leaving waterside deposits when deactivating boilers.

RATINGS

New Facilities	Retrofit	O&M

Most of the solids that are dissolved in boiler water decrease in solubility when the water temperature is lowered. Therefore, when a boiler is cooled down, dissolved material deposits on the internal surfaces of the boiler. Also, suspended material falls out of suspension. To prevent this, reduce the concentration of solids in the boiler water while the water is still hot. Do this by increasing blowdown for several days prior to shutdown.

Keep the water treatment chemicals at their normal concentration while increasing blowdown. The purpose is to eliminate the products of water treatment, not the treatment chemicals themselves.

Do not drain the boiler while it is still hot, because the heat of the boiler may bake any floating matter to the waterside surfaces, and may solidify sludge in the bottom of the boiler. As soon as the boiler is cooled and drained, wash it out vigorously.

If the boiler is being put into storage, take steps to prevent corrosion. If the boiler is stored with water in it, ask your water treatment specialist which chemicals to add during storage.

Combustion Gas Heat Transfer And Heat Recovery

The largest source of energy waste in a properly operating boiler is failure to transfer all the heat of combustion into the steam or hot water. The energy waste is large even in the best conventional boilers. The energy loss may be much larger in boilers that are inefficient in design or that have poorly matched burners.

The Measures of this Subsection capture additional heat from the combustion gases, either inside the boiler or after the gases have left the boiler. Accomplishing these Measures in the most efficient manner, and without doing damage to the boilers, requires a thorough understanding of the principles involved. These principles are presented in the Measures.

Some of these Measures are unusual, so approach them with caution. Their large potential savings make them worth considering by sophisticated plant operators.

INDEX OF MEASURES

1.7.1 Install a flue gas heat exchanger to recover additional heat.

1.7.1.1 Install a conventional (non-condensing) economizer.

1.7.1.2 Install a heat recovery air preheater.

1.7.1.4 Install a water spray heat recovery unit.

1.7.2 In firetube boilers, install turbulators.

RELATED MEASURES

- [Subsection 1.12](#), for replacing inefficient boilers with more efficient units
- [Measure 1.4.4](#), reduce burner capacity in relation to boiler size

MEASURE 1.7.1 Install a flue gas heat exchanger to recover additional heat.

In an ideal boiler, all the energy of the fuel would be absorbed in the water or steam, and the flue gases exhausted from the boiler would have the same temperature as the entering air. In reality, the flue gases of efficient modern boilers have temperatures in the range of 300°F to 600°F, and even higher if they operate at high pressure. Less efficient boilers may have exhaust gas temperatures that are much higher.

These temperatures represent a large amount of energy that is being wasted. It may be practical to recover more heat from the flue gases by installing a heat exchanger in the flue gases.

The four subsidiary Measures cover the available flue gas heat recovery methods, including unconventional ones.

What Determines Flue Gas Temperature

To approach flue gas heat recovery intelligently, you need to understand the factors that determine flue gas temperature. The main factors are:

- **the boiler's heat transfer capacity.** Many older boilers have high flue gas temperatures because of insufficient heat transfer surface and unsophisticated heat transfer features. Some newer boilers may skimp on heat transfer surface as a cost cutting measure.
- **burner capacity.** Getting too much heat out of a boiler by installing an oversized burner is another cost cutting measure that raises flue temperature.
- **boiler water temperature.** The combustion gases must be hotter than the boiler water in order for heat transfer to occur. Practical limitations in heat transfer require the gas temperature to be 50°F to 100°F higher than the temperature of the boiler water. For example, a boiler operating at 600 PSI has a water temperature of about 490°F, so it cannot have a flue gas temperature leaving the boiler lower than about 550°F.
- **superheated steam temperature.** In steam boilers with superheaters, the limiting temperature usually is the temperature of the water, not the temperature of the superheated steam. Typically, boilers are designed so that combustion gases flow over the superheater tubes first, then through the tubes where water is boiled. However, if the boiler has superheaters that are fired in a separate firebox that exhausts directly to the flue, the flue gases coming

from the superheater firebox must be hotter than the superheated steam temperature.

- **preventing acid condensation.** The flue gas temperature may be kept high to avoid condensing acids in the flue. This is explained in [Measure 1.7.1.1](#), below.
- **latent heat of water vapor.** Fuels that contain hydrogen produce water as a combustion product. When the water vapor is lost as part of the exhaust gases, it carries away about 1,000 BTU of energy per pound of vapor in the form of latent heat, i.e., the heat needed to transform liquid water into vapor. This heat can be recovered only at temperatures lower than the condensing temperature of the water vapor. This temperature depends on the concentration of water vapor in the flue gas.

A large fraction of the heat that is contained in high-temperature flue gas can be recovered by passing the flue gas through a heat exchanger after it leaves the boiler. The limitation of this technique is finding an application for the relatively low-temperature heat that is recovered. Heating feedwater and combustion air are the common applications.

Acid condensation and the lack of low-temperature recovery applications limit recovery of the lowest temperature component of flue gas heat, but methods do exist to capture this component.

Other Ways of Improving Heat Transfer

It may not be prudent to add an expensive heat recovery device to a boiler that has inferior efficiency characteristics, such as inefficient burners, insufficient combustion chamber volume, or other limitations that either cannot be improved or that would be expensive to improve. Also, it is risky to install expensive new equipment on a boiler that may be approaching the end of its service life. So, consider the other available methods of improving heat transfer.

Turbulators are an inexpensive way to improve heat transfer in firetube boilers that lack sufficient tube surface area. See [Measure 1.7.2](#) for more about turbulators.

If a boiler is inefficient because it is being fired beyond its efficient capacity, consider reducing the burner output. See [Measure 1.4.3](#) for this.

At the high end of the cost spectrum is purchasing a more efficient boiler. See [Measure 1.12.1](#) if you consider this approach.

MEASURE 1.7.1.1 Install a conventional (non-condensing) economizer.

This subsidiary Measure covers the most conventional method of recovering heat from flue gas after it leaves the boiler. This is to add an “economizer.” An economizer is a heat exchanger that recovers heat from the flue gas to warm a liquid. Economizers are available from a number of manufacturers as standard items.

The conventional economizers covered by this Measure recover only the sensible heat of the flue gas.

Applications and Potential Savings

Figure 1 shows how an economizer is used in a typical feedwater heating application. In most cases, the liquid being heated is the boiler’s own feedwater. Heating feedwater is a well balanced application, because the need for the recovered heat coincides with its availability. Also, only a small amount of piping is required, which makes for a compact installation and reduces cost.

In this example, the energy saving is about five percent. This is about the maximum saving that an economizer can provide. A saving much less than this usually does not justify the cost of the economizer. Therefore, economizers have a limited range of application, especially as retrofit items.

The temperature of the gas leaving the boiler is the key issue that determines whether an economizer is worthwhile. There are two general categories of applications. One consists of all boilers that operate at high pressure or high temperature. The other consists of existing boilers that are inefficient because they have inadequate heat transfer.

High-pressure boilers can benefit from economizers because the high temperature of the water or steam forces the gas to leave the boiler with a large amount of heat remaining. For example, if a boiler operates at 600 PSI, the gas temperature leaving the boiler is at least 550°F. If this boiler burns a fuel with an acid dew point (discussed below) of 250°F, and a safety margin of 100°F is needed to protect the flue, this leaves 200°F to be recovered.

For this reason, efficient high-pressure boilers usually include an economizer as an integral feature. Economizers are easy to include in the design of watertube boilers at modest cost, resulting in a compact overall package. In new construction, this is usually the best way to acquire an economizer. The main exception would be a firetube boiler operating near the maximum pressure for this type of boiler. Economizers cannot be made an integral part of firetube boilers.

With an existing boiler, if the flue gas temperature is too high, verify that the reason is inherent to the boiler, i.e., either high operating pressure or insufficient heat transfer surface. If the gas temperature is high for a reason that can be fixed, such as dirty firesides or watersides, it would be folly to install an economizer. Also, consider whether an old boiler has enough remaining life to justify the expense of an economizer. You may be able to substantially improve the efficiency of a large old boiler by adding an economizer, but the expense may not be justified if the boiler has to be replaced within a few years.

Retrofit economizers are expensive, and they have economies of scale, so they are economical only for larger boilers. The smallest standard economizers are rated at about 3 million BTU’s per hour.

Efficient boilers that operate at low pressure or temperature cannot benefit from conventional economizers. The acid dew points of typical fuels range between 140°F and 250°F. If the flue gas temperature is raised about 100°F above the acid dew points to protect the flue, this results in flue gas temperatures that must be kept at 240°F to 350°F, respectively. A steam boiler operating at 15 PSI has a water temperature of 250°F, and good boiler design can reduce the flue gas temperature to within 50°F of this, or about 300°F. Thus, there is little or no opportunity to reduce flue gas temperature.

Construction of Freestanding Economizers

An economizer can be made from virtually any type of gas-to-liquid heat exchanger. A common type that is made in small sizes consists of one or more tubes coiled inside a cylindrical shell. Feedwater is passed through the tubes, and flue gases are passed through the shell. This design is simple and compact. The economizer

can be inserted in-line in the flue, provided that a length of flue is accessible. Figure 2 shows an economizer of this type.

Most larger economizers consist of a bundle of straight finned tubes installed in a rectangular enclosure. These are typically installed alongside the boiler on a separate stand. This requires a large empty space adjacent to the boiler breeching. Moving things around to create this space may add significantly to the cost of the installation.

The finned tubes in this type of economizer increase heat transfer and reduce the overall bulk of the unit. The fin spacing is selected for the dirtiest fuel that the boiler burns, to allow for soot removal. A typical selection is 2 fins per inch with No. 6 oil, 3 fins per inch with No. 2 oil, and 4 to 6 fins per inch with gas.

The flue gas side of an economizer is a trap for soot, so economizers usually include integral soot blowers. Some manufacturers install soot blowers on all models, while others install soot blowers only on units that are used with oil and solid fuel. (Soot blowing is covered by [Measures 1.6.2](#) and [1.6.3](#).)

Easy access to the heat transfer surfaces is a critical feature for an economizer. Even if the unit has a soot blower, you need access to the heat transfer surfaces for inspection, localized cleaning, and repair.

Acid Dew Point Limitations on Heat Recovery

Sulfur or sulfur compounds are present in virtually all petroleum and coal, and even in natural gas. The sulfur burns to become the gas sulfur dioxide. This gas can combine with water to form corrosive (sulfurous and sulfuric) acids. Water vapor is always present in the flue gas. It is created by combustion if the fuel contains hydrogen. It also enters as humidity in the air, and as a contaminant of the fuel. The acids are harmless as long as they remain in the vapor state. However, if the acid vapors contact a surface that is cold enough, they will condense and corrode steel components.

As with water, the condensation temperature of flue gas acids can be expressed as a dew point, which is called the "acid dew point." The acid dew point depends on the acid's boiling point and the amount of acid that is present in the flue gases. The boiling point of sulfuric

Kentube

Fig. 1 Example of economizer installed to heat feedwater

acid ranges from 332°F to 626°F, depending on the degree of binding with water. Like water, acid can condense well below its boiling point. (A fogged window illustrates this.) A higher concentration allows acid to condense at a higher temperature.

The acid concentration in flue gases varies widely among different types of fuels, depending on the amount of sulfur that the fuels contain. Typical acid dew points for some common fuels are:

Fuel	Typical Acid Dew Point, °F
Natural Gas	140
No. 2 oil	180
No. 6 oil	200 - 250
High-Sulfur Coal	250

In practice, the minimum flue gas temperature coming out of the economizer should be considerably higher than these figures. Two temperatures must be controlled to prevent acid condensation. First, the temperature of the economizer surface must be kept higher than the acid dew point to prevent corrosion of the economizer itself. Second, the gases leaving the economizer should be hot enough to prevent corrosion of the flue system (the breeching and the stack).

The flue gas temperature varies widely with boiler load. The limiting condition is the flue gas temperature at the boiler's minimum load.

In the case of the economizer itself, the most vulnerable part is the end where the feedwater enters. Both the feedwater and the flue gases are coolest at this point. (The problem of corrosion at this point in an economizer is called "cold end corrosion." To maximize heat transfer, economizers are designed with counterflow circuiting, i.e., the feedwater enters at the top of the unit, where the flue gases exit.)

To estimate the inlet feedwater temperature that must be maintained to prevent corrosion, first find out the highest acid dew point that may occur with the type(s) of fuel being used. The fuel supplier should be able to provide this information.

The surface of the economizer must be kept slightly warmer than the acid dew point at all times. For example, if the economizer is used for feedwater heating, and the maximum expected acid dew point is 200°F, then the inlet feedwater temperature should not drop below about 210°F.

The temperature of the gases leaving the economizer must also be controlled. This is to protect the flue system from acid corrosion. All parts of the flue that can corrode must be kept warmer than the acid dew point. Gases cool as they travel through the flue because they lose heat to the flue surfaces. To account for this, a rule of thumb has arisen that the flue gas temperature leaving

the economizer should be at least 100°F higher than the acid dew point. Another rule of thumb calls for a 0.5°F increase in gas outlet temperature for each foot of flue.

Less temperature margin is needed if the flue and stack are completely insulated. If the stack or flue liner are made of non-corrosive materials, such as brick, the acid dew point can be ignored in these parts of the system.

How to Protect Economizers and Flues from Acid Condensation

If the economizer is sized for maximum heat recovery, there may not be enough hot gas generated at low boiler loads to keep the inlet end of the economizer warmer than the acid dew point. One solution is to preheat the feedwater before it enters the economizer. The preheater is thermostatically controlled to maintain a minimum feedwater inlet temperature, and it should operate only at low boiler loads. Boiler steam or hot water is used as the heat source. Most of the energy used by the preheater is recovered.

Kentube
Fig. 2 Economizer installed on a small boiler A larger economizer would be installed on its own stand, alongside the boiler.

Another technique for protecting the economizer is to recirculate a portion of the water leaving the economizer back to the economizer inlet. This requires a separate small pump.

The flue can also be protected at low boiler load by preheating the feedwater. The feedwater in turn heats the flue gases. The same preheater can be used for both purposes. The preheater is controlled to maintain both the appropriate stack temperature and the appropriate economizer temperature. The flue temperature sensor should be located near the highest point of the flue system that is vulnerable to corrosion.

Heat that is used to keep the flue gases warm cannot be recovered. Therefore, to provide an economical net saving, the economizer needs to recover substantially more heat, at higher loads, than is needed to keep the flue gases warm at lower loads.

There is no way to prevent acid condensation in a cold flue or stack. For this reason, make sure that any draft inducing fan turns off when the boiler is not firing. (See [Measure 1.5.3.1](#) about this.) Corrosion of the upper few feet of a steel stack or flue liner is unavoidable because turbulence allows air to enter the top of the stack, which cools it below the acid dew point. You can observe that the tops of steel stacks are often seriously corroded.

Rain causes more stack corrosion when the flue gas temperature is reduced, because the rain is able to penetrate deeper into the stack and linger in the liquid state longer. Therefore, it may be advisable to add a rain cap to the stack when installing an economizer.

Examples

Here are some examples that illustrate the key points of controlling acid condensation:

- Oil with an acid dew point of 200°F is being burned. The inlet feedwater temperature is 160°F, and the gas temperature leaving the economizer is 300°F at low load. In this case, the feedwater must be preheated to prevent corrosion of the economizer, but the flue is safe.
- Oil with an acid dew point of 200°F is being burned. The inlet feedwater temperature is 210°F, and the gas temperature leaving the economizer at low load is 230°F. In this case, the economizer is safe. The flue is likely to corrode if it is made of corroding material or if it is not well insulated.
- Natural gas with an acid dew point of 140°F is being burned. The inlet feedwater temperature is 160°F, and the gas temperature leaving the economizer at low load is 230°F. In this case, there is no risk to either the economizer or the flue.

Consider Future Fuels

The previous discussion showed that the allowable reduction of flue gas temperature depends on the fuel,

and particularly on its sulfur content. In other words, installing an economizer commits the facility to burning only fuels that have a certain maximum sulfur content. Take this into account when considering an economizer. Depletion of low-sulfur fuels is forcing the substitution of higher-sulfur fuels. Environmental laws may require burning low-sulfur fuels, but regulations cannot override the reality of future fuel supply.

This has already been strongly evident in the depletion of low-sulfur coal, and its increased substitution with high-sulfur coal. The same trend toward higher acid dew points may occur with other fuels, especially if shortages of natural gas recur. The last of the previous examples shows that natural gas allows more aggressive heat recovery than does oil. However, if a gas-fired boiler is capable of burning oil, it is prudent to assume that it will become necessary to burn oil again at some time in the future. In summary, be realistic in considering all the types of fuels that a boiler may burn during its remaining life.

Heat Exchangers that are Not Limited by Acid Dew Point

You can avoid all the temperature limitations created by flue gas acids if you use an economizer and a flue that do not corrode. [Measure 1.7.1.3](#), below, covers this possibility. Another possibility is condensing the flue gases using a water spray, which is covered by [Measure 1.7.1.4](#). However, both of these techniques are limited in application by the low temperature of the recovered heat.

Increased Draft and Pump Pressure Requirements

Economizers add resistance to the flow of flue gases. Typically, the resistance of an economizer is in the range of one inch of water gauge at maximum firing rate. This may or may not require modifications to increase draft. Such modifications may include increasing the power of the forced draft fan, replacing the burner assembly with one having a stronger fan, adding an induced draft fan, or increasing the height of the stack. Sources of draft are covered in [Measure 1.5.1](#).

Economizers have long water passages, and the flow is turbulent to maximize heat transfer. This increases resistance to feedwater flow. In most cases, the feedwater pump has ample reserve pressure to deal with this. However, verify that the pump is able to provide the maximum required feedwater flow once the economizer is installed. If not, you will have to increase the pressure output of the feedwater pumps, either by increasing the diameter of the pump impeller or by installing a new pump.

The additional fan and pump energy that is required should be factored into the cost-benefit calculation.

Using an Economizer With More Than One Boiler

Economizers are expensive, so it is tempting to consider using one economizer to serve more than one boiler. This arrangement is a candidate for serious trouble. If one boiler is operated while another is idle, some gas will flow from the active boiler to the idle boiler, causing acid corrosion in the idle boiler. Attempting to operate more than one boiler simultaneously through a single economizer would require complications to maintain the proper draft within each boiler.

In a plant with several boilers, the most economical approach is to install economizers on the boilers that can be operated most efficiently, and to use these boilers as the lead units. The other boilers without economizers are kept in reserve, or are used only when required by a heavy load.

ECONOMICS

SAVINGS POTENTIAL: 2 to 10 percent of fuel cost.

COST: Economizers typically cost \$200 to \$600 per million BTUH of boiler capacity. The unit cost declines

considerably with size. Installation cost varies widely, but it will be high if it is necessary to move piping and equipment to make room for the economizer.

PAYBACK PERIOD: Several years or longer.

TRAPS & TRICKS

DESIGN: The main performance issues are heat recovery and avoiding acid condensation. Consider all fuels that may be used in the boiler. Make sure that the boiler retains adequate draft. Design the physical layout for ease of maintenance.

SELECTING THE EQUIPMENT: Do your shopping thoroughly. Economizers come with a range of features, and in a range of quality. Avoid units that lack adequate access for cleaning.

OPERATION AND MAINTENANCE: Soot blowing and cleaning must be done regularly. If the economizer has variable modes of operation, such as preheating feedwater to prevent acid condensation, monitor these features and be alert to problems. Install effective instruction placards, if appropriate.

MEASURE 1.7.1.2 Install a heat recovery air preheater.

RATINGS

New Facilities	Retrofit	O&M
B	D	

This is the second of four subsidiary Measures devoted to recovering additional heat from flue gas after it leaves the boiler. The method covered here is installing a heat exchanger that recovers heat from the flue gas to preheat the combustion air. This is a well balanced heat recovery application, because the need for the recovered heat coincides with its availability.

Combustion air preheaters are bulky because they transfer heat from one gas to another at relatively low temperature. This makes them expensive. In the past, economies of scale have limited air preheaters to very large boilers, such as those used for power generation and large industrial processes. Newer technology, discussed below, may make air preheaters less bulky and expensive, and hence allow them to be economical in smaller sizes. Keep an eye on developments.

Applications and Potential Savings

Air preheaters compete with economizers as a method of recovering heat from flue gas. Within the range of flue gas temperatures where both apply, conventional economizers are generally less expensive and easier to install. However, air preheaters have an advantage over conventional economizers in being able to recover the bottom range of temperature from flue gas. This is because the outside air used for combustion air is typically much cooler than feedwater, so it can absorb more heat from the flue gases. As a result, a combustion air preheater may increase boiler efficiency by 1% to 4% more than a conventional economizer.

The difference is especially important in plants with high-pressure boilers, because the feedwater is especially warm as a result of passing through deaerating feedwater heaters. For example, outside air may have an annual average temperature of 50°F, whereas the feedwater entering the boiler may have a temperature of 200°F.

(You may wonder why an economizer could not be used for warming condensate before it enters the feedwater heater, while it is still relatively cool. The reason is that the condensate is heated by steam as part of the deaerating process, and more heat cannot be added because the pressure within the deaerating tank must be kept reasonably low. There are ways to use flue gases to heat condensate, but these create further complications.)

Where boilers are used to drive high-pressure steam turbines, the feedwater may be heated deliberately to much higher temperatures to increase the cycle efficiency. In such cases, the temperature of the feedwater becomes too high for recovery of flue gas

SUMMARY

Expensive and bulky, air preheaters are commonly installed on large boilers. They offer an additional increment of efficiency that is not available with conventional economizers. They are rarely installed on a retrofit basis.

heat, and air preheating then becomes the method of choice for recovering all flue gas heat.

Air preheaters are usually found in plants where boiler efficiency is being pushed to the limit. Such plants have economizers, so the role of the air preheater is limited to removing the last increment of heat from the flue gases. In principle, an air preheater could be used without an economizer, in which case it would remove much more heat from flue gases, and presumably would provide better economics. In such an application, the air from the preheater would be very hot, and a retrofit installation would probably encounter major engineering obstacles. For example, the density of the air might be too low to enter the boiler through the existing openings and it might not provide proper burner operation.

Because air preheaters can cool flue gas to low temperatures, they can condense the water out of the flue gas that is formed during combustion. This may offer a significant energy recovery advantage, because this recovers much of the latent heat of the water vapor in the fuel. For a given outside air temperature, the actual amount of latent heat recovered depends on the dew point of the water vapor in the flue gases. In turn, this depends on the concentration of water vapor, which depends on how much hydrogen is in the fuel. Gaseous fuels contain much hydrogen, so they produce a large amount of water vapor.

Petroleum produces much less water vapor than gas. Coal produces little water vapor by combustion. (However, coal may contain a large amount of free water as a contaminant.)

(Recovery of the latent heat of water vapor is also a feature of the unconventional heat recovery methods covered by [Measures 1.7.1.3](#) and [1.7.1.4](#), next.)

The inherent disadvantage that goes along with condensation of the water vapor is that any sulfur in the fuel will combine with the water to form acids. The preheater itself must be able to tolerate acids, which makes it more expensive. The portion of the flue downstream of the preheater must be non-corroding, so preheaters are usually found in boiler plants that have brick or concrete stacks. The corrosion problem effectively bars combustion air preheaters from many plants that already have economizers.

Types of Air Preheaters

In principle, any type of gas-to-gas heat exchanger could be used for preheating combustion air, and many types have been proposed and tried. In the current state of technology, the following are types worth considering.

■ Tube Bundle (Tubular) Preheaters

A tube bundle, or tubular, air preheater uses metal tubes as the heat transfer surface. Usually, the flue gas flows inside the tubes, and the incoming air flows around the outside. The tubes typically are straight, and are held in parallel bundles by tube sheets. The tube sheets

Kentube

Fig. 1 Tubular air preheater The flue gas flows through the tubes, entering at left. The incoming combustion air flows across the outside of the tubes.

also direct the flow of air around the tubes. Figure 1 shows a typical unit.

Tubular preheaters are fairly popular. They are simple, and easy to clean. Their main disadvantage is that they are rather bulky in relation to their heat transfer capacity. However, they can be made in many configurations to fit different spaces.

■ Parallel-Plate Preheaters

A parallel-plate heat exchanger is an assembly of metal plates held in parallel so that the flue gas and combustion air streams pass between alternate plates. Heat is transferred from flue gas to air by conduction through the plates.

This type of air preheater was one of the first to be used. Its advantages are simplicity, compactness, and relatively easy cleaning. It has fallen out of popularity, probably due more to effective marketing by competitors than because of any serious disadvantages. This type appears to be a leading candidate for use with smaller boilers.

■ Rotary Preheaters

A rotary air preheater is a rotating cylinder filled with air passages in the axial direction. Exhaust gas flows through one side of the rotor, and combustion air flows through the other. The material of the rotor, which is a thin metal honeycomb, absorbs the exhaust gas heat. The rotor turns slowly, at about 3 RPM, transferring heat from the exhaust stream to the incoming air stream.

Combustion air is at higher pressure than the flue gas. This causes air to leak from the air side to the flue side of the heat exchanger, wasting fan power. To minimize this loss, the unit includes seals between the frame and the cylinder to isolate the two sides. The seals require maintenance.

Rotary air heaters for boilers are specialized items made by a small number of manufacturers. They are offered in a large range of sizes. For example, one manufacturer offers units with rotor diameters ranging from 4 feet to 17 feet. (Smaller units are used in air conditioning heat recovery applications, where they are called “heat wheels.” The latter are made by a different group of manufacturers.)

The main advantage of rotary preheaters is that they are compact. Their disadvantages include complexity, leakage around the seals, difficulty in cleaning, and a need for maintaining moving parts.

■ Heat Pipe Heat Exchangers

Heat pipe heat exchangers are described in [Measure 4.2.8](#). They are commercially available as packaged units for heat recovery in air handling systems, and have been used for this purpose since the 1970’s. They are not yet standard items for flue gas heat recovery. However, they may appear in a future generation of air preheaters for smaller boilers.

The potential advantage that heat pipes promise is reduced size. This is important because bulk is a limiting factor both in the cost of the heat exchanger itself, and in the feasibility of installation in an existing boiler room. Heat pipe heat exchangers are simpler than rotary preheaters, although they do have some moving parts.

Cleaning Air Preheaters

All fuels except gas produce a significant amount of dirt in the flue gas. If a preheater is used, it should have an effective means of periodically clearing the dirt from the flue gas passages. This is typically done with a device similar to a soot blower. With some fuels, it may be appropriate to have a detergent washing system.

Expect Acid Condensation

The basic principles of acid condensation from flue gas are covered in [Measure 1.7.1.1](#). In most plants, the economic advantage of an air preheater over a conventional economizer rests on its low heat recovery temperature. Therefore, expect acid condensation in the heat recovery unit.

Some preheaters may deal with acid corrosion by periodic replacement of the corroded parts. For example, one manufacturer of rotary preheaters makes the low-temperature portion of the rotor (where the air enters and the flue gases exit) easily replaceable. Acid-resistant coatings also are used to retard corrosion. Pinhole perforations of the rotor material by corrosion are not damaging, because the rotor material is used only as a mass for heat storage, and does not separate one gas stream from another.

Other types of heat exchangers are made of non-corrosive materials, which greatly increases cost.

An air preheater reduces the flue gas temperature to the region of acid condensation, so the stack must resist corrosion. Also, the condensate drained from the stack is somewhat acidic. This may require neutralization to conform to environmental regulations dealing with acid sewage.

Increased Draft Requirement

Any type of flue gas heat recovery unit increases resistance to the flow of flue gas and combustion air. If stack draft is not adequate to overcome the added resistance, it may be necessary to increase draft by

increasing the power of the combustion air fans or by increasing the height of the stack. Sources of draft are covered in [Measure 1.5.1](#). The additional fan power reduces the overall energy saving provided by the preheater.

Plant Modifications and Installation Costs

All types of heat recovery preheaters are bulky in themselves. In addition, a great deal of space is needed for the ducting that carries the flue gas and combustion air. Expect to relocate equipment that is in the way. Such work is expensive. The cost of installation is one of the major reasons why air preheaters are usually found only in very large boiler plants.

ECONOMICS

SAVINGS POTENTIAL: 1 to 4 percent of fuel cost, assuming that an economizer is installed. Up to 10 percent of fuel cost, if no economizer is installed. Deduct the increased fan energy requirements from these savings.

COST: Tubular air preheaters typically cost from \$5 to \$10 per SCFM of heated air. Installation cost, including the cost of extra combustion air ducting, varies widely. In retrofit, the cost of relocating existing plant equipment and structure may be very high.

PAYBACK PERIOD: Ten years or longer, typically.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Each type of air preheater has advantages and disadvantages. Do your shopping thoroughly, study the literature, and discuss candidate equipment with owners who have used it.

DESIGN: The main performance issues are heat recovery and avoiding acid condensation. Consider all fuels that may be used in the boiler. Make sure that the boiler retains adequate draft. Design the physical layout for ease of maintenance. If the air preheater is used with high flue temperatures, the high combustion air temperature may add significant engineering problems.

OPERATION AND MAINTENANCE: Air heaters, especially rotary types, are specialized items that require understanding and skill to keep in operation. Cleaning must be punctual if the fuels are dirty. Be alert for problems.

MEASURE 1.7.1.3 Install a condensing economizer.

RATINGS

New Facilities	Retrofit	O&M
C	D	

This is the third of four subsidiary Measures devoted to recovering additional heat from flue gas after it leaves the boiler. This method uses a variation of the conventional type of economizer covered in [Measure 1.7.1.1](#). Conventional economizers are limited in their heat recovery potential by the need to avoid acid condensation in the heat exchanger itself and in the flue. A condensing economizer differs primarily in using a larger heat transfer surface to condense water vapor from the flue gases, and in using non-corrosive materials for the low-temperature portion of the heat exchanger.

The first widespread use of condensing heat exchangers occurred in the 1980's with the introduction of gas-fired residential-sized condensing boilers and gas furnaces. These use stainless steel for the low-temperature portion of the heat exchanger. At present, condensing economizers for heat recovery in larger boilers are unusual items that would be built on a custom basis. You will be a pioneer if you attempt this.

Where to Consider a Condensing Economizer

The advantage of a condensing economizer is its ability to recover the latent heat of the water vapor in the gases. Significant amounts of water vapor may come from two sources: hydrogen in the fuel, and water that is included in the fuel as a contaminant. Hydrogen is an important source in gas fuels, and is less important in oil. Contaminant water is most important in coal, and there may be a substantial amount in heavy oil. See [Reference Note 20](#), Fossil Fuels, for more on the hydrogen content of different fuels. The latent heat present in the combustion gases of common fuels is given in reference books. The energy content of unconventional fuels, such as municipal refuse and wood waste, must be analyzed on an individual basis.

The concentration of water vapor in the flue gases determines the amount of latent heat that is present, and also the fraction of the latent heat that can be recovered. Latent heat is not recovered unless the water vapor condenses. The concentration (or dew point) of the water vapor determines whether it condenses. If the flue gas has only a small amount of water vapor, little latent heat will be recovered at any useful temperature. For example, a condensing economizer may not be effective when burning oil, because oil creates too little water vapor to condense at useful heat recovery temperatures.

Here are several examples to illustrate how the hydrogen content of the fuel and the temperature at which heat is recovered determine whether a condensing economizer can be useful:

SUMMARY

An improvement on conventional economizers. Requires custom design and fabrication. Most likely to be economical with gas fuels. With sulfur-bearing fuels, expect to deal with acid sewage and flue corrosion.

- Natural gas with an acid dew point of 140°F is being burned. The inlet feedwater temperature is 110°F. In this case, the flue gas temperature could be reduced to a range of 120°F to 160°F, depending on load. A substantial amount of water will condense, recovering latent heat, and some acid will also condense. Consider a condensing economizer for this application.
- Natural gas with an acid dew point of 140°F is being burned. The inlet feedwater temperature is 200°F. In this case, the flue gas temperature which exits the economizer cannot fall below about 210°F. No condensation will occur in the economizer, and probably none in the flue. There is no point in using a condensing economizer in this application.
- Heavy oil with an acid dew point as high as 230°F is being burned. The inlet feedwater temperature is 210°F. The stack is made of concrete with a non-corrosive liner. In this case, the flue gas temperature which exits the economizer cannot fall below about 220°F. At the minimum flue gas temperature, some condensation might form in the economizer, and condensation in the flue would be unimportant. No latent heat would be recovered. A condensing economizer would make little difference in this application. It would be more economical to use a conventional economizer and to design it to keep the flue gas temperature above 220°F during low boiler loads.
- Heavy oil with an acid dew point as high as 230°F is being burned. The inlet feedwater temperature is 110°F. The stack is made of concrete with a non-corrosive liner. In this case, the flue gas temperature could be reduced to a range of 120°F to 160°F,

depending on load. A large amount of acid would condense in the economizer, as well as in the flue. Some latent heat would be recovered, limited by the amount of hydrogen in the fuel and the water dew point. The efficiency would be higher than that of a conventional economizer, but probably not enough to justify the cost of dealing with the acids.

These examples lead to the conclusion that a condensing economizer is useful only if the heat recovery temperature is low. The most favorable applications are inefficient boilers burning natural gas. For such application, the total efficiency improvement of the boiler system might be 10 to 15 percent.

The major disadvantage of condensing economizers is their high cost, which results from:

- the large surface area required in relation to the relatively small temperature reduction achieved
- the need for expensive corrosion-resistant materials
- the custom design and fabrication required.

The cost limits practical application of condensing economizers to boilers with a long remaining life. Newer boilers are likely to be more efficient than older boilers, so their savings potential is likely to be lower. Thus, condensing economizers occupy an even narrower niche than conventional economizers.

Dealing with Acid Condensation

If water is condensed out of the flue gases, the sulfur in the fuel combines with the water to form acids, mostly sulfuric acid. The acids must be drained from the economizer. The amount of acid depends on the amount of sulfur in the fuel, and the amount of water depends on the amount of hydrogen in the fuel. If the fuel has a high hydrogen content and a low sulfur content, the acid solution is weak. If the acidity is high, you may have to neutralize the condensate to protect the plant's sewage system and to conform to environmental regulations dealing with acid sewage.

A condensing economizer requires a flue that is made of non-corroding materials. After the gases exit the economizer, they cool further in the flue, where they deposit more acid and more water. If the existing flue cannot tolerate the acidity and moisture, a new flue is required. The flue used with a condensing economizer can be somewhat smaller than the original because the cooler gases occupy less volume.

In small condensing gas furnaces and boilers, plastic pipe has been used successfully as a flue material. However, this may be dangerous with larger units. An economizer fire caused by soot accumulation would burn a flue made of combustible material.

ECONOMICS

SAVINGS POTENTIAL: 5 to 15 percent of fuel cost, in feasible applications.

COST: \$300 to \$1,000 per million BTUH of boiler capacity. Installation costs vary widely, but may be very high if it is necessary to relocate piping and equipment to make room for the economizer.

PAYBACK PERIOD: Several years or longer.

TRAPS & TRICKS

DESIGN: Condensing economizers are unusual items in large boiler applications, so be sure you deal with all the issues. Provide easy access for cleaning and repair. If you burn sulfur-bearing fuels, deal with acid condensate and protect against flue corrosion.

EQUIPMENT: The equipment should be fabricated by a manufacturer of economizers who has successful experience in making units of corrosion-resistant materials. Check references.

OPERATION: Cleaning must be done regularly if dirty fuels are used.

MEASURE 1.7.1.4 Install a water spray heat recovery unit.

This is the last of a series of four subsidiary Measures devoted to recovering heat from flue gas after it leaves the boiler.

In this method of heat recovery, the flue gas is passed through a water spray. This lowers its temperature to between 120°F and 200°F, depending on the application. The water spray is heated by the sensible heat of the exhaust gas and also by the latent heat of the water vapor produced during combustion. The latent heat is an important energy component that is not recovered by ordinary economizers. (Latent heat recovery is explained in Measures 1.7.1.1 and 1.7.1.3.) The water spray unit takes heat recovery near its theoretical limit of efficiency.

Heat Recovery Vessel

The heat recovery unit consists of a corrosion-resistant vessel in which a water spray can pass through the flue gas. Because there is no conducting barrier that separates the flue gas from the water it is warming, this type of vessel is sometimes called a “direct contact heat exchanger.”

The heat recovery unit is continuously wetted and cooled, and it does not contain any pressure. In principle, it could be cheap to manufacture, perhaps with plastic materials. However, typical commercial units have a stainless steel tank, and stainless steel surfaces for distributing the water flow, so they are expensive. A typical unit is shown in Figure 1, and the installation is shown in Figure 2.

Application Limitations

The major application limitation of this technique is that heat is recovered at a low temperature. The temperature must be kept low to maximize sensible heat recovery, to maximize the capture of latent heat, and to minimize water loss from evaporation. (All the water would be lost to evaporation if its temperature rose to 212°F, or less at higher altitudes.) By the same token, you should look for an application that uses the spray water directly. Using a heat exchanger between the spray water and the application would cost a large fraction of the available temperature of the recovered heat.

The Condition of the Water

The water from the spray unit is contaminated by anything that is in the flue gases, including particulates, fly ash, and miscellaneous chemical compounds. The degree of contamination depends on the fuel. A clean

fuel, such as natural gas, gives clear water. The water condensed from other fuels may require filtration or other treatment.

Fuel that contains sulfur makes the water acidic. However, the acidity is mild. With natural gas, the pH may be reduced by only a tenth of a point, e.g., from a pH of 7 to a pH of 6.9. Even with high-sulfur fuels, the dilution by the large volume of water limits the pH change to no more than about one point. If necessary, this amount of acidity can be neutralized easily.

In some cases, the spray water could be used for boiler feedwater makeup. To calculate whether this is economical, consider the value of the energy recovered, the cost of treatment for the spray water, and the cost of treatment for the conventional water source. This application is practical only for boilers systems that require a large amount of makeup water.

Exploit the Environmental Benefits

The spray system acts as an air washer, removing a considerable fraction of solids and acids. The cost of the unit may substantially reduce the need for other pollution abatement equipment. Also, the acid removal benefit may allow you to burn less expensive fuels that contain larger amounts of contaminants.

Match the Heat Requirement to Heat Availability

To keep the water temperature within the narrow limits that are necessary for heat recovery, the temperature and flow rate of the water must be kept in balance with the temperature and flow rate of the exhaust gases. If the water flow rate is too low, the water overheats and evaporates, taking the recovered heat with

it. If the water flow rate is too high, the water temperature is too low.

If the need for recovered heat exceeds the amount that is available, the volume of spray water is adjusted to provide the desired water temperature. Additional heat must be provided by other sources.

If the available flue gas heat exceeds the requirement, you have to limit contact between the flue gas and the water. You can do this by diverting flue gas from the heat exchanger or by changing the spray pattern within the heat exchanger. The latter method increases the temperature inside the heat exchanger, perhaps requiring more expensive materials.

ECONOMICS

SAVINGS POTENTIAL: 5 to 20 percent of the energy content of the boiler fuel, depending on the type of fuel and efficiency of the boiler. The economic value of the

Ludell Manufacturing Company

recovered heat depends on energy costs and the nature of the application.

COST: A packaged, stainless steel unit may cost about \$10,000 for a boiler of 3 million BTUH capacity, and about \$30,000 for a boiler of 25 million BTUH capacity. In new construction, installation adds little to plant cost, and flue cost may be reduced. In retrofit, modifications

Ludell Manufacturing Company

to the boiler breeching and moving existing equipment may be expensive.

PAYBACK PERIOD: In the most favorable applications (gas fuels and the ability to use large amounts of low-temperature heat), the equipment may pay for itself in less than one year. In less favorable applications, the payback period may be several years or longer.

TRAPS & TRICKS

DESIGN: The method is unusual, but it has been done before. Achieving maximum efficiency requires a good grasp of the theory, combined with a talent for practical innovation.

EQUIPMENT: Some manufacturers make the equipment as a catalog item, typically from stainless steel. You might be able to make the heat exchanger from less expensive materials. The manufacturer may be pioneering along with you. Check his references.

INSTALLATION: The fact that the equipment is unconventional increases the risk of installation problems. Work closely with the installer.

OPERATION AND MAINTENANCE: You may have unexpected problems. Stay on top of operation until it becomes routine. Once operating procedures stabilize, install instruction placards.

MEASURE 1.7.2 In firetube boilers, install turbulators.

RATINGS

New Facilities	Retrofit	O&M
	C	

“Turbulators” are devices inserted inside the fire tubes of boilers to increase heat transfer between the combustion gases and the tube walls. Turbulators may take many forms, such as twisted strips or coils of steel. Figures 1 and 2 show these forms.

Turbulators have been used in boilers for many years, but they are still controversial. Their actual benefit, and even the way they work, have not been well documented. Turbulator manufacturers claim typical efficiency improvements in excess of 10 percent, which is dramatic. However, more independent authorities claim that savings do not exceed 3 percent in the best of cases.

The most compelling advantage of turbulators is that they are much less expensive than any other method of improving heat transfer. This suggests that you should consider them before using more expensive methods of improving heat transfer or retiring an existing boiler to replace it with a more efficient one.

Alleged Principles of Operation

Turbulators are intended to improve heat transfer within the tubes of firetube boilers by changing the flow of the combustion gases through the tubes. The specific action, or actions, of turbulators are open to question. Manufacturers offer these explanations:

- **increased turbulence at the tube surface.** Heat transfer from a gas to a metal surface is increased by turbulence. The name “turbulator” derives from the assumption that turbulators function by

increasing the turbulence of the flue gases. However, turbulator manufacturers typically recommend installing turbulators in only a portion of the length of the tubes, and only in the last pass. This leaves a large fraction of tube area unaffected by the alleged benefit of increased turbulence.

- **improved gas distribution through the tubes.** In most firetube boilers, the tubes are arranged in several passes. Gas flow reverses direction at the ends of the boiler in going from one pass to the next. The inertia of the gas as it makes the turn may cause unequal gas flow into the following tubes. Turbulators may reduce this tendency (if it

exists) by increasing resistance to flow, thereby causing the gas to distribute itself more evenly. Vendors typically recommend that longer strips be inserted in the upper tubes of a pass, which are the ones that might receive the most gas flow if inertia is a factor.

- **increased gas residence time.** One vendor claims that turbulators slow the flow of gases out of the firebox, thereby increasing the time that the gas is in contact with the flame and the time that the flame is in contact with the tubes. This cannot be true as a primary cause. The velocity of a given volume of flue gas is a function only of its density and the size of the tubes. Cooling reduces the density of the gas and slows it down, but this is an effect, not a cause.

In addition to these unconvincing explanations, the literature of turbulator manufacturers includes various other assertions that are overtly wrong. Nonetheless, it

WESINC

Fig. 2 Turbulators installed in a firetube boiler These turbulators are in the form of coils. They are kept from sliding into the tubes by pigtails that extend outside the tube sheet.

is widely believed that turbulators work. One possibility is that turbulators do improve efficiency, but that nobody really knows why.

Where to Consider Turbulators

The typical candidates for turbulators are older firetube boilers that have one or two passes. High stack temperature is the symptom that indicates a need to increase heat transfer. Read the stack temperature when the boiler is clean and working perfectly. If the boiler exit temperature exceeds the acid dew-point temperature of the fuel by much more than 100°F, consider turbulators. (The relationship of stack temperature to acid dew point is explained in [Measures 1.7.1 ff.](#))

Test combustion efficiency before and after turbulators are installed. Estimate the potential for improving efficiency from the initial efficiency test and the acid dew point of the fuel. Based on this, negotiate with the vendor for a guarantee that the turbulators will produce a stated efficiency improvement.

Turbulators have a tendency to trap soot inside the tubes. For this reason, one manufacturer of turbulators advises that they should be used only with gas and light oil fuels. However, another manufacturer states that turbulators can be used even in coal-fired boiler, but only with frequent soot blowing.

Alternative: Reduce Burner Capacity

Many boilers that are candidates for turbulators are inefficient because they have an unsophisticated design that is not capable of recovering the heat of the flue gases with great efficiency. However, some boilers are inefficient because the burner has too much capacity for the boiler. In such cases, an alternative is to reduce the capacity of the burner. [Measure 1.4.3](#) recommends this approach.

Effect on Draft

Proper boiler draft is crucial to efficiency, for the reasons explained in [Measure 1.5.1](#). If turbulators are installed, they will reduce the draft at the burner, upsetting the air-fuel ratio. Therefore, adjust the draft at the burner after installing turbulators.

The stack must be able to provide enough additional draft to overcome the added resistance of the turbulators. Verify this before ordering turbulators. If the stack cannot provide sufficient draft for the existing burner, you have various expensive ways to deal with the problem. In most such cases, the best choice is to install a burner that has a more powerful fan. If you take this approach, select the burner for high efficiency, as recommended in [Measure 1.4.2](#).

Reduction of Standby Losses

The resistance to gas flow added by turbulators reduces standby loss, which results from convective flow

Fuel Efficiency, Inc.

Fig. 3 Turbulator installation pattern This is how several manufacturers suggest installing turbulators. The details vary with the boiler configuration.

of air through the boiler while the boiler is not firing. The reduction of standby loss depends on whether the boiler has a damper that closes when the boiler is not firing. If the boiler has such a damper, either in the burner or in the flue, turbulators provide little additional benefit. If the boiler does not have such a damper, turbulators are a poor substitute for installing one. See [Measures 1.5.3 ff](#) for methods of reducing standby loss.

Installation Procedures

Turbulators are ordered custom for each boiler. Typically, they are installed in the last pass only. It does not seem to matter which end of the tubes they are inserted into. A set of turbulator strips is supplied in various lengths. The longer strips are installed in the top row of tubes, and progressively shorter strips are installed in the lower rows, as shown in Figure 3.

The strips are held in place by spring action, and have no fasteners. The strips are slid into the tube until a tab at the outer end of the strip is stopped by the end of the tube. Installation typically takes one day. The work can be done by the facility staff, if they are sophisticated enough to perform routine maintenance on the boiler.

One manufacturer states that if the flue gas temperature is reduced excessively, risking acid condensation, the turbulators strips should be shortened to adjust the flue gas temperature.

Interference with Fireside Cleaning

Turbulators must be removed when firesides are cleaned. This should not be difficult or time consuming in most cases.

One manufacturer states that soot blowers can be operated with turbulators in place. However, if you have soot blowers, confirm compatibility with the manufacturer of the soot blower. (Soot blowers for firetube boilers are described in [Measure 1.6.2.](#))

Manufacturers claim that turbulators reduce the need for cleaning because the increased turbulence inhibits the deposition of soot. View this claim skeptically. It is conceivable that turbulators could trap soot, at least in local areas of the tubes.

Possible Damage to Boiler

It does not appear that the performance of boiler turbulators has been studied extensively, so it is not possible to predict whether turbulators will cause boiler trouble. With respect to efficiency, a tendency of turbulators to trap fireside deposits would undercut any increase in heat transfer that they provide. With respect to maintenance, be wary of possible problems, such as tube erosion or stress cracking at the tube sheet. Discuss this with other operators of similar boilers who have used turbulators for a period of years.

ECONOMICS

SAVINGS POTENTIAL: *Who knows? Turbulator manufacturers claim efficiency improvements in excess of 10 percent, but such performance claims do not seem credible. Estimate your boiler's potential for improving efficiency. Then, require a guarantee from the vendor that installing turbulators will improve efficiency in your boiler by a stated amount.*

COST: *Typically \$10 to \$15 per tube. Firetube boilers have 25 to 150 tubes in the last pass, in which the turbulators are installed, for a total material cost of \$250 to \$2,500. Installation typically requires less than one day.*

PAYBACK PERIOD: *Maybe about one year, in favorable applications.*

TRAPS & TRICKS

CHOICE OF METHOD: *One big question is whether the equipment will produce the promised efficiency improvement. Another is whether turbulators will harm the boiler. Before buying, discuss performance with other purchasers who have operated with the same type of turbulator in your type of boiler. Ask vendors for references. Get a guarantee of efficiency improvement and a warranty against boiler damage.*

INSTALLATION: *The method of installing turbulators may be critical to maximizing efficiency, avoiding draft problems, and avoiding tube damage. Follow the manufacturer's instructions.*

MAINTENANCE: *Turbulators must be removed for boiler cleaning, and they must be reinstalled in the original pattern. This increases cleaning cost. Make sure that removal and reinstallation procedures are documented in a manner that is clear to the people who do boiler cleaning.*

Condensate, Feedwater, and Water Treatment

The condensate system is the return portion of a steam system. “Condensate” is the liquid residue of steam that is used by equipment or that condenses in steam pipes because of heat loss from the pipe.

The feedwater system is the input system to the boiler. “Feedwater” is purified and/or treated water that is pumped into the boiler.

The condensate system feeds into the feedwater system. In many cases, the two systems are merged, so that the same set of equipment performs the functions of both condensate and feedwater system.

“Makeup water” is treated water that is added to the feedwater or condensate system to compensate for losses from the system.

Functions of Condensate and Feedwater Systems

Condensate and feedwater systems perform some or all of these functions:

- filling the boiler system and replacing water that is lost
- collecting and returning condensate from steam-using equipment
- draining liquid water from steam lines and idle equipment
- injecting water into the boiler against the boiler’s internal pressure
- purifying and/or treating the boiler water to prevent damage and inefficiency in the boiler and in steam-using equipment
- preheating feedwater, usually with recovered heat
- recovering heat from condensate, such as the heat of condensate flash steam
- creating a vacuum in condensate return systems to improve condensate flow and to improve the temperature control of steam heating equipment
- creating a vacuum for steam machinery condensers.

Each of these functions consumes energy or affects the efficiency of the boiler system. One of these functions, water treatment, also has a major effect on maintenance costs and equipment life.

Condensate Systems

Condensate systems are simple. They consist of a condensate tank (“receiver”) and a system of pipes that lead condensate from the steam-using equipment to the tank. In larger facilities, a number of satellite condensate receivers may be installed at distant sites, each of which pumps condensate to a primary condensate receiver located in the boiler plant. A typical condensate receiver is shown in Figure 1.

The condensate system begins at the steam traps that drain condensate from steam-using equipment and from steam lines. The steam traps keep steam from blasting through the equipment before the steam gives up all its latent heat. Steam traps operate by recognizing the difference between steam and water, and they pass only the water that has condensed inside the equipment. Steam traps are essential for efficient condensate return. See [Measures 1.10.3](#) and [1.10.4 ff](#) for details about them.

In many boiler systems, makeup water is introduced into the system by pouring it into the condensate receiver. Makeup water input is controlled by a float valve located in the receiver.

Spriax Sarco, Inc.

Fig. 1 Condensate receiver This is the basic element of a condensate system. It is just a tank with a pump that is activated by a float switch. (One pump is a spare.) The pump sends the condensate to the boiler, or to a feedwater tank, or to another receiver that is closer to the boilers. The tank is heavy because a failed steam trap may subject it to steam pressure. Also, it may be under vacuum when the condensate pipes cool down.

Fig. 2 One-pipe steam system This old type of steam system combined steam distribution and condensate return in single pipes. Its simplicity is offset by difficulty in controlling heating equipment at low output temperatures. It deserves more attention for high-temperature heating applications.

The details of a condensate system depend on its operating pressure. Some condensate systems operate at pressures higher than atmospheric, and others operate at pressures well below atmospheric. These types of systems are “closed,” i.e., they are not open to the atmosphere. Many condensate systems operate at atmospheric pressure. These have vents to the atmosphere located at the condensate receiver or receivers. An important advantage of closed systems is that they keep air out of the water. Air is a primary cause of corrosion on all parts of the system. On the other hand, vented systems may be simpler, especially in facilities where condensate is returned from long distances.

■ High-Pressure Condensate Systems

High-pressure closed condensate systems can be used in cases where the lowest heating temperature that is required corresponds to a steam pressure that is higher than atmospheric. Typical examples are industrial process heating and drying applications. All parts of a steam system that has a high-pressure condensate system are under pressure that is higher than atmospheric. Therefore, such systems have the least amount of trouble from air entering the system.

In high-pressure condensate systems, the steam-using equipment is usually located near the boilers. Otherwise, heat loss from the condensate pipe would

Fig. 3 Vented (atmospheric pressure) condensate system This is the most common type of boiler water system for heating applications. It is simple and fairly reliable. Its main weakness is allowing air to contact the boiler water.

cause large variations in condensate system pressure, creating problems in pumping the condensate.

■ One-Pipe Systems

The “one-pipe” heating system is a combination of a steam distribution system and a condensate return system. Figure 2 shows a typical system. As the name implies, the system uses only a single pipe to each item of heating equipment for supplying steam and returning condensate. The condensate from the heating equipment drains back to the boiler by gravity through the steam supply pipe. The system is unique in that it does not require steam traps, and it usually requires no condensate receivers. This is an old system that was once common for space heating with cast iron radiators in multi-story buildings.

At first glance, the one-pipe system appears to be a closed system. Unfortunately, in typical space heating applications, it is not. In order for the radiators to control temperature properly, they require air vents. (Measure 5.2.7 explains why.) The air vents allow air to enter the system in large amounts.

■ Atmospheric-Pressure Condensate Systems

Most condensate systems that extend over a considerable distance are vented. The condensate tank

itself is vented, and the entire condensate system operates at atmospheric pressure. Figure 3 shows a typical system.

Heat loss from the pipe keeps most parts of the system at a temperature well below the boiling point of water. Therefore, the water vapor pressure inside the system is below atmospheric. The difference in pressure is made up by atmospheric air that enters the system through vents and leaks. Therefore, vented systems act to mix air into the condensate. The air must be removed before the water enters the boiler, if the boiler is to survive for long.

In most vented condensate systems, condensate drains from the steam-using equipment into a receiver by gravity. For this reason, the condensate receiver is usually located below the equipment it drains. If the condensate cannot flow by gravity all the way back to the boiler room, it is first collected in a local receiver. From this receiver, a float-actuated pump sends the water to a condensate receiver in the boiler plant, or to a separate feedwater system.

■ Vacuum Condensate Systems

Some closed condensate systems operate at pressures well below atmospheric. These are called “vacuum” condensate systems. A condensate system may be operated under a vacuum to aid steam flow, to improve control of low-pressure steam equipment, or to improve the efficiency of steam-powered machinery. Condensate systems for steam machinery may operate

Spirax Sarco, Inc.

Fig. 4 Vacuum condensate receiver This is the heart of a vacuum condensate system. In addition to the tank and pump of a conventional condensate receiver, it has a vacuum pump that removes air and other gases. Therefore, the pressure in the system depends entirely on the condensate temperature.

WESINC

at high vacuum, while systems for heating equipment typically operate at a moderate vacuum.

Vacuum condensate systems are closed. However, the fact that the system is below atmospheric pressure invites air leakage into the system. Air and other non-condensable gases are removed from these systems by various types of positive-displacement pumps or by venturi “air ejectors.” As long as the system is operating properly, the amount of air that enters the boiler water is much less than with a vented system.

The main equipment difference between a vacuum condensate system and an atmospheric system is the condensate receiver, which includes the vacuum pumps. Figure 4 shows a typical vacuum condensate receiver.

Feedwater Systems

The feedwater system begins at the condensate receiver in the boiler room. In the simplest cases, the only major component of the feedwater “system” is a pump that takes water from the condensate receiver and pushes it into the boiler. The feedwater pump, or a feedwater inlet valve, is controlled by the water level in the boiler. Figure 5 shows a typical system of this type.

In more complex boiler plants, there may be a separate feedwater tank. This tank is almost always used for removing air and other gases from the feedwater. The feedwater tank is a closed unit that removes oxygen from the feedwater and heats the feedwater by blasting steam through it. Installing a separate deaerating tank requires the system to have a separate feedwater pump. Figure 6 shows a boiler water system that includes a deaerating tank.

In this system, the condensate pump or a separate pump can circulate water through the feedwater tank to deaerate it prior to starting the boiler system. The deaerating tank usually operates at a pressure higher than atmospheric, but some plants use feedwater tanks that operate at pressures below atmospheric.

The feedwater tank may also be used as a site for recovering waste heat to heat the feedwater. Waste heat may be extracted from a flue gas economizer, from

Fig. 6 Boiler water system with a deaerating feedwater heating tank This system is appropriate for higher boiler pressures and larger systems, primarily because it provides for better water treatment. Using a separate feedwater tank requires a separate feedwater pump.

blowdown, or from other sources. Makeup water may also be added at the feedwater tank, after initial treatment.

In large steam systems that drive high-pressure turbines, there may be several feedwater tanks that serve as feedwater heaters at progressively higher temperatures. This arrangement increases the efficiency of the steam turbine cycle.

Separate feedwater systems tend to be found in plants that operate at higher steam pressure. This is because the oxygen that is trapped in boiler water becomes much more damaging at higher pressures. Also, high-pressure steam systems tend to have more opportunity for heat recovery. Nonetheless, deaerating feedwater tanks are often found in steam systems that operate at relatively low pressures.

Water Treatment

Water treatment is a primary function of condensate and feedwater systems. There are many types of water treatment, just as there are many types of medical treatment, each of which is intended to solve specific conditions. Water treatment processes can be grouped into three broad categories: (1) treatment of makeup water, by “softening” and other techniques, (2) adding chemicals to the boiler water, and (3) removing oxygen

and other gases by mechanical separation in a deaerating feedwater tank.

The particular combination of water treatment methods that is best for a boiler plant depends on the pressure and temperature of the system, the exposure of the system to the atmosphere, the contents of the makeup water, environmental regulations, and the preferences of the people doing the treatment.

In addition to water treatment, boiler systems use blowdown to control water contaminants. Blowdown is the controlled dumping of a certain fraction of the boiler water in order to reduce the concentration of contaminants.

Hot Water Boiler Systems

Hot water boilers do not require condensate or feedwater systems as such. In a hot water system, there is no change of state from water to steam and back. The water is moved by pumping, in a continuous loop. The boiler can be considered as a heater located on the loop.

Water treatment is important for hot water systems. However, for a given water temperature, water treatment in a hot water system is generally less elaborate and less demanding than in a steam system.

Water treatment is the most important day-to-day maintenance in a boiler plant. Inadequate or incorrect water treatment may reduce the efficiency of the boiler quickly. Sooner or later, it will ruin the boiler and the entire steam system. Figure 1 shows what neglect of water treatment can do to boiler tubes.

Water treatment is customized for each boiler plant. Treatment requirements may change as conditions change. Review your treatment program periodically to refine the procedures. There are many water contaminants, each of which must be considered individually. You may have a selection of water treatment methods to deal with each one. The chemical and physical actions of water contaminants and water treatment chemicals are extensive and complex. Incorrect water treatment can be harmful in two ways, by failing to prevent damage and by damaging the system itself.

This Measure gives you a good introduction to boiler water treatment. It starts by listing the reasons why water treatment is important. It describes the boiler plant characteristics that determine the need for water treatment. It tells you how neglecting water treatment can harm a boiler system, so you can keep a lookout for the signs of trouble. It summarizes the main water treatment methods. And, it outlines how to test your boiler water to adjust your treatment to conditions.

This introduction will not make you an expert. It is intended to give you enough information to deal intelligently with water treatment specialists, and to judge how well they are doing their jobs. In most cases, you will hire a water treatment consultant to lay out your water treatment program, and you will have the boiler plant staff or a contractor perform routine testing and treatment. Water Treatment Benefits and Costs

Effective water treatment provides several important benefits:

- ***maintaining heat transfer efficiency.*** Insufficient water treatment leads to scaling of boiler tubes, which reduces boiler efficiency significantly.
- ***reducing the need for blowdown,*** which wastes energy and water
- ***reducing the need for boiler cleaning,*** which is much more arduous than water treatment. In many boilers, water treatment can eliminate the need for periodic cleaning of watersides.

- **minimizing boiler damage**, especially failed tubes and leaky tube sheets.
- **minimizing distribution system and user equipment damage**, such as corrosion, valve leakage, and turbine blade fouling.

The cost of water treatment varies widely, but the cost is less than the cost of neglect. Know which water treatment costs to expect, and be prepared to justify them. These costs include consulting services, service contracts, chemicals, chemical feeders, test equipment, maintenance of water treatment equipment, staff training, and labor.

Factors that Determine the Type and Amount of Water Treatment

Tailor your water treatment program to the conditions that exist at your plant. Do all boilers need water treatment? The answer is that almost all boilers do.

About the only situation in which water treatment is not critical is operation at very low pressure or temperature, in a system with very low water loss, and with “soft” makeup water.

The main factors that determine the methods and intensity of water treatment are:

- **the rate of water replacement (makeup)**. Water quality does not degrade significantly inside the boiler. Water treatment is needed almost entirely to remove the contaminants in makeup water, or to render them harmless. A totally closed steam or hot water system that has no leaks requires little water treatment, although the small amount that is required may be important.

(For this reason, eliminating water loss from the system is a principal way of reducing water treatment requirements. [Measure 1.8.4](#) improves condensate return, and the [Measures in Subsection 1.10](#) reduce water loss from the system.)

- **the type and amount of contaminants in the makeup water**. Water that originates underground (i.e., well water and spring water) typically is saturated with dissolved minerals. For example, in locations where water flows through limestone, it is “hard,” i.e., loaded with calcium compounds that can leave hard deposits inside boilers. Also, the carbonate component of limestone forms carbonic acid, carbon dioxide, and related compounds that cause corrosion.

Surface water (i.e., river water that originates from surface runoff of rain) is saturated with oxygen because of its contact with the atmosphere. Surface water may also carry large amounts of suspended organic and inorganic matter.

- **whether the condensate system is open or closed**. An open (atmospheric) condensate system allows

air to be dissolved in the water with each pass through the system. An open system requires additional steps to remove the air and to neutralize the carbonic acid that is formed by dissolving the carbon dioxide in air. It may also require additional water treatment methods to protect the condensate system.

- **the boiler pressure and temperature**. Water treatment requirements increase radically with increasing pressure and temperature because chemical reaction rates rise exponentially with temperature and pressure. An adverse reaction that may be negligible at low temperature can become seriously destructive at high temperature. Also, the solubility of contaminants may be affected strongly by temperature. Some compounds that cause scaling are less soluble at higher temperature, so that higher pressure boilers have a greater tendency to form scale and sludge.

For example, domestic water heaters, which operate at low temperature and pressure, survive in many areas without water treatment, even though contaminants are being introduced at a high rate. (Water heaters do form considerable scale, which should be flushed out periodically.) In contrast, high-pressure shipboard boilers require exacting water treatment, even though they distill their makeup water.

- **whether the boiler produces steam or hot water**. Other factors being equal, steam boilers require considerably more water treatment than hot water boilers. There are several reasons for this:
 - leakage from a steam system is primarily from the steam-carrying parts of the system, leaving contaminants behind in the water. In contrast, leakage from a hot water system carries a proportionate amount of dissolved matter along with it.
 - evaporation of water in the boiler leaves the contaminants behind to become increasingly concentrated within the boiler. In a hot water system, contaminants are distributed throughout the system.
 - formation of steam bubbles at the heat transfer surfaces leaves dissolved solids behind on these surfaces. This is discussed further, below.
- **the purposes for which the steam or hot water is used**. If steam or hot water is to be consumed, select water treatment methods that are compatible with the application. For example, if the steam is used for humidification of ventilation air, do not use toxic water treatment chemicals, such as amines, that can get out of the system.
- **environmental regulations**. The blowdown from boilers contains the water treatment chemicals and their by-products. Environmental regulations limit

the dumping of certain types and concentrations of these products into sewage systems.

Once you define the water treatment needs of the boiler plant, decide how to satisfy these requirements. You often have options. The choices depend on relative cost and on the types of water treatment equipment already installed. For example, you can minimize oxygen in feedwater by chemical treatment or by installing a deaerating feedwater tank.

Adverse Effects of Inadequate Water Treatment

The problems caused by inadequate water treatment can be grouped into the following classes. These problems may be caused by neglect of water treatment, by inappropriate water treatment, or by failing to remove the products of water treatment.

■ Scale Formation

Scale is a general name for hard deposits that form on heat transfer surfaces. Scale typically has a stony appearance. The type of scale that may form depends on the local water conditions. Scale forms from whatever mineral and organic matter is in the water if the concentration of the material becomes too high.

The most rapidly accumulating types of scale are compounds of calcium and magnesium. Boilers that operate at high temperatures may also form a scale from compounds of silica (the ingredient of common sand), which is hard, tenacious, and has a high insulating value. Oil, grease, and dirt that are not removed from new or newly repaired boilers also contributes to scaling.

Scale has these adverse effects:

- **reduced heat transfer.** If scale accumulates to any visible extent, it inhibits the flow of heat from the combustion gases enough to cause a significant loss of efficiency. Common scale compounds have thermal conductivities that are only a few percent of the conductivity of boiler steel.
- **tube destruction by heat.** The combustion temperature inside a boiler is high enough to destroy the steel of boiler materials. Damage does not occur in normal operation because the boiler water cools the steel. Scale inhibits this cooling. In extreme cases, scale may even obstruct water flow. The reduced cooling allows the flame to heat the metal to failure. Failure is most likely to occur while the boiler is under heavy load, which maximizes the damage and the hazard that results.
- **increased need for waterside cleaning.** Scale is difficult and dirty to remove, and the removal process has the potential of damaging the boiler. (See [Measure 1.6.4](#) for more about this.)

One way that scale forms is that the solubility of certain compounds diminishes when water temperature rises. This is the case with calcium compounds, which

deposit calcium carbonate (the ingredient of limestone) and calcium sulfate (the ingredient of gypsum). If the water is saturated with a substance having this solubility characteristic, the substance deposits on the hottest surfaces, which are the tubes. This process can be prevented by keeping the concentration of the scale-forming contaminants below their saturation level.

Another process of scale formation applies mostly to steam boilers. When a steam bubble forms, the solid matter that was dissolved in the water may deposit on the tube surface. If the concentration of the material in the boiler water is below saturation, the material deposited on the boiler surface may be re-dissolved by the boiler water, but if the concentration is high, the rate of deposition exceeds the rate of dissolving.

Some materials undergo a chemical change in the boiler that results in deposition of scale. An example is the conversion of magnesium sulfate to magnesium hydroxide, a hard scaling material. This reaction also produces sulfuric acid.

■ Obstruction by Sludge

Sludge is a muddy accumulation of precipitated material and dirt that tends to collect in low points in the boiler and in areas where the water is stagnant. Sludge is a normal product of water treatment. It is removed by bottom blowdown. It becomes a problem if blowdown is not controlled properly.

Its worst effect is obstructing water flow. For example, if sludge piles up in the bottom header of a watertube boiler, it blocks convective flow of water into the bottoms of the tubes in that area, leading to failure of the tubes. Sludge may harden and plug blowdown lines if it is left in a boiler that is allowed to cool.

■ Oxygen Corrosion

Oxygen corrosion rusts away the boiler steel. Oxygen corrosion in higher pressure boilers takes the form of deep, scattered pitting that eventually leads to pinhole leaks.

There are two kinds of iron oxide, one beneficial and the other associated with corrosion. The beneficial iron oxide is black and magnetic. It forms a thin protective coating on steel, and then stops forming. One of the objectives of water treatment is to preserve this coating. The harmful iron oxide is ordinary rust, which is brown. It continues to eat away the steel as long as oxygen is present.

Water absorbs oxygen anywhere that it is exposed to air. Air dissolves in condensate that is returned through an atmospheric condensate system. Even in a closed system, oxygen can be introduced by leaks in portions of the system that are below atmospheric pressure, such as the suction of a feedwater pump. When a boiler system is shut down, the condensate and feedwater systems are flooded with air, which dissolves into the water that enters the system when it is restarted.

■ Acid and Alkali Damage to Steel

The most common acids occurring in boiler water are sulfuric, hydrochloric, and carbonic. All are formed by chemical reactions that start with minerals that enter with the makeup water, or with chemicals that are added for water treatment. In addition, carbonic acid is derived from atmospheric carbon dioxide and organic matter in makeup water. Excessive alkali concentration usually results from improper water treatment.

Some acids and alkalis attack the grain structure of steel, weakening it in a manner that is more subtle than the highly visible rusting caused by oxygen corrosion. One effect of this microscopic damage is localized cracking at points of stress, for example, where tubes are held in tube sheets.

In steam systems, lack of proper water treatment may corrode the condensate system as well as the steam system. This is mainly the result of carbon dioxide being formed in the boiler water from bicarbonate alkalinity. The carbon dioxide travels with the steam and dissolves in the condensate, where it forms carbonic acid.

■ Carryover

Nothing but pure steam is supposed to leave the boiler. However, certain conditions can cause vigorous eruption at the water surface that carries contaminants out of the boiler. This eruption is called “foaming” or “priming,” depending on its nature and causes.

Carryover is caused by materials that float on or near the water surface, such as oil, suspended solids, organic matter, and some carbonates. Carryover also results from a high level of dissolved solids. The adverse effect is fouling of steam pipe, steam valves, and steam using equipment. Silicates carried in steam from high-pressure boilers may travel for long distances, depositing on components such as valves and turbine blades.

■ Destruction of Sealing Materials

Certain types of boilers, mostly cast iron sectional boilers, require gaskets or other sealing materials to prevent leakage. Some boiler treatment chemicals attack the seals, requiring major disassembly for repairs. Figure 2 shows an example of this.

General Methods of Water Treatment

In principle, you could prevent water problems in boilers by using only perfectly pure water as makeup. However, this method is too expensive for general use. (It is used on oceangoing ships, which must distill their makeup water from seawater.) The common approach is to treat makeup water by a variety of methods to remove as much harmful matter as possible, and to render the remaining contaminants harmless.

The following are the main classes of water treatment methods. Have a water treatment expert select an appropriate combination of them for your boilers. Water treatment procedures are critical. For example,

chemicals should be injected at specified points in the system, and feed rates should be precisely controlled. The boiler is literally a pressure cooker that promotes chemical reaction among all the compounds in the boiler water and with the metal of the boiler. *It is dangerous to add water treatment chemicals without understanding all the chemical consequences.*

■ Cleaning the System Before Filling

Thoroughly clean out the boilers and the rest of the system before putting the system into service for the first time, and before returning the system to service after maintenance or modifications. Preservatives used in new or mothballed boilers cause scaling and foaming. Dirt that is left in a boiler after maintenance, such as mechanical cleaning of watersides, can cause scaling and priming.

■ Removing Suspended Matter from Makeup Water

Use filtration to remove suspended organic and inorganic matter in the makeup water if the water is not provided by a clean source. Remove smaller particles by adding coagulants, such as alum.

■ Softening Makeup Water

Calcium and magnesium compounds in makeup water cause “hardness,” i.e., a strong tendency to form scale. Getting rid of these compounds is called “softening.”

WESINC

Fig. 2 Leakage at the seals of a cast iron sectional boiler. This problem can be caused by using the wrong water treatment methods.

A common method of softening is chemical treatment that converts the original compounds into other compounds that remain dissolved instead of forming scale. For example, the “hard” makeup water can be circulated through a bed of ordinary salt (sodium chloride) to convert the calcium and magnesium compounds into sodium compounds, which are much more soluble. This general method of swapping atoms between similar molecules is called “ion exchange.” A number of ion exchange processes are available commercially, most of which are based on a combination of chemicals called “zeolite.” Figure 3 shows an ion exchange water softener.

Ion exchange processes may make the water corrosive. Correcting this requires additional chemical treatment.

Precipitation is another method of softening water. A combination of chemical processes is used to convert the calcium and magnesium compounds into solids that can be filtered out. The most common of these methods is the “soda-lime” process.

■ Chemical Removal of Oxygen

Oxygen can be removed from boiler water by adding a chemical to the water that combines with any oxygen to form a harmless compound. The most common chemical used for this purpose is sodium sulfite. Boilers that operate at high pressure may use hydrazine, because

sodium sulfite has a number of disadvantages that become serious at high pressures.

■ Mechanical Deaeration of Feedwater

Oxygen and other gases that are dissolved in the feedwater can be removed by heating the feedwater and spraying it inside a tank. The solubility of the gases drops at high water temperature, and the agitation and large surface area of the spray causes the gases to separate out. The gases are vented to the atmosphere.

Most deaerating tanks “scrub” the entering feedwater spray with a blast of steam. Figure 4 shows a deaerating feedwater tank that operates on this principle. The steam heats the feedwater as well as scrubbing it. Little energy is lost in the process, provided that the steam is not allowed to vent to the atmosphere. (See [Measure 1.10.5](#) about correcting this problem, if it occurs.)

Deaerating tanks are expensive, but they reduce the need for chemicals to remove oxygen. Consider installing a deaerating tank for boilers that produce more than about 10 million BTU’s per hour.

■ Chemical Prevention of Scaling in Boiler Water

“Softening” makeup water may not be sufficient to prevent scaling in boilers that operate at higher pressures. You can add phosphates to the boiler water to combine with calcium and magnesium, the elements that form

Cleaver-Brooks

Fig. 3 Water softening system This is used to treat makeup water before it enters the boiler system. It replaces minerals that cause scaling with other materials that remain dissolved in the boiler water.

Cleaver-Brooks

Fig. 4 Deaerating feedwater heating tank The incoming feedwater is sprayed downward into the upper tank, separating air and other gases that are dissolved in the water. scale. The resulting compounds precipitate, and are removed by blowdown.

The precipitated material itself is a potential hazard as long as it remains within the boiler, because it can clump together and form deposits. To prevent this, add dispersants to the boiler water to keep the insoluble products of chemical treatment in suspension.

Chelants can be used to increase the solubility of calcium and magnesium compounds. Careful control of chelants is necessary. If the hardness is too low, chelants tend to attack the boiler steel instead.

Reducing carbonates in the boiler water (expressed as “alkalinity”) increases the solubility of silica, which prevents the formation of silicate scale.

■ Chemical Protection Against Acid Corrosion

One way to prevent acid corrosion is to keep acids from forming. This is done by eliminating the materials that form acids, such as carbon dioxide, or by avoiding the conditions that cause acids to form.

Another method is to neutralize acids with an alkali.

Still another method is to form a surface on the steel that resists corrosion. For example, chromates and nitrites added to the boiler water react with the iron in the boiler to form a corrosion resistant surface.

■ Blowdown

The concentration of matter dissolved in the boiler water increases as steam is lost from the system. The solution is to continuously dump a fraction of the boiler water so that it can be replaced with makeup water having a lower concentration of dissolved matter. Blowdown is covered by [Measures 1.8.2 ff](#), below.

■ Eliminating Carryover

Baffles are installed inside the steam outlets of most boilers to prevent carryover of water with the steam. Additional protection is provided by putting additives into the boiler water to suppress carryover. This saves energy by reducing the need for blowdown to reduce the concentration of dissolved solids, which is a factor in carryover. Corn starch is one material used for this purpose, among others.

■ Chemical Protection Against Corrosion of the Condensate System

Condensate systems are vulnerable to corrosion by carbonic acid. Also, air enters the condensate system when it is shut down, admitting oxygen. Dealkalizing, a process similar to water softening, keeps carbonic acid from forming. Neutralizing agents, such as amines, can be injected into the steam line to reduce the severity of both problems. When the steam condenses, it carries the agents into the condensate system.

Boiler Water Testing

As we said before, water treatment must be tailored closely to the condition of the water. To determine the condition of the water, you must perform testing. In

addition, you must test the water to check the effect of your water treatment. This is a continuing process. In some plants, it is appropriate to perform chemical tests every few hours, and to monitor certain conditions continuously. In other plants, it may be satisfactory to test the water every few weeks. Testing requirements may vary. For example, if the boiler is steaming at a high rate, it requires more water treatment chemicals than if it is idling.

Water condition is indicated by a number of standard tests. Each test measures a particular characteristic. The most common of these are:

- **hardness**, a measure of the concentration of minerals that have a strong tendency to form scale. The predominant “hardness” minerals are calcium and magnesium compounds. You can measure hardness with chemical tests for these specific elements. A simple, more general test is to measure the amount of soap solution that must be added to a water sample to form bubbles.
- **pH**, the basic measure of acidity. Pure water has a pH of 7.0. pH that is too low or too high can cause damage to metal directly. pH is also a controlling factor in many chemical reactions that occur in boiler water. You can measure pH with a simple chemical test. Or, you can install a pH meter that reads continuously.
- **oxygen**, which causes corrosion in any concentration. Keep the oxygen concentration as close to zero as is economically possible. Measure oxygen content with a chemical test.
- **alkalinity**, primarily a measure of the concentration of naturally occurring bicarbonates, which are associated with several adverse boiler conditions. Alkalinity also indicates the presence of alkaline water treatment chemicals. Despite its name, the alkalinity test is not directly related to pH. Two chemical tests for different sources of alkalinity are phenolphthalein (called “P alkalinity”) and methyl orange (called “M alkalinity”).
- **silica**, which forms a scale in high-pressure boilers that is particularly difficult to remove. Measure silica with a chemical test.
- **iron**, which combines with phosphates and hydroxides to form scale. Measure iron with a chemical test.
- **total dissolved solids (TDS) in boiler water**, is mostly an indication of the concentration of the by-products of chemical treatment, provided that boiler water is properly treated. The key word is “dissolved.” TDS remain safely dissolved in the water and do not deposit on the steel surfaces as long as they are kept within the limits that are appropriate for the boiler conditions.

Blowdown is the primary method of keeping TDS within safe limits. Blowdown wastes energy and

requires makeup water treatment, so the objective is not to minimize total dissolved solids, but to let them rise to a safe maximum.

The easiest way to measure TDS is by measuring the electrical conductivity of the water with a permanently installed meter that is calibrated in terms of TDS. You can also measure TDS chemically.

- **total dissolved solids (TDS) in condensate**, which is independent of the boiler water TDS. Condensate TDS typically reflects chemical treatment to protect the condensate system, such as with amines.

Not all of these characteristics are important for all boilers. Your water treatment consultant should specify the appropriate tests, how often to perform them, and the acceptable range of results.

You should also measure the concentration of treatment chemicals in the boiler water. For example, if you use phosphates and sulfite for water treatment, measure the levels of these chemicals to determine the quantity to be added.

Pennsylvania Separator Co.

Fig. 5 Sample cooler This is valuable when taking water samples from a boiler that operates above boiling temperature. Without it, tests will show concentrations higher than they actually are. It also reduces the risk of scalding when taking samples.

With high-pressure boilers, install a sample cooler to take samples of boiler water for testing. Otherwise, a large part of the water sample will flash into steam, and the material dissolved in the sample will register higher concentrations than actually exist inside the boiler. Sample coolers designed to be cooled with domestic water are available commercially. Figure 5 shows a typical unit.

The visible condition of the boiler during maintenance is also a form of water testing. In particular, scaling is very visible, and it will be cursed by those who must remove it. Other defects, such as acid embrittlement of steel, may not be visible.

Coordinate with Other Water Treatment

Cooling towers need a water treatment program, as recommended by [Measures 2.3.3 ff.](#) Hydronic systems may need some water treatment, although they are much less demanding. In many locales, it is desirable to treat the domestic water. It would save effort, and perhaps increase reliability of service, if you find a water treatment specialist who can deal with all your requirements. However, do not compromise to achieve this. Each application has different water treatment requirements, and one specialist may not be competent to handle them all.

ECONOMICS

SAVINGS POTENTIAL: Typically several percent of boiler fuel cost; plus, elimination of most waterside cleaning cost; plus, elimination of water-related boiler damage.

COST: Varies widely, depending on water condition, boiler pressure, and other factors.

PAYBACK PERIOD: Immediate. Appropriate water treatment always costs less than neglecting it.

TRAPS & TRICKS

SETTING UP THE PROGRAM: Water treatment is complex. Different treatment methods are required for different water conditions, different types of boilers, and different operating conditions. Have a qualified specialist set up the water treatment program. See [Measure 1.8.1.1](#), next.

SKILLS: Once the water treatment program has been set up, routine water testing and treatment can be done by the facility staff. This requires training and diligence. If it is not practical to do water testing and treatment in-house, hire these services.

MONITOR CONDITIONS: Regular testing does no good unless it results in appropriate action. Record water test results and review them on a continuous basis. At every opportunity, inspect the watersides to judge the effectiveness of treatment and to look for adverse effects. Make corrections to the treatment program as indicated.

MEASURE 1.8.1.1 Hire a qualified consultant and contractor to perform water treatment.

Measure 1.8.1 makes the point that water treatment is a complex subject. To do it correctly and economically, you need to bring together the right combination of people. The participants are the in-house staff, an expert water treatment consultant, and a reliable water treatment contractor.

The ultimate check on the effectiveness of water treatment is the condition of the boiler. Examine watersides at every opportunity. This reveals how well the staff, the consultant, and the contractor are doing their jobs.

Functions of the Consultant and Contractor

The functions of the water treatment *consultant* are to:

- test the facility’s water source
- specify the appropriate treatment methods, taking into account all the factors described in Measure 1.8.1
- specify the appropriate boiler water tests to be done by the facility staff (or a contractor), how often to perform them, and the acceptable ranges of results
- periodically check the performance of the in-house staff and/or the contractor in maintaining proper water conditions.

The functions of a water treatment *contractor* are to:

- provide the appropriate chemicals on a continuing basis
- provide the appropriate test equipment
- install automatic chemical feeders, if appropriate (see Measure 1.8.1.2, next)
- in a plant that does not have specialized boiler operators, accomplish testing and perhaps other routine functions.

Failing to distinguish between the roles of the consultant and the contractor can be expensive. Water treatment companies make money primarily by selling chemicals, and they have no interest in keeping your costs down. They may treat water excessively or with unnecessarily expensive methods. A particular contractor may not offer the most appropriate methods, or may not be familiar with them. For these reasons, you need a consultant who is a genuine expert in water treatment and who has no financial interest in sales of chemicals or equipment. Be prepared to pay the consultant a fee for a service that the contractor claims to offer “free.”

How to Select the Consultant

Selecting a water treatment consultant is like selecting a surgeon. Since you are not an expert in the

subject matter yourself, you have to judge by the results that the expert has produced elsewhere. Call other facilities that have equipment like yours, and ask for recommendations. Your consultant may be an independent expert, a professor, or a large company specializing in water consulting. If your boiler plant is at least moderately large, you can afford to bring in a water treatment consultant from anywhere in the country. In fact, don’t be surprised if you have to bring in someone from out of town.

Again, as in selecting a surgeon, get an expert who has experience with your specific set of problems. An expert in municipal water systems may not be appropriate for setting up a water treatment program for a boiler plant. Furthermore, an expert in large, high-pressure utility boilers may prescribe a program that is too elaborate for your low-pressure heating boilers.

How to Select the Contractor

You want a water treatment contractor from the local area. Otherwise, your plant will not get the regular attention it needs. Unfortunately, not all water treatment companies provide good service. More than one plant has suffered damage at the hands of water treatment companies, even major ones. Water treatment companies have as much trouble training and keeping qualified staff as other organizations. This is another reason why you need a separate water treatment consultant.

If your consultant is familiar with the local area, he may be able to recommend a contractor. In any event, contact the operators of other boiler plants in the vicinity who have boilers like yours. Be aware that the opinions of other operators may not be reliable. They are not water treatment experts, either. Other boiler operators may not be competent to judge the results that they are getting, and they may be more influenced by the

contractor's charm than by performance. In the end, you have to know enough about water treatment to ask the right questions.

Relationship to the Boiler Plant Staff

How much should the boiler plant staff be involved with water treatment? This depends on the complexity of treatment requirements and the sophistication of the staff. If there is at least one trained boiler operator, this person can do at least the routine chemical treatment and water testing. However, many commercial and institutional facilities do not have staff capabilities to handle water treatment reliably. In such cases, contract the water treatment functions, and ask your water treatment consultant to make periodic checks of the contractor's performance.

On the other hand, a sophisticated staff may be able to purchase its own chemicals and test equipment, eliminating the need for a water treatment contractor, provided that the staff is properly advised by the consultant.

MEASURE 1.8.1.2 Install automatic water treatment equipment.

RATINGS

New Facilities	Retrofit	O&M
B	B	

Automatic feeders for water treatment chemicals are an effective means of ensuring that chemicals are injected properly. Chemical feeders are fairly simple, consisting of a chemical storage bin, an injection pump, and controls. Enough bulk chemical is stored in the bin to avoid the need for frequent handling of chemicals. Figure 1 shows a typical chemical feeder.

An automatic feeder can inject chemicals frequently, which would be a bother for human operators. How desirable is this? It depends on the rate of water loss from the system. If the system loses only a small fraction of its water volume per day, individual small doses of treatment chemicals suffice. In such cases, the only advantage of a chemical feeder is that it automatically mixes and injects the dose.

On the other hand, a system having a high rate of water loss benefits significantly from automatic injection. If chemicals are added manually when the loss rate is high, the concentration of chemicals in the boiler water rises at the time of treatment and tapers off

until the next treatment. This procedure requires more chemicals than if the concentration is kept steady.

Methods of Control

Chemical feeders can be controlled to inject an individual dose, to inject fixed doses at periodic intervals based on time, or to inject different quantities of treatment chemicals based on water conditions.

Timed feeding alone cannot respond to changes in boiler load. For example, in comfort heating applications, changes in load throughout the day and from one day to the next affect the rate of water loss. Feeding at a steady rate under these circumstances could lead to chemical levels in the boiler water that are too high or too low.

The best control for most purposes is based on water conditions. A sensor is installed on the boiler to control each chemical being fed. The sensor controls the operation of the pump on the feeder.

There are several hazards to automatic control. One is that a failure of the control sensor could cause too little or too much chemical to be injected, which could have serious consequences. Another hazard is that automatic operation causes human operators to neglect monitoring the boiler water conditions.

Even with automatic control, monitor the condition of the boiler water with a separate alarm having its own sensor. Continue manual water testing even with automatic chemical feeding.

Maintenance

While chemical feeders are useful in reducing routine labor, they require maintenance of their own. Many automatic chemical feeders are abandoned

because of inadequate maintenance. Chemical feeders are fairly simple, but maintaining them is another bit of specialized knowledge that the staff must learn.

If the facility does not have the ability to maintain its own water treatment program, and a contractor is hired for this function, the contractor should maintain the chemical feeder. This arrangement is most likely to be successful if the contractor provides the feeder and its associated controls and alarms.

ECONOMICS

SAVINGS POTENTIAL: Included in *Measure 1.8.1*. This is primarily a means of reducing the costs of chemicals and labor.

COST: Equipment and installation typically cost several thousand dollars. Water treatment contractors may

install the equipment “free” as part of a service contract, or the contractor may lease the equipment to the facility.

PAYBACK PERIOD: Immediate, if the feeders are rented or provided by the water treatment contractor. Several years or longer, if the feeders are purchased. Purchasing the feeders provides a larger net saving in the long term.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Ask other boiler operators with similar water treatment requirements about their experience with chemical feeders. Shop thoroughly.

SKILLS AND TRAINING: Even though the equipment is fairly simple, it will be neglected unless operators are trained to maintain it. Automatic water treatment requires as much supervision and follow-up as manual methods.

MEASURE 1.8.2 Control top and bottom blowdown to maintain required water quality and minimize waste of boiler water.

RATINGS

New Facilities	Retrofit	O&M
<input type="checkbox"/>	<input type="checkbox"/>	A

Blowdown is the deliberate dumping of boiler water to flush out accumulated contaminants. Most contaminants are brought into the system by makeup water. Chemical treatment converts contaminants that are harmful in small quantities into substances that can be tolerated in much larger quantities. Eventually, even these substances accumulate to the point that they must be removed from the system to avoid trouble.

For example, in treating “hardness” (mainly calcium and magnesium compounds), two pounds of phosphate water treatment chemicals combine with one pound of “hardness” compounds to produce three pounds of a material that sinks to the bottom of the boiler and becomes sludge. The sludge must be blown out before it hardens in place or accumulates enough to restrict water flow.

Blowdown, therefore, is an integral part of water treatment. The necessary percentage of blowdown depends on the contaminant concentration in the makeup water and on the allowable contaminant concentration in the boiler water. In boiler plants that have pure makeup water, the blowdown percentage may be very low. In applications where makeup water is heavily loaded with contaminants, the percentage of blowdown may be large.

SUMMARY

Insufficient blowdown results in fouling of the heat transfer surfaces, which can seriously degrade efficiency. It also leads to serious damage to the boiler, ranging from various types of corrosion to obstruction of water flow that can cause tube failure.

Excessive blowdown wastes energy, increases water treatment cost, and wastes raw water.

Excessive blowdown occurs in many boiler plants because boiler operators try to stay “on the safe side.” A contributing factor is the crude method of controlling blowdown on many boilers, which is to partially open a manual blowdown valve and allow an unknown quantity

WESINC

of water to gush out. Instead of this haphazard approach, control blowdown rationally. Monitor water conditions continuously, and adjust the blowdown rate accordingly.

This Measure gives you the principles of controlling blowdown, which you can do manually. The subsidiary [Measure 1.8.2.1](#) recommends installing automatic blowdown control, where appropriate, to control blowdown most accurately.

Top Blow and Bottom Blow

Some solid contaminants are heavier than water, and these settle to the bottom of the boiler. These are removed by one or more blowdown drains at the bottom of the boiler. This is called “bottom” blowdown. Figure 1 shows the bottom blowdown valve of a large boiler.

The sludge that concentrates in the bottom of the boiler is in a relatively undisturbed area, and can wait

WESINC

there until enough has accumulated to justify blowing it out. In boilers that have several isolated low points, such as watertube boilers with several lower headers, a blowdown drain is installed at the bottom of each. The lower headers of watertube boilers are called “mud drums” because the solids accumulate there in the form of a sludge.

Other solid contaminants are lighter than water. In steam boilers, these contaminants float to the surface. Also, dissolved contaminants come out of solution at the water’s surface as the water evaporates. These contaminants are removed at a blowdown drain that is installed just below the waterline. This is called “top” or “surface” blowdown. Figure 2 shows the top blowdown connection of a large boiler.

It is better practice to control the concentration of dissolved contaminants by blowing from the top blowdown drain, rather than from the bottom drain. Contaminants and water treatment products that float to the surface carry over with the steam. Also,

FORMULA 1

$$\text{Blowdown rate} = \text{Makeup rate} \times \frac{\text{TDS of feedwater}}{\text{TDS in boiler} - \text{TDS of feedwater}}$$

where:

- TDS means “total dissolved solids”
- the blowdown rate and makeup rate are expressed in any identical units of mass flow, for example, pounds per hour

evaporation at the surface makes the contaminant concentration highest there.

Can Bottom Blow Cause Tube Burnout?

In watertube boilers, there is some concern that extended bottom blowdown may cause burnout of generating tubes. The concern is that opening the blowdown valve offers a path of least resistance so that water in the bottom drum will flow out the blowdown connection instead of up into the tubes. Reduced flow within the tubes allows the tube temperature to rise dangerously. This risk is alleged to be most severe in headers serving waterwall tubes, which are exposed to the full heat of the firebox.

It seems doubtful that blowdown connections would be installed where using them might damage the boiler, but only brief periods of blowdown may be intended. In case of doubt, check with the boiler manufacturer. It may be good practice to limit bottom blow to periods when the boiler is at a lower firing rate.

How to Calculate the Blowdown Rate

You can calculate the blowdown rate easily from the concentration of contaminants in the water by using Formula 1.

For example, if the TDS of the feedwater is 5 percent of the TDS desired in the boiler, the blowdown rate should be slightly more than 5 percent of the makeup rate. If the system is losing 10,000 pounds of steam per hour, the proper blowdown rate is 526 pounds per hour.

The Energy Penalty of Blowdown

The amount of energy carried away by blowdown is proportional to the temperature of the boiler water and to the blowdown rate. (The energy content of water inside the boiler is entirely sensible heat, which is linearly proportional to the temperature.)

For example, if the boiler pressure is 250 PSI, the boiler water temperature is 405°F. If the makeup water temperature is 65°F, then each pound of water that is lost requires another pound of makeup water to be heated 340°F, which requires about 340 BTU.

If the boiler has the same blowdown rate that we calculated in the previous example, about 180,000 BTU per hour is being lost. This is about 1.8 percent of the energy content of the steam.

In this example, the heat loss is unavoidable because blowdown is necessary to maintain proper water conditions. However, any blowdown in excess of the minimum is a waste of energy and water.

How to Control Top Blowdown

Ask your boiler manufacturer or water treatment consultant (see [Measure 1.8.1.1](#)) to specify the water

conditions that you should maintain with blowdown. Usually, blowdown is controlled on the basis of maintaining the maximum allowable level of total dissolved solids (TDS).

To a large extent, the concentration of TDS in boiler water is related to “hardness,” i.e., the concentration of calcium and magnesium ions. In a well treated boiler, TDS mostly consists of the residue of chemical treatment to neutralize hardness.

Unusual circumstances may make it appropriate to control blowdown on the basis of some other water characteristic, but this is rare. Other boiler contaminants or conditions, such as pH and alkalinity, are controlled by appropriate chemical treatment rather than by blowdown.

■ Should Top Blowdown be Continuous or Intermittent?

As a practical matter, blow down intermittently if you have a low blowdown rate, and blow down continuously if you have a large blowdown requirement. The limiting factor is knowing your actual blowdown rate. If you open the blowdown valve fully for a measured period of time, you can judge the amount of blowdown accurately. On the other hand, you cannot judge your blowdown rate accurately if you keep the blowdown valve open slightly. (In principle, you could meter the blowdown or calibrate your blowdown valve, but this is an unnecessary complication.)

The main issue is keeping the blowdown rate as close to optimum as possible. Blowdown requirements vary enormously from one boiler plant to another. If you need a high blowdown rate, you may need continuous blowdown to keep the TDS from drifting too far away from its ideal value. On the other hand, if the makeup rate is low and the makeup water is clean, it may be satisfactory to blow down every few hours.

■ How to Measure TDS

The easiest way to measure TDS is with a TDS meter. This is actually a meter that measures the electrical conductivity of the boiler water, but it is calibrated in terms of TDS. A TDS meter has the advantage that it provides a continuous readout. If you have a high blowdown rate, a TDS meter is practically a necessity.

The main disadvantage of the TDS meter is that it can get out of calibration. This is not likely, but a false reading can result in the wrong blowdown rate, with possibly serious consequences. If you can afford it, install two TDS meters and compare them regularly.

You can also measure TDS by using an inexpensive chemical test. This may be satisfactory in a small boiler plant that has a low blowdown requirement. The TDS should not be able to drift far from its ideal value between tests. You can also use a chemical test to check your electrical TDS meter.

■ Manual Control Methods

If you blow down intermittently, open the blowdown valve for a fixed period of time, such as ten seconds, and observe the effect on the TDS meter. Repeat this as necessary to keep the TDS at its proper level.

With a steam boiler, the TDS meter will register the effect of blowdown quickly because all the TDS are circulating vigorously within a confined space. In a hot water system, the TDS are circulating throughout the facility, so you have to wait for the water to circulate through the system before the effect of blowdown will register properly on the TDS meter.

If you blow down continuously, keep adjusting the blowdown valve based on the TDS meter reading. The operators have to monitor the TDS meter continuously to do this right.

If the manual procedure seems too difficult or too risky, install an automatic blowdown control, as recommended by [Measure 1.8.2.1](#).

How to Control Bottom Blowdown

Do bottom blowdown intermittently. Determine the appropriate interval by piping the discharge into a safe container and seeing what settles out. If the bottom blow does not contain a significant amount of visible material, extend the interval.

Minimize the Need for Blowdown

The formula for blowdown rate given above states that the need for blowdown is proportional to the makeup rate and to the concentration of solids in the feedwater. Let's examine this important point more closely. First of all, if the boiler system has minimal water loss, it needs only minimal blowdown because there is little makeup to bring contaminants into the system. Second, if the makeup water is perfectly pure, the need for blowdown is minimal because the makeup water is not bringing contaminants into the system. Therefore, to

reduce the need for blowdown, (1) reduce system leakage as much as possible, and (2) treat the makeup water as effectively as possible before it becomes feedwater.

To reduce system leakage, see [Measures 1.10.1](#) and [1.10.2](#). Reducing "hardness" is the part of water treatment that has the greatest effect on reducing blowdown requirements. Do this with a water softening process, as described in [Measure 1.8.1](#). Also, remove suspended solids in the makeup water by filtration and coagulation.

Recover Blowdown Heat, Maybe

If the system still requires a substantial amount of blowdown after all improvements have been made, consider recovering the heat from blowdown water. [Measure 1.8.3](#) tells you how.

SETUP AND MONITORING: Develop the appropriate blowdown schedule based on water conditions, the type of boiler, and boiler operating conditions. Use water testing results, especially TDS, as the primary guide to blowdown.

When the boiler is cold, inspect the watersides to verify adequate blowdown. Inspect the bottom drain area for adequate bottom blowdown.

TRAINING AND SUPERVISION: Blowdown will be forgotten unless it is done on a regular basis. Establish a blowdown schedule and put it on the boiler operating log, along with appropriate instructions. Check that the procedure is being followed.

RATINGS

New Facilities	Retrofit	O&M
B	C	

The formula in Measure 1.8.2 shows that the blowdown rate should be proportional to the makeup rate. If the makeup rate fluctuates, the boiler operators cannot optimize the blowdown rate manually. The solution is to install an automatic valve for the top (surface) blowdown that senses the appropriate condition in the boiler water. Usually, this condition is the concentration of “total dissolved solids” (TDS). The equipment for this is a standard boiler accessory.

Equipment and Installation

To control blowdown automatically, install an automatic valve in the top blowdown line. Typically, this is a solenoid valve. The solenoid valve is controlled by a sensor that measures the electrical conductivity of the boiler water, which relates to the TDS concentration. Figure 1 shows a typical blowdown controller.

Automatic blowdown may operate continuously or intermittently, depending on the blowdown rate. If the blowdown requirement is small, intermittent blowdown is more practical. A modulating valve operating at a low flow rate would require frequent maintenance because of scoring of the valve seat.

If you use a solenoid valve, it is a good idea to control it through a cycle timer. The conductivity sensor triggers the cycle timer, which keeps the valve open for a fixed period of time, such as ten seconds. This method reduces the TDS in small increments and allows the TDS concentration to stabilize between blowdown cycles, preventing erratic operation of the blowdown valve.

Limit the capacity of the blowdown valve to keep the water level from falling to an unsafe level if the valve fails in a fully open position. Make the blowdown line, or the valve, small enough so that the feedwater pump can maintain the water level while the boiler is at full output and the blowdown valve is fully open.

Do not install the blowdown valve in a descending pipe. This would allow dirt to settle in the valve and foul it. Do not install a strainer anywhere in the blowdown line. A strainer might clog and then blow out explosively.

As a safety feature, monitor the condition of the boiler water with a separate alarm having its own sensor. The alarm should activate if the controlling parameter (usually, the TDS) is either too high or too low.

Top Blowdown Only

Usually, only top blowdown is controlled automatically. Do bottom blowdown manually, which allows you to inspect the blowdown for accumulated solids. In most plants where operators are not on duty continuously, you can defer bottom blowdown to normal working hours.

Continue Water Testing

Installing automatic blowdown does not reduce the need for regular boiler water testing. Blowdown controls only one water condition, hardness. You need to keep other water conditions within proper limits.

Furthermore, you need testing to verify that the automatic control is functioning properly.

CHECKING: Review the water test results continually, especially TDS, to make sure that the blowdown is operating properly. Failure is easy to overlook until serious damage occurs. Test the TDS alarm on a daily basis.

MEASURE 1.8.3 Install blowdown heat recovery.

RATINGS

New Facilities	Retrofit	O&M
C	C	

Blowdown water contains valuable heat. You can recover this heat easily. Whether it is economical to do so depends mainly on these factors:

- the amount of heat available for recovery, which mainly depends on the blowdown rate. The blowdown rate is proportional to the makeup water requirement, which is equal to system water loss plus blowdown.
- whether an application is available that can use heat at the temperature of the blowdown
- whether the potential application is synchronized with the time of blowdown.

In brief, blowdown heat recovery is most likely to be practical with larger boilers that require a large amount of makeup. In such cases, the payback period for blowdown heat recovery may be short. On the other hand, blowdown heat recovery is unlikely to be practical with smaller boilers, or in steam systems that have only small water losses.

Recover Heat from Water, Flash Steam, or Both?

You can recover almost all the heat from blowdown water, regardless of the boiler pressure, if you cool the blowdown water enough in the process. However, raising the heat recovery temperature reduces the fraction of the heat that is recovered. This is because all the energy of the blowdown water is in the form of sensible heat (i.e., proportional to temperature).

In many applications, it would be desirable to use the recovered heat in the form of steam. For such applications, you can exploit the fact that a certain fraction of the blowdown water will flash into steam when it is exposed to the lower pressure outside the

SUMMARY

Worth considering in boilers that require a significant amount of blowdown. Heating makeup water is the most common application. High-pressure systems offer a greater variety of applications.

boiler, provided that the water is not cooled first. The flashing occurs because the heat contained in the water boils part of the liquid into steam.

Flashing occurs instantly, resulting in a quantity of liquid at boiling temperature and a quantity of steam at the same temperature. Both the steam and the remaining water contain heat energy. The question is, how much of the original energy goes into the steam, and how much remains in the water?

First of all, the total amount of energy contained in blowdown water is proportional to the temperature of the boiler water, which is directly related to the boiler pressure. For different boiler pressures, this table shows the amount of water that remains as a liquid, the amount that flashes into steam, and the amount of energy in each:

Boiler Pressure, PSI gauge	Weight, lb		Energy, BTU		Percent of Energy to Steam
	Water	Steam	Water	Steam	
10	0.97	0.03	202	33	14
35	0.93	0.07	167	82	33
88	0.88	0.12	158	143	47
205	0.81	0.19	146	218	60
655	0.68	0.32	123	365	75
1310	0.58	0.42	104	485	82

(The table assumes a baseline of zero energy for water at 32°F, which is standard practice. The table also assumes that the condensate discharges to atmospheric pressure.)

This table reveals some interesting results that help to decide whether it is practical to recover the blowdown heat as flash steam, or from the liquid:

- At low boiler pressures, most of the energy remains in the water.
- Above about 100 PSI, there is more energy in the flash steam than in the remaining water. At still higher pressures, the fraction of the energy contained in flash steam rises rapidly.
- The energy content of the water actually declines as boiler pressure rises. The reason is that the increased energy content of the water causes more of it to flash into steam. The water always cools to the same temperature once it gets outside the boiler, so less water means less energy.

The conclusion is clear. Recovering blowdown heat in the form of flash steam is much more attractive at higher boiler pressures.

Equipment for Recovering Blowdown Heat

Recovering heat from the liquid is usually done with a simple heat exchanger. Figure 1 shows a typical blowdown heat recovery unit, which is available as a standard product.

A heat exchanger is usually needed when recovering heat from the liquid blowdown water, because it is contaminated with water treatment chemicals and their residue. Therefore, you usually cannot add the blowdown water directly to the liquid you are heating. The heat exchange process reduces heat recovery to some extent.

To recover blowdown heat in the form of flash steam, the water is dumped into a tank, called a “flash tank.” A portion of the water flashes to steam inside the tank, and the steam is piped away to its application. The flash tank has a steam trap, or float valve. The steam trap is needed to keep the steam from flowing into the sewer along with the remaining blowdown water.

The flash tank may drain the remaining liquid to a heat exchanger to recover the heat in the liquid. The heat of the steam is recovered at steam temperature, while the heat in the liquid is recovered at lower temperature. Figure 2 shows a typical heat recovery

Cleaver-Brooks

Fig. 1 Liquid-to-liquid blowdown heat recovery unit In this packaged unit, the flow of blowdown water is regulated to maintain the desired temperature of the liquid being heated, as long as blowdown occurs. Heat may be recovered at any temperature up to the temperature of the boiler water. However, the amount of heat recovered is inversely proportional to the recovery temperature. The steam trap at lower right keeps any flash steam from blowing out of the unit.

vessel for recovering heat from both the steam and the liquid.

For some applications, you can recover the energy of flash steam without a heat exchanger. To do this, simply bubble the steam through the liquid or other material to be heated. This captures all the heat of the steam, and it also recovers the pure water condensed from the steam. The main limitation is that the application must be at atmospheric pressure, or at least, at a pressure much lower than boiler pressure. Of course, the heated material must tolerate the added water.

You need a heat exchanger to recover the heat from the flash steam if you want to heat a substance that cannot be exposed to the steam, or to heat a material that is under pressure.

Using Blowdown to Heat Makeup Water

A common application for blowdown heat recovery is heating makeup water. This is a good application because the outgoing flow of blowdown water is synchronized with incoming flow of makeup water. The

Fig. 2 Blowdown heat recovery unit providing steam and hot water The blowdown water enters through the metering valves on the right. It flashes in the upper tank. The remaining liquid drops through the float valve to give up its heat in the heat exchanger below.

quantity of makeup water to be heated is always greater than the quantity of blowdown, because the amount of makeup water equals the blowdown plus the total system water loss.

Here are some examples to illustrate makeup water heating:

- A boiler operates at 10 PSI, and the makeup water rate is five times the blowdown rate. If all the blowdown heat is recovered, it can raise the temperature of the makeup water by 43°F.
- A boiler operates at 655 PSI, and the makeup water rate is five times the blowdown rate. If all the blowdown heat is recovered, it can raise the temperature of the makeup water by 94°F.
- A boiler operates at 655 PSI, and the makeup water rate is two times the blowdown rate. If all the blowdown heat is recovered, it can in principle raise the temperature of the makeup water by 235°F. However, if the makeup water starts at 50°F, the final temperature is 285°F, which is too high for the feedwater system. Instead, some of the blowdown heat is used to heat makeup water, and the rest is sent to the deaerating tank in the form of flash steam..

These examples suggest that most boilers can use their blowdown heat entirely for heating makeup water. A possible exception is high-pressure boilers with low makeup water rates, which cannot recover all the heat.

■ Installation Considerations

Packaged blowdown-to-makeup heat exchangers are standard items available from several manufacturers. They come in a wide range of sizes. Some units include thermostatic controls to proportion the flow of blowdown and makeup water for optimum heat transfer. Installation is usually inexpensive, because the blowdown and makeup water piping are close to each other.

The heated makeup water flows into the feedwater tank. Make sure that the feedwater tank has enough capacity to accommodate rapid changes in water level during blowdown. Normally, water level changes are not a problem, because the water drawn from the feedwater tank to compensate for blowdown is replaced by heated makeup water. However, if feedwater is fed to the boiler with on-off control, the flows may temporarily get out of balance. One solution to this problem is better control of feedwater flow. If the feedwater tank lacks sufficient capacity, consider installing an insulated holding tank to accept the heated makeup water until it can flow into the feedwater tank.

A single heat recovery unit can serve any number of boilers. Simply pipe the blowdown from all the boilers to the heat recovery unit. This arrangement should be satisfactory if a common feedwater tank is used for the same boilers.

Using Blowdown to Heat Feedwater

In a boiler system that uses an open (vented to atmosphere) feedwater tank, 200°F is about the maximum practical temperature to which makeup water can be heated. If the makeup water is heated more, it will flash away through the tank vent.

If the system uses a deaerating feedwater tank, flash steam from the blowdown can contribute to the steam needed by the deaerator to “scrub” oxygen out of the feedwater. This is economical because only a flash tank is required. However, blowdown usually occurs in brief discharges, so the feedwater system must be designed to exploit the brief bursts of flash steam.

Figure 3 shows a blowdown heat recovery system that heats both feedwater and makeup water.

Other Applications

The heat contained in blowdown can be used for any application that is compatible in terms of temperature, quantity of heat, and time synchronization.

Blowdown is not a steady source of heat. Makeup water heating is the only application in which the need for blowdown is synchronized with its availability. In most other applications, consider blowdown heat as a supplemental source. Domestic water heating and fuel oil tank heating might be applications.

In high-pressure plants, most of the blowdown will flash into steam. Such plants may have a low-pressure steam system that is used primarily for heating. In such cases, simply feed the flash steam into the low-pressure system.

If the application requires higher temperatures, less heat can be extracted from the blowdown. Only higher-pressure boilers produce blowdown water that is hot enough for heating applications above the boiling point of water.

Combination with Condensate Heat Recovery

In some applications, it is necessary to dump the condensate from steam equipment, rather than return it

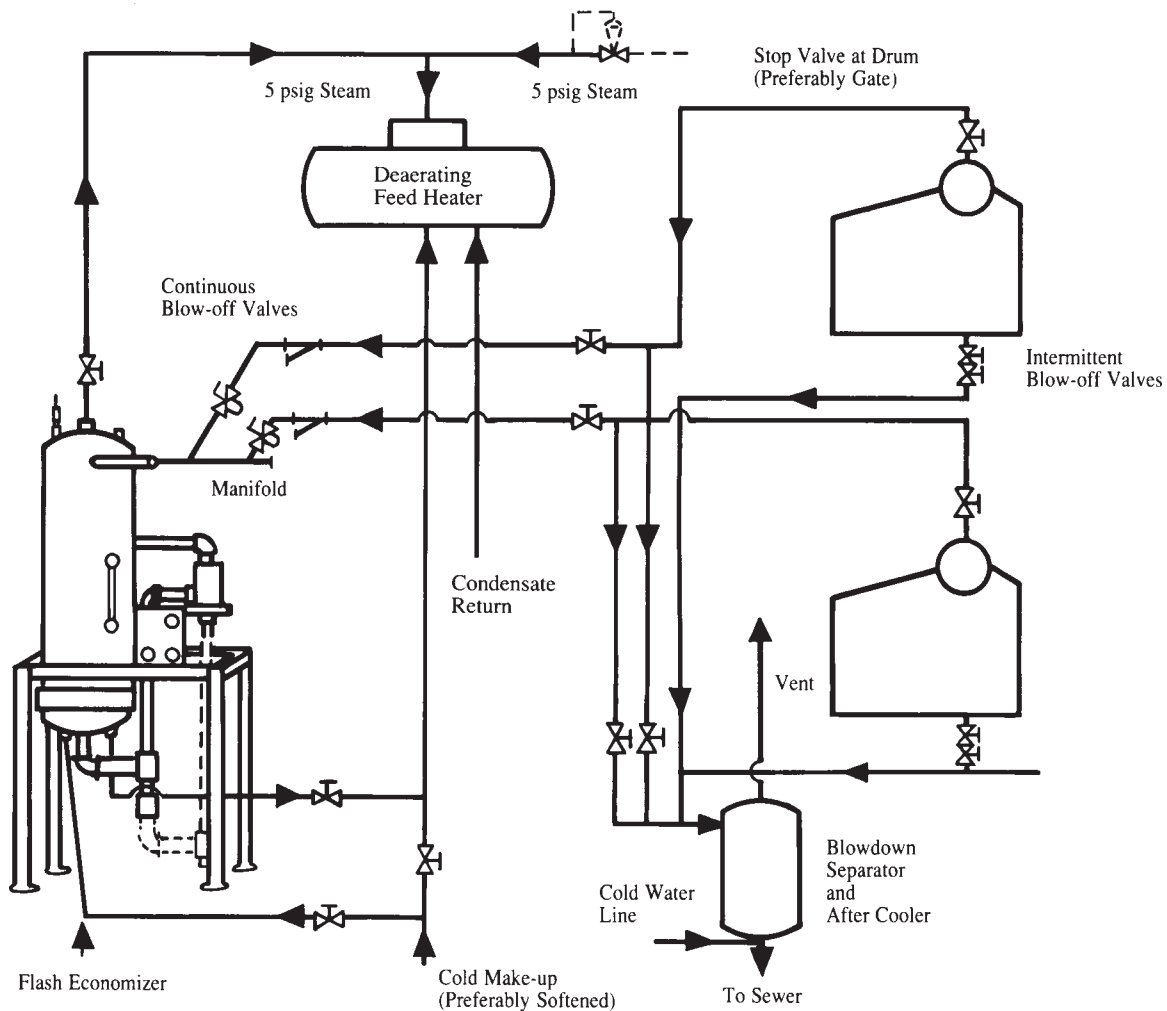

Fig. 3 Blowdown heat recovery system for makeup water and feedwater The deaerating feedwater heater needs a constant supply of steam, which is supplemented by flash steam. The makeup water can accept heat as it becomes available. This system recovers heat from both top and bottom blowdown.

Pennsylvania Separator Co.

to the boiler. (For example, there may be a risk that the condensate is contaminated by materials that would foul the boiler.) You can still recover the heat of the dumped condensate by using the blowdown heat recovery system. See [Measure 1.8.4.1](#) for this application.

Heat Exchanger Fouling and Maintenance

Blowdown water is laden with dissolved materials. As the blowdown water cools, some of these materials precipitate on the surfaces of the heat exchanger. The mess that occurs in the heat exchanger consists of the substances that were removed from the boiler to avoid leaving a mess there. Plan regular cleaning of the heat exchanger to remove these deposits. Design the heat exchanger to make cleaning easy.

The blowdown heat recovery units offered by several manufacturers have stainless steel heat exchanger tubes. This is desirable because the heat exchanger is hot, wet, and open to the atmosphere. It would corrode quickly if it were made of plain steel.

Treat the makeup water before it passes through the heat exchanger. This minimizes fouling of the makeup water side of the heat exchanger.

Safety Issues

If you plan to use flash steam at a pressure higher than atmospheric, select the flash tank for the expected pressure.

Design the heat recovery system to deal with the possibility that the blowdown valve may stick in the fully open position. If the blowdown is recovered in a closed tank or heat exchanger, it should have a pressure relief valve sized for the maximum blowdown rate.

No component of the heat recovery system should be able to become so fouled that it can block the blowdown discharge. If this occurs, full boiler pressure will be applied upstream of the blockage, possibly causing a dangerous blowout. For this reason, don't install any strainers in the blowdown circuit of the heat recovery system.

ECONOMICS

SAVINGS POTENTIAL: 0.1 to 2 percent of boiler fuel, depending mainly on the blowdown percentage.

COST: Typically, several thousand dollars for a smaller boiler plant. Up to \$20,000 for a sophisticated system that serves a larger boiler plant.

PAYBACK PERIOD: Less than one year, to many years, depending mainly on the blowdown rate and boiler pressure.

TRAPS & TRICKS

CHOICE OF METHOD: Consider all your heat recovery options. Estimate your potential savings carefully.

SELECTING THE EQUIPMENT: Select the equipment to tolerate heavy fouling and to be easily cleaned. Ask vendors for references. Talk with purchasers who have used the equipment for several years.

MAINTENANCE: Schedule cleaning at appropriate intervals. Fouling reduces heat recovery.

EXPLAIN IT: The purpose of a blowdown heat recovery unit is not obvious from its appearance. Install a placard on it that indicates what it does and how it works. See [Reference Note 12, Placards](#), for details of effective placard design and installation.

MEASURE 1.8.4 Maximize condensate return.

RATINGS

New Facilities	Retrofit	O&M
A	C	

Try to recover condensate wherever it is economical to do so, and keep the condensate as warm as possible. The condensate contains a considerable amount of energy, and the treated water is valuable in itself.

All steam-operated equipment generates condensate, unless the steam is used in a process that consumes the steam or releases it to the atmosphere. Even so, condensate may be dumped rather than being returned to the boiler. This may occur because of cost cutting in the original installation, or because condensate lines were abandoned instead of repairing them, or because facility additions neglected to connect to an existing condensate system. Design errors, installation errors, inadequate maintenance, or improper plant operation may prevent an installed condensate system from functioning.

Condensate is often returned over long distances, as shown in Figure 1. If you cannot afford to return condensate, try to recover its heat energy at the site. See subsidiary Measure 1.8.4.1 for this. To minimize loss of condensate by flashing from high-pressure equipment, see subsidiary Measure 1.8.4.2.

Reasons to Return Condensate

These are the reasons to return condensate:

- **to recover the heat contained in the condensate.** The energy saving is significant if the steam-using equipment is close enough to the boiler plant so that you can keep the condensate warm until it returns to the boiler. Condensate retains its heat better if there is a large condensate flow rate and the lines are well insulated. In many installations, return lines would be so long that condensate could not remain warm.

SUMMARY

Consider this any time condensate is being discarded. Usually expensive.

- **to reduce water treatment cost.** This cost is related to the quality of the raw water in the locale. Condensate return is more attractive if the makeup water is expensive to treat.
- **to conserve raw water.** Water costs are rising everywhere. Even though water is still cheap in most places, saving raw water may be a significant cost factor.
- **to satisfy environmental regulations.** Condensate may be considered to be contaminated water, although the quantity of water treatment chemicals that pass through the steam system is small. Or, there may be objections to the high temperature of the condensate if it is discharged into a body of water.

Heat Recovery Potential

The amount of energy in condensate depends on the characteristics of the steam-using equipment. In an ideal steam system, the steam-using equipment would extract all the thermal energy of the steam, and return

WESINC

Fig. 1 Steam and condensate lines on a large military base

only cold water. This is almost never possible in practice, for two reasons. One is that the application requires heat at some minimum temperature. For example, if steam is used for heating a batch of material at 300°F, the condensate is formed at a temperature of 300°F.

The second reason relates to the thermal characteristics of water and steam. Below boiling temperature, pure steam has a pressure lower than atmospheric. However, the steam inside the equipment must be above atmospheric pressure to push the condensate out of the equipment. As a result, condensate enters a vented condensate system at a temperature somewhat higher than the boiling temperature.

(Vacuum condensate systems allow steam to condense in the equipment at a much lower temperature. Hence, the condensate in a vacuum system carries much less energy. See [Measure 1.8.5](#), below, for more about vacuum condensate systems.)

As a typical example of condensate recovery, condensate returns to the boiler at a temperature of 180°F, and the makeup water has a temperature of 60°F. In this case, each pound of condensate that is recovered saves 120 BTU. If steam is produced at 15 PSI, this represents 10.5% of the energy that would be needed to make the steam from cold makeup water.

■ Loss of Heat in Condensate Piping

If there is a long distance between the boiler and the steam-using equipment, much of the condensate's heat may be lost through the walls of the pipe on the way back to the boiler. Before spending money to install condensate piping, calculate how much of the condensate's heat will survive the trip. Your estimate should not exaggerate the effectiveness of insulation. Straight sections of pipe can be heavily insulated, but expansion rollers, pipe hangers, exposed flanges, and other features conduct heat through the insulation. On the other hand, if you can run the condensate pipe inside hot steam tunnels, heat loss is greatly reduced.

The rate of condensate flow has a major effect on the temperature of the returning condensate. The rate of heat loss from a pipe depends on its insulation and surface area. The loss is constant for a given temperature. If there is a large flow inside the pipe, the heat loss may comprise a small percentage of the total heat being transmitted, and the condensate arrives hot. However, if there is only a low flow rate, the heat loss from the pipe results in the condensate being cold by the time it arrives. This is a mathematical way of saying that a long condensate return may be worthwhile for a large steam user but not for a small one.

Flash steam forms when the condensate exits the steam-using equipment, and it keeps the liquid condensate warm. For example, condensate that is originally at 240°F cools to 212°F as soon as it leaves the trap. The energy corresponding to the 28°F temperature difference is contained in the flash steam. The steam travels through the condensate pipe, keeping the pipe warm until it all condenses. (The flash steam also displaces air from the condensate pipe, preventing corrosion and contamination of the condensate.)

■ Recovery of Condensate Heat in High-Pressure Applications

In high-pressure applications, the condensate is substantially hotter than the atmospheric boiling temperature. If the condensate is returned through a vented condensate system, a large fraction of it will flash into steam. Capturing the energy of the flash steam involves additional steps. These are covered by subsidiary [Measure 1.8.4.2](#).

General Approach

The first step is to find out whether you are losing condensate. See [Measure 1.10.1](#) for methods of monitoring water loss.

If you find that you are losing condensate, the second step is to find out where it is going. Find any steam-

Fig. 2 Steam powered condensate mover This is essentially a positive-displacement steam pump without a piston. It is especially useful where the condensate system is not tall enough to provide adequate suction pressure for a centrifugal pump.

Armstrong International, Inc.

using equipment that is not returning condensate. See [Measure 1.10.2](#) for methods of detecting leakage from the condensate return system. Also, look for blowing steam vents and other places where water may be disappearing.

The third step is to take whatever action is necessary to return condensate, subject to the limitations of economics and practicality. Install condensate returns where they are missing. Repair the condensate return system where it is defective.

Condensate System Layout

The types of condensate systems are summarized in the introduction to this Subsection. Recovering condensate is a two-step process of draining by gravity into a receiving tank (“condensate receiver”), and then pumping from the receiver back to the boiler plant. To avoid complications, the receiver must be located below the equipment that it serves, and the condensate must be able to flow downhill from the receiver. All condensate piping must be pitched downward. To satisfy these requirements in a large facility, there may be many receivers in different locations. For example, each building in a facility that is served by a central steam plant might have its own receiver.

How to Pump High-Temperature Condensate

If the condensate pipe is so well insulated that condensate reaches a condensate or feedwater pump at a temperature above about 180°F, the pump may be unable to function properly. The problem is that the hot water partially flashes into steam at the reduced pressure of the pump suction. The presence of steam bubbles in the pump reduces pump capacity and efficiency, hastens deterioration of the impeller and bearings, and makes a loud rattling noise. This problem causes some facilities to deliberately cool the condensate. This wasteful practice is not necessary, because there are several ways to pump hot condensate.

One solution is to install the condensate pump below the condensate receiver. The hydrostatic pressure of the water column between the receiver and the pump prevents flashing. Calculate the required height from the suction pressure requirement of the particular pump. (This requirement is called “net positive suction head,” and it is indicated on the pump curves.) A height of 8 to 15 feet usually suffices for water at the boiling point, with less height being required for cooler water.

Another solution is to use a steam-powered condensate mover instead of a centrifugal pump.

Figure 2 shows how this equipment works. It consists of a tank, a float valve, two check valves, and a steam connection. In operation, condensate is allowed to drain into the tank. Then, steam is admitted to the tank to blow the condensate out, after which the cycle repeats. The unit is essentially a reciprocating steam pump without a piston. It can be made with hardware similar to that found in steam traps, and compact units are offered by several steam trap manufacturers. In fact, these units are sometimes called “pumping traps.”

Upgrade Your Water Treatment Program to Deal with Condensate

Condensate returning through an atmospheric condensate system dissolves oxygen and carbon dioxide from the air. This in turn causes the water to corrode the iron in the pipe and to dissolve iron compounds. Revise your water treatment program to deal with these contaminants. See [Measure 1.8.1](#) about water treatment.

ECONOMICS

SAVINGS POTENTIAL: 3 to 12 percent of fuel cost for the portion of the system that does not return condensate; plus, major reduction of water treatment cost; plus, major reduction of makeup water cost.

COST: Condensate receivers typically cost several thousand dollars. Condensate piping costs from \$10 to \$20 per foot (\$30 to \$60 per meter) in typical sizes. Trenching, if required, costs from \$0.50 to \$2.00 per foot (\$1.50 to \$6.00 per meter). Piping in insulated conduit, if required, costs \$20 to \$40 per foot (\$60 to \$120 per meter). (U.S. installed prices.)

PAYBACK PERIOD: Varies widely. Typically, several years or longer.

TRAPS & TRICKS

DESIGN: Condensate systems are conventional, but don't overlook unusual options, such as steam-powered condensate movers. Design details have a major effect on system performance and life. Be generous with insulation. Minimize heat loss at insulation breaks, such as pipe hangers. The life of the system is determined by the rate of corrosion, both inside and outside the pipe. Keep the pipe and insulation dry. Lay out the pipe with adequate pitch to keep it drained. Use appropriate corrosion protection methods. Select the most corrosion-resistant steel that you can afford. In open condensate systems, arrange vents so they minimize entry of air into the system.

MEASURE 1.8.4.1 Recover the heat from condensate that must be discarded.

RATINGS

New Facilities	Retrofit	O&M
C	C	

The condensate from some equipment may be contaminated, making it undesirable to return it to the boiler. For example, a leak inside a steam heated fuel oil heater would get oil into the boiler, causing a particularly nasty form of waterside fouling. Therefore, this condensate is dumped.

Even so, you can still recover the heat from this condensate. Do this with a heat exchanger, in the usual way. Perhaps add a flash tank, if the condensate is delivered at high pressure. Since the condensate may be dirty, use a heat exchanger that is especially easy to clean.

Combine with Blowdown Heat Recovery

A blowdown heat recovery system (Measure 1.8.3) is a method of extracting heat from blowdown water that is dumped to the sewer. If the condensate is being dumped near the boiler, you may be able to use a common heat exchanger to recover heat from condensate and blowdown.

MEASURE 1.8.4.2 Recover the energy of high-temperature condensate that would be lost by flashing.

RATINGS		
New Facilities	Retrofit	O&M
C	C	C

If condensate returns in a condensate system that works at atmospheric pressure, you will lose a certain percentage of the heat in the form of flash steam. Only liquid water returns to the boiler. Any flash steam that remains by the time the condensate gets back to the receiver is lost through the vent on the receiver. The amount of flash steam depends on the pressure, and hence the temperature, at the discharge of the steam-using equipment.

If steam equipment operates at high temperature, much of the energy of the condensate may be wasted. For example, if steam is used to heat a vat to 330°F, the condensate temperature is also 330°F inside the heating equipment. When the condensate drains to a condensate system operating at atmospheric pressure, approximately half of the condensate flashes into steam. Part of this flash steam condenses in the return pipe, and keeps the condensate warm. The rest is lost through the vent at the condensate receiver.

You can use a variety of techniques to recover the heat of high-temperature condensate, rather than letting it flash away to the atmosphere. These are some approaches:

Spirax Sarco, Inc.

Fig. 1 High-temperature condensate heat recovery In this example, condensate from high-temperature air heating coils is drained to a flash tank, where it produces a large quantity of steam. This diagram illustrates a host of steam system accessories, not all of which are necessary for simpler applications.

- Recover the heat locally. If you have a possible low-temperature heating application near the point where the condensate is discharged, discharge the condensate through a heat exchanger that serves the lower-temperature process. This cools the condensate, so it will return through the atmospheric condensate system without flashing.

If you need the recovered heat in the form of low-pressure steam, use a flash tank.

The main feasibility question is whether the low-temperature application can be synchronized in time with the operation of the equipment that discharges the high-temperature condensate.

- If a low-pressure application exists elsewhere, install a low-pressure steam line and allow the condensate to flash into it. If no low-temperature heat recovery application is available, return the flash steam in a separate line. Drain the high-pressure condensate to a flash tank, which produces low-pressure steam. Figure 1 shows a typical application.

The steam is returned to the boiler plant or elsewhere for use in low-pressure applications, such as feedwater heating. This method is feasible only with large volumes of high-pressure condensate. A small quantity of low-pressure steam would condense before it is able to travel any great distance.

- Use a closed, high-pressure condensate system. There is no inherent reason why a condensate system must operate at atmospheric pressure. The condensate system could operate at the discharge pressure of the steam-using equipment, returning the condensate as high-temperature liquid. A closed system eliminates water loss from vents, and has reduced water treatment requirements.

A high-pressure condensate is restricted to applications that discharge at the same high pressure. It cannot accept condensate from any lower-temperature applications. Also, the higher pressure requirements on pipe, receivers, and other hardware may add significant cost.

Feasibility and Energy Saving Potential

The purpose of this Measure is to recover the energy that would be lost as flash steam in an atmospheric condensate system. The amount of energy that appears as flash steam depends on one factor: the temperature at which the steam is condensed in the steam-using equipment. Here is a table that shows the amount of condensate energy that would be wasted in flash steam at different condensing temperatures:

Steam Pressure (PSI)	Condensate Temperature (°F)	Percent of Condensate Energy in Flash Steam at Atmospheric Pressure	BTU's in Flash Steam, per Pound of Condensate
10	240	14	33
35	280	33	82
88	330	47	143
205	390	60	218
655	500	75	365

This table shows that the amount of condensate heat lost by flashing is modest unless the heating application requires a temperature much higher than the atmospheric boiling point. This limits the range of applications of this Measure.

Furthermore, not all the flash steam is wasted in a conventional condensate system. [Measure 1.8.4](#) explains that flash steam maintains the temperature in the condensate system, replacing heat lost by conduction. This effect is valuable in longer condensate systems.

Providing a Steady Flow of Flash Steam

If you want to keep the flow of high-temperature condensate as steady as possible, use steam traps of the float-and-thermostatic type. Bucket traps pass condensate in intermittent slugs. Thermostatic traps, impulse traps, and disk traps release condensate in pulses, but over shorter intervals. Selecting steam traps involves other issues, which are covered in [Measure 1.10.3](#).

ECONOMICS

SAVINGS POTENTIAL: Typically a few percent of the fuel required to make steam for the heating application.

COST: A typical compact flash tank installation costs several thousand dollars. For the costs of an extended condensate system, see [Measure 1.8.4](#).

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

DESIGN: If you don't do much design of steam equipment, review your steam theory before tackling this job. Make sure that nothing can obstruct the flow of condensate.

MEASURE 1.8.5 Keep vacuum condensate systems operating properly.

RATINGS

New Facilities	Retrofit	O&M
		A

Vacuum condensate systems are sometimes found in facilities that have low-pressure steam heating equipment, such as steam radiators for space heating. The purpose of these systems is poorly understood, so they tend to be neglected. If a vacuum condensate system is defective, the steam-using equipment usually continues to function, but with poor control and reduced efficiency. Fortunately, vacuum condensate systems are simple and they are easy to maintain. If you have one, keep it working properly.

Vacuum condensate systems are similar to conventional atmospheric condensate systems. The piping is laid out in the same manner. The main difference is that the condensate receiver is closed and the entire system is kept below atmospheric pressure by a vacuum pump. The specialized condensate receiver is the item that needs the most attention. Figure 1 shows a typical unit.

Why Vacuum Condensate Systems Are Used

There are three main reasons to operate a condensate system under vacuum. Two of them apply to low-pressure steam heating systems, and one is important for the operation of steam machinery.

■ Improved Control of Low-Pressure Heating Equipment

If the temperature of pure steam inside a heating unit is less than 212°F, its pressure is lower than atmospheric. This has always been a vexing problem in designing heating equipment to operate at temperatures lower than 212°F.

For example, a radiator that is supplied with steam at 230°F is limited to a narrow range of stable temperature control between 230°F and about 210°F. If the steam valve is throttled to the point that the steam pressure falls below atmospheric, air backflows into the radiator from the condensate system, mixing with the steam and reducing the heating capacity of the radiator. This causes the thermostatic control or the human occupant to open the steam valve. Then, the air vent on the radiator gradually purges the air, which restores the radiator's capacity.

This sequence produces a cycle of unstable temperature control. As a result, occupants of buildings with steam radiators tend to keep the radiators turned up to maximum output and they open windows to vent the excess heat. Needless to say, this is a very wasteful way to operate a heating system.

The only practical way to achieve stable temperature control of steam equipment at low temperatures is to use a vacuum condensate system. This allows the steam

within the equipment to condense and drain at a lower temperature. For example, if the pressure in the condensate system is kept 10 PSI below atmospheric pressure, steam can condense and give up its heat down to a temperature of about 162°F.

■ Improved Steam Distribution for Low-Pressure Steam Heating

As we have seen, a vacuum condensate system allows steam heating equipment to operate at a much lower inlet pressure. Thus, there is a larger pressure differential that is available to drive steam through the system. This allows a low-pressure boiler to serve equipment in a relatively long distribution system without excessively large pipes.

Vacuum condensate systems were essential to the steam heating of early highrise buildings that used radiators. The greater pressure differential helped to overcome the gravity head of the steam in the supply pipes.

■ Improved Efficiency of Steam Machinery

Designing steam machinery to exhaust into a vacuum was one of the major advances in steam engine efficiency that occurred in the nineteenth century. In most cases, the machinery is closely coupled to a condenser, and there is no need for a vacuum condensate system to connect them.

How Vacuum Condensate Systems Work

A vacuum condensate system is simply a closed condensate system. In the absence of air, the pressure inside the condensate system is determined solely by the temperature of the water vapor and condensate. The system uses a vacuum pump to extract air and other non-condensing gases out of the condensate system.

The only unusual equipment in a typical vacuum condensate system is a specialized condensate receiver, which includes the vacuum pump and the condensate pump. There is also an air separator that recovers water vapor from the air that is pumped out of the system.

Maintenance

The two main items of maintenance for a vacuum condensate system are minimizing leakage of air into the system and keeping the vacuum pump in good operation. Air leakage reduces the vacuum inside the condensate system, and increases the energy used by the vacuum pump. Vacuum condensate receivers come in a number of designs. They are fairly easy to repair if you follow the manufacturer's instructions.

The condensate receiver has a vacuum gauge. Keep it in good condition and properly calibrated. This gauge is your primary indication of system performance. If the condensate system is spread out, it should have vacuum gauges at one or more extreme locations. These help you to identify air leakage that is distant from the condensate receiver.

Explain It!

One of the main obstacles to maintenance is that the purpose and operation of the system is not obvious

to plant operators. If the system fails, they may not understand that problems with temperature control throughout the building are being caused by a failed vacuum condensate unit located in the basement. Therefore, install a placard near the equipment that states what it is and explains how it works. Be sure to state the vacuum that should be maintained. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: 5 to 50 percent of heating system energy. Failure of the vacuum system causes people to operate steam heating equipment in a wasteful manner.

COST: A few hundred dollars per year, on average.

PAYBACK PERIOD: Immediate. Appropriate maintenance is always cheaper than neglecting it.

TRAPS & TRICKS

EXPLAIN IT: Install a prominent placard at the vacuum pump that identifies the equipment, describes how it works, and states the vacuum that should be maintained in the system. Train new operators about the system.

WESINC

This receiver has a vacuum pump that sucks air and other non-condensing gases out of the system, lowering the pressure to a value that is determined by the condensate temperature. MONITOR PERFORMANCE: Keep checking the operation of the system. Add a column to your plant operating log to record condensate system vacuum. Then, review the logs.

Fuel Oil Systems

A fuel oil system may use energy to pump the oil from the storage tank to the burner, to pressurize the oil for atomization, and to heat the oil for pumping and burning. In most cases, these functions absorb only a small fraction of the boiler plant's energy consumption. Still, improving these functions may provide significant energy savings. The Measures of this Subsection exploit the potential for saving energy and cost in performing these functions.

Fuel oil that is burned in land-based boilers is commonly classified by numbered grades, ranging from Number 1 to Number 6. The properties of fuel oil can vary considerably within a grade. They depend on the location of origin, the refining and "cracking" processes used, and blending that is done by the seller. See [Reference Note 20](#), Fossil Fuels, for an overview of the properties of fossil fuels.

MEASURE 1.9.1 Adjust fuel oil temperature to provide the optimum viscosity for burner efficiency.

RATINGS

New Facilities	Retrofit	O&M
<input type="checkbox"/>	<input type="checkbox"/>	A

Viscosity is the thickness, or resistance to flow, of a liquid. Fuel oil viscosity must stay within a particular range in order for the burners to function properly. This is a potential problem because viscosity varies widely with temperature, and from one batch of oil to another.

The viscosity of heavy oils is adjusted for combustion by heating it in a thermostatically controlled heater that is located in the fuel line ahead of the burners. Figure 1 shows a typical fuel oil heating station. (Heaters may also be installed in storage tanks to preheat the oil to make it easier to pump.)

You should control the viscosity of your heavy fuel oils, typically, Number 4 and heavier. Lighter oils have viscosities that are low enough at normal storage temperatures to atomize properly without preheating. There are exceptions. Some burners for Number 2 oil have heaters as an aid for cold starting.

You can install controls that automatically adjust fuel oil viscosity, which eliminates the need for manual testing or adjustment. See [Measure 1.9.1.1](#), next, about installing this equipment.

Why Fuel Viscosity Matters

If the viscosity of fuel oil is too high, the burner cannot atomize it properly. This causes incomplete combustion and sooting. Trying to compensate for the incomplete combustion by increasing the amount of combustion air would significantly reduce the combustion efficiency of the boiler. Poor atomization causes a longer flame length because the fuel is thrown farther into the boiler before it is burned. In extreme cases, the flame may reach the inside surfaces of the boiler, fouling the surfaces and quenching the flame.

If fuel viscosity is too low, the fuel components that are more volatile may separate from the less volatile components within the burner and ignite prematurely. This disrupts combustion of the remaining fuel and fouls the burner. In the worst case, the flame can be blown out, creating an explosion hazard as raw fuel enters a hot firebox. Excessive oil temperature increases the risk of a boiler room fire in the event that a fuel line ruptures.

Excessive oil heating also consumes additional energy in the fuel oil heater. Most of this heat is recovered inside the boiler. If the energy source for heating is more expensive than boiler fuel (for example, if the boiler uses an electric fuel heater), excessive heating wastes money.

Expect Fuel Oil Viscosity to Vary

Heating fuel oil to a particular temperature maintains proper viscosity if the characteristics of the fuel remain constant. However, viscosity can vary dramatically within a given grade of fuel. For example, different Number 5 fuel oils may vary in viscosity from 150 to

WESINC

Fig. 1 Heater for heavy fuel oil Keep the temperature set to provide best burner efficiency.

800 SSU units at the standard test temperature. (Burners for heavy fuel are designed to operate with a fuel viscosity close to 150 SSU units.) Furthermore, if fuel is stored for a long time, viscosity may change with time within a given batch as the lighter components of the oil float toward the top of the storage tank.

Finding the Optimum Viscosity by Combustion Efficiency Testing

In principle, the most accurate way to optimize fuel oil viscosity is to adjust the fuel oil temperature until the combustion efficiency of the boiler peaks, while providing the correct amount of excess air. Combustion efficiency test methods are explained in [Subsection 1.2](#), and the significance of excess air is explained in [Subsection 1.3](#).

There is a tricky aspect to this adjustment. The combustion efficiency test is not able to account for unburned fuel. Improving atomization slightly increases the amount of fuel that is burned, which increases the stack temperature. The combustion efficiency test interprets the higher stack temperature as a reduction in efficiency. To correct for this, keep the carbon monoxide or smoke level constant as you perform the tests. Combustion efficiency testing also reveals any loss of efficiency that may be occurring for other reasons.

Rapid-reading test equipment makes this adjustment less tedious. See [Measure 1.2.1](#) for guidance in selecting of boiler efficiency test equipment.

Alternative: Measure the Fuel Oil Viscosity

An alternative way to adjust for differences in fuel batches is to measure the viscosity of the new batch of fuel. A variety of fairly simple and inexpensive methods are available for testing viscosity. The simplest is just a container with a calibrated orifice. Calculate the viscosity by timing how long it takes for a sample of oil to drain out of the container. Another method measures the friction drag on a disk spinning in a sample of oil. Viscosity testing equipment is available from chemical supply houses and boiler equipment suppliers.

To achieve meaningful comparisons, conduct all viscosity tests at the same temperature. This requires a thermostatically controlled heater that consistently heats fuel oil samples within a tolerance of a few degrees. Chemical supply houses have expensive heaters for this purpose. A fondue pot with a good thermometer serves just as well.

■ Units of Viscosity

A system of viscosity units used specifically with petroleum is Saybolt Seconds. This system is based on the number of seconds required for a sample of oil to drain out of a standardized cup. To complicate matters, there are two different Saybolt systems of measurement. Saybolt Seconds Universal (SSU) is used with lighter oils, and Saybolt Seconds Furol (SSF) is used with

heavier oils. SSU is measured at 100°F, and SSF normally is measured at 122°F.

The metric unit of viscosity is the “poise.” Another parameter called “kinematic viscosity” is measured by a unit called the “stoke.” As conversion to the metric system becomes universal, you may encounter these units in fuel oil specifications. Regardless of the units that are used, the key point is that the viscosity of the fuel must match the viscosity requirement of the burners and pumps.

How Often to Adjust Viscosity

Adjust fuel oil viscosity any time that a significant change in fuel properties may occur. Viscosity and other properties vary depending on the origin of the oil, and on the refining and “cracking” processes that it undergoes. Even if the same supplier is used, changes in blending by the supplier may significantly change viscosity. For example, fuel suppliers may change the blending of heavy oil during cold weather to provide easier pumping.

The safest practice is to adjust viscosity any time a new batch of fuel is started. This includes fuel that has sat undisturbed on the premises for a long period of time, for example, from a previous heating season. Stagnant fuel in a tank may stratify into layers of different viscosity. To compensate for stratification, you would need to adjust the fuel oil temperature as the fuel level is drawn down. To avoid this problem, consider preventing stratification with the methods recommended by [Measure 1.9.3](#).

Batches of fuel oil may differ in a number of other important characteristics. Differences in energy content require adjusting the air-fuel ratio, which is covered in [Subsection 1.3](#). Various adverse characteristics of fuel oil can be treated with additives and other methods, which are covered by [Measure 1.9.3](#).

ECONOMICS

SAVINGS POTENTIAL: 0.1 to 1.0 percent of boiler fuel cost.

COST: Cup-type viscosity measurement devices are available for less than \$100. Other types of viscosity test equipment can be much more expensive, but they are not necessary for this purpose. See [Measure 1.2.1](#) for the costs of efficiency testing.

PAYBACK PERIOD: Short, in boiler plants that burn a substantial amount of heavy fuel oil.

TRAPS & TRICKS

TRAINING AND DILIGENCE: Viscosity testing is not complicated, but it is a kind of procedure that tends to be forgotten. Use the boiler operating log to tell operators when to adjust for viscosity, for example, “when changing fuel tanks.”

You can install controls that automatically measure and adjust fuel oil viscosity. This eliminates the need for manually readjusting the fuel oil heater temperature. Figure 1 shows a typical controller.

Automatic viscosity control is built around a viscosity sensor that is installed on the discharge side of the fuel oil heater. The viscosity measurement generates a standard pneumatic, electric, or electronic signal that is used to reset the temperature of the fuel oil heater.

Different types of viscosity sensors are available. The choice depends on the range of oil viscosities, whether the sensor is subject to high pressure, and whether the sensor is to be installed in a tank or pipe.

MEASURE 1.9.2 Use the most economical heat source for fuel oil heating.

Heavy oil requires heating in order to atomize and burn properly. Heating may also be needed to allow heavy oil to be pumped from the storage tank. Electricity is often used as a source of heating energy because electric fuel oil heaters are inexpensive and easy to install. Also, electric heating allows starting up a cold plant. However, if the fuel used by the boiler is significantly less expensive than electricity, it may be worthwhile to use steam or hot water for fuel oil heating.

In calculating the cost of heating with steam, consider the boiler efficiency. Also, note that condensate from fuel oil heaters usually is dumped. This is to avoid the danger of contaminating the boiler if a leak develops inside the fuel oil heater. The most economical situation is using waste steam to heat fuel oil, if enough waste steam is available.

Consider each of the three main portions of the fuel oil system:

- **storage tank heating.** This may use a substantial amount of energy if the storage tank is located above ground. The storage tank should have a hot well, which is an isolated area surrounding the discharge point that can be heated without heating all the fuel in the tank. Tank heating is a good application for steam or hot water heating, including condensate and flash steam.
- **transfer piping** is heated typically with steam tracing lines. If the piping is exposed to external conditions, the steam requirement varies widely depending on the weather. This is not a good application for waste heat unless the source is available continuously.
- **pre-combustion heating**, immediately ahead of the burner, can easily be accomplished with a steam heat exchanger.

Using Waste Heat to Heat Fuel Oil

Fuel oil heating is an attractive application for waste heat because it allows recovery of heat at low temperature. Larger boiler plants often have a considerable amount of otherwise useless low-temperature heat, such as the heat contained in blowdown water and condensate flash steam, the exhaust steam from auxiliary equipment drive turbines, etc. Another advantage of this application is that the need for fuel oil heating and the availability of waste heat both tend to be proportional to boiler load, so that availability of heat is synchronized with need.

If you have an excess of waste steam for heating the storage tank, route the steam to the hot well first. Let any remaining steam heat the bottom of the tank

through separate coils. Keeping the oil warm reduces stratification and sludge formation. See [Measure 1.9.3](#) for details.

Back up the waste heat source with a primary source of energy, such as a low-pressure steam main. If waste heat is used to supplement another heat source, be sure to install a placard at the relevant valves or controls so that operators understand the arrangement. Otherwise, operators may valve off the waste heat source and rely solely on the back-up source. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

MEASURE 1.9.3 Use fuel oil additives to improve combustion efficiency and/or improve other fuel oil properties.

RATINGS

New Facilities	Retrofit	O&M
		D

A wide variety of fuel oil additives have been marketed over the years. Some of these provide a real benefit, some are harmful, and some have effects that are minimal or unknown. Most additives are marketed to correct problems associated with heavy oil. Light oil is generally free of troublesome conditions that require corrective action.

Figure 1 shows a fuel oil additive being injected into a boiler that burns heavy oil.

Alleged Benefits and Mechanisms of Action

Some fuel oil additives claim to correct specific conditions, while others claim a range of benefits. Here are some of the benefits claimed by various fuel oil additives.

■ **Improved Atomization**

Good burners are capable of burning fuel virtually completely. However, all burners require some excess air to achieve complete combustion because they cannot mix the air and fuel in perfect proportions. Some fuel oil additives claim to improve atomization, on the theory that finer atomization allows combustion to be completed closer to the burner, reducing the requirement for excess air. Whether this is true in practice is questionable. These are two ways that different additives claim to improve atomization:

- **reducing surface tension.** Some additives reduce the surface tension of the oil, allowing it to break up more easily.
- **steam formation in the oil droplets.** The oldest additive claimed to improve combustion is water. The theory is that water added to the fuel explodes into steam in the heat of the firebox, breaking apart large droplets of oil. The purpose of the additive is to hold the water in emulsion in the fuel oil.

In order for this to work in theory, the microscopic water droplets in the oil must be much smaller than the oil droplets themselves. The quantity of emulsifying agent is inversely proportional to the water droplet size, which means a lot of emulsifying agent is needed if the droplets are to be small. If less than the required amount of emulsifier is added, the water droplets are too large to be useful.

(Emulsifiers work by encapsulating water droplets in a chemical film. The volume of the droplet drops in proportion to the third power of its radius, but the surface area drops only in proportion to the second power, so encapsulating a given quantity of water in smaller droplets requires much more emulsifier.)

SUMMARY

Fuel oil additives range from useful to harmful, and some are simply useless. Understand the properties of any additive you consider. If an additive claims to solve a boiler problem, you may be able to solve the problem better in other ways.

■ **Enhancing Combustion by Catalytic Action**

Heavy fuel oil consists of large molecules. These go through a series of chemical reactions in the process of being reduced to carbon dioxide and water. Combustion catalysts hasten the decomposition by reducing the input energy required for each of the intermediate reactions. Catalysts typically are metals or metal compounds.

Modern burners that are properly matched to the combustion chamber are capable of almost completely burning fuel, so catalysts cannot significantly improve burning efficiency. However, quicker breakdown of the fuel might reduce the need for excess air with some burners.

■ **Reduced Fireside Fouling**

Improving the atomization of fuel prevents the formation of large particles of combustion products that cause smoke and adhere to boiler tubes. However, a properly operating burner does not form excessively large particles of fuel. Therefore, additives cannot improve this aspect of combustion.

Additives may prevent fouling by the non-combustible fuel contaminants that are common in heavy oil. For example, it is believed that iron, sodium, and vanadium compounds that deposit on boiler tubes act as catalysts for forming corrosive compounds from the sulfur in fuel. Some additives change the melting temperature of the metal compounds so that they do not adhere to the tube surfaces. Other additives soften the fouling so that it can be removed more easily.

Abnormal fireside deposits may occur for a variety of reasons that cannot be corrected by fuel oil additives. For this reason, you should diagnose the cause of fouling before resorting to additives.

■ Preventing Fuel System Corrosion by Fuel Acids

Fuel oil contains a variety of contaminants that either are acidic or that form acids in combination with water. The acids cause corrosion throughout the fuel oil system, especially in storage tanks. Additives may protect against acids by:

- *neutralizing the acids*, with alkaline substances.
- *forming a protective film at the metal surface*. A number of different mechanisms of action are claimed.

■ Eliminating Free Water in the Fuel

Water in fuel causes a variety of problems. It corrodes the system directly, and it combines with sulfur and other matter in the fuel to form corrosive acids. It is also a factor in the formation of sludge in tanks. In large amounts, it may interfere with combustion. Additives use two opposite approaches to dealing with water:

- *keeping the water in the fuel emulsified* to minimize its contact with metal surfaces. This is done with a variety of agents that act as emulsifiers.
- *causing water to settle out*. This is done with “demulsifying” agents. If you add a demulsifier, you must promptly pump out the water that separates, or it will corrode the bottom of the tank.

■ Reducing Sludge Formation

Sludge forms in the bottom of fuel tanks. The sludge is a combination of impurities in the fuel oil, corrosion residue, heavy fractions that settle out of the oil, and chemical changes in the oil that cause semi-solid compounds to form. Water plays a part in chemical reactions that form sludge. Additives may inhibit sludge formation by these processes:

- *keeping particles from clumping together*. “Dispersants” are the class of additives that perform this function.
- *inhibiting sludge-forming chemical reactions*. Different reactions occur in different circumstances, so the additive must be tailored to the fuel conditions.
- *keeping free water out of the fuel*. Water is involved in forming sludge. The methods of getting rid of water that were mentioned previously also reduce this cause of sludge.

■ Preventing Stratification in Storage

Heavy oil separates into fractions of different weight if it sits for a long time, and the lighter fractions rise above the heavier ones. The extent of this stratification depends on the oil composition, storage temperature, and mostly, the length of time that the oil has been stagnant. The primary means of reducing stratification are rotation of the oil stock and recirculation. Some additives may reduce stratification, especially those intended to reduce sludge formation.

WESINC

Fig. 1 Fuel oil additive being injected into a boiler's fuel oil system This is a test being conducted to determine the actual improvement in performance.

Be Skeptical

The effectiveness of fuel oil additives is controversial. A particular fuel oil additive may be valuable, or useless, or harmful. Be clear about diagnosing any conditions that an additive is supposed to cure, or else the additive may correct a problem that does not exist in your plant. Judging the merits of a fuel oil additive may require outside expertise. Do not use any additive without the advice of an unbiased expert who has the ability to evaluate the claimed benefits.

Additive vendors may be secretive about the composition of their products. It is reasonable to suspect that this is because the contents are ordinary materials being sold at a high markup. You can determine the contents of an additive by sending it to a laboratory for chemical analysis, but this does not answer the question of whether the additive will actually provide a benefit in your particular boiler.

A boiler efficiency test will tell you whether there is room for improving efficiency. No additive can improve efficiency beyond the heat exchange characteristics of the boiler. ([Measure 1.2.1](#) covers efficiency testing.) If the additive is proposed to correct a maintenance or fuel storage problem, consult an expert in boiler plant operations to find the best solution, which may or may not involve fuel additives.

Be suspicious of tests that claim to demonstrate the effectiveness of an additive. Even if an objective observer witnesses a test, any measured improvement

of efficiency may be mostly the result of cleaning and adjusting the boiler prior to the test. The only reliable way to test efficiency improvement claims is to rig a test setup that allows the boiler to switch back and forth between treated and untreated fuel.

It is difficult to verify a claim that a particular additive improves maintenance. A long time must pass for an effect to be noticeable. During this time, other conditions related to the problem may change.

Alternatives to Fuel Additives

Fuel oil additives almost always address problems that can be corrected in other ways. The most direct solution to a fuel oil problem is to purchase fuel oil that has better properties, e.g., less sulfur, less water, refining by a process that has less tendency to form sludge, etc. An informed purchaser can avoid most fuel oil problems at the outset by specifying the fuel properly and checking it when it arrives.

Recirculation prevents stratification and probably reduces sludge formation and water settling.

Another approach is to keep heavy fuel warmer in storage. This reduces the solidification of heavier fractions, prevents formation of wax crystals that interfere with atomization, reduces condensation of water, and reduces sludge formation. If the bulk of the oil in a tank is kept heated, consider improving the tank

insulation to save energy. Also, see [Measure 1.9.2](#) about using waste heat to keep the fuel oil warmed.

ECONOMICS

SAVINGS POTENTIAL: Additives can improve efficiency less than one percent in a modern, properly operating boiler. If a condition is causing a larger efficiency loss than this, fix the underlying problem. In the case of additives claimed to reduce maintenance problems, calculate the savings on an individual basis.

COST AND PAYBACK PERIOD: These vary too widely to allow a general estimate.

TRAPS & TRICKS

SELECTING THE ADDITIVE: Even legitimate additives can provide only small improvements in boiler operation, so it is difficult to measure the actual benefit provided. Discuss any additives you are considering with boiler operators who have used them. But, be skeptical. People tend to believe in bogus cures. If possible, arrange for an objective test in one of your boilers.

USAGE: If an additive is appropriate for your plant, it must be used properly to be effective and economical. Provide clear instructions to operators. Keep the injection equipment working properly. Schedule periodic checks to verify that the additive is having the intended effect, and no adverse effects.

MEASURE 1.10.1 Monitor boiler system water loss.

RATINGS

New Facilities	Retrofit	O&M

Steam and water carry the energy of the boiler system. If the system leaks, the energy is lost along with the steam and water. Leakage is worst in systems that are long, in poor condition, and operating at higher pressures.

Monitoring leakage is the first step in controlling it. You can track leakage easily by installing a water meter on the makeup water line. In most systems, the amount of makeup water equals the loss, including losses both inside and outside the boiler plant. Recording makeup water is the only reliable method you have for detecting and measuring leakage that is invisible, such as from underground distribution pipe.

The Costs of Water Loss

Measuring water loss is important primarily because it indicates the amount of energy by lost from the system. For example, loss of one pound of water in the form of steam wastes about 1,000 BTU. Water loss also incurs the cost of treating makeup water, along with the cost of the replacement water itself.

Condensate loss wastes much less energy than steam loss, for a given weight of water that is lost. The makeup water reading itself cannot distinguish between the two. If the entire steam system has condensate return, it is likely that most water loss is in the form of steam, because steam is under pressure. But, this is not true of all steam systems. A defective condensate system can waste a large amount of water. See [Measure 1.8.5](#) for improving condensate return.

Record Water Loss Patterns to Locate Leaks

Record the amount of makeup water on the boiler plant operating log. A time plot of makeup water consumption, at hourly or shorter intervals, may provide valuable clues about the causes of water loss. See [Measure 1.10.2](#) for more about this.

Makeup water readings at the boiler plant cannot distinguish steam or water that is consumed in processes, such as steam laundry presses, aircraft catapults, etc. Also, there may be portions of the distribution system that dump condensate, rather than returning it to the boiler plant. You can distinguish these steam losses by

installing steam meters at the individual items of equipment, or on the portions of the distribution system that do not return condensate. (See [Measure 1.8.4](#) about returning condensate to the boiler plant.)

Act on the Information

Analyzing water loss is a useless effort unless you take action to reduce it. [Measure 1.10.2](#) spells out the appropriate corrective action.

ECONOMICS

SAVINGS POTENTIAL: Up to 20 percent of fuel cost; plus, reduced water treatment cost; plus, reduced makeup water cost. Leakage varies widely, depending on the characteristics of the system. Credit the savings to the specific actions that you take to correct the leakage.

COST: Minimal, if a makeup water meter is already installed. Installing a water meter typically costs several hundred dollars.

PAYBACK PERIOD: Cannot be stated in terms of this activity alone.

TRAPS & TRICKS

DILIGENCE: This kind of good plant management practice tends to be neglected. Include a column for makeup water consumption in the boiler plant operating log. Schedule periodic analysis of water consumption in your maintenance calendar. If monitoring indicates significant water loss, act on the information.

Monitor system water loss as recommended in [Measure 1.10.1](#). If your water loss is significant, search for leaks on a regular schedule. Repair visible leaks as soon as they appear. Individual leaks grow rapidly. Once a leak starts, the flow of steam or water erodes the passage, enlarging it.

In some plants, fixing leaks may be neglected because the task looks overwhelming. A fog of steam leaking from pipe joints, valve packings, pump glands, and vents gives the false impression that leaks are everywhere. Not every situation is as bad as the one shown in Figure 1, but steam leaks always waste significant amounts of energy. The solution is to start repairs one leak at a time, just like picking up trash along a road. In less time than you expect, the leaks are fixed and losses are greatly reduced.

Potential Savings

Leakage from the distribution system continues as long as the system is under pressure. Furthermore, the rate of leakage is almost constant, regardless of the heating load, because the system pressure is what forces the steam and water out of the system. Because the leakage is continuous, even small leaks waste a considerable amount of steam or hot water. In facilities that have extensive hydronic or steam distribution, serious leakage may waste a large fraction of the total energy input. The costs incurred by leakage include:

- the energy consumed to heat the lost steam or water

Analyze Makeup Water as the First Step in Finding Leaks

[Measure 1.10.1](#) recommends monitoring your makeup water rate. This tells you when you need to check for leaks, and it may also tell you the general areas where leaks are occurring. A time plot of makeup water consumption at hourly, daily, and monthly

Fig. 1 Major steam leaks This government facility was wasting a lot of taxpayers' money by letting steam escape from the boiler plant and the distribution system.

WESINC

intervals may provide strong evidence about the causes of water loss.

As we said before, water loss from the distribution system tends to remain constant, as long as the pressure in the system remains constant. This is an approximation. The downstream pressure in a long distribution system changes with load because of flow resistance. Also, you may want to modulate the system pressure to follow the load to reduce water and heat loss. See [Measure 1.1.5](#) for more about this.

An increase in water loss at certain times indicates leakage or water consumption by certain equipment, or leakage from parts of the distribution system that are used only at certain times. For example, if you have laundry presses, examine your makeup water records to see how much the water loss increases during the hours when the presses are operating to estimate the amount of water they are consuming. Similarly, if water loss increases during cold weather, suspect leakage from space heating equipment.

Don't bother trying to estimate the loss from individual steam leaks that you can see. Fix all leaks, regardless of size. Little leaks become big leaks.

Leaks in Pipe Systems

Expect all sealing materials used in pipe systems to develop leaks eventually, and to require occasional replacement. Sealing materials fail because of hardening, loss of adhesion, cracking, and corrosion. Seals around valves and other moving components also wear mechanically. The most common sealing elements are gaskets and valve packings.

Leakage is hastened by thermal expansion and mechanical motion, which tend to concentrate stresses at the joints where the sealing materials are used. A system design that fails to allow for thermal expansion and ground motion invites leakage at joints. The worst design mistake is to allow bending stresses to occur at joints.

As the system ages, the pipe itself starts to leak. This is most likely to occur first at welds where flanges and fittings are attached, and may also occur along the longitudinal weld of the pipe itself.

Older steam pipe may develop pinhole leaks. These start with pits formed inside the pipe by oxygen corrosion resulting from inadequate water treatment. Pinhole leaks concentrate at localized flaws in the steel. If pinhole leaks start to proliferate, the piping system is probably ready to be scrapped.

Condensate pipe deteriorates most seriously from carbonic acid corrosion. This tends to uniformly eat away the thickness of the metal that is in contact with the liquid condensate. Therefore, the bottom of condensate pipe usually leaks first.

The outside of pipe may suffer massive corrosion if it remains wet. This is a major problem of buried pipe. Pipe in this condition cannot be repaired economically, and it must be replaced sooner or later. Repairs can be very expensive, in the multi-million dollar range for large systems. To place this in perspective, serious leakage in a large system may cost millions of dollar in energy in a few years.

If you cannot survey your pipe systems adequately yourself, consider hiring pipe surveying services. Specialists who do this work have the latest equipment for detecting leaks, eliminating the need for you to purchase the equipment and learn how to use it. As with all specialized services, check references thoroughly before signing the contract.

■ How to Find Leaks in Above-Ground Pipe Systems

Leaks are generally easy to find in parts of the system that are visible. This includes equipment in the boiler house, in steam tunnels, in pipe chases, in attics, etc. The main part of the job is tracing all the pipe.

In hot water distribution systems, leaks are usually easy to find as drips. Steam leaks may create a visible plume, but not always. Try to search for steam leaks on a humid day, as they are more visible then. In climates where the air is dry, small steam leaks may be difficult to find.

You can listen for steam leaks, but this works only in a quiet environment, or when you are very close to the leak.

You can also detect leaks by feel, passing a hand around areas where leaks may occur, such as gaskets and packings. Do not feel too closely, as this risks burns from the steam itself and from hot surfaces. Do not use this technique in high-pressure plants, where leaking steam can travel far and burn severely.

■ How to Find Leaks in Buried Pipe Systems

Underground conditions in many locations promote pipe deterioration, so buried distribution systems typically account for most steam and water loss.

Leaks may be difficult to find in buried pipe. You may be able to find them from visual clues. In cold weather, leakage may cause faster snow melting above the location of the leak. In warmer weather, the water leaking from a pipeline may stimulate the growth of vegetation above the leak.

You can use infrared thermal scanners to detect leaks in buried pipe. They work by detecting small temperature differences on surfaces. The escaping steam or water heats the material at the point of leakage, and this temperature change is detected by the scanner. Infrared sensing equipment is not reliable for detecting escaping steam or water itself. This is because gases and liquids do not radiate strongly in the infrared

spectrum. Infrared scanning works best in cold weather, at night. See [Reference Note 15](#), Infrared Thermal Scanning, for more about this method.

Abnormal surface warming over a distribution system may be caused by leakage or by defective insulation. Defective insulation usually appears on an infrared scan as an area of broad warming, whereas leakage shows up as a localized hot spot. To resolve the question, you may have to dig into the hot spot. Check insulation condition at the same time you check for leaks. See [Measure 1.11.1](#) about improving insulation condition.

Leaks in buried low-temperature hot water systems (and in buried chilled water systems) may not be detectable from changes in surface temperature.

If you find bad pipe, determine whether the pipe deterioration is local or widespread. The most reliable inspection procedure is to remove a section of pipe in a part of the system where leakage occurs, strip the insulation off the pipe, and examine the exterior and interior surfaces in detail. If leakage appears to be a possible major problem, examine sections at different locations in the distribution system. If you suspect severe corrosion, sacrifice a length of pipe for sectioning and metallurgical examination. Specialists in this type of work can diagnose the cause of the corrosion by inspecting such samples.

You can inspect the interior of pipe with a specialized video camera that you insert into the pipe anywhere you can create an opening. However, this method does not tell you the condition of the pipe's outside surface.

■ Don't Skimp When Repairing Joints

Leaks occur most commonly at pipe joints, and these are the easiest leaks to repair. However, these repairs do require some care. Discard all the old sealing materials and components, such as gaskets. These materials are not intended to be reused, and they will fail quickly if they are. Remember that energy loss and labor, not expendable materials, are your major cost items in repairing leaks.

Refinish the metal surfaces that contact the sealing materials. You can buff out mild erosion with abrasive cloth. More severe erosion requires cutting or grinding the metal surface. Be sure to finish the metal surface flat, and make the surfaces of adjacent pipe or fittings parallel. If the sealing surface is badly worn, try to take the pipe section to a machine shop. If you have to do major refinishing in place, make sure that you have the proper tools to do the job properly.

If you cannot stop a valve packing leak by tightening the packing nut moderately, replace the entire packing. In such cases, consider removing the valve and taking it to the shop for a complete overhaul of the packing, stem, disk, seat, and gasket surfaces.

Leakage from Steam Vents

There is a tendency to overlook dramatic leaks, such as a blowing vent on a piece of equipment. People may believe that anything so obvious is intentional, so major leaks can persist for years. In fact, there is usually no valid reason to discharge visible amounts of steam. The only exceptions are industrial processes in which the steam is necessarily lost to the atmosphere.

Steam systems have vents for removing air and other gases at certain points in the system, such as at deaerating feedwater heaters and condensate receivers. A large amount of steam can be lost from such vents. If a vent is blowing heavily, there is usually a defect, such as a leaking steam trap. You may be able to save venting steam by installing a vent condenser (see [Measure 1.10.5](#)).

Internal Boiler Leakage

Major steam leaks can occur inside boilers, where they are invisible. Internal leaks commonly occur at pressure fitted joints. In firetube boilers, leaks occur where tubes enter tube sheets. In watertube boilers, leaks occur where tubes enter upper and lower drums. In cast iron sectional boilers, leaks occur between sections.

Tubes can develop leaks in a number of ways. Corrosion causes pinhole leaks. A weakness in a welded seam that is aggravated by corrosion can result in a lengthwise split that can quickly develop into a major leak. Accumulation of scale can overheat a tube, causing it to weaken or burn. The result may be a progressive leak or an abrupt catastrophic failure.

Find internal leaks by inspecting the boiler when it is cold. An exceptionally large internal leak in an operating boiler may be revealed by a small drop in stack temperature. An operator would have to be exceptionally alert to catch this.

You can often correct small leaks at tube sheets and drums by re-expanding the tube end into the tube sheet or drum. More severe leaks require removing tubes and refinishing the holes in the tube sheet or drum. Any defect in the tube itself requires the tube to be replaced.

Losses in Condensate Return

Not just steam leaks out of a steam system. Do not overlook the possibility of leaks in the condensate return system. Leakage of steam may be visible and noisy, while serious leakage of condensate may occur quietly.

The worst case of condensate loss occurs when there is no condensate return system. See [Measures 1.8.4 ff](#) about this.

Steam Trap Leakage

Leakage of steam traps is a cause of invisible steam loss that requires specialized corrective measures. Steam traps are covered in [Measures 1.10.3](#) and [1.10.4 ff](#).

ECONOMICS

SAVINGS POTENTIAL: 0.1 to 50 percent of total system energy consumption. Larger losses occur in systems with extensive distribution systems, and in systems that operate at higher pressures, and in systems that have not been well maintained.

COST: Labor is the major cost for routine leak repair. For fixing indoor leaks, labor cost depends on whether plant operators have spare time to perform maintenance. Materials for repairing external leaks typically consist of inexpensive gaskets and packings. Repairing leaks in buried pipe involves major digging costs.

The cost of extensive pipe replacement is high, especially if the pipe is buried.

See [Reference Note 15](#), *Infrared Thermal Scanning*, for the cost of thermal scanning equipment and services.

Repairing internal boiler leaks typically costs hundreds or thousands of dollars.

PAYBACK PERIOD: Short, if only minor repairs are needed. Several years or longer, if extensive pipe replacement is needed. Eliminating leaks generally costs less than neglecting them, until a point is reached at which major pipe replacement is required.

TRAPS & TRICKS

DILIGENCE: It is easy to forget this, or to let other concerns take priority. Do a leakage survey whenever the makeup water rate indicates a problem.

WORKMANSHIP: Workmanship makes a big difference in how long repairs last. Leak repair is tedious, which invites sloppy work, such as failure to refinish sealing surfaces adequately. Do it right the first time.

MEASURE 1.10.3 Use the most efficient type of steam trap for each application.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Steam traps are vital components of a steam system. If they do not perform properly, they can be a source of major energy and water loss. Normal wear of traps is a major cause of steam leakage. Steam traps can fail in a way that effectively creates a hole in the steam system. Using the wrong type of trap can cause improper operation of the steam-using equipment, damage piping, and destroy the trap itself. Loss of steam through a trap is almost invisible, because the steam disappears into the condensate system.

Make sure that each steam trap is individually matched to its application in terms of type and size. About half a dozen different types of steam traps are in common use today. The variety of types results from differences in application requirements and differences in cost. Trap types differ in reliability and time-between-overhaul. Some types of steam traps have higher average leakage than others. The cost of the trap should be a lesser factor in selecting one type of trap over another, because the trap cost is dwarfed by the cost of wasted steam.

In existing systems, you may find traps that are not the best type for the application. Proper trap application requires a certain amount of specialized knowledge, so traps may have been installed without considering all the relevant factors. Also, facility operators tend to favor trap types that are cheap and compact.

This Measure gives you an introduction to steam trap selection, with an emphasis on selecting traps that have the lowest average leakage over the life of the plant. Supplement this with manufacturers' literature for the specific types of traps that apply to your facility.

Once you understand trap selection, survey all the steam traps in your facility to determine whether each is the appropriate type and capacity for its application.

Finally, replace all inappropriate traps with the proper types and capacities.

This Measure deals with selecting steam traps and replacing inappropriate or less efficient types. See [Measures 1.10.4 ff](#) for trap maintenance.

The Two Applications of Steam Traps

Steam traps are devices that block the passage of steam while allowing liquid condensate to pass. Traps are used in two general applications, which are illustrated in Figure 1:

- *on the outlets of steam-using equipment*, to keep steam confined inside the equipment until it has condensed inside the equipment until it has

Armstrong International, Inc.

Fig. 1 The two functions of steam traps One is to keep steam inside heating equipment until it has condensed and given up its latent heat. The other is to drain condensed water from steam lines before it damages the system.

given up its heat, i.e., to keep the steam from blowing straight through the equipment

- **on steam lines**, to remove condensate that forms in the pipe. Condensate forms because of heat loss from the pipe. If allowed to accumulate, slugs of condensate propelled by steam pressure may accumulate enough kinetic energy to destroy valves, piping, and equipment. Traps used to drain steam lines are called “drip traps.”

In many steam systems, the traps also serve as an important means of removing air and other non-condensable gases from the system. If these gases are not removed, they may block the flow of steam. For example, in a steam coil with many circuits, air that accumulates in the coil causes most of the steam to be routed through a few of the circuits, rendering the rest of the coil useless. Also, non-condensable gases are the source of corrosion in steam pipe and equipment. Oxygen corrodes steel directly, while carbon dioxide forms carbonic acid, which causes acid corrosion.

To minimize these problems, most applications require steam traps to have the ability to remove, or “vent,” non-condensable gases (i.e., gases other than steam). Traps need a large venting capacity to clear air out of the steam system after a period of shutdown. Traps need a smaller venting capacity to vent the system continuously while it is in operation, to remove gases that are carried in the steam.

Steam traps usually vent non-condensable gases into the condensate system. The location of the traps may not allow complete venting of the system. Parts of a steam system may trap air by letting it become stagnant, so it is not carried along by steam flow. Separate air vents are installed in these parts of the system. These vents typically discharge air directly to the atmosphere, rather than to the condensate system.

How Steam Trap Leakage Wastes Energy

Most of the useful energy of steam is in the form of latent heat, which is the heat required to turn liquid water into steam inside the boiler. For a steam system to operate efficiently, all the steam must condense inside the steam-using equipment, so that the latent heat is transferred to the heating application. If steam leaks through a trap, most of the energy of the leaked steam is wasted.

Little or none of this energy is recovered on the way back through the condensate system. Steam that leaks through a trap into the condensate system is condensed by conductive heat loss through the pipes of the condensate system. In an atmospheric or vacuum condensate system, any steam leakage that is not condensed in the pipes is blown out of the condensate system vents, which are typically located at the condensate receiver.

Causes of Steam Trap Leakage

A large part of this Measure deals with the leakage characteristics of different types of steam traps. Before getting into the individual types, it is worth noting that all steam traps may leak for these reasons:

- **inherent leakage of the trap design.** In principle, all types of traps, except orifice traps, are capable of blocking steam completely. However, all traps will leak eventually. Field experience suggests that some trap types tend to operate longer before developing leakage. Also, some types of traps will leak if they are not installed in a certain way, whereas the method of installation does not cause leakage in other types.
- **sticking in an open or partially open position.** All types of traps are subject to complete failure as a result of fouling, corrosion, or mechanical failure. Failure in the open position is the equivalent of having a hole in the system the size of the trap’s internal discharge passages. Failure in the closed position causes steam equipment to cease operating because it cannot discharge condensate. Failure of drip traps in the closed position is dangerous because slugs of condensate remain in steam lines. Some traps tend to fail in an open position, while others tend to fail in a closed position. This tendency may also be influenced by the characteristics of the steam system.
- **wear and fouling of sealing surfaces.** All types of steam traps (except orifice traps) block the flow of steam by metal-to-metal contact of sealing surfaces. Even if a trap continues to close properly, it will eventually develop leakage because of steam abrasion, fouling, and hammering of the sealing surfaces. Once leakage begins, it typically progresses rapidly. Some types and models of traps develop this type of leakage more quickly than others.

Steam loss also depends on the size of traps. Larger traps can waste more steam, and they cost more to replace. Survey all your traps, large and small, to make sure that each is appropriate for its application.

Steam Trap Types and Leakage Characteristics

The following is an introduction to the types of steam traps that are presently in common use, with emphasis on their steam leakage characteristics. The trap types are covered in approximate order of condensate draining capacity.

This comparison of efficiency characteristics requires broad generalizations. Information on trap leakage provided by manufacturers is sketchy and may lack credibility. One problem is that all types of traps can leak seriously under certain conditions, so any comparison depends on assumptions about the application. The major trap manufacturers tend to be

Fig. 2 How float-and-thermostatic (F&T) traps work

Armstrong International, Inc.

cautious about pointing the finger at certain trap types, probably because they make a variety of types themselves.

■ Float-and-Thermostatic (F&T) Traps

F&T traps are used for draining steam equipment and as drip traps. They are one of the most popular types, and they are used in a wide range of sizes. Figure 2 shows how they work.

As the name implies, a float-and-thermostatic trap is a combination of two separate devices, a float trap and a thermostatic vent. The float trap is the essence of simplicity. It consists of a chamber with a discharge valve at the bottom. The discharge valve is actuated by a float and lever. When the chamber is dry, the weight of the float keeps the valve closed. When the chamber fills with condensate, buoyancy lifts the float and opens the discharge valve. The float is usually spherical in shape to resist the pressure of the steam.

Float traps are efficient in separating condensate from steam because the trap directly senses the presence of condensate through its great buoyancy. Furthermore, the float ball can be made as large as needed to provide a strong operating force for the condensate valve. Steam cannot leak through the trap because the discharge is located under water.

A simple float trap cannot vent air. It would eventually fill with air and keep the valve from opening (“air bind”). To prevent this, virtually all float traps include a separate thermostatic valve near the top of the trap. This gives them the name “float-and-thermostatic.” The thermostatic valve remains open until the trap heats up. F&T traps are able to vent large amounts of the air from the system, which is an important feature.

In F&T traps, the thermostatic element can become a source of steam leakage. Fortunately, the thermostatic

element in an F&T trap wears out more slowly than the element in a thermostatic trap. This is because it remains closed most of the time, opening only when a volume of air accumulates inside the trap.

Float traps are vulnerable to dirt. The discharge valve is located near the bottom of the trap, where large dirt particles may accumulate. Also, float traps can operate steadily in a partially open position, which allows

debris to become lodged between the plug and seat of the discharge valve. The protection against dirt is to buy a trap that has an integral strainer, or to install a strainer ahead of the trap.

You can recognize F&T traps from their large, rounded shape, which accommodates the spherical float ball inside. Figure 3 shows typical units.

■ Inverted Bucket Traps

Inverted bucket traps are used for draining steam equipment and as drip traps. They are used in a wide range of sizes. Figure 4 shows how they work.

An inverted bucket trap is built around a floating bucket that has its open side facing downward. Steam entering the trap is fed into the bucket, causing it to float to the top of the surrounding pool of condensate and close the discharge valve. When only condensate enters the trap, the steam in the bucket condenses and the bucket sinks, opening the discharge valve. Thus, condensate drains in cycles.

Inverted bucket traps allow little steam leakage when they are operating properly because the buoyancy of the bucket provides strong closure of the discharge valve. As with float traps, inverted bucket traps are relatively reliable because the bucket can be made as large as needed to provide a strong operating force for the condensate valve.

The top of the bucket has a small vent hole. This allows non-condensable gases to escape from the bucket

and be discharged. The vent hole also allows a small quantity of steam to escape from the bucket into the main body of the trap, where it condenses. The presence of the vent hole also allows the trap to open more quickly when condensate enters it. In normal operation, loss of steam through the vent is limited by the rate at which steam condenses in the trap, which is small.

Inverted bucket traps are resistant to dirt because the discharge valve is located at the top of the trap, away from dirt that settles in the bottom of the trap body. The discharge valve opens abruptly and fully, so dirt carried in the condensate does not become lodged in the valve seat.

Inverted bucket traps are most likely to fail in the open position. They fail in the open position if they run dry, because then the bucket cannot float. (This problem is most likely to occur if the steam is superheated.) They may also fail from misalignment of the internal mechanical linkage. When they fail in the open position, the size of the discharge orifice is the only factor that limits steam loss.

You can recognize inverted bucket traps from their cylindrical shape, which conforms to the shape of the bucket inside. Figures 5 and 6 show two different models.

■ Thermostatic Traps

Thermostatic traps are used for draining steam equipment and as drip traps. They are most common in smaller capacities. Figure 7 shows typical units, which are characterized by small physical size.

Thermostatic traps operate by sensing the difference between the temperature of live steam and the temperature of condensate or non-condensable gases that cool inside the trap. Their operating principle is simple: steam cannot cool below its condensation temperature, but condensate and non-condensable gases can cool. When a thermostatic element inside the trap senses a temperature lower than steam temperature, it assumes that it is surrounded by water and opens the discharge valve.

Presently, there are two main categories of thermostatic traps:

- **bimetallic traps**, which consist of a valve that is moved by a simple bimetallic element that is located on the steam side of the valve. This type has a fixed operating temperature, so it cannot respond to changes in the pressure and temperature of the steam.

Bimetallic traps are compact because they require space only for the small thermostatic element. The housing may have any shape.

Armstrong International, Inc.

Fig. 7 A pair of thermostatic wafer steam traps The main attraction of these is their small size and low cost.

- **bellows traps** close a discharge valve using the pressure of a boiling fluid contained inside a bellows. The fluid in the bellows is selected to boil at a temperature lower than steam temperature, so the bellows wants to expand when steam is present. The pressure inside the bellows is partially balanced by the steam pressure, so the opening temperature of the bellows trap can adapt to changes in steam pressure. Figure 8 shows how a bellows trap works. This type of trap should not be exposed to superheated steam, because the pressure inside the bellows may exceed the steam pressure enough to burst the bellows.

1. On start-up, condensate and air are pushed ahead of the steam directly through the trap. The thermostatic bellows element is fully contracted and the valve remains wide open until steam approaches the trap.

2. As the temperature inside the trap increases, it quickly heats the charged bellows element, increasing the vapor pressure inside. When pressure inside the element becomes balanced with system pressure in the trap body, the spring effect of the bellows causes the element to expand, closing the valve. When temperature in the trap drops a few degrees below saturated steam temperature, imbalanced pressure contracts the bellows, opening the valve.

Armstrong International, Inc.

Fig. 8 How a thermostatic bellows trap works

Bellows traps are small. Some have a cylindrical housing that conforms to a cylindrical bellows. Others have a compact housing that surrounds capsules of different shape, one of which resembles a large button.

Thermostatic traps are prone to leakage because they open and close relatively slowly. This provides time for erosion by high velocity steam and water while the sealing surfaces are barely separated. The partially open discharge valve may trap dirt, preventing tight closure.

The piping layout of thermostatic traps may be critical. The trap does not open until the condensate cools somewhat. If the condensate does not cool quickly enough, condensate may back up into the steam equipment or steam line. Therefore, install thermostatic traps so that they are surrounded by air that is substantially cooler than steam temperature. With low-pressure steam, the trap may have to be installed at a certain distance from the equipment or steam lines. Do not insulate the trap or the pipe that leads to it.

A standard thermostatic steam trap may be used as an air vent. You can recognize this application from the fact that the trap is installed at a high point on the steam equipment or pipe, rather than at a low point.

■ Disc Traps

Disc traps are used primarily as drip traps and for low steam loads, such as steam tracing lines. They are used in smaller capacities. (Disc traps are sometimes called “thermodynamic” traps. This may be a derivation of the name Thermo-Dynamic, which is a trade mark of Sarco Spirax, the original producer of disc traps.)

A disc trap consists of a flat disc resting on a circular seat that is smaller than the disc. The disc is enclosed in a chamber above the seat, where it moves freely. Figure 9 shows how simple these traps are in construction. Figure 10 shows how they work.

Condensate or steam enters the trap through the center of the seat, flows over the seat, and discharges through ports located under the perimeter of the disc. The disc is confined in a small chamber, into which it fits loosely so that steam can leak into the space above the disc. When condensate is present, it lifts the disc and exits. When steam enters the trap, Bernoulli effect reduces the pressure between the disc and seat. (Perhaps, this type of trap should be called “aerodynamic” rather than “thermodynamic.”) Steam at full steam pressure leaks into the space above the disc, aiding the Bernoulli effect, and the trap snaps shut. Once the trap is shut, the disc is held down by the steam pressure above the disc.

The main advantage of disc traps is their small size in relation to their condensate capacity. You can usually identify them from the disc chamber, which is a small cylindrical housing that forms the top of the trap. Some disc traps are installed in-line, and these may be barely

Spirax Sarco, Inc.

The cap over the disc forms a chamber in which the disc is enclosed. At the top is an insulating cover, which improves trap performance.

larger than the steam pipe itself. Figure 11 shows an installed unit.

The reliability of disc traps is a controversial issue. One leading trap manufacturer (who manufactures all the major types) asserts that disc traps are as reliable as other trap types. Other parties assert that leakage increases after a relatively short time because the sealing surfaces become deformed from hammering and steam abrasion. Also, the large contact area of the sealing surface makes disc traps vulnerable to leakage caused by fouling. Increasing leakage at the sealing surface allows the steam above the disc to vent quickly to the outlet, causing the trap to cycle more and more rapidly. Some manufacturers admit to this weakness, and they design their models for quick replacement of the disc and seat.

Even the way that disc traps operate is controversial. All agree that disc traps operate in a cyclic manner. Many parties say that disc traps cycle open periodically even when there is no condensate in the trap. This occurs because the steam above the disc condenses, eliminating the pressure that holds the disc closed. A puff of steam is lost with each operating cycle. However, one major

manufacturer denies that their traps open in the absence of condensate. This manufacturer states that live steam never reaches the trap, but that the trap is closed by the flashing of condensate that is near steam temperature. This manufacturer insists that a water seal should be created ahead of the trap.

All seem to agree that trap cycling increases if heat loss through the trap body causes the steam above the disc to condense. For this reason, some manufacturers offer insulating caps for the disc cover. Other manufacturers offer more expensive models that surround the disc chamber with an outer chamber that is filled with inlet steam.

The design of the seat is also controversial. Some manufacturers assert that the operation of disc traps depends on a controlled rate of leakage between the disc and seat to ensure that the trap will open. They create this small leak with a tiny groove or a carefully roughened surface. However, one leading manufacturer uses sealing surfaces with no deliberate leakage. All agree that hardness of the sealing surfaces is important to resist deformation.

Fig. 10 How a disc trap works

Armstrong International, Inc.

WESINC

Fig. 11 Disc trap installed This type is very small, as you can see in comparison with the valves and strainer.

The most common failure mode of disc traps is increasingly rapid cycling that is caused by fouling or deformation of the sealing surfaces. When this occurs, steam is lost in puffs. The rate of steam leakage is limited by the interrupted flow and by the small size of the passages. If the steam plant or the application is shut down periodically, the trap might also stick shut or fully open.

Try to install disc traps so that the disc lies on its seat horizontally, equalizing the forces on the disc. Disc traps are sometimes installed with the disc vertical, but this hastens deterioration.

■ Orifice Traps

Orifice traps are used almost exclusively as drip traps. They are made only in smaller sizes.

An orifice trap, as its name implies, consists of nothing more than a small hole. A screen typically is installed upstream of the hole to prevent clogging. This type was introduced formally in the 1970's. The fixed orifice is essentially an adaptation of the practice of draining condensate manually by slightly opening a drain valve.

Orifice traps can be considered a controlled leak, whose principal merit is that the volume of the leak is known in advance. They are limited to use as drip traps, and they must be sized closely to match the expected condensation rate. They are not practical for steam-using equipment, which has large and variable steam consumption.

The housing of an orifice trap is very compact, typically only slightly larger than the pipe diameter. A sloppy insulation job may hide the device entirely.

The *ASHRAE Handbook* explains the operation of orifice "traps" as follows: "... an orifice of any size has much greater capacity for condensate than it does for steam because of the significant differences in their densities and because flashing condensate tends to choke the orifice ..." This explanation is not persuasive, because steam flows much more easily than water, in terms of volume. It is true that condensate chokes an orifice. However, a continuously open orifice is passing dry steam most of the time in a drip trap application,

especially if the steam has any superheat. The *ASHRAE Handbook* goes on to say that “the steam loss is usually comparable to that of most cycling-type traps,” but does not state which types.

Orifice traps are vulnerable to dirt because the orifices are quite small. The orifice must be protected by a screen that has a smaller mesh than the orifice size, and such a screen easily becomes clogged.

■ Other Types of Steam Traps

Various other types of traps have emerged over the years. Some, such as piston traps and open bucket traps, have become obsolete because of poor reliability, complexity, or large size. Other types of traps are limited to specialized applications, such as a variant of the inverted bucket trap designed to lift condensate. Consider replacing obsolete or inappropriate traps, rather than repairing them.

Other Selection Characteristics

From the standpoint of efficiency, ability to block steam flow is the main consideration in selecting traps. In addition, you need to consider other characteristics, especially these:

- **reliability.** Most steam is wasted by trap failure, rather than by inherent leakiness of certain types of traps. Different trap types vary in susceptibility to the three failure modes discussed previously.

All traps can be expected to fail, but the average time between failures may vary widely among different types of traps. Many people feel that F&T traps and inverted bucket traps have the longest intervals between failure. Thermostatic traps probably have shorter intervals between maintenance because of their gradual closing characteristics. The reliability of disc traps is controversial, as discussed previously. Orifice traps are very vulnerable to clogging.

All traps, except orifice traps, will eventually fail by leaking steam, but they may also stick fully open or fully closed. The latter modes are more likely in systems that shut down periodically, because this allows the mechanism to corrode into position. Inverted bucket traps tend to fail in the open position, because this is their shut-down position. Float traps tend to fail in the closed position, which is their shut-down position. A float trap can also fail by corrosion of the float ball, which closes the valve. Thermostatic traps can fail by failure of the thermostatic element. Orifice traps, of course, can fail only to a closed state by clogging.

If an F&T trap fails in the closed position, its thermostatic element will cause it to behave like a thermostatic trap. This may reduce its capacity considerably, but will make the failure difficult to diagnose.

No trap is reliable unless it is properly matched to its application. For example, float traps are vulnerable to water hammer, freezing, and dirt, whereas inverted bucket traps are resistant to these problems.

- **capacity range.** Float, bucket, and thermostatic traps block steam efficiently from zero condensate flow up to their maximum rated capacity. Disc traps adapt to different drainage rates, but they are limited to small capacities because of the way they operate. Orifice “traps” continuously leak steam when condensate is not present, so they must be sized accurately for the maximum expected condensate flow rate.
- **system pressure.** Inverted bucket traps are available for any pressure. Float traps are limited in pressure by the possibility of crushing the float. Bellows-type or encapsulated thermostatic traps are limited in pressure by the possibility of crushing the thermostatic element. Orifice and disc traps are limited in pressure by the erosion that occurs when high-pressure steam passes through narrow passages.

Some disc traps require a minimum pressure drop between the steam side and the condensate side to operate properly, typically 10 PSI or more. In addition, disc traps are vulnerable to back pressure because proper operation requires steam to be able to exit from the trap at high velocity.

- **venting a cold system at start-up.** Thermostatic traps provide rapid venting of cold systems. Thermostatic elements are included in F&T traps for cold system venting.

Inverted bucket traps do not vent air rapidly because the smallness of the vent hole in the bucket limits the flow of gases through the trap. To compensate for this, a thermostatic element can be fitted to the bucket that increases the size of the vent hole when the bucket is cold. This added complication reduces the reliability of the trap, all other things being equal.

Disc traps vent a cold system very slowly because the trap is closed by air in the same way as by live steam.

Orifice traps are poor for venting a cold system because of the typically small size of the orifice.

You can vent a cold system by using separate air vents, which gives you greater latitude in selecting trap types.

- **venting a warmed-up system.** F&T traps, inverted bucket traps, and orifice traps all do a good job of venting non-condensable gases from a system that is operating at normal temperature.

If a thermostatic trap is kept flooded by condensate, air never has a chance to reach the thermostatic element, so the trap cannot vent a warmed-up

system. This limitation is characteristic of most thermostatic traps because the thermostatic element must be set to close at some temperature lower than the steam temperature.

Disc traps vent an operating system slowly for the same reason that they vent a cold system poorly, namely, that non-condensable gases cause the trap to close rather than to open. Venting becomes impossible if the trap is installed with a water seal ahead of it to reduce cycling, as one manufacturer suggests.

- **vulnerability to freezing.** Inverted bucket traps and float traps remain partially filled with water when they are idle, which invites freezing damage. Of the two, float traps are more vulnerable because they contain a float ball and a thermostatic element (in F&T traps) that are easily crushed by ice expansion.

Bimetallic thermostatic traps, disc traps, and orifice traps are less likely to be harmed by freezing.

Installation practice is a major factor in avoiding freeze damage, both for traps and for other steam equipment. The basic principle is to completely drain the portions of the system that may be exposed to freezing temperatures. Competent steamfitters have a variety of techniques for accomplishing this. Major trap manufacturers publish guidance in avoiding freezing in steam systems.

- **operation with superheated steam.** Superheated steam can be a problem for several trap types when they are used in drip legs. If superheated steam reaches an inverted bucket trap, the steam will rush through and keep the trap dry, causing the trap to remain in the open position. Superheated steam may cause a disc trap to chatter and pass steam. Superheated steam may burst the expanding element of a bellows trap. Superheated steam may increase the loss through orifice traps.

In principle, you could use any of these types with superheated steam, provided that you install them so that liquid condensate always forms ahead of the trap. However, this is a bad gamble, especially if the trap can be damaged by contact with superheated steam. Under some circumstances, the condensate may not form as you hope.

- **vulnerability to water hammer.** A slug of condensate propelled by high steam pressure has enough energy to crush trap components, especially thermostatic elements and float balls. Float traps and bellows-type thermostatic traps are sensitive to water hammer. Other common types resist damage much better.
- **size.** Float traps and bucket traps are bulky, whereas other common types are small.
- **cost.** Float traps and bucket traps are more expensive than other common types.

Other characteristics may be significant, and putting all the selection factors into perspective requires experience. Several steam trap manufacturers publish detailed selection guides. Experienced manufacturers' representatives can offer valuable advice. Recognize that vendors are biased toward the types that they offer, especially if they are proprietary, and toward more expensive models.

Sizing and Surge Capacity

Do not select traps with excess flow capacity. The capacity of the trap determines the size of the valve orifice (or internal passages, in the case of a disc trap). If the trap fails in the open position, the orifice size determines the rate of steam loss.

Select trap sizes using the instructions in the manufacturers' catalogs. Calculate sizing from the maximum condensate load, the pressure differential across the trap, and the nature of the application (which dictates extra capacity as a safety factor). Typically, F&T traps and inverted bucket traps are offered in a range of body sizes, which are combined with a range of orifice sizes to satisfy the full range of capacity requirements.

Consider the surge capacity inside the body of the trap. Surges of condensate must be kept from backing up into steam equipment or into steam lines. Float traps and bucket traps have a significant amount of surge capacity. You can also gain surge capacity by increasing the volume in the pipe that leads to the trap.

Strainers

As we have seen, dirt is a potential problem with steam traps. It can keep the valve from closing completely (all types, except orifice traps) and it can clog the trap passages (especially orifice and disc traps). The general solution to these problems is to install a strainer ahead of the trap. Figure 11 shows a strainer that is properly installed.

The strainer itself is an item that requires periodic inspection and cleaning. Unless the steam system has a particular dirt problem, inspection is needed only at long intervals. This leads people to forget about them. Make sure that your maintenance schedule includes such multi-year inspections. Figure 12 shows a strainer that has likely been forgotten.

To simplify the installation, you can get traps with integral strainers in most types and sizes. However, these do not eliminate the need to clean out the strainers periodically.

Piping Details

Proper operation of a steam trap depends on the way it is installed. As we have seen, installation practice is important for freeze protection, and it may be a factor in providing adequate surge capacity. Piping the trap to

WESINC

maintain a water column ahead of the trap may be necessary for satisfactory operation and longevity of thermostatic and disc traps. Refer to the manufacturer's literature for more details.

Avoid Sharing Traps

Do not use a single trap to serve more than one item of equipment. Condensate drainage is sensitive to

discharge pressure, so if two units discharge to a common line, the discharge from the higher pressure unit can block the flow of condensate to the other unit. This problem is especially severe with modulating equipment. Sharing traps makes it difficult to diagnose problems in traps or the equipment they serve.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely. For traps serving equipment, the wrong types of traps may waste 1 to 30 percent of the steam flow to the equipment. For drip traps, an orifice trap or a malfunctioning trap of any type may drain much more steam than condensate.*

COST: *F&T traps and inverted bucket traps typically cost from \$100 to \$500 each, in sizes where less efficient types of traps might be used.*

PAYBACK PERIOD: *Several months to several years.*

TRAPS & TRICKS

SELECTING THE TRAPS: *Start by educating yourself about steam traps. Know where to use each type of trap, and how to size traps. Take one of the courses offered by major trap manufacturers. Buy your traps from reputable manufacturers.*

INSTALLATION: *Trap installation requires special practices for each type of trap and application. Do your homework.*

MEASURE 1.10.4 Test and repair steam traps on a continuing basis.

RATINGS

New Facilities	Retrofit	O&M
		

All steam traps become leaky in time. The most reliable types of steam traps may operate several years before starting to leak seriously. The least reliable types may develop significant leakage after several months of service. (The characteristics of different types of steam traps are covered in [Measure 1.10.3](#).) Therefore, all steam plants should have a continuing program of steam trap inspection and maintenance.

The techniques of steam trap testing tend to be skill-intensive and somewhat uncertain. Furthermore, testing tends to be awkward and uncomfortable, especially with traps that are installed in hot, inaccessible locations. This makes the operation of an effective inspection and maintenance program a challenge of boiler plant management.

The appropriate response to finding a defective trap may be to repair the trap, to replace the trap with a similar new unit, or to replace the trap with a more efficient type (as recommended in [Measure 1.10.3](#)).

There are two subsidiary Measures that provide alternative ways to ease trap testing. The first, [Measure 1.10.4.1](#), recommends installing special equipment to help diagnose the condition of traps. The second, [Measure 1.10.4.2](#), recommends hiring trap testing specialists to do this job for you.

Energy Waste from Trap Leakage

Leaking steam traps can be serious sources of energy waste. A leaking steam trap acts as a short circuit from the high-pressure portion of the system to the condensate system, and the loss continues as long as the steam system is operating. If the trap drains to a condensate line, the steam loss is invisible, so it may persist for years.

The worst energy loss occurs when the steam trap fails in a fully open position. In this case, the rate of steam loss is proportional to the size of the orifice in the trap and to the pressure difference across the trap. These same characteristics determine the rated load of the trap, so steam loss from a stuck-open trap is proportional to its rated capacity. (This is an important reason to avoid oversizing traps.)

The range of steam loss in typical applications varies enormously. For example, a leaky steam trap on a radiator in a low-pressure steam system may lose 5 pounds of steam (about 5,000 BTU) per hour. At the other extreme, a large steam trap with a valve seat diameter of 1/2", serving a process application at 300 PSI, may waste over 2,000 pounds of steam per hour (over 2 million BTU per hour) if the trap sticks fully open.

SUMMARY

Important steam system maintenance that is often neglected. Trap testing requires special skill. Trap repair requires a delicate touch.

If the steam leaking through a trap is mixed with condensate, the water chokes the flow of steam through the orifice, reducing steam loss. This redeeming effect is most likely to occur in traps installed on steam-using equipment. In drip trap applications, the condensate flow may be low in relation to the trap capacity, so there is not enough condensate to choke the flow through a failed trap. In steam lines with superheat, the line may be completely dry.

Other Consequences of Steam Trap Malfunctions

Failure of a trap in the closed position may have serious consequences. If the trap is installed on steam-using equipment, a closed trap will prevent the equipment from working. If a drip trap is stuck closed, condensate can accumulate in the pipe. The condensate forms slugs that are propelled at high speed by the pressure of steam in the system, and these slugs can destroy pipe, valves, and equipment.

Causes of Steam Trap Failure

The common causes of trap failure are:

- wear of sealing surfaces from cyclic operation, and from abrasion by steam, water, and particles
- restricted motion of the valve parts because of corrosion or fouling
- inability to close fully because dirt or corrosion scale is trapped between the valve and seat
- misalignment of the sealing surfaces because of water hammer, freezing, or incorrect installation of replacement parts
- rupture or distortion of floats and thermostatic bellows by freezing, water hammer, or corrosion
- in inverted bucket traps, loss of the water seal, causing the trap to hang fully open
- in disc traps, lack of a water seal at the inlet, causing the trap to chatter.

The first two of these causes will eventually occur with any trap that stays in service long enough. The third is likely with certain types of traps, especially if inadequate water treatment has allowed the system to become corroded. The last four problems arise mainly from improper installation or from installing an inappropriate type of trap.

Expect any trap to leak eventually. If the system is shut down often, expect certain types of traps to stick fully open or fully closed because of corrosion while the system is filled with air and residual water. Float traps tend to fail fully closed in this case, and inverted bucket traps tend to fail fully open.

All types of traps, except orifice traps and disc traps, contain a condensate discharge valve that consists of a hard metal plug that seats in a hard metal orifice. The plug typically has the shape of a ball or cone, and the orifice typically has an angled shoulder against which the plug rests. This arrangement allows the plug and seat to wear into each other, maintaining a tight seal even as the components deform from usage. However, this self-correcting action cannot continue indefinitely. At some point, the valve starts to leak, after which leakage accelerates. This will occur eventually in any steam trap that has a discharge valve.

All types of traps have a certain amount of snap action in opening and closing. Snap action occurs because a portion of the seat area is exposed to the lower pressure of the discharge side when the valve is closed. When the valve starts to open, this area is exposed to the higher pressure of the steam side, which assists in opening the valve. The opposite occurs as the valve closes. The snap action keeps the trap from operating in a barely open position, which would trap debris and hasten erosion. The snap action is more forceful at higher steam pressures and with larger orifices.

(Orifice traps are an exception to these behavior patterns. This type can be considered as being failed in an open position while it is working, but otherwise fails to a closed position.)

Trap Testing Methods

Over the years, many methods of testing steam traps have been tried. No method yet developed is completely reliable, and most methods require special skill. The following are the most common methods being used today.

■ Checking Condensate System Vents

With condensate systems that operate at atmospheric pressure, you can detect heavy leakage of steam traps from steam blowing at the condensate system vents. The vents are usually located at the condensate receiver. Venting steam does not indicate which trap is leaking, but it does indicate that a trap somewhere in the system is failing.

In long condensate systems, steam from a moderate trap leak is likely to condense before it reaches the condensate receiver vent. Therefore, a blowing vent indicates a leaking trap, but a quiet vent does not mean that the traps are working properly.

■ Test Valves

Steam trap test valves are described in subsidiary [Measure 1.10.4.1](#). A test valve allows you to temporarily divert the output of the trap from the condensate system to the atmosphere, so you can see the trap output. The test valve setup should also allow you to briefly shut off the trap discharge and vent the condensate system, so you can see if any blowing steam is coming from the condensate system rather than from the trap itself.

Test valves work well with traps that alternately open and close, such as inverted bucket traps, thermostatic traps, and disc traps. With such traps, operation of the trap is apparent as the discharge valve opens and closes.

Test valves may require more skill when used with float traps, F&T traps, and thermostatic traps. These traps may discharge condensate continuously, rather than in cycles, when the condensate load is high. If the trap discharges continuously, it may be difficult to distinguish between live steam and flash steam. (Flash steam is the steam that is formed instantly from condensate as soon as the condensate passes through the trap into the lower pressure of the atmosphere.) If the system pressure is high, the condensate carries a large amount of energy that produces flash steam, which emerges from the test valve vigorously. Don't let flash steam mislead you into believing that a healthy trap is leaking.

Using test valves with disc traps may be deceiving if the condensate system operates at a pressure higher than atmospheric. This is because the performance of disc trap depends on the pressure differential across it. Opening the test valve to atmospheric pressure may give the false impression that a failing disc trap is behaving properly.

Stress safety when using test valves. If a trap fails in the open position, live steam will blast out of the test valve when it is opened.

■ Audible Sounds of Trap Operation

Each type of steam trap has characteristic sounds that indicate whether the trap is operating properly. For example, most traps snap audibly as they close. Rapid rattling of an inverted bucket trap indicates that it is stuck open. Cycling of a disc trap at too high a rate indicates that it is leaking excessively. And so forth.

You can hear the sounds of trap components opening and closing with an inexpensive stethoscope of the kind used by automobile mechanics. If you don't have one, hold the tip of a screwdriver on the trap and place the handle on your cheekbone. Some special stethoscopes amplify the sound and can highlight certain frequency

ranges. Ordinary stethoscopes do not pick up the high-frequency sound of leaking steam.

Background noise is a problem in using sound to diagnose traps. Sound travels well in metal, so the sounds of the trap may be masked by other system noise. If a number of traps are located close together, their sounds may mingle. Moving the listening device from one location to another can resolve the origin of sounds.

The main weakness of this method is that it requires a detailed knowledge of how each type of trap sounds under different conditions, and a good deal of experience in listening to trap sounds.

■ Ultrasonic Listening Devices

Even if a trap is cycling properly, worn valve surfaces or misalignment may allow considerable leakage. Steam leaking through a narrow restriction emits a large amount of sound in the ultrasonic range, but little in the audible range. Therefore, listening for ultrasound is a valuable method of diagnosing leakage. This requires an ultrasonic “stethoscope,” which is a device that converts ultrasound into audible sound or some other form of output. Figure 1 shows a typical unit.

Using this equipment effectively requires experience. An ultrasonic listening device does not detect ordinary trap noises very well, so use it in combination with a conventional stethoscope or other means of detecting audible noise.

■ Gauge Glasses on Traps

Some models of bucket traps and float traps are equipped with gauge glasses, as described in subsidiary [Measure 1.10.4.1](#). These allow you to directly observe the water level inside the traps. However, if no water level is visible, you cannot tell whether the trap is full of water (stuck closed) or steam (stuck open).

■ Temperature Difference

No method of steam trap testing has raised more false hope than temperature testing, which is based on the assumption that condensate leaving a trap is cooler than steam leaking through the trap. This assumption is false. It overlooks the fact that the temperature on the discharge side of a steam trap depends on only one thing: the pressure of the condensate system.

When steam leaks into the condensate system, its pressure drops immediately to the pressure in the condensate system, and its temperature changes immediately to the corresponding saturation temperature. On the other hand, when the trap passes liquid condensate into the condensate system, the condensate flashes to steam at the same temperature. For example, if the condensate system is operating at sea level atmospheric pressure, the temperature of the trap discharge is always 212°F, whether the trap is operating properly or not.

Spirax Sarco, Inc.

Fig. 1 Ultrasonic trap tester This device picks up high-frequency trap sounds with its probe, and converts them to audible sounds. It is especially useful for detecting leakage through worn valve seats.

In a system that operates at higher pressures, leaking steam may increase the temperature of the discharge for a short distance below the trap, before the steam or condensate has time to equilibrate with the condensate system pressure. However, you may not be able to tell whether a high surface temperature is caused by leaking steam or by conduction through the metal of the components. Furthermore, the condensate itself discharges from the trap at an elevated temperature.

The only exception is a trap that holds condensate long enough for it to cool below the boiling point temperature of the condensate system. This can occur only with thermostatic traps. However, to avoid backing up condensate, thermostatic traps are designed to cool condensate only a small amount below the temperature of the steam system. Some thermostatic traps are designed to deliberately “subcool” condensate, but such applications are unusual.

The trap temperature does provide a reliable indication if a trap is stuck closed or valved off. In this case, the body of the trap is substantially cooler than the system temperature. You can measure the surface temperature of the trap by holding a thermometer against the surface with a rag over it, or by using crayons that melt at calibrated temperatures, or by using a pyrometer. If the system operates at low pressure, you can tell whether the trap is near normal operating temperature by squirting water on it. Checking by feel is asking for trouble.

■ Infrared Imaging Scanners

Infrared cameras are a versatile tool that allow a user to actually see patterns of temperature variation. Although spot testing of trap and system surface temperature is a poor method of checking steam traps, for the reasons given previously, infrared imaging can be effective. If you have the right equipment and enough experience, you can observe heat patterns on the surface of the trap and adjacent pipe that indicate whether the trap is operating properly. You may also be able to detect leaks.

See [Reference Note 15](#), Infrared Thermal Scanning, for more about this equipment. Scanning equipment is expensive, fragile, and somewhat awkward, but it may be the best method for facilities with many traps.

■ Proprietary Trap Performance Indicators

In the continuing search to find reliable methods of diagnosing steam trap performance, various devices have been invented for installation on or near steam traps to indicate whether they are operating properly. [Measure 1.10.4.1](#) describes several of these devices that are presently on the market.

Preferred Test Methods

For most applications, consider a combination of test valves and acoustical and/or ultrasonic testing. If a trap is not discharging condensate, check its surface temperature to tell whether it is stuck closed or some other stoppage exists.

Between test periods, keep an eye on the condensate system vents.

Test Both Start-Up and Hot Operation

Steam traps perform different functions at start-up and during warmed-up operation. Therefore, test your traps under both conditions. For example, an F&T trap may appear to function properly in warmed-up operation because the float is draining condensate. However, the thermostatic element may be defective, failing to vent the system at start-up.

Drip traps are easy to check. On start-up, a drip trap should drain clearly observable amounts of condensate. After the system is warmed up, the trap should pass little condensate and no steam.

Traps installed on steam-using equipment may be more difficult to check, especially in high-pressure systems. If the equipment has a heavy load, the heavy condensate drainage may make it difficult to distinguish direct steam leakage from flash steam. If the equipment has modulating control, the steam pressure inside the equipment is reduced at lower loads. A leak that is easy to find under high pressure may not be apparent at low load.

How Often to Test

If a trap fails the day after you test it, it continues to waste energy until the next test. Therefore, test your traps as often as practical. Use these guidelines to develop an appropriate testing schedule:

- ***the types of traps installed.*** Inverted bucket traps and float traps are the most reliable types. In average service, they may work for years without developing problems. Disc traps are considered the least reliable, and may start to have escalated steam consumption within a few months. The less reliable types also have a broader variation in failure rate, making it less certain that an individual trap will survive for a given period of time.
- ***the number of traps in the system.*** The more traps there are in the system, the greater is the probability that a failed trap is leaking steam at any given time.
- ***trap capacity.*** The rated capacity of a steam trap reflects its orifice size and the pressure difference under which it operates. Both of these factors determine the leakage rate in the event of failure. Thus, it pays to test big traps often because they can waste a lot of energy when they fail. On the other hand, smaller traps do not have the strong opening and closing forces of larger traps, and their components are not as strong, so they may not last as long as larger traps on average.
- ***availability of personnel.*** Balance the cost of steam loss against labor cost. There is no reason why traps in boiler plant should not be tested daily if the plant is manned and operators have free time.
- ***accessibility of traps.*** Accessibility is a major factor in labor cost. If a trap is in an awkward location, consider moving it to a more accessible location.

The large cost penalty of steam trap leakage in a large, high-pressure steam plant may make it worthwhile to test steam traps daily or weekly in such plants. At the other extreme, a low-pressure steam plant with only a few traps may need trap testing only several times per year.

Group Repair and Reduced Testing Interval

After a facility has been in service for several years, the lives of the traps are no longer synchronized, so trap failures are likely at any time. This forces you to test traps more often to keep traps from leaking for long periods. Therefore, in steam systems that have a large number of similar traps, it may be more economical to overhaul all the traps of each type as a group. This provides a period of time during which there are few trap failures, so you can reduce trap inspections during this period. Later, when the failure rate starts to rise, overhaul all the traps of that type.

The optimum time-between-overhaul varies for different types of traps. Therefore, each type of trap should have its own group overhaul schedule.

Trap Repair Procedures

Good traps are designed to allow easy replacement of worn parts, and parts kits are available for common models. Replacement parts are few and simple, but training and care are needed to install them properly. Follow overhaul instructions exactly. For example, valve plugs and seats are supplied in matched sets. Replacing one without the other virtually guarantees leakage. Aligning the parts in some traps requires a delicate touch.

Where to Get Training

Trap testing and repair requires hands-on training. Trap diagnosis can be learned properly only in a setting where students can observe functioning equipment, including their sounds and other behavior when operating properly and when defective. Some trap manufacturers have excellent training facilities that provide these opportunities. Some demonstration setups have piping, steam coils, and traps made of transparent materials. These are invaluable because the operation of steam equipment is difficult to visualize through steel.

The training provided by trap manufacturers to steam users is either free or it costs only a modest amount. This training is one of the best bargains in energy conservation.

ECONOMICS

SAVINGS POTENTIAL: 1 to 20 percent of system steam production, depending largely on the size and condition of the steam distribution system.

COST: Most of the cost is for labor. This cost depends on the amount of free time that plant operators have available. Steam trap testing equipment typically costs a few hundred dollars. The cost of accessory devices installed on traps for diagnosis is covered in subsidiary [Measure 1.10.4.1](#).

See [Reference Note 15, Infrared Thermal Scanning](#), for the cost of thermal scanning.

PAYBACK PERIOD: Immediate. Maintaining steam traps always costs less than neglecting them.

TRAPS & TRICKS

DILIGENCE: Steam trap maintenance tends to be neglected because leakage is invisible and inspection may be awkward. It becomes easier with practice. Schedule trap inspections in your maintenance calendar, and give them priority.

TRAINING AND EXPERIENCE: Steam trap testing requires a knowledge of trap operation, experience, and a certain amount of intuition. Invest in training one or more talented individuals as trap testers. Get hands-on training with your types of traps from a trap manufacturer or other effective source of instruction. If possible, have the same individuals test and repair traps, because the two activities enhance each other. Alternatively, hire expert testing services, which are covered in subsidiary [Measure 1.10.4.2](#).

SELECTING TEST METHODS: Select the most effective test methods for your types of traps. In case of doubt, discuss testing methods with operators of other facilities who have your types of traps. Install appropriate test devices, if they can speed testing or increase the certainty of diagnosis (see subsidiary [Measure 1.10.4.1](#)).

MEASURE 1.10.4.1 Install accessory devices to assist in steam trap diagnosis.

RATINGS

New Facilities	Retrofit	O&M
B	B	

This is the first of two subsidiary Measures that help you test your steam traps. The method here is to install an accessory testing device at each trap that tests the condition of the trap.

The uncertainty and difficulty of steam trap diagnosis keeps people inventing new devices for testing steam traps. Some of these are installed as permanent trap accessories. The best ones may greatly increase the speed and certainty of testing when the user is familiar with them. Installed trap test devices are especially worth considering for facilities that have a large number of traps. You can use some of these accessory devices with all types of traps, but others are limited to certain trap types.

Applications and Alternatives

All permanently installed steam trap testing devices require a certain amount of space in the condensate discharge piping. This makes them impractical for traps that are installed in tight quarters, such as the traps on many steam radiators. Also, the devices are somewhat expensive, which makes them uneconomical with most small traps.

Some of these accessory devices can be a mixed blessing. Using each type requires its own specialized techniques, and requires more theory for the trap tester to learn. Furthermore, each device introduces its own failure modes and maintenance requirements. As a

result, they are more applicable to plants that have skilled operators. In other facilities, they will add confusion.

Test Valves

Test valves are simple and fairly obvious to use. They can be used with all types of steam traps. They indicate some trap problems clearly, but not all.

The simplest arrangement is a single valve in the trap discharge that diverts the discharge to the atmosphere. For example, see Figure 6 in [Measure 1.10.3](#). This allows you to observe whether steam is

Armstrong International, Inc.

Fig. 1 Steam traps with inlet and outlet test valves Note how the discharge pipe for each test valve is aimed away from the valve handle.

Armstrong International, Inc.

Fig. 2 A steam trap with integral test valves

leaking through the trap, or whether it is stuck in a closed position.

If a trap is used as a drip trap, the test valve cannot indicate a stuck-closed condition when the system is warmed up. This is because the steam line may be dry at that time. To test whether a drip trap is stuck closed, install a test valve in the inlet side of the trap. This will show whether water is backed up ahead of the trap. Figure 1 shows a group of traps that have both inlet and outlet test valves. This method is reliable with float traps and with inverted bucket traps. However, it is not

reliable with thermostatic, disc, and orifice traps, because water may back up ahead of these trap types in normal operation.

Figure 2 shows a steam trap that is equipped with integral inlet and outlet test valves. This simplifies installation.

It can be difficult to tell whether steam blowing from a trap discharge is the result of a steam leak in the trap, or is flash steam from the condensate, or is steam that is coming from the condensate system. The amount of flash steam from condensate increases considerably with boiler pressure.

Also, a steady flow of steam, without condensate, may come from the condensate system itself. This can occur if other traps have serious steam leaks. To determine whether blowing steam is coming from the trap or from the condensate system, install a set of three test valves, as shown in Figure 3. One valve closes the discharge line to the condensate system, one opens a sampling line from the trap discharge, and one opens a sampling line from the condensate system. Use the valves in this way:

- **normal operation.** The discharge valve from the trap to the condensate system is open. The other two are closed. This is the state shown in Figure 3.
- **trap test.** Close the discharge valve, and open the valve above it. This discharges the trap to the atmosphere, so you can observe the discharge directly. A steady flow of steam indicates a leaking trap. If nothing comes out, this may indicate that the trap is stuck in a closed position. However, this may be normal for a drip trap on a warmed-up steam line.
- **condensate system test.** Close the discharge valve, and open the valve below it. This lets you see

Armstrong International, Inc.

Fig. 4 Steam trap with gauge glass

whether blowing steam is coming from the condensate system, rather than from the trap itself. This indicates that there are leaks in other traps connected to the same condensate system.

At least one manufacturer makes a three-position stainless steel valve that accomplishes the same purposes as this set of three valves. It is more compact, and easier to install.

Test valves are exposed to heat, moisture, and air, so they should be made of non-corrosive materials.

Try to install test valves so that condensate and debris cannot come to rest inside the valves. The best practice is to install the test valve in a vertical pipe. Figure 3 shows how to do this.

Test valves add a potential safety hazard. Bear in mind that opening a valve ahead of the trap vents the full pressure of the steam system. Also, if the trap fails in the open position, live steam will blast out of the sampling valve with the potential to cause severe burns. For this reason, pipe the discharge from the test valve in a safe direction. The test valves and the connecting pipe should have the smallest practical diameter, to protect people and to minimize steam blast in case any of the connections breaks from corrosion or impact.

Label test valves to indicate their purpose, to indicate the valve positions for each purpose, and to warn of the safety hazard. See [Reference Note 12](#), Placards, for placard design, materials, and installation methods.

Gauge Glasses

With float traps and inverted bucket traps, the level of water inside the trap is a reliable indication of whether the trap is working properly. You can't see the water level inside a trap, but a gauge glass makes this possible. The gauge glass used with a trap is similar to the gauge glasses used on boilers, feedwater tanks, or other pressurized vessels. Some traps are offered with gauge glasses as an option. Figure 4 shows an example.

Gauge glasses cannot be installed on steam traps unless the traps are designed to take them. The bottom of the gauge glass must be connected to the body of the trap, using a special fitting ahead of the discharge valve.

Gauge glasses add a potential safety hazard because they contain full steam pressure. For this reason, gauge glasses must be sturdy and well protected. Both top and bottom connections should include small orifices to limit steam release if the gauge glass breaks.

Gauge glasses are subject to fouling that can make it difficult to see the water level inside. Therefore, the gauge glass should have a blowdown valve at the bottom connection to allow it to be cleared out occasionally.

Proprietary Test Devices

New types of devices for testing steam traps keep emerging. For example, Armstrong International, a major trap manufacturer, offers a sensor that is installed

Armstrong International, Inc.

Fig. 5 Trap testing device that senses conductivity and temperature This device can detect a trap that is stuck open or closed. It can monitor traps remotely and continuously. It requires specially designed traps.

in the bottom of its inverted bucket traps to measure the temperature and conductivity of condensate inside the trap. See Figure 5. Using this information, an electronic logic circuit determines whether the trap is operating properly. The Armstrong device detects either a steam leak or a stuck-closed trap. The device indicates trap condition either with signal lights installed on individual traps, or the traps can be monitored remotely. The remote monitoring feature is valuable for large systems because it allows continuous monitoring with minimal labor.

Spirax Sarco, another major trap manufacturer, offers a sensing device that is installed ahead of each trap. See Figure 6. The Spirax device senses steam flow but not condensate flow, so a steam leak through the trap generates an alarm signal. Newer models of this device detect a stuck-closed trap by using a sensor that measures conductivity and temperature. The Spirax device can be used with most types and models of traps. Traps can be monitored locally or remotely.

Proprietary devices have a number of disadvantages. One is that the manufacturer's monopoly on the device raises the price. At the same time, the manufacturer is less motivated by competitive pressure to improve the product. One-of-a-kind devices that are discontinued leave users with equipment that cannot be repaired. Nonetheless, trap diagnosis is important enough to justify the effort and risk of considering new methods of doing it better.

ECONOMICS

SAVINGS POTENTIAL: The savings that result from trap testing are given in [Measure 1.10.4](#). This Measure improves the reliability and reduces the effort of trap testing. The potential savings depend on labor costs, the skill of the staff, the size and number of traps, and the accessibility of traps.

COST: Varies widely. Test valves may cost less than \$100 per trap, while a remote monitoring system for a small number of traps may cost several thousand dollars per trap.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

SELECTING THE METHOD: Favor test methods that provide reliable diagnosis without the need for special expertise or extensive experience. Select equipment for ruggedness and longevity in the harsh environment of the traps. Consider ease of installation and ease of use. Avoid units that require frequent or difficult maintenance. Ask vendors for references, and check them. Beware of proprietary devices that may become obsolete, especially if they contain electronics. Favor major manufacturers, especially manufacturers of traps and other steam specialties, who are likely to remain in business and support the product.

INSTALLATION: Most trap testing devices have specialized installation requirements. Follow the manufacturer's instructions. Install to avoid internal fouling and external impact damage, and for ease of use and maintenance.

EXPLAIN IT: Describe the equipment and its operation in a manner that is accessible to everyone involved with trap testing. If appropriate, install placards at the test devices. Train your staff how to use and maintain the test devices. If possible, combine this with the general training in trap testing and maintenance recommended in [Measure 1.10.4](#).

MAINTENANCE: Schedule regular maintenance of the test devices along with maintenance of the traps.

MEASURE 1.10.4.2 Hire specialists to perform periodic steam trap inspections.

RATINGS

New Facilities	Retrofit	O&M
□	□	C

This is the second of two subsidiary Measures that help you test your steam traps. The approach here is to hire specialists to take care of the whole job, or most of it. For example, some steam trap manufacturers offer trap inspection as a service, as in Figure 1. This may be the only practical approach for a facility that cannot maintain a skilled boiler staff.

This approach does not eliminate the uncertainties of trap testing. Inspection companies have the same problems in training and keeping personnel as other companies, and personnel assigned to a particular customer may be spotty in skills or initiative. Therefore, check the reputation of the company. Ask about the facilities and staff that the company uses for training its personnel, about the number of trained personnel, their length of service with the company, etc.

There is a conflict of interest when hiring contractors to perform trap testing. If the contractor is also given responsibility for trap repair, there is a tendency to do unnecessary work. A possible solution is to hire a contractor for testing only, and let the in-house staff do

Fig. 1 Trap inspection service Consider a professional service to test and/or repair your steam traps if this approach would provide greater skills or consistency.

SUMMARY

Consider this approach if you cannot maintain a skilled in-house staff to do trap testing.

the repair work. The logic in this division of labor is that testing requires more subtle skills than repair. However, this motivates the contractor to be hasty in doing the testing.

Reducing Inspection Costs with Group Overhaul

The need for frequent trap testing raises the cost of using contractors. One way to increase the inspection interval is to overhaul all traps as a group. See [Measure 1.10.4](#) for details.

Consider In-House Trap Testing and Repair

If the facility has a skilled physical plant staff, it is usually best to do steam trap testing in-house. In-house personnel can be selected and supervised more effectively than contractor personnel. The major steam trap manufacturers offer excellent training for facility maintenance personnel, as discussed in [Measure 1.10.4](#).

However, do not be excessively optimistic about in-house testing if conditions are not favorable for it. Trap testing will be neglected if there is high staff turnover, or if physical plant maintenance does not have the attention of upper management, or if existing staff do not have the capability to stay proficient, or if the staff are overworked. In such cases, hire a reputable contractor and hope for the best.

ECONOMICS

SAVINGS POTENTIAL: The savings that result from trap testing are given in [Measure 1.10.4](#). This Measure improves the reliability and reduces the effort of trap testing in facilities where it is not appropriate to perform trap testing and maintenance in-house.

COST: Varies widely. For large facilities, the cost of hiring competent outside services is probably about the same as the cost of training and maintaining a skilled in-house staff for trap maintenance. With smaller non-

industrial facilities, hiring outside services may be the only practical way of keeping traps maintained.

PAYBACK PERIOD: Immediate, since no initial investment is required. In order to be economical, the cost of using a contractor must be less than the additional savings achieved by using a contractor.

TRAPS & TRICKS

SELECTING THE CONTRACTOR: Look for experience. Ask contractors how many skilled test personnel they

have, and how long they have been employed by the company. Ask what test methods they use. Ask for references, and check them.

MONITOR PERFORMANCE: Schedule periodic checks of the contractor's work, immediately after an inspection cycle. Look for failed traps that they may have missed, and check that repaired traps are functioning properly. This requires at least one trained trap tester on your own plant staff, or available from another source.

MEASURE 1.10.5 Recover heat and water from steam vents.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
B	C	

A blowing steam vent is like a flare at an oil refinery. It is unmistakable evidence that a large amount of energy is being wasted. Even a small vent that operates continuously can waste a considerable amount of energy and money. Do not miss an opportunity to recover this energy.

Another reason to recover vented steam is to recover the pure water that comes from condensing the steam. Recovering the water saves the cost of replacing it, and also reduces water treatment costs.

Recovering the heat and the water is usually a simple matter of heat exchange. You can use any liquid, gas, or solid medium to condense the steam if its temperature is below the boiling point of water. Most of the energy of steam is latent heat, so the temperature of the condensing medium does not matter much, as long as it is cooler than the boiling temperature. For example, you can use warm condensate to condense venting steam. This warms the condensate, reducing fuel cost, and allows the condensed steam to be used as makeup water. If a large amount of steam is being vented, consider using it for heating domestic water, heating fuel tanks, process heating, etc.

Heat Recovery Methods

You can use an ordinary steam-to-liquid heat exchanger for many applications. Where the application is heating liquid in a tank, consider a steam immersion coil.

There is no need for a heat exchanger if you can mix the vented steam with the condensing medium. One method is to pipe the steam into a tank of liquid. Or, spray the liquid into a pipe that contains the vent steam.

SUMMARY

Consider this anywhere a significant amount of steam is venting. Usually simple.

A vent condenser is a specialized heat exchanger designed specifically to recover heat and water at steam vents. A vent condenser is cooled by a liquid, and the condensed steam falls back into the vessel. Vent condensers are common on deaerating feedwater heating tanks.

If there is no application for heat recovery, but you want to recover the water, pass the steam through an air coil to condense it.

How to Find Leaking Steam Vents

There are many industrial processes that involve steam vessels with vents. To find them, look for plumes of steam. A major plume of steam may persist for a long time because everyone assumes that it is intentional or necessary.

Within the boiler plant itself, the deaerating feedwater tank (if one is installed) is the equipment most likely to be venting steam. Deaerators use steam to

separate air from the feedwater, and the pressure within the tank typically ranges up to 15 PSI. At the vent where the air is ejected from the tank, a considerable amount of steam may be lost along with the air. The tank may already have a vent condenser installed. If so, check that the vent condenser is operating properly.

Sizing the Heat Exchanger

You need to estimate the amount of steam that is being wasted in order to size the heat exchanger and to estimate the potential savings. Engineering tables are available that give the rate of steam flow through a hole, based on the diameter of the hole and the pressure difference. Do not be fooled by a vent that is discharging both air and steam, where the size of the hole or the appearance of the plume exaggerates the amount of steam being wasted.

One way of measuring the amount of steam being wasted is to run a hose from the steam vent into an empty drum. Cool the drum by spraying it with cold water to make the steam condense. The rate of steam loss, by weight, equals the rate at which water condenses in the

drum. Each pound of condensate represents about 1,000 BTU of recovered steam energy.

ECONOMICS

SAVINGS POTENTIAL: *Depends on the application. For deaerating feedwater heaters, the loss of vented steam can account for 0.1 to 1 percent of fuel input.*

COST: *Piping steam directly to a nearby application may cost several hundred dollars. Installing a typical vent condenser and piping to an application may cost several thousand dollars.*

PAYBACK PERIOD: *Less than one year, to several years.*

TRAPS & TRICKS

EXPLAIN IT: *The purpose of the steam recovery equipment is not obvious from its appearance. Install a placard that identifies it, states how it works, and states that there should be no steam plume coming from the equipment. See [Reference Note 12, Placards](#), for details of effective placard design and installation.*

Conduction and Radiation Losses

The equipment in boiler plants and heat distribution systems is hot, so it loses heat by radiation and by conduction to the air in the space. Heat loss from the boiler itself and its auxiliary equipment typically wastes about two percent of the boiler's full-load energy consumption. Heat loss from the distribution system varies enormously, depending on the size, design, and condition of the distribution pipe and its accessories. In long distribution systems, a large part of boiler energy input may be lost by conduction and radiation.

The Measures in this Subsection reduce conductive heat losses from the boiler plant equipment and distribution system. The third Measure recovers part of this heat.

RATINGS

New Facilities	Retrofit	O&M

Insulation is what keeps the heat energy of a boiler system from leaking out of the system on its way to the end users. Inspect the condition of your insulation often enough to keep the insulation from becoming seriously deteriorated. This Measure summarizes what insulation does, what to insulate, and how to insulate. It also gives you several methods of finding defective insulation, even if it is buried.

Basics of Boiler System Insulation

■ Heat Loss of Bare Surfaces

Surfaces lose heat by radiation and convection. If the surface has little insulation value, such as the surfaces of steel pipe and fittings, the rate of heat loss depends almost entirely on the surface area and surface temperature. Convective heat loss occurs strongly even at low temperatures, but levels off to a maximum rate. In contrast, radiation heat loss continues to increase exponentially with temperature.

Radiation becomes the dominant mode of heat loss from exposed surfaces in high-temperature plants. For example, a bare pipe carrying 15 PSI steam is about 150°F hotter than typical boiler room air, and it loses about 400 BTU per hour per square foot of surface area. By comparison, a bare pipe carrying 600 PSI saturated steam loses about 1,600 BTU per hour per square foot.

The amount of bare surface in a heating plant is usually minor, so bare surface heat loss is not a major consideration. Still, it may pay to insulate localized bare surfaces, as recommended below.

■ Upgrading Intact Insulation

If a surface is insulated, the rate of heat loss is determined primarily by the surface area, the thermal resistance (the R-value, in English units) of the insulation, and the insulation thickness.

The shape or curvature of insulation is also a factor. Insulation that is curved has more outer surface area in relation to its thickness, and hence more heat loss. This is significant in the case of pipe insulation. Because of this effect, a given thickness of insulation is more effective with larger pipe diameters.

Insulation that is kept dry and free of physical damage remains effective indefinitely. In most heating plants, the insulation was installed properly at the time of construction, although certain minor areas may have been neglected. Damage over the years may lead to some loss of insulation, but incidental damage usually does not justify replacing insulation. For example, see Figure 1.

If insulation is in reasonably good condition, the remaining question is whether there is enough of it. In many heating plants, the amount of insulation may be inadequate in terms of present economics. It may be economical to supplement the original insulation, or to replace the existing insulation with new material having higher thermal resistance. Upgrading is most likely to be worthwhile in systems that have extensive piping that is easily accessible.

However, upgrading existing insulation usually has a low rate of return. Each additional increment of insulation thickness provides less benefit. Economics favors installing plentiful insulation on new equipment. A large fraction of the cost of insulation is for labor, and it does not require much additional labor to increase the insulation thickness.

Select your insulation quantity using engineering calculations. The principles and formulas are simple. Refer to ASHRAE publications or other books dealing with heating systems.

■ Heat Loss of Wet Insulation

Moisture is the worst enemy of insulation. If fibrous or open-cell insulation becomes wet, its insulation value falls drastically, and it may be permanently damaged. If buried pipe insulation of this type becomes soaked, it becomes ineffective, and the surrounding soil determines the rate of heat loss. Closed-cell insulation may lose little insulation value if wetted, provided that it is installed snugly. Even closed-cell foam may not keep the pipe itself from becoming wetted, which causes corrosion.

In indoor locations, insulation becomes wet if there is a leak, usually in the pipe or equipment that the insulation is covering. A leak may soak the insulation. Insulation should be installed so that a leak inside the insulation can drain out, but this is rarely done in practice.

The worst moisture damage to insulation occurs in buried pipe. Deterioration of buried insulation is a common, insidious source of major energy waste in large distribution systems. In the past, engineers tended to underestimate this problem, causing many facilities to suffer high heat loss from their underground pipe. Fortunately, piping system designs and equipment that preserve the integrity of the insulation have now become widely available. Unfortunately, replacing underground pipe is very expensive.

In steam tunnels and pipe trenches, as in Figure 2, the relative humidity of the air surrounding the insulation may remain at 100% if the soil is wet. This does not cause the insulation to become wet, provided that the pipe remains warmer than the air inside the tunnel. The higher temperature of the pipe keeps the relative humidity inside the insulation well below 100%. (Just the opposite situation exists with chilled water piping, which faces a serious problem of waterlogging when it

is installed inside tunnels.) If the piping system is shut down at certain times, the insulation may become wet. Whether this is a problem depends on the type of insulation.

What Should Be Insulated

Install adequate insulation on all equipment and piping that carries heat, unless the heat is being discarded. Equipment that may lack adequate insulation includes return hot water piping, condensate piping in closed systems, and fuel oil piping that carries heated oil.

Small items matter if they are very hot. In high-pressure systems, insulate system accessory equipment, such as valves and the larger types of steam traps.

■ Where Not to Insulate

Not every bare steel surface in a heating plant should be insulated. Do not insulate:

Armstrong International, Inc.

The main points are whether the insulation is dry and snugly fitted, and whether there is enough of it. The main problem with the insulation of this tank is peeling paint. The lower pipe insulation is in bad condition, and should be repaired.

If the pipe is warm, the insulation will remain dry regardless of the humidity in the tunnel. However, this is a challenging environment for chilled water pipe insulation, especially if hot and cold pipe run in the same tunnel.

- *pipe carrying unheated fluids*, such as domestic water
- *thermostatic steam traps and the condensate pipe that leads to them*, for the reasons given in [Measure 1.10.3](#)
- *condensate pipe leading to disc traps*, in some cases. See [Measure 1.10.3](#) for details.
- *soot blower elbows*, which are hot only briefly while soot is being blown. The heat in the elbows cannot be retained until the next operation. Metal “reflective insulation,” which is explained below, may be installed primarily to act as safety guards.
- *boiler air casings*, if the casings are not hot to the touch. The air entering the boiler through the casing captures most of the heat radiated from the hot interior hardware.

You may harm some boiler room equipment by insulating it. Any hot equipment that is covered by insulation becomes much hotter. Damage can occur in ways that are not apparent, such as from thermal expansion. For example, it would not be prudent to add insulation over the sheetmetal skin of a boiler, because the skin may deform excessively from thermal expansion.

■ Whether to Insulate Condensate Systems

The question arises whether it is correct to insulate condensate return systems. The answer depends on the design of the system. Closed (pressurized) condensate systems should be insulated. In the case of open (atmospheric pressure) condensate systems, some people say that insulation is a bad idea because keeping the condensate warm causes it to evaporate away. This is

wrong. Evaporation occurs only through the small vent or vents, usually located only at the condensate receiver. As long as the temperature inside the condensate system is below the boiling point, the vapor pressure of the water is below atmospheric pressure, so water vapor is not actively forced out of the system.

Condensate coolers are sometimes installed in condensate systems to prevent flashing of steam at the inlet of a condensate pump or feedwater pump. In such cases, insulating the condensate piping defeats the purpose of the condensate cooler. You may be able to avoid this obstacle by changing the pump installation or by installing a steam-powered condensate mover. See [Measures 1.8.4 ff](#) for these methods.

How to Find Defective Insulation

Visual inspection is usually good enough for insulation that is under roof and accessible, as in boiler rooms, pipe chases, and steam tunnels. If the insulation is intact, fits snugly, and remains dry, it is almost certainly doing its job. Damage that is serious enough to reduce the effectiveness of insulation is usually obvious. The only subtle case is where insulation may become wet from a leak in the equipment it surrounds.

You can use infrared cameras and other types of thermal scanners to survey large areas of insulation and inaccessible equipment. See [Reference Note 15](#), [Infrared Thermal Scanning](#), for details.

In a buried steam distribution system, you can estimate the rate of heat loss from the pipe insulation by measuring the rate of condensate flow from the drip traps. Each pound of condensate represents a conductive energy loss of about 1,000 BTU. If the system has an intact condensate return, pick a time when all the end user equipment can be turned off, so the condensate flow is returning only from the drip traps. Alternatively, drain the drip traps into containers and time how fast they fill.

This test method works only if the steam in the lines is saturated. Some facilities superheat the steam to keep it from condensing in the lines. To get around this, turn off the boiler’s superheaters during the test, or use the desuperheater.

Steam becomes superheated in passing through a pressure reducing valve. If the line is fed from a pressure reducing valve, reduce the boiler pressure enough to allow you to bypass the pressure reducing valves for test purposes.

You can localize defects in buried insulation by using the same methods used to find leaks. See [Measure 1.10.2](#) for details.

Insulation Methods and Materials

Extensive insulation repairs are usually done by contractors having the specific skills and equipment appropriate to the type of insulation being installed. Experience indicates that some methods of insulation

are much better than others, particularly for buried pipe. Become familiar with the advantages and disadvantages of all the insulation methods before initiating the work.

Refer to the *ASHRAE Handbook* or other references for an overview of insulation materials and installation practices, and for the formulas needed to calculate heat loss. After selecting your general method of insulation, study the manufacturers' literature. The following highlights deserve particular attention.

■ Moisture Resistance

No insulation system is able to keep moisture away from the insulation in the long term. The thermal resistance of insulation can be preserved entirely only by keeping it in a well drained enclosure. The enclosure may be the boiler house, a steam tunnel, or in the case of buried pipe, a drained conduit.

If it is impossible to keep the insulation dry at all times, as with buried pipe, the insulation itself should be impermeable to moisture. But, be aware that impermeable insulation alone cannot maintain thermal integrity or protect the pipe. Joints and cracks in the insulation allow water to travel between the insulation and the pipe, causing at least localized heat loss and corrosion. No insulation material is entirely impermeable when exposed to continuous moisture.

■ Insulation Temperature Ratings

All new insulation should be rated for the highest temperature of the equipment being covered. This is true even if the insulation is being used to cover existing insulation, because a break in the original insulation can expose the new insulation to the temperature of the equipment.

With organic insulation, long-term exposure to heat reduces the strength of the material. The rate of decay rises exponentially with temperature, so organic insulation should have a temperature rating that is substantially higher than the maximum operating temperature of the equipment.

■ Workmanship

Insulation should fit snugly all around the equipment. Also, adjacent sections of insulation should fight together tightly. Otherwise, heat is lost by convection between the heated surface and the insulation.

Using tape to cover gaps or hold insulation together is not satisfactory. All tape adhesives deteriorate with time, exposing any openings in the insulation.

Make the insulation removable at locations that may require access for maintenance, such as flanges, in-line traps, etc. Anticipate that water leakage may occur at such places, and install the insulation so that leakage at these points cannot soak the insulation. Leave an opening in the bottom of a removable segment of insulation to allow any water leakage to drain out.

■ Preformed Insulation

Preformed pipe insulation is a great labor saver. If it is sized properly, it provides snug contact with the pipe, reducing convection losses.

The elegant plant operator can now purchase custom fitted insulating covers for valves, steam traps, and other items.

■ Reflective Insulation

Reflective insulation is nothing more than a sheetmetal shell surrounding a hot surface. It is a supplemental method of reducing heat loss from localized surfaces of very high temperature, such as superheater elbows, where it would be awkward to use conventional insulation. The same metal shell may also be used as a safety guard. Reflective insulation is not appropriate as general insulation. Reflective insulation has little or no application in heating plants that operate at low and medium pressures. The metal covers sometimes seen on outside pipe systems are for protection against weather, and they do not function as reflective insulation.

Reflective insulation functions simply as a heat reflector. At very high temperatures, such as the temperature of high-pressure steam, radiation from a bare surface may account for much more heat loss than convection. Heat radiation from hot surfaces is electromagnetic radiation in the infrared range, with a much longer wavelength than visible light. This radiation is reflected by a smooth metal surface. To function properly, the reflector must not touch the hot surface. The reflector should remain at low temperature so that it does not radiate heat.

The shell does not reflect perfectly, and the hot surface does not reabsorb all the reflected heat. As a result, heat radiation bounces back and forth between the pipe and the shell. The shell itself absorbs some of the radiated heat, becomes hot, and loses this heat to the environment. The efficiency of reflective insulation declines seriously as it becomes oxidized or dirty. Even at best, heat loss from reflective insulation is much higher than with conventional insulation.

Don't expect to enhance the performance of conventional insulation with reflecting insulation. The outer surface of the conventional insulation is so cool that it does not lose much heat by radiation.

SAVINGS POTENTIAL: *Up to 40 percent of boiler energy input. Savings depend on the condition of insulation, how well insulation is protected from moisture, the extent of the distribution system, soil conditions, operating temperature, and other factors.*

COST: *The cost of repairs and improvement per unit of energy saved varies enormously, depending on the*

accessibility of the insulated surfaces, the size of the project, and other factors.

PAYBACK PERIOD: Less than one year, to several years, for insulating bare surfaces. Several years or longer, for replacing defective insulation.

TRAPS & TRICKS

PLANNING: Your most productive investment is the effort you spend in selecting insulation materials and installation methods. Especially with underground distribution, some insulation methods provide virtually

unlimited service, while others start to deteriorate almost as soon as they are installed. Do your homework.

INSTALLATION: Workmanship has a major effect on insulation effectiveness. Each type of insulation requires its own specialized installation techniques. Know the proper techniques before the work begins. Monitor the installation.

FOLLOWUP: Repeat insulation inspections at long intervals. Have a long-term maintenance calendar for scheduling this.

MEASURE 1.11.2 Minimize cooling or ventilation of pipe tunnels and other unoccupied spaces surrounding hot distribution equipment.

RATINGS

New Facilities	Retrofit	O&M
A	C	B

If steam or hot water pipe runs in tunnels or chases, you can reduce heat loss from the pipe by keeping the tunnels or chases as warm as possible. This may be a simple matter of closing manhole covers and access doors. For example, see Figure 1.

If no closures presently exist, add them. Improve existing closures, if appropriate.

If a pipe chase passes through a structure that is sensitive to heat, such as the occupied portion of a building, the pipe chase may be vented to keep it from heating the adjacent structure. A more efficient alternative is to insulate the walls of the chase.

Limitations

Safety is an important consideration if people are able to enter the heated space. For example, a tunnel should not be so hot that a worker might collapse from heat prostration while walking through the tunnel. Many countries have safety regulations covering this situation, but use common sense and alertness in any case.

Do not cut off ventilation to any spaces that need air for combustion.

If the space contains equipment that is cooled, such as chilled water lines or air conditioning ducts, calculate whether there is a higher net benefit in keeping the space warm or letting it cool. This compromise may change with the seasons. For example, if a tunnel carries both steam and chilled water lines, it may be best to keep the tunnel heated in winter and to keep it vented in summer.

A certain amount of venting may be required to remove humidity. The amount of venting that is needed

depends on the amount of moisture released into the space, which may come from pipe leaks, the surrounding soil, rain, etc. High humidity does not harm heated pipe and fittings, because the heat of the pipe prevents condensation of moisture on the pipe or its insulation. MEASURE 1.11.3 Route combustion air to the boiler by a path that recovers heat from the boiler room.

RATINGS

New Facilities	Retrofit	O&M
C	D	

As all boiler operators know, the air in boiler plants can be quite warm, and some parts of the boiler house are much warmer than others. You can improve boiler efficiency by drawing combustion air from the warmest part of the boiler room. This may be simple to accomplish, although it may require some strange and bulky contraptions.

Energy Saving Potential

Boiler efficiency increases by about one percent for each 40°F increase in combustion air temperature. Usually, the limiting factor in the effectiveness of this Measure is the temperature rise that you find inside the boiler room, rather than the amount of waste heat available. The temperature rise is limited by heat loss from the air to the boiler room envelope, and by the need to keep most of the space cool enough for people.

In an existing boiler plant, if combustion air is drawn directly from the outside, you can increase the combustion air temperature by moving the combustion air intake to a warm area inside the boiler room. For example, if the outside air temperature is 32°F (0°C), moving the combustion air intake to the inside may easily achieve a temperature rise of 40°F (about 20°C). You may be able to achieve an even greater average temperature increase in colder climates.

If the combustion air intake is already located inside the boiler room (typically near the burner front), rearranging the air intake may be able to increase the combustion air temperature by 20°F to 40°F (about 10°C to 20°C). Even this smaller increase saves one half to one percent of boiler fuel, which is economically important in all but the smallest heating plants.

Thus, the range of possible efficiency improvement is typically from 0.5 to 2 percent, based on temperature rise. The next question is whether enough heat is present in the boiler room to sustain this temperature rise. In most cases, the answer is yes. At full load, a typical boiler loses about two percent of its energy input into the space by convection and radiation. At partial load, the percentage of energy loss is higher. This is because the exterior surface of the boiler tends to remain at the same temperature regardless of load. This is a primary reason why overall boiler efficiency drops at low loads.

(Heat loss from the boiler surface is most constant with firetube boilers, because the shell of the boiler is filled with water and steam that remains at constant temperature. With watertube boilers, radiation losses may decrease significantly as the load falls, because the

combustion gases lose more of their heat to the tubes before they reach the outer surfaces of the boiler. [Measure 1.1.5](#) recommends lowering the steam pressure or water temperature as the load drops. This may reduce the heat loss into the space significantly.)

Relative heat loss tends to decrease with larger boilers because larger boilers have less surface area in relation to their capacity. Boilers with air casings may have relatively low heat loss, because the flow of air in the casing captures the surface heat of the boiler. Thus, with larger boilers, the availability of waste heat in the space is likely to be the limiting factor in raising the combustion air temperature. Still, larger boilers provide savings that are large in absolute terms.

An important amount of heat may be lost into the boiler house by hot piping and auxiliary equipment. Furthermore, if the boiler room is connected to adjacent steam tunnels and pipe chases, it may be practical to draw heat from these spaces. However, the latter may be self-defeating, because it increases the rate of heat loss from the piping. See [Measure 1.11.2](#) for more about this.

■ **Relationship to Boiler Plant Insulation**

Improving the insulation of the heated equipment in the boiler plant reduces heat loss, so it somewhat reduces the potential benefit of this Measure. Improving insulation enough to make a major difference in the total plant heat loss is expensive, unless there are serious localized defects in the insulation. In most cases, the benefit of this Measure is not reduced much by potential insulation improvements.

General Approach

The basic idea is to use the boiler room (and other connected spaces that contain hot equipment) as a preheater for the combustion air. Figure 1 sketches the concept in its basic form. Heat lost from the surfaces of the boiler and other hot equipment heats the boiler room air. The heated air rises and is confined. A duct is installed to draw the heated air into the boiler for combustion.

To keep people cool, locate the outside air intake so that outside air flows to the operator station before it flows over hot equipment.

The challenge is to maximize the amount of waste heat that is recovered. This may involve a variety of changes to the boiler room. Many different configurations are possible, and there is plenty of opportunity for ingenuity. Follow these guidelines:

- **Keep the waste heat from escaping.** Ideally, to recover the heat of boiler room air, the exterior surfaces of the boiler room should be well insulated and sealed against air leakage. In the real world, boiler rooms have little or no insulation, and they typically have copious air leakage. Give priority to minimizing air leakage, which is usually simple. It is usually not economical to insulate the boiler room, except perhaps to substitute insulating panels for useless windows or other openings. Try to minimize conduction loss by routing combustion air away from exterior surfaces.
- **Route the air through the space by a path that maximizes heat collection from hot equipment.** Don't bother trying to tailor heat collectors closely

to hot sources. Simple baffles and hoods may adequately collect the warmer air by convection.

- **Avoid diluting the combustion air with non-combustion air.** To maximize the temperature of the combustion air, only combustion air should flow through the heated part of the space. If extra air is needed, for operator ventilation or to feed draft regulators, try to keep this air flow away from the heated equipment and keep it from entering the boilers.

If the job is done well, most of the air within the boiler space remains still, especially air near the exterior surfaces of the space. Only enough air is circulated around hot equipment to satisfy the combustion requirement.

This Measure creates a zone of hot air in some elevated part of the boiler plant. This zone is too hot for people to occupy. Therefore, design the air flow path so that the heated air does not traverse normally occupied space as it flows toward the collection point.

Rate of Combustion Air Flow

Combustion of hydrocarbon fuels requires about 10 to 20 pounds of air per pound of fuel, including an allowance for excess air. The low end of this range applies to coal, and the upper end to natural gas. For fuel oil that lies in the middle of this range, burned in a boiler of average efficiency, the combustion air flow is roughly 250 CFM per million BTUH of boiler heat output. Use this figure to estimate the approximate amount of air flow through the space. The air flow changes with the load on the boilers.

Fig. 1 The basic concept Use the warmest air in the boiler room as combustion air, to improve combustion efficiency.

In small boilers, the combustion air flow is barely noticeable. In larger boilers, it can create quite a draft where the outside air enters the boiler room. If the draft is noticeable, route it to provide operator comfort as well as efficient heat collection.

How Heat Moves in the Boiler Room

The way hot equipment loses heat depends on its surface temperature. Insulated surfaces lose most of their heat by convection, whereas surfaces at steam temperature lose heat primarily by radiation, with a large amount of convection loss also. In a properly insulated boiler room, most heat is lost by convection. If the waste heat reaches the cold surfaces of the boiler room, by convection or radiation, it cannot be recovered.

Convection is a two-step process. Heat is first transferred to the air by conduction. Then, the heated air rises because it is less dense than the surrounding air.

Heat radiation passes through air without stopping until it reaches a surface. For all practical purposes, air does not absorb heat radiation or radiate heat itself.

How to Channel the Waste Heat

Ideally, combustion air should flow over all the heated equipment in the space, collecting as much heat as possible, and then flow into the boiler. It should avoid cold surfaces. The typical boiler room is not laid out for this to happen, so you need to guide the heated air to the combustion chamber. This involves collecting air in a hot area of the boiler room, and then routing it to the burner through a duct. Here are the main steps.

■ Close Penetrations in the Boiler Room Envelope

Boiler rooms typically have openings in the walls and ceiling to vent heat, such as roof ventilators and high windows. Keep these closed, and provide comfort ventilation for the operating personnel as suggested below. If you cannot close the openings permanently, mark them prominently to indicate that they should be kept closed for the purpose of heat recovery. See [Reference Note 12](#), Placards, for effective marking techniques.

■ Partition the Boiler Space

If the boilers are installed in the same space as other equipment, such as chillers or air handling units, consider installing partitions to help concentrate the heat from the boiler plant. This may also improve the efficiency and longevity of the cooling equipment by a modest amount. Partitions for this purpose can be very light, perhaps consisting of nothing more than fireproof fabric.

■ Install Heat Collecting Hoods

Heated air rises, so you can collect heated air by installing a hood over the boiler, and perhaps over other equipment that loses a significant amount of heat. The basic idea is sketched in Figure 2. Hoods keep the heated air from coming into contact with cold exterior surfaces before it is recovered. Boiler rooms typically have minimal insulation, so this can be important. It is especially important if the boiler space is much larger than the boiler itself.

Installing hoods over the boilers may allow ventilators to be installed in the ceiling or walls. This may be the best way to collect waste heat while providing adequate cooling for people.

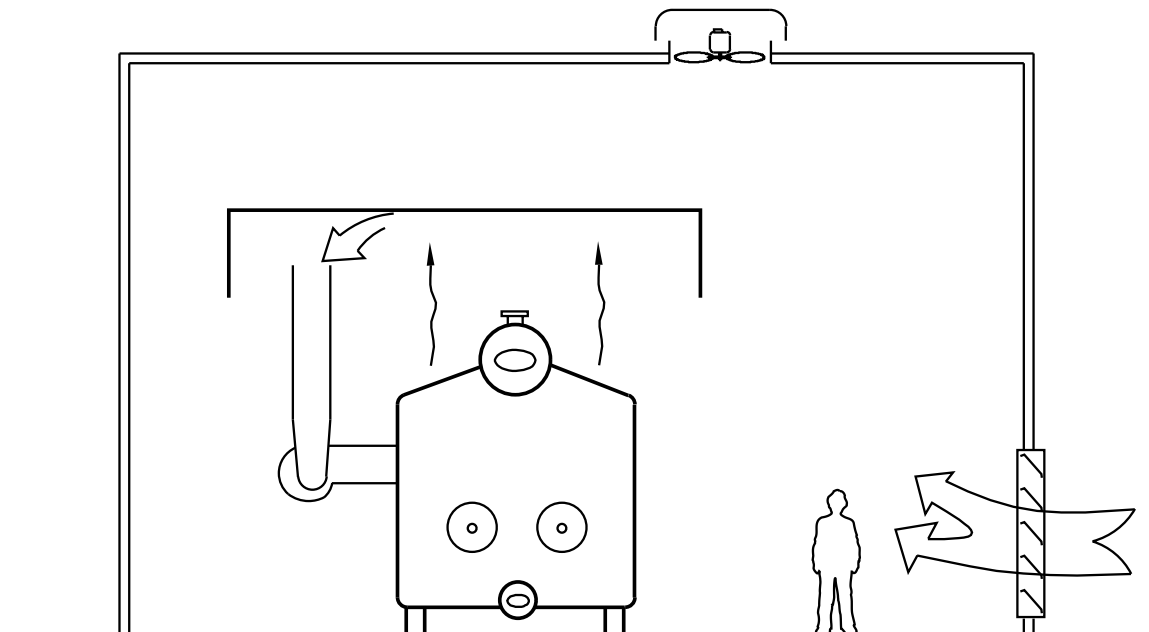

Fig. 2 Heat collecting hood The hood captures the air heated by the boiler and other hot equipment before it is cooled by contact with exterior surfaces.

You can make the hoods of lightweight material. To improve performance slightly, add a thin layer of insulation to either the top or bottom. For example, duct board should work well. The material should be fire-resistant and have little fuel value. The major installation problem is working around the clutter of pipes and pipe hangers that exist above the equipment.

The height of the hood above the equipment does not matter much, unless there are ventilators moving air through the space. Install hoods high enough to provide space for working on the equipment.

The major disadvantage of this method is that fails to recover heat from equipment that is not located under the hood. To do this, you can install additional hoods that feed air into the main hood. The air should rise into the main hood through large slanted ducts or chutes, like a water slide turned upside down. There should be only one combustion air collection point for each boiler, because it is impractical to balance the air flow from different collecting points.

Hoods recover radiant heat only by absorbing it or by reflecting it back to the hot equipment. Radiant heat travels in all directions, so the only way to capture more radiant heat is to surround the hot equipment more completely. Any opaque material stops radiant heat, no matter how thin it is. Metal surfaces reflects a large part of heat radiation.

■ Separate the Air Flow into Draft Regulators

If the flue system uses draft hoods or barometric draft regulators, they may be a serious impediment. Both types of draft regulators must draw air from the interior of the boiler room in order to regulate draft properly. Unfortunately, these dampers are typically located right

above the boiler, where they may draw a large portion of the heated air directly into the flue. Figure 3 illustrates the problem.

The only solution is to install a heat collecting hood below the level of the draft hood or barometric regulator. See Figures 1 and 2 in [Measure 1.5.1](#) to see what you have to work around in order to accomplish this.

■ Isolate Comfort Ventilation

Operator comfort may require additional outside air, especially in smaller boiler plants where the amount of air brought in for combustion air is not sufficient to provide comfort ventilation first. If possible, keep the additional air separate from the combustion air stream. For example, consider providing an enclosure for operating personnel that has a separate fan for comfort cooling.

Where to Locate the Outside Air Intake

The air that is drawn from the space for combustion must be replaced with outside air. The location of the outside air intake determines where the flow of air through the space begins. If you want to relocate the intake in an existing plant, consider using a duct to route air from the existing outside air louver.

Bring in outside air at a low point in the space. This helps to preserve the stratification needed to keep the entering air from diluting the warmer air in the space. Also, the lower level is where people are usually located.

■ A Layout That Won't Work

It may seem easy to route incoming air over the boilers just by placing an opening in the ceiling over the boiler. You hope that the entering cold air blankets

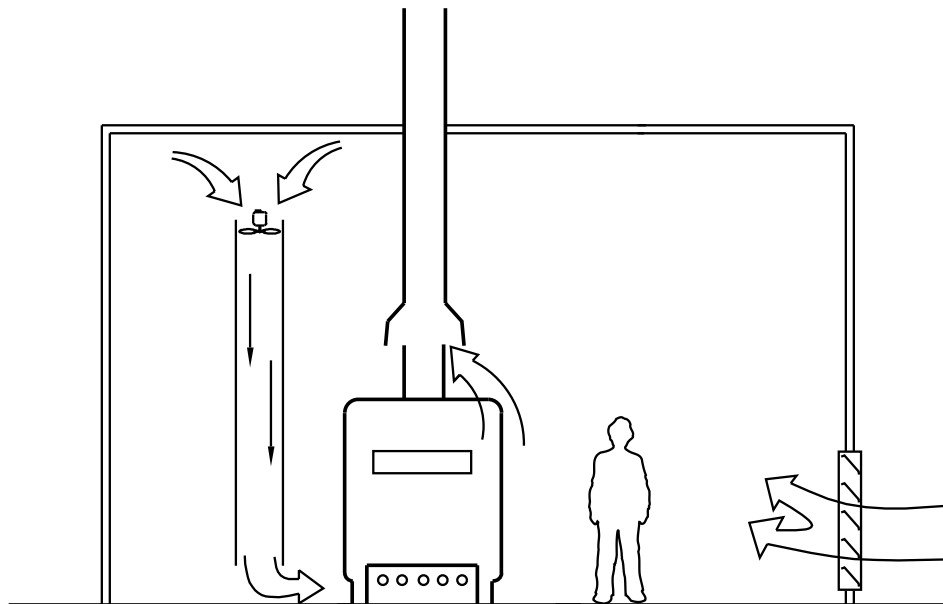

Fig. 3 Two problems If a draft hood or barometric damper is installed in the flue, it will draw the heated air out of the boiler room. If the boiler does not have an enclosed burner system, the heated air cannot be routed into the boiler reliably.

the boiler and is warmed before it gets to the burners. Unfortunately, this won't work. Figure 4 shows why. If there is a hole in the roof, the warm air in the space will rise by convection and exit the hole. Cold outside air will enter the same hole and fall to the floor in a confined stream, picking up little heat along the way.

Where to Collect Boiler Room Air

If you don't use a heat collecting hood, locate the inlet to the combustion air duct above the major heat producer, typically above the boiler itself. The height of the duct inlet is not critical, as long as it is above the top of the tallest heat producer. Do not locate the inlet immediately below the ceiling, as this would drag air along the ceiling and cool it.

It might seem clever to make a survey of the temperatures in the space, and draw air from the warmest point. This may mislead you. For example, it is very warm right above the steam drum of a watertube boiler, but the heat emitting surface is so small that the amount of heat to be recovered is also small.

Connecting the Duct to the Combustion Air Fan

Attaching the duct to the fan or burner assembly may be easy or it may be the Achilles heel of the job. If you go to a lot of trouble to collect hot air all over the boiler room, you have to be sure that the air goes into the boiler. There are three distinct possibilities, as follows.

■ Air Intake with Separate Forced-Draft Fans

If the boiler system has a separately mounted combustion air fan, you can run a duct to it from anywhere inside the boiler room. This is may be easy to accomplish.

■ Bolting the Duct to the Burner Assembly

Burner assemblies that include an integral combustion air fan may have flanges for attaching ducts or intake silencers to the combustion air intake. This makes it easy to install the combustion air duct, provided that the air intake is not in an awkward location, such as facing downward. In the latter case, see whether you can make the fan housing more accessible. Larger burner assemblies may be designed so that the fan housing can be rotated to make the intake face in a variety of directions. If this is not possible, you may be able to attach a sheetmetal transition box.

Design the duct so that it does not significantly reduce the fan capacity or increase its power requirement. Make the duct large, and use smoothly rounded bends. The construction can be very lightweight because there is only negligible pressure on the duct.

The duct should not hinder access to the burners for operation and maintenance. If the burner assembly must be removed to provide access to the inside of the boiler, design the duct to swing out of the way or to be easily removable.

An easy installation is to suspend the duct from the ceiling. This saves structural cost, and also makes it easier to swing the duct out of the way for burner maintenance.

■ If the Duct Cannot be Attached to the Burner Assembly

Making an airtight connection between the duct and the fan inlet may not be practical, especially with smaller boilers. In such cases, terminate the duct as near to the fan inlet as practical. Cover the burner assembly as much as possible to prevent air leakage. For example, you might terminate the duct with a fireproof fabric shroud over the burner.

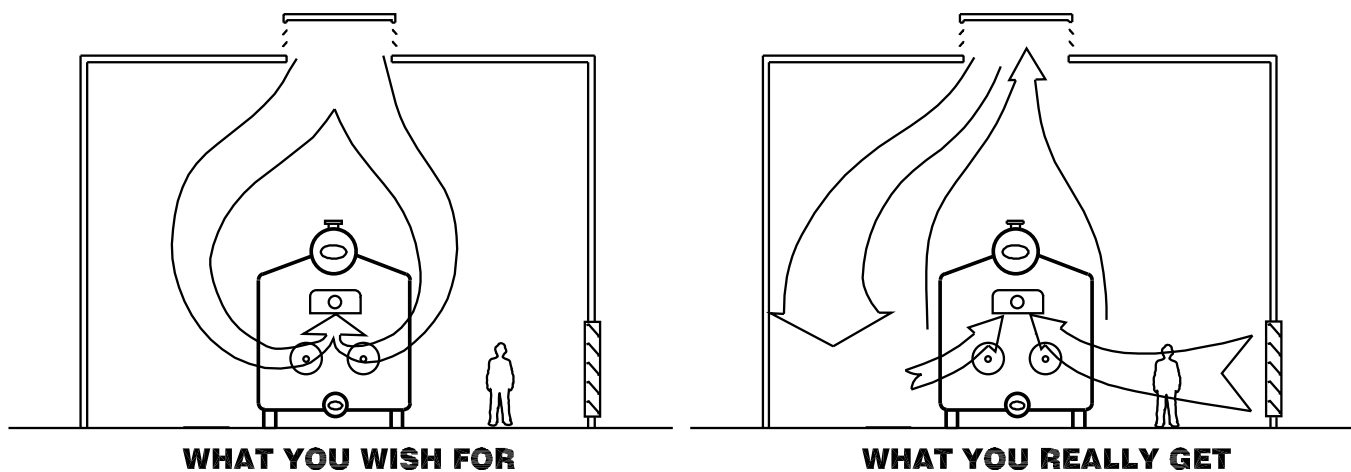

Fig. 4 Why the outside air intake must be located at a low point If cold outside air enters at a high point in the space, it will drop to the floor and enter the burners without collecting much heat from the boiler. The warm air in the space will escape out of the same hole.

If the boiler does not have a combustion air fan, as with atmospheric burners that draw air from floor level, it may be impossible to achieve a good seal. Atmospheric burners are sensitive to ambient air pressure, so it is not advisable to surround the burner assembly with any sort of enclosure.

If the boiler does not have a combustion air fan, install a fan inside the duct. The location of this fan is not critical. Installing the fan at the top of the duct allows the duct to be made of lightweight material, such as fireproofed fabric. The air discharge keeps the duct inflated if it is suspended properly. Figure 3 shows how this is done. It also illustrates that dumping the warm air into the open is less effective than ducting the warm air directly into the burner.

Interlock the operation of the fan with the operation of the burners. Preferably, the fan speed should change if the burner firing rate changes. This maintains the highest combustion air temperature. The energy consumption of the fan is minor if it is selected properly.

This configuration is less efficient than a tight connection to the burner because a greater volume of air is pulled through the area at the top of the duct, lowering the temperature in that area. Also, some dilution of the hot air may be unavoidable.

Operator Comfort and Safety

■ Provide for Work in the Hot Air Collecting Area

This Measure creates one or more regions of hot air in the boiler room. Design the air flow path so that this does not create discomfort or a safety hazard for the people in the space. Any area of the boiler room may have to be entered at some time. For example, there may be light fixtures within the hot zone that require lamp replacement, or pipe joints that may develop leaks. For these occasions, make it possible to cool down the hot zone. You may be able to do this by switching boilers, or by venting the hot area, or by ventilating the hot area with a fan.

■ Don't Trap Explosive and Suffocating Gases

An important safety consideration in boiler room design is venting dangerous gases, both in normal operation and in the event of a casualty, such as a fuel line rupture. Do not let your heat recovery system concentrate or trap potentially explosive vapors.

Natural gas and some other gaseous fuels are lighter than air, so your heat collecting areas might trap them in the event of a gas leak. If your boilers can burn gas, consider fail-safe safety vents that are activated by combustible vapor detectors.

Most of the vapors of liquid fuels, the gases of incomplete combustion, and refrigerant vapors are heavier than air. If the boilers cannot burn gas fuels, your heating collecting system probably cannot cause a problem.

Explain It!

The purpose of the heat recovery system is not obvious from its appearance, so install a prominent placard in the boiler room to explain it to plant operators. Spell out any actions needed to maintain the efficiency of heat recovery, such as keeping doors and windows closed, using appropriate ventilators for comfort, etc. See [Reference Note 12](#), Placards, for effective placard design and installation techniques.

System Design for Efficient Low-Load Heating

The load on a typical boiler plant varies widely with the season and the time of day. Large boilers become inefficient at low load. Boiler auxiliary equipment, such as fans, pumps, and air compressors, may consume excessive amounts of energy at low load. The Measures of this Subsection correct these inefficiencies by matching the boiler plant's energy consumption to the facility's heat requirements. Some of the Measures also reduce distribution losses, which may be a major source of energy waste in large facilities.

These Measures may provide major benefits in addition to energy savings, especially improved reliability and reduced plant overhead cost.

These Measures are major, expensive activities. They may not add much to the cost of a new boiler plant. In some cases, they may even reduce construction cost. However, they are generally expensive to retrofit, except when replacing old equipment or expanding an existing boiler plant.

INDEX OF MEASURES

1.12.1 In facilities that operate for extended periods with low heating loads, install a small, efficient lead boiler.

MEASURE 1.12.1 In facilities that operate for extended periods with low heating loads, install a small, efficient lead boiler.

RATINGS

New Facilities	Retrofit	O&M
A	C	

Boiler plants commonly waste energy because the boilers and other equipment are sized for the peak load requirement, ignoring the fact that heating plants typically operate for a large fraction of the time at low output. You can correct this deficiency by installing a small, efficient boiler to satisfy low heating loads. The smaller boiler is called a “lead” unit because it is the first to operate at low loads.

How Improper Sizing Wastes Energy

A boiler plant may waste energy in these areas when the load is low:

- **the boiler itself.** Boilers of good design typically do not lose much efficiency until the load is reduced to a small fraction of full load, say 30% or less. Below this level, efficiency starts to fall rapidly. Boilers that have on-off or two-stage firing control do not suffer low-load efficiency loss in combustion efficiency because they always fire at higher load levels. However, such boilers may suffer serious standby losses at low loads, depending on their designs. Large boilers typically have modulating burners, which can turn down their firing rate into the region where overall boiler efficiency (but not necessarily combustion efficiency) drops seriously.
- **auxiliary equipment.** Large boilers typically require a large amount of energy for operation of auxiliary equipment, such as forced draft fans, feedwater pumps, fuel oil pumps, air compressors for control air, and other equipment. Auxiliary equipment is often designed in such a way that its energy consumption remains high at all loads. For example, auxiliary energy consumption may account for only 2% of plant energy consumption at full load, but may account for 5% to 10% at low loads.

Auxiliary equipment that operates in an on-off manner suffers little efficiency loss at partial boiler loads. However, continuously operating fans and pumps typically are commonly controlled by throttling their output, which is inefficient.

The type of boiler and the kind of fuel have a large influence on auxiliary energy requirements. For example, a small gas-fired boiler may have a minimal auxiliary load, whereas a fluidized bed coal boiler has an enormous energy requirement for fans and fuel handling.

- **plant overhead.** A large part of the cost of operating a boiler plant is related to the size and complexity of the systems that are kept in operation, regardless of the actual heating load. Such overhead costs

SUMMARY

Appropriate for many boiler plants. In addition to saving energy, it may provide opportunities for reducing maintenance and labor costs, and for using less expensive energy sources. In new facilities, this is basic good design that can save money as well as energy. In existing facilities, the change is expensive.

include labor, maintenance, and housekeeping energy consumption, such as lighting and ventilation for the boiler house.

- **distribution losses.** The pressure and temperature within distribution systems typically remains constant as the load changes. Leakage is proportional to system pressure, and conductive heat loss is proportional to system temperature, so distribution losses are independent of boiler load. At low loads, these losses waste a relatively larger fraction of plant output.

If the existing boiler plant operates for long periods of time at low loads, you can reduce inefficiency in the first three of these areas by installing a small, efficient lead boiler system to carry low loads. This allows you to shut down the larger boilers for much of the time. (To reduce inefficiency in distribution, see the Measures in Subsections 1.10 and 1.11, as well as Measures 1.1.5, 1.12.2, and 1.12.3.)

An Example

A typical example is a college campus having an original estimated peak heating load of 200 million BTU/HR. To serve this load, the campus has two boilers of 250 million BTU/HR capacity, one of which serves as a standby unit. The boiler plant operates primarily to provide space heating, but it continues to operate in warm weather to provide heat for domestic water, cooking, and other functions. The nighttime load in summer typically is less than 5 million BTU/HR, and the daytime load in summer is always less than 30 million BTU/HR.

We could improve efficiency substantially by installing a 30 million BTU/HR boiler to handle the load during warm weather. This allows shutting down the existing 250 million BTU/HR boilers for the entire warm season.

We could go further by installing an additional 5 million BTU/HR boiler to handle the summertime night load. However, the marginal efficiency improvement provided by this boiler (compared to the 30 million BTU/HR boiler alone) would probably be much smaller than the marginal efficiency improvement provided by the 30 million BTU/HR boiler (compared to the original 250 million BTU/HR boilers).

Weather data for mid-latitude locations shows that the heating load typically is less than half the peak load for most of the year. Therefore, we could improve efficiency during the spring and autumn heating seasons by adding a boiler with a capacity of about 100 million BTU/HR. This allows the original boilers to remain shut down except for one or two months per year.

Many other combinations are possible. For example, installing a single 50 million BTU/HR boiler would allow shutting down the original oversized boilers for about half the year, and would keep them operating in a more efficient range of loads. A boiler of this capacity would handle the summer daytime load fairly efficiently, although it would still be too large for efficient handling of the summer nighttime load.

Cost vs. Efficiency

The previous example would be very expensive, especially if two new boilers are installed. This would be true of any retrofit application, unless it is necessary to replace existing boilers. In addition to buying one or more new boilers, you have to expand the boiler house.

Another apparent disadvantage in existing facilities is that this modifications will idle a large fraction of the equipment capacity most of the time. This disadvantage is psychological rather than economic. In retrofit applications, this Measure may be resisted because it leaves a large monument to the original sizing mistake in the form of the original equipment.

From a purely economic standpoint, the correct approach is to view the original investment as a sunk cost. The economic analysis should consider only the new investment and the savings that the new investment will provide, along with the salvage value of any equipment that can be sold. In retrofits, consider selling some of the equipment that is rendered unnecessary. There is a thriving market for used boilers and accessories.

If you are building a new facility, the principles illustrated by the previous example can reduce total construction cost. This is because you will need less reserve capacity.

Maximize Efficiency in the New System

The efficiency of a lead boiler depends on much more than its sizing. Optimize every aspect of the boiler plant that relates to the lead system. With respect to the boiler itself, high combustion efficiency and low standby losses are the primary criteria, so select a boiler with these characteristics.

Select the lead boiler and its auxiliary equipment to maintain high efficiency at all fractions of load. The lead boiler usually operates over a wider range of load, and for a longer time, than any of the other boilers.

For boilers that are fired by gas fuels, consider condensing boilers, which provide higher efficiency than conventional boilers. Figure 1 shows typical units. Condensing boilers are described in [Reference Note 30, Boiler Types and Ratings](#). Flue gas condensation in general is explained in [Measure 1.7.1.1](#).

Size, in itself, does not have a significant effect on peak efficiency. The best models of boilers of all sizes approach the theoretical limits of combustion efficiency as long as they operate within their efficient load range. At present, condensing boilers are available only in relatively small capacities, but you can successfully operate a large number of these units in parallel.

Select your new boiler to minimize auxiliary load. For example, some unusual types of boilers require large circulation pumps, and they offer no significant benefit in return. Techniques for matching auxiliary energy

WESINC

consumption to variable boiler loads are found in [Subsection 1.4](#) for burner systems, [Subsection 1.8](#) for feedwater and condensate pumps, and [Subsection 1.9](#) for fuel oil pumps. Many of these techniques are unconventional, and a great deal of thought is needed to derive the most efficient, reliable, and economical design.

Specify your new equipment by manufacturer and model number when purchasing. Otherwise, contractors or suppliers may substitute cheaper equipment that is less desirable in efficiency, features, or reliability.

Feasibility Analysis

You need a detailed feasibility study to decide whether it is economical to add a small lead boiler or a combination of lead boilers. The analysis should emphasize the following issues.

■ Duration of Low-Load Periods

Determine the shortest intervals for which it is practical to shut down the larger boilers, and compare this to your typical operating profile. For example, a boiler plant serving a large commercial facility may have a substantial drop in load from midnight to 0500, but it may not be practical to shut down the boiler plant for such a short time. Frequent shutting down and restarting of a boiler causes leaks, deteriorates refractories, introduces oxygen into the boiler water, and promotes corrosion of flues. In addition, starting a large boiler system requires at least an hour of effort by one or more skilled operators. Balance the energy saving against these additional maintenance costs.

■ Comparative Efficiency and Cost

If your heating load fluctuates in typical fashion, calculate the cumulative energy consumption of the original plant and each potential new configuration over the course of a year of typical operation. This calculation should include the energy consumptions of the boilers, auxiliary equipment, and plant overhead functions (air compressors, lighting, etc.). To simplify this tedious calculation, use an appropriate computer program. See [Reference Note 17](#), Energy Analysis Computer Programs, for details.

Consider different combinations of boiler sizes. If the boiler load varies widely, the analysis will not point to a combination that is clearly the best. Instead, one combination of sizes will provide the highest overall system efficiency, and a different combination will provide the best economics. In the end, you will have to make an informed judgement call.

In existing facilities, measure the actual efficiencies of the existing boilers over their entire load range, using the methods and equipment recommended in [Measure 1.2.1](#). At the same time, use a wattmeter to measure the

energy consumption of electrical auxiliary equipment having variable output, such as forced draft fans and feedwater pumps that operate against a throttling valve. Also, measure the energy consumption of equipment having a steady output, such as on-off pumps, plant lighting, and air compressors. You can measure their durations of operation by using an interval recorder.

■ Ability to Reduce Plant Overhead Costs

Try to minimize plant overhead, which consists of costs external the boiler system itself, such as labor, maintenance, and plant utilities. For example, you may be able to operate a small lead boiler automatically, even though the larger boilers must be manned.

This may provide an opportunity to reduce staffing, which could substantially increase total cost savings. However, staffing reductions usually are practical only if you can limit operation to the lead boiler for an entire shift or for an entire season. Staffing requirements in many jurisdictions are dictated by the operating pressure and/or the capacity of the boiler.

Boiler maintenance cost depends largely on the number of operating hours, so reducing the operation of larger boilers should save cost. (On the other hand, starting and stopping a boiler increases some maintenance costs.) To achieve a saving in plant overhead energy consumption, such as lighting and ventilation, you would have to shut down the space in which the main boiler equipment is located.

■ Potential Fuels

Use the feasibility analysis as an opportunity to consider using different fuels that may provide advantages in cost, plant efficiency, reliability, maintenance, or environmental factors.

Distribute the Boiler Load Efficiently

To gain the potential benefit of this modification, you need to start and shut down the boilers in the sequence that satisfies the heating load most efficiently. This requires effective operator training, well documented procedures, and continuing supervision.

[Measures 1.1.4 ff](#) gives procedures for distributing the load among boilers most efficiently. Usually, you should load the lead boiler system to full capacity before starting larger units, but this is not always true. To avoid running out of capacity, operators need to foresee the possible need to start larger boilers. This requires supervisors to keep track of weather forecasts, plant equipment operating schedules, or other factors that may require additional heating capacity.

Automatic sequencing controls for boilers are commercially available. These are an effective method of ensuring that the most efficient combination of boilers is operated as load conditions change. [Measure 1.1.4.1](#) covers these controls.

Alternative Measures

An alternative approach is to shut down the boiler plant entirely during periods of low loads, and to install localized heating units. [Measure 1.12.2](#), next, covers this approach. It has the advantage of eliminating distribution losses during the period of time when the boiler plant is shut down.

If a facility is served by more than one boiler plant, you may be able to handle low loads efficiently by cross connecting the plants. This allows you to increase the average load on the boilers that operate, and to select the most efficient boilers to operate with priority. [Measure 1.12.4](#) gives this approach.

If energy waste at low load is caused mainly by inefficient operation of auxiliary equipment, rather than by inefficiency of the boiler itself, then improve the efficiency of the auxiliary equipment. See [Subsection 1.4](#) for burner systems, [Subsection 1.8](#) for feedwater and condensate pumps, and [Subsection 1.9](#) for fuel oil pumps.

ECONOMICS

SAVINGS POTENTIAL: 5 to 20 percent of boiler plant operating cost, in eligible applications.

COST: The typical cost of efficient gas- and oil-fired boilers ranges from about \$50 per thousand BTUH of capacity in residential sizes, to about \$15 per thousand BTUH in large commercial sizes, to about \$5 per thousand BTUH in large industrial sizes. Packaged stoker-fired coal boilers cost from \$15 to \$30 per thousand BTUH, depending on size. In new construction, this Measure may reduce the overall boiler plant cost.

PAYBACK PERIOD: May be immediate, in new construction. Several years or much longer, in retrofit applications.

TRAPS & TRICKS

DESIGN: Don't rush into this. Do your feasibility analysis carefully to get the sizing right. Consider all your configuration options.

SELECTING THE EQUIPMENT: Select a proven boiler design from a major manufacturer. Select the model with the highest efficiency. If you consider an innovative type, such as a condensing boiler, check its performance history.

OPERATION: It does no good to install an efficient lead boiler unless you operate it properly in relation to the other boilers. Be sure to accomplish [Measure 1.1.4](#) or [1.1.4.1](#).

MEASURE 1.12.2 Install localized heating units to allow shutting down the central plant during periods of low load.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Measure 1.12.1 explains why it is inefficient to operate a large boiler plant to serve small heating loads. If the boiler plant is serving only small items of equipment when it is operating at low load, you can shut down the plant by replacing those items with independently heated units.

For example, if a central boiler plant operates during the summer only to provide domestic hot water to various buildings, provide each of those buildings with its own hot water heater. This may allow you to shut down the central plant for a large part of the year, eliminating all its energy losses, and perhaps eliminating all its operating costs.

This Measure applies to facilities, such as college campuses and military bases, where the central plant exists primarily to provide winter heating. The boiler plant is typically operated during warm weather for domestic water heating, cooking, and other low-energy applications.

Feasibility Considerations

A major facility modification such as this deserves a detailed feasibility study before you start spending serious money. Consider the following factors.

■ **The Condition of the Distribution System**

The choice between this Measure and Measure 1.12.1 is likely to be determined by the amount of distribution system losses. Refer to Measures 1.10.1, 1.10.2, and 1.11.1 for methods that you can use to estimate energy loss in the distribution system. Distribution system losses may be large in systems that are extensive or old.

■ **Fuel Choices for the Central Plant**

If the central plant can use fuels that are significantly less expensive than the fuels that are available for localized heating units, this Measure is unlikely to be economical. Only a central plant can burn coal, heavy oil, and most waste fuels.

Don't overlook the possibility of converting the central boiler plant to use fuels that are less expensive or more desirable in other ways.

■ **Fuel Availability and Storage for Localized Units**

If the localized heating units burn natural gas, you have to install gas lines and metering, if these are not already present. If the localized units burn a liquid fuel, you have to install fuel tanks and associated piping. If the localized units use electricity, you probably have to increase the amperage, and maybe the voltage, of the electrical service.

SUMMARY

Appropriate for facilities where the boiler plant load is mostly seasonal. Especially desirable for reducing losses in long distribution systems. May reduce plant overhead costs. Expensive to retrofit.

■ **Ability to Reduce Central Plant Operating Cost**

Shutting down the central plant may eliminate most of its physical operating overhead for the season, especially boiler maintenance and housekeeping energy consumption, such as lighting and ventilation for the boiler house. The savings depend on the size and complexity of the systems that can be shut down.

Aside from energy cost, the largest plant operating cost is for labor. Shutting down the boiler plant on a seasonal basis may or may not let you reduce labor cost. It is difficult to get skilled boiler operators to work on a seasonal basis, so the boiler plant staff may have to be kept on the payroll all year. One possible way of reducing labor cost is to reassign boiler operators to seasonal duties that normally require other personnel.

■ **Ability to Control Localized Units**

This Measure increases the number of units that need to be controlled, and hides them from the physical plant staff. This is an invitation to excessive operation of the localized units, which can dissipate much of the potential savings. Therefore, a critical part of this Measure is providing reliable controls to limit operation of the localized units to times when they are needed. This may be feasible in some environments, but not in others. Refer to Subsection 5.1 for methods of controlling localized units.

■ **Options for Localized Units**

Consider alternative ways of installing localized heating units. For example, you may have a choice between installing a small number of small water heaters in a building, or installing a larger central unit to serve the whole building. Consider the relative costs of

equipment, installation, connections to the existing internal distribution system, and the value of space that is taken up or that must be added.

■ Relative Heating Unit Efficiencies

In the past, good central plant boilers had higher efficiencies than small fuel-fired heating units. This is no longer a valid generalization. In particular, small furnaces and boilers that exploit the heat of condensation of flue gases have seasonal efficiencies that range from about 86% to about 96%. This is much better than the efficiencies of large conventional boilers.

Most localized units that have very high efficiencies require gas fuels. Condensing oil-fired units are now making a hesitant entry into the market. The best conventional small oil-fired heating units approach the efficiencies of the best central plant boilers. All electric heating units have an efficiency of virtually 100%.

Small high-efficiency units experienced reliability problems when they were first introduced during the 1980's. Some models have survived long enough to establish a reasonable record of reliability. Investigate the performance records of the specific models you consider.

Less efficient small heating units still remain on the market because of their lower cost. The seasonal efficiencies of such units range from less than 70% to about 80%, typically worse than the efficiency of large boilers.

With the broad range of efficiencies that are available, be specific in designating the models of equipment you want. In most countries, new heating units carry efficiency ratings. These are approximate, primarily because standby losses cannot be estimated accurately. (The most efficient units avoid standby losses by using sealed combustion chambers.)

Of course, if the boilers in an existing facility are old and inefficient, this further improves the feasibility of installing local units.

■ Boiler Plant Auxiliary Energy Consumption

Refer to [Measure 1.12.1](#) about the energy consumption of boiler plant auxiliary equipment, which varies widely. Localized heating units usually have minimal auxiliary energy consumption.

Alternative Measures

Installing a small, efficient lead boiler in the boiler plant can improve the low-load efficiency of the central plant considerably, but it does not reduce distribution losses. See [Measure 1.12.1](#) for this approach.

You can reduce distribution losses somewhat during low-load conditions by reducing the pressure and temperature of the distribution system. See [Measure 1.1.5](#). You may have to make the system changes recommended by [Measure 1.12.3](#) in order to reduce the system pressure.

You may be able to reduce low-load energy waste in the boiler plant's auxiliary equipment. See [Subsection 1.4](#) for burners and fans, [Subsection 1.8](#) for feedwater and condensate pumps, and [Subsection 1.9](#) for fuel oil pumps.

If the facility is served by more than one boiler plant, you may be able to handle low loads more efficiently by cross connecting the plants. This allows you to shut down some boilers while increasing the load on others. Refer to [Measure 1.12.4](#) for this approach.

ECONOMICS

SAVINGS POTENTIAL: 5 to 30 percent of total heating energy consumption. There may also be significant savings in maintenance and operator labor costs.

COST: Efficient gas-fired air heating units cost about \$20 per million BTUH of capacity. Efficient gas- and oil-fired boilers cost \$30 to \$50 per million BTUH in residential sizes. Retrofit installation may double or triple these prices. In new construction, adding localized units may reduce the cost of the main boiler plant.

PAYBACK PERIOD: Several years or longer, except shorter in especially favorable situations.

TRAPS & TRICKS

DESIGN: You may have to invest a lot of thought and analysis to achieve the maximum potential of this activity. Investigate conditions at each of the locations where localized heating equipment would be installed, do load calculations for each location, and figure out the best method of installing the new equipment.

SELECTING THE EQUIPMENT: Stress efficiency when selecting small heating units. Use condensing boilers and furnaces where you can.

OPERATION: This activity increases the number of units that need to be controlled, and hides them from the physical plant staff. Provide reliable controls to prevent unnecessary operation. Include the appropriate control Measures from [Subsection 5.1](#).

MEASURE 1.12.3 If it is desirable to reduce the boiler operating pressure, eliminate high-pressure steam users or provide separate high-pressure steam boilers.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Measure 1.1.5 recommends that you keep the boiler pressure as low as possible. This may provide a number of benefits, including:

- reduced steam leakage
- reduced conductive heat loss
- improved boiler efficiency
- reduced scaling and corrosion
- reduced control valve erosion
- improved control valve stability
- reduced operator licensing requirements.

(Reducing the pressure of an existing boiler has some disadvantages, including steam metering error and possible boiler circulation problems. See Measure 1.1.5.)

In some cases, you may be prevented from lowering the system pressure in the boiler plant because one or more small users of steam require a substantially higher pressure than is needed by the rest of the users. For example, sterilizers or laundry presses may require a much higher pressure than steam heating.

The limitation may also occur inside the plant. For example, a boiler may have steam atomizing burners that require a pressure of 150 PSI, while the steam pressure requirement of the facility may be lower than this for much of the year.

WESINC

Fig. 1 High-pressure boiler in a laundry This remote boiler in a large hotel avoided the need to design the main boiler plant to provide high pressure for a specialized application.

In such cases, you can reduce the steam pressure requirement in two ways:

- **provide a separate small boiler at the high-pressure application.** For example, if a campus clinic needs high-pressure steam to operate sterilizers, install a small, high-pressure boiler at the clinic to serve this need. Small high-pressure boilers typically do not require operators. Figure 1 shows an example.
- **replace the user equipment with a different type.** An alternative solution in the previous example is to replace the steam sterilizer with an electrically heated unit. Similarly, if steam atomizing burners dictate a high boiler pressure, replace them with air atomizing burners.

ECONOMICS

SAVINGS POTENTIAL: Applications vary too much to allow general estimates.

COST: Small high-pressure boilers cost \$20 to \$40 per MBH of capacity, and retrofit installation may double or triple these costs. In new construction, other substitutions of equipment may cost little or nothing extra.

PAYBACK PERIOD: Several years or longer, usually.

TRAPS & TRICKS

PLANNING: Consider all the potential consequences of a change. For example, if you change from steam-atomizing to air-atomizing burners, will the new burners have a satisfactory turndown ratio, will you have the space for a large air compressor, will the compressor noise be objectionable, etc.?

MEASURE 1.12.4 If a facility has several boiler plants, provide cross connections that allow shutting down the least efficient boilers.

If your facility is served by several independent boiler plants, you may be able to interconnect the heating systems. This will allow you to select the most efficient combination of boilers and auxiliary equipment for each level of heating load. The efficiency improvement is likely to be greatest at low loads. If the boilers in individual plants are too large to handle low loads efficiently, having one boiler serve more than one system allows that boiler to operate at higher load.

Potential Savings

The savings that result from improved boiler loading are explained in [Measure 1.12.1](#). The savings that result from shutting down a boiler plant are explained in [Measure 1.12.2](#).

On the negative side, interconnecting systems may increase distribution losses because of the added piping. This is significant only if you have to add a long run of piping to interconnect the systems, and if this additional piping serves no other purpose. If heat is distributed by means of hot water, additional pump power may be required. Be sure to include these losses in the overall savings calculation.

System Compatibility

A facility with a number of different boiler plants may have a hodgepodge of different types of distribution systems. Separate plants may have been built as a part of successive facility expansions that did not consider overall facility efficiency. The differences in system characteristics may prevent interconnections from being made, or they may limit the choices. For example, a high-pressure steam system can feed a low-pressure system, but not the reverse. In this case, connecting the systems is useful only if the higher pressure system is the one that provides more efficient operation during low-load conditions.

You can feed heat from a steam system into a hot water distribution system by using heat exchangers. You can even do the reverse, if the temperature in a hot water distribution system is hot enough. However, in both cases, the heat can move only from the hotter system into the cooler one.

An Example

Consider a facility that has two separate boiler plants. Both of the plants are intended primarily to provide space heating, but they also provide heat for domestic water, cooking, and other functions. One of the plants has two boilers rated at 500 million BTU/HR

SUMMARY

each, and the other boiler plant has two boilers rated at 100 million BTU/HR each. Both boiler plants distribute steam at the same pressure. The heating season lasts six months, and both boiler plants operate efficiently during the heating season. However, during the warm season, the larger plant has an average daytime load of only 30 million BTU/HR, and the smaller plant has an average daytime load of only 10 million BTU/HR.

The individual load on each boiler plant during the long warm season is too low for efficient operation. But, if the two systems are connected, one of the 100 million BTU/HR boilers can serve the total average summer daytime load of about 40 million BTU/HR, which is a fairly efficient situation. Equally important, the larger boiler plant can be shut down for the entire warm season, saving a considerable amount of plant auxiliary and overhead cost.

The efficiency benefits extend into the early and late parts of the heating season. Typical heating loads in mid-latitude locations are only a fraction of the peak load for most of the heating season. In this example, one of the 100 million BTU/HR boilers can continue to supply the total facility load during the early and late parts of the heating season. During the coldest part of the year, the small boiler plant can be shut down entirely, and the entire facility can be served by the larger plant alone. A single boiler plant crew could shuttle between the two plants as the seasons change.

In this example, the great flexibility of the interconnection depends on the fact that both steam systems operate at the same pressure. If the smaller system operated at higher pressure than the larger system, an interconnection would still provide

substantial savings, but it would not be possible to shut down the smaller plant in winter. In the opposite case, if the larger system operated at a higher pressure than the smaller system, there would be little benefit in connecting the two systems.

How to Minimize Piping Cost

Installing piping is the main expense of interconnecting boiler plants. Pipe diameter is the dominant factor in the materials cost of the piping and accessories. Therefore, minimizing pipe diameter is a primary way to limit cost.

In steam systems, the piping must be large enough so that steam arrives at the remote ends of the system with adequate pressure. Pressure losses increase greatly with increasing flow rate, so you may have to compromise between cost and efficiency by limiting operation of the interconnections to times when flow rates are low. This may not be a serious limitation if the primary purpose of the interconnection is to improve efficiency during low loads.

If the facility has several boiler plants, you may have a choice of several ways of connecting the systems. The most versatile, and most expensive, is a loop that allows steam or hot water to flow from any boiler plant to any user. This may be an unnecessary extravagance. If you focus on the conditions when interconnection would save the most energy and money, this may narrow down the choices.

Pumping Efficiency in Hot Water Distribution Systems

In a hot water distribution system, minimizing pump power is a major efficiency consideration. It is pointless to save energy in the boilers by connecting systems, only to lose energy in the pumps. Pumps have a hunger for energy that is insidious because they are small and operate quietly. If a pumping system operates at full flow under all load conditions, pump energy consumption can become a major part of total plant energy consumption.

The pump power required to overcome the resistance of the added piping depends on the flow velocity, and hence, on the pipe diameter. In brief, bigger pipe allows smaller pumps. The energy cost saving with smaller pumps may eventually offset the higher cost of larger pipe. Calculate the best balance between pump power and piping cost.

Consider reducing pump energy consumption by using variable-flow pumping. You may be able to avoid installing supplemental pumps for the interconnections by converting the existing pumps to variable-flow operation.

As with steam distribution systems, you may be able to limit pipe size by designing the interconnections to operate only during low-load conditions.

Use Cross Connection to Increase Effective Capacity

If you can foresee a need for additional heating capacity, interconnecting existing plants may be a less expensive alternative to purchasing new boilers. Because of diversity, an interconnected system needs less total boiler capacity than isolated boiler plants. This benefit occurs only if the different systems have their peak loads at different times.

Use Cross Connection to Improve Reliability

Interconnections provide reserve capacity in the event of a boiler failure in any of the connected plants. This reserve capacity is limited by the capacity of the interconnections. This may argue in favor of larger pipe sizes, which are also more efficient.

Condensate Return

When steam systems are interconnected, provide for returning condensate to the correct boilers. For example, you could install a level sensor in the condensate receiver of one plant that causes additional condensate to be pumped to another plant. In retrofit, the details of modifying each plant depend on how the condensate and feedwater systems of the plants are presently arranged.

Sequence the Boilers Efficiently

Interconnection requires more sophisticated control of boiler sequencing and loading. In a solitary plant, boilers can be started in a fixed sequence. When boilers at different sites are interconnected, operators have to start and stop boilers at one plant with respect to conditions that exist at other plants, and these conditions change. If the operators don't do this efficiently, the benefit of the interconnections is wasted. For this reason, make sure that plant operators remain aware of the correct sequencing and loading procedure. These are the main points:

- turning on the most efficient boilers first
- selecting the boilers that operate most efficiently at each level of load
- minimizing energy consumption by boiler auxiliaries
- controlling the interconnections, including operation of valves and pumps.

Subsection 1.1 recommends various methods for accomplishing these functions, including automatic controls for sequencing the operation of equipment. Automatic controls are better at “remembering” repetitive functions than people. However, automatic controls do not relieve managers of the responsibility of understanding the control functions and ensuring that they are accomplished. Plant operators will override sequencing controls that they do not understand.

Feasibility Analysis

A major facility modification such as this deserves a detailed feasibility study. Consider these factors:

- **pressure and temperature compatibility.** This determines whether interconnection is possible at all.
- **duration of low-load periods.** It may not be practical to shut down large boilers for short periods, for reasons explained in [Measure 1.12.1](#). Consider whether major equipment can be shut down for periods long enough to justify interconnection.
- **fuels usable by different boiler plants.** You may gain a major cost saving with an interconnection that allows a plant burning a less expensive fuel to serve a larger load.
- **ability to reduce plant overhead costs.** If you can shut down a plant for an extended period of time each year, you may be able to gain a large saving in plant overhead costs. The main overhead factors are covered in [Measure 1.12.2](#).
- **the value of increased reliability.** Interconnections provide increased reliability in case of equipment failures. Consider how important this is in your circumstances.
- **ability to increase capacity or to avoid adding new capacity.** An interconnection may make it unnecessary to add new boilers or to replace old ones. This can be a major economic advantage.
- **comparative efficiency and cost analyses.** If your analysis of the previous factors indicates that it may be desirable to interconnect plants, make detailed efficiency and cost calculations.
- **capacity of the interconnecting piping.** The capacity of the interconnecting piping may have a major effect on cost. It may also determine whether the interconnection can improve system reliability.

Alternative Measures

You can improve the efficiency of each boiler plant individually during low-load conditions by having a small, efficient lead boiler in each plant. See [Measure 1.12.1](#) for this alternative.

Another approach is to shut down the boiler plants entirely during periods of low loads, and to install localized heating units. This solution eliminates distribution losses as well as avoiding inefficient operation of boiler plant equipment. See [Measure 1.12.2](#) for this solution.

If inefficient operation of auxiliary equipment at low loads is a problem, try to improve the efficiency of auxiliary equipment. See [Subsection 1.4](#) for burners and fans, [Subsection 1.8](#) for feedwater and condensate pumps, and [Subsection 1.9](#) for fuel oil pumps.

ECONOMICS

SAVINGS POTENTIAL: 2 to 20 percent of total boiler plant energy consumption.

COST: Varies widely, from tens of thousands of dollars for short interconnections, to millions of dollars for large facilities. This Measure may offer an immediate net saving if it provides an alternative to installing new boilers.

PAYBACK PERIOD: Several years or longer, typically. The payback period may be shorter in especially favorable situations.

TRAPS & TRICKS

DESIGN: Although the concept is simple, it is easy to be hasty and overlook opportunities for improving efficiency and reducing cost. A lot of money is at stake, so take your time.

OPERATION: For this expensive modification to be successful, the boilers and the system valves at different sites must be sequenced in a precisely defined manner. Operators in different locations must be well trained, coordinated, and alert. Review [Measures 1.1.4](#) and [1.1.4.1](#).

Section 2. CHILLER PLANT

INTRODUCTION

Cooling accounts for a large fraction of the energy cost of modern buildings in most locations. In warm and humid climates, cooling and dehumidifying may account for more than half of a facility's energy cost. Cooling is also a major cost of many industrial processes.

There is a rich field of opportunity for improving the cooling efficiency of existing buildings and plants. Many improvements in cooling technology have made it possible to build new facilities with improved cooling efficiency. There are also many techniques for improving the efficiency of existing cooling equipment. These range from simple adjustments to expensive plant modifications.

Many of these improvements pay back quickly. As in the case of boiler plants, a large fraction of the total energy consumption of the facility enters at the chiller plant. For this reason, an improvement in the chiller plant may save much more energy than improvements at individual items of end user equipment.

How to Use Section 2

This Section is organized by the components of the chiller plant and by particular types of modifications. The cheaper, more universal Measures are in the earlier Subsections, and the most expensive and specialized Measures are in the later Subsections. [Subsection 2.1](#) is the place to start with any chiller plant. Go through the rest of the Subsections in their approximate order, selecting the Measures that apply to your plant.

Equipment Scheduling And Operating Practices

Turning off equipment when it is not needed is the most powerful principle of energy conservation. The Measures in this Subsection recommend operating practices and automatic controls that limit operation of the cooling plant and its major components to conform to need. In addition, the first Measure provides for selecting the most efficient combination of equipment for each set of conditions. These Measures all deal with control. They may provide large savings at modest cost. Most of them are easy to accomplish.

INDEX OF MEASURES

2.1.1 Distribute the cooling load among chillers in the manner that minimizes total plant operating cost.

2.1.1.1 Install an automatic chiller scheduling controller.

2.1.2 Use automatic controls to shut down the entire chiller plant when there is no cooling load.

2.1.2.1 Control chiller plant operation by sensing the end-user cooling load.

2.1.2.2 Limit the operation of the chiller plant based on the temperature or enthalpy of the outside air.

2.1.2.3 In applications with regular schedules, use time controls.

2.1.2.4 In applications where pre-cooling is required, use optimum-start controllers.

2.1.2.5 In applications where automatic starting of chillers is undesirable, use automatic controls to alert personnel to start them manually.

2.1.3 Turn off and isolate heat rejection equipment when the corresponding chiller turns off.

2.1.4 In plants with multiple water chillers, minimize the operation of chilled water pumps and isolate idle evaporators.

2.1.5 Install power switching that prevents unnecessary operation of spare pumps.

2.1.6 Turn off compressor sump/crankcase heaters during extended shutdown intervals.

MEASURE 2.1.1 Distribute the cooling load among chillers in the manner that minimizes total plant operating cost.

If you have more than one chiller, you may be able to reduce your operating costs significantly by paying attention to the sequence in which you start the chillers, and by the way you distribute the load among the chillers. Here is why:

- if a chiller can operate at more than one level of output, its efficiency varies with load
- if you have more than one type of chiller, they may differ in their efficiency characteristics
- different chillers and combinations of chillers may have different auxiliary equipment energy requirements.

The chiller operating sequence is most important when the chillers have different efficiency characteristics. For example, if you have added newer chillers to an existing plant, the new machines are probably more efficient than the older units. Also, different types and models of chillers may have large differences in their part-load characteristics. For example, reciprocating chillers suffer less efficiency loss at low cooling loads than centrifugal chillers, even though they have lower peak efficiency.

Once you have figured out the optimum chiller loading schedule, you need to ensure that it is followed. Manual setting is satisfactory only if the chillers are tended continuously, and even this does not guarantee reliability. The subsidiary Measure recommends a controller to perform this function automatically.

How to Sequence Chillers

The most efficient way to load chillers depends on the way that they unload or modulate individually. To avoid confusion, we will discuss each type of modulation separately.

■ Optimum Sequence for Single-Stage Chillers

Single-stage chillers operate at constant output. They respond to changes in the cooling load by turning on and off, usually in response to the temperature of the returning chilled water. They usually have reciprocating or scroll compressors.

If all the chillers are single-stage and identical, the operating sequence does not matter.

If you have single-stage chillers with different efficiency characteristics, start the chillers in order of their efficiency, regardless of their capacity.

The only complication arises if different chillers have different auxiliary energy requirements. For example, a larger, more efficient chiller might require a larger condenser water pump. In this case, calculate the overall energy consumption of each chiller plus its

auxiliary equipment, and operate the chillers in the sequence that uses the least energy overall.

■ Optimum Sequence for Multi-Stage Chillers

Most reciprocating chillers adjust their output in fixed stages. They usually do this by disabling, or “unloading,” individual cylinders in the compressor. Older reciprocating machines had from one to four cylinders, and typically each cylinder could be unloaded separately. This provided a number of stages equal to the number of cylinders. It is becoming more common for the individual compressors of reciprocating chillers to operate in only two stages, and to achieve a larger overall number of stages by using several compressors. (For the reasons, see [Reference Note 32](#), Compression Cooling.) For example, a modern reciprocating chiller might have three compressors, each with two stages, for a total of six steps of cooling output.

Reciprocating chillers are most efficient at full output, because friction losses are constant, and unloading the cylinders incurs some losses. Therefore, it is usually best to load the first chiller up to full output before starting the next. If a chiller has several compressors, the manufacturer arranges the compressors to start and stop in the most efficient sequence.

If you have multi-stage chillers with different efficiency characteristics, sequence the chillers in order of their efficiency, regardless of their capacity. The output of staged chillers is usually controlled by sensing the temperature of the returning chilled water.

The only complication arises if there are differences in the auxiliary energy requirements of different chillers. For example, a larger, more efficient chiller might require a larger condenser water pump. In this case, calculate the overall energy consumption of each chiller plus its auxiliary equipment, and operate the chillers in the sequence that uses the least energy overall.

■ Optimum Sequence for Modulating Chillers

Centrifugal and screw chillers adjust their cooling output by continuous modulation, down to a minimum load. At the minimum load, the compressor must turn off, or the machine must resort to false loading. (False loading is very wasteful. Measures in [Subsections 2.6](#) and [2.8](#) attack this problem.) Chiller operation normally is controlled to maintain a fixed chilled water supply temperature.

Both centrifugal and screw chillers suffer serious efficiency loss at low loads. Therefore, your first guideline is to operate the minimum number of chillers.

If all the chillers are similar in efficiency characteristics but differ in size, it is generally best to start the smallest chiller first. This exploits the fact that the efficiency of modulating chillers improves with load, up to a large percentage of full load. This is especially important if the smaller chiller operates with less auxiliary power, for example, if it is served by smaller pumps.

When you have to start an additional chiller, distribute the load so that all operating chillers are at the same percentage of load. This is true even if the chillers are of different size, provided that their curves of COP versus load are similar. (This is not obvious. If you are interested in the mathematical proof, it derives from the fact that the efficiency curves of most modulating chillers are convex upward at all points.)

If the chillers are identical, it is easy to distribute the load evenly between the chillers. Simply control each chiller to maintain the same chilled water supply temperature. Be sure that the chilled water thermostat for each chiller is installed where it senses only the discharge from its own chiller.

If the efficiency characteristics of the chillers differ, operate the most efficient units first. For example, newer centrifugal chillers are more efficient than older units, so operate them first.

Control becomes complicated if there is a combination of chillers with different efficiency characteristics. For example, consider a chiller plant that has one older centrifugal chiller and a new screw chiller. The screw chiller is more efficient than the centrifugal machine at low load, but is less efficient at high load. In this case, it might be most efficient to operate the screw machine up to 60% of full capacity, then turn off the screw machine and transfer all the load to the centrifugal machine. If the load climbs to the point that both machines are needed, the load is shared between the two machines in a ratio that varies with the load.

In a complex case where dissimilar chillers operate together, develop a table that specifies which chillers to run, and the distribution of load between the chillers, at each total facility load from zero to maximum. To develop this table, you need to know the efficiencies of

all the chillers throughout their load ranges. From this, calculate the energy input to the chillers at each percentage of load. You may have to communicate with the manufacturers' engineering departments to get reliable part-load efficiency data for your chillers.

Similarly, calculate the chilled water pumping energy, the condenser water pumping energy, and the cooling tower fan energy for each level of load. Fan energy can be complicated, as explained in [Measure 2.2.2](#). You may have to make some simplifying assumptions.

With this information in hand, plot operating cost versus output for each chiller, including any significant differences in maintenance cost. Then, for each level of total plant load, tabulate the least expensive combination of chillers and auxiliary equipment.

Methods of Setting Chiller Load

If you have to distribute the load in unequal percentages to maximize efficiency, you need a reasonably accurate and convenient means of setting the load of each chiller individually. Some larger chillers have panel-mounted load limiters (commonly called "demand limiters") that you can use for this purpose. Figure 1 shows an example. Don't expect the calibration of these controls to be precise.

With water chillers, you can shift the load among chillers by setting different units to provide different chilled water temperatures. This is a relative adjustment, because resetting the chilled water temperature of one chiller will change the loads on all chillers.

This method has an efficiency penalty. It requires the most heavily loaded chillers to operate at a supply

Fig. 1 "Demand limiter" This control limits the maximum output of the chiller. It is called a demand limiter because it is intended to limit electricity demand charges. You can also use it to shift the cooling load among chillers.

temperature that is lower than average, which reduces their efficiency. The chilled water temperature setting has a strong effect on a chiller's efficiency. (See [Measure 2.2.1](#) for details.) Therefore, if you lower the temperature setting of one chiller to make it carry more of the cooling load, raise the temperature settings of the other chillers to achieve the highest average chilled water temperature that satisfies the cooling requirement.

How to Determine Chiller Output

If your chillers do not have a direct method of setting their individual or relative outputs, you need a method of measuring the chiller output. Use one of these methods:

- **the manufacturer's chart that shows how output relates to supply and return water temperatures.** To use this method, make sure that all your supply and return water thermometers are well calibrated. This method assumes particular water flow rates through the evaporator and condenser. The actual rates may be quite different. Therefore, this method works only as a relative indication of output, and only if the water flow rates are consistent in all the chillers.
- **a BTU meter in the chilled water line of each chiller.** This is the only way to measure cooling output directly. See [Reference Note 16](#), Measurement of Liquid, Gas, and Heat Flow, about BTU meters.
- **motor wattage.** Measuring wattage requires a wattmeter, which is not a standard item on most chiller control panels. To tell actual cooling output, find the chart in the manufacturer's catalog that shows how input wattage relates to load, as corrected for evaporator and condenser temperatures. This method tells you true output, provided that nothing has changed the efficiency characteristics of the chiller since the catalog data were measured.
- **motor amperage.** Amperage provides only a relative indication of load, so it is useful only for identical chillers. It does not provide a true indication of output, because the power factor of the motor varies with load over a wide range.
- **calibrate the position of mechanical control linkages,** such as the positioner for centrifugal chiller inlet guide vanes. This provides only a relative indication, as the output will change with evaporator and condenser temperature. Therefore, this method is useful only with identical chillers.
- **with steam-fired absorption chillers,** measure the steam flow rate or the condensate flow rate. Convert this to output by using the catalog data.

- **with direct-fired absorption chillers,** measure the fuel flow rate. Convert this to output by using the catalog data.

Sequencing Combinations of Compression and Absorption Chillers

In a chiller plant that has both absorption and compression machines operating in parallel, the procedures for distributing the cooling load are the same as above, but it may be more complicated to calculate the optimum distribution of load between the two types.

One type or the other will be more economical at a particular moment. However, don't expect the same type to be more economical all the time. Compression chillers operate with electricity (except for engine-driven units), while absorption machines operate with some form of fuel or heat input. The relative costs of the electricity and heat sources may change dramatically over the life of the facility. Therefore, you have to repeat the calculation periodically.

Another complication is that electricity prices may vary over a wide range from moment to moment. The major variable component is the "demand charge," which may be a large fraction of total electricity cost. (See [Reference Note 21](#), Electricity Pricing, for details.) The desire to avoid high electricity demand charges is often a major factor in selecting absorption chillers. Be sure to include demand charges in the comparative cost calculations. For example, it may be most economical to operate absorption chillers during periods of peak electricity prices, and to operate compression chillers at other times.

ECONOMICS

SAVINGS POTENTIAL: 1 to 20 percent of the cost of chiller operation. Depends on the relative efficiency characteristics of the chillers that are installed.

COST: Small. The main cost is for the analysis required to create the optimum operating schedule.

PAYBACK PERIOD: Less than one year.

TRAPS & TRICKS

CALCULATIONS AND EFFICIENCY MEASUREMENTS: To do this right, you need to know the real efficiencies of all your chillers, including their auxiliary equipment. Don't make assumptions. Get certified chiller data from the manufacturer, and figure the auxiliary energy inputs yourself.

TRAINING AND COMMUNICATION: The big challenge is keeping the plant operators on top of the procedure. This requires effective training and supervision.

MEASURE 2.1.1.1 Install an automatic chiller scheduling controller.

RATINGS

New Facilities	Retrofit	O&M
B	C	

Measure 2.1.1 explains how to sequence chillers to minimize energy costs. If the plant has different types and/or sizes of chillers, the manual optimization procedures described in Measure 2.1.1 may require too much attention from the plant operators to be reliable. In such cases, install an automatic controller to perform this function.

Should You Install a Scheduling Controller?

An automatic optimizing controller is most desirable for chillers that have modulating controls, because this is the most difficult case. It is especially difficult if you combine modulating chillers of different types. In the latter case, the optimum distribution of load among the chillers varies with the overall cooling load.

There may be little or no reason to use a scheduling controller with single-stage or multi-stage chillers. You can usually sequence these satisfactorily by staggering their chilled water temperature setpoints. However, a controller may still be desirable if the staged chillers differ in both size and efficiency.

Selecting and Programming the Controller

A chiller scheduling controller is a simple computer that senses the chilled water temperature and sends the appropriate starting, stopping, and loading signals to the chillers in response. A variety of chiller load schedulers are available commercially for these functions. If the controller is not designed specifically for your combination of chillers, you have to do the analysis described in Measure 2.1.1. Do this analysis before you buy the controller, as it will help you to recognize which features you need.

The less expensive units perform elementary sequencing functions. The most elementary function is to turn on successive chillers as the previous chillers load up to specified levels. Another function is shutting down smaller chillers when they become fully loaded, and transferring the load to the larger chillers. You have to input the compressor loading sequences desired. Controllers in the middle of the range can distribute the cooling load among modulating chillers at specified ratios.

You may need more sophisticated control capability than this to deal with complex combinations of chiller characteristics. If you have different types or models of chillers with modulating compressors, the controller must be able to distribute the load optimally throughout the load range. This requires a controller that can memorize and process the efficiency characteristics of

each chiller in the plant. You have to input the desired load for each chiller at each chilled water temperature.

■ Don't Forget to Control the Auxiliary Equipment

If the chiller plant has separate auxiliary equipment, such as chilled water and condenser water pumps, select a chiller scheduler that can optimize the operation of these also, to provide the optimum combination of auxiliary equipment under all load conditions.

In some plants, optimum scheduling of auxiliary equipment may be complex. You have to program the controller to deal with each item of auxiliary equipment individually. To do this, you have to define the conditions under which each auxiliary should run. If the auxiliary has variable output, you have to decide the level of output for each level of cooling load.

Do not use a controller to operate auxiliary equipment if you can perform that function efficiently with a simple electrical connection between the chiller and the auxiliary equipment.

See Measure 2.1.3 about turning condenser cooling equipment on and off. See Measure 2.2.2.2 about control of cooling tower fans. See Measure 2.1.4 about turning chilled water pumps on and off. See Measure 2.5.2 about variable-flow chilled water pumping.

Alternative: Use An Energy Management Computer

If you have an energy management computer, you may be able to use it to optimize chiller sequencing and loading. This may be the most economical approach if the appropriate software is available and debugged. Otherwise, programming an energy management computer to perform this specialized function may be impractical. See Reference Note 13, Energy Management Control Systems, about the difficulties you may face.

ECONOMICS

SAVINGS POTENTIAL: 2 to 10 percent of chiller plant energy consumption. Depends on the relative efficiency characteristics of the chillers that are installed.

COST: \$4,000 to \$30,000, depending on the complexity of the plant and installation.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

SELECTING THE CONTROLLER: Be sure to select a controller that can deal with the characteristics of all your chillers. If you have chillers of different types or models, you may need a relatively complex and expensive controller. Resist the temptation to use a general-

purpose energy management computer for this purpose, unless you certain that it can be programmed properly. Also, such a computer is likely to become obsolete long before the chillers wear out. If you know how to use programmable logic controllers (PLC's), you can create virtually any chiller control sequence. But, even if you use a PLC, you still have to interface the PLC to the chillers.

PROGRAMMING: Account for all load conditions. Selecting the optimum schedule may be tricky, especially for combinations of types or models.

MONITOR PERFORMANCE: Schedule periodic checks to ensure that the controller is doing what you want, and that no one has tampered with the scheduling sequence.

MEASURE 2.1.2 Use automatic controls to shut down the entire chiller plant when there is no cooling load.

A chiller plant should not operate when there is no need for cooling. If a chiller plant operates unnecessarily, it may waste energy in a number of ways. With plants that are required on a seasonal basis, it is common practice to start the plant and shut it down manually. This results in inefficient operation at the beginning and end of the season, and inability to provide cooling when it may still be needed.

The general solution to these problems is to use automatic controls to start and stop all the chiller plant equipment in response to actual need for cooling. The five subsidiary Measures provide different methods of controlling chiller plant operation, adapted to different situations:

- **Measures 2.1.2.1 and 2.1.2.2** sense the presence of an actual cooling load. The first of these senses thermostatic control signals in the cooled spaces. The second senses the outside air temperature.
- **Measures 2.1.2.3 and 2.1.2.4** control chiller plant operation by time. The second of these provides for pre-cooling based on weather conditions.
- **Measure 2.1.2.5** is a hybrid of automatic and manual control for situations where safety considerations make it inadvisable to control equipment automatically.

In many cases, you want to control the running of the chiller plant on the basis of both load and time. In these cases, combine the subsidiary Measures as appropriate.

Energy Saving Potential

This Measure can prevent or reduce these sources of energy waste:

- **unnecessary auxiliary equipment energy consumption.** Even if the chiller stops running, the chilled water pumps, condenser water pumps, and perhaps the cooling unit fans continue to operate. The power consumption of this equipment is typically 5 to 20 percent of the plant's full-load power consumption.
- **false loading.** In some chillers, especially older ones, the chiller does not stop when the cooling load disappears. Instead, a false load is used to keep the chiller running above its minimum load, typically by hot gas bypass. If false loading is used, it typically consumes 10 to 40 percent of the plant's full-load energy consumption.
- **distribution losses.** Chilled water distribution pipe loses some cooling energy by conduction. This loss is minor in small systems. In large central cooling systems with pipe insulation in poor condition,

conduction loss may waste as much as 10 percent of the plant's full-load power consumption.

- **waste of cooling by end users.** Certain applications tend to waste cooling if it is available during mild weather. This is a problem in apartment complexes, military bases, and campuses, where tenants do not pay directly for their own utilities. Buildings with openable windows are especially vulnerable.

Not a Substitute for Local Control of Cooling

Turning off cooling at the chiller is not an acceptable substitute for good control of cooling equipment within the spaces. For one thing, the chiller plant must operate as long as any space requires cooling, even though the other spaces may not. For example, if the chiller plant is turned on to serve one classroom in a school after hours, the entire school will be cooled. Another reason is that turning off the chiller plant does not stop the energy consumption of end-use equipment accessories, such as the fans in fan-coil units and air handling units.

The chiller plant equipment and the end-use cooling equipment each need their own appropriate controls. For example, it might be appropriate to control space cooling units with timeclocks and to control the chiller plant based on outside air temperature.

Provide Separate Cooling for Small After-Hours Loads

A common waste of energy is keeping a large chiller system in operation to serve a few small spaces that operate during hours when the rest of the facility is shut down. An example is the cooling of computer rooms in office buildings. In such cases, consider installing separate cooling units to serve the spaces with longer operating schedules. See [Measure 2.8.2](#) for this approach.

Coordinate with Measure 2.1.3

The purpose of this Measure is to shut down all chiller plant equipment during periods when there is no cooling load. [Measure 2.1.3](#), below, interlocks the chiller's condenser cooling equipment with the running of the compressor under all conditions. Both Measures involve common control and wiring work, so try to accomplish both as a common project.

Coordinate with Control of Boiler Plant Equipment

The subsidiary Measures recommend techniques similar to those used for limiting the operation of the boiler plant ([Measures 1.1.1 ff](#)). If the boiler plant is located near the chiller plant, consider using the same control device for both heating and cooling equipment.

MEASURE 2.1.2.1 Control chiller plant operation by sensing the end-user cooling load.

RATINGS

New Facilities	Retrofit	O&M
B	C	

This is the first of five subsidiary Measures that automatically shut down the cooling plant when it is not needed. In this method, the plant shutdown controls sense whether there is an actual cooling load anywhere in the system. The control system does this by monitoring the thermostatic signals that control the end-use cooling equipment, such as fan-coil units in individual spaces. If none of the space thermostats calls for cooling, all chiller plant equipment is turned off.

This method applies to any type of cooling load, including solar load, heat gain from equipment and people, etc. The key point is that the thermostatic control system must be able to recognize the presence of a cooling requirement anywhere in the building. Figure 1 shows that this can be tricky.

Fig. 1 Why it is tricky to sense cooling load Some spaces on this face of the building are in deep shade, while the rest are exposed to strong solar gain. To turn off the chillers that cool this zone, sensors must be located where they will detect a cooling load in any part of the zone.

SUMMARY

The only accurate method of controlling the operation of the chiller plant based on actual cooling load. The cost and complexity depends on the sophistication of the present thermostatic controls.

See Reference Note 14, Control Signal Polling, for methods of collecting load information from a large number of thermostats. If a centralized system for monitoring all space temperatures is already installed, this Measure should be cheap. Otherwise, installing a system to monitor space temperatures may be considerably more expensive and complex than the subsidiary Measures that follow.

ECONOMICS

SAVINGS POTENTIAL: Typically a few percent of total chiller plant energy consumption, but may be more in some cases.

COST: Several hundred to several thousand dollars, typically. Maybe much more, if the areas served by the chiller plant are dispersed.

PAYBACK PERIOD: Several months, to several years.

TRAPS & TRICKS

MAINTENANCE: This method will not work properly unless all thermostats being monitored are intact and properly calibrated.

EXPLAIN IT: Explain this control feature to the plant operators, so they will not be surprised when the entire plant shuts down by itself. Write a clear explanation in the plant operating manual.

MONITOR PERFORMANCE: Operators in a hurry to fix cooling problems will be tempted to bypass the shutdown control. Schedule periodic checks to make sure it is working properly.

MEASURE 2.1.2.2 Limit the operation of the chiller plant based on the temperature or enthalpy of the outside air.

This is the second in a series of five methods for shutting down the chiller plant automatically when it is not needed. In this method, the system shutdown controls sense the temperature or enthalpy of the outside air. The main virtue of this method is that it is simple and easy to retrofit. Only one sensor is needed, and it is relatively easy to install. The advantages of this method over Measure 2.1.2.1 are much lower cost and greater control reliability. However, this method is satisfactory in a much more limited range of applications.

Where to Use this Method

Limit this technique to applications where the need for cooling is related closely to the outside air temperature or to the outside air enthalpy. Unfortunately, in many applications, the need for cooling does not correlate well with the outside air temperature. The cooling load of a space is the sum of several different heat loads, including solar radiation heat gain, internal heat gains, cooling and dehumidification of ventilation air, and conduction through the building envelope. This method is desirable only in applications where sensing the outside temperature provides a fair approximation to the effect of all these heat loads.

In particular, this method is unsatisfactory for facilities that have large solar heat gains. The intensity of solar radiation can overwhelm the effect of outside air temperature on the cooling load. Also, there are large differences in solar heat gain between different parts of a building and different times of day. This variability makes it impossible to compensate for large solar gains by fudging the outside air temperature setting.

On the other hand, in facilities where the windows can be opened, the high degree of ventilation provided by windows tends to make this method feasible. For example, this method of control may be satisfactory in multi-family housing complexes.

If some of the space served by the chiller system has high internal heat gains, you can compensate by lowering the outside temperature at which the chiller plant turns on. This works even if the heat gains are fairly high, provided that the heat gain is predictable. Lighting in office buildings is a typical example of large, regular internal heat gains. (We are assuming here that the interior spaces are cooled by outside air ventilation when the outside air is cool. This is called an “economizer cycle.” See Measure 4.2.5 for details.)

Whether to Use Temperature or Enthalpy as the Controlling Factor

In climates that tend to remain dry during the transition season, ordinary (dry-bulb) temperature is satisfactory for controlling the running of the chiller system.

Where high humidity may occur during the transition seasons, consider enthalpy controls instead of simple temperature controls. Enthalpy controls start and stop the chiller in response to humidity as well as to temperature. For example, an enthalpy control might start the chiller plant at an outside temperature of 65°F if the relative humidity is 100%, and at a temperature of 76°F if the relative humidity is 30%.

Use a type of enthalpy sensor that is accurate and stable. Some cheaper types of enthalpy sensors used in HVAC work, including all the early types, require too much maintenance and re-calibration to be practical. See Measure 4.2.6 for more about enthalpy controls.

How to Install the Outside Air Sensor

The way you install the outdoor temperature sensor is critical. An improper installation can affect the temperature reading by several degrees, which may be enough to render the Measure useless. Install the sensor so that:

- it is exposed to the prevailing outdoor air temperature
- sunlight does not heat the sensor, either directly, by reflection, or by heating surrounding surfaces
- building air leaking through the wiring penetration cannot reach the sensor

- precipitation cannot reach the sensor, either directly or by splashing
- if an enthalpy sensor is used, the unit is far away from foliage, cooling towers, and other sources of moisture
- it is protected from physical impact.

A typical good location is on top of a tall mast at the upwind edge of the roof, under a shield.

Explain It!

Install a placard on the chiller controls to inform operators why the chillers do not operate on mild days. See [Reference Note 12](#), Placards, for effective placard design and installation techniques.

ECONOMICS

SAVINGS POTENTIAL: Typically a few percent of total chiller plant energy consumption, but may be more in some cases.

COST: Several thousand dollars, typically.

PAYBACK PERIOD: One year, to several years.

TRAPS & TRICKS

CHOICE OF METHOD: Do not use this method if solar load is a significant part of the cooling load. If humidity is a large part of the cooling load, consider using an enthalpy sensor rather than a thermostat.

DETAILS: The location and shielding of the outside air sensor are critical, whether it senses temperature or enthalpy. If you control using enthalpy, be sure to select a sensor that is stable and reliable in the long term.

EXPLAIN IT: Tell the plant operators what to expect. Describe the controls in the plant operating manual. Install an effective placard at the chiller controls

MONITOR PERFORMANCE: Operators in a hurry to fix cooling problems will be tempted to bypass the shutdown control. Schedule periodic checks to make sure it is working properly.

MEASURE 2.1.3 Turn off and isolate heat rejection equipment when the corresponding chiller turns off.

RATINGS		
New Facilities	Retrofit	O&M
A	B	

Every mechanical cooling system requires heat rejection equipment to get rid of the heat that is collected in cooled spaces or processes. This equipment consumes energy for fans, pumps, or both. It does not need to operate when the chiller is not operating.

In systems that are assembled from separate components, the condenser cooling equipment may not be controlled properly to turn off when the chillers turn off. Or, if the heat rejection system is complex, the equipment may not turn off in a manner that minimizes energy consumption under all operating conditions. Figure 1 shows a typical cooling tower system where such inefficiency may arise.

Check your heat rejection systems to see if they have equipment that operates unnecessarily. If so, you can save energy by making some changes that are usually fairly simple.

Applications and Energy Saving Potential

This Measure applies to all types of chillers, unless they run continuously. The savings are proportional to the size of the equipment and to the length of time that the chiller or chillers are turned off completely.

SUMMARY
 Worth considering for all chillers where the compressor does not operate continuously. Control modifications are usually simple. Saves the most energy in water-cooled systems. In multi-chiller systems, you may have to install special valves.

Chillers using reciprocating and scroll compressors are designed to change output by cycling or staging the compressors. They turn off completely during periods of low load, allowing the condenser cooling units to be turned off. Single-stage compressors turn off for the largest fraction of the time, but these are used only in smaller systems.

Centrifugal and screw compressors modulate their output. Even these types must turn off below a certain fraction of full load, unless they are kept running by false loading.

If the system has some form of “free cooling” that requires the operation of the cooling tower, then the condenser cooling equipment probably has to keep running as long as there is a cooling load. See [Subsection 2.9](#) for details.

How to Control the Equipment

The method of control depends on the type of heat rejection equipment that the cooling system uses. The following are the usual situations.

■ Condenser Water Pumps and Condenser Isolation Valves

If a water-cooled chiller has its own cooling tower or cooling tower cell, turn off the condenser water pump when the compressor stops.

If a single cooling tower serves several water-cooled chillers, the design of the cooling tower and the configuration of the pumps determine whether you can turn off individual pumps when a chiller compressor turns off. Consider these factors:

- you have to keep the flow rate through each operating condenser high enough to maintain good heat transfer and minimize fouling. The chiller manufacturer normally specifies this flow rate. To satisfy this condition, the pump configuration must allow you to turn off individual pumps as chillers turn off, without reducing the flow rate in other condensers excessively.

- you have to valve off the condensers of idle chillers when the corresponding pumps turn off. You can operate the condenser valves manually if you start and stop the chillers manually. However, if the chillers are started and stopped automatically, you need automatic motorized valves.
- reducing the flow rate in the cooling tower may reduce its cooling ability. Gravity-flow towers typically need a certain flow rate to maintain good contact between the air and water. The manufacturer always specifies the upper limit of flow, but you may have to ask about the lower limit. The actual flow requirement may be increased by installation or maintenance defects, such as distributor trays that are not level or nozzles that are partially obstructed. If the tower has separate cells, you may be able to connect individual cells to individual chillers. This requires some piping modifications and the installation of motorized valves.

■ Cooling Tower Fans

The simplest and most common cooling tower fan controls simply operate the fans whenever the cooling water temperature is higher than the fan setting, even if the chillers served by the tower are turned off. A variation of this method operates the fans on the basis of outside air wet-bulb temperature.

It is easy to prevent unnecessary fan operation if a cooling tower serves only one chiller. Simply power the fan through an auxiliary contactor in the chiller controls.

Baltimore Aircoil Company

Fig. 1 Typical cooling tower system This system is divided into three cells, and each cell has two fans. This system could waste fan and pump energy by operating more of the cells than needed, and it could waste fan energy by inefficient control of the fans.

If a cooling tower serves more than one chiller, the modification is only slightly more complicated. In this case, energize the motor starters for the pumps and fans through relays from each of the chiller controls. The relays are wired so that operation of any chiller energizes the pumps and fans.

You don't need these methods if you install the sophisticated controls recommended by [Measure 2.2.2.2](#). Refer to [Measures 2.2.2 ff](#) and [2.4.2](#) for details of efficient fan control.

■ Evaporative Condenser Fans and Circulating Pumps

An evaporative condenser uses a pump to spray water over smooth coils that contain the compressed refrigerant from the compressor. A fan circulates air over the wetted coils, cooling them by evaporation. The fan in an evaporative condenser typically runs continuously, since the unit has no cooling ability without the fan. There is no need for the pump or fan to operate when the compressor is turned off. Avoid unnecessary operation simply by powering the pump and fan through an auxiliary contactor in the chiller controls.

■ Cooling Fans in Air-Cooled Chillers

With air-cooled chillers, operation of the cooling fans is usually an integral part of the chiller control circuitry. Operation of the fan is normally controlled on the basis of compressor operation or condenser pressure, so that the fan(s) will not run unless needed. Sometimes, fan operation is also controlled by outside air temperature. In such cases, you may find that the fans run during hot weather even when the compressor

is not running. This is a control oversight. Correct it by modifying the fan controls so that the fans run only when the compressor operates.

ECONOMICS

SAVINGS POTENTIAL: 5 to 30 percent of the energy used by the condenser water pumps and cooling unit fans.

COST: Several hundred to several thousand dollars for simple control modifications. Motorized valves for condenser water and related piping modifications cost much more.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

DETAILS: Exploit the chiller's installed features for controlling auxiliary equipment, if it has any. Be sure to provide adequate safety features to ensure chilled water flow and condenser cooling when starting the chiller. When making this change to an existing plant, be sure that you understand the existing controls for starting equipment, including the internal starting sequences of chiller-mounted controls.

EXPLAIN IT: Make sure that the plant operators understand how the equipment is supposed to be linked. Otherwise, the control interlocks will eventually be disconnected. Install a system diagram and an explanation of system operation at a prominent location. See [Reference Note 12, Placards](#), for guidance.

MONITOR PERFORMANCE: Schedule periodic checks of the procedures and/or controls in your maintenance calendar.

MEASURE 2.1.4 In plants with multiple water chillers, minimize the operation of chilled water pumps and isolate idle evaporators.

Figures 1 and 2 show two common chilled water pumping arrangements that are used in plants with several chillers. With either of these configurations, there are two simple things you can do to save energy as the cooling load falls: (1) turn off pumps that are not needed to carry the load, and (2) close valves to stop flow through the evaporators of idle chillers.

Both actions save pump energy. Turning off a pump saves pump energy. Shutting off flow to an idle chiller also reduces pump energy slightly, by reducing the flow rate through the pump.

Shutting off the chilled water flow to an idle chiller allows you to reduce the energy consumption of the remaining chillers. This is because the warm return water flowing through the evaporator of the idle chiller dilutes the chilled water from the chillers that are running. The mixing requires the operating chillers to produce chilled water at lower temperature.

For example, consider a low-load situation where only one of the chillers in Figure 2 is operating. The return water temperature is 48°F, and the system requires 46°F chilled water to satisfy the cooling load. The chilled water of the operating chiller is mixed with the warm return water coming through the idle chillers, so the operating chiller must produce chilled water at 42°F, instead of the system requirement of 46°F.

The lower chilled water temperature wastes energy because chiller efficiency typically declines about two percent per degree Fahrenheit that the chilled water temperature is reduced. (See Measure 2.2.1 for details.) You avoid this loss of efficiency simply by stopping the flow of water to the idle chillers.

In some systems, you will be able to accomplish both these actions at the same time. In others, you must do them at different times. Which you do depends on the sizing and connections of the pumps in relation to the chillers. It also depends on whether the end-use equipment has throttling valves or bypass valves. You can save much more energy if the system uses throttling control valves, rather than bypass valves. In many cases, you can convert a system that has bypass valves to operate with throttling valves.

Applications and Energy Saving Potential

These factors determine whether this Measure is appropriate for your plant, and how much energy it can save:

- **whether the chillers use supply water temperature control.** This Measure will not work with return water temperature control if you want to use automatic control of the pumps and isolation valves.

SUMMARY

An easy operating procedure that saves chilled water pump energy and improves chiller efficiency. Some piping and valve changes may be needed. Can damage chillers if you do it wrong. Easy to forget. In new construction, use variable-flow pumping (Measure 2.5.2) instead.

You can accomplish this Measure manually with return water temperature control.

- **the cooling load profile.** Savings are possible only when the load is low enough to allow one or more pumps to be turned off. Therefore, savings are greatest if the system operates for long periods at low loads.
- **the number and sizes of the chillers.** The savings are greatest if the chillers are sized so that unused chiller capacity can be turned off as the load falls. In other words, the saving potential is greatest in a plant with a larger number of chillers, or in a plant where a smaller chiller is installed to carry low loads.
- **the relationship of pump and chiller sizes.** You can achieve the greatest saving when the capacities of individual pumps correspond to the flow requirements of individual chillers. The worst case is a plant in which one pump is sized to carry the full chilled water flow of the system. In the latter case, the potential for saving pump energy is minimal, and you may not even be able to isolate the evaporators of idle chillers.
- **the types of control valves in the end-use equipment.** The savings potential is larger if the end-use equipment uses throttling valves instead of bypass valves. You can modify bypass valves on the end-use equipment, or replace them with throttling valves, to exploit this fact.

- **the length of the distribution system.** If the system uses bypass control valves, the savings potential is greater if the distribution system is long. This is because a larger fraction of pump power is devoted to overcoming piping loss, which declines radically as flow is reduced.

Dangers

The procedures in this Measure can damage equipment if they are done incorrectly. Be sure to avoid these three potential problems:

- **inadequate evaporator water flow.** Stopping the evaporator flow in a chiller that is operating will freeze the evaporator. In addition to bursting evaporator tubes, this gets water into the refrigerant circuit, which may destroy the compressor.
- **excessive evaporator water flow.** Shutting off the flow in idle chillers may accelerate the flow in the operating chillers. This may cause tube erosion. This hazard does not exist if each chiller has a dedicated chilled water pump.
- **pump cavitation.** If flow through a centrifugal pump is restricted too much, there is great turbulence in the impeller blades, which is aggravated by the formation of bubbles of water vapor. This is called “cavitation.” Cavitation makes noise, and can wear out pumps.

The following discussion tells you how to avoid these problems.

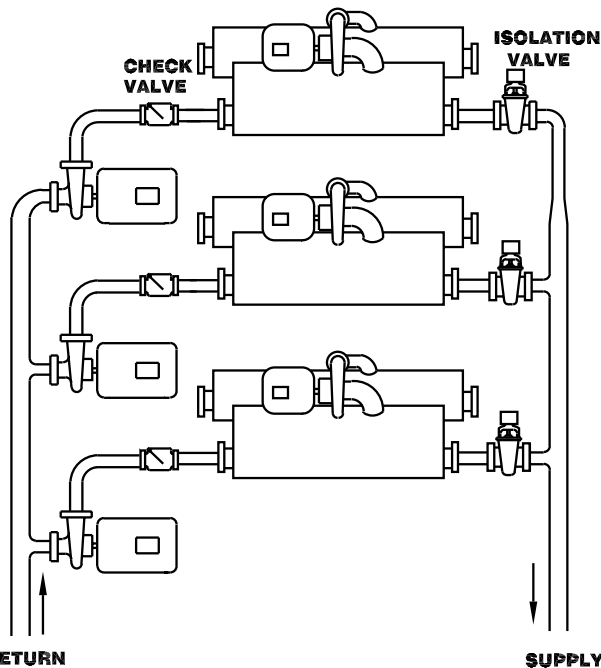

Fig. 1 Series chilled water pumps A chilled water pump is dedicated to each chiller. This is the easiest system to control efficiently. Its only disadvantage is that a pump failure will make a chiller unavailable.

How to Operate Pumps with a System Bypass Valve

In some constant-flow chilled water systems, a bypass valve is installed between the system pumps and the rest of the system. This is shown in Figure 3.

The bypass valve may have one or two functions. One function is to limit system pressure. The bypass valve dumps supply water flow back to the pumps if the system pressure becomes excessive. Another function is to maintain a minimum flow through the pumps. This is to prevent pump cavitation, which occurs when the flow through an operating pump is restricted. A bypass valve is used most commonly in systems where the end-use equipment has throttling valves.

If the system has chilled water pumps that are matched in capacity to the chillers, the procedure is simple. Operate the same number of pumps and chillers. Whenever a chiller is turned off, turn off the corresponding pump and isolate the evaporator of the chiller.

If the pump and chiller capacities are not matched, use a pressure sensing control to control the number of pumps that operate. How to determine the minimum acceptable system pressure is explained below.

This method of control should eliminate the need for the bypass valve under all or most conditions. Pump cavitation is not a problem with this Measure, because it reduces the number of pumps in operation. To make sure that the bypass valve does not waste energy by bypassing water unnecessarily, determine the maximum safe pressure for the system. Set the bypass valve to the highest allowable pressure.

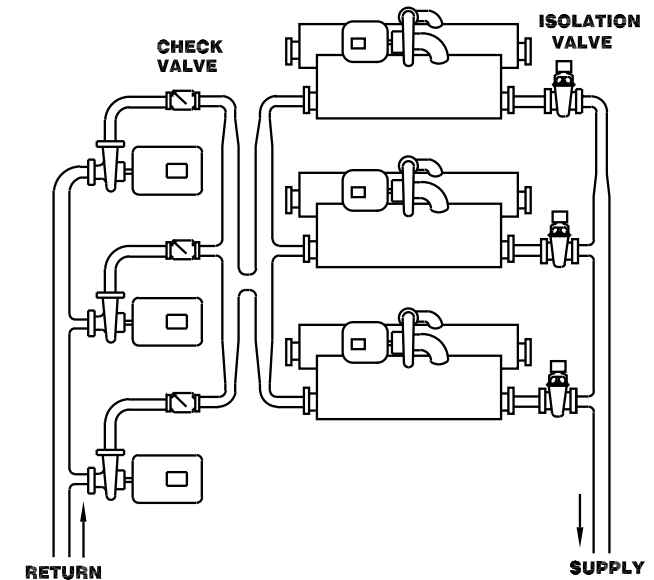

Fig. 2 Parallel chilled water pumps This arrangement is efficient only if the capacity of each pump is matched to the flow requirement of each chiller. Its only advantage is that it allows a single pump to serve as a reserve unit for any other pump.

How to Operate Pumps if the Cooling Equipment has Bypass Control Valves

In many chilled water systems, bypass control valves are installed on the end-use equipment, rather than throttling valves. Bypass valves control equipment output by splitting the flow of chilled water, passing some through the equipment and shunting the rest. As in the previous case, bypass valves are used to limit system pressure, or to maintain a minimum flow through the system pumps, or both. Also, some engineers believe, incorrectly, that bypass control valves are necessary for stable control. Figure 4 shows a chilled water distribution system that uses bypass control valves on the end-user equipment.

(We are using “bypass valve” as a broad term to contrast with “throttling valve.” If a bypass valve is installed on the return side of equipment, it may be called a “mixing valve.” If it is installed on the inlet side, it may be called a “diverter valve.”)

Figure 5 shows a typical bypass control arrangement on a cooling coil. The sketch shows that a balancing valve is installed in addition to the bypass valve. The balancing valve is adjusted to provide the same flow resistance as the cooling coil. This arrangement provides better control by the control valve, especially at low loads. In many cases, a balancing valve is not used. As an alternative to using a balancing valve, the bypass valve is selected to provide the characteristics of the balancing valve. (With this type of balancing valve, the bypass path has a minimum flow resistance approximately equal to the resistance of the controlled equipment.)

Some equipment that uses chilled water may have no control valves at all, i.e., they are always “wide open.” For example, the cooling coils of multizone air handling units sometimes have no control valves. Such equipment behaves in the same way as equipment that is controlled by bypass valves.

The most efficient approach is to get rid of bypass valves, and replace them with throttling valves, as explained below. Bypass valves limit your ability to turn off chilled water pumps because they keep the flow (almost) constant, regardless of the cooling load. If you turn off a pump, the system pressure will drop. You can turn off pumps only to the point that the pressure drop is not excessive. This seriously limits your ability to turn off chilled water pumps.

If you retain the bypass control, you will have to do some preliminary work to find out how to operate the pumps most efficiently. To do this, turn off a chilled water pump and see what happens to the system pressure. The pressure drop that occurs will depend on the characteristics of the pumps and of the system. Centrifugal pumps produce more flow as output pressure requirement is reduced. The relationship between pressure and flow depends on the characteristics of the

specific pumps used. (See [Reference Note 35](#), [Centrifugal Pumps](#), for more about this.)

One factor in your favor is that the pressure requirement of the end-use equipment drops significantly as load lessens. However, be careful when exploiting this fact to reduce pump power. Make sure that none of the end-use equipment requires maximum pressure while the rest of the system is at low load. For example, an air handling unit for a computer room may operate at high load continuously, even though the load on other air handling units varies with the weather.

If the chilled water system has a lot of distribution pipe resistance, you are more likely to get away with turning off a pump. Piping resistance is proportional to the third power of the flow rate, so it drops radically as flow is reduced, partially compensating for the reduced pump output. As a result, when you turn off a pump, the pressure loss at the end-use equipment is less than the pressure drop at the pump end of the system.

■ Operate Pumps on the Basis of System Pressure and Cooling Load

The objective is to minimize the number of pumps in operation under all load conditions. Or, if pumps of

Fig. 3 System bypass valve This arrangement is wasteful if all the pumps operate continuously and the valve is used to maintain constant system pressure. However, it is a useful safety device if pumps are operated efficiently, and the bypass valve is set only to relieve excess pressure.

different sizes are installed, the objective is to minimize the total pump power. You have to judge how many pumps to operate from the system pressure and flow requirements. Stay within these limits:

- keep the system *pressure* high enough to satisfy the requirements of the end-use equipment and their control valves, but low enough to prevent control valve instability and other problems
- keep the system *flow* high enough to maintain good heat transfer in the chiller evaporators, and to avoid cavitation in the pumps.

The system must provide enough pressure to force chilled water through the end-use equipment and its control valves. So, first determine the pressure requirements of the end-use equipment. Find this information in the mechanical drawings. For example, the coils in air handling units typically have a full-load pressure requirement ranging from 2 to 15 PSI.

Additional pressure is needed for satisfactory control valve operation. A general rule is that control valves should have at least as much resistance as the controlled equipment. The actual resistance of the control valves may not be stated anywhere in the plant records, so start by assuming that the combined resistance of the

Fig. 4 Bypass control valves on cooling equipment This common arrangement is the most wasteful because it requires the maximum continuous pump output. The preferred remedy is to replace the bypass valves with throttling valves.

Fig. 5 Typical coil bypass control valves The bypass valve controls the flow through the coil. The balancing valve equalizes the flow resistance between the two paths. Completely closing the balancing valve converts the bypass valve to a throttling valve.

equipment and its control valves is twice the resistance of the equipment itself.

To measure the system pressure, install a pressure differential gauge between the supply and return lines near the end of the distribution system. Install the gauge as far away from the pumps as possible to account for pressure drop in the distribution piping. This gauge installation becomes the key control point for turning pumps on and off. Install the gauge where it is easy to read, or alternatively, install a pressure differential sensor that indicates remotely at the pump control location.

(Install a gauge that measures pressure differential directly, rather than using two separate pressure gauges. If you use separate gauges, errors in the gauges can combine to produce a large error in the pressure differential.)

Then, conduct a series of trials throughout the range of system loads to measure the lowest pressure differential that is satisfactory for each level of cooling load. Deficiencies in cooling capacity are likely to appear first in the end-use equipment that has the highest design pressure requirement. If there is some equipment that operates at high load while the average system load is low, pay particular attention to this equipment.

From these trials, prepare a schedule that tells the plant staff which pumps to operate at each level of cooling load, based on the indicated pressure differential.

Eliminate Chilled Water Bypassing to Increase the Energy Saving

To maximize your ability to turn off pumps, you have to eliminate bypass operation at the control valves. This may be easy. Also, it becomes much simpler to relate the operation of the pumps to the operation of the chillers.

If your end-user equipment has balancing valves in the bypass line, you can eliminate bypass operation simply by closing the balancing valve. In effect, the bypass valve becomes a throttling valve. The valve is likely to behave in a satisfactory manner because you are turning off pumps, which prevents excess pressure on the valve. But, check the valve performance to be sure. If you do this, tag the balancing valve in a permanent manner, stating that it should be kept in the closed position.

If your cooling equipment has bypass valves, but no balancing valves, you may be able to achieve the same effect by closing off the bypass line. Figure 6 shows an example where this has been done successfully with a very large air handling unit.

If these cheap expedients do not work well, replace the bypass control valves with throttling control valves. It may not be economical or even necessary to replace all the bypass control valves in the system. For example, in a system that serves large air handling units and small fan-coil units, it may only be economical to replace the valves on the air handling units.

If you do convert to throttling control valves, consider installing a pressure-actuated bypass valve between the supply and return legs as a safety device, as in Figure 3. This protects the equipment in case someone neglects to turn off pumps when the load is low. Analyze your system to decide whether this is necessary to prevent damage from either excessive pressure or pump cavitation. If you do use a system bypass valve, make sure that it operates only as a safety device.

How to Isolate Idle Evaporators

Ideally, you want to valve off the evaporator of each chiller that is not operating. As we discussed before, this keeps return water from flowing through the idle chillers and forces all flow through the operating chillers. In this way, there is no separate return water path to dilute the chilled water.

The simplest case is shown in Figure 1. Here, each chiller has its own evaporator circulation pump. In this case, simply turn off the pump for each chiller and close its isolation valve when the chiller turns off. Note that this assumes that you are able to make the chilled water

flow rate in the system proportional to the cooling load, as discussed previously.

The situation in Figure 2 is almost as simple. In this case, operate the same number of pumps as the number of operating chillers, and close the isolation valves of the idle chillers. Again, this assumes that you are able to make the chilled water flow rate in the system proportional to the cooling load.

The situation becomes more complicated and less efficiency if the number of chilled water pumps does not equal the number of chillers. For example, a system with three chillers may have two chilled water pumps, each of which is sized for the total capacity of the plant. In such cases, you cannot simply valve off each evaporator as its chiller turns off. This is because you may cause water flow rates through the evaporators of the operating chillers that are too high or too low, as follows.

■ Evaporator Flow Rate Limits

Keep the flow rate in operating chillers within these limits:

- **low enough to avoid tube erosion.** Valving off all the idle evaporators may cause excessive water velocity through the operating chillers, which

WESINC

Fig. 6 A large bypass control valve converted to throttling operation The control valve for this enormous air handling unit was converted to throttling operation simply by eliminating the bypass path. Major energy savings result. However, it becomes more critical to operate the correct number of chilled water pumps.

WESINC

Fig. 7 Automatic evaporator isolation valves These greatly increase the reliability of efficient operation. They are not cheap, but with chillers this size, they pay back quickly.

accelerates tube erosion. This problem is most likely to occur in systems where the individual pump capacities are not matched to individual chiller flow requirements.

This problem occurs if the chilled water pumps are sized to handle more than one chiller. For example, if one pump is sized for the flow of two evaporators, you may have to keep both evaporators open to flow, whether or not both chillers are operating.

A generally accepted figure is that the water velocity in an evaporator should not exceed 11 feet per second (3 meters per second). Calculate whether any combination of chillers and pumps will exceed this flow rate. To do this, look up your chillers' characteristics to see how their evaporator water velocities relate to flow rate. Also, be aware that the flow rate produced by the pumps may be significantly higher than their rated values when the pumps are operating against reduced system pressure.

- **high enough to maintain proper heat transfer.** Heat transfer depends on turbulent flow of the chilled water. Turbulence occurs naturally at water velocities above a threshold value, which should be specified in the chiller catalog. For smooth evaporator tubes, this water velocity is about 3 feet per second (1 meter per second).

Failing to maintain proper water velocity can cause serious trouble. If idle evaporators are not valved off when some of the pumps are turned off, flow through the operating chillers will be inadequate.

This reduces chiller efficiency substantially, and may cause evaporator freezing.

In cases where you cannot simply isolate the evaporator of a chiller when the chiller is turned off, you have to develop a schedule that states which evaporators to valve off as the load changes.

■ Operate Evaporator Isolation Valves Automatically, If Practical

Evaporator isolation valves are almost always installed as part of the original equipment. However, do not expect to operate these valves manually unless you also start and stop the chillers manually. Starting a chiller with the evaporator valved off can freeze the water in the evaporator, seriously damaging the chiller. (Chillers have safety devices to protect against this occurrence, but don't rely on safety devices as a means of control.)

If the chillers start and stop automatically, install motorized valves that are interlocked with the chiller controls. Figure 7 shows motorized chilled water valves on an evaporator.

If you must operate the valves manually, at least install safety interlocks that prevent chiller operation unless the valves are open.

Regardless of whether you operate the valves manually or automatically, install placards at the valves explaining the operation of the system. See [Reference Note 12, Placards](#), for effective placard design and installation techniques.

Keep at Least One Pump Running

You have to keep at least one chilled water pump running as long as the chiller plant is in operation, even if no chiller is running at the moment. This is because chilled water temperature provides the information about cooling load needed to start the first chiller. To avoid the energy waste of running this last pump unnecessarily, use one of the methods recommended in [Measures 2.1.2 ff.](#)

Potential Problems with Return Water Temperature Control

Reciprocating compressors and other compressors that control output in steps usually control their output on the basis of return water temperature. You cannot use this Measure with return water temperature control if the pumps are started and stopped automatically. In that case, the pumps and chillers would oscillate on and off in attempting to follow the changes in return water temperature caused by the changes in flow rate.

If the pumps are started and stopped manually, this Measure probably can work with return water temperature control. Stopping a pump reduces the flow rate, causing a higher return water temperature for a given load. The system will stabilize with a lower average supply water temperature.

Use Chilled Water Temperature Reset

Isolating idle evaporators allows the operating chillers to increase their chilled water supply temperature. However, you will not reduce energy cost unless you actually exploit this opportunity. Use automatic reset controls for this function, because the system load fluctuates continuously. See [Measures 2.2.1 ff](#) for details.

A More Efficient Alternative

Variable-flow chilled water pumping is the most efficient design for a chilled water system. It perfectly matches pump power to the system flow requirements under all load conditions. See [Measure 2.5.2](#) for details.

Variable-flow pumping has the greatest advantage over this Measure in plants that use one or two large chilled water pumps. In retrofit applications, variable-flow pumping is much more expensive than this Measure. In new construction, variable-flow pumping adds relatively little cost in systems of medium and large sizes.

ECONOMICS

SAVINGS POTENTIAL: 20 to 70 percent of chilled water pump energy. 1 to 5 percent of chiller energy.

COST: If the right kinds of valves are already installed, the cost is limited to installing effective placards, which may cost about one hundred dollars.

The cost of converting bypass control valves to throttling valves varies widely. If you are lucky, it will cost almost nothing.

Simple interlocks to prevent chiller operation with the evaporator valves closed may cost several thousand dollars.

Automatic chilled water reset controls may cost several thousand dollars.

If you need to install automatic evaporator isolation valves, they will cost from thousands of dollars to tens of thousands, depending mainly on the pipe size.

PAYBACK PERIOD: Immediate, if you do everything manually. One year to many years, if you need to install automatic valves and controls.

TRAPS & TRICKS

PLANNING AND DESIGN: You will have to spend some time studying the characteristics of your chillers and pumps to work out the optimum schedule of pump and valve operation. Consider all the possibilities for adding or changing valves to exploit this technique as much as possible.

OPERATION: The plant operators will determine whether this activity succeeds or fails. So, provide clear instructions. Install highly readable placards on the valves and pump controls that explain how to operate them. Include this information in your training curriculum for new plant operators. Schedule periodic checks of proper operation.

MEASURE 2.1.5 Install power switching that prevents unnecessary operation of spare pumps.

Refer to [Measure 10.4.1](#).

WESINC

Fig. 1 Pump row of a large hotel All these pumps are in duplicate sets. Only one of each needs to be running. A transfer switch for each pair is a cheap, foolproof way to avoid unnecessary operation.

Cooling plants commonly have duplicate chilled water and condenser water pump sets for the sake of reliability. Figure 1 shows a facility with many duplicate pumps. Typically, these are installed with no controls or instructions to avoid unnecessary operation of the reserve pumps. Unnecessary operation of duplicate pumps is a common cause of energy waste, because operating personnel may not be sure how many pumps should be running.

A simple solution is to install a power switch for the pumps that keeps the spare pump from operating at the same time as the others.

Before proceeding, check the flow requirements of the system to verify that the pumps actually duplicate the required capacity. For example, if the plant has two chillers, each pump may be sized for only one chiller, in which case there is no standby pump.

You need more flexible pump control if you are able to run different numbers of pumps in response to changing load conditions. See [Measure 2.1.3](#) for control of condenser water pumps, and [Measure 2.1.4](#) for control of chilled water pumps.

MEASURE 2.1.6 Turn off compressor sump/crankcase heaters during extended shutdown intervals.

RATINGS

New Facilities	Retrofit	O&M
□	□	D

Most halocarbon refrigerants mix freely with the compressor lubricating oil. In chillers that use such refrigerants, a substantial amount of refrigerant may mix with the oil in the compressor sump (or crankcase) when the compressor is not running. When the compressor restarts, the pressure in the sump is suddenly reduced, and the refrigerant boils out of the oil. The frothing that results keeps the oil pump from delivering adequate lubrication to the machine, and the compressor may be seriously damaged.

A common accessory installed to prevent this problem is a small electric heater that warms the oil. The heater keeps the temperature of the oil high enough to drive off excessive dissolved refrigerant. The heater is usually a low-wattage electric resistance heating element. It may be wrapped around the outside of the compressor sump, or it may be installed inside the sump.

Sump heaters typically consume about 100 watts in the smallest compressors that are used in central systems, and up to several hundred watts in larger compressors. The control of sump heaters is simple. Typically, the heater turns on when the compressor is off, and vice versa.

If the chiller is shut down for an entire season, the sump heater may operate for that entire time. This is unnecessary. The sump heater has to operate for only a few hours prior to start-up to expel refrigerant from the oil. The manufacturer should recommend the minimum time required.

You can prevent unnecessary heater operation simply by disconnecting the heater power circuit during extended periods of shutdown.

The practical problem is ensuring that the heater is turned on well before restarting the chillers. Failure to do this can destroy the compressors. As a minimum,

Optimum Operating Temperatures

Optimizing the operating temperatures of cooling machines is one of the most important aspects of efficient operation. The COP of any machine depends strongly on the temperature difference against which it operates. (Reference Note 32, Compression Cooling, explains this issue.) Cooling plants typically keep this differential higher than it needs to be, providing you with an opportunity for major energy savings.

You can reduce the temperature differential from the bottom by increasing the evaporator temperature. You can reduce it from the top by lowering the condensing temperature. Both adjustments are physically easy to make. The appropriate temperatures depend on the cooling load, the weather, chiller design, and conflicts with the efficiency of other equipment in the cooling system. Your main challenge is figuring out the optimum temperature settings for all operating conditions. In most applications, the optimum temperatures change over a wide range as load conditions change. Therefore, try to use automatic controls to adjust the temperature settings on a continuous basis.

This Subsection has two principal Measures. The first optimizes evaporator temperature, and the second optimizes condenser temperature. The two Measures are similar in theory, and both may provide major savings. However, the two differ greatly in practice. Optimizing the evaporator temperature is usually easy, simple to understand, and safe. Optimizing the condenser temperature sometimes requires a lot of analysis, and the chiller may be damaged if the condensing temperature is set too low.

MEASURE 2.2.1 Keep the chilled water supply temperature as high as possible.

Keeping the chilled water temperature as high as possible provides major energy savings. Manufacturers' technical literature shows a saving of approximately two percent of input energy per degree Fahrenheit (or about four percent per degree Celsius) that the chilled water temperature is raised. This number applies to all types of chillers, with minor variations. Figure 1 shows how COP improves with increasing chilled water temperature, for a typical chiller.

This simple procedure applies to virtually all chilled water systems. Raising the chilled water temperature generally does not create any risks to equipment. And, it costs little or nothing to accomplish.

The amount that you can increase the chilled water temperature is limited only by the need to satisfy the cooling load. Most of the work of accomplishing this Measure consists of determining the maximum allowable chilled water temperatures over the range of cooling loads. The two subsidiary Measures offer manual and automatic methods, respectively.

Fig. 1 Improve chiller COP dramatically by raising the chilled water temperature This curve is for a typical centrifugal chiller. Similar improvement is available with other types of chillers.

The Potential for Raising Chilled Water Temperature

Chilled water systems are commonly designed to provide full cooling load with a chilled water temperature of about 42°F. Plant operators typically leave the chilled water temperature fixed at this value or some other. This is inefficient for most applications, such as air conditioning, where the load is well below its maximum most of the time. Typically, you can raise the chilled water temperature by 5°F to 10°F for much of the time. Even at full load, the typical oversizing of airside components (air handling units, fan-coil units, etc.) usually allows some increase in chilled water temperature.

A single space or a small number of spaces may require colder chilled water than is needed by the rest of the facility. In such cases, determine the limiting factor (e.g., inadequate air flow to the space) in the offending spaces. Consider spending some money to eliminate the problem in order to reap the savings that result from higher chilled water temperature.

Compromise with Fan Power in VAV Systems

In a variable-air-volume (VAV) air handling system, space cooling is controlled by varying the supply air flow, and the supply air temperature is nominally kept constant. Raising the chilled water temperature may raise the air temperature, which will cause the fans to operate at higher power.

Typically, more energy is saved in the chiller than is lost in the fans, so the best efficiency is usually produced by raising the chilled water temperature as much as possible. However, this may not be true in all cases. In case of doubt, calculate the optimum compromise between chiller power and fan power.

Compromise with Pump Power in Variable-Flow Chilled Water Systems

A variable-flow chilled water system saves pump energy by distributing chilled water only in the quantities needed by the air handling systems and older equipment. (Older conventional design bypassed unused chilled water around the user equipment.) In a variable-flow system, increasing the chilled water temperature increases the amount of chilled water that must be pumped, for a given cooling load.

Typically, you save more energy in the chiller than you lose in the pumps, so you get the best efficiency by raising the chilled water temperature as much as possible. However, this may not be true in all cases. In case of doubt, calculate the optimum compromise between chiller power and pump power.

MEASURE 2.2.1.1 Reset chilled water temperature manually.

RATINGS

This is the first of two subsidiary Measures that optimize the chilled water temperature. The simplest and cheapest method is to set it manually at the chiller control panel. See Figure 1.

The practical limitation with manual resetting is that the cooling load changes continuously. Don't expect operators to keep the chilled water temperature fine-tuned on a continuing basis. Therefore, manual adjustment is practical primarily in response to seasonal changes in cooling load. This limits savings to perhaps less than half the potential maximum savings, which can be achieved only with automatic reset controls (recommended by subsidiary Measure 2.2.1.2, coming up next).

If your budget limits you to setting the chilled water temperature manually, give your chiller operators a table of chilled water temperature settings to follow. You have to develop this table from experience over a period of time. As conditions change, raise the chilled water temperature until cooling capacity becomes inadequate at some location in the facility, and note the conditions (the time of day, the outside air temperature, the

percentage of occupancy, etc.). Repeat this until you have covered all conditions.

For convenience, schedule chilled water temperature adjustments at the same time as condenser water temperature adjustments. See Measure 2.2.2.1 about this.

MEASURE 2.2.1.2 Install an automatic chilled water temperature controller.

RATINGS

New Facilities	Retrofit	O&M
A	B	

This is the second, and preferable, method of optimizing chilled water temperature. Wherever it is economical to do so, reset the chilled water temperature using an automatic control. This is a simple, common control function that can be accomplished with a few standard control components. You can also use your energy management computer system for this purpose, if you have one. Some manufacturers offer specialized chiller controllers that perform this function.

The challenge with automatic controls is designing them to maintain the most efficient relationship between the chilled water temperature and the cooling load. Failing to do this accurately wastes some of the savings potential of the Measure, or causes comfort problems. The cooling load relates to several conditions, including the outside air temperature, the humidity, the amount of sunshine, the number of occupants, and the heat emitted by equipment.

The most accurate way of responding to the cooling load is to use the signals from the space thermostats. When the signal from any one thermostat indicates that the airside unit is unable to satisfy the load in that space, the chilled water temperature is lowered incrementally. See [Reference Note 14](#), Control Signal Polling, for methods of selecting the critical thermostat signal.

A cruder method of controlling chilled water is to sense the load at the chiller, for example, by sensing the difference between the supply and return chilled water temperatures. This method is less accurate than sensing space loads directly, but it is simple, cheap, and reliable.

With either method, do not let a single space or piece of equipment force the entire chiller system to operate at a much lower chilled water temperature. See [Measure 2.2.1](#) about this.

ECONOMICS

SAVINGS POTENTIAL: 5 to 15 percent of annual chiller energy consumption. The saving is partially reduced by increased fan power in variable-air-volume (VAV) air handling systems, and by increased pump power in variable-flow chilled water systems.

DESIGN: If the cooling system is complex, for example, if it includes variable-flow chilled water pumping or VAV air handling units, optimizing the chilled water temperature to achieve the lowest overall system energy consumption may be complex. Make sure that the control design is correct, keep the control as simple as possible, and make it easy to diagnose.

OPERATION AND MAINTENANCE: Select a control system that is compatible with the people who operate the chiller plant. For example, a common response to cooling complaints is to defeat any automatic chilled water controls and manually lower the chilled water temperature. Make sure that this sort of thing does not occur.

DOCUMENTATION: The purpose of the controls is not obvious. Put a clear description of the controls in the plant operating manual. (You do have a book of operating instructions for your plant, don't you?) Install an effective placard at the controls.

MONITOR PERFORMANCE: Failure of this kind of non-critical control is invisible. Schedule periodic checks in your maintenance calendar.

MEASURE 2.2.2 Optimize the condensing temperature.

You can reduce the energy consumption of your chillers by keeping the condensing temperature as low as possible. Typically, compressor power drops by about 1.5 percent per degree Fahrenheit (about 3 percent per degree Celsius) of condensing temperature. [Reference Note 32](#), Compression Cooling, explains the reasons.

Figure 1 shows how the coefficient of performance improves with lower condensing temperature, for a typical reciprocating chiller. However, not all cooling equipment benefits as much as the chiller represented in Figure 1. For reasons which we will discuss, the benefit provided by minimizing the condensing temperature varies widely among different types of cooling equipment.

Chiller manufacturers may be vague about condenser temperature requirements, or they may specify condenser temperatures without explaining them. As a result of confusion about chiller requirements, the condensing temperature in an operating chiller plant may be left higher than necessary. Correcting this is an important energy conservation opportunity.

There are two subsidiary Measures. [Measure 2.2.2.1](#) recommends setting the condensing temperature manually, if the plant has no automatic controls that can perform this function. This is an operator activity that is quick and costs nothing. However, manual setting is unreliable, and it cannot maintain optimum settings at all times. Subsidiary [Measure 2.2.2.2](#) avoids these limitations by recommending automatic controls to reset the condenser temperature.

Cautions

Unfortunately, optimizing the condenser temperature is not as simple as optimizing the chilled water temperature (which is covered by [Measures 2.2.1 ff](#)). It is complicated by these factors:

- In condensers that use fans for cooling, **lowering the condenser cooling temperature setting increases fan energy consumption**. Fans for condenser cooling typically consume 5 to 20 percent of system energy consumption. At some point, attempting to reduce the condensing temperature by increasing fan operation will cost more fan energy than is saved in compressor energy. Remember that the objective is to reduce the total energy consumption of the chiller system, not just the energy consumption of the compressor.
- Unlike ideal chillers, **real chillers do not always use less energy as the condensing temperature is reduced**. Reducing condenser temperature

improves the COP of all types of chillers at the high end of the temperature range. However, the energy consumption of some chillers may actually increase if the condensing temperature is reduced too much. This behavior occurs most commonly under low loads. Different types and models of chillers vary greatly in this regard.

- **Many chillers and chiller systems require a minimum condensing temperature** to operate properly or to avoid damage. There are a variety of reasons for this that are specific to individual chiller models.

Because of these complications, it is not appropriate to say simply, “lower the condenser temperature as much as possible.” In some cases, the minimum condensing temperature is a fixed number that is easy to determine. In other cases, you have to calculate the optimum condenser temperature for each combination of load and ambient temperature.

Fig. 1 Improve COP by lowering condensing temperature
This curve is for a modern reciprocating chiller. Centrifugal chillers may respond less favorably, especially at low loads. Be aware that many kinds of cooling equipment have a minimum allowable condensing temperature.

How Energy Consumption Depends on Condensing Temperature

Two major energy users in a cooling system, the compressor and the heat rejection fans, are affected by the condensing temperature. The compressor power depends on the condensing temperature, which is determined by the operation of the fans. The fan power is determined by the cooling load and by the air temperature (for dry coolers) or by the wet-bulb temperature (for cooling towers and evaporative condensers).

■ Response of Compressor Power to Condenser Temperature

For most chillers under most load conditions, lowering the condensing temperature reduces the energy consumption of the compressor. However, there are exceptions in some chiller models, especially centrifugal chillers. These exceptions occur at lower condensing temperatures and at low loads.

■ Response of Condenser Temperature to Fan Power

The condensing temperature is limited by the temperature of the cooling medium. If the chiller uses a dry cooler, the fans cannot cool the condenser below the outside air dry-bulb temperature. If the chiller uses a cooling tower or evaporative condenser, the fans cannot cool the condenser below the outside air wet-bulb temperature.

Fans operate at full power if they attempt to maintain a condensing temperature lower than allowed by the ambient air temperature (dry-bulb or wet-bulb, as appropriate). Fan power drops rapidly if the fans are controlled to maintain a condensing temperature higher than ambient, but this reduces compressor COP in most cases.

Based on this behavior, a fairly good approximation in most cases is to set the fan control temperature from 5°F to 15°F higher than the ambient dry-bulb or wet-bulb temperature. The actual optimum temperature differential depends on the heat transfer efficiency of the cooling unit, and on the cooling load.

At lower cooling loads, you can set the cooling unit temperature somewhat closer to the ambient temperature, because there is less temperature loss in the condenser system. This is not a big factor. Typically, the cooling load affects the optimum condenser cooling temperature setting within a range of less than 10°F.

■ Combined Compressor and Fan Power

In view of the previous, you can usually calculate a condenser temperature setting that is close to optimum. At high loads, the curve of compressor power versus condenser temperature is steep, so keep the condenser temperature as low as possible, but slightly above the ambient (dry-bulb or wet-bulb) temperature. At high

chiller load, the optimum fan temperature setting is typically about 10°F above ambient.

This temperature differential does not change much at lower cooling loads, because two effects tend to cancel. On one hand, the curve of compressor input versus condensing temperature is less steep, making the fan energy curve more dominant, and hence tending to push the optimum condensing temperature higher to minimize fan energy. On the other hand, the fan power curves are shifted toward the left at lower loads. So, on balance, the same differential between ambient temperature and condensing temperature may be satisfactory for all load levels.

There is an obvious exception. If the compressor energy input starts to increase at lower condensing temperatures, do not reduce the condensing temperature below the point where the compressor energy requirement is lowest.

Why Cooling Machines Have Minimum Allowable Condensing Temperatures

If your cooling equipment has a minimum condenser temperature limit, be sure to find this out. Condenser temperatures that are too low may reduce capacity, reduce efficiency, or cause damage.

Most cooling machines do have such a limit. The manufacturer may express the limit in various ways. For example, the manufacturer may specify a fixed minimum condensing temperature, typically around 70°F or 85°F. Or, the manufacturer may require a minimum difference between the condensing and chilled water temperatures. In some cases, the minimum condensing temperature may depend on load, but this degree of detail is not usually specified. In case of doubt, pick up the telephone and call the manufacturer's engineering department.

Some of the reasons why a particular machine may have a minimum condensing temperature are:

- **to provide enough pressure to force refrigerant from the condenser back to the evaporator.** Both the evaporator and the condenser contain refrigerant vapor in equilibrium with liquid refrigerant. Therefore, the pressure in each vessel is proportional to its temperature. The pressure in the condenser must be higher than the pressure in the evaporator to force refrigerant through the metering device that separates the two. If the pressure difference is not great enough, the reduced refrigerant flow limits the cooling capacity of the unit.

The required temperature difference between condenser and evaporator is greatest in chillers that use refrigerant metering devices that have considerable resistance to flow, especially expansion valves. The superheat that is required

in the operation of an expansion valve further increases the temperature differential.

(It is an article of faith among most engineers that the condensing temperature must always be higher than the evaporator temperature. In fact, there are ways of avoiding this requirement, but they require exotic design. For example, such designs may be used in heat pump loop systems, where the condensing temperature may be colder than the evaporator temperature. In principle, if the condenser is colder than the evaporator, the compressor could be designed to behave like a motor, providing energy recovery.)

- **with air-coil evaporators**, to keep the evaporator coil from frosting. If the evaporator is starved of refrigerant, the suction of the compressor lowers the evaporator pressure, which lowers the temperature inside the coil enough to allow frosting.
- **to keep lubricating oil that is mixed with the refrigerant from pooling in the condenser**. This would deprive the compressor of oil for lubrication. This limitation occurs only in chiller systems where the lubricant travels with the refrigerant.
- **with flooded evaporators**, to keep the refrigerant level from falling below the level of some tubes in the evaporator. This reduces heat transfer. This problem occurs in some flooded evaporators if the chiller lacks a separate refrigerant storage vessel of sufficient volume.
- **with some centrifugal chillers**, to avoid unstable gas flow through the impeller. The condensing temperature at which this occurs depends on the load.
- **in absorption chillers**, to avoid carrying salt from the generator to the condenser section of the distiller. A condenser temperature that is too low may increase the vapor velocity in the distiller to the point that the vapor carries salt over to the pure water.
- **in absorption chillers**, to avoid the risk of crystallizing the salt solution with sudden changes in load or cooling water temperatures. Low cooling water temperature increases this risk.
- **in systems that are operated during freezing weather**, to limit excessive ice formation in cooling towers and evaporative condensers. Keeping the condenser water warm melts frost.

These are all practical problems, rather than theoretical limitations. By the 1990's, some manufacturers were aggressively redesigning their

chillers to avoid the need to maintain elevated condensing temperature.

How to Calculate the Optimum Condensing Temperatures

Unfortunately, there is nothing you can observe directly that tells you the optimum condenser temperature. You have to calculate the optimum temperature based on the chiller's characteristics, the cooling load, and the temperature or enthalpy of the outside air. You have to create a table or graph of the compressor power and the fan power for all operating conditions. Then, for each combination of compressor load and outside air temperature (dry-bulb or wet-bulb, as appropriate), you have to set the condenser cooling temperature that provides the lowest overall power.

You may not have all the data you need to develop these curves. If the chiller is fairly modern, you can get the full-load curve of compressor power versus condensing temperature from the chiller catalog. Getting part-load curves may require a call to the chiller manufacturer's engineering department. Get data for the cooling unit fans from the cooling unit manufacturer.

Account for All Methods of Limiting Condenser Cooling

Identify all the methods that your chiller system uses to limit condenser cooling. Make appropriate adjustments at each control. With virtually all condensers that depend on a fan for cooling, whether wet or dry, controlling fan operation is the primary method of controlling condensing temperature.

The system may use additional methods to maintain a minimum condensing temperature. These include:

- **dampers** on one or more fans of the cooling unit. This method is used most often with dry coolers.
- a **bypass valve** to divert cooling water around wet coolers
- a **throttling valve** in the cooling water line
- **flooding the refrigerant side** of the condenser to reduce surface area
- **shutting off individual sections** of condensers.

If the system uses one of the latter methods, set the fan control so that the fan does not operate in a futile attempt to reduce the cooling temperature below the temperature being set by the other method. For example, a cooling tower may serve a number of cooling units that maintain a minimum condensing temperature of 85°F by using thermostatic throttling valves in their cooling water lines. If the cooling tower serves only these units, control the cooling tower fan so that it does

not attempt to reduce the cooling water temperature below 85°F.

Most of the latter methods increase fan or pump energy. Do not use any of them as a primary method of controlling condenser temperature. Generally, they should operate only when needed to maintain a minimum condenser temperature during cold weather, when turning off the fan is not adequate.

Improve Condensing Temperature Control Accuracy

If the method of controlling condenser temperature allows the temperature to swing over wide limits, the

average temperature has to be higher. The method of controlling the fan air flow determines how accurately you control the condenser water temperature. For example, a single-speed fan is the worst case, because large swings in cooling temperature occur as the fan turns on and off.

You can achieve more efficient control of condensing temperature with multi-speed fan control, or multiple fans, or some combination of these. Variable-speed drives provide the greatest efficiency. See [Subsection 2.4](#) for fan efficiency improvements.

MEASURE 2.2.2.1 Adjust the condenser temperature manually.

RATINGS

New Facilities	Retrofit	O&M
□	□	A

This is the first of two subsidiary Measures that offer ways of minimizing the condenser temperature. The cheap way is to adjust the condensing temperature manually. This requires virtually no effort. Just turn a screw in the thermostat that controls the condenser temperature. Or, if you have electronic controls, tap a few keys on the keyboard.

But, you have to invest in some brain work beforehand. Calculating the optimum condensing temperatures can be complicated. Unlike setting evaporator temperatures, where you can optimize by trial-and-error, you have to calculate the optimum condenser temperatures from chiller system characteristics that you measure or acquire from manufacturers. See [Measure 2.2.2](#) for the procedures.

Once you develop the curves explained in [Measure 2.2.2](#), you face the administrative problem of getting the plant operators to use them on a regular basis. The cooling load and the outside air conditions change from hour to hour, so it may be necessary to adjust the condenser temperature setting several times per day. This is most likely to be practical if the facility has an operator continuously on duty who can perform this task as a regular assignment.

How to Measure the Wet-Bulb Temperature

If your system uses a wet cooler, control the temperature settings of the condenser cooling equipment on the basis of the wet-bulb temperature of the outside air. The cheapest and most reliable way to measure wet-bulb temperature is with a sling psychrometer,

shown in Figure 1. The only disadvantage of this method is that you have to take the psychrometer outside and whirl it whenever you want to take a reading.

An alternative is to install sensors to indicate wet-bulb temperature directly. To do this, you need a temperature sensor, a humidity sensor, and appropriate electronics to convert the readings to wet-bulb temperature. You can get this as a package. If you take this approach, be careful to install both sensors properly. See [Measure 1.1.1.2](#) for installation tips.

How to Determine the Chiller Load

This is the more efficient of two subsidiary Measures that offer methods of optimizing condensing temperature. The manual method of control that is covered by [Measure 2.2.2.1](#) is tedious if the optimum condensing temperature may change much with changes in the chiller load and outdoor temperature and humidity. Therefore, it is inaccurate and unreliable in these circumstances. To avoid these limitations, install automatic controls to optimize the condenser water temperature.

Your Control Choices

If you are buying new chillers, you may now be able to specify a standard control that performs this function. Chiller manufacturers are starting to design their controls to exploit lower condensing temperatures. (More fundamentally, be sure to select chillers that are designed to operate efficiently at low condensing temperatures.)

If a customized control is available for your specific model of chiller, this avoids the analysis chore needed to do the control design yourself. This is most likely with packaged air-cooled chillers. With water-cooled chillers, you still have to determine the characteristics of the separate condenser heat rejection equipment.

Some systems need relatively simple controls, while others may need controls that are more complex. The simplest case is maintaining a constant differential between the condensing temperature and the outside air temperature (either dry-bulb or wet-bulb). You can make a control to do this by using a signal offset relay and a few other standard control components.

For more complex control characteristics, consider using your energy management control system, if you have one. But, first review [Reference Note 13](#), Energy Management Control Systems.

If you know how to use a programmable logic controller (PLC), you can create virtually any chiller control sequence. If you use a PLC, you have to know how to interface it to the chiller’s capacity controls.

If you are going to install a chiller sequencing controller, as recommended by [Measure 2.1.1.1](#), try to find a unit that can control condensing temperature as well. Such units may or may not be on the market by the time you read this.

How To Define Your Own Control Schedule

If a customized control is not available for your particular chiller system, you need to make the analysis

of condenser water temperature explained in [Measure 2.2.2](#). Doing the analysis will show you how complicated your automatic control needs to be. You want the condensing temperature to remain fairly near optimum under all load conditions, but don’t make the control excessively complicated.

The simplest case is a control that simply keeps the condenser temperature at a fixed differential about the ambient (dry-bulb or wet-bulb) temperature. This is described in [Measure 2.2.2](#). This method of control yields good efficiency in many chiller installations. It is likely to be satisfactory if the compressor power always declines with a reduction of condenser temperature. All chillers behave this way during warm weather, but some may not behave this way during cooler weather.

If the chiller has a minimum condenser temperature, you can accommodate this with a supplemental control that overrides the normal control when the minimum condensing temperature is reached.

Optimizing the condenser temperature becomes more complex if the compressor power increases with a drop in condenser temperature. This behavior occurs only with certain models of chillers, and only when they operate during colder weather. A custom control to deal with such characteristics is much more complex than a simple differential temperature control. If the system operates only for a limited amount of time at low loads and low temperatures, forget about trying to design a control that follows the characteristics of the chiller in this range. Instead, simply set a limit on the minimum condensing temperature at this point.

ECONOMICS

SAVINGS POTENTIAL: 5 to 15 percent of the average annual chiller energy consumption.

COST: Several thousand dollars, typically. The cost can be much higher in more complex chiller systems.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

KEEP IT SIMPLE: If control may be complex, try to find a dedicated controller that can handle the job with sufficient accuracy. Otherwise, you may need to find exceptionally good control skills, either for designing the controls or for programming your energy management computer. Don't create a complex control monster that

the operating staff cannot understand or maintain properly.

SELECTING THE EQUIPMENT OR SOFTWARE: Study the details of any controller that you consider buying, to make sure that the equipment or software can do what you want.

EXPLAIN IT: Explain the operation of the control clearly in the plant operating manual. If you use specialized hardware, identify it with an effective placard.

MONITOR PERFORMANCE: The control may fail without anyone ever noticing until there is equipment damage or loss of capacity. Schedule periodic checks of the control in your maintenance calendar, including the calibration of temperature and humidity sensors.

Condenser and Evaporator Heat Transfer Efficiency

The evaporator, the condenser, and the condenser heat rejection equipment lose heat transfer efficiency as a result of fouling. Fouling increases chiller energy consumption and reduces capacity. (The reasons are explained in [Reference Note 32](#), Compression Cooling.) The Measures in this Subsection maintain the effectiveness of heat transfer primarily by improved maintenance to minimize fouling. The last Measure improves the heat transfer efficiency of the evaporators in water chillers by installing turbulators, a technique that is old but still controversial.

MEASURE 2.3.1 In systems with open-loop cooling towers, clean condenser tube watersides regularly.

RATINGS

New Facilities	Retrofit	O&M

Cooling towers are effective traps for dirt, and they are nutritious breeding sites for fouling organisms. Therefore, condensers that are cooled by open-loop cooling towers are susceptible to serious fouling. Under adverse conditions, fouling accumulates rapidly. Condenser fouling increases chiller energy consumption by raising the condensing temperature. Heavily fouled condensers can increase energy consumption and reduce capacity by more than 10%.

Clean condenser tubes regularly, before they can accumulate significant fouling. Use approved methods. You can remove moderate fouling with specialized tube cleaning brushes. Figure 1 shows a typical cleaning tool.

Severe fouling, or fouling of inaccessible heat transfer surfaces, may require cleaning using strong chemical solutions. Cleaning condensers is laborious, and it may hasten the development of leaks and tube cracking. Make sure that the persons who do it are well trained.

You can reduce or eliminate the need for manual tube cleaning by installing automatic tube cleaning equipment inside the condenser. This is covered by subsidiary [Measure 2.3.1.1](#).

When to Clean Condensers

Monitor the need for condenser cleaning by watching these temperature differences in the condenser:

- the temperature difference between liquid refrigerant and the water discharged to the cooling tower should be low. This indicates effective transfer of heat from the refrigerant to the cooling water.
- the difference between the condenser water inlet and outlet temperatures should be large. This indicates that the condenser water is absorbing heat effectively.

These temperature differences are only a few degrees, so you need well calibrated thermometers to measure them with enough accuracy to be useful.

The temperature differences change with chiller load, so develop a chart that shows what they should be at each level of chiller output. If your chillers have modulating output, use one of the methods described in [Measure 2.1.1](#) to determine the chiller output.

Take baseline readings immediately after you clean the condenser, with the chiller operating properly in all respects, including proper refrigerant charge. Clean the condenser again when the temperature differentials change by a few degrees.

Inspect the condenser visually whenever you open it up. Relate what you see to the temperature differences that you record while the chiller is operating. Over the long term, this will help you see useful patterns in your cleaning methods and water treatment. Experience should indicate the approximate interval between cleanings, although this interval may change significantly with changes in weather and other environmental factors.

Prevention First

Effective condenser water treatment should be your primary approach to keeping condensers clean. Effective

water treatment can prevent biological fouling entirely, and it can greatly retard the deposit of fouling from other causes. Chemical treatment is covered in [Measures 2.3.3 ff](#), below.

ECONOMICS

SAVINGS POTENTIAL: 2 to 10 percent of chiller energy consumption.

COST: The cost of typical rotating brush cleaning equipment for condenser and evaporator tubes ranges from \$1,500 to \$3,000, depending on size and features. An average chiller can be cleaned in one day.

PAYBACK PERIOD: Short. Over the long term, the savings from condenser cleaning greatly exceed the cost of doing it.

TRAPS & TRICKS

SKILLS: Wire brushing is not difficult to learn, but requires care. Chemical cleaning usually is done by specialists, and involves a significant risk of damage if done wrong.

MONITORING: In your chiller operating log, make sure to have columns for water inlet temperature, water outlet temperature, refrigerant gas temperature, and chiller load. Review these temperatures periodically and compare them to your baseline figures.

MEASURE 2.3.1.1 Install automatic condenser tube cleaners.

RATINGS

New Facilities	Retrofit	O&M
C	C	

An alternative to the manual condenser cleaning recommended by [Measure 2.3.1](#) is installing automatic condenser tube cleaning equipment. In principle, continuous automatic cleaning is better than manual cleaning because the tube surfaces are always kept as clean as possible.

One such device has brushes in each tube that shuttle back and forth within the condenser tubes while the chiller is operating. The brushes have plastic bristles. To make the brushes shuttle, the flow in the condenser tubes is reversed by using a reversing valve in the condenser water line. The brushes are cycled several times per day by an automatic controller.

When the brushes are not operating, they are held in place outside the condenser tubes by a retainer basket. The idle brushes and their retainer add a flow resistance of about one PSI, or two feet of water column. This is a small fraction of the flow resistance of the tubes themselves and the system as a whole. It amounts to about 0.0015 pump horsepower per ton of cooling, in compression chillers. In retrofit applications, the additional resistance may not be noticeable. In fact, it may save a tiny amount of power by throttling excess pump capacity. (See [Measure 10.2.2](#) about this.)

Because condenser pipe is large, the reversing valve is expensive, typically accounting for about three fourths of the cost of the installation. The brushes themselves are inexpensive, although there are many of them. The brushes typically last from one to five years, depending

SUMMARY

on water conditions, and the retainer basket is expected to last for the life of the chiller.

Some condenser tubes have surface features to enhance turbulence and heat transfer, such as spiral grooves. Automatic tube brushes can accommodate some of these designs, although perhaps not all. Investigate this issue before installing an automatic tube cleaner in a chiller with condenser tubes that are not smooth cylinders.

No independent analysis of the long-term effectiveness, reliability, and possible operating problems of automatic tube cleaners has been found.

There is some concern that automatic tube cleaners may damage or wear out condenser tubes. However, plastic bristles seem unlikely to cause either corrosion or abrasion problems.

Needs Its Own Maintenance

If an automatic tube cleaner works properly, it may eliminate the need for all or most manual tube cleaning. However, it does not eliminate all labor, because it requires its own specialized maintenance. The reversing valve must be lubricated periodically, and the brushes must be replaced at intervals ranging from one year to five years. Replacing the brushes requires the condenser water box to be opened at one end. Also, an automatic tube cleaner does not eliminate the need for chemical water treatment or strainer maintenance.

ECONOMICS

SAVINGS POTENTIAL: 3 to 12 percent of chiller energy consumption. In new installations, the resistance of the cleaning equipment adds about 0.002 kilowatts of pump power per ton of cooling capacity, offsetting a small fraction of the savings. There is also a net saving in chiller maintenance cost, averaging from several hundred dollars to several thousand dollars per year.

COST: Typical prices of complete systems are about \$30 per ton for a 1,000-ton chiller, about \$50 per ton for a 300-ton chiller, and \$100 per ton for a 100-ton chiller. These prices include all equipment, and installation of the brushes inside the evaporator. They do not include installation of the reversing valve and other modifications to the condenser water pipe. The brushes alone, needed for occasional replacement, cost about \$2 apiece, one being needed for each condenser tube.

PAYBACK PERIOD: 5 to 15 years, typically. Depends on energy costs, chiller size, water conditions, operating schedule, etc.

TRAPS & TRICKS

SELECTING THE METHOD: Automatic tube cleaners are not well proven, so you are pioneering. Talk to others who have used the particular model of equipment for several years in chillers similar to yours.

OPERATION AND MAINTENANCE: Although the equipment operates automatically, train the plant operators to monitor and maintain it. Insert a clear description of the equipment in the plant operating manual.

MEASURE 2.3.2 With water chillers, clean evaporator tube watersides at appropriate intervals.

RATINGS

New Facilities	Retrofit	O&M
□	□	B

Fouling of the waterside surfaces of the evaporator increases energy consumption by forcing the evaporator to operate at a lower temperature to provide a given cooling temperature.

All new chilled water systems need to be cleaned thoroughly to remove dirt, preservatives, and sealant materials left over from construction. Small particles are collected by the system strainers, but some of the material dissolves and deposits on the system surfaces. A new system may need to be cleaned several times, at successively longer intervals.

Chilled water systems are closed, and under normal conditions they accumulate fouling very slowly. The high velocity of the water in the tubes tends to keep the tube surfaces clean, except for a very thin film. In an older system, the appropriate interval for cleaning the chilled water system may be several years or longer. Fouling is usually not serious, so you can schedule the cleaning for convenience, for example, when the condenser watersides are being cleaned.

The evaporator is the coldest part of the chilled water system. The solubility of most solids declines as the water temperature falls, so any solids that are dissolved to the point of saturation tend to precipitate out in the evaporator. However, this is not a problem if you keep the dissolved solid content of the chilled water well below saturation.

Cleaning Methods

Evaporator watersides are usually cleaned by brushing, using the same equipment used for cleaning condenser watersides. Evaporator fouling is less serious than condenser fouling, and it is usually easier to remove. Still, be careful to avoid tube damage.

Unfortunately, if you find significant fouling inside the chiller, fouling is likely to be a worse problem throughout the chilled water system, where the same thickness of fouling can clog or greatly reduce the flow of water through the narrow passages of air coils. In that case, you may have to clean the entire chilled water system using an appropriate chemical method.

Prevention is Better Than Repeated Cleaning

After you clean the chilled water system thoroughly, it should not be necessary to clean it again for a long time. Use appropriate chemical additives to prevent

fouling in normal operation. These stabilize the fouling at a low “fouling factor.” If your system needs an antifreeze solution in the chilled water, this solution may include an appropriate fouling inhibitor. Check to be sure.

Systems with “Strainer Cycles”

If a chiller system has a “strainer cycle,” the chilled water circuit may need periodic cleaning. The strainer cycle, described in [Measure 2.9.3](#), admits filtered cooling tower water directly into the chilled water circuit.

ECONOMICS

SAVINGS POTENTIAL: 0.5 to 3 percent of chiller energy consumption.

COST: The cost of typical rotating brush cleaning equipment for condenser and evaporator tubes ranges from \$1,500 to \$3,000, depending on size and features. An average evaporator can be cleaned in one day.

PAYBACK PERIOD: Varies. The long-term saving substantially exceeds the cost.

TRAPS & TRICKS

SCHEDULING: Since this is something that needs to be done only at long intervals, it is likely to be forgotten. Make sure that your maintenance schedule can accommodate long-term items such as this.

SKILLS: Evaporator tubes are somewhat delicate. Make sure that cleaning is thorough, while taking care to avoid tube damage or loosening of tube joints.

MEASURE 2.3.3 With wet condenser cooling systems, test and treat cooling water on a continuing basis.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

Wet condenser cooling systems tend to grow or accumulate matter that creates fouling at a rapid rate. You can eliminate or minimize fouling by using a combination of three techniques:

- **treat the water.** Add appropriate chemicals to the water to deal with the different types of contaminants that may grow or accumulate in the system. Water treatment additives are sold commercially for this purpose, as well as dispensing equipment and water treatment services. Additives should be selected by a person trained in water treatment, based on the specific water conditions that exist at the site.
- **bleed a fraction of the water from the system.** The concentration of contaminants dissolved in the water increases with time. The only way to keep the dissolved material within acceptable limits is to bleed water from the system at a controlled rate. See [Measures 2.3.4 ff](#) for details.
- **physically remove solids from the system.** Normal water treatment cannot be effective in any part of the system where solids have accumulated. The system has strainers. Clean them out periodically. Solids may also accumulate in the cooling tower sump. Scoop these out.

There are two subsidiary Measures. The first recommends hiring specialists to help with these functions. The second recommends installing automatic water treatment equipment.

Causes of Fouling and General Solutions

There are several causes of cooling water fouling, each of which requires individual corrective measures. The following are the main classes of fouling.

■ **Microorganisms**

Microorganisms are usually the main cause of fouling in cooling towers and evaporative condensers. The highly aerated cooling water is a rich medium for growth of microorganisms, including algae, bacteria, mold, and fungi, which it traps from the atmosphere. These grow quickly in wet cooling units if conditions permit. They become troublesome when they form matted colonies that are capable of inhibiting heat transfer and clogging parts of the system.

Microorganisms are killed with biocides. The available selection is being progressively restricted by concerns about the environmental effects of cooling tower effluent. Figure 1 shows a simple iodine injection system to kill microorganisms.

SUMMARY

Important maintenance needed by virtually all wet cooling systems. Minimizes condenser losses, minimizes the need for severe condenser cleaning methods, and preserves equipment. Requires specialized knowledge.

Certain diseases, of which Legionnaires’ Disease is the most notorious, have been linked to the growth of organisms in cooling towers. The danger may exist even if growth of visible colonies has not occurred. The biocides normally used in water treatment are believed to eliminate the hazard in most cases.

Algae and some other fouling organisms require sunlight for growth. For this reason, cooling units that have enclosed sides, such as evaporative condensers and upflow cooling towers, may have less trouble with biological fouling than cooling units that are open to sunlight. In principle, you could add sun shielding to the latter types, but this involves serious practical problems, such as wind forces and air recirculation.

■ **Airborne Dirt and Debris**

Dirt is washed out of the atmosphere by the action of wet cooling units, and the dirt is carried by the water to settle throughout the condenser system.

The treatment is to use detergent or specialized polymeric agents to keep the dirt in suspension until it is bled from the system or is trapped by the strainers.

Determine the concentration of chemical treatment needed to control dirt by checking the rate of dirt accumulation visually. Keep monitoring this, because the amount of dirt in the environment may vary considerably.

■ **Waterborne Minerals**

The minerals that cause trouble most commonly are compounds of calcium (dissolved from limestone) and magnesium. As water evaporates from the cooling unit, the concentration of minerals in the system rises. If the concentration is allowed to rise excessively, the minerals deposit on the surfaces of the system in the form of scale.

The content of minerals capable of depositing scale is expressed as the “hardness” of the water.

The primary method of dealing with dissolved minerals is to bleed water from the cooling unit and replace it with fresh water at a rate that keeps the mineral concentration low enough to prevent scaling. See [Measures 2.3.4 ff](#), below, for details of bleed control.

Chemical water softening may also be advisable in locations where the water supply is very hard. In such cases, the usual treatment is ion exchange with salts, the same type of treatment used to reduce the hardness of domestic water.

Get Help from Specialists

Unless you are an expert in water treatment, hire a water treatment consultant to analyze the cause of fouling in your system. The consultant uses visual inspection and chemical tests to identify each source of fouling, for which he prescribes appropriate corrective measures.

You have to decide whether to treat the system yourself or to hire a contractor to perform this service. The answer depends on the capabilities of the facility staff. Treatment requires periodic inspection and application of chemicals, at intervals ranging from several hours to several days. Periodic functions tend to be neglected, so water treatment by the staff may not be sufficiently reliable. In many cases, it is best to hire a contractor to perform water treatment, as recommended by [Measure 2.3.3.1](#), the first subsidiary Measure.

Automatic water treatment equipment reduces the labor required to treat condenser water, but it does not eliminate the problem of neglect. See [Measure 2.3.3.2](#), the second subsidiary Measure.

Coordinate with Other Water Treatment

Boilers also need a carefully controlled water treatment program, as recommended by [Measures 1.8.1 ff](#). These Measures also provide more guidance on how to set up a water treatment program.

Hydronic systems may need some water treatment, although they are less demanding. This is described in [Measure 2.3.2](#). You may also have a need to treat your domestic water.

It saves effort to find a specialist who can handle all these aspects of water treatment. But, don't compromise to do this. You may need different specialists to deal with the different water treatment requirements.

ECONOMICS

SAVINGS POTENTIAL: 1 to 5 percent of chiller system operating cost, depending on the severity of water conditions. Water treatment reduces maintenance cost and lengthens equipment life.

COST: Several hundred to several thousand dollars per year, typically, depending on plant size and water conditions.

PAYBACK PERIOD: Short. Over the long term, the savings greatly exceed the cost.

TRAPS & TRICKS

PREPARATION: Water treatment is a specialty that requires considerable experience, especially to select the best methods for a particular system. Have your program set up by a qualified specialist. See [Measure 2.3.3.1](#).

TRAINING AND MANAGEMENT: Water testing and water treatment are not difficult, but they may seem somewhat mysterious at first. Also, they are easy to neglect. If it is not practical to do water testing or treatment in-house, hire these services.

MONITOR CONDITIONS: At every opportunity, inspect the cooling tower and the condenser watersides to check the effectiveness of treatment and to look for adverse effects. Schedule inspections at intervals appropriate for your water conditions. Make adjustments to the water treatment program as indicated.

In most cases, combine automatic control of chemical treatment with automatic control of cooling water bleed. [Measure 2.3.4.1](#) covers automatic bleed control.

WESINC

Fig. 1 Automatic chemical feeder for cooling tower water The plastic drum stores the chemicals. A pipe feeds the chemicals into the tower along with the makeup water. A solenoid valve and controller regulate the dose. The water meter reads the makeup water because water used by evaporation is deducted from the sewage bill.

MEASURE 2.3.4 With wet cooling systems, adjust the bleed rate to maintain proper water conditions with minimum water consumption.

Water evaporates rapidly from cooling towers and evaporative condensers. This loss of water is compensated by adding makeup water from the local water supply. The makeup water contains dissolved minerals and a certain amount of particulate matter. In addition, the water spray captures significant amounts of atmospheric pollutants. If only enough water were added to the system to compensate for evaporation, the minerals and other matter would concentrate rapidly. This accumulation would soon deposit as fouling on the surfaces of the cooling unit, the chiller condenser, and the entire piping system.

To prevent this, you have to bleed water from the cooling system at a controlled rate. This carries away the contaminants that would cause fouling if they became too concentrated. Water is usually bled from a drain located in the sump. Bleed is necessary in all wet cooling systems, and it must continue as long as the system is operating.

Bleed has a significant cost. It is a significant loss of water, and it also carries away a portion of the chemicals that you add to control fouling.

Even if you hire a water treatment contractor to take care of chemical treatment, do not assume that the contractor will optimize the bleed rate. After all, he is in the business of selling chemicals, and his primary job is to prevent fouling, so his motivation leans toward setting the bleed rate too high. Therefore, deal with control of bleed as a separate cost saving issue.

You can set the bleed rate manually or automatically. Manual setting of bleed rate is always wasteful because the evaporation rate varies with the cooling load. A bleed rate that is set to maintain a safe concentration at high cooling load is wasteful under low cooling load. Figure 1 shows a cooling tower that depends on manual bleed.

The most efficient way to control bleed is to install a bleed valve that is controlled by a concentration sensor. This technique is covered by the subsidiary [Measure 2.3.4.1](#).

How to Calculate the Bleed Rate

The appropriate bleed rate is determined by the evaporation rate and by the concentration of impurities in the makeup water. The evaporation rate is proportional to the cooling load. If the impurity level is high in the incoming water, the dissolved material soon reaches a concentration in the cooling unit that causes fouling unless the material is flushed out.

Formula 1 shows how the bleed rate relates to these factors. This formula neglects the effect of drift (loss

of unevaporated water spray) and the addition of dirt washed out of the air. These factors are usually minor.

In the language of the water treatment trade, the ratio of the maximum contaminant concentration in the cooling water to the contaminant concentration in the makeup water is called “cycles of concentration.” Formula 2 expresses bleed rate in these terms.

For example, your water treatment specialist may determine that three cycles of concentration are allowable. From this, the formula tells us that the bleed rate should be set to half the evaporation rate.

The Cost of Bleed

Although water is usually cheap in terms of unit cost, the bleed requirement is continuous as long as the chiller operates. Also, if you need to use water treatment chemicals, bleeding may be responsible for most of the consumption of chemicals.

Here is an example to illustrate the magnitude of the water cost. Any cooling tower evaporates about 1.5 gallons per ton-hour of heat rejected, a figure determined solely by the latent heat of water. At a water cost of 0.1 cents per gallon, this translates into a cost of 0.15 cents per ton-hour, or about 0.15 cents per kilowatt-hour input to a chiller system of typical efficiency. If the cooling water is kept at two cycles of concentration, the bleed rate equals the evaporation rate, adding another 0.15 cents per kilowatt-hour.

The bleed rate can easily get out of control, in the direction of either too little bleed or too much. The plumbing involved in controlling the bleed of many cooling towers is primitive. Bleed may be controlled with a manual bib valve, i.e., a garden hose spigot, which cannot control flow accurately. It is not extraordinary to find water being bled at a rate ten times greater than necessary. Using the previous example, this would raise chiller system water cost to 1.5 cents per kilowatt-hour. A poorly controlled cooling tower bleed may account for a large fraction of total water cost of a facility.

FORMULA 1

$$\text{Bleed rate} = \text{Evaporation rate} \times \frac{\text{Concentration (M)}}{\text{Concentration (T)} - \text{Concentration (M)}}$$

where:

- Concentration (M) is the concentration of critical contaminants in the makeup water
- Concentration (T) is the maximum allowable contaminant concentration in the cooling tower
- bleed rate and evaporation rate are expressed in identical units, for example, gallons per hour, percentage of condenser circulation rate, etc.

FORMULA 2

$$\text{Bleed rate} = \frac{\text{Evaporation Rate}}{\text{Cycles of Concentration} - 1}$$

where:

- bleed rate and evaporation rate are expressed in consistent units, for example, gallons per hour, percentage of condenser circulation rate, etc.

Test the Makeup Water

The first step in setting the bleed rate is testing your water supply. In many geographic areas, the determining factor is the “hardness” of the water, which is a measure of its calcium carbonate (dissolved limestone) content. In other locations, other substances in the water supply determine the bleed rate. Vendors of water treatment supplies offer inexpensive chemical test kits for the common types of impurities.

Your water treatment specialist will tell you which contaminants to test for in your water supply. Repeat water testing at appropriate intervals, and adjust the bleed rate as necessary.

The other thing you need to know is the maximum allowable contaminant concentration. Again, your water

treatment specialist will tell you this. Or, if you don’t have one, you can get this information from reference publications, or perhaps from your chiller manufacturer.

The condition of your equipment cannot tell you whether you are bleeding enough, because visible fouling may occur even at an excessive bleed rate if you do not treat the water properly.

Use Continuous Bleed Rate

In most applications, use continuous bleed as long as the tower is operating. An amount of water equal to the total volume of the cooling system may evaporate within several hours of operation. Intermittent bleed is unsatisfactory unless you find a way to do it reliably on an hourly basis. Even better, use automatic bleed control, which is recommended by the subsidiary Measure.

ECONOMICS

SAVINGS POTENTIAL: Up to 80 percent of the cost of water and water treatment chemicals used in cooling units. Also, reduction of equipment maintenance costs.

COST: At most, several hundred dollars per year for testing supplies. Labor costs should be minimal.

PAYBACK PERIOD: Short, except in small systems. The saving is much greater than the cost over the long term.

TRAPS & TRICKS

TRAINING: Write clear instructions for controlling the bleed rate, and train the operators how to follow them.

MONITOR PERFORMANCE: Controlling bleed rate will be forgotten unless it is done on a regular basis. Add a column to the chiller plant operating log for water test results. Check the logs, and follow up to ensure that the procedure is being followed.

WESINC

Fig. 1 Cooling tower with manual bleed The middle sized pipe is the tower drain and bleed line, which has a manual valve. This is an unreliable way of controlling bleed.

MEASURE 2.3.4.1 Install and maintain an automatic bleed control.

The rate of evaporation from a cooling tower changes continually with changes in cooling load. Only automatic control of bleed can follow these changes and minimize waste of cooling water and water treatment chemicals. To control bleed automatically, install an automatic valve at the bleed connection. The valve is controlled by a sensor that measures the contaminant concentration.

The equipment and installation are simple. You can use automatic control with virtually any cooling tower or evaporative condenser. However, the blowdown control becomes another item of equipment that you have to maintain. It will work reliably if you inspect it regularly and maintain it as necessary.

Equipment and Installation

■ **Type of Valve**

Automatic bleed may operate continuously or intermittently, depending on the bleed rate. Intermittent bleed is more practical, except for the largest systems. Use a solenoid valve for intermittent control. They are simple and reliable. A modulating valve is more complex and more sensitive to the harsh environment of a cooling tower. A modulating valve operating at a low flow rate would require frequent maintenance because of valve seat erosion.

If you use a solenoid valve, add a control feature that keeps the valve from cycling frequently. One method is to control the valve through a cycle timer. The contaminant sensor triggers the cycle timer, which keeps the valve open for a fixed period of time, such as two minutes. This method reduces the contaminant concentration in small increments and allows the concentration to stabilize between bleed cycles.

■ **Valve and Drain Location**

The bleed valve can be installed anywhere in the bleed line. The bleed line is usually connected to a point in the sump. In most cases, the original drain connection of the bleed line is satisfactory.

As a safety feature, locate the bleed connection at a point in the sump where it cannot drain the sump completely if it sticks open.

Water is driven out of the bleed line by gravity. Make sure that there is enough difference in height between the water level in the sump and the discharge point of the bleed line. Otherwise, there may not be enough gravity head to force the bleed water out of the system at the rate needed.

SUMMARY

Provides more accurate control of bleed rate. Another thing to maintain.

Do not install the bleed valve in a descending pipe. This would allow dirt to settle on top of the valve when it is closed.

Do not install a strainer anywhere in the bleed line. A strainer would eventually clog, preventing bleed.

■ **Type of Sensor**

The type of sensor you use to control the valve depends on the nature of the contaminant that controls the blowdown rate. Your water treatment specialist should select the type of sensor. For example, if the controlling factor is hardness, you may use a sensor that measures the electrical conductivity of the cooling tower water.

■ **Control Setting**

To minimize the cost of makeup water and chemicals, set the sensor to control the bleed rate so that the concentration of impurities remains just below the point where they cause trouble.

■ **Safety Alarm**

It is good practice to monitor the contaminant concentration of the water with a separate sensor that sounds an alarm if the concentration is too high or too low. A concentration that is too high indicates that bleed is not adequate. A concentration that is too low indicates that the bleed valve is probably stuck open.

Coordinate with Automatic Chemical Feeding

This method of control is similar to automatic feeding of water treatment chemicals, and their functions are closely related. To avoid duplication of effort, install both functions at the same time. See [Measure 2.3.3.2](#) about automatic chemical feeders.

ECONOMICS

SAVINGS POTENTIAL: 30 to 60 percent reduction in water and additive costs, compared to manual bleed control.

COST: One thousand dollars to several thousand dollars.

PAYBACK PERIOD: Less than one year, to several years, compared to manual feeding.

TRAPS & TRICKS

EQUIPMENT SELECTION AND MAINTENANCE: Select the equipment for reliability and ease of maintenance. A bleed valve failure is likely to occur at an awkward time, and it needs to be corrected quickly.

MONITORING: Review the water test results from the chiller operating log periodically to make sure that the bleed rate is correct.

EXPLAIN IT: Describe the automatic bleed valve in the plant operating manual. Install a placard that identifies the valve and states what it does.

MEASURE 2.3.5 In chilled water systems, install turbulators in the evaporator tubes.

RATINGS		
New Facilities	Retrofit	O&M
□	D	□

In evaporators, heat transfer efficiency increases with surface area. Unfortunately, evaporator surface area is also a major factor in the cost of a chiller system. For this reason, some chillers lack sufficient surface area for good efficiency.

In a chilled water system, you may be able to improve the heat transfer efficiency on the water side of the evaporator by installing “turbulators.” These are inserts placed inside the water tubes of tube-and-shell heat exchangers to increase the turbulence of the water flowing through the tubes. The increased turbulence at the tube surface improves heat transfer.

(The same principle applies to condenser tubes. However, turbulators do not appear to be practical in condensers, because they would trap the dirt that is present in the cooling water.)

Turbulators have many configurations, including helical wire coils and twisted metal strips. They usually extend the full length of the tube, or almost the full length. They must be easily removable for tube cleaning.

Where to Consider Turbulators

The main candidates for turbulators are chillers that have a substantial temperature drop across the evaporator. Call the manufacturer to find out the design temperature drop of the evaporator. If the manufacturer’s catalog for the chiller is available, see whether the chiller is an economy model that has an evaporator at the small end of the size range.

As a last resort, measure the difference between the temperature of the chilled water leaving the evaporator and the temperature of the liquid refrigerant, with the

chiller under full load. In evaporators that use an expansion valve, do not use the suction gas temperature to judge this temperature differential, because the expansion valve acts to superheat the vapor. See [Reference Note 32](#), Compression Cooling, for details.

The evaporator tubes used in some newer chillers are made with a texture that enhances heat transfer. Turbulators are not useful in these chillers.

Energy Saving Potential

The energy saving potential of turbulators is limited. Flow is inherently turbulent above a certain velocity, and chiller systems are designed to exceed this velocity. Therefore, be skeptical of the savings claims of turbulator vendors. In the absence of a formal efficiency testing program by a competent and objective agency, it is easy to fall prey to wishful thinking.

Potential Equipment Damage

Turbulators have been used for decades, and they are controversial. The record suggests that turbulators have been involved in tube failure, perhaps by several mechanisms:

- the increased turbulence causes mechanical erosion of the tubes by the fluid itself
- vibration of the turbulators against the tube surfaces, causing mechanical damage
- electrolytic erosion that may occur as a result of dissimilarity of metals between the turbulators and the tubes.

A systematic study of the nature and prevalence of these problems has not been found, so it is impossible to predict with certainty whether turbulators will cause trouble, or which type of turbulator is least likely to cause trouble. The best approach is to check with other people who have extended experience with the types of turbulators you are considering. Also, check with the chiller manufacturer, who may have received field reports about the long-term effects of turbulators.

Secondary Effects on System Efficiency and Capacity

Turbulators increase the resistance of the evaporator to chilled water flow. The resistance arises from the reduction of the tube cross section, the friction of the turbulators, and the turbulence they cause. Adding turbulators with no other adjustments to the chilled water system will reduce chilled water flow somewhat. This throttling effect will reduce the power consumption of the chilled water pumps by a small amount. If chilled water temperature reset is used to maximize chiller efficiency (see [Measures 2.2.1 ff](#)), the reduced flow rate will require a lower chilled water temperature to serve a given cooling load, and this reduces the chiller's efficiency.

These are small effects that are not likely to be significant. Even so, you can restore the original chilled

water flow rate if the system was installed with flow regulating (“balancing”) valves. Open these enough to compensate for the added resistance of the turbulators. The reduced energy loss in the balancing valves compensates for the increased energy loss in the evaporator. While you are at it, optimize the chilled water system flow. See [Measures 10.2.1](#) and [10.2.2](#) for details.

If the system has variable-flow chilled water pumping ([Measure 2.5.2](#)), pump power will be increased somewhat.

If the system's chilled water pumping capacity is already marginal, the reduced flow will limit system cooling capacity. Look into this before making any changes. It is not economical to modify the pumps to overcome the resistance of turbulators.

ECONOMICS

SAVINGS POTENTIAL: *Up to 3 percent of chiller energy. The saving is higher in less efficient chillers. The overall saving may be reduced by higher pump power.*

COST: *Spiral turbulators typically cost from \$10 to \$20 per tube. A large chiller may have several hundred tubes.*

PAYBACK PERIOD: *Several years, typically.*

TRAPS & TRICKS

CHOICE OF METHOD: *Turbulators are something of a gamble. Their efficiency improvement and potential for creating problems are not well known. Check with other plant operators who have used the kinds of turbulators that you are considering.*

INSTALLATION: *Follow the instructions. The method of installation may affect the potential benefit and the potential for problems.*

EXPLAIN IT: *Put the installation instructions in the plant operating manual. The turbulators need to be removed and reinstalled whenever the tubes are cleaned.*

Heat Rejection Equipment

Every mechanical cooling system must get rid of the heat that it collects in the process of cooling spaces or processes. The heat is dumped into the environment, either into the atmosphere, or into a body of water, or into the soil of the earth. The cooling system needs special equipment for rejecting the heat. The Measures in this Subsection maintain or improve the efficiency of heat rejection equipment that rejects heat to the atmosphere.

The heat rejection equipment is often the condenser itself, in the form of a finned coil that is aided by a fan. Such condensers are called “air-cooled condensers.”

The heat rejection of an air-cooled condenser can be enhanced by keeping it wet to take advantage of evaporative cooling. This variation is called an “evaporative condenser.” Figure 1, on the next page, sketches an evaporative condenser.

In many cooling systems, especially larger ones, water is cooled by evaporation in a remote “cooling tower,” and the water is pumped some distance to the condenser for cooling. Figure 2 sketches a simple cooling tower, and Figure 3 shows details of a different type.

The fans in these units are major consumers of energy, accounting for typically 5 to 20 percent of chiller system energy consumption. The least fan energy is used in systems that are aided by evaporation, and the most is used by equipment that is directly air-cooled. Heat rejection equipment also has a major effect on the efficiency of the chillers, through its effect on condensing temperature. This important aspect is covered in [Subsection 2.2](#).

Heat can also be rejected through water coils that are immersed in bodies of water, such as rivers, lakes, and underground aquifers. Or, coils can be buried in soil. [Reference Note 22](#), Low-Temperature Heat Sources & Heat Sinks, covers these methods of heat rejection.

The water drips down layers of “fill” material, which increases the surface area for evaporation. Air flows across the fill from both sides, drawn toward the center by the fan. Water lost by evaporation is replaced by a float valve that maintains the level of the water in the collecting basin. “Drift eliminators,” which may be located anywhere in the air discharge path, minimize the loss of unevaporated water droplets.

MEASURE 2.4.1 Modulate fan output in heat rejection units to follow the cooling load.

This Measure eliminates or minimizes energy waste due to the cycling of fan output that occurs in cooling units with single-speed, fixed-pitch fans. Cycling fan output wastes fan power and raises the average condensing temperature. The solution is to install a fan drive that is better able to follow the actual cooling load. In the current state of technology, one of these fan drives will be best for your application:

- **electronic variable-speed fan drives**, which are covered by subsidiary [Measure 2.4.1.1](#). These provide the best efficiency. They are easy to install, even in retrofit applications.
- **variable-pitch fans**, covered by subsidiary [Measure 2.4.1.2](#). These provide efficiency that is comparable to the efficiency of variable-speed drives. They may be the best choice in cases where the adverse side effects of electronic drives are too expensive to overcome. They are limited to cooling units of larger size. They may be difficult to retrofit.
- **multi-speed or dual fan motors**, which are covered by subsidiary [Measure 2.4.1.3](#). These are a compromise. They have lower average efficiency

than the previous two types. They are inexpensive, easy to install, and free of serious problems. They are most likely to be the best choice in cooling units of small and medium size.

Energy Saving Potential

The best overall chiller system efficiency is achieved if the condenser cooling fans modulate their output efficiently to match the heat rejection requirements of the chiller. In contrast, if a fan must change its output in stages, fan energy is wasted and the average condenser temperature is raised.

The methods recommended by this Measure to improve fan modulation are expensive. Whether any is worthwhile depends on the potential efficiency improvement. The least efficient operation occurs when condenser cooling depends on a single fan that turns on and off. If a single-stage fan motor is larger than a few horsepower (or kilowatts), analyze whether a fan drive modification would be economical. If the fans presently operate with two or more steps of speed, upgrading to continuous modulation is likely to be economical only if the fans are very large.

■ Fan and Drive Energy

Average fan energy consumption is higher with a cycling fan because fan power is proportional to the third power of the air flow rate. For example, consider an ideal fan that requires 100 kilowatts to produce full output. If this fan operates at full output half the time, it consumes an average of 50 KW. If the same fan is run continuously and is modulated to move the same amount of air, it consumes 12.5 KW. Thus, the cycling fan uses four times as much energy as the continuously operating fan.

The energy-saving potential depends on the cooling load profile. The previous example is almost a worst case. In contrast, if the cooling load remains near maximum at all times, the single-speed fan does not waste much energy. At the other extreme, if the cooling load is usually low, the fan does not operate enough to provide a large opportunity for saving. The most energy is wasted if the fan operates between 30 to 70 percent of the time, which is typical of chiller applications.

If the cooling unit has more than one fan serving each cell, then the flow is varied in stages, which is more efficient than turning a single fan on and off. (In units with multiple fans, be sure that the fan speeds are sequenced efficiently, as recommended by [Measure 2.4.2.](#))

Account for these factors when you estimate fan and drive energy savings:

- **drive losses.** Cycling and staged fan speeds have only minimal drive losses. Variable-pitch fans have little or no drive losses, but motor efficiency drops at low loads. Electronic variable-speed drives have average drive losses in the range of 5% to 20%, depending on the load profile, drive type, and size.
- **variations in fan efficiency with flow rate.** The fixed-pitch propeller fans used in most cooling units become more efficient as their speed is reduced. Variable-pitch fans are designed for maximum efficiency at some intermediate speed. The effect of pitch on efficiency is relatively small in most applications.
- **motor starting current.** When a cycling fan starts, it has an exceptionally high starting current. This involves energy losses, but only for a brief period during each starting cycle.
- **differences in the amount of air flow required.** For a given amount of condenser cooling that is required, cycling requires more total air flow than modulated fan operation. For example, if the cooling load is half of maximum, substantially less than half the maximum cooling air flow is required to maintain the condenser temperature.

■ Effect on Condensing Temperature

Modulating the fans provides more accurate control of condenser temperature, which can be used to improve

chiller efficiency. If a fan is cycled or staged, the condenser water temperature fluctuates between the temperatures at which the fan turns on and off. This temperature difference is typically set at 3°F to 6°F to prevent excessive fan cycling. The temperature fluctuation wastes energy in itself, by raising the average condensing temperature.

If a heat rejection equipment has more than one fan, it is common to divide the cooling unit into separate cells, to avoid short-circuiting air through the fans that are not running. (This is discussed in [Measure 2.4.6.](#)) However, different portions of the heat transfer surface still receive different degrees of cooling, which reduces overall cooling efficiency. Operating all the fans together with continuous modulation eliminates this inefficiency.

To get the most benefit from fan modulation, you have to select the most efficient condenser temperatures. This aspect is covered in [Measure 2.2.2.](#)

Other Benefits

Eliminating or reducing fan cycling extends the life of the fan, the transmission, and bearings. Propeller fans have large moments of inertia, requiring motors with high starting torque. This results in a great deal of stress during starting. Modulating fan drives reduce or eliminate high-torque fan starting.

Eliminating cycling also eliminates the overt change in noise level that occurs when the fan turns on and off, which may be more objectionable than the steady noise itself.

Minimizing the air flow velocity through the cooling tower minimizes “drift,” which is the escape of unevaporated water droplets. This is only a minor efficiency factor.

Comparison of Methods

In many applications, all three methods of modulating fan output may be usable. The choice is a compromise involving the following factors.

■ Efficiency

Electronic variable-speed drives and variable-pitch fans are comparable in efficiency. Both can track the cooling load perfectly, down to a small fraction of full load. Multi-speed fan motors are not able to track the cooling load as closely, so they are less efficient than fully modulating methods.

Electronic variable-speed drives have some internal electrical losses that depend on the load profile, drive type, and size. These drives also cause some electrical losses in the motor, because the power provided by the electronic drive contains harmonics that cannot be used efficiently by the motor. Losses added by the drive are around 5% at full speed. Combined drive and motor losses may exceed 30% at low speeds, but energy input has dropped to a small fraction of full load input by

then. From the standpoint of the fan, speed control is efficient because aerodynamic losses are reduced as fan speed and load are reduced.

Variable-pitch fans are efficient because they add no drive losses. From the standpoint of the fan itself, variable-pitch control is aerodynamically efficient, although not as efficient as changing fan speed. The propeller remains at maximum speed, so the friction loss of the blades does not decline much at lower cooling loads. At low output, there is some waste of energy because the inner portion of the blade is moving more air than the outer portion. As the fan approaches zero output, the outer portion of the blade actually reverses. This effect sacrifices little efficiency under typical loads.

There is some loss of motor efficiency with variable-pitch fans when the load falls below about half of full load. Larger motors suffer relatively less efficiency loss at lower loads. See [Measure 10.1.1](#) for more detail.

Multi-speed fan motors provide less accurate tracking of the cooling load than the other two methods. Therefore, this method involves some waste of fan power and excessive condensing temperature. Even so, these inefficiencies are much lower than with single-speed fans.

From the standpoint of drive efficiency alone, multi-speed motors compare well to variable-frequency drives and variable-pitch fans. Two-speed motors are somewhat less efficient than single-speed motors, especially at the lower speed, but they require no separate mechanical or electrical components. By the same token, replacing a single-speed motor with a multi-speed motor involves no additional equipment. Three- and four-speed motors are somewhat less efficient than two-speed motors. From the standpoint of the fan, varying speed is aerodynamically the most efficient means of reducing output.

Baltimore Aircoil Company

Fig. 1 Cooling tower fan drive gearbox This is a common method of matching the motor to the fan in larger cooling towers. Before retrofitting a speed reduction device for the motor, make sure that the gearbox remains properly lubricated at low speed.

If a cooling unit has more than one fan per cell, using multi-speed fan motors incurs an additional efficiency penalty because the fans do not always operate at the same speeds. See [Measure 2.4.2](#) for details.

■ Number of Fans

If a cooling unit has more than one fan, the best efficiency is achieved by operating all the fans at the same speed. This is simple and economical with electronic drives, because one drive can be used to operate all the existing fans and fan motors. In contrast, a separate variable-pitch replacement would have to be installed for each fan. Similarly, a multi-speed motor would have to be substituted for each of the existing fan motors.

■ Fan Size

Variable-pitch fans are available only in larger sizes. Electronic drives are available for fan motors down to about one horsepower (or kilowatt), and they have no upper size limit. Efficient multi-speed fan motors are available in sizes down to about one horsepower (or kilowatt).

■ Resonances

Each of the subsidiary Measures gives methods of avoiding resonances. In brief, resonances are usually easy to avoid with variable-pitch fans and two-speed motors. Variable-speed drives operate fans over a wide range of speeds, so they may trigger serious mechanical vibration of the cooling tower structure. The controllers of some variable-speed drives give you the option of locking out speeds that may cause resonances.

■ Electrical Noise

Electronic drives may introduce an objectionable level of electrical noise throughout the electric power supply system of the facility. Correcting this problem may be expensive, especially in facilities that use equipment that is sensitive to power supply quality. Some newer models of electronic drives are designed to reduce this problem substantially.

This problem does not occur with variable-pitch fans and multi-speed motors.

■ Gearbox Lubrication

Many larger cooling units use a right-angle gearbox to drive the fan. Figure 1 shows a typical installation. If the gearbox uses splash lubrication, installing a variable-speed drive may slow the fan enough to cause a loss of lubrication. This problem can be avoided by maintaining a minimum fan speed, but this wastes a small amount of energy, and may not allow the fan to reduce output sufficiently at low loads. Check with the cooling tower or gearbox manufacturer before retrofitting a variable-speed motor drive.

Installing a two-speed fan usually does not cause lubrication problems, but verify this with the tower or gearbox manufacturer.

Lubrication problems do not occur with variable-pitch fans, which operate at fixed speed.

■ Maintenance

A variable-pitch fan has its critical moving components located in the hub, which is continuously exposed to a humid and corrosive atmosphere. As a result, variable-pitch fans require regular inspection and maintenance.

Electronic drives have no moving parts, and require no routine maintenance. The vulnerable electronic components can be installed remotely from the cooling tower, in an enclosure. The components are subject to occasional failures, but they typically can be replaced easily.

Multi-speed motors operate in the same environment as the motors they replace, and they have minimal maintenance requirements.

■ Starting Stress

Electronic drives are limited in starting current, which gives them an inherent “soft” starting characteristic. Additional soft starting features are available on many models.

Variable-pitch fans have high starting inertia, and hence, high starting stress. The stress can be reduced by installing a conventional “soft” motor starter. In any event, a variable-pitch fan has far fewer starting cycles than a cycling fan.

Multi-speed fans have the same starting stresses as single-speed motors, if they are controlled to start at high speed. After starting initially, multi-speed motors have lower stresses in switching from one speed to another, and these stresses occur less often than with single-speed motors.

■ Audible Noise

The noise produced by a fan increases radically with the fan speed. Lowering the fan speed to, say, 70% of full speed provides a substantial reduction in fan noise. Therefore, variable-speed drives reduce the average fan noise level considerably. In contrast, the noise produced by variable-pitch fans is always near maximum.

Multi-speed fans are much less noisy at the lower speeds. There is an overt change in sound level as the

fan speed changes, but the change is less noticeable than with the original single-speed fan.

■ Ease of Retrofit

Installing an electronic drive requires no mechanical changes to the cooling tower, unless stiffening is required to avoid resonances. The electronics cabinet is relatively small and its location is not critical.

Installing a variable-pitch fan may require significant alteration of the fan mounting to accommodate the greater weight and deeper hub dimensions.

Replacing a single-speed motor with a multi-speed motor usually requires little or no modification of the cooling unit. However, the multi-speed motor may be larger than the original, which may hinder installation in tight quarters.

■ Cost

Like all electronic products, variable-speed drives have experienced a large drop in price over the years. They are now much cheaper than variable-pitch fans for most applications.

As noted previously, the relative cost of an electronic drive becomes much lower if one unit can be used to control several fans.

Multi-speed fan motors are typically much cheaper than the other two methods. The only costs are for a new motor, a modest amount of installation labor, and simple controls.

Beware of Reduced Cooling Surface Area in Some Cooling Towers

All cooling towers increase their evaporating surface area by using “fill” that forms passages over which the water flows. In some towers, the passages are so small that reducing the air flow through the tower would cause the passages to become plugged by water held in place by surface tension. This raises the water temperature, which causes the controls to increase the fan output to compensate. This involves some efficiency loss. In such cases, it may be economical to modify the passages so they remain open under all air flow rates.

MEASURE 2.4.1.1 Install variable-frequency fan drives.

This is the first of three subsidiary Measures that provide alternative methods of improving the fan modulation of cooling towers and dry coolers. Review “Comparison of Methods,” in [Measure 2.4.1](#), to help you decide which to choose.

This Measure covers electronic variable-frequency drives (VFD’s). These drives operate fans at the precise speed needed to satisfy each load condition. See [Reference Note 36](#), Variable-Speed Motors and Drives, for the characteristics of variable-frequency drives and for the selection factors that you should consider.

Operate All Fans at the Same Speed

The lowest energy consumption occurs when all the fans serving a particular cooling system are operated at the same speed (assuming that the fans are identical). This arrangement is also simple to control. Any number of fans can be controlled from a single electronic drive if it has enough power output. Figure 1 shows a typical installation.

Turndown Ratio

In principle, variable-frequency drives are able to reduce motor speed efficiently almost to zero. Some models are now available that operate very well at low speed. However, be aware that certain types of variable-frequency drives may cause a strong pulsation of the fan at very low speed, which is sometimes called “cogging.” Drives with this characteristic are typically less expensive. With such units, you can avoid trouble by setting the lower speed limit of the drive above the speed at which cogging becomes troublesome. In most cooling unit applications, this compromise has only a negligible effect on efficiency.

Dealing with Mechanical Resonances

Both fans and cooling unit structures may have strong resonances at a number of frequencies. These resonances may create troublesome noise, or even damage the equipment. A unit may have several resonances within the speed range of the fan. This is especially likely in larger, loosely constructed units. The problem occurs primarily with cooling units that have propeller fans, rather than centrifugal fans. The resonant frequencies of centrifugal fans are usually too high to trigger serious vibration in heavy structures.

One solution to this problem is to lock out certain fan speeds using the fan control circuitry. This is a standard feature with some variable-speed drives. Locking out speed ranges invites the fan to “hunt” above and below these speeds when the cooling load happens

to coincide with them. The speed control should be able to prevent the fan from hunting excessively.

Another solution is to dampen or eliminate the resonances by modifying the structure, installing braces, or pre-tensioning parts of the structure that may vibrate.

Install vibration sensors on the tower to shut down the fans if vibration becomes dangerous. Larger towers may have such sensors as part of their original equipment.

Dealing with Power System Distortion and Electrical Noise

This is the worst area of trouble for VFD’s in general. It is a big subject. See [Reference Note 36](#), Variable-Speed Motors and Drives, for the details.

Control Issues

Variable-frequency drives are now commonly equipped to accept standard pneumatic and electric control signals. This should make it easy to retrofit the drive controls to the thermostatic controls that sense the condenser cooling load. Acquire the equipment from a vendor who is able to supply a control package specifically designed for cooling tower applications.

An important factor to consider is the long time lag in control response, especially with wet coolers. When the fan speed increases in response to a rise in condensing temperature, the effect is not felt at the condenser until the water has time to circulate from the tower to the chiller. This causes oscillation of the fan controls, unless they are set to respond slowly. A more sophisticated approach is to use proportional-integral-derivative (PID) controls. These are covered in [Reference Note 37](#), Control Characteristics.

If the drive defaults to full-speed operation in the event of a drive circuit failure, the controls should include an alarm to alert operators that the control has failed.

The most difficult part of optimizing the control settings is determining the optimum condenser temperature. [Measures 2.2.2 ff](#) describe how to do this.

Remove Existing Dampers

Some smaller heat rejection units, both wet and dry, employ dampers to throttle air flow as a means of modulating the cooling capacity of the cooling tower. Dampers should become unnecessary when this Measure is accomplished. Remove the dampers or lock them fully open.

If the dampers must be kept in operation to limit air flow at minimum fan speed, ensure that the damper controls open the dampers fully at higher fan speeds. Try to avoid this control complication, which is another potential failure mode.

Eliminate Cooling Tower Bypass, If Appropriate

Some cooling tower installations have a diverter valve that bypasses a portion of the condenser cooling water around the cooling tower. This may be done to provide more accurate control of condenser water, to maintain a minimum condenser temperature, or as part of a freeze protection scheme. Installing a fully modulating fan should eliminate the need for tower water bypass.

Graham Company

Fig. 1 Variable-frequency drive for cooling tower fans
This is a good application for variable-frequency drives. Retrofit is especially easy. A single drive can operate any number of fans at identical speed, which is the most efficient way of operating multiple fans.

If a cooling tower bypass is installed, find out why. If installing a variable-flow fan eliminates the need for the bypass, either remove the bypass valve entirely or lock the bypass closed. In the latter case, install a placard on the bypass valve to indicate that it is no longer used.

The effect of a bypass valve on pump energy consumption is minor, in conventional condenser cooling systems. The main reason for eliminating the bypass is to avoid unnecessary complication and possible conflict with the fan controls.

Some chillers require a minimum condenser water temperature, typically about 65°F (18°C). If the chiller is turned off during cold weather, the temperature of the water standing in the tower may fall below the minimum allowable temperature. If a bypass is installed to maintain a minimum cooling water temperature, make sure that it opens only when needed for this purpose. The warm-up interval is usually no longer than a few minutes. Also, make sure that the fan controls keep the fans turned off as long as the bypass is open.

Important Features for Cooling Unit Applications

See [Reference Note 36](#) for the selection issues that apply to all electronic drive applications. Drive features that are important for cooling tower fans in particular are:

- the ability to lock out specific resonant speed bands
- a control package that is appropriate for condenser cooling
- if a wet cooler is used during cold weather, the ability to reverse the fans to melt ice.

Whether to Replace the Fan Motor

Electronic drives produce distorted power waveforms. The high-frequency distortion components cannot be used efficiently by motors, and they are converted to heat inside the motor. The amount of distortion varies widely among different types and models of VFD's. Not surprisingly, those with smoother waveforms cost more, other things being equal.

Newer motors that are designed for use with electronic drives suffer less efficiency loss from drive distortion. If you install a drive that does not produce especially smooth motor power, it may be advisable to replace older fan motors. See [Reference Note 36](#) for the details.

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of fan energy, 0.5 to 3 percent of chiller energy, because of lower condensing temperature.

COST: Variable-frequency drives cost from \$50 to \$400 per horsepower (or kilowatt), depending on size, type, and optional features. High-efficiency motors cost \$50

to \$100 per horsepower. In retrofit applications, several man-days of installation labor are typically required.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

CHOICE OF METHOD: Variable-speed drives should be installed on most heat rejection units of large and

medium size. Variable-frequency drives are probably the wave of the future for this application. Several years ago, you would have been a pioneer retrofitting a VFD to a cooling tower, but no longer. Electronic variable-speed drives are still improving and becoming cheaper. Be familiar with the selection issues explained in Reference Note 36.

This is the second of three subsidiary Measures that improve the fan modulation of cooling towers and dry coolers. Review “Comparison of Methods,” in Measure 2.4.1, to help you decide which to choose.

This subsidiary Measure covers variable-pitch fans. Like variable-frequency drives, which are covered in the previous Measure, variable-pitch propellers provide precisely the degree of cooling required by the load. Instead of changing the speed of the fan, they change the pitch. A mechanism in the hub of the propeller changes the pitch of the blades by any desired amount, so the air flow can be adjusted anywhere from full output to almost zero flow.

The propeller and its accessories are specially designed for the corrosive and dirty environment of cooling towers. The propeller blades are typically aluminum alloy or fiber-reinforced plastic, and the pitch mechanism usually is actuated by pneumatic pressure.

Variable-pitch fans are losing ground to variable-speed drives, primarily because of their higher cost. Even before this competition arose, variable-pitch fans were limited by economics to larger cooling towers. They are worth considering in cases where the disadvantages of electronic drives cannot be tolerated. However, these disadvantages are being lessened in newer models of electronic drives, further limiting the application of variable-pitch fans.

Retrofitting a variable-pitch fan is feasible in most cooling towers above a certain size. Installation service is offered by the major cooling tower manufacturers. The modification is straightforward, although not as simple as Measures 2.4.1.1 and 2.4.1.3. The replacement propeller fits into the same opening as the original fan, but you may have to modify the fan transmission mounting.

Operate All Fans at the Same Speed

If a single cooling system is served by more than one variable-pitch fan, the lowest energy consumption occurs when all fans are operated at the same pitch. This arrangement is simple to control. Any number of variable-pitch fans can be controlled by providing the same control signal to all the fans.

Turndown Ratio

Variable-pitch propellers have the best turndown ability of any type of variable-output fan. They are able to reduce air circulation smoothly from full load to almost zero.

Dealing with Resonances

Resonances of the fan and the cooling tower structure are not likely to be a problem with variable-pitch fans, but consider the possibility. Resonances are relate to the fan speed and the number of propeller blades. The speed is constant, so you can avoid

resonances simply by operating the fan at a speed that does not excite any resonances.

In retrofit applications, verify that there will be no resonance at the anticipated operating speed. This may occur if the variable-pitch fan has a number of blades different from the original fixed-pitch fan. If the fan has a belt drive, you can easily change the fan speed by a small amount to avoid a resonant frequency. The capacity of the heat rejection unit is not affected by a small speed adjustment because the propeller pitch changes to compensate for it.

Eliminate Cooling Tower Bypass, If Appropriate

Refer to this heading in [Measure 2.4.1.1](#), previous. The considerations are identical when dealing with variable-pitch propellers.

Belt or Gear Drive?

Gear drives may achieve 98% efficiency, in the best of cases. Belt drives have somewhat lower efficiencies, typically in the range of 92% to 96%.

Belt drives provide great flexibility in varying the speed of the fan in relation to the motor speed. This can be valuable in avoiding resonances.

Another advantage of using a belt-driven fan is that it may avoid the need to remount the power transmission between the motor and the fan. On the other hand, a gear drive may be an integral part of a variable-pitch fan package, avoiding any problems of separate mounting.

Control Issues

The controls for a variable-pitch fan are relatively simple. They are available as a standard package from some fan vendors. The typical control senses condensing temperature to change the air pressure delivered to the variable-pitch mechanism in the hub of the fan.

The most difficult part of optimizing the control settings is calculating the optimum condenser temperature for each chiller load and outside air temperature. [Measures 2.2.2](#) ff describe how to do this.

Standard control packages allow the designer to select a fail-safe pitch setting in the event of failure of

the pitch control. For most applications, the appropriate fail-safe position is full pitch, providing maximum cooling capacity. If freezing is a potential problem, it may be more desirable to have the pitch control fail to minimum pitch.

An important factor to consider is the long time lag in control response, especially with wet coolers. When the fan speed increases in response to a rise in condensing temperature, the effect is not felt at the condenser until the water has time to circulate from the tower to the chiller. This causes oscillation of the fan controls, unless they are set to respond slowly. The control packages provided by the manufacturers of variable-pitch fans for cooling towers should deal with this problem satisfactorily.

The cooling tower will continue to operate with a failed pitch control, so include an alarm in the control package to alert operators if the pitch control fails.

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of fan energy, 0.5 to 3 percent of chiller energy, because of lower condensing temperature.

COST: Approximately \$30 per ton of cooling tower capacity, for the equipment. Retrofitting a variable-pitch propeller to an existing cooling tower involves a large labor cost, which varies widely depending on circumstances.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

SELECTING AND INSTALLING THE EQUIPMENT: Installing variable-pitch fans is specialized work. Buy the equipment from the people who will install it, so that there is no question about who is responsible for fixing problems. Make sure that both equipment and installer have a good reputation. Check with others who have used both.

MAINTENANCE: The variable-pitch mechanism operates in a harsh environment, so maintenance is critical. Make sure that you have a way of scheduling the maintenance reliably.

MEASURE 2.4.1.3 Install dual or multi-speed motors.

RATINGS

New Facilities	Retrofit	O&M
B	C	

This is the last of three subsidiary Measures that improve the fan modulation of cooling towers and dry coolers. Review “Comparison of Methods,” in [Measure 2.4.1](#), to help you decide which to choose. This subsidiary Measure covers the use of dual motors and multi-speed motors in cooling towers and dry coolers. Both methods have virtually identical efficiency characteristics, in most applications.

Multi-speed motors offer two or more fixed speeds. Most heat rejection units equipped with multi-speed motors have only two speeds, but three or more speeds may be worth considering. Multi-speed motors may be easy to retrofit to existing single-speed heat rejection units.

In dual-motor installations, one motor at a time drives the fan, while the other motor idles. Figure 1 shows a typical installation. Dual motors offer only two speeds, but virtually any ratio of two speeds can be obtained if at least one of the motors is connected with a belt drive. Usually, multi-speed cooling tower fans operate at a 2:1 ratio, but there is no inherent reason why you should not select a different ratio. The power rating of each motor is selected for the speed at which it drives the fan. This configuration is generally limited to new equipment, as it would be difficult to retrofit.

The two methods are similar in cost. They are much less expensive than the variable-output drives covered by the previous two Measures. The main disadvantage of both methods is that they are less efficient than the two previous Measures.

Efficiency Characteristics of Multi-Speed Fan Control

If a single-speed fan would operate about 50% of the time, then installing dual motors or a multi-speed motor will provide a significant improvement.

A typical condenser cooling unit retains about 70% of its maximum cooling capacity if the fan speed is reduced to half. Therefore, a 2:1 speed ratio provides substantial fan power savings if the system operates much of the time in the vicinity of half load. The fan input power is reduced to about 20% of full-load power when it operates at half speed, which includes a motor efficiency loss at the lower speed.

Since there is a relatively small change in cooling capacity when the motor switches between the two speeds, the condensing temperature does not rise much when the fan switches to lower speed.

On the other hand, the multi-speed fan offers much less benefit if the system lingers at low load. This occurs, for example, in the air conditioning systems of many types of facilities located in temperate climates. When

the load is low, the fan does not run very long with either a single-speed or multi-speed motor, so not much motor energy is saved. Also, the fluctuations in condenser temperature are large in both cases.

A multi-speed fan also offers less benefit if the cooling unit operates most of the time near full load. In this case, either a single-speed or multi-speed motor would operate at full output most of the time.

How to Select the Motor

See [Reference Note 36](#), Variable-Speed Motors and Drives, for details of multi-speed motors and dual motor installations. In most cases, a motor with two speeds is the best choice. Motors with three or four speeds are available on a custom basis, but they are larger and more expensive, and they suffer higher efficiency losses.

Control Issues

Controlling a multi-speed motor is simple. Use a multi-stage thermostat having the same number of stages as the available speeds. With a two-speed motor, one stage of the thermostat turns the fan to low speed when the condensing temperature rises to a certain setting, and to full speed at a slightly higher temperature. In cooling towers, the thermostat is usually installed to sense the temperature of the water in the sump. With air-cooled condensers, the fan speeds are controlled by the temperature or the pressure of the refrigerant in the condenser.

An important factor to consider is the long time lag in control response, especially with wet coolers. When the fan speed increases in response to a rise in condensing temperature, the effect is not felt at the condenser until the water has time to circulate from the tower to the chiller. This causes the fan controls to hunt between fan speeds. One solution is to build a delay

Baltimore Aircoil Company

Fig. 1 Two-motor cooling tower fan drive Only one motor operates at a time. Using two fan speeds instead of one provides major advantages in some applications, but not in all. The ratio of fan speeds may strongly affect the efficiency gain. Because these motors have belt drives, the fan speed with each motor can be adjusted over a wide range.

into the starting and stopping of each stage. A more sophisticated approach is to use proportional-integral-derivative (PID) controls. These are covered in [Reference Note 37](#), Control Characteristics.

The most difficult part of optimizing the control settings is determining the optimum condenser temperature. [Measures 2.2.2 ff](#) give the procedures for doing this.

Control of Speeds in Multi-Fan Installations

In heat rejection units where a cell has more than one fan, the manner in which the fan speeds are sequenced has a significant effect on energy consumption. See [Measure 2.4.2](#) for the details. In this type of cooling unit, this Measure suffers a greater efficiency disadvantage when compared to the preceding two Measures.

Dealing with Resonances

Both fans and cooling unit structures may have strong resonances at a number of frequencies. These resonances may become loud enough to annoy people, and they may even damage equipment. Select all the operating speeds of the fan to avoid any resonant frequency.

In retrofit applications, you can use the original single-speed motor to check for resonances at the intended speeds of the multi-speed motor. Do this by changing pulleys to operate the original fan at the intended high and low speeds for test purposes.

If a resonance does appear at any of the intended operating speeds, several solutions are available. If a belt drive is used, you can adjust the fan pulleys to avoid the resonant speeds.

Another approach is to change the resonant frequencies of the structure or to dampen the resonances. You can do both by modifying the structure, installing braces, or pre-tensioning parts of the structure that may vibrate.

Remove Dampers in Retrofit Units

Some small heat rejection units, both wet and dry, employ dampers to throttle air flow as a means of modulating the cooling capacity of the cooling tower. For example, you may find dampers if the chiller must maintain a minimum condenser temperature. Dampers are inefficient as a means of controlling the output of a heat rejection unit, and they can usually be eliminated when multi-speed fan modulation is installed. Remove the dampers, or lock them fully open, if you provide efficient modulation.

If the dampers must be retained for control at low fan speed, ensure that the damper controls open the dampers fully when the fan is operating at high speed. Avoid this control complication, if possible, because it is another potential failure mode.

Eliminate Cooling Tower Bypass, If Appropriate

Refer to this heading in [Measure 2.4.1.1](#), above. The considerations are similar when dealing with multi-speed motors.

ECONOMICS

SAVINGS POTENTIAL: 30 to 60 percent of fan energy. 0.5 to 2 percent of chiller energy, because of lower condensing temperature. The life of all drive components is extended.

COST: Single-winding 2:1 motors cost about \$400 per horsepower in small sizes and about \$100 per horsepower in large sizes. The cost of dual motors is similar. Controls add several hundred to several thousand dollars. In retrofit applications, labor for motor replacement is a relatively small cost, if there are no installation difficulties.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

DO YOUR HOMEWORK: You have more choices of multi-speed motors than you may realize. See [Reference Note 36](#) for the full story. Figure out the best motor speed ratio for your application based on the cooling load profile.

INSTALLATION: This feature is so simple and reliable that there is no excuse for problems. Set the speed controls for maximum overall efficiency. In retrofit, make sure that the motor or motors are aligned properly.

MEASURE 2.4.2 In multiple-cell cooling units, sequence the fans efficiently.

Some heat rejection units have a number of fans, each of which operates in one or two stages. The sequence of fan operation affects the overall fan power, the condenser temperature, or both. The fan sequence that provides the lowest fan energy consumption also provides the lowest average condenser temperature. Minimizing the condenser temperature increases chiller efficiency, for reasons explained in [Measure 2.2.2](#).

In some cases, you may find that the sequence is not the optimum one. You are most likely to find this in multi-cell cooling towers that are installed as a part of engineered (i.e., not packaged) cooling systems. Multi-fan dry coolers that serve a single chiller generally include controls that sequence the fans in an optimum manner. But, don't assume this. It takes only a brief period of observation during the cooling season to check the fan sequence. Changing the fan sequence is usually a simple control modification.

Optimum Fan Sequencing

If the fans have continuous fan speed modulation, best efficiency occurs if all the fans are kept running, and at the same speed. (If the fans do not have continuous modulation, consider installing it, as recommended by [Measures 2.4.1.1](#) and [2.4.1.2](#).)

If the fans are staged, keep the loading of all the fans that serve a particular cooling circuit as close together as possible. For example, in a cooling unit with three two-stage fans, the first fan starts at low speed, then the second fan, then the third. Next, the first fan goes to high speed, then the second, then the third. The fans should unload in reverse order.

This manner of fan sequencing applies to all the fans that serve a single chiller system. A cooling tower with several cells may be connected to more than one chiller system. Optimize the fans for each chiller system as a group.

Be sure of the cooling unit circuiting before proceeding. In the case of wet cooling units, this is usually easy to trace. Be careful with multi-cell cooling towers that have piping connections that allow different cells to serve different loads. With such towers, the optimum fan sequence is different for different water flow connections.

In dry coolers and evaporative condensers, circuiting may be less obvious. For example, if a reciprocating chiller has several compressors, each compressor is likely to have its own condensing coil circuit. If the sequence of fan operation in a packaged heat rejection unit appears to differ from the sequence recommended

below, there may be a good reason. In case of doubt, contact the manufacturer before making any changes.

Why Optimum Sequencing Saves Fan Energy

All the fans that serve a particular cooling circuit should keep their loading as close together as possible. The reason is that fan energy is proportional to the third power of flow volume, rather than being directly proportional to flow. For example, two fans operating at half speed consume considerably less energy than one fan operating at full speed.

Why Optimum Sequencing Lowers Condenser Temperature

Similarly, the lowest condensing temperature is achieved when all the fans that serve a particular cooling circuit keep their loading as close together as possible. To see why, consider a cooling tower with two cells serving a single circuit, each fan having two speeds. If one fan operates at full speed and the other fan is off, the temperature reduction is limited to about half of maximum, because the water from idle cell is mixed with the water from the active cell. On the other hand, if both fans operate at half speed, the temperature drop is near maximum, because half the maximum air flow provides full cooling at low cooling load.

assembled units, the manufacturer has a specific reason for the way the fans are sequenced. You are most likely to find an outright sequencing mistake in a field-erected cooling tower. If you find that the fan sequencing is not the most efficient, suspect that this may be related to freeze protection or other functions. If so, you have to find ways to accommodate those other functions.

MEASURE 2.4.3 Clean heat rejection units at appropriate intervals.

RATINGS

New Facilities	Retrofit	O&M
		A

Heat rejection equipment seems to give the impression that its condition has no effect on cooling system efficiency until it physically falls apart. This is not true. If heat rejection units are not kept clean, heat transfer suffers. This reduces chiller system efficiency and capacity, and increases the fan power requirement. Also, neglecting cleaning hastens equipment deterioration.

Cleaning heat rejection equipment is straightforward. This Measure tells you what needs to be done. The subsidiary Measure recommends changes to heat rejection units that reduce their tendency to become fouled.

How Lack of Cleaning Wastes Energy

Lack of cleaning wastes energy in a number of ways, depending on the type of heat rejection equipment:

- ***dry coolers suffer restricted air flow from dirt and debris.*** Dirt that settles on the fin surfaces restricts the flow of air through the coil and reduces heat transfer efficiency. The fan uses more energy as it tries harder to maintain the condenser temperature setting.
- ***evaporative condensers and closed-loop cooling towers*** have heat transfer surfaces between the evaporating water and the refrigerant or condenser cooling water, respectively. Fouling of these surfaces raises the condensing temperature. Obstruction of cooling water flow by accumulation of debris in piping, strainers, and drains raises the condensing temperature. Fan energy consumption increases as the fan tries harder to maintain the condenser temperature setting.
- ***open-loop cooling towers, i.e.,*** units that do not use heat exchangers, do not suffer an efficiency loss themselves as a result of fouling. Water evaporates from slimy splash bars as efficiently as from clean

ones. The trouble with fouling that accumulates and grows in the cooling tower is that it travels to the heat transfer surfaces of the condenser. (Condenser cleaning is covered in [Measures 2.3.1 ff.](#)) Obstruction of condenser water flow by accumulation of debris in condenser tubes, piping, strainers, and drains raises the condensing temperature.

Factors that Increase Dirt Accumulation

The height of the unit above ground, especially above surrounding foliage, is a major factor that determines how fast debris accumulates. Units located below grade, either in wells or in basement mechanical equipment rooms, may accumulate debris prodigiously. Birds may clog units with feathers, nest material, and food leftovers. The bird problem is worst when the unit is located inside a well, behind a decorative screen, or in other sheltered locations. Improving the installation to reduce debris accumulation is recommended in the subsidiary Measure.

In wet cooling units, the nature of the local water supply determines the potential for mineral scaling of heat transfer surfaces. [Measures 2.3.3 ff](#) recommend ways to control these problems.

How to Clean Dry Coolers

If a dry cooler has a coil that is horizontal or slanted, debris falls off the bottom side of the coil when the fan turns off. The air flow is usually upward, which blows debris off the top of the coil when the fan is running. If the environment is clean, rain may provide all the cleaning that is necessary. Vertical coils, including the condenser coils of packaged air handling units, do not have this advantage.

In less satisfactory installations, airborne debris is drawn into dry cooling units by wind and by the action of the fans. The debris accumulates:

- over the coil fins
- between the coil fins
- on intake screens
- on fan guard screens.

Inspect each of these areas carefully. Some deposits are not obvious. In particular, a coil may become almost totally obstructed, even though the outer fin surfaces have been cleaned by superficial washing. You have to look through a coil and see light on the other side to be sure that it is clear.

If the dry cooler is installed so that the passage for the entering air is restricted, the velocity of the entering air is increased. This increases the tendency of the air to carry debris into the cooler. Such installations may also make it difficult to inspect the coil for debris. If you are unable to inspect the coil easily, suspect a problem.

Cleaning dry coolers is usually just a matter of sweeping the debris out of the cooling unit and cleaning the area surrounding the unit. Clear the surrounding area because any loose material will be drawn into the unit by the suction of the fan.

If dirt has collected between the coil fins, it is likely to be muddy in nature, so that it tends to cement itself in place. Water washing with a garden hose nozzle may dislodge the material after dissolving it. This may require patience. If the garden hose does not work, a high-pressure water lance can usually do the job, but be careful to avoid damaging the fins.

How to Clean Wet Coolers

The water sprays used in open-loop cooling towers, closed-loop cooling towers, and evaporative condensers are effective traps for atmospheric contaminants. These include inorganic particulate matter, general debris, gases, chemical pollutants, and a large variety of microorganisms. Each of these creates its own categories of problems.

The combination of water, warmth, heavy oxygenation, and nutrient matter fosters prolific growth of microorganisms, especially algae, bacteria, mold, and fungi. These may form colonies that insulate heat transfer surfaces and clog the system. In addition, some organisms may create health problems, such as Legionnaires' Disease. These are the areas that need periodic cleaning:

Baltimore Aircoil Company

Fig. 1 Water distribution orifices in a crossflow cooling tower These are easily obstructed by debris that falls into the open top of the cooling tower. This causes uneven water flow in the tower. The easy access to the trays makes them easy to clean out.

- **intake and fan guard screens**, which are easy to inspect and clean
- **drift eliminators**, which are baffles installed in cooling towers to prevent water droplets from being blown out. A water lance is effective for cleaning these.
- **water distribution nozzles**, which typically are simple orifices in the bottoms of the distributor trays at the top of gravity-flow towers. Figure 1 shows how they are arranged. The nozzles are typically a fraction of an inch (one or two centimeters) in diameter. Although the nozzles have large diameters, it is not unusual for them to become clogged. The trays in many towers are open, making it easy for large debris, such as leaves and dead animals, to fall in. Also, the nozzles in older steel cooling towers may become obstructed by rust chips. By the same token, the trays are easy to clean out, even with the tower in operation.
- **water spray nozzles**, in induced-draft towers. In this type of tower, air flow is induced without fans by spraying the water into the tower at high pressure. The venturi effect of the spray nozzles draws air into the spray. Unfortunately, this requires small nozzles that are easily clogged. This type of tower needs continuous filtration of the cooling water and frequent inspection of the nozzles.
- **heat transfer coils**, in evaporative condensers and closed-loop cooling towers. Most fouling can be cleaned off with detergent and brushing. Tenacious fouling, especially from mineral scaling, may require more brutal treatment, including specialized chemical cleaning.
- **sumps**, from which debris should be removed using methods similar to cleaning a swimming pool
- **condenser water strainers**, which should be flushed periodically. Failure to do so makes the trap itself an obstruction to cooling water flow, and can substantially raise condensing temperature.

- **fill media**, consisting of splash bars or water film surfaces. There is generally no need to clean fill media unless debris accumulates to the point it reduces the evaporating surface area significantly. The cleaning method for heavily fouled fill media depends on the type of fill. If the surfaces are accessible, mechanical brushing or high-pressure washing may be best. Chemical cleaning may be needed for packed fill media.

How to Prevent Fouling in Wet Coolers

Eliminate biological fouling by effective water treatment, which is recommended by [Measures 2.3.3 ff.](#) Chemical treatment, combined with bleed (see [Measures 2.3.4 ff.](#)), can also help to keep dirt from depositing on system surfaces. Water treatment cannot keep large debris, such as leaves and rust chips, from obstructing flow. You have to remove debris manually.

MEASURE 2.4.3.1 Install and screen heat rejection units to minimize debris accumulation.

RATINGS

New Facilities	Retrofit	O&M
A	B	C

Take a look at your heat rejection units, and see whether they are picking up an excess amount of debris. If so, it may be worthwhile to modify the cooling units to reduce the rate of debris accumulation. This saves labor, and maintains higher efficiency between cleanings. There are two fairly easy solutions that cover most cases. One is to increase the height of the cooling unit above sources of debris. The other is to install screens that prevent debris from entering the cooling unit.

Install Screens

In most situations where cooling units tend to foul by larger debris, you can protect the unit by installing screens. Usually, it is best to install the screen so that it covers the entire air intake to the heat rejection unit. If you do this, install the screens so that the screens themselves do not become choked. To keep the screens clear, install them so that entering air must flow upward into them. In this way, debris is pulled away from the screens by gravity when the fan stops..

Do not let screens obstruct air flow. A coarse screen that is appropriate for stopping leaves and birds will not interfere with air flow itself. However, if the screen may become partially obstructed, compensate by making the surface area of the screen larger.

In some cases, it is more practical to install a screen surrounding the unit. Figure 1 shows an example. This arrangement does not provide complete protection, but it cannot clog the air flow.

Elevate Cooling Units

If the cooling unit is being fouled by leaves and other foliage, it may help to elevate the unit. This is because debris is typically sucked up from an adjacent surface by the high velocity of the intake air. Adding legs, or extensions to existing legs, may be fairly easy. Keep the air intake path as open as possible to minimize entering air velocity. Exploit this opportunity to improve access to the cooling unit for cleaning and maintenance.

MEASURE 2.4.4 In gravity-flow cooling towers, ensure proper water distribution.

RATINGS

New Facilities	Retrofit	O&M
□	□	A

In cooling towers where the water flows over the fill by gravity, it is important to maintain uniform distribution of water. Any gaps in the curtain of water allows air to short-circuit through the tower without cooling. This reduces cooling effect, increases fan power, and reduces tower capacity.

In gravity-flow cooling towers, water typically is pumped into distributor trays at the top of the unit. (See Figure 1.) The water falls down to the fill or splash bars through holes (“nozzles”) in the bottoms of the trays. The water should be equally deep at all points in the distributor trays to provide uniform flow. The depth is typically no more than one or two inches (a few centimeters). If the tower is tilted even slightly, portions

WESINC

If these are not adjusted properly, water flow will be uneven.

of trays may run dry or have weak flow. You can correct the tilt by adjusting the trays individually or by shimming the supports for the entire tower, depending on the design of the unit.

Cooling towers may have a number of separate trays. To achieve uniform filling, the cooling water pipe filling each tray may have a balancing valve. If so, be sure that these valves are set properly. If you find that the valves have different settings, suspect a water distribution problem that should be corrected.

If the water levels in the trays are too low to provide good distribution, even with all valves in the system fully open, check that the strainer is not clogged. If the strainer is clear, the nozzles may be too large, or there may be a problem of inadequate pump capacity (which is rare).

If the balancing valves are heavily throttled, verify that the water depths in the trays are adequate. If so, you may be able to save energy by trimming the condenser water pump capacity. See [Measure 10.2.1](#) for this.

MEASURE 2.4.5 Keep heat rejection unit housings and fittings intact.

RATINGS

New Facilities	Retrofit	O&M

The efficiency of a heat rejection unit is mainly a matter of how effectively air is brought in contact with the cooling water or the cooling coils. The air is guided by the outer enclosure and by internal structures. Defects in these components may persist unnoticed, because the unit continues to operate, although with reduced efficiency and capacity. Check your heat rejection units periodically to make sure that all the parts are intact. Combine this with the periodic cleaning recommended by Measure 2.4.3.

Defects in the enclosure waste energy in two ways: (1) inefficient air flow increases the average condensing temperature, which reduces chiller efficiency for the reasons explained in Measure 2.2.2, and (2) the fans use more energy in trying to maintain the condenser temperature setting. Defects also reduce the capacity of the cooling system.

Insist that all the fasteners be used to secure removable panels, rather than allowing panels to hang in place with one or two bolts. This keeps panels from

blowing loose, and motivates people to replace them properly.

Make Access Doors and Panels Easy to Secure

A common problem is neglecting to replace access panels that are not attached to the casing by a positive means. To reduce this problem, install retainers in a manner that motivates replacing the panels. For example, attach the panel to the casing with a cable in such a way that the panel dangles in front of the opening when the panel is removed. Ease of use is a key feature. Design and install access panels so that they are easy to install and easy to latch securely.

Keep Fill Intact

In older wet coolers and in wet coolers that have been rebuilt, some of the internal “fill” material that increases the evaporating surface area may be broken or missing. Serious defects are usually obvious. The corrective action consists of replacing the decayed, broken, or misplaced elements.

A more subtle problem may exist in rebuilt towers, where the geometry of the fill may be wrong or portions of the fill may be missing. When a cooling tower is

rebuilt, check the geometry of the fill material against the latest version of the cooling tower drawings.

Keep Drift Eliminators Intact and Clear

Drift eliminators are baffles installed in the air discharge path to minimize the discharge of unevaporated water droplets, which are returned to the sump. Not all cooling towers have them. If drift eliminators are missing or defective, tower water consumption increases. Drift eliminators that are clogged by debris, slime, or other material reduce air flow and cooling effectiveness.

ANALYZE THE PROBLEM: When you find a big gap where none belongs, figure out what caused it. Then, fix it in a way that makes it unlikely to recur.

MEASURE 2.4.6 Avoid recirculation of air through the same or adjacent heat rejection units.

The way a heat rejection unit is installed may cause air to circulate from the discharge back to the intake. The recirculated air has little remaining cooling capacity, so recirculation wastes fan energy, reduces the capacity of the cooling unit, and increases the increased condensing temperature.

A similar problem may occur where cooling units are installed adjacent to each other. In this case, the discharge from one cooling unit may be drawn into the intake of another.

Take a look at all your heat rejection units to see whether recirculation may be a problem. The possibility of significant recirculation varies with wind, temperature, and humidity. Consider all the possibilities.

How Much Energy is Really Being Wasted?

You may be able to spot a recirculation problem by observing the vapor plume of a heat rejection unit, but don't expect to judge the severity of the problem from the appearance alone. A few wisps of water vapor recirculating back to the intake do not necessarily indicate a significant problem, although they may. On the other hand, serious recirculation may occur invisibly during warm or dry weather, when the discharge is invisible.

Judge the potential for energy waste by examining the installation to see whether it has any of the characteristics that tend to cause recirculation, which are explained below. Then, if you suspect trouble, you can estimate the percentage of recirculation easily by taking air temperature or humidity measurements under a variety of typical wind conditions.

The air temperature and humidity at the intake of the heat rejection unit should be the same as the

temperature and humidity of free air away from the unit. If the intake air is warmer or more humid, then some recirculation is occurring.

To estimate the amount of recirculation in dry coolers, use Formula 1, making the air temperature measurements indicated.

Formula 1 is not accurate for wet coolers, because they perform a large fraction of cooling by evaporation. Formula 1 may still give you a rough estimate of recirculation under humid conditions, when evaporation is limited.

For an accurate estimate of recirculation in a wet cooler, use Formula 2. Measure the humidity with a psychrometer (see Figure 1 in Measure 2.2.2.1) or relative humidity sensor, and convert to absolute units by using a psychrometric chart.

If the cooling unit does not have a localized intake point where you can take readings, take an average of

FORMULA 1

for dry coolers,

$$\text{Percent recirculation} = \frac{\text{intake temperature} - \text{ambient temperature}}{\text{discharge temperature} - \text{ambient temperature}} \times 100$$

where:

- the temperatures can be expressed in any consistent set of units

FORMULA 2

for wet coolers,

$$\text{Percent recirculation} = \frac{\text{intake humidity} - \text{ambient humidity}}{\text{discharge humidity} - \text{ambient humidity}} \times 100$$

where:

- humidity is expressed in absolute units of moisture content, for example, grains of moisture per pound of air

readings around the unit, especially upwind and downwind.

If you find that significant recirculation occurs under conditions that exist often, consider corrective measures.

What Determines the Amount of Recirculation

The design of the cooling unit and the way it is installed tell whether the unit is likely to have recirculation problems. Consider these are factors:

- **discharge velocity.** Recirculation is reduced by high discharge velocity, which throws the discharge air away from the unit. The discharge air is warmer than the ambient air, so it tends to rise clear of the unit once it is beyond the influence of air currents in the vicinity of the unit.
- **intake velocity.** Recirculation is increased by high inlet velocity, which creates a low-pressure area near the inlet that attracts recirculation. High intake velocity may be caused by a small intake size in the cooling unit. It may also be caused by a tight air passage leading to the unit.
- **fan modulation.** A variable-flow fan may increase recirculation by reducing the discharge velocity, especially at low loads. However, the intake velocity is reduced in the same proportion, which tends to reduce recirculation into the same unit.

WESINC

Fig. 1 Horizontal-flow cooling tower If wind blows opposite the direction of discharge, a certain amount of recirculation will occur. Recirculation is aggravated by the location of the tower alongside a wall. This type of tower causes serious recirculation to any other heat rejection units located in the general direction of the discharge.

Furthermore, fan speed is controlled in response to cooling load, so any loss of cooling capacity is compensated automatically by increased fan output. Fan power is wasted, but chiller efficiency may not be seriously affected. Fan modulation is not likely

WESINC

Fig. 2 Cooling tower installed in a well This installation invites serious recirculation. A stack has been installed on the fan on the right to minimize recirculation. Even so, you can see that some of the discharge is being drawn back down into the cooling tower. The discharge plume is visible because of the high relative humidity in this location.

to cause recirculation unless the air flow around the tower is confined.

- **wind speed.** Wind blows the discharge air in a downwind direction. Wind also creates a suction on the downwind side of the cooling unit because the unit is not streamlined. Therefore, discharge air tends to tumble into the downwind side of the same or adjacent units. You can reduce this effect by shielding the unit from wind, but the structure used for shielding may cause recirculation itself, as explained below.
- **orientation and wind direction.** If a heat rejection unit does not discharge vertically, its orientation is important. Figure 1 shows a unit that discharges horizontally. If the unit discharges into the wind, a significant amount of recirculation is likely. Also, a unit that discharges horizontally is likely to inject warm air into adjacent cooling units.
More generally, an air inlet located on the downwind side of any cooling tower tends to recirculate air. Wind direction is variable, so some recirculation is likely to occur for part of the time.
- **enclosures and surrounding structures.** Serious recirculation is likely if a heat rejection unit is surrounded. For example, the unit may be hidden by a decorative enclosure, or it may be installed in a well. The problem is especially severe if the enclosure rises to the top of the cooling unit or higher. Figure 2 shows an extreme case. This geometry forces the incoming air to pass near the exiting air stream, which invites mixing. This effect is aggravated by wind, which tips the discharge air column into the entering flow.
- **adjacent structures.** Tall parapets and adjacent buildings that are upwind of the cooling unit may have strong downdrafts that mix the discharge air with the entering air. In some cases, a downdraft may exist far downstream of its source.

All other factors being equal, the least recirculation occurs in induced-draft heat rejection units, i.e., units in which the fans are located at the discharge end of the unit. These units have relatively high discharge velocity and relatively low inlet velocity. Most dry coolers use an induced-draft fan arrangement, as do most crossflow cooling towers.

Updraft, or counterflow, cooling towers typically have a forced-draft fan arrangement, i.e., with the fan blowing into the tower. These units have relatively low discharge velocity and relatively high inlet velocity, so they are more susceptible to recirculation.

How to Minimize Recirculation

The following is a menu of techniques for reducing recirculation. The best solution for your equipment is a matter of layout, cost, appearance, and other factors.

Consider combining some of these methods, if appropriate.

■ Modify the Enclosure to Reduce Recirculation

As explained previously, enclosures that surround a heat rejection unit tend to cause recirculation. The severity of this effect depends on the relative height of the enclosure. If the top of the enclosure is as high as the discharge point or higher, contact between the entering and leaving air streams is almost unavoidable. You can avoid this problem or reduce it by modifying the enclosure. Here are some ways to do this:

- **install cutouts at the bottom of the enclosure** to allow air to enter, as illustrated in Figure 3. Make the cutouts large enough. If there is a prevailing wind during the cooling season, try to install the cutouts on the windward side. This technique may be inexpensive, and it preserves the decorative screening effect of the enclosure, especially where the unit is installed on a roof.
- **substitute open latticework** for unbroken panels, as illustrated in Figure 3
- **reduce the height of the enclosure** as much as possible. If the unit is located well above viewers, the enclosure does not have to be as tall as the cooling unit to hide the unit completely. The esthetics of the building may even allow a glimpse of the upper portion of the unit.
- **increase the clearance** between the enclosure and the inlet sides of the heat rejection unit.

■ Install an Exhaust Stack on the Heat Rejection Unit

Adding a stack to the cooling unit is a way of raising the discharge point without raising the heat rejection unit itself. Figure 4 sketches how this is done. Figure 2 shows an actual retrofit of a stack to an existing cooling tower.

Figure 5 shows how a stack can reduce recirculation that is caused by the cooling tower being installed close to a wall.

The cross sectional area of the stack should be the same as the cross sectional area of the original discharge of the heat rejection unit. This is important to maintain the discharge velocity. A stack that is reasonably short, i.e., no taller than several diameters, does not significantly increase fan power.

If the stack is tapered toward the outlet, the discharge velocity is raised. The higher velocity reduces recirculation. However, the fan power requirement increases because the fan must add more kinetic energy to the discharge air. The reduction of recirculation probably does not justify the increase in fan power, except in specialized circumstances.

If you install a stack, brace it well to withstand wind. You may have to brace a stack directly to the building structure, rather than to the heat rejection unit itself, if

the heat rejection unit does not provide a strong attachment point.

■ **Raise the Heat Rejection Unit Above Surrounding Structures**

Raising a heat rejection unit may be the only available option if the unit is tightly enclosed within a well, or if you want to exploit wind to aid evaporation.

Figure 4 sketches this solution. The cost of the supporting structure and the cost of modifying the piping makes it expensive.

The change in height does not affect cooling water pumping. The increased pressure needed to pump water to the top of the tower is balanced by the increased pressure in the return leg.

Fig. 3 How to reduce recirculation in an enclosure

Fig. 4 How to reduce recirculation in a well

■ Isolate Adjacent Heat Rejection Units

If one heat rejection unit discharges toward the intake of another, install a barrier to deflect the discharge. Figure 6 sketches an example.

If adjacent heat rejection units all discharge vertically, a recirculation problem is not likely unless there are aggravating factors, such as those discussed previously.

■ Relocate the Heat Rejection Unit

An approach of last resort is to move the heat rejection unit to some other location. This is very expensive because of the costs of rigging, piping, and fabrication of support structures.

BAD

BETTER

BAD

BETTER

Fig. 6 How to reduce recirculation from one heat rejection unit to another

In deciding whether to move a heat rejection unit, consider whether you have an opportunity of moving the unit to a location where the ambient air is cooler, such as the shaded side of a building. This would be most valuable with dry coolers, whose condensing temperature relates directly to the dry-bulb temperature. Location is less relevant with wet coolers, whose condensing temperature depends on the wet-bulb temperature. The wet-bulb temperature of the air is not affected by shading.

Especially with wet coolers, consider any possibility of exploiting ambient wind to reduce fan power requirements.

ECONOMICS

SAVINGS POTENTIAL: 5 to 30 percent of the fan energy of the heat rejection unit. 0.1 to 2 percent of chiller energy consumption.

COST: In new construction, there may be little or no additional cost. In retrofit, modifications may cost less than one hundred dollars, to several thousand dollars.

PAYBACK PERIOD: Short, in new construction. One year to many years, in retrofit.

TRAPS & TRICKS

ANALYZE THE PROBLEM: Before you go to a lot of effort, make sure that you really have a problem. For example, do not worry about recirculation caused by strong north winds in winter if your chiller is loaded only during warm weather. Calculate the actual recirculation under conditions that matter. Then, if you have a problem, make sure that your intended solution will actually solve it.

MEASURE 2.4.7 Install fan and pump motors having the highest economical efficiency.

See [Measure 10.1.1](#) for the details. Also, consider the following points that relate specifically to motors in heat rejection units.

Electronic variable-speed drives modify the frequency, voltage, and waveform of the power provided to the motor. This makes it desirable to select motors intended specifically for variable-frequency drives. (See [Measure 2.4.1.1](#) about installing these drives on cooling towers.)

For motors that drive variable-pitch propellers (see [Measure 2.4.1.2](#)), the part-load efficiency of the new motor is important, so check the efficiency figures for partial loads.

For single-speed motors, the only efficiency figure that matters is the efficiency at the percentage of load at which the motor operates. This percentage should be 60% to 90% of the motor's full-load rating.

Be prepared to replace a failed motor with a model that has the highest practical efficiency. If a motor is exceptionally large and inefficient, you may even want to replace it before it fails.

Pump Energy Consumption

The Measures in this Subsection are equipment modifications and operating practices that reduce the energy required to pump chilled water and condenser cooling water. These Measures apply to systems of any size, from a small building to a district cooling system that serves an entire city.

A NOTE ON UNITS

It is common practice to specify pressures in water distribution systems in terms of height of water column, such as “feet of head.” One foot of water column equals 0.43 PSI. The pressure output of pumps and the flow resistance of coils and other equipment are both expressed this way. This simplifies system pressure calculations by equating pressure requirements due to gravity (“static head”) with pressure requirements due to pipe friction and equipment resistance.

- **Measure 2.1.5**, avoiding unnecessary operation of standby pumps

MEASURE 2.5.1 Adjust the discharge of pumps to match system flow and/or pressure requirements.

Pumps are used in chiller systems for distributing chilled water and for circulating condenser cooling water. If the pumps operate at constant speed, adjust their output so that they provide the minimum flow needed for efficient system operation. This reduces energy input, and in some cases, it may also reduce tube erosion and improve control valve performance.

The subsidiary Measures are two common methods of adjusting pump output. [Measure 2.5.1.1](#) is much more efficient. [Measure 2.5.1.2](#) is a stopgap measure that is quick and cheap.

Matching Flow Requirements

In both chilled water and condenser water systems, the flow rate has a major effect on heat transfer efficiency, and hence chiller efficiency. These flow rates are specified by the chiller manufacturer. When you make adjustments, err on the side of high flow.

The need for chilled water flow may also be determined by the cooling equipment that uses the

chilled water. This occurs if the flow rate needed by the chilled water system is higher than the flow rate needed by the evaporator. Be sure to accommodate the needs of the cooling equipment.

The minimum flow rate of condenser water pumps may also be determined by the need of the cooling tower for a minimum flow rate. This would be unusual. It might occur if the cooling towers, or individual cells, are connected to chillers in odd ways.

Alternative: Adjust Impeller Speed

The output of a pump can be reduced efficiently by reducing the pump speed. The effects on pump flow, pressure, and power input are almost the same as for impeller trimming. To reduce pump speed on a one-time basis, you have to change the motor or insert a speed changing device between the motor and pump. These are unconventional modifications. In chilled water distribution (see [Measure 2.5.2](#)), using a variable-speed drive can save large amounts of energy in many applications.

MEASURE 2.5.1.1 Trim pump impellers.

Some pumps in a chiller plant may develop more pressure than needed, usually because of excess capacity that is built into the design as a safety factor. This wastes energy, so consider adjusting the pump pressure to the

minimum needed for proper operation. The most efficient method of doing this is reducing the diameter of the pump impeller. See [Measure 10.2.1](#) for the details.

If the capacity of a pump is excessive, you can save a small amount of energy by partially closing a valve in the pump discharge line, or by placing some other

restriction in the discharge. This method is much less efficient than impeller trimming, but you can do it easily, and it is reversible. See [Measure 10.2.2](#) for the details.

RATINGS

New Facilities	Retrofit	O&M

Variable-flow chilled water distribution is a major advance in chiller system efficiency that became popular in the late 1970's. It saves a considerable amount of the energy required for chilled water distribution, while preserving good regulation of the chilled water pressure that is supplied to the end-use equipment.

Variable-flow pumping had been possible in earlier years, but the development of efficient variable-flow pump drives was probably the main stimulus that motivated designers to attempt it. The layout is simple, but understanding it requires some study. There are traps to avoid, especially in the many variations that are possible. The basic layout may seem too simple to be true. As a result, early variable-flow systems had complications that were unnecessary and counterproductive.

In new construction, consider variable-flow pumping for all but the smallest systems.

In existing facilities, you can retrofit variable-flow chilled water pumping in existing chiller systems. The feasibility of retrofit depends on the size of the system and the amount of equipment that needs to be modified. Variable-flow pumping requires a larger number of pumps than conventional chilled water distribution, although the total pump capacity is no greater. Expect to modify piping within the chiller plant. Also, you will probably want to modify at least some of the chilled water control valves at the end-use equipment.

The Basic System

Figures 1 and 2 compare an old-style constant-flow chilled water distribution system with a basic variable-flow system. The main difference is that the variable-flow system consists of two loops, each of which has its own pumps. We will call the two loops the "chiller loop" and the "load loop," respectively. (The terminology is

not standardized.) The two loops share a common "bypass line."

The easiest way to understand the system is to visualize the chiller loop, including the bypass line, as an independent system. It circulates water through the chillers at a constant flow rate that is independent of the load. The load loop taps chilled water from the chiller loop as necessary to satisfy the cooling load. The number of chillers that operate in the chiller loop is controlled by the cooling load.

These are the characteristic features of a variable-flow system:

- *The evaporator circulating pumps are sized to serve individual chillers.* Each pump is sized for the flow required by the evaporator of one chiller,

and the pump produces only enough pressure to overcome the resistance of the evaporator. Only one pump runs for each operating chiller.

- **The flow rate in the chiller loop is always higher than the flow rate in the load loop.** Therefore, the direction of flow in the bypass line is always as indicated. (This is true of the basic system of Figure 2. It is not true for one variant of the system, which is discussed below.) This is necessary to

Fig. 1 Constant-flow chilled water system The main features of this system are the constant flow requirement of the end-use equipment and the series connection of the chiller plant to the chilled water distribution system. This keeps the pump load high at all times, regardless of the cooling load. It also reduces the average chiller efficiency at partial cooling loads.

maintain the chilled water temperature in the load loop. The direction and volume of water flow in the bypass line control the number of chillers that operate, as described below.

- **Each operating chiller is controlled individually,** to maintain its own chilled water supply temperature. There is no need for collective chiller control. Centrifugal and screw chillers use conventional controls. Return water temperature

Fig. 2 Variable-flow chilled water system The main feature of this system is that the flow through the chillers is uncoupled from the flow to the facility cooling equipment. This makes it possible to independently optimize pumping of water through the evaporators and pumping to the facility loads. In turn, this allows water flow through the chillers and water flow to the facility loads to be reduced in proportion to the cooling load.

control is not practical, so reciprocating and scroll compressors may need special controls to adapt them to supply water temperature control. Chilled water temperature reset (recommended by [Measure 2.2.1](#)) may be done in the usual manner.

- **All the equipment that uses chilled water is controlled by throttling (two-way) valves**, instead of by bypass valves. This allows the flow rate in the load loop to be reduced to match the cooling load, thereby saving pumping energy.
- **The load loop pump, or pumps, are selected and controlled to maintain the pressure needed by the load loop.** The load loop pumps satisfy the pressure requirements of the end-use equipment, and overcome the resistance of the distribution piping. Their characteristics are independent of the chiller characteristics.

These are the essential features. Design and installation details are explained below, along with more complicated variations of the system.

Energy Saving Potential

■ Pump Energy Savings

The power consumed by any pump is proportional to the pressure difference produced by the pump, multiplied by the flow rate through the pump. In a conventional constant-flow chilled water system, the chilled water pumps continuously deliver the flow rate and the pressure that are required at maximum load. This is wasteful because both the flow and pressure requirements decline as the load drops. Furthermore, the flow requirement varies differently from the pressure requirement.

The variable-flow system saves energy by making it possible to optimize the pump pressures and the pump flow rates separately, and to continuously adjust these values as the cooling load changes.

To illustrate the potential for saving pump energy, consider a typical constant-flow system that uses three 1000-ton chillers, as in Figure 1. The chilled water flow rate is based on 3,000 tons, because this is the capacity of the chillers. This flow rate is constant, regardless of the number of chillers in operation, because the pumps must continue to satisfy the flow requirements of the bypass valves on the end-use equipment.

If the chillers produce maximum output at a temperature differential of 8°F, the chilled water flow rate is 9,000 GPM. The pumps produce a total pressure of 80 feet head, which is needed to overcome these system pressure drops:

- 10 FTHD (12.5%) in the evaporator
- 30 FTHD (37.5%) in the end-use equipment
- 40 FTHD (50.0%) in distribution piping loss.

With pumps and motors of average efficiency, the chilled water pumping requires a total continuous power input of 300 horsepower.

Now, compare this to the variable-flow system shown in Figure 2. To calculate the savings, you need to know the load profile of the system. In this example, experience shows that the peak load is 2,400 tons and the average load is 800 tons. Also, you have recorded that one chiller operates for 100% of the cooling season, a second chiller operates for 40% of the season, and a third chiller operates for 10% of the season. From this, you calculate these savings:

- **in the evaporator.** From the length of time that each chiller operates, it is easy to calculate that the average quantity of chilled water flow through the evaporators is 50% of the maximum. The pressure drop across the evaporators is always the same. Therefore, the energy needed to pump water through the evaporators is reduced to 50% of the original amount.
- **in the end-use equipment.** The equipment end-use pressure requirement remains unchanged. The flow rate is roughly proportional to the cooling load. Since the average load is 800 tons and the original pump was sized for 3,000 tons, pumping energy is reduced to 27% of the original figure. Pump speed reduction incurs an additional 20% drive and pump loss, which increases this figure to 32%.
- **in the distribution piping.** Pumping energy to overcome pipe friction is proportional to the third power of the flow rate. You would need to know the precise load profile to estimate this precisely. You probably can't get this information, so assume that this portion of pumping energy, including drive loss, is 30% of the original.

Adding these savings together yields an overall savings of two thirds of the original pump energy, or an average saving of 200 horsepower for the duration of the cooling season.

■ Savings from Eliminating Chilled Water Temperature Mixing

Many constant-flow chilled water systems need to maintain maximum chilled water flow at all times because the end-use equipment uses bypass valves to control capacity. (Some end-use equipment, such as multizone air handling units, may have no control valves at all.) Without keeping full pump capacity running, the pressure at the end-use equipment would become too low to provide full flow to any equipment that needs it. In this situation, the pumps must maintain full evaporator flow through all chillers, even those that are turned off. Otherwise, the flow velocity through the active chillers would be excessive.

Unfortunately, this reduces the efficiency of the chillers that are running. The chilled water produced by the operating chillers is mixed with return water passing through the idle chillers. As a result, the active chillers must produce chilled water at a lower temperature than if mixing did not occur. Lowering the

chilled water temperature reduces chiller efficiency, for the reasons explained in [Measure 2.2.1](#). The loss in chiller efficiency is typically about two percent per degree Fahrenheit.

For example, consider a plant with three identical chillers in which only one chiller is operating. The return water temperature is 48°F and the system requires 46°F chilled water to satisfy the cooling load. Mixing through the idle chillers forces the operating chiller to produce chilled water at 42°F, which is 4°F lower than the water temperature needed by the end-use equipment.

Variable-flow pumping completely eliminates this inefficiency.

■ Savings from Reduced Heating of Chilled Water by Pump Losses

Most of the energy consumed by a chilled water pump eventually is converted to heat in the chilled water. With a chiller of average efficiency, this pumping heat requires an additional cooling energy input equal to about 20% of the pump power. A variable-flow pumping system reduces this energy penalty in proportion to the saving in pump energy.

Where to Use Variable-Flow Pumping

The potential benefit of variable-flow chilled water pumping depends on these factors:

- **the size of the pumps.** Variable-flow pumping is more economical in larger systems. In new construction, variable-flow pumping may be less

Fig. 3 Bypass control valve for an air handling unit This type of control keeps the water flow requirement essentially constant, regardless of the load. Replacing bypass valves with throttling valves is a basic step in converting to variable-flow pumping.

expensive than a constant-flow system, above a certain size.

- **the cooling load profile.** Variable-flow pumping produces its benefit when the cooling load is low. Therefore, it is most economical in systems with long durations of reduced load.
- **whether the system uses bypass valves.** Constant-flow systems commonly use bypass valves on the user equipment, or they may use a single large bypass valve that is located near the pump discharge. Either way, bypass valves force all the system's pumps to operate under all conditions. If variable-flow pumping is installed, no bypass valves are needed. In retrofit, it is usually economical to replace bypass control valves on equipment. Or, you may be able to convert existing bypass control valves to act as throttling valves.

(If a constant-flow system uses several pumps, you can save energy in a similar way by turning chilled water pumps on and off in relation to the cooling load, after modifying the valves. See [Measure 2.1.4](#) for details. This method does not save as much energy as a variable-flow system, but it is much cheaper to retrofit.)

- **whether distribution system resistance is a major factor.** If pipe friction accounts for a large fraction of pump power, variable-flow pumping can greatly reduce the energy requirement. This part of pump power is proportional to the third power of the flow rate.
- **the potential for using chilled water temperature reset.** Chilled water supply temperature reset, which is explained below, reduces the advantage of variable-flow pumping. This is because it tends to keep the flow in the load loop more constant. The potential for chilled water temperature reset is limited if the different loads served by the system do not increase and decrease together.
- **whether it is desirable to load certain chillers preferentially.** A variable-flow chilled water system allows you to load some chillers before others. This feature can improve average chiller efficiency when recovering heat from a chiller at elevated temperatures. It may also be valuable when the chillers have differing efficiency characteristics.

Some of the variations of the basic system, which are explained below, increase the advantage of variable-flow pumping, while other variations reduce the advantage.

Design and Installation Details of the Basic System

Although variable-flow pumping is simple in layout, the details are critical. To avoid confusion, let's start by considering only the factors that relate to the basic layout of Figure 2. We will cover the variations a few pages later.

■ Install Throttling Control Valves on the End-User Equipment

The cooling equipment that is served by the chilled water system should be controlled with simple throttling valves. This keeps the total flow in the load loop proportional to the cooling load, which minimizes pump power.

Select the valve actuators to keep the valves closed against the maximum pressure that may develop in the load loop. Maximum pressure occurs when a failure of the variable-flow controls causes the pump(s) to develop maximum output under low-load conditions.

Avoid oversizing any throttling valves that you install. Oversized valves wear out rapidly at low load, and they may cause noise and control problems.

In conversion projects, you may find that the existing end-use cooling equipment is controlled by bypass valves. Constant-flow chilled water systems use bypass valves specifically to maintain a constant flow rate in the chilled water system. The control valves bypass water that is not needed for cooling to the return line. Figure 3 shows this common arrangement on an air handling unit.

(There are two main reasons for maintaining constant flow in the original distribution system. One is to keep the flow rate through the chiller evaporator high enough to maintain good heat transfer. Another is to prevent cavitation in the chilled water pumps, which wears out impellers and makes noise. These requirements do not exist in a variable-flow system, because the flow through the evaporators and pumps is not tied to the flow in the end-use equipment. Still another reason for the popularity of bypass valves is a superstition among engineers that they are needed to provide stable control.)

You may be able to convert existing bypass control valves to operate as throttling valves. If you block the bypass line, the bypass valve becomes a throttling valve. The valve is likely to behave in a satisfactory manner because the variable-flow operation of the pumps in the load loop maintains a fixed pressure on the valve. But, check the valve performance to be sure.

This is especially easy if your end-user equipment has balancing valves in the bypass line. In this case, simply close the balancing valves. Install permanent tags on the balancing valves that state that the valves should be kept in the closed position.

If this cheap expedient does not work well, replace the bypass control valves with throttling control valves. It may not be economical or even necessary to replace all the bypass control valves in the system. For example, in a system that serves large air handling units and small fan-coil units, it may only be economical to replace the valves on the air handling units.

Some types of end-use equipment do not use any chilled water control valves, so they always take

maximum flow. Typically, such equipment needs to maintain a constant low temperature. A common example is multizone air handling units, which regulate air temperature by mixing chilled air from a chilled water coil with warm air from a heating coil. You can install throttling valves on such equipment, because they typically need only a fraction of maximum coil flow for much of the time. (Throttling valves also make it possible to use cold deck temperature reset with multizone air handling units. See [Measures 4.6.1 ff](#) for this.)

■ How to Install the Evaporator Circulating Pumps

In the chiller loop, flow of water through the evaporators is provided by a separate pump for each chiller. Each pump operates only when its chiller is operating, and each pump operates at constant flow.

Select the pump pressure only to overcome the resistance of the evaporator, because the pump plays no role in circulating water through the load loop. Select the pump flow rate to optimize the efficiency of the chiller, following the chiller manufacturer's specifications. Evaporator flow rate involves a compromise between pump power and evaporator temperature. Also, a flow rate that is too low increases fouling, while a flow rate that is too high hastens tube erosion.

Converting an existing system to variable-flow operation requires new evaporator pumps. The conversion reduces the pressure requirement in the chiller loop so much that the existing chilled water pumps cannot be converted efficiently for evaporator circulation.

■ Install Evaporator Check Valves

Each evaporator should have a check valve in its discharge line to prevent supply chilled water from flowing backward through the evaporator when the chiller is off. Backflow would lower the return water temperature to the running chillers, reducing their efficiency. Also, it would waste a certain amount of pump energy.

In conversions, the original system may have motorized shutoff valves that close when the chiller turns off. These can serve the same purpose as check valves. However, check valves are more reliable because they require no power source and no controls.

■ How to Start and Stop Chillers and Pumps

In a variable-flow system, chillers are started and stopped individually in response to the flow demands of the load loop. (The flow in the load loop is proportional to the cooling load.)

The flow rate in the chiller loop should always be higher than the flow rate in the load loop. When this condition is met, the direction of flow in the bypass line is as shown in Figure 2. If this condition is not met, some return chilled water is recirculated through the bypass line. This would dilute the chilled water from

the chiller loop, raising the chilled water supply temperature.

Subject to the previous condition, the flow rate in the chiller loop should be kept at the minimum needed to satisfy the flow requirement of the load loop. The flow rate in the chiller loop is determined by the number of chillers in operation, since the flow through each evaporator is fixed. Operating more chiller capacity than needed increases circulation of chilled water within the chiller loop. This lowers the evaporator temperature, reducing efficiency. Also, operating excess chiller capacity is inefficient, for the reasons given in [Measure 2.1.1](#).

The individual chillers are started and stopped by the two sensors in the bypass line, the flow direction sensor and the flow rate sensor. The flow direction sensor starts an additional chiller if it senses that the flow direction is about to reverse from its normal direction. The flow rate sensor stops a chiller when it senses that the flow in the bypass line exceeds the flow produced by the last chiller in the starting sequence.

If the chillers are not identical, start them in order of their efficiency. See [Measures 2.1.1 ff](#) for details.

■ How to Control Chiller Loading

Control of chiller output in a variable-flow system is simple for centrifugal and screw chillers. All chillers that are running are controlled to maintain a fixed chilled water supply temperature. Each operating chiller uses its individual controls in the normal manner to maintain a set chilled water supply temperature. There is no need for collective chiller control. When converting from a constant-flow system, you usually do not have to make any changes to the chiller controls.

The most common practice is to set all chillers to maintain the same supply chilled water temperature. Since all chillers receive return water at the same temperature, this approach loads all chillers to the same percentage of full load, regardless of size or type. With chillers having similar characteristics of efficiency versus load, this is the most efficient way of distributing load. With chilled water temperature set in this way, you achieve the best overall efficiency simply by starting chillers in the order of their efficiency.

To ensure uniform distribution of load, set the chilled water supply temperatures of all chillers to the same value. Small differences in the temperature settings cause significant shifts in loading among the chillers.

In some cases, you may want to load some chillers at a higher percentage of load than others. This is somewhat tricky, and usually reduces overall efficiency somewhat. Methods of preferential loading are covered below.

Reciprocating chillers and other types that control output in abrupt steps usually control their output by sensing the return water temperature. Conventional return water controls cannot maintain a fixed supply

water temperature, because they would hunt in attempting to follow the abrupt changes in supply temperature that occur as stages turn on and off. To control staged chillers on the basis of supply chilled water temperature, you need more sophisticated controls that anticipate the supply water temperature changes that occur as the chiller changes its output. Such controls are available commercially.

(Return water temperature is not feasible in variable-flow systems, because the return water temperature is not a reliable indication of the system load. A variable-flow system tends to hold the return water temperature constant, regardless of load. Also, the return water temperature is affected by the relative flow rates in the chiller and load loops, which fluctuate widely as chillers are started and stopped.)

■ How to Design the Bypass Line

The flow of chilled water through the bypass line is completely unrestricted. The line should be large enough to accommodate the full evaporator flow of the largest chiller with minimal resistance. The size of the bypass line has minimal effect on system cost because the bypass line can be very short.

The flow rate and flow direction sensors are installed in the bypass line. The configuration of the line should allow these sensors to operate accurately.

■ How to Control the Distribution (Load Loop) Pumps

Control the chilled water distribution pumps to maintain a constant pressure in the load loop. The pressure setting is determined by the needs of the cooling equipment that is served by the chilled water system.

The most efficient and precise way to control the load loop pressure is to regulate the speed of the distribution pumps. The best way to do this is to install electronic variable-speed drives for the pump motors. See [Reference Note 36](#), Variable-Speed Motors and Drives, for details.

In a retrofit project, installing an electronic variable-speed drive allows you to use the existing pumps. A single electronic drive can operate several pumps. If extra pumps are installed as standby units, an electronic drive can easily be switched between pumps. However, you may want to upgrade the pump motors for the reasons given in [Reference Note 36](#).

If the original chilled water distribution system uses several pumps in parallel to achieve maximum system flow, another possibility is operating these pumps in sequence to provide variable flow. The abrupt changes in pressure as an individual pump turns on or off may cause some control oscillation at the end-use equipment, but this may be tolerable.

Pressure losses in the distribution piping decline as the flow rate drops. This may be significant in a long distribution system. In such systems, you can save pump

energy by reducing pressure enough to exploit the reduced piping losses. To do this, simply locate the pressure sensor that controls pump output near the end of the distribution system. In a large system, this may put the pressure sensor miles away from the pumps. The cost of the signal line is minimal in comparison with the additional energy saving.

In principle, you could save additional pump energy under reduced-load conditions by lowering the pressure setting as the cooling load drops. This exploits that fact that the end-use equipment needs less flow at low loads. However, this poses the risk of inadequate pressure for any item of end-use equipment that may need to operate at high load while the rest of the system is at low load.

Effect of Chilled Water Temperature Reset

Raising the chilled water supply temperature increases chiller efficiency. ([Measure 2.2.1](#) explains why.) In constant-flow systems, a good rule is simply to keep the supply water temperature as high as possible. However, in a variable-flow system, this is not always the most efficient method of operation. The reason is that raising the water temperature requires more water to be pumped for a given cooling load, increasing pump power.

Calculate the optimum compromise between chilled water temperature reset and pumping power for your installation. If the distribution system does not have much resistance, you will probably find it most efficient to keep the chilled water temperature as high as possible. However, this may not be true in systems that have long distribution systems, where distribution pumps consume more power in comparison with the chillers.

If the plant has more than one chiller, the variable-flow system increases the opportunity for chilled water temperature reset, by eliminating mixing of supply water with return water. (See “Savings from Eliminating Chilled Water Temperature Mixing,” above.)

Variations of the Basic Layout

Variable-flow chilled water distribution provides a great deal of flexibility for improving pumping efficiency. The following are variations that you may want to consider. Variations from the basic layout are more complex in behavior, and they may have unwanted effects. Approach them carefully.

■ Mixing Chiller Types

The basic variable-flow system that we described previously can handle any combination of chiller types and sizes without complications. This is because each chiller has its own independent evaporator pump, and because circulation of water in the load loop is independent of the chiller characteristics. This makes it easy to add chillers to increase capacity or to improve system efficiency.

A requirement when mixing chiller types is that all the chillers must produce full output at the same supply and return temperatures. To achieve maximum overall efficiency when chillers of different types are operating simultaneously, they should have similar efficiency-versus-load characteristics (but not necessarily the same efficiencies). See [Measure 2.1.1](#) for more about this.

■ Parallel or Dedicated Evaporator Pumps

The evaporator circulation pumps can be arranged in parallel, as shown in Figure 2, or each chiller can have a dedicated evaporator pump. The latter arrangement is shown in Figure 1 of [Measure 2.1.4](#). The choice does not affect the operation of the variable-flow system, but it has some other aspects that affect reliability and efficiency.

The parallel arrangement allows you to add a reserve pump (or more than one) in parallel with the others. This provides a high degree of pumping reliability at modest cost. However, the presence of a reserve pump increases the likelihood of running more pumps than necessary. See [Measure 10.4.1](#) for ways of avoiding this problem.

Installing a dedicated evaporator pump for each chiller makes it easier to avoid unnecessary pump operation, but it has the disadvantage that failure of an evaporator pump will disable the chiller that it serves. This is not a serious limitation in typical installations with more than one chiller. Centrifugal pumps are reliable, and they are less likely to fail than the chiller itself. In order for a pump failure to reduce cooling output, it would have to occur at a time when the remaining chillers are incapable of carrying the load.

■ How to Accommodate Diverse Pressure Requirements Efficiently

If some chilled water users or some parts of the distribution system require higher pressure than others, pump power is wasted because the load loop pumps must operate at the highest pressure required in the system. In this case, try to refine the layout of the load loop to accommodate the different pressure requirements efficiently.

One method is to use separate distribution pumps and piping for loads having different pressure requirements. This may be economical if only minimal extra piping is needed, for example, if high chilled water pressures are needed in one piping leg and lower pressures are needed in another. Piping is expensive, so it is rarely economical to have separate piping systems running in the same direction just to carry different pressures.

Another approach is to use booster pumps feeding from the main piping to serve loads with higher pressure requirements. Variable-flow booster pumps may be economical with larger loads. For smaller loads that do not merit the cost of a variable-flow booster pump, use a small constant-flow pump. In these cases, retain

bypass valves on the end-use equipment. Control the booster pumps so that they operate only when needed.

■ The Ultimate in Distribution Efficiency

All conventional distribution systems use pumps to create enough pressure to provide maximum flow through the end-use devices. The flow is regulated by valves. This is true of contemporary variable-flow systems, also. The pumping arrangements discussed previously reduce the excess energy output of the pumps, but they still waste energy in two ways. One is the dissipation of energy across all the control valves and

Fig. 4 The ultimate in pumping efficiency This arrangement uses a separate variable-flow pump for each item of end-use equipment. It eliminates all control valves, thereby eliminating the pump energy needed to overcome the resistance of the valves. It requires no central distribution pump. However, it may require a system pressurizing tank to ensure adequate suction pressure at each pump.

balancing valves in the system. The other is the excess energy dissipated if different end-use equipment has different pressure requirements. The previous heading dealt with the latter issue, but as we saw, it is not practical to completely eliminate this cause of energy waste if there is a great deal of diversity in pressure requirements.

However, we can completely eliminate energy waste of both types by taking an entirely different approach, which is shown in Figure 4. This is to install a separate variable-flow pump for each load, and to control each pump thermostatically. For example, the pump may be controlled to maintain a particular coil discharge temperature or a particular space temperature. This approach allows you to eliminate control valves entirely, along with their energy losses. Flow through the equipment is controlled entirely by pump speed. In effect, each item of equipment is served by its own distribution pump. For this reason, balancing valves are no longer necessary, and their energy losses are eliminated, also.

In this arrangement, there is no need for a separate pump to force water into the distribution system. Each load pump is selected to have enough pressure capacity to account for its share of the resistance in the load loop. Because each pump is sucking from the load loop distribution pipe, make sure that there is enough static pressure in the load loop to provide adequate suction to all the load pumps. Otherwise, friction in the distribution lines may restrict flow to the load pumps enough to cause pump cavitation.

Each item of end-use cooling equipment needs an external valve to stop flow completely when cooling is not needed. A centrifugal pump is an open passage when it is turned off. In most cases, a check valve should do the job. This is because the pressure on the discharge side of the equipment should always be higher than the pressure on the inlet side. (The opposite would be true if the load loop has its own distribution pump, as in the “conventional” variable-flow configuration.) Otherwise, there is no way of limiting flow in the forward direction. For this reason, the load loop cannot use a separate distribution pump to overcome the resistance of the pipe.

This idea is entirely novel, so be careful. Its time is coming because of the declining cost of variable-speed motor drives. This approach is already economical for larger items of end-use equipment, such as air handling units of medium and large size. Variable-speed motors are rapidly becoming economical in smaller sizes, such as those appropriate for fan-coil units.

■ How to Shift Chiller Loading by Adjusting the Supply Water Temperature

As discussed previously, the basic variable-flow system loads all operating chillers by the same percentage. This is usually the most efficient distribution of load, or nearly so. However, if you want to shift more of the load to a particular chiller, you can do this

easily by setting the supply chilled water temperature of that chiller lower than the setting of the other chillers.

For example, consider a situation where two chillers are operating. You set the supply temperature of one at 45°F and the supply temperature of the other at 42°F. If the return temperature is 48°F, then the first chiller will carry one third of the load, and the second will carry two thirds.

Typically, you would load one chiller preferentially if it is more efficient than the rest. But, this is worthwhile only if unloading the other chillers does not make them much less efficient, which would forfeit the overall efficiency advantage. Make a careful analysis when assigning load between chillers with dissimilar efficiency characteristics. See [Measures 2.1.1 ff](#) for details.

A chiller's supply chilled water temperature setting has a strong effect on its efficiency. Therefore, when lowering the supply temperature of one chiller to take on more of the cooling load, raise the supply temperature of the other chillers. This minimizes the net energy loss due to reduced chiller efficiency.

■ How to Load a Chiller Preferentially by Locating It Ahead of the Bypass Line

A more radical method of shifting load to one particular chiller is to install that chiller, along with its evaporator pump, on the load side of the bypass line. We will call this chiller the “lead” chiller.

When only the lead chiller is operating, the system acts like the basic variable-flow system. The lead chiller's evaporator flow is kept constant by the chiller's evaporator pump. The load loop pump varies flow to match the cooling load, and any excess flow is recirculated through the bypass line..

The behavior of this configuration differs when any of the other chillers are operated. Because of the direction of flow in the bypass line, water returning from the load loop first enters the lead chiller. Only the return water flow that exceeds the evaporator flow of the lead chiller flows to the other chillers. As a result, the lead chiller is always loaded to 100% load, and the remaining chillers share the remainder of the load.

Typically, you might use this method of preferential loading to exploit an especially efficient chiller as the lead chiller. This is valuable if the lead chiller loses efficiency at lower loading. However, for this configuration to provide an overall benefit, the remaining chillers must operate at reasonably high efficiency at lower loads. For example, a centrifugal or screw chiller might be used as the lead chiller, while the rest are reciprocating chillers.

This method makes a permanent commitment to keeping the lead chiller loaded whenever it is running. Before installing this configuration, make sure that operating conditions of the plant will always favor it.

Alternatively, you can install some valves and short pieces of pipe to give you the option of “moving” the bypass line to the load side of the lead chiller. Before adding such a clever feature, consider that it may utterly confuse operating personnel.

This method is also used with chiller heat recovery, which is covered in [Subsection 2.10](#). Preferential loading is valuable in cases where heat is recovered at

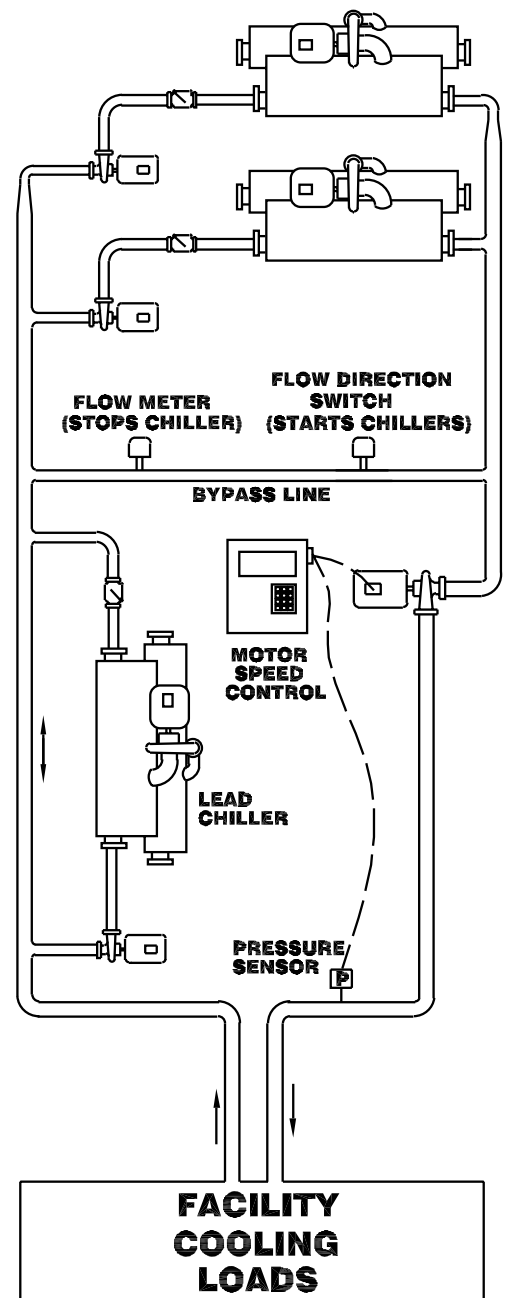

Fig. 5 Preferential loading arrangement for a heat recovery chiller The lower chiller, ahead of the bypass line, operates at a load that satisfies the heat recovery requirement. Additional cooling, when needed, is provided by the chillers above the bypass line. This provides the most efficient control of chilled water temperature.

elevated condensing temperature from a particular chiller, and you want to shift the load to this chiller.

Trouble may arise if the heat recovery chiller is controlled to satisfy the heat recovery load, rather than the cooling load. In this case, the chilled water supply temperature floats. When a second chiller is started to meet a rising cooling load, chilled water at the fixed supply temperature of the second chiller is mixed with chilled water at the floating supply temperature of the

Fig. 6 Two variable-flow chiller plants serving a single facility Control is somewhat trickier than with a single system because each system may try to respond to changes created by the other. For minimum trouble, control each system to maintain a constant pressure in its own system. In this arrangement, the cooling load is distributed between the two systems by adjusting their relative output pressures.

heat recovery chiller. This reduces average chiller efficiency.

Also, if the heat recovery chiller is large compared to the other chillers, its chilled water supply will dilute the chilled water of the other chillers when the heat recovery load is low. This reduces total chiller capacity and requires an excessive number of chillers to keep operating.

■ How to Load a Chiller Preferentially by Locating It In the Return Line of the Load Loop

If you want to operate a heat recovery chiller based on the heat recovery load, rather than the cooling load, you can minimize the previous efficiency problems by installing the heat recovery chiller in the return line of the load loop, as shown in Figure 5. In this arrangement, the heat recovery chiller operates in series with the other chillers. The heat recovery chiller cools the return water, reducing the temperature differential across the other chillers.

This series arrangement affects the efficiency of all the chillers. See [Reference Note 32](#), Compression Chillers, for more about series evaporator connections. Under some conditions, this arrangement may provide higher total plant efficiency. However, over the course of a typical range of load conditions, total plant efficiency is likely to be reduced. You have to make a detailed estimate for your particular situation to determine how much the value of the recovered heat exceeds the additional cost of cooling.

When the heat recovery chiller is able to carry the entire cooling load alone, water flows in the bypass line opposite to its normal direction. This is okay, but it complicates the control logic needed to sequence the chillers.

This arrangement could be used to preferentially load any chiller, not just a heat recovery chiller. However, it is difficult to imagine an application, other than heat recovery, for which this arrangement is best.

■ How to Interconnect Different Chiller Plants

Variable-flow pumping applies to a chilled water system that has chillers at different locations. Such a system is depicted in Figure 6. There are two distinguishing features in such a layout: (1) a separate variable-flow distribution pump draws water from each chiller loop, and (2) each distribution pump has a check valve at its discharge. Without the check valves, the flow from one chiller plant would short-circuit through the bypass lines of the other chiller plants.

Control of the system is fairly simple, but be careful to avoid unstable operation. These are the main features of the controls:

- Control of chiller output in the individual plants is not affected.
- The distribution pump for each system is set to maintain a constant output pressure.

- The load is distributed among all the operating plants by adjusting the relative pressures of the distribution pumps. Increasing the output pressure of one of the distribution pumps increases the load carried by the corresponding chiller(s).
- A distribution pump may be called upon to produce more flow than its chillers can provide. To prevent this, the reverse flow sensor in the plant's bypass line should activate control logic that limits further output by the distribution pump. This may require some complication, especially because the flow from a centrifugal pump varies with pressure, even with the speed constant.
- For given pressure settings, the distribution of load among plants depends on the pressure loss in the distribution piping between the plants. If there is minimal piping pressure loss, the plant set for higher pressure will carry all the load, up to its maximum capacity. Then, the plants set for lower pressure will carry the remainder. On the other hand, if there is large pressure loss in the distribution piping, each plant will serve the loads closest to it.
- There is a tendency for the output of the distribution pumps to oscillate because the pressure sensor controlling each pump feels the pressure output of the other pumps. This "hunting" tendency is damped by pressure drop in the distribution piping, but this damping may not be adequate. To avoid oscillation, make the distribution pump control response of the lead chiller system (the system that starts first) substantially slower than the control response of the distribution pumps of the chiller systems that follow it. Also, the pump curve of the lead chiller plant should be flatter (i.e., the pump output should be less sensitive to discharge pressure) than the pump curves of the following chiller plants.

Explain It!

By now, it should be obvious that variable-flow chilled water pumping may confuse plant operators. Make it easy for operators to understand the system

layout, the purpose of the system, and the control logic. Otherwise, they may defeat the controls and operate the system inefficiently. This will take a well prepared formal training session. Install effective placards on the system components. See [Reference Note 12, Placards](#), for tips on how to do this.

ECONOMICS

SAVINGS POTENTIAL: 40 to 70 percent of chilled water pumping energy; 0.5 to 4 percent of chiller energy, provided that the chiller has chilled water temperature reset controls.

COST: In new construction, variable-flow pumping may cost no more than constant-flow pumping, especially in larger systems. Retrofitting variable-flow pumping may cost several thousand dollars for the smallest eligible systems, and much more for large or complicated systems.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

DESIGN: As with the formula $E = MC^2$, the apparent simplicity of a well-designed variable-flow system masks a lot of theory. Be sure you understand how your system will work under all operating conditions. Variations of the basic system may be tricky.

TRAINING AND DOCUMENTATION: Although the system operates automatically, operators must understand how it works. Otherwise, controls will be set or repaired incorrectly, and the system will operate wastefully. Install a large, well designed system diagram where everyone will see it, along with a clear explanation of how the system works. Put the details in the plant operating manual.

MONITOR PERFORMANCE: Keep an eye on the chiller sequencing and chilled water pump output. On the chiller plant operating log, include columns to record chiller loading (usually determined from chiller amperage) and chilled water discharge pressure. Review the logs regularly to ensure that the system is operating efficiently.

MEASURE 2.5.3 Install pump motors having the highest economical efficiency.

See [Measure 10.1.1](#) for the details. Installing efficient motors throughout the system is an effortless opportunity that should not be missed.

Be prepared to replace failed motors with models that have the highest practical efficiency. If a motor is exceptionally large and inefficient, you may even want to replace it before it fails.

When replacing a pump motor, consider whether you can reduce the pump power requirement to use a smaller motor. See [Measures 2.5.1](#) and [2.5.2](#) about this.

If you plan to use a motor with a variable-frequency drive, select a motor that is designed for this application. For details, see [Reference Note 36](#), Variable-Speed Motors and Drives.

Subsection **2.6**

Compressors

Most of the energy that is consumed for cooling goes into the compressors of the cooling units, or actually, into the motors that drive them. A single action to improve the efficiency of these components may save as much energy as many other actions to reduce the cooling load. However, compressor improvements are typically expensive, involving replacement or addition of major equipment.

There are large differences in the efficiency characteristics of different types of compressors. Also, there are large differences in the efficiency of different models of the same type. In existing facilities, be prepared to exploit the fact that compressors available today are significantly more efficient than the best models available a few decades ago.

Chillers have large motors. In the past, when a chiller motor failed, it was usual procedure to rewind the motor, rather than replacing it. Rewinding costs about half as much as a new motor. However, the potential savings in energy cost make it worthwhile to consider replacing the failed motor with a new motor that is selected for maximum efficiency.

See [Measure 10.1.1](#) for the factors to consider when you upgrade motors for efficiency. The following points relate specifically to chiller drive motors.

Emphasize Part-Load Efficiency

Unless the compressor has only a single stage, the motor operates at a fraction of full load for a large part of the time. If you replace the motor on a staged or modulating compressor, select the motor with an eye toward part-load efficiency.

Chillers Driven Variable-Frequency Drives

If the motor is driven by an electronic variable-frequency drive, note the special requirements for motors used with these drives. See [Reference Note 36](#), Variable-Speed Motors and Drives. Also, see [Measure 2.6.3](#), below, about adding a variable-frequency drive to an existing chiller.

Replacing Hermetic Motors

Motors for hermetic chillers are made specifically for those chiller models, so there are rarely any options among replacement hermetic motors. However, you may need a new motor if you are converting the chiller to a different refrigerant to satisfy environmental regulations. The insulation and other materials used in original hermetic motors may be incompatible with the new refrigerants. As a bonus, the newer motor may offer some efficiency improvement.

Refrigerant conversions typically require other changes to the chiller, such as reducing impeller

SUMMARY

In open-drive chillers, installing a new motor provides greater efficiency than rewinding the original motor. There may be options even in hermetic chillers, where refrigerant substitution may be an important consideration.

SAVINGS POTENTIAL: 1 to 5 percent of motor energy, for substituting a high-efficiency motor instead of rewinding the old motor.

COST: A new motor costs about twice as much as rewinding a motor. In addition, the cost of a high-efficiency motor is roughly 20% higher than the cost of an average motor, but this figure varies widely.

If a chiller has a compressor that is relatively inefficient, you may be able to improve efficiency substantially by replacing the compressor with a more efficient unit. This is possible with compressors of all sizes. Furthermore, you may be able to replace a compressor of one type with a compressor of a more efficient type. Figure 1 shows a large replacement centrifugal compressor.

In the past, you would consider this option when a compressor failed or neared the end of its service life. Now, you should also consider replacing the compressor as one way of satisfying requirements to use newer types of refrigerants. See [Reference Notes 32 and 34](#) for more about these issues.

Select the Compressor for Efficiency at All Loads

When you select a compressor, be careful to compare the efficiency characteristics of competing compressors for identical rating conditions. The conditions under which the compressor operates, especially the evaporator and condenser temperatures, can have a larger effect on performance than the characteristics of the machines themselves. See [Reference Note 31](#), How Cooling Efficiency is Expressed, for more about this important point.

Consider the efficiency of the compressor across the entire load. A major benefit of newer compressors is their ability to operate more efficiently at low loads.

In typical HVAC applications, this may be more valuable than the improvement in full-load efficiency.

Matching the Replacement Compressor to the Chiller

The feasibility of upgrading a compressor is largely a question of how the compressor is connected mechanically to the other system components, especially to the evaporator and condenser. The easiest situation is one in which the compressor is entirely separate from the other components, connected only by ordinary piping. Reciprocating compressors, even those installed as part of a packaged chiller, are usually installed in this manner.

At the other extreme are chillers in which the compressor is mounted directly to the evaporator and/or condenser with custom fittings as part of a compact package. This is typical of centrifugal chillers. Replacing the compressor with a unit made by a different manufacturer may require considerable adaptation and additional space. Unless the replacement compressor is a custom fit, it is mounted on a separate stand and piped to the original heat exchangers.

You may be able to replace one type of compressor with a different type. For example, you might replace a small single-stage reciprocating compressor with a scroll compressor. Or, you might replace a large reciprocating compressor with a screw compressor. Such changes require specialized knowledge, because the evaporator, condenser, and refrigerant metering apparatus may have features that are intended for a particular type of compressor.

Another issue is matching the replacement compressor to the chiller system controls. A variety of schemes are used for controlling the output of chillers. If the replacement compressor does not use the same control signals as the original, special skill is needed.

Consider Reducing the Compressor Size

In a plant that has excess chiller capacity, you may be able to reduce the cost of replacing the compressor by substituting a smaller size. Doing this makes the existing evaporator and condenser larger with respect to the compressor, which should increase the average efficiency. This is because the temperature drop across a heat exchanger increases with the load. Using a smaller compressor eliminates the least efficient operating range of the heat exchangers, which is high load.

Using this approach, you can convert one of your existing chillers to serve as a smaller lead chiller of improved efficiency. This is desirable in systems that operate for long periods at low cooling loads. See [Measure 2.8.1](#) about lead chillers.

Reducing the compressor size may not reduce the power required for pumping water through evaporators or condensers. Do not expect to reduce system pump power along with compressor power. The evaporator and condenser pumps must continue to provide adequate flow velocity within the evaporator and condenser, even though the amount of heat rejected may be significantly reduced.

Update the Refrigerant at the Same Time

If you are presently using a refrigerant that is due to be phased out for environmental reasons, replacing the compressor makes it much easier to change to a new type of refrigerant. Most refrigerant compatibility problems occur in the compressor, so you can avoid these problems by installing a replacement compressor that is designed for the new refrigerant. In fact, the marketing of replacement compressor kits mushroomed in the late 1980's in response to concern about the atmospheric effect of refrigerants. (For details, see [Reference Note 34](#), Refrigerants.)

Also, the new compressor is designed for maximum efficiency with the new refrigerant. Even so, the new refrigerant may not be optimum for the existing evaporator and condenser, because of differences in density, heat transfer properties, and other characteristics.

(You may be able to substitute a new refrigerant without changing the compressor, but such swaps are beset by problems. For example, HCFC-123 attacks the seals used in CFC-11 machines, and the swap results in a loss of cooling capacity and some loss of efficiency. Also, HCFC-123 attacks the insulation of hermetic

motors that are not designed to operate with that refrigerant.)

Feasibility and Alternatives

This Measure is most likely to be economical when the present compressor needs to be replaced. If the original compressor is worn out, consider whether the rest of the chiller system is in sufficiently good condition to justify installing a new compressor.

Replacing a functioning compressor solely to gain improved efficiency improvement is not economical, except in unusual circumstances. A better alternative is replacing the chiller entirely with a new, highly efficient unit (see [Measure 2.8.1](#)). All aspects of chiller efficiency have been improved in recent years, including major advances in heat transfer efficiency.

In facilities that have more than one chiller plant, another alternative is connecting the chiller plants together ([Measure 2.8.3](#)). This may allow you to operate your least efficient chillers much less. Of course, this works only if the other chillers are more efficient.

ECONOMICS

SAVINGS POTENTIAL: 10 to 35 percent of chiller operating energy.

COST: Depends on the basis of comparison. This method is cheaper than purchasing an entirely new chiller system. The premium for purchasing a compressor of higher efficiency varies widely. The cost of other equipment modifications to adapt to a different compressor may be substantial.

PAYBACK PERIOD: Less than one year, to many years, depending on the circumstances.

TRAPS & TRICKS

PLANNING: Consider all your options. Compare efficiency, cost, and difficulty. This Measure is most desirable where it saves a lot of money compared to installing a new chiller, while providing comparable efficiency. If you convert to a different type of compressor, be prepared for tricky control modifications. Talk with others who have already installed the same compressor you are considering. Discuss installation problems and how well the chiller performs with the new compressor.

INSTALLING THE EQUIPMENT: It is prudent to let the compressor manufacturer be responsible for the installation. That way, you don't have to go to court to find out who is responsible if you have problems.

MEASURE 2.6.3 In centrifugal chillers, install variable-speed compressor drives.

RATINGS

New Facilities	Retrofit	O&M
<input type="checkbox"/>	D	<input type="checkbox"/>

Centrifugal chillers are the most efficient type when operating near full load, but their efficiency suffers seriously at low loads. This is due to inherent characteristics of centrifugal compressors that are explained in [Reference Note 32](#), Compression Cooling.

Centrifugal compressors also have limited turndown ratio. This means that the minimum load at which the machine can operate is a larger fraction of full load than with other compressor types. It is not desirable to turn a centrifugal chiller on and off frequently, so there is a temptation to create a false load to keep the chiller running. This is a very wasteful practice.

SUMMARY

Significantly improves the efficiency of centrifugal chillers at low loads, and extends the turndown range. Make the change only with the approval of the chiller manufacturer. Not well proven as a retrofit.

Ease of Retrofit	😊 😊

You may be able to improve both the part-load efficiency and the turndown ratio of a centrifugal chiller by installing an electronic variable-speed compressor drive. This is a device that controls the speed of the compressor by varying the frequency of the power provided to the motor. See [Reference Note 36](#), Variable-Speed Motors and Drives, for details of electronic drives. Figure 1 shows a unit designed to operate chillers.

A big advantage of this method of speed control is that no major changes to the chiller hardware are required. The electrical connections to the compressor drive motor are relatively easy. The electronic control package can be installed in any reasonably well protected location. Retrofit kits for centrifugal chillers are now being offered.

The modification makes speed control the primary means of controlling capacity in approximately the top half of the load range. At lower loads, the compressor operates at a fixed minimum speed, and further reduction in capacity is provided by the chiller’s original inlet guide vanes. This more complex control arrangement must be interfaced with the existing chiller controls.

Energy Saving Potential and Limitations

The energy saving provided by variable-speed drives depends on the amount of time that the chiller operates in the inefficient portion of its load range. In typical air conditioning applications, the load is low for a large fraction of the time. In such cases, the distribution of chiller sizes determines how much load can be maintained on individual chillers. The opportunity for saving energy is greatest if the plant has only one or two large chillers, so they are forced to operate at low load for much of the time.

Trane Company

Fig. 1 Variable-frequency chiller drive This drives the electric motor of the compressor at variable speed to follow the cooling load. It is quiet, and has no moving parts. It is a mainstream feature of new chillers, but approach retrofit with caution.

The savings are especially large if false loading is presently used to maintain a minimum load to satisfy the chiller. The false loading may occur within the chiller system itself, usually in the form of hot gas bypass. Or, the staff may create an artificial cooling load, for example, by disabling the economizer cycles of air handling units. Be sure to identify any false loading of the system, which may not be recognized if it has become habitual.

Variable-speed drives do not offer the same range of turndown with centrifugal chillers as they do with centrifugal fans and pumps. One of the compromises of centrifugal chiller design is that the impeller dimensions can be optimized only for a single speed. As a result, varying the impeller speed is efficient only in a limited range of speed reduction. This is why control at low loads requires the inlet guide vanes originally installed on the chiller.

Using an electronic drive reduces chiller efficiency somewhat at the top end of the load range, because of losses within the drive itself and because of increased heating losses in the motor.

Be skeptical of performance claims. New concepts in energy efficiency are prone to exaggeration, even if they are made by large and reputable manufacturers. A variable-speed drive cannot turn a sow's ear into a silk purse. The efficiency of a chiller depends on many factors, and this Measure improves only one aspect of chiller efficiency.

Potential for Chiller Damage

Adapting a centrifugal chiller to variable-speed drive is much more of a challenge than adding a variable-speed drive to a pump or fan. The flow of refrigerant gas in a centrifugal compressor is vulnerable to several modes of instability that occur when the speed of the impeller is not matched to the gas flow. These instabilities reduce efficiency, make noise, and may damage the compressor.

Also, changing the compressor speed may destroy an impeller or other rotating component by torsional resonance. Three-phase motors are smooth power sources, as long as the phases are balanced. However, serious torsional resonances may still occur somewhere within the speed range of the drive. Also, the irregular power waveform produced by electronic drives may introduce some torsional vibration.

Therefore, consult with the chiller manufacturer before installing a variable-speed drive. The drive should be designed as a package intended for the particular chiller model, and the work should be done by someone who can provide a credible warranty of reliability and efficient performance.

Beware of trouble when modifying a chiller with a conversion kit sold by another manufacturer. In case of trouble, each party is likely to blame the other, and any remaining chiller warranty may be voided.

Avoid Problems Outside the Chiller Plant

Variable-frequency drives have matured, and they now function reliably. However, they do have problems that you need to consider. The most serious problem is electrical noise, which can cause interference with other equipment throughout a facility. See [Reference Note 36](#), Variable-Speed Motors and Drives, for details.

Other Ways of Improving Low-Load Efficiency

The purpose of this Measure is to improve efficiency at low cooling load. The most efficient way to do this is to install a small, efficient lead chiller to carry low loads. See [Measure 2.8.1](#).

If a facility is served by several chiller plants, you may be able to improve efficiency at low loads by connecting the plants together. See [Measure 2.8.3](#).

ECONOMICS

SAVINGS POTENTIAL: 10 to 40 percent of chiller input energy. Even more, if this Measure allows false loading to be reduced or eliminated.

COST: Retrofit variable-speed compressor drives cost about \$25,000 for a 400-ton chiller, and about \$35,000 for a 600-ton chiller.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

CHOICE OF METHOD: Consider all your options, even installing a more efficient chiller. Talk to the manufacturer of your chiller about the change. Talk to other operators who have made the same conversion. Be prepared to deal with control modifications that may be tricky.

SELECTING AND INSTALLING THE EQUIPMENT: Buy the equipment only from (or through) a manufacturer of centrifugal chillers. Anyone else lacks the expertise to avoid chiller problems. Have the installation done by the equipment manufacturer.

Refrigerant Condition

Managing the refrigerant of your cooling equipment is the most important routine maintenance for keeping the equipment at maximum efficiency. You need to maintain the proper amount of refrigerant, neither too little nor too much. You also need to make sure that nothing enters the equipment but refrigerant. The Measures in this Subsection guide you in these activities. They apply to both compression cooling and absorption cooling, and they apply to cooling units of all sizes.

These Measures also reduce expensive equipment failure, and they extend equipment life. Maintaining efficiency and avoiding equipment damage are closely related aspects of refrigerant management, especially with low-pressure refrigerants.

Before getting started with these Measures, you may want to review [Reference Note 34, Refrigerants](#). It will give you a good introduction to refrigerant properties and to the contemporary issues that affect your choice of refrigerants.

MEASURE 2.7.1 Repair chiller system leaks.

RATINGS

New Facilities	Retrofit	O&M
		

Leakage is the first cause of most problems that relate to refrigerants and the refrigerant side of the chiller system. It is not unusual for chillers to leak large amounts of refrigerant. Older chillers that are not well maintained typically lose a substantial fraction of their total charge in the course of a year. Newer chillers are designed to minimize refrigerant loss, but all chillers develop leaks that need to be repaired. Only small, truly hermetic chiller systems are immune from normal leakage, and even these may suffer failures of soldered joints that allow leakage.

You have to keep checking for leaks, and repairing them, as long as you have chillers. Schedule this as a regular maintenance item. This Measure tells you about the problems that leakage can cause, and how to find leaks. Leaks occur in defective equipment. When you find a leak, repair the equipment as recommended by the manufacturer.

Types of Leakage

There are three modes of system leakage to monitor: loss of refrigerant, leakage of air and water vapor into the system, and leakage of water into the system. Each of these can create serious problems. Which of these problems may occur depends on the pressure characteristics of the refrigerant and the design of the system.

■ **Loss of Refrigerant**

If the pressure of the refrigerant inside the system is higher than atmospheric pressure, the system may lose refrigerant. Loss of refrigerant causes a chiller to operate inefficiently, and it may cause equipment damage. Problems related to improper refrigerant charge are explained in [Measure 2.7.2](#), below.

In order of increasing pressure, the common refrigerants HFC-134a, CFC-12, ammonia, HCFC-22, and CFC-502 are high-pressure refrigerants. The vapor pressures of these refrigerants are above atmospheric even on the suction side of the compressor.

Some low-pressure refrigerants, notably the common refrigerants CFC-11 and HCFC-123, operate at pressures higher than atmospheric on the discharge side of the compressor, which includes the condenser. Therefore, the high-pressure side of these systems can lose refrigerant.

In addition, low-pressure refrigerants are lost from the system by the action of purge units, which are required in all systems that use low-pressure refrigerants. This is not leakage in the literal sense, but it has the same effects. The operation of purge units is related to

leakage of air into the system, which is discussed next. See [Measures 2.7.3 ff](#) about purge units.

The cost of replacing lost refrigerant is significant. Packaged water chillers typically use several pounds of refrigerant per ton of cooling capacity. Distributed chiller systems may use even more. If you do not monitor leakage, you may lose an expensive quantity of refrigerant before a chiller operating problem alerts you to the leakage. Refrigerant cost is escalating as more expensive refrigerants are required to satisfy environmental concerns.

In the United States and other countries, laws require the repair of significant leaks if the refrigerants are designated as environmentally harmful.

■ **Leakage of Air and Water Vapor into the System**

If the pressure of the refrigerant inside the system is lower than atmospheric pressure, air may leak into the system, along with the water vapor that air contains. The presence of non-refrigerant gases in the chiller reduces efficiency.

In chillers that use the common halocarbon refrigerants, air and moisture can also cause serious damage. Air and moisture commence to damage chillers as soon as they enter the system, even though dryers and purge units may be installed to remove them. The problems caused by air and moisture are explained in [Measure 2.7.3](#), below.

Refrigerants that have low vapor pressures invite leakage of air and atmospheric water vapor into the system. The refrigerants CFC-113, CFC-11, HCFC-123, and some others have vapor pressures below atmospheric pressure at room temperature. With such refrigerants, air can leak into the chiller whether it is operating or idle.

Even if a refrigerant has a high vapor pressure at room temperature, air may leak into the evaporator of the chiller if the evaporating temperature is low enough. For example, the refrigerants ammonia, CFC-12, and HFC-134a have evaporating pressures lower than atmospheric when used in low-temperature applications, such as cold storage and making ice cream.

With any refrigerant, air and water vapor may enter the system as a result of improper refrigerant charging and oil filling procedures.

■ Leakage of Water into the System

Water chillers and chillers with water-cooled condensers face the additional problem of water leakage into the refrigerant side of the system. Water that leaks into a chiller in the liquid state causes the same kinds of damage as water that leaks into the chiller as vapor. With a liquid leak of any size, the effects may be much more severe.

The most likely route of water leakage is through the evaporator of a water chiller. This part of the system has lowest internal pressure. The critical factor is the pressure differential in the evaporator when the compressor is running. Even with some high-pressure refrigerants, the water pressure in the evaporator may be higher than the refrigerant pressure. This is because the evaporator may be subjected to large hydrostatic pressure from a tall chilled water distribution system. (If you have a tall chilled water system, be aware of

whether it includes a heat exchanger to isolate the chiller from high chilled water pressure.)

Water can leak into the system through a water-cooled condenser, in some cases. This risk exists primarily in systems that use low-pressure refrigerants. Most high-pressure refrigerants have a pressure that is high enough to resist water leakage at the condenser. The maximum water pressure on the condenser is determined by the height of the cooling tower above the condenser. This height is usually too low to cause trouble with high-pressure refrigerants, but there are exceptions.

To make the story complete, be aware that water may enter any type of compression chiller as a contaminant of lubricating oil. Water vapor in the air is absorbed by refrigerant oil if the container is not kept properly sealed. This is not leakage in the literal sense, but it has the same effect. The small amount of water introduced with contaminated oil can cause harm.

Where Leaks Occur

Leaks can occur anywhere in a chiller system, but most leaks occur in these locations:

- shaft seals of compressors with external drive motors
- operating shafts for the inlet guide vanes of centrifugal chillers. Figure 1 shows this vulnerable site.
- anywhere else that mechanical motion is transmitted through the casing
- packing boxes for wiring that passes into the refrigerant side of the system for internal motors, cylinder unloaders, sensors, etc.
- charging connections
- gauge taps
- threaded fittings
- gaskets
- fins of refrigerant coils, especially at brazed connections

WESINC

Fig. 1 Potential leakage site in a centrifugal chiller This actuator for the machine's capacity control penetrates the casing. It is a moving component, so suspect leakage here. The refrigerant operates below atmospheric pressure, so leakage anywhere on this machine will be inward, making conventional leak detection methods ineffective. This fitting is located at the compressor suction, increasing any leakage that occurs here.

WESINC

Fig. 2 Leakage at an original weld of an old chiller

- welded joints, especially in older units where internal corrosion may have penetrated through imperfections in the weld. Figure 2 shows a leak at a welded joint.

In water chillers or in chillers that have water-cooled condensers, there may be internal leakage between the liquid side and the refrigerant side. This usually occurs at the tube sheet of shell-and-tube heat exchangers, either because of defective fit between the tubes and the tube sheet, or because of stress cracking of the tubes.

Symptoms of Leakage

The first step in managing leakage is knowing whether there is a problem. Keep a continuous record of the amount of refrigerant that you use to refill the system. In systems with positive-pressure refrigerants, loss of refrigerant indicates the existence of leaks. In systems with negative-pressure refrigerants, loss of refrigerant indicates an inefficient or malfunctioning purge unit, or a major air leak into the system.

In systems with purge units, keep track of the length of time that the purge unit operates. This indicates the rate of air leakage into the system. Some sophisticated purge units record the cumulative amount of air removed, as explained in [Measure 2.7.3.1](#).

Air that leaks into a chiller raises the condensing pressure. This is because the partial pressure of the non-refrigerant gases adds to the partial pressure of the refrigerant gases. If you measure a condensing pressure that is higher than indicated in the table, suspect air in the system. This is a good test because the pressure rise is proportional to the efficiency loss caused by the excess air. ([Measure 2.7.2](#) explains how to figure out what the condenser pressure should be.)

However, this symptom does not become apparent if the chiller has a purge unit that is operating properly. The purge unit does not allow enough air to accumulate to affect the condensing pressure noticeably.

If the system is undercharged, the lack of refrigerant may create a drop in pressure that masks the rise in pressure caused by the presence of air. This is a very inefficient condition.

The usual way of detecting the presence of moisture in the refrigerant circuit is to use a refrigerant dryer that contains a chemical indicator that changes color when a certain amount of moisture is absorbed. This works only in chillers that have a sight glass on the dryer, or that have a removable dryer element. Consider installing a visible dryer for this purpose if none is presently installed. If a purge unit is installed, the purge unit may indicate the presence of moisture. The performance of purge units in revealing and removing moisture varies widely, as explained in [Measures 2.7.3 ff.](#)

Eventually, the presence of air and water will be revealed during repair by their adverse effects: corrosion, acidification and sludging of oil, restriction of throttling valves, clogging of screens, etc.

Methods of Finding Leaks

Most refrigerant leaks start very slowly, which makes them difficult to detect. The methods that you can use to detect leaks depend on the type of refrigerant and on the location of the leak in the system, as follows.

■ Leakage of Refrigerant Out of the Chiller into the Surrounding Space

Check for leaks at likely leakage points everywhere that the system is under positive pressure. You can detect outward leakage of refrigerant with a variety of methods. These are the main ones:

- **visible appearance of corrosion.** Escaping refrigerant combines with water vapor in the air to create highly corrosive acids. Look for localized rust in steel components, and green corrosion of copper alloys.
- **soap bubbles.** A bottle of soap or detergent solution is cheap and easy to use. You can use it with any type of refrigerant. The procedure is to wet the suspect area and look for bubbles. Even slow leaks create bubbles if the soap solution covers the leak long enough. This method fails if the leak is located where the detergent solution drains off quickly or cannot be observed well. A clear oil may work in locations where a detergent solution is too runny.
- **the halocarbon torch.** This is an old, reliable method of detecting leaks of halocarbon refrigerants. It consists of an ordinary propane torch with an attachment that holds a small copper surface in the flame. A sniffer tube draws air into the flame from the suspect location. Leaking refrigerant breaks down in the heat of the flame and reacts with the copper to produce a distinct blue-green flame. The open flame is a fire hazard if there are fuels or flammable materials in the vicinity.
- **the electronic ionization detector,** which is a newer type of tester for halocarbon refrigerants. It functions by ionizing the halocarbon gas between charged platinum electrodes and sensing the ionization current. It is very sensitive.
- **dyes in the refrigerant oil.** This is an older method that is suitable for refrigerants that carry oil through the system. The dye travels with the oil, and appears at points of leakage. Fluorescent dyes are available that can be seen in small amounts with a portable ultraviolet lamp.
- **smell,** which works for ammonia and other gases with strong odors, if the leak is large enough.

■ Leakage of Refrigerant into Evaporator and Condenser Water

Your first clue that high-pressure refrigerant is leaking into the waterside of the evaporator or condenser is usually indirect. If you have to add refrigerant but you can't find any external leaks to account for the loss, suspect a leak into the waterside. To localize the leak, drain the evaporator or condenser and test for refrigerant leakage using the methods given above.

As a first check for leakage into the evaporator, use a leak detector at the vent of the chilled water system surge tank. This test cannot detect a small leak, and it cannot detect refrigerant that is entirely dissolved or chemically changed by water.

As a first check for leakage into the condenser, use a sensitive refrigerant detector at the point where cooling water is pumped into the cooling tower or at the suction point of the sump, with the cooling water pumps turned off. This test cannot reveal a small leak.

You may have to test the water itself to find leaking refrigerant in it. If your water treatment contractor cannot do this test, send a sample to a laboratory that tests for refrigerant pollution in water wells.

■ Leakage of Air into the Refrigerant Circuit

There is no simple, reliable method of finding the location of an air leak into a chiller system. This is a problem if the chiller uses a refrigerant that operates below atmospheric pressure. The best you can do easily is to seal suspect areas and observe whether the rate of air leakage into the system drops.

Purge units that record the amount of air removed from the chiller are handy for seeing the effect of a repair within a reasonably short time. In the case of slow leaks, this may be a few days.

[Measure 2.7.4](#) recommends equipment that keeps chillers with low-pressure refrigerants under positive pressure while they are idle. This keeps air from leaking into idle chillers. You can use the same equipment to pressurize a chiller enough to force refrigerant out of any leaks that exist, making it possible to find the leaks with ordinary refrigerant leak testing equipment.

■ Leakage of Water into the Refrigerant Circuit

Leakage of water into the refrigerant is revealed in the refrigerant dryer, as mentioned above. If water accumulates in the dryer rapidly, suspect a leak from the waterside, rather than water vapor entering along with air.

If a chiller that uses a high-pressure refrigerant shows a water leak while it is running, the leak is almost certainly in the evaporator. To find the leak, drain the evaporator and search for escaping refrigerant using the test methods given previously.

If a low-pressure refrigerant has a condensing pressure higher than atmospheric, you may be able to localize a water leak to the evaporator or condenser without draining them. (CFC-11, HCFC-123, and some other low-pressure refrigerants have condensing pressures higher than atmospheric.) Use a fresh moisture indicator in the purge unit, and see if it indicates moisture while the chiller is running continuously. If there is no moisture, the leak is in the condenser.

To localize the leak, drain whichever heat exchanger has the leak, and inspect it carefully. If you have the equipment recommended by [Measure 2.7.4](#), discussed previously, you can use it to pressurize the system above atmospheric pressure. This allows you to find the leak with conventional refrigerant leak detection equipment.

MEASURE 2.7.2 Maintain the proper refrigerant charge.

RATINGS

New Facilities	Retrofit	O&M
		A

The efficiency of all chillers suffers if the system has either too little or too much refrigerant charge. Also, the compressor may suffer damage if the system is overcharged. Some systems have only minimal reservoir capacity, making it important to charge the system precisely. Such systems are more vulnerable to loss of efficiency from small leaks. Other systems have a large amount of reservoir capacity. In these systems, a small leak may persist for a long time before being noticed.

Check the refrigerant charge in your cooling units often enough to keep the charge within proper limits. This Measure gives you procedures for checking and maintaining the proper refrigerant charge and explains the effects of improper refrigerant charge.

Bad Effects of Incorrect Refrigerant Charge

Both the COP and the capacity of a cooling unit suffer if the refrigerant charge is too low. When that occurs, evaporator capacity is reduced because less of its surface is wetted, and the average evaporator temperature differential increases. The compressor must work harder to satisfy the same cooling load.

In hermetic chillers, in which the motor is cooled by the refrigerant gas, low charge can overheat the motor, reducing its life.

If there is too much refrigerant in the system, the excess may back up in the condenser, reducing its effective surface area and increasing the average temperature differential across the condenser. In chillers that have a flooded cylindrical evaporator and no device to regulate the refrigerant level in the evaporator, high refrigerant level reduces the evaporation surface area.

In some types of systems, excess refrigerant can travel through the evaporator in the liquid state, continuing into the compressor. This can destroy a positive displacement compressor immediately, and it can destroy a centrifugal compressor gradually.

How to Measure Refrigerant Charge

The most difficult aspect of maintaining the proper refrigerant charge may be measuring the charge that is presently in the system. In some cases, this can be tricky, tedious, or both. The best method of checking the refrigerant charge depends on the type of system. Use the best method or combination of methods for your system. The following are the various methods that are available.

■ **Liquid Level Indicators and Sight Glasses**

Some chiller units, and some vessels in a chiller system, may have a means to indicate the refrigerant quantity directly. These work only if a predictable quantity of refrigerant remains in one part of the system. The most common liquid level indicator is a sight glass on the vessel where the refrigerant collects.

Refrigerant level sight glasses are common accessories of packaged water chillers. They are useful

on these machines because all the refrigerant remains within the shell of the machine and drains freely into the evaporator. Figure 1 shows a typical sight glass. It can be used when the machine is running or turned off, although the level is more stable when the machine is not running.

Many refrigerant level sight glasses are perversely small, making it difficult to check the level if it is above or below the level of the sight glass. In such cases, it helps to look at the sight glass as the chiller is being started. If the refrigerant surface is above the sight glass, you can probably see bubbles as the chiller starts, or the refrigerant level drops to the level of the sight glass. If the refrigerant level is below the sight glass, you may be able to see splatter on the sight glass, which indicates that the charge is low.

Some older units have a liquid level test cock on the evaporator shell. However, these require venting some refrigerant to test the liquid level. This practice is now considered very bad form, for environmental reasons.

In chiller systems where the components are spread out, refrigerant quantity indicators do not work as well, or they may not work at all. The problem is that refrigerant migrates from one part of the system to another. When the chiller is running, the distribution of refrigerant in the system varies with load. When the chiller is not running, refrigerant migrates to the coldest part of the system. For example, the refrigerant might accumulate in the condenser during winter and in the evaporators during summer.

If a spread-out chiller system has a receiver (refrigerant surge tank) or a shell-and-tube evaporator, it may be practical to use a level indicator in one of these vessels. In such cases, the level indicator provides useful information only when the system is running and stabilized. Even then, the level of refrigerant varies with the cooling load. The refrigerant level indicator should be readable anywhere within the acceptable charge range. When the system is turned off, refrigerant pools in the coldest parts of the system, and the level indicator gives a false reading.

If your chiller system does not have an easy-to-read refrigerant level indicator, consider adding one, if possible. If you do, install a placard at the sight glass or gauge that indicates the normal range of readings, and the conditions under which the readings are valid. For example, the placard might say, "Refrigerant level indicator valid only if the compressor is running, or if the receiver temperature is at least 10°F colder than the outside air temperature." (See [Reference Note 12](#), Placards, for tips on how to create an effective placard.)

Any kind of refrigerant level gauge or sight glass should be strong and well protected. A broken sight glass or gauge connection would vent the entire refrigerant charge into the surrounding space. With high-

pressure refrigerants, the blowout continues at full pressure as long as there is liquid in the system, which is a dangerous situation.

■ Discharge and Suction Pressures

With all types of compression cooling equipment, you can check the state of refrigerant charge by measuring the discharge and suction pressures in the system. Do this while the compressor is operating and the system is in stable operation.

Larger machines usually have gauges installed that indicate the evaporator and condenser pressures at all times. Figure 2 shows a typical example. Use portable gauges if the machine does not have gauges installed.

The normal discharge pressure depends on the condensing temperature. To check system charge, use a table of refrigerant pressures and temperatures. This tells you what the condensing pressure should be at the current condensing temperature. If the discharge pressure is lower than it should be at that temperature, the system is low on charge.

Refrigerant pressure gauges often have the corresponding saturation temperatures printed right on the gauge dials. This saves you the trouble of finding a refrigerant pressure chart. Portable refrigerant gauges typically show the saturation pressures for several of the most common refrigerants. If you need to use a refrigerant table, you can find one in many reference books. Also, refrigeration supply houses commonly give away refrigerant tables that are printed on handy cards. If the type of refrigerant used in the chiller system has been changed, be sure to use a refrigerant table for the current refrigerant.

If the refrigerant charge is low, both the discharge and suction pressures will be lower than normal. The discharge pressure is low because there is not enough gas in the system for the compressor to squeeze to the normal discharge pressure. The suction pressure drops

Fig. 2 Evaporator and condenser gauges These tell you immediately whether the machine has the minimum amount of refrigerant for efficient operation. They do not tell you the actual amount. The condenser pressure provides an uncertain indication of excessive charge.

because there is not enough liquid refrigerant in the evaporator to boil off vapor at the normal vapor pressure. As a result, the vapor expands into the compressor suction, lowering its pressure. In other words, the compressor starts to act like a vacuum pump.

Low suction pressure also creates abnormally low suction temperature. This occurs because the refrigerant gas is cooled below its saturation temperature by the greater expansion. The suction temperature can eventually fall enough to freeze the evaporator coil. In a water chiller, this can cause major damage.

Suction pressure could be lower than normal for other reasons, such as obstructed air flow through an air-cooled evaporator. For example, opening the evaporator coil access panel in an air handling unit short-circuits the flow of air around the coil, causing its refrigerant pressure to drop.

Discharge pressure is much less reliable as a clue to excessive refrigerant charge. If the condenser floods from excess charge, its cooling capacity is reduced, so the discharge pressure rises. A noticeable pressure rise occurs only under high load. A condenser that is heavily flooded with excess refrigerant will also cause cooling water or cooling air temperatures that are lower than

normal, because the condenser is not rejecting as much heat. However, this symptom is subtle.

(If the discharge pressure is lower than normal and the suction pressure is higher than normal, the compressor may be worn out, or the compressor or system may have an internal leak from the discharge side to the suction side, or the system may have hot gas bypass.)

So, the suction and discharge pressures are a reliable indicator of low charge, and the discharge pressure is a less reliable indicator of excessive charge. However, system pressure cannot tell how much refrigerant is in the system within the normal range of charge. As long as there is enough liquid within the system to keep the evaporator supplied, the readings are normal. In systems without refrigerant quantity indicators, you have to check the refrigerant pressure at appropriate intervals to detect the first sign of inadequate charge. When leakage finally causes liquid starvation in the evaporator, pressures start to decline. The rate of decline depends on the leakage rate and on the volume of refrigerant in the system.

On the other hand, air in the system causes all pressures to be higher than normal. This can mask a

Fig. 3 Evaporator liquid line sight glass It is generally located as shown here, close to where the refrigerant liquid enters the evaporator. Bubbles in the sight glass while the system is running probably indicate low refrigerant charge, but they may also indicate an obstruction of the refrigerant line in the direction of the condenser.

low refrigerant charge. Keep air out of the system at all times. This is covered by [Measures 2.7.1](#) and [2.7.3](#).

■ Evaporator Liquid Line Sight Glass

In chillers that use a throttling type of refrigerant metering device (an “expansion valve,” capillary tubes, etc.) to control the flow of refrigerant to the evaporator, a sight glass may be installed in the refrigerant line leading to the evaporator. Figure 3 shows where to look for the sight glass.

Bubbles in the sight glass indicate that there is not enough liquid in the system to keep the line filled. Bubbles first appear under high cooling load, when liquid is being drawn out of the line most rapidly. Bubbles that occur when the system first starts may be normal, and do not indicate low charge.

Bubbles in a sight glass are not a foolproof indication. If the sight glass is located upstream of a partially obstructed filter or dryer, the back pressure may keep bubbles from forming even when the charge is low. Conversely, if the sight glass is downstream of a clogged filter or dryer, the reduced pressure at the sight glass may cause bubbles to form even though the amount of refrigerant in the system is proper. Adding more refrigerant based on this false indication may overcharge the system and cause compressor damage.

A liquid line sight glass cannot reveal excessive refrigerant charge.

■ Suction Gas Superheat

In direct-expansion chiller systems (which send the refrigerant directly into the cooling coils), low charge is indicated by high superheat in the gas leaving the evaporator, especially when the compressor is operating at full load. Superheat is the excess of the gas suction temperature above the gas saturation temperature. When the evaporator becomes “starved” for refrigerant, the available refrigerant boils off quickly and the unsatisfied heat load of the evaporator superheats the refrigerant gas excessively.

In systems that use a thermostatic expansion valve, the valve is designed to maintain a fixed amount of superheat. The purpose of the superheat is to ensure that liquid refrigerant does not enter the compressor. Do not let this superheat fool you into believing that the charge is low. If the superheat setting of the valve is unknown (it is typically 10°F to 20°F, or 5°C to 11°C), the charge is probably not low if the superheat remains essentially the same at all loads.

■ Condensate Subcooling

In systems with air-cooled condensers, excessive charge is indicated by excessive subcooling of the refrigerant. Subcooling is cooling of the liquid refrigerant below its saturation temperature. When the system is overcharged, the condenser fills with liquid refrigerant, the condenser capacity drops, and the liquid

lingers in the condenser long enough to become excessively subcooled.

The difference in temperature between normal and subcooled refrigerant from a condenser is small. This makes the test too subtle for any but experienced technicians. Look for condenser subcooling as confirmation of excess charge if the discharge pressure is too high.

This symptom is accompanied by abnormally high condenser pressure, especially at high cooling load.

■ Bleeding Refrigerant Pressure

As a last resort, you can bleed refrigerant from the system until the operating pressures drop, and then add the recommended amount of extra refrigerant. Do not use this method with any environmentally harmful refrigerant unless you have the equipment to salvage the refrigerant.

Should You Add a Receiver?

All chiller systems have a certain amount of storage volume for liquid refrigerant, but the amount varies widely. Ample refrigerant storage capacity ensures that refrigerant is available to the evaporator. It compensates for accumulation of refrigerant in different parts of the system under different operating conditions. It prevents back-flooding of refrigerant into the condenser. And, it provides a reserve to make up for leakage.

Some chillers inherently have large storage volume. For example, packaged centrifugal water chillers store a large amount of refrigerant in their evaporator shells. On the other hand, direct-expansion chillers may have little storage capacity, because air coils have small liquid volumes. In the past, it was common practice to install a “receiver” in such systems, which is simply a storage tank, or surge tank. Different chiller system designs may have receivers in different parts of the system.

It has become commonplace to eliminate the receiver from chiller systems as a cost saving measure. In such systems, storage volume is limited to the condenser itself and to the piping downstream of the condenser. Therefore, a relatively small overcharge may cause refrigerant to back up into the condenser, and a relatively small undercharge may starve the evaporator of refrigerant. For example, a difference of a few ounces of refrigerant charge may affect chiller performance in a small split system.

In systems that lack refrigerant storage capacity, it may be desirable to add a receiver to the system. The mechanical installation is usually not complicated, but it should be done by a refrigeration specialist familiar with proper piping practices and other aspects of assembling cooling systems. Finding the proper location for the receiver in the system requires a clear understanding of chiller system design.

Installing a receiver is not a substitute for keeping the system free of leaks. If the system operates properly when it is properly charged, it probably does not need a receiver. Instead, put your emphasis on proper charging procedure and checking for leaks.

How to Add Refrigerant

Follow the refrigerant charging procedures specified by the manufacturer. If your system does let you measure the refrigerant charge directly, find the point of minimum charge as described previously. Then, add refrigerant in the amount specified by the manufacturer. If you use a large bulk container of refrigerant, put it on a portable scale as you charge the system. Calculate the amount of refrigerant added from the change in weight.

Be careful to keep air from entering the system when you recharge it. This requires great care if the refrigerant in the chiller is below atmospheric pressure. Even with high-pressure refrigerants, be careful to purge all the refrigerant gauge and filling hoses before opening the chiller service ports.

If you are filling a chiller system that has been opened to the atmosphere, you have to use a vacuum pump to remove all air and vapor from the system before

recharging. Don't try this without training. Chiller servicing should be done only by technicians who fully understand what they are doing. Inadequate training of maintenance personnel is a common cause of chiller damage and inefficiency.

MEASURE 2.7.3 Operate purge units appropriately.

RATINGS

New Facilities	Retrofit	O&M
□	□	A

Air and moisture can leak into any chiller system if the pressure inside the system is lower than atmospheric. For this reason, chillers that operate at low internal pressure are equipped with purge units to remove the contaminants. Figure 1 shows a typical purge unit.

Proper operation of the purge unit is essential for efficient operation, and to minimize corrosion damage. This Measure tells you what purge units do, how to keep them working, and how to operate them appropriately.

Water may enter a chiller along with the air, in the form of water vapor. Also, water may leak into the system from the chilled water side of the evaporator and from the condenser side of a water-cooled condenser. Liquid water that leaks into the chiller partially vaporizes inside a low-pressure system. The vapor travels in the same manner as water vapor that enters through air leaks. Purge units can remove some of the water that remains inside the system as a liquid, but their ability to do this varies with the type of purger.

Newer models of purgers have performance that is much better than the performance of older models, and they are easier to use. Subsidiary Measure 2.7.3.1 recommends installing the best type of available purger.

Purging is not a substitute for repairing leaks. As soon as air and moisture enter a chiller, they start to combine with the refrigerants to form acids, which in turn form oil sludge. The acids and sludge are not removed by purging. The only completely effective way to prevent damage is to keep contaminants out of the chiller in the first place. See Measure 2.7.1 about this important maintenance.

Chillers That Require Purging Equipment

Leakage of air and atmospheric moisture into chillers is a problem with refrigerants that have evaporating pressures below atmospheric pressure. (The system pressure is lowest in the evaporator circuit.) Expect to find purge units on systems that use refrigerants CFC-11, CFC-113, HCFC-123, and other low-pressure refrigerants. All absorption chillers that use water and lithium bromide as the refrigerant operate under high vacuum, and these require purge units.

Even if a refrigerant has a high saturation pressure at normal temperatures, the evaporating pressure may be less than atmospheric if the evaporating temperature is low enough. For example, the refrigerants ammonia and HFC-134a have evaporating pressures lower than atmospheric when used in low-temperature applications, such as frozen food storage. Such systems may not have purge units, even though they would be desirable. See the subsidiary Measure about adding a purge unit.

Energy Waste Caused by Air in the Refrigerant

In chillers that use compressors, non-refrigerant gases reduce efficiency by wasting the compressor energy that is required to compress the gases through the system. These gases have minimal refrigeration effect. This energy waste is proportional to the increase in condensing pressure.

In chiller systems that use air coil evaporators and condensers, air that accumulates in the coils can substantially reduce their heat exchange surface area, reducing efficiency and capacity. The same effect occurs in water-cooled condensers.

In absorption chillers, non-condensable gases reduce the vacuum that is necessary to achieve rapid evaporation of the refrigerant. Small amounts of air substantially reduce efficiency and capacity.

Equipment Damage Caused by Air and Moisture

Air and moisture leakage into chillers causes equipment damage and interferes with performance in a variety of ways, of which the most serious are:

- **corrosion.** In chillers that use halocarbon refrigerants (the most common types), water combines with the refrigerants to form powerful acids, primarily hydrochloric and hydrofluoric. Even small quantities of these acids can cause expensive damage and shorten chiller life. The acids preferentially attack weaknesses in steel, such as welds in compressor casings, causing microscopic leaks. Acid also preferentially attacks polished surfaces, such as valve plates.
- In absorption chillers that use a lithium bromide solution (the most common type), air hastens corrosion by interaction with the salt solution.
- **electrical burnout,** in chillers that have internal motors. The same acids that cause corrosion also

attack motor insulation. Eventual arcing of the insulation causes catastrophic failure, which requires expensive motor repair or replacement. The burnout itself creates contaminants that disperse throughout the chiller system, requiring tedious and expensive system cleaning.

- **damage by oil breakdown products.** The acids that are formed by reactions between the refrigerant and water react with the lubricating oil to form sludge. The sludge blocks oil filter screens and dryers, and deposits on heat transfer surfaces. The results are higher operating pressure and compressor temperature. In turn, the increased temperature hastens carbonization of the oil, which acts as a catalyst for further acid formation.
- **copper plating.** Copper is dissolved from copper alloy system components and is then deposited on hot surfaces, such as crankshaft journals. This occurs in a series of chemical reactions involving water that leaks into the system.
- **higher operating temperatures.** Air in the system causes the compressor to run hotter, because the air must be compressed along with the refrigerant,

requiring higher discharge pressure and creating more heat of compression. The higher temperature shortens compressor and motor life, and aggravates all the previous adverse effects.

- **obstruction of refrigerant flow.** Moisture that remains free freezes in the coldest components in the system, where it obstructs refrigerant flow. Freezing is especially likely to occur in the refrigerant metering device.

Operation and Types of Purge Units

Purge units expel non-condensable gases that leak into the system. To do this, they continuously draw vapor from the inside of the chiller, condense the refrigerant and return it to the chiller, and vent the gases that do not condense.

Purge units come in a variety of designs. Some are self-contained cooling units with their own compressors, condensers, and separation equipment. These units can operate whether the chiller itself is running or not. Other purge units use the liquid refrigerant or chilled water generated within the chiller as the means of condensing the refrigerant in the purge unit, so these types cannot operate unless the chiller is running. Some purge units use cold domestic water as the condensing medium to allow purge operation when the chiller is turned off. The modern high-efficiency purge units covered by [Measure 2.7.3.1](#), below, are self-contained units that provide low condensing temperatures.

In low-temperature applications, such as ammonia food freezers, purging can be done with a simple device similar to an inverted-bucket steam trap. This device contains a refrigerant condensing coil that is operated by the chiller system itself.

■ How Purgers Remove Water Vapor

Purge units remove water by two processes. One of these is inherent in the operation of the purger, and the other is not. Water is only slightly soluble in halocarbon refrigerants. As refrigerant and water vapor condense in the purge unit, the fraction of the water that separates from the refrigerant floats to the top of the refrigerant in the purger, where it is tapped off. With some purge units, the water must be drained from the purger manually.

The solubility of water in halocarbon refrigerants decreases as the temperature of the refrigerant decreases. If the purge unit cools the condensed refrigerant below the evaporator temperature, no free water will exist inside the chiller, although some water remains dissolved in the refrigerant. On the other hand, if the purge unit does not cool the condensed refrigerant below the evaporator temperature, free water can exist in the chiller. Free water causes severe corrosion as it reacts with the refrigerant to create an acid solution. In a water chiller, especially severe corrosion occurs where water condenses on the steel surfaces of the evaporator shell.

WESINC

Fig. 1 Purge unit on chiller with low-pressure refrigerant
This older purge unit discharges non-condensable gases through the jug of refrigerant oil on the floor. Bubbles in the oil show that air is leaking into the chiller. Refrigerant ejected by the purger dissolves in the oil, so it does not form bubbles.

A chemical dryer element may be installed to remove the water that is not removed by the action of the purge unit. The dryer typically consists of a disposable cartridge of hygroscopic (water-absorbing) material. The dryer element must be replaced when it becomes saturated with water. This is usually indicated by a chemical added to the dryer that changes color when the dryer is near saturation.

The dryer element is not an inherent part of the purger, but the purger is a logical location for the dryer because the refrigerant vapor is recirculated through the purger. The dryer may be built into the purge unit, or it may be installed separately in the line that returns liquid refrigerant from the purger to the chiller. Dryers may be installed in other parts of the system not related to purge operation, such as the liquid refrigerant line in chillers that use expansion valves. Some of the high-efficiency purge units covered in [Measure 2.7.3.1](#) use a water removal process that does not require a separate chemical dryer to remove normal amounts of moisture.

Liquid water can leak into a chiller through the evaporator of a water chiller, or through the condenser of a water-cooled chiller. No purge unit can deal effectively with a water leak. This is because the purge unit draws only vapor from the inside of the chiller system. The pressures that exist inside chillers with low-pressure refrigerants are high enough to keep water in the liquid state, and the purger cannot remove water as a liquid.

For this reason, water chillers or water-cooled chillers that use low-pressure refrigerants should have a reliable method of indicating a water leak into the refrigerant circuit as soon as it occurs, along with a chemical dryer to absorb water until a repair is made.

Refrigerant Loss with Purge Operation

Purge units vent a certain amount of refrigerant along with the air they remove. In fact, an older purge unit may remove several times as much refrigerant as air. Replacing refrigerant is expensive, and the escaped refrigerant may be an environmental hazard. Therefore, older purge units are usually operated intermittently, based on experience with the rate of air leakage into the chiller.

This is not a concern with the newer high-efficiency purge units recommended by [Measure 2.7.3.1](#), below. These units waste much less refrigerant, and their operation is controlled automatically.

How to Check Purge Operation

Different types of purgers provide different ways of checking their operation. Start by reading the purger instruction manual.

With many units, if the unit is ejecting non-refrigerant gases, you can see the gases bubble through

a liquid seal, or through a bubbler that is installed specifically for this purpose. If the purge unit does not have a liquid seal that you can see, pipe the purge vent into a transparent container of compressor lubricating oil. The ejected gas forms visible bubbles.

The absence of bubbles does not necessarily mean that the purge unit is not working, because there may be only a minimal amount of air inside the chiller. On the other hand, a small quantity of bubbles emitted continually may be refrigerant, rather than non-condensable gases. This loss of refrigerant is characteristic of older, less efficient purgers.

Some purgers are constructed so that moisture eliminated from the chiller is visible in a sight glass.

You can check accumulation of moisture from the color of the dryer element, if your chiller has a chemical dryer that indicates moisture by changing color.

Check the operation of the purger indirectly by monitoring the relationship of the pressures and temperatures in the condenser and evaporator. See [Measure 2.7.2](#) for details. If both these pressures are higher than normal, there are foreign gases in the chiller.

Purge Idle Chillers

If chillers are idle for long periods, or if the rate of leakage is substantial, operate purge units at appropriate intervals while the chillers are idle. For example, if a CFC-11 chiller is located in an unheated equipment space, the refrigerant vapor pressure remains below atmospheric pressure throughout much of the cold weather season, inducing air leakage.

An alternative for such chillers is to install equipment that prevents air leakage into idle chillers by pressurizing them above atmospheric pressure. See [Measure 2.7.4](#), below.

Absorption chillers that use water as the refrigerant have high internal vacuum. This makes them susceptible to air leaks. Any air that enters causes rapid corrosion because of the action of the salt solution inside the chiller. For this reason, absorption chillers should be purged continually, whether they are operating or not.

If the present purge unit cannot operate unless the chiller is running, consider replacing it with a unit that can operate with an idle chiller. This is an opportunity to upgrade the purge unit, as recommended by [Measure 2.7.3.1](#), next.

MEASURE 2.7.3.1 Install high-efficiency purge units.

RATINGS

New Facilities	Retrofit	O&M
A	C	

Purge units manufactured as late as the 1980's may extract several times more refrigerant than air from the system. Newer models of purge units were introduced during the 1990's specifically to reduce the emission of halocarbon refrigerants into the atmosphere. The best new purge units radically reduce loss of refrigerant, simplify use, and provide a record of leakage. Figure 1 shows a modern unit.

If your chillers with halocarbon refrigerants don't have high-efficiency purge units, consider installing them. Low-loss purgers are available as retrofit units for older chillers. Some chiller manufacturers offer them as standard equipment on new chillers.

If a chiller does not have a purge unit, but it operates with an evaporating pressure lower than atmospheric pressure, consider installing a purge unit. This will improve efficiency with all types of refrigerants. It will also prevent damage if the refrigerants have harmful reactions with air or water. Measure 2.7.3 explains purge units in detail.

Advantages of High-Efficiency Purgers

The main feature of high-efficiency purge units is that they cool the recirculated refrigerant vapor to a low temperature. This condenses most of the refrigerant, allowing it to be recovered. It also minimizes the solubility of water in the liquid refrigerant, so that the water separates from the refrigerant in the purger.

High-efficiency purge units reduce the cost of refrigerant wasted during purging, along with the presumed environmental problems caused by refrigerants. One prominent manufacturer claims to cut the loss of refrigerant to less than one percent of the quantity of air removed.

High-efficiency purgers operate only in response to an accumulation of air or water. Thus, they run whenever needed, but not more than needed. Some high-efficiency

purge units use a water removal process that does not require an expendable dryer cartridge.

A valuable feature of some purge units is the ability to keep track of the amount of air removed from the chiller. This is helpful for indicating whether leaks exist, and how bad they are.

Purgers for Refrigerants that do Not React with Air or Moisture

Some refrigerants do not have harmful reactions with air or water. Ammonia is the most important example. Water mixes readily with ammonia, forming a harmless solution. Water and air may still rust the steel components of the system, but not in the aggressive manner that occurs with halocarbon refrigerants.

Air that enters the system still increases compressor power and wastes energy. So, even with these refrigerants, it is still important to have a purger. In low-temperature applications, such as ammonia food freezers, purging can be done with a device similar to

an inverted-bucket steam trap that contains a refrigerant condensing coil. This simpler type of purger operates well because it exploits the low-temperature operation of the system itself.

ECONOMICS

SAVINGS POTENTIAL: Savings in refrigerant cost vary with the size and leakiness of the chiller system. Several hundred dollars per year is typical. More effective purging reduces long-term maintenance costs.

COST: Approximately \$1,000 for the equipment. In retrofit applications, installation may cost several hundred dollars.

PAYBACK PERIOD: Several years, or longer. The payback period may be shorter than this if the high-

efficiency unit is installed as a replacement for a failed unit.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Purgers are an evolving product, so shop the market for features. Favor the equipment of major manufacturers. Check with other users of models you are considering.

INSTALLATION: Good installation workmanship is important to keep the purger connections from becoming an air leak. Follow the manufacturer's instructions precisely.

OPERATION: Train the staff in using the equipment. Provide clear instructions in the plant operating manual. Install an effective placard at the unit.

MEASURE 2.7.4 Install accessories that prevent air leakage into idle chillers.

If you have chillers with low-pressure refrigerants that stand idle for long periods, you can prevent air leakage into the chillers by pressurizing them to keep the internal pressure higher than atmospheric. This approach has the advantage that air is never allowed to enter the chiller, while purging removes air only after it has entered the system.

There are two practical ways to pressurize an idle chiller. One is to warm the refrigerant in the chiller, and the other is to add an inert gas to the refrigerant. This Measure applies to several common refrigerants that have a saturation pressure that is only slightly below atmospheric pressure. It does not apply to absorption chillers, which have a high internal vacuum.

Don't expect these methods to prevent water leaks into the chiller from the evaporator or condenser. The amount of pressurization required would be much too high, forcing refrigerant out of the system. Instead, see [Measure 2.7.5](#) about preventing water leakage into idle chillers.

Pressurization by Warming the Refrigerant

The newest method of pressurizing chillers is to heat the refrigerant until its vapor pressure is slightly higher than atmospheric. This method is limited to refrigerants having saturation pressures that are not much below atmospheric pressure. In practice, this limits the technique to compression chillers with the common low-pressure refrigerants. The refrigerant temperature needed is about 76°F (24°C) for CFC-11, and about 84°F (29°C) for HCFC-123.

Accessory units that warm the refrigerant are available commercially. One type uses an electric heating blanket that is wrapped around the evaporator or refrigerant sump. Another type uses a small water heater that is piped to circulate through the chilled water side of the evaporator. The heater is typically electric, but the same effect could be achieved with a heater that uses other energy sources.

Both types require a sensitive gauge to measure the difference between the inside and outside pressures, and an electronic control to regulate the heating element. Thermostatic control allows the pressure differential of the refrigerant to be controlled precisely, typically to about 0.01 PSI higher than atmospheric pressure. The smallness of the pressure differential minimizes the amount of refrigerant that is forced out of the system through any leaks.

The chilled water isolation valves of the evaporator must close tightly if the refrigerant is warmed. Otherwise, the chilled water will conduct the heat away

SUMMARY

from the chiller, requiring the heating unit to operate at a high power level and waste energy.

Pressurization by Adding Inert Gas

An older method is pressurizing chillers by using a pressurized source of dry nitrogen. Nitrogen is inert and inexpensive. A specialized pressure regulator is needed to provide only a slight pressure differential in the chiller. The nitrogen must be removed completely before the chiller is started. This is done by the chiller's purge unit.

Also Finds Refrigerant Leaks

As discussed in [Measure 2.7.1](#), it is difficult to find air leaks into a chiller that has low-pressure refrigerant. The methods in this Measure can be used to pressurize the chiller to force refrigerant out of the chiller through any leaks that exist. Then, ordinary refrigerant leak testing methods will reveal where the air leaks are located. For finding leaks, the pressure is increased temporarily to several PSI. This is a standard feature of refrigerant warming systems.

ECONOMICS

SAVINGS POTENTIAL: Savings in refrigerant vary with the size and leakiness of the chiller system. Several hundred dollars per year is typical. The main benefit is a long-term saving in chiller maintenance costs.

COST: Approximately \$2,000 to \$3,000 for the equipment. Several hundred dollars worth of connecting pipe are needed. Installation typically takes about 12 hours.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Refrigerant warming equipment is less cumbersome to use than inert gas pressurization, and it allows precise control of the pressure differential. However, refrigerant warming is still novel, so check performance with current users before you buy. Pressurization with inert gas may be the best option if idle chillers are located in a very cold space, or if the evaporator isolation valves are not tight.

INSTALLATION: Let the vendor install the equipment. This avoids warranty disputes. Good workmanship is needed to avoid an air leak at the sensor connections.

SCHEDULING: Use your yearly maintenance schedule to remind you to follow the procedures for idling the chillers. Schedule periodic checks of operation during the season when chillers are idle. Put a place for this on the plant operating log.

EXPLAIN IT: Operators will have no idea what the equipment is supposed to do unless you explain it. Install a permanent, clearly written instruction placard at the equipment.

MEASURE 2.7.5 Drain the water from the evaporators and condensers of idle chillers.

RATINGS

New Facilities	Retrofit	O&M

A small leak that allows liquid water to enter a chiller from an evaporator or condenser is much more serious than a small air leak. Much more water enters the chiller this way. Purge units are much less able to remove liquid water. The hydrostatic pressure in the chilled water system or cooling tower system creates a much larger pressure differential to force the water into the system than does atmospheric pressure.

You can easily prevent water leakage into the chiller when the chiller is idle for extended periods. Simply drain the water from the evaporator and condenser. You don't have to drain the entire water system to do this. You already have isolation valves that are installed to allow maintenance on these heat exchangers. Close these valves and drain the heat exchangers.

(You cannot use the method of [Measure 2.7.4](#), pressurizing the inside of the chiller, to prevent leakage of water into the chiller from evaporators and condensers. Even if you could pressurize the refrigerant side enough to overcome the hydrostatic pressure of the water, the high internal pressure would accelerate loss of refrigerant through any leaks in other parts of the system.)

Piping Improvements

If you do not drain the entire system when you drain the chiller, you may need some pipe and valve modifications to make draining easy and trouble-free. Expect the isolation valves to leak somewhat. The drained condenser or evaporator is filled with air, so water that leaks into it can rust the steel parts.

To prevent this, arrange the piping so that any leakage through an isolation valve is diverted to the sewer without the water entering the heat exchanger first. A simple drain tap at a low point in the water line should suffice. Visualize where water from a leaking isolation valve would pool. If this is in a portion of pipe outside the chiller, install a small drain at this point.

If water from a leaking isolation valve would drain into the evaporator or condenser, or into the water box of a larger heat exchanger, modify the pipe to keep the

System Design for Efficient Low-Load Cooling

The Measures in this Subsection are major changes to the chiller plant that increase cooling efficiency at low cooling loads. The three Measures are alternative approaches to this goal. Some of the Measures in other Sections can improve the part-load efficiency of a chiller system, but they are usually less effective.

In most applications, the cooling load is much lower than the peak load for most of the cooling season. To achieve good efficiency under all load conditions, you need chillers that are sized so that no chiller is forced to linger at an inefficiently low load. In addition, you may want a chiller of a separate type to satisfy low loads.

One class of energy waste that results from low-load operation is inefficiency of the chillers and their auxiliary equipment. Unfortunately, the types of chillers that are most efficient at full load (centrifugal and screw compressor types) suffer serious loss of efficiency at reduced loads. While modern versions of these chiller types have greatly improved part-load performance, many machines that are presently installed have poor part-load efficiency. (See [Reference Note 32](#), Compression Cooling, for more about chiller efficiency characteristics.)

Another class of low-load energy waste is false loading. This is done to avoid cycling chillers on and off when the cooling load is less than their minimum capacities. False loading throws away the portion of the chiller output that is not required. This is an extremely wasteful way of dealing with reduced cooling loads. It is often encountered with centrifugal chillers, because of their inability to operate at low output. Especially with older centrifugal chillers, the minimum load is a large fraction of full load. False loading is also encountered with cooling machines having other types of compressors, including screw and reciprocating compressors.

Chillers can be false-loaded internally, which is done by using hot gas bypass. Or, chillers can be false-loaded externally, by adding unnecessary cooling load. For example, chillers can be loaded by increasing reheat in air handling systems, by increasing outside air quantities, or by cooling vacant spaces.

Defects in the chiller may restrict throttling ability, raising the load at which false loading is employed. For example, if the external linkage that actuates the inlet guide vanes of a centrifugal chiller is not adjusted properly, the vanes may not close fully, limiting turndown. Another problem is instability of the control system, so that the chiller output oscillates wastefully at low load. This can result from play in linkages, improper control installation, improper charge, and other causes.

If some parts of a facility continue to require cooling outside the normal cooling season, cooling

efficiency will be especially low during this period. For example, chillers that serve multizone units must operate continuously in order to maintain a constant cold deck temperature in the air handling units. You may be able to eliminate such waste by modifying the application. For example, [Subsection 4.6](#) recommends modifications of multizone air handling units that eliminate the need for continuous chiller operation.

Inefficient chiller operation at low load reduces the benefit of energy conservation measures that you accomplish to reduce the cooling load. For example, if you add expensive sun shades to reduce solar load, they provide no economic benefit during periods when false loading is used. When the cooling load rises above this minimum, the conservation benefit of the sun shades is limited to the difference between the actual cooling load and the false loading level.

MEASURE 2.8.1 Install chillers and auxiliary equipment of appropriate size to avoid extended operation at low load.

RATINGS

New Facilities	Retrofit	O&M
A	C	

Your primary method of avoiding inefficient operation at low loads is to select the chiller sizes carefully, and to match the sizing of the chiller auxiliary equipment to the individual chillers. Your goal is to select a combination of chiller sizes that allow the plant to operate efficiently under every level of cooling load that may occur for a significant length of time.

For example, if the chiller plant provides air conditioning, it should be able to handle spring and fall loads as efficiently as summer loads, and it should handle nighttime loads as efficiently as daytime loads. This may seem obvious, but you probably don't have to travel far to find a chiller plant that violates this principle. Commonly, you will find a plant that has two enormous chillers. One is sized for the peak cooling load, plus a large margin. The second chiller, identical to the first, sits there as a standby unit. For most of its operating hours, the one chiller that runs is operating at greatly reduced efficiency.

In both new construction and retrofits, you face a dilemma when selecting chiller sizes: the chiller types that are more efficient at full load tend to be most limited in their ability to operate efficiently at low load. This conflict between full-load and part-load efficiency is most severe with centrifugal chillers, and it is also significant with screw compressors. The best of the newer models of centrifugal and screw chillers have greatly improved their part-load efficiency, but this factor is still important.

In new construction, you can usually select an efficient combination of chiller sizes and types without adding much to the cost of the plant. You can typically maintain efficient chiller performance with only one or two chiller sizes. In a large plant with a highly variable load profile, you may wish to use three chiller sizes. You may actually save some money by using a combination of sizes. This is because you need less reserve capacity if you combine chiller sizes intelligently.

Retrofit applications are more challenging. You probably already have all the chiller capacity you need. The cost of installing another chiller to handle low loads is high. Cost usually limits you to one additional chiller. This chiller will usually be smaller than the existing chillers. It must be small enough to handle the lowest loads efficiently, but large enough to avoid operating an existing chiller at inefficiently low load. Modern chillers are substantially more efficient than older units. If the existing chillers are old, you want to make the new chiller larger so that it carry more of the cooling load.

SUMMARY

Avoids a major cause of inefficiency with centrifugal, screw, and absorption chillers. May also reduce maintenance and labor costs. May cost nothing in new construction. Expensive as a retrofit.

In a group of chillers, the one that operates first is called the "lead" unit. This chiller is the most efficient at the low loads that it serves. It is usually the smallest unit in the plant. As the cooling load increases to the point that the lead chiller cannot carry the load alone, another chiller starts. The best distribution of the cooling load between the chillers depends on their relative efficiency characteristics. See [Measure 2.1.1](#) for details.

Base Your Decision on the Future, Not the Past

In retrofit applications, an apparent disadvantage of this Measure is that it keeps more of the original chiller capacity idle. This is a matter of psychology rather than engineering or economics. There is a natural inhibition against correcting a chiller sizing mistake if the original equipment remains as a monument to the mistake.

However, from a purely economic standpoint, the correct approach is to view the original investment as a sunk cost, and to consider only the economics of the new investment. Your economic analysis should consider the salvage value of any chillers that you may be able to sell as a result of adding the new lead chiller.

Efficiency Features of the Main Chiller Types

See [Reference Note 32](#), Compression Cooling, and [Reference Note 33](#), Absorption Cooling, for the characteristics of different types of chillers. The following discussion deals primarily with the chiller characteristics that matter when selecting chiller sizes to maximize efficiency.

Although the chiller type is the main factor in part-load efficiency, there are major differences among different models of a given type. Pay attention to the

differences between different models. Be specific about acceptable model numbers when acquiring a chiller by using a bid specification. Otherwise, contractors or suppliers may substitute cheaper equipment that is less desirable in efficiency, features, or reliability.

■ Centrifugal Chillers as Lead Chillers

Some centrifugal chillers now combine variable-speed drives with conventional inlet guide vane throttling. This substantially improves their COP at partial loads. This improved part-load performance may make a centrifugal chiller appropriate for use as a lead chiller, if it is small enough in relation to typical low loads. Centrifugal chillers are available in sizes as small as 100 tons, although their cost per ton is high in small sizes.

■ Screw Compressor Chillers as Lead Chillers

The peak efficiency of screw compressor chillers is less than the peak efficiency of centrifugal machines, but they are able to operate at reduced loads with less loss of efficiency. Furthermore, most modern screw chillers are tolerant of cycling on and off at minimum load, unlike centrifugal machines. Screw machines are available in sizes as small as about 25 tons, although their cost per ton is relatively high in smaller sizes.

■ Reciprocating Chillers as Lead Chillers

The full-load efficiency of reciprocating chillers is substantially less than that of centrifugal and screw compressor machines. This difference in efficiency exists for fundamental physical reasons, and it will probably widen as centrifugal and screw chillers become more efficient. Reciprocating chillers unload more efficiently than centrifugal chillers, but even their advantage at low load is disappearing. The remaining niche for reciprocating chillers is small cooling loads, less than about 100 tons. Most reciprocating chillers tolerate cycling well, and they lose relatively little efficiency down to zero load.

A difficult control problem arises if a reciprocating chiller is used as the lead chiller with centrifugal chillers or screw compressor units. Reciprocating chillers use step control of capacity, so their output is usually controlled by sensing return water temperature. In contrast, centrifugal and screw chillers typically control output by sensing supply water temperature.

One way to use a reciprocating chiller as a lead unit is to shut down the reciprocating chiller when a larger non-reciprocating chiller is started. However, this approach makes the lead chiller useless for carrying part of the load in the event that one of the larger chillers should fail.

Another approach is to use supply water temperature control with the reciprocating chiller. This requires the control system to anticipate the changes in supply chilled water temperature as the compressor stages. This is a touchy method of control for reciprocating chillers,

especially if they are operating in parallel with other types of chillers.

■ Scroll Compressor Chillers as Lead Chillers

Chillers that use scroll compressors control output by cycling on and off. They are presently similar to reciprocating chillers in efficiency. They may gain an advantage in the future because they do not have all the inherent efficiency limitations of reciprocating units. Like reciprocating chillers, they generally control output based on return water temperature, and therefore they have the same problems in operating in parallel with throttling types of chillers. At present, scroll compressors occupy the bottom end of the size range, but they can be ganged together to achieve any desired capacity.

■ Absorption Chillers

Absorption chillers are unsuitable as lead units in most applications. Start-up and shutdown is slow, and requires a careful sequence to avoid crystallizing the salt absorbing solution, as well as to avoid other troubles. Absorption chillers are best used to exploit an inexpensive source of heat, and to minimize electricity demand charges.

Exploit Low Condensing Temperatures

Chiller efficiency improves radically at lower condensing temperatures, provided that the chiller is designed to exploit low condensing temperature. This feature is especially important for chillers that operate at low loads, because low loads typically occur at times when the outside air temperature is low. Make this an important factor in selecting your lead chiller. Be aware that chillers typically have limitations in their ability to exploit reduced condensing temperature. See [Measure 2.2.2](#) for details.

How to Select Chiller Size

Sizing is most critical for the lead chiller, because it operates at the lowest percentages of load. If the lead chiller is a throttling type and if it is too large, it too will operate inefficiently at low loads. If the lead chiller is too small, the next chiller may operate at inefficiently low load when it starts. Consider these factors in sizing a lead chiller:

- **cooling load profile.** Analyze the cooling load profile in detail, and match it to the part-load efficiency profiles of the chiller types you are considering. In existing facilities, measure the cooling load profile with hourly measurements of chiller load over the course of a cooling season. The cooling load pattern varies from one season to another, so try to get data from several years. If the plant is new, or if you do not have load data, you have to calculate the load profile. In most cases, you should use an energy analysis computer program for this.

- **reserve capacity requirements.** In an existing chiller plant, adding a small lead chiller always increases reserve capacity. If you are installing a new chiller plant, cost limitations may force you to compromise between part-load efficiency and reserve capacity.

For example, with a design load of 2,000 tons, it would be common to install three 1,000 ton chillers, one of which is a spare unit. In contrast, a combination of a 400 ton lead chiller and two 1,000 ton units would be considerably more efficient, and it would cost less. The disadvantage is that failure of one of the 1,000 ton chillers would reduce the available capacity to 1,400 tons. However, with a typical load profile, this capacity would suffice most of the time. Even if a chiller failure occurred during a peak load period, capacity would probably be adequate to keep the facility operating while the failed chiller is repaired.

- **other cooling conservation activities.** Consider the effect of other energy conservation measures on the cooling load, especially measures that reduce cooling load during low-load conditions. For example, eliminating reheat in air handling systems (see [Section 4](#)) and window treatment (see [Section 8](#)) dramatically reduce the cooling load during mild weather. These improvements reduce the total plant capacity requirement and provide more freedom in selecting the lead chiller for efficient part-load performance.
- **efficiency of the other chillers.** When sizing a lead chiller for an existing facility, consider which chiller will be started second. It might be the smallest of the original chillers, or a different one that is more efficient. Select the relative sizing of the first and second chillers so that both can operate efficiently at the point where the second chiller starts, or the second can operate efficiently if the first is turned off. If one or more of the original chillers is especially inefficient, consider increasing the size of the new lead chiller to allow the inefficient machine(s) to be placed out of service either permanently or on a seasonal basis.

Ability to Reduce Auxiliary Load

In retrofit applications, adding a smaller lead chiller may or may not give you an opportunity to reduce the energy consumption of auxiliary equipment. It depends on these factors:

- **chilled water pumping.** You can reduce chilled water pumping energy only if one of the chilled water pumps is sized to match the capacity of the lead chiller. Also, the end-use equipment needs to use throttling control valves instead of bypass valves. See [Measure 2.5.2](#) for more about this.

- **condenser water pumping.** If the new lead chiller has a water-cooled condenser that is served by an existing cooling tower and condenser water system, you can save pumping energy by installing a condenser water pump sized specifically for the new chiller.
- **condenser cooling fans.** If the condensers are cooled by water, the fan energy used by the cooling towers is proportional to the cooling load. So, adding a lead chiller probably will not save much fan power. However, if you improve fan capacity modulation (see [Measures 2.4.1 ff](#)) when you install the lead chiller, this will save fan energy.

Base Your Decisions on Detailed Calculations

The cooling load fluctuates continuously in most applications. Dealing with this accurately requires you to calculate the moment-to-moment energy consumption of the plant over the course of a year. Repeat the calculation for different chiller size combinations to find the most economical combination. In a retrofit application, calculate how a system with a lead chiller would compare to the existing system. To simplify these tedious calculations, use an appropriate computer program. See [Reference Note 17](#), Energy Analysis Computer Programs, about these programs.

Control the Chiller Loading Efficiently

Clever equipment sizing will not provide the expected benefit unless you arrange to start and stop the chillers in the sequence that satisfies the cooling load most efficiently. Doing this reliably requires operator training, effective documentation of procedures, and continuing supervision. Or, it requires reliable controls. In plants that have a variety of chiller types and/or sizes, you need to decide the proper sequence in terms of the percentage of load at which each chiller is turned on or off. See [Measures 2.1.1 ff](#) for details.

Consider Using the Lead Chiller for Heat Recovery

You may be able to use some of the heat that is rejected by the chillers. Sometimes, this is done with a small chiller that has special characteristics for heat recovery. The heat recovery chiller is usually loaded ahead of the other chillers, so consider combining the functions of a lead chiller and a heat recovery chiller. See [Measure 2.10.3](#) about chiller heat recovery.

Comparison to Measure 2.8.2

[Measure 2.8.2](#) deals with a particular situation in which a chiller plant is kept in operation at inefficiently low loads to serve a few small applications. To deal with this situation, it may be more efficient to shut down the chiller plant entirely during periods of low loads, and to provide local cooling units for the small

applications. For a comparison of the two approaches, see [Measure 2.8.2](#).

ECONOMICS

SAVINGS POTENTIAL: 5 to 20 percent of chiller plant operating cost, in typical applications. Savings are greatest if false loading is presently used to reduce chiller output.

COST: In new facilities, selecting chiller sizes for optimum efficiency may cost little or nothing extra. In retrofit applications, an additional chiller costs from \$300 to \$1,000 per ton of capacity, including design, auxiliary equipment, and installation.

PAYBACK PERIOD: In new facilities, the payback period may be short. In existing facilities, the payback period ranges from several years to many years. The payback period may be immediate if a new lead chiller replaces a chiller that needs to be replaced.

TRAPS & TRICKS

PLANNING: The design procedures are routine, but you need to make an exceptionally thorough analysis to select the optimum chiller sizes. If you combine different types of chillers, be sure that you can control them to operate together efficiently. Design the auxiliary equipment to minimize the auxiliary load.

SELECTING THE EQUIPMENT: Select the lead chiller(s) with an emphasis on high turndown ratio. Invest in efficiency options.

TRAINING AND FOLLOWUP: The benefit of this major aspect of plant design may be lost if the plant operators do not understand how to sequence the chillers efficiently. Make sure that they are properly trained. Put clear instructions in the plant operating manual. Check the chiller plant log periodically to verify that the chillers are being sequenced and loaded efficiently. Review [Measures 2.1.1 ff.](#)

MEASURE 2.8.2 Install local cooling units to allow shutting down the central chiller plant during periods of low load.

A common problem is that a few small cooling applications require the operation of a large chiller for long periods of time while the rest of the facility is shut down. For example, the computer rooms in an office complex typically need continuous cooling, even though most of the complex is shut down more than half the time.

The same problem occurs on a larger scale if a central chiller plant serves an extended facility, such as a college campus or a military base. For example, if a college campus is mostly shut down during the hot summer months, the chiller plant may still have to operate to serve one administrative building.

In such cases, consider installing separate small cooling units to serve the applications that operate on longer schedules. This allows you to shut down the central chiller plant entirely for a large part of the time.

Potential for Energy and Cost Savings

The benefit of this Measure is based on marginal differences in efficiency and energy costs. When you calculate the potential benefit, take the following factors into account.

■ **Relative Energy and Demand Costs**

The energy used by local cooling units may not cost the same as the energy used by the central plant. Even if the central chillers and the local cooling units both use electricity, the electricity cost may differ if the local cooling units are not served by the same electricity meter. The cost difference is greatest if the different meters are subject to different rate schedules. For example, a central chiller plant may be served under a lower rate than the other buildings in a complex.

Even if the rate is the same, differences in the amount of electricity consumed through each meter may affect the average cost. This effect does not occur if the consumption through all meters is consolidated before the rate is applied.

If the central chillers and the local cooling units use different energy sources, the energy costs are certain to be different. The most common example of this situation is that the central plant uses absorption chillers that are direct-fired or operated by steam.

Another possibility is that the local cooling units use an energy source other than electricity. For example, small cooling units operated by fuel-fired reciprocating engines have gone through several episodes of popularity in recent decades.

Comparing the cost of electricity and other energy sources is complicated by electricity demand charges,

which differ by hour, day, and month. [Reference Note 21](#), Electricity Pricing, explains demand charges. To account for the fluctuations in electricity prices, you may need to use an energy analysis computer program to calculate your total yearly costs. These programs are explained in [Reference Note 17](#), Energy Analysis Computer Programs. Even then, you face the possibility of large future changes in the relative cost of electricity and other energy sources.

■ **Relative Efficiencies of Central and Local Cooling**

To calculate the comparative performance of central and localized cooling, you have to know the detailed efficiency characteristics of both sets of equipment.

Smaller, standard cooling units made in the United States and some other countries are rated for efficiency. See [Reference Note 31](#), How Cooling Efficiency is Expressed, about the types of ratings being used. Be clear about the energy consumption that is covered by the efficiency ratings of local cooling units. For example, the Seasonal Energy Efficiency Rating of a split system may or may not include the energy consumption of the condenser cooling fans. Include the energy needed for any external equipment, for example, for a separate condenser cooling water system.

For larger, engineered cooling systems, don't depend on the efficiency figures in the catalogs. Require certified performance data from the manufacturer. Remember that the COP's given for large chillers apply only to the chiller itself. They do not include energy requirements for separate condenser cooling equipment, for chilled water distribution, or for the end-use equipment, such as air handling units and fan-coil units.

These are large energy loads, so be sure to include them in your calculation. For example, with a central chiller plant, the saving in chilled water pumping may be the major factor that justifies installing local cooling units.

In retrofit applications, you may or may not be able to get reliable chiller efficiency information from the manufacturer. Reliable data may not be available for older chillers, and older machines may have lost efficiency for a variety of reasons. Since a lot of money is at stake, make the effort to measure the efficiency of installed chillers. Install an accurate BTU meter in the chilled water output, and use a reliable method of measuring the energy input. See [Reference Note 16](#) for methods of measuring energy output, and [Measure 2.1.1](#) for various methods of measuring chiller energy input.

The efficiency of chillers varies with load, especially if they have modulating control. To calculate the energy consumptions of both system configurations over a yearly cycle of operation, you may need to use an energy analysis computer program.

■ Ability to Reduce Central Plant Operating Cost

Shutting down the central plant may eliminate most of its non-salary overhead costs, including chiller maintenance, water treatment, and housekeeping energy consumption, such as lighting and ventilation.

Labor is usually the largest overhead cost. It is difficult to get skilled plant operators on a seasonal basis, so the chiller plant staff may have to be kept on the payroll all year. One possible way of reducing labor cost is to reassign chiller operators to seasonal duties that normally would require other personnel.

How to Select Local Cooling Units

See [Measure 5.5.3](#) for tips on selecting local cooling units for efficiency. See [Reference Notes 32](#) and [33](#) for details of different types of cooling equipment.

For most applications, local cooling units are so small that they are limited to reciprocating or scroll compressors. In extended facilities where even the local loads are large, it may be appropriate to use a screw chiller or even a centrifugal chiller to carry local cooling loads. In this case, see [Measure 2.8.1](#) about installing smaller chillers to serve low loads.

Installation Considerations for Local Cooling Units

Central chiller plants are popular because localized cooling units have a number of disadvantages, or at least, they are more bother. If you install local cooling units, minimize the potential problems. Consider the following points.

■ Ability to Control the Operation of Local Units

It takes more effort to monitor efficient operation of a number of distributed cooling units. Local units are less apparent to the physical plant staff, so they may

operate unnecessarily for long periods of time. This can dissipate much of the potential savings. Therefore, provide reliable controls to limit operation of the local units to times when they are needed. Refer to [Subsection 5.1](#) for methods of controlling local units.

Even cooling units that are supplied by a central chiller plant can operate when they are not needed. However, units served by the central plant cannot waste energy when the plant is not operating, whereas local cooling units can waste energy at all times.

■ Ability to Provide Condenser Cooling

Any local cooling unit requires an external condenser or heat rejection unit. Simple split systems are usually satisfactory if the cooled space is located a short distance from a suitable condenser location. For longer distances, consider water-cooled units that are served by a small cooling tower. This configuration has the advantage that a single cooling tower can serve any number of local cooling units.

In extreme cases, you may have to cool condensers using domestic water. This requires about 50 gallons of domestic water per ton-hour. If you use this method, try to save water cost by recovering the used water for further use. Even better, try to exploit the heat collected in the water. See [Measure 5.5.9](#) for details.

■ Space and Appearance

Local cooling units take up space and affect the decor. A large variety of units are available that may minimize the space requirement, or even avoid it. For example, some units are made for installation in ceiling plenums. Others are available with attractive evaporator enclosures that are mounted on the wall above the working level. Another possibility is installing the cooling unit in an adjacent vacant space, and ducting air into the cooled space.

■ Noise

The compressor makes most of the noise, so try to select units that keep the compressor out of the occupied space. Great strides have been made in reducing the noise levels of condenser and evaporator fans, so shop for a quiet unit.

■ Wiring Amperage

Cooling units are large users of electricity compared to other equipment in the spaces they serve, so you may have to increase the amperage capacity of the wiring that serves the area you plan to cool locally.

■ Distribution of Local Units

If there is more than one candidate for localized cooling within an area, there may be several ways to provide the cooling. For example, there may be a choice between installing a number of small air conditioning units for individual spaces, or installing a larger local unit to serve several spaces.

Comparison to Measure 2.8.1

In many cases, this Measure is an alternative to installing a small lead chiller in the central plant, as recommended in [Measure 2.8.1](#). In deciding between the two approaches, consider these issues:

- **how much the efficiency of the central plant will be improved during the main cooling season.** Careful chiller sizing ([Measure 2.8.1](#)) can virtually eliminate inefficiency caused by operation at low loading. If you shut down the chiller plant for extended periods, such as the winter season, the chillers may still operate at inefficiently low loads, although not as long. This is because periods of low load occur even during the seasons of heavy cooling. Furthermore, removing some of the load from the central chiller plant ([Measure 2.8.2](#)) worsens the mismatch between the capacity of the chillers and the cooling load they serve.
- **relative cooling efficiency during the low-load season.** [Measure 2.8.2](#) eliminates chilled water pumping power, distribution losses, and auxiliary equipment energy consumption during the chiller plant shutdown period. On the other hand, the local cooling units may or may not be more efficient than the central plant chillers when they are operating at low load. If the local cooling units are less efficient than the central chillers, this is not important if the local cooling units are small and the low-load energy losses of the chiller plant are large. It may be important if a substantial fraction of the cooling load is converted to localized cooling.
- **relative cost.** If you need only a small number of local cooling units to shut down the central plant during low-load periods, this Measure may be much less expensive than [Measure 2.8.1](#).

These factors balance in a complex way, so that it may not be obvious which Measure is better. Use the

same computer program discussed previously to compare the two approaches.

ECONOMICS

SAVINGS POTENTIAL: 5 to 30 percent of total cooling energy consumption. There may also be significant savings in central plant maintenance and labor costs.

COST: The cost of local cooling units ranges from \$5 to \$15 per square foot (\$50 to \$150 per square meter) of conditioned space, for common applications. In new construction, local cooling reduces the capacity requirement of the central chiller plant, which partially offsets the cost of the local cooling units.

PAYBACK PERIOD: Less than one year, to many years, depending on the amount of local cooling equipment that has to be installed.

TRAPS & TRICKS

DESIGN: It may take lot of thought and analysis to get the most out of this approach. Investigate conditions at each of the locations where you would install local cooling units, do load calculations for each location, and figure out the best method of installing the new equipment. Consider whether the units should also have heating capability, and coordinate this with [Measure 1.12.2](#).

SELECTING THE EQUIPMENT: There is a wider range of efficiencies in small cooling units than in large central chillers. Shop the market thoroughly. Stress efficiency, along with other important characteristics, such as noise level and control features.

OPERATION: This activity increases the number of units that need to be controlled, and hides them from the physical plant staff. Provide reliable controls to prevent unnecessary operation. Use the appropriate control Measures from [Subsection 5.1](#).

MEASURE 2.8.3 If a facility has several chiller plants, provide cross connections that allow shutting down the least efficient chillers.

Larger facilities may be served by several independent chiller plants. In new facilities, this may be done to allow separate areas to operate independently, or to reduce distribution cost. In existing facilities, separate plants may have been built as the facility expanded at different times, perhaps with insufficient regard to the equipment that already existed.

In all these cases, interconnecting the separate plants may save energy by:

- allowing the most efficient chillers in any plant to serve the whole facility
- allowing large chillers to operate at higher, more efficient loading during periods of low cooling load
- reducing the total energy required for condenser cooling and plant overhead.

The savings potential of the first two points is covered in [Measure 2.8.1](#). The savings potential of the third point is covered in [Measure 2.8.2](#).

On the negative side, interconnecting the plants requires extending the distribution piping. This may require additional chilled water pump power, and it may increase heat loss.

An Example

Consider a facility that has two separate chiller plants. One plant has two centrifugal chillers rated at 1,000 tons each, and the other plant has two centrifugal chillers rated at 500 tons each. Both chiller plants operate efficiently during the peak cooling season. However, during the transitional season, the larger plant has an average load of only 200 tons, and the smaller plant has an average load of only 100 tons. These loads are inefficient for both plants.

If the plants are connected, the total average transition season load of 300 tons is combined to become an efficient load for one of the 500-ton chillers. The larger chiller plant can be shut down for the entire transition season, saving a considerable amount of plant auxiliary and overhead cost.

During the warmest part of the year, you may be able to shut down the small chiller plant except during peak days, and to serve the entire facility with the larger plant alone. If the plant sizes and other conditions are favorable, a single chiller plant crew might shuttle between the two plants as the seasons change.

Piping Design Issues

The major expense of interconnecting chillers is the cost of the piping, which in many installations can rival the cost of chillers themselves. Pipe diameter is the

dominant factor in the cost of piping. Both material and installation costs of piping are high.

Design the interconnection to minimize pump power. It is pointless to save energy in the chillers only to lose it in the pumps. Pumps have a hunger for energy that is insidious because they are small and operate quietly. If a pumping system operates at full flow under all load conditions, pump energy consumption can become a major part of total plant energy consumption. Pump energy consumption in distribution systems can be reduced by using variable-flow pumping, which is recommended by [Measure 2.5.2](#).

The pump power needed to overcome the resistance of the added piping is sensitive to the pipe diameter. Bigger pipe allows smaller pumps. The cost saving with smaller pumps may substantially offset the higher cost of larger pipe. Do enough sketching and calculating to find the best balance between pump power and piping cost.

Use these techniques to minimize piping cost:

- **be selective about the interconnections.** In facilities where there are several chiller plants, you may be able to interconnect them in various ways. If cost were no object, the best approach would be to create a large loop header that allows chilled water from any chiller plant to flow to any user. This may be an unnecessary extravagance. Most of the benefit of this Measure occurs under low-load conditions, so the connections can be optimized to transmit water from the low-load chillers to the low-load applications.

- **limit the use of the interconnections to periods of low cooling load**, i.e., to periods when some of the chillers are turned off. Pressure losses increase rapidly as the flow rate increases, so consider limiting operation of the interconnections to times when flow rates are low. This is a practical approach because the interconnections typically are not needed during periods of high load, when all the chiller plants are operating. However, this strategy adds control complications that may be difficult for plant operators to understand.
- **minimize average flow velocity with variable-flow pumping**. The higher cost of larger pipe is a strong motivation to reduce the average flow rate. Variable-flow pumping is an effective way of doing this. See [Measure 2.5.2](#) for details.

In retrofit applications, if the connections are fairly short, you may be able to use the existing chilled water pumps to push water through the connecting lines. Resistance to chilled water flow comes from the end-use coils, control valves, chiller evaporators, and piping. The resistance of straight pipe is relatively low. If you use variable-flow chilled water pumping, the piping resistance drops when the cooling load is low, because the resistance is proportional to the square of the flow rate.

Pipe resistance becomes a major factor if the connections are long, especially if the connections are used when the cooling load is high. In this case, you may need additional pumps. Consider adding variable-flow pumping, especially if chilled water pump modifications are required. This may substantially reduce the average pump power.

Exploit Interconnections to Improve Reliability and Capacity

In deciding how to design the interconnections, consider the value of improving the facility's overall reliability and capacity. If you foresee a need for additional cooling capacity, interconnection may be a less expensive alternative to purchasing new chillers. This possibility is enhanced if there is diversity of cooling loads, so that an interconnected system needs less total chiller capacity than isolated chiller plants.

Interconnections provide reserve capacity in the event of a chiller failure in any of the connected plants. This reserve capacity is limited by the capacity of the interconnections. This may argue in favor of larger pipe sizes.

Optimize Control of the Entire System

Interconnection requires more sophisticated control of chiller operation. Instead of simply starting chillers and letting them run, operators will have to continually start and stop chillers and control the interconnections in a manner that optimizes overall efficiency. Failure

of the operators to control the flow of energy between plants will reduce or negate the purpose of the modification. For this reason, proper training of plant operators is a vital part of this activity.

Automatic controls are better than people at "remembering" repetitive functions. Use them wherever it is practical to do so. [Subsection 2.1](#) presents automatic methods of sequencing chiller plant equipment. However, using automatic controls does not relieve managers of the responsibility of understanding the control functions and ensuring that they are accomplished. Automatic controls that are not understood will be overridden by plant operators.

Try to Reduce Central Plant Operating Cost

Shutting down a central plant eliminates most of its non-salary overhead cost. These include chiller maintenance, water treatment, and housekeeping energy consumption, such as lighting and ventilation. Labor is usually the largest overhead cost. Shutting down a chiller plant provides a saving in labor cost only if the size of the staff can be reduced, or if the staff can be assigned to other duties during the period of time that plants are shut down.

Base Your Decisions on Accurate Calculations

This modification is very expensive, and it produces its benefit by marginal improvements in efficiency. These improvements depend on the load profiles of the facilities served by all the chiller plants, on the efficiency profiles of all the chillers, and on the other factors discussed here. Calculations that include all these factors are complex. To get the most accurate analysis, use a computer program of the type covered by [Reference Note 17](#), Energy Analysis Computer Programs. Most of those programs are not designed to handle separate chiller plants serving a distributed load, so you may need ingenuity to get the program to model this configuration with acceptable accuracy.

ECONOMICS

SAVINGS POTENTIAL: 5 to 20 percent of total chiller plant energy consumption.

COST: Varies widely, from tens of thousands of dollars for short interconnections to millions of dollars for large facilities. This Measure may offer an immediate net saving if it provides an alternative to installing new chillers.

PAYBACK PERIOD: Several years or longer, except in especially favorable situations.

TRAPS & TRICKS

PLANNING AND DESIGN: Although the concept is simple, it is easy to be too hasty and overlook

opportunities for improving efficiency and reducing cost. A lot of money is at stake, so take your time.

TRAINING AND OPERATION: *For this expensive modification to be successful, chillers and system valves at different sites must be sequenced in a precisely defined manner. Operators in different locations must be well trained, coordinated, and alert. Automate the*

controls wherever it is practical to do so. Review the methods of [Measures 2.1.1 ff.](#)

EXPLAIN IT: *Make it easy for system operators to understand how the system is laid out and controlled. Install a large, well rendered diagram of the system at each operator stations. Install well designed placards on the cross connection valves and controls.*

Exploiting Low Ambient Temperature for Water Chilling

When the outside air temperature is lower than the inside temperature, you can use the low outside temperature to cool the water in a chilled water system. The cooling is enhanced by the evaporative cooling effect of the system cooling towers. The Measures of this Subsection use this principle to reduce the load on the chiller, or even to allow the chiller to be turned off.

These Measures can provide only a fraction of the full-load capacity of the chiller system. However, in air conditioning applications, the cooling load is usually low when the weather allows these techniques to be used. Some of the Measures require the chiller to be turned off, while others can reduce the load on the chiller while it is running.

Where to Consider These Measures

These Measures are expensive, so they must be able to operate for many hours per year to pay for themselves. The potential running time depends primarily on the following factors, which apply to all the Measures in a similar way.

■ Favorable Cooling Load Characteristics

These Measures are useful only if the facility requires a significant amount of cooling when the weather conditions are able to provide it. In other words, look for applications that have high heat gains during cool weather.

Buildings with a large amount of glazing have high solar heat gain, and these may be good candidates. Buildings with high internal heat gains may also be good candidates. High internal heat gain may come from intense lighting, energy-consuming equipment, and concentrations of people. The interior zones of large buildings always have net internal heat gain, because they have no natural path for rejecting heat.

Industrial process cooling may also benefit from these Measures.

At the other end of the spectrum, these Measures are not justified in buildings that avoid the need for cooling in cool weather, typically by opening windows. For example, apartment complexes, typical primary and secondary schools, and older buildings of all types tend to be ineligible.

■ Eligible Cooling System Characteristics

The feasibility of these Measures depends on the temperature requirement of the cooling application. In air conditioning applications, the goal is to maintain a space temperature around 75°F (about 24°C). In a typical mechanical air conditioning system, the air used to cool the space has a temperature of about 55°F (about 13°C). This air is cooled in a coil by chilled water, which typically has a temperature of about 42°F (about 6°C) at full load.

In order to use outside air to cool the chilled water, the temperature of the outside air must be lower than the temperature of the chilled water by some margin. In the case of evaporatively cooled systems, the wet bulb temperature of the air must be lower than the chilled water temperature.

From the preceding numbers, it is clear that cooling with outside air is not practical unless the temperatures in the system can be raised considerably. Fortunately, if the cooling load is low, the chilled water temperature and the supply air temperature may be much warmer than in normal operation. The feasibility of these methods depends on the extent to which higher temperatures can be used in the cooling systems.

The savings potential is greatest if the chiller plant serves only single-zone air handling systems or fan-coil units. In these types of equipment, the supply air temperature rises proportionally as the cooling load falls, so these units can use chilled water at higher temperatures. This provides the greatest opportunity to exploit the temperature differential between the outside and inside.

Variable-air-volume (VAV) systems and reheat systems provide substantially less opportunity for exploiting these methods. This is because the supply air must be held at a lower temperature to account for diversity in the cooling loads of the different spaces served by the air handling system. In these systems, it is essential to use supply air temperature reset (see [Measures 4.4.1 ff](#)) so that the systems can operate with the highest possible chilled water temperatures.

■ Whether Humidity Control is Needed

In normal operation, the humidity in spaces can be controlled by adjusting the temperature of the chilled water. Colder chilled water wrings more moisture out of the air at the cooling coils, reducing the space humidity. However, the Measures of this Subsection cannot provide much savings unless the chilled water temperature is allowed to rise as much as possible. This effectively eliminates humidity control.

In many locations, the lack of humidity control with these Measures is acceptable. Also, raising the chilled water temperature provides important energy conservation benefits, of which the most important are improving chiller efficiency and reducing reheat. High chilled water temperatures are not acceptable in locations

that are humid during cool weather, such as New Orleans and London. In such climates, the dehumidification provided by low coil temperature is as important as cooling.

(Modern air conditioning seems to increase the sensitivity of people to humidity level. To a large extent, this results from poor coordination of temperature with humidity. It also relates to the nature of indoor activities, to fashions in clothing, and to other factors that are less well understood.)

■ Favorable Weather Profiles

To make these Measures pay off, there must be many hours of weather that is cold enough to cool the chilled water adequately while the facility is operating. The Measures are most likely to be economical in moderate or cooler climates. They are unlikely to be economical in consistently warm climates, such as those of Miami or Singapore. They are also uneconomical in many applications in colder climates, such as those of Minneapolis or Hamburg, because cooling may not be required for a large number of hours.

These Measures also require a climate in which the relative humidity is usually low when the outside temperature is cool. This is because of the comfort considerations discussed previously, and also because most candidate cooling systems use evaporative cooling towers. The evaporative cooling is essential to making the Measures effective with the low outside-to-inside temperature differentials under which they operate.

With evaporative cooling towers, the “wet-bulb” temperature is the relevant factor, rather than the “dry-bulb” temperature. A rule of thumb is that feasibility of these Measures requires a large number of hours during which the wet-bulb temperature is below about 45°F. In arid climates, this corresponds to outside air temperatures less than about 60°F. In general, for a given outside air temperature, these Measures are more effective if the climate is drier.

The need to avoid freezing sets a lower limit on the condenser water temperature. The fill structure of most cooling towers is not designed to carry an ice load, so the cooling tower must be controlled to keep ice from accumulating. Evaporative cooling can cause freezing at air temperatures well above 32°F. The usual minimum condenser water temperature is about 43°F with a crossflow tower, and about 40°F with a counterflow tower. (Crossflow towers have a higher temperature limit because they do not cool the water uniformly.)

These temperatures are low enough for cooling chilled water in most applications. However, achieving these low temperatures without freezing the cooling tower requires accurately modulating the cooling tower output in proportion to load. Typically, this requires a variable-output fan drive (see [Measures 2.4.1 ff](#)), and perhaps additional features, such as periodic fan reversing to de-ice the tower.

In applications that need to chill a liquid during predominantly cold weather, consider using a dry heat rejection unit and antifreeze in the cooled liquid. This system is simple, which makes it reliable. However, it is restricted to applications that need cooling during colder weather. Dry coolers suffer too much temperature loss to be effective with the higher outside air temperatures of typical applications.

■ Ability to Use Heat Sinks Other Than Outdoor Air

With all these Measures, a cooling tower is commonly used to reject heat, using the atmosphere as a heat sink. More broadly, you can adapt these Measures to use any other available heat sink, provided that the heat sink has sufficient capacity and a temperature that is low enough. See [Reference Note 22](#), Low-Temperature Heat Sources & Sinks, about the various heat sinks that are available. Among these are ground water, rivers, and lakes.

Comparison of the Measures in this Subsection

All the Measures of this Subsection are alternatives to each other. They differ in these significant characteristics, which are summarized in Table 1:

- *whether the Measure can operate in conjunction with compressor operation.* Some of the Measures

cannot function while the chiller is operating. They are useful only when the cooling load is low enough for them to provide all the cooling that is needed. They are limited to a smaller number of hours of operation than the other Measures.

If the plant has more than one chiller, the chiller that exploits ambient cooling might operate in parallel with another chiller. However, this would require controls to limit the output of the chiller that does not have ambient cooling. Alternatively, the chiller with ambient cooling could feed chilled water to the other chiller for further cooling. However, this would require a series piping arrangement. Both of these approaches involve an additional level of complexity.

- *heat transfer steps.* The Measures of this Subsection move heat solely by the differential between the space temperature and the outside air temperature (dry-bulb or wet-bulb). This valuable temperature difference is usually small, so it is important to dissipate as little of it as possible in heat transfer. Table 1 shows the relative number of heat transfer steps needed by each Measure. The table does not include the evaporative heat transfer in the cooling tower or heat transfer from the chilled water to the end-use cooling equipment, because

these are common to all the Measures. This comparison is useful for understanding the theoretical limits of each technique. However, the number of heat transfer steps is not an accurate guide to relative efficiency. For example, the refrigerant-to-liquid heat transfer steps in chiller free cooling involve less temperature loss than typical liquid-to-liquid heat transfer.

- ***parasitic equipment load.*** These Measures can save only a fraction of chiller energy consumption because they operate only at low cooling loads. Therefore, the system pump and fan energy consumptions are large in relation to the savings, and may offset them substantially. The table shows which auxiliary equipment must operate for each of the Measures.
- ***whether variable-flow chilled water pumping increases the feasibility of the Measure.*** Variable-flow chilled water pumping (see Measure 2.5.2) is growing in popularity as an energy conservation feature in chilled water plants. One of the effects of variable-flow pumping is to increase the return chilled water temperature. This increases the feasibility of the Measures because the warmer return chilled water has a greater tendency to reject heat to the outside.

Variable-flow chilled water pumping is not an issue with one of the Measures, a “waterside economizer,” because this approach does not use the chilled water system. Variable-flow pumping may be incompatible with another Measure, the “strainer cycle.”

Alternatives to the Measures in This Section

You have a rich assortment of choices if you want to exploit the coolness or dryness of the outside air for cooling during mild weather. Consider all the possibilities before making a selection.

The most direct competitor to the Measures of this Subsection is the airside economizer (Measure 4.2.5), which brings outside air directly into the air handling systems. This technique offers the greatest energy saving

potential because it involves no heat transfer steps. It is simple in concept, and well proven in actual experience. An airside economizer is the preferred method in most cases where it is practical to install the necessary ductwork and dampers.

The only major disadvantage of the economizer cycle is increased intake of outside air pollutants. Prevailing opinion tends to view outside air as less dangerous than inside air, so this disadvantage occurs only in a limited number of locales. Airside economizers cannot be used in multizone and dual-duct air handling systems unless you make unusual modifications to the air handling units.

A variety of other low-energy methods of cooling are available for cooling spaces directly. These include:

- ***ventilating the space directly,*** by installing openable windows, by using existing windows effectively, or by installing ventilation openings and fans
- ***using space air circulation fans,*** which cool people by “wind chill factor.” Circulation fans can enhance the effect of mechanical air conditioning.
- ***using room dehumidifiers.*** These provide a significant cooling effect by themselves in humid climates. They may also work in combination with conventional air conditioning to reduce overall energy consumption.
- ***using evaporative space coolers.*** This method of cooling has much lower energy consumption than mechanical cooling. It is limited to dry climates.

Other Measures that Reduce the Effectiveness of These Measures

The benefit of the Measures in this Subsection and of the Measures mentioned previously is reduced by any actions that reduce heat gain. These include the Measures that improve envelope insulation (Section 7), that shade the spaces from solar gain (Section 8), and that improve lighting efficiency (Section 9).

The benefit of these Measures is also reduced by chiller heat recovery (Subsection 2.10), which offsets heating cost, and which may be an alternative to these Measures in some applications.

MEASURE 2.9.1 Install chiller “free cooling.”

RATINGS		
New Facilities	Retrofit	O&M
B	D	

“Free cooling” is a modification of a chiller or cooling system that allows direct heat exchange between the evaporator and condenser. In effect, the chiller acts as a heat exchanger between the cooling tower and the chilled water system.

The modification consists of a pipe with a valve that is installed between the refrigerant sides of the evaporator and condenser. The pipe bypasses the compressor, allowing refrigerant vapor to migrate freely between the evaporator and condenser when the compressor is not operating. Figure 1 shows how free cooling is installed in a chiller that has a multi-stage compressor.

When the outside air wet-bulb temperature is low enough to make the condenser water colder than the chilled water, refrigerant evaporated by the warmer chilled water migrates to the colder condenser. The

NORMAL CHILLER OPERATION

FREE COOLING

Trane Company

Fig. 1 Chiller free cooling Focus on the lower right. The weather is cold, so the condenser, on top, is colder than the evaporator, on the bottom. Therefore, refrigerant evaporates from the warmer evaporator, migrates to the condenser, and condenses. The liquid refrigerant flows back down to the evaporator, completing the cycle. The hardware on the left is for an inter-stage economizer, which is not necessary for free cooling.

refrigerant condenses in the condenser, giving up its latent heat, and the liquid refrigerant returns by gravity to the evaporator. This is a rapid and efficient means of heat transfer.

You may recognize that this is how a heat pipe works. So, you can consider free cooling as a way of using the chiller as a heat pipe between the cold outside air and the warm inside air. Heat is moved from the inside of the building to the outside solely by the differential between the space temperature and the outside air wet-bulb temperature.

To use free cooling, the compressor is turned off, the refrigerant bypass connection is opened, and the chilled water and cooling tower systems are kept running. Heat rejection from the building occurs as long as the chilled water temperature is higher than the cooling tower water temperature.

(The term “free cooling” is not unique to this technique. It may be used for any or all methods of cooling without operating the chiller compressor.)

Appropriate Applications

Refer to the Subsection introduction about the general application of free cooling and the alternative methods to consider.

This method can be used only with chillers and chiller systems that allow rapid migration of the refrigerant vapor from the evaporator to the condenser, and drainage of the condensed vapor back to the evaporator. Packaged water chillers are typically well adapted to free cooling. A chiller system with a remotely mounted evaporator and/or condenser may be adaptable to free cooling, but custom design of such an installation would require exceptional skill.

This method of free cooling with packaged centrifugal water chillers was patented by the Trane Company, which offers it as an option on some of its models. Investigate the status of patent coverage before attempting to adapt this technique to existing chillers or chiller systems.

This method does not work with air-cooled condensers or with direct-expansion evaporators. The refrigerant gas passages in the coils are too restricted to allow adequate convective circulation, and the liquid refrigerant would not flow properly without the pressure differential provided by the compressor. Exceptions are conceivable, but you would have to become an inventor to make them work.

Advantages and Disadvantages

In systems where this Measure applies, it may be easier and cheaper to accomplish than the other Measures of this Subsection. Chiller free cooling requires no modifications or additions outside the chiller itself.

The main efficiency disadvantage of free cooling is that it cannot be used in conjunction with normal chiller operation. Therefore, in order for free cooling to be useful, the cooling load must be low enough for free cooling to satisfy the entire cooling that occurs during the times when weather conditions allow free cooling to be used.

Free cooling requires the largest number of heat transfer steps of the Measures in this Subsection. On the other hand, the refrigerant heat transfer is highly efficient. This is because the high latent heat of the refrigerant provides a large amount of heat flow in relation to the mass that is evaporated.

One major chiller manufacturer claims that free cooling can provide as much as 45% of normal chiller capacity in its centrifugal machines. However, this would occur only at the lowest acceptable outside air temperature. The average capacity of free cooling under typical conditions is much less than this.

Free cooling involves a failure mode that is subtle and may waste large amounts of energy. If the refrigerant bypass valve leaks or fails to close fully when the compressor is operating, high-pressure gas is bypassed back to the compressor suction. This accidental form of hot gas bypass may waste a large amount of energy.

How to Control Free Cooling

Control of the free cooling connection itself is simple. The refrigerant bypass line must be tightly closed when the compressor is operated, and it must be open when free cooling is used.

The number of hours that free cooling can operate is determined by the chilled water temperature at which the compressor turns on. Therefore, keep the chilled

water temperature setting as high as possible. Refer to [Measure 2.2.1](#) about chilled water temperature reset.

Similarly, keep the condenser water temperature as low as possible when free cooling is used. However, many cooling units require an elevated condenser water temperature when they are running. (See [Measure 2.2.2](#) for the reasons why.) In such cases, provide controls that raise the condenser water temperature when the compressor starts.

In order to exploit the potential of this Measure without wasting fan energy, the controls for the cooling tower fans must be fairly sophisticated. Water in cooling towers does not evaporate as well at the lower temperatures at which free cooling operates, so the cooling fans must expend energy to maintain the lowest possible cooling water temperature. Such fan usage is excessive for normal chiller operation, so the fan control system must be adaptable to the different modes of operation. Refer to [Measures 2.2.2 ff](#) for details.

If the modification is offered as a standard package by a chiller manufacturer or other vendor, make sure that the controls included in the package satisfy all these requirements, and any others required by the chiller system.

■ Changeover Should be Automatic

Free cooling is available only at irregular times, as allowed by load and weather conditions. It is unrealistic to expect chiller plant operators to remain alert enough to grab at these opportunities. The changeover from chiller operation to free cooling, and vice versa, must be done automatically in order for the technique to pay off. Make sure that the controls are designed to maximize the duration of free cooling by minimizing the condenser water temperature and keeping the chilled water temperature as high as possible.

ECONOMICS

SAVINGS POTENTIAL: 5 to 30 percent of compressor energy, in appropriate applications.

COST: \$8,000 to \$16,000 as an accessory of new centrifugal chillers, depending on chiller size.

PAYBACK PERIOD: Several years or longer, the period depending primarily on the climate, the facility's cooling load, and energy costs.

TRAPS & TRICKS

PLANNING: Remember, this kind of free cooling cannot operate while the chiller is running. Make sure that your load and weather conditions allow free cooling for enough hours per year to make it pay. Don't kid yourself about how much cooling capacity this modification can provide under typical conditions. Talk with plant operators who have used the equipment for several cooling seasons.

EQUIPMENT AND INSTALLATION: The modification is a standard option of at least one chiller manufacturer. The hardware is simple, so it should be reliable. However, optimum control is somewhat complex. Let the manufacturer install the equipment, to avoid performance and warranty disputes. Then, check out performance thoroughly after installation. In particular, make sure that the chiller turns off and changes to free cooling whenever load conditions permit, and that the cooling tower water temperature is kept as low as possible during free cooling operation. Be sure to use chilled water temperature reset.

STAFF COMMUNICATION: Make sure that plant operators understand how free cooling works, or they will defeat it sooner or later in attempting to solve cooling problems. Explain the free cooling system in the plant operating manual. Install a placard at the bypass valve and controls. Put a column in the chiller plant log that indicates when free cooling is operating.

MAINTENANCE: Only minimal routine maintenance is required. A leak in the bypass valve will waste energy, and it is invisible. Schedule checks of this in your maintenance calendar.

MEASURE 2.9.2 Cool chilled water with a heat exchanger in the cooling tower circuit.

RATINGS		
New Facilities	Retrofit	O&M
C	C	

Another method of exploiting cool weather conditions to chill water is to install a heat exchanger between the cooling tower water and the chilled water, as shown in Figure 1. This method is conceptually similar to Measure 2.9.1, but has the advantage that it can be used to pre-cool chilled water while the chiller is operating. Also, it is readily adaptable to most chilled water systems that use water-cooled chillers.

Appropriate Applications

This method applies to all water-cooled water chillers. Refer to the Subsection introduction for general application considerations and alternative methods.

Advantages and Disadvantages

The relative efficiency characteristics of the Measures in this Subsection are shown in Table 1 of the Subsection introduction. The table shows that this Measure lies in the middle of the pack. This Measure has no major advantages or disadvantages of a practical nature. Installation should be fairly easy, even in retrofit. The largest item is a compact heat exchanger. Pipe connections are short.

Heat Exchanger and Piping Installation

This method of cooling recovery can be piped in a variety of ways. Figure 1 shows a simple arrangement that is satisfactory for many applications. The major feature is a heat exchanger installed in the chilled water return line. Cooling tower water is pumped through the heat exchanger in the counterflow direction. There is

no need for a control valve in the operation of the heat exchanger.

■ Deal with the Flow Resistance of the Heat Exchanger

Installing the heat exchanger in the chilled water return line increases flow resistance. In retrofit, you may have to install a chilled water pump with greater pressure output. In some cases, the chilled water system has a throttling (“balancing”) valve that can be adjusted to account for the difference in flow resistance. Figure this out beforehand, as equipment changes are expensive. After installing the equipment, verify that the flow rate is adequate.

A possible alternative is installing a bypass around the heat exchanger in the return chilled water line, so that the resistance is removed when the heat exchanger

is not in use. The reduction in flow rate that occurs when the heat exchanger is used should be tolerable because the cooling load is low then.

Before changing the chilled water pump, consider installing variable-flow chilled water pumping, as recommended by [Measure 2.5.2](#).

■ Condenser Recirculation Line

If necessary, you can add a recirculation line around the chiller condenser to maintain a minimum condensing temperature for chillers that have this requirement. See [Measure 2.2.2](#) about chiller condensing temperature limitations. In order for the heat exchanger to be effective, the cooling water temperature must be as low as the cooling tower can provide. The condenser recirculation line resolves the conflict between the two different temperature requirements.

Some chillers tolerate low condensing temperatures, which may allow you to omit the recirculation line. However, note that the cooling tower water temperature may be lower than the chilled water temperature. Most chiller manufacturers presently do not conceive of chiller operation with the condensing temperature lower than the evaporating temperature.

How to Control the System

Control details vary among different possible configurations. The general control steps are:

- the heat exchanger pump operates whenever the temperature of the cooling tower water is lower than the temperature of the returning chilled water, and it is turned off at other times
- the condenser pump operates when the compressor runs, and is turned off at other times
- the chilled water supply temperature is reset continuously to keep it as high as possible. (Refer to [Measure 2.2.1](#) about chilled water temperature reset.)
- if a condenser recirculating line is installed, the chiller condenser water temperature is controlled by the recirculating valve when the heat exchanger pump is operating. When the heat exchanger pump is off, the recirculating valve is shut and the condenser water temperature is controlled by the operation of the cooling tower fan. This control changeover keeps the fan from running excessively when the heat exchanger is not used.

To exploit the potential of this Measure without wasting fan energy, the cooling tower fans need controls

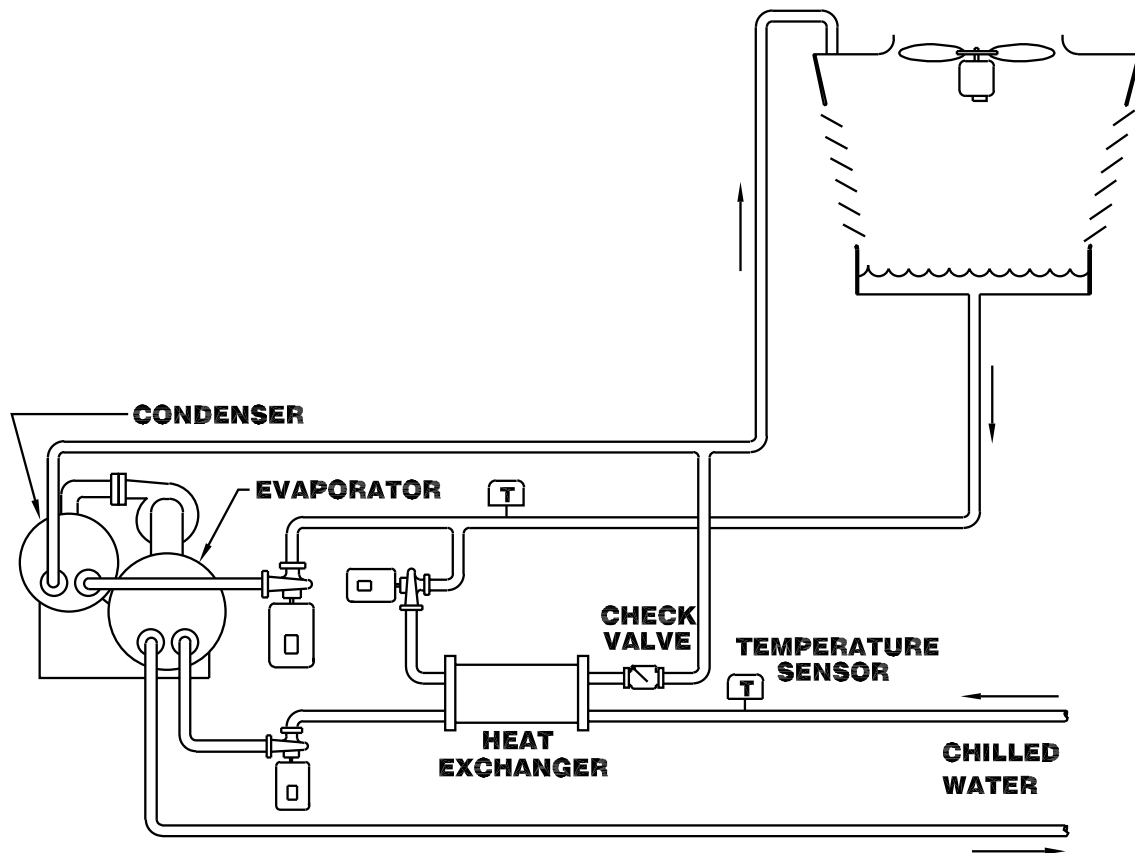

Fig. 1 Heat exchanger installed between condenser water system and chilled water system The heat exchanger circulating pump operates only when the temperature sensors indicate that the water from the cooling tower is colder than the chilled water.

that are fairly sophisticated. Water in cooling towers does not evaporate well at the lower temperatures at which the heat exchanger operates, so the cooling fans must operate aggressively to maintain minimum cooling water temperature. Such fan usage is excessive for normal chiller operation, so the fan controls should adapt to the different modes of operation. See [Measures 2.2.2 ff](#) for details.

ECONOMICS

SAVINGS POTENTIAL: 10 to 30 percent of compressor energy, in appropriate applications.

COST: Heat exchangers and a moderate amount of piping cost from \$150 to \$400 per ton of free cooling capacity, in typical applications.

PAYBACK PERIOD: 3 to 15 years, depending mainly on climate and energy costs.

TRAPS & TRICKS

YOU ARE PIONEERING: The design is unconventional, so work out the details carefully. Achieving efficient control is challenging.

EXPLAIN IT: Put a clear explanation of the system in the plant operating manual. Install placards on the heat exchanger and the controls.

MONITOR PERFORMANCE: Include columns in the chiller plant operating log to record the outside air wet-bulb temperature and the inlet and outlet temperatures of the heat exchanger. Failure or bad calibration of the controls is invisible, so review the logs regularly to check performance.

MEASURE 2.9.3 Install a strainer system to use cooling tower water directly in the chilled water system.

RATINGS		
New Facilities	Retrofit	O&M
D	D	□

From the standpoint of heat flow, the most direct way of cooling a building during cold weather is to use the cooling tower water directly in the chilled water system. This approach avoids most heat exchange steps. You can accomplish it with a simple arrangement of valves and crossover connections.

This type of system must resolve a serious conflict. Cooling tower water is dirty. At the same time, the water in the chilled water system must be kept clean to avoid clogging the narrow passages in the heat exchange coils throughout the facility. To deal with this problem, the system includes a high-efficiency strainer to clean the cooling tower water before it enters the chilled water system. For this reason, this approach is sometimes called a “strainer cycle.”

Figure 1 shows a typical strainer cycle installation. When the strainer cycle goes into operation, the cooling tower water is connected into the chilled water system, the chilled water pump discharges through a high-efficiency strainer, rather than through the chiller evaporator, and the cooling tower water pump is turned off.

Efficiency Characteristics

The relative efficiency characteristics of strainer cycles are shown in Table 1 of the Subsection introduction. Strainer cycles eliminate the condenser

and evaporator heat transfer steps, along with the operation of the cooling tower water pumps. As a result of these advantages, the strainer cycle is one of the most efficient means of exploiting low outside air temperature for cooling.

On the other hand, strainer cycles cannot operate while the chiller is running. As a result, they fail to provide savings during many hours when cool outside temperatures could be used to augment the cooling provided by chiller operation. On balance, the inability of a strainer cycle to supplement compressor operation

usually makes this method less efficient overall than some of the other Measures of this Subsection.

Applications

This Measure is used with chilled water systems that employ water-cooled chillers. This Measure is not practical in all facilities, because some design requirements of strainer cycles are not adaptable to all chilled water systems. Refer to the Subsection introduction about the general application of free cooling and the specific methods to consider.

Design Issues

The equipment of a strainer cycle is easy to install, and it does not require much space. The largest additional item is the high-efficiency strainer. Piping connections and valve installations are simple. The following are the main design issues.

■ Cleaning Cooling Tower Water

Cooling tower water is dirty because cooling towers wash dirt and debris out of the atmosphere and trap it. Isolating the chilled water system from this dirt is a primary concern.

Cooling tower systems normally have strainers to prevent clogging of the system and to protect the cooling water pumps and the condensers. These functions can

be accomplished with coarse strainers, which are not satisfactory for protecting the chilled water system. To protect the small passages of chilled water heat exchangers, the strainer cycle uses a high-efficiency strainer to remove small particulate material.

The strainer is an area of serious risk. A strainer failure will quickly distribute dirt throughout the chilled water system and clog the insides of coils. Fixing this requires shutting down the entire chiller system and doing tedious cleaning. Therefore, install a strainer cycle only if you are sure of a high level of maintenance discipline over the long term. The only requirement is to check and flush the strainers periodically. This is not difficult, but the procedure can never be neglected.

Install the high-efficiency strainer on the discharge side of the chilled water pump. Otherwise, the resistance of strainer may reduce pump suction pressure too much, causing pump cavitation. Select a strainer that has a large capacity in relation to flow, reducing resistance.

In retrofit applications, the additional resistance of the strainer should not be a problem. The strainer is located in the evaporator bypass line, so it does not increase flow resistance during normal chiller operation. During strainer cycle operation, the increase in resistance causes a moderate reduction of flow. This should be tolerable with the low cooling load that exists when the strainer cycle is used.

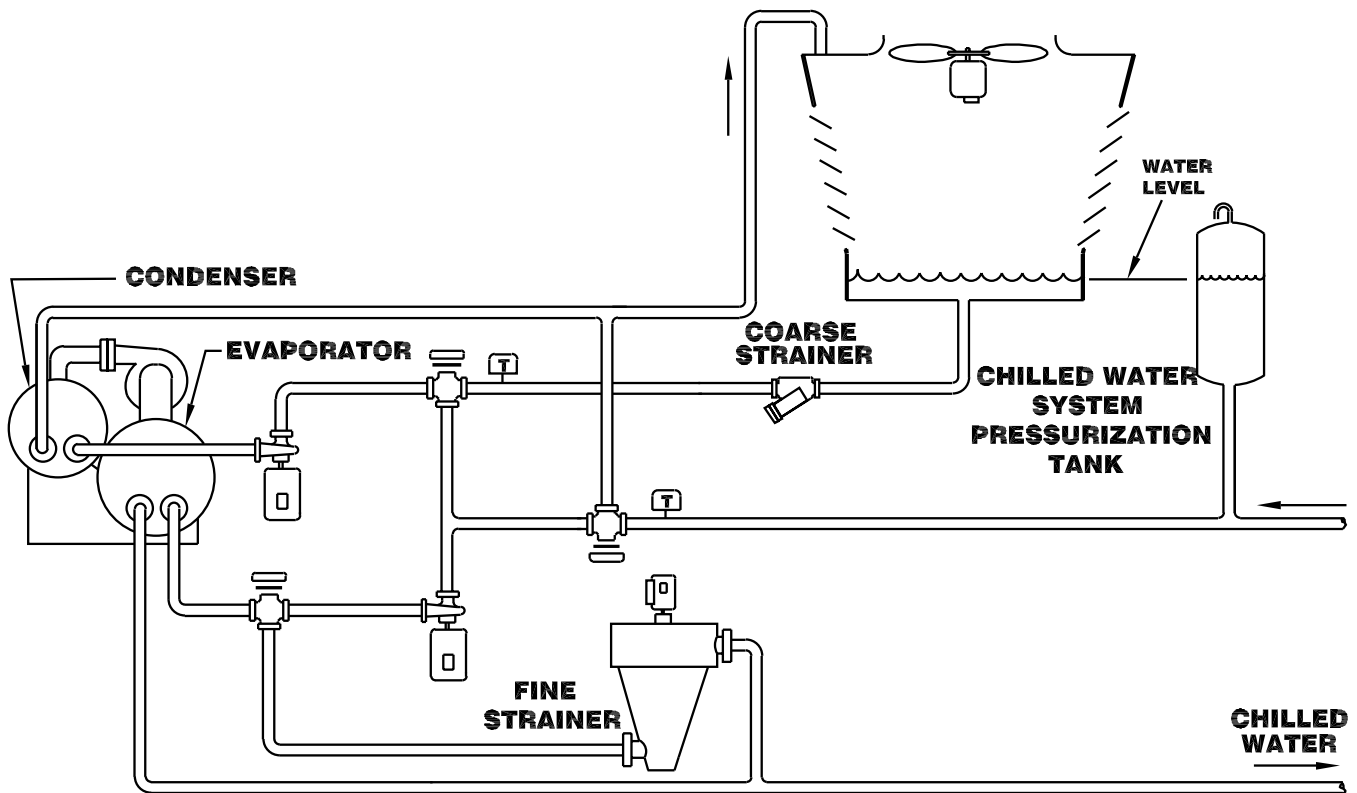

Fig. 1 Strainer cycle The main efficiency advantage of this system is that the cooling tower water is used directly in the chilled water system. This characteristic is also the system's most serious liability. A high-efficiency strainer is needed to clean the tower water sufficiently to use in the narrow coils of the cooling equipment. If the strainer fails, the entire chilled water system may be fouled.

■ Water Treatment

Cooling tower systems have dirty water for three broad reasons. One is that they collect dirt and debris from the surrounding atmosphere and environment. Another is that the cooling tower acts as a growth site for a wide range of biological fouling. Thirdly, since cooling towers operate by evaporation, they require continuous intake of raw water. This replacement water carries mineral fouling and a certain amount of dirt.

Dirt is removed by the strainers. These must be flushed periodically. In a strainer cycle, the operation of the strainers is so critical that you should consider installing strainers with automatic backflushing.

Biological fouling is controlled by chemical treatment of the cooling tower water. This is part of the proper operation of any cooling tower system. See [Measures 2.3.3 ff](#) about chemical treatment. Remember that cooling tower water treatment is normally designed for the condenser cooling water system, not for the chilled water system. If a strainer cycle is installed, adjust your water treatment accordingly. For example, consider using more suspension agents to keep dirt from depositing on system surfaces.

Failure of water treatment is even more likely than failure to keep strainers cleaned out, because water conditions are not directly visible and water treatment requires specialized skills. Consider it virtually certain that some lapses in water treatment will occur during the life of a facility.

Mineral fouling is prevented by keeping the concentration of minerals in the cooling tower water low enough. This requires proper control of cooling tower bleed. See [Measures 2.3.4 ff](#) about this function.

■ Dealing with Expansion Tanks

A chilled water system needs an expansion tank to deal with expansion and contraction of the water. In conventional systems, the expansion tank can take one of two forms. The simplest is an open, vented tank, which must be located above the highest point in the system. The other is a closed tank that is pressurized with air, which may be installed at any point in the system.

During strainer cycle operation, the cooling tower creates an opening in the chilled water system. In effect, the cooling tower sump also acts as an expansion tank. For this reason, the chilled water system's normal expansion tank must be located so that its water level is the same as the water level in the cooling tower sump. If the expansion tank were lower, water would drain out of its vent. If it were higher, water would drain out of the expansion tank into the cooling tower sump.

You cannot use a pressurized expansion tank in a system with a strainer cycle, because the pressurization tank would blow water out of the system when the strainer cycle is operating.

A strainer cycle is probably impractical if you cannot install the cooling tower sump higher than the tallest point in the chilled water distribution system. In that case, the chilled water system would tend to drain out through the cooling tower sump. Preventing this would require complex plumbing and control. The benefit would not justify the complications, especially since other Measures can achieve the same purpose without the complications.

A related issue is that the cooling tower sump must be high enough above the chilled water pump to provide good pump suction. This condition is satisfied if the chilled water pump is installed at the same elevation as the condenser water pump, or lower.

■ Relative Cooling Tower and Chilled Water Flow Rates

Cooling towers are designed for optimum performance at a particular flow rate. By serendipity, compression chillers require about the same chilled water and condenser water flow rates. This makes it simple to use the chilled water pump to circulate water through the cooling tower.

This lucky coincidence does not occur with absorption chillers, which require a much higher condenser water flow in relation to the chilled water flow. In an absorption chiller system, the water flow provided by the chilled water pump during strainer cycle operation is only a fraction of the normal cooling tower flow rate.

The same problem arises in a compression chiller system if the system uses variable-flow chilled water pumping ([Measure 2.5.2](#)). In a variable-flow system, the flow of chilled water is proportional to the cooling load. The strainer cycle operates when the cooling load is low, so the chilled water flow rate is greatly reduced.

There are two potential solutions for the latter cases. One is to operate the cooling tower at the reduced flow rate. Some cooling towers may provide sufficient cooling for the reduced cooling load, and some may not. Check this with the cooling tower manufacturer. Operation of cooling towers at reduced flow rates is an area of uncertainty.

The other solution is to maintain full cooling tower flow by operating the condenser water pump. A bypass valve is used to tap off the part of the flow needed by the chilled water system. The energy penalty of operating the condenser water pumps is a major factor. The additional complexity increases the possibility of operating the system in an inefficient manner.

How to Control the Strainer Cycle

Control the strainer cycle to operate as long as the temperature of the cooling tower water is low enough to satisfy the cooling load, instead of running the chiller.

As the cooling load increases, the chilled water supply temperature needs to be lower, and the chilled water return temperature increases. When the return water temperature rises to a certain point, the strainer cycle must be turned off and the chiller must be started. Refer to [Measure 2.2.1.2](#) for controls that keep the allowable chilled water temperature as high as possible.

The cooling tower fan controls need to be sophisticated to maintain the optimum balance between saving chiller energy and not wasting fan energy. Water evaporates slowly at the lower temperatures at which free cooling operates, so the cooling tower fans must operate more aggressively to create evaporative cooling. Such fan usage is excessive for normal chiller operation, so the fan control system should be adaptable to the different modes of operation. See [Measures 2.2.2 ff](#) for details.

■ Changeover Should be Automatic

The strainer cycle can operate only at irregular times that are determined by the cooling load and the weather conditions. It is unrealistic to expect chiller plant operators to remain alert enough to grab at these opportunities. The changeover from chiller operation to strainer cycle operation, and vice versa, must be automatic.

ECONOMICS

SAVINGS POTENTIAL: 5 to 30 percent of compressor energy, in appropriate applications.

COST: Several thousand dollars, up to considerably more.

PAYBACK PERIOD: Less than one year, to many years. The payback period is shorter in larger systems, all other factors being equal.

TRAPS & TRICKS

CHOICE OF METHOD: Are you sure you want to do this? The simplicity of the concept and the high potential efficiency are appealing, but this technique is appropriate only for a plant that will always have reliable operation and maintenance. When calculating the potential benefit, remember that the strainer cycle cannot operate while the chiller is running. Make sure that your load and weather conditions allow strainer cycle operation for enough hours per year to make it pay.

DETAILS: The hardware design is fairly simple, but designing the controls to optimize the benefit of the system is challenging. Make sure that the chiller turns off and the system switches to strainer cycle operation whenever load conditions permit. Design the controls to keep the cooling tower water temperature as low as possible during strainer cycle operation.

MAINTAIN IT: A strainer cycle needs maintenance that never fails. A failure that allows cooling tower dirt to get into the chilled water system could require an expensive cleaning operation and an extended cooling shutdown. Failure of the strainers is easy to overlook until serious system fouling has occurred. Controls may malfunction indefinitely, or they may not be set for maximum efficiency, without the problem being noticed.

EXPLAIN IT: Make sure that plant operators understand how the strainer cycle works, or they will defeat it sooner or later in attempting to solve cooling problems. Explain the system in the plant operating manual. Install placards at the valves and controls. Put a column in the chiller plant log that indicates when the strainer cycle is operating.

MEASURE 2.9.4 Install a “waterside economizer” system using separate cooling coils.

RATINGS		
New Facilities	Retrofit	O&M
B	D	□

Another way to move low outdoor temperatures indoors is to install separate cooling coils in the air handling units or other cooling equipment that is fed by water from the cooling tower. This type of system is commonly called a “waterside economizer.” (The name distinguishes this method of capturing outside air cooling from the “airside economizer,” which is covered by Measure 4.2.5.)

Figure 1 shows a typical waterside economizer installation. A unique aspect of the waterside economizer is that it can use an atmospherically cooled water system to supplement direct-expansion (DX) cooling, as shown in Figure 1. In fact, this is the only common application where waterside economizers are preferable to the other methods of this Subsection.

Where to Consider a Waterside Economizer System

Refer to the Subsection introduction for a comparison of the different methods of free cooling that are available.

The waterside economizer has an exclusive niche. It is the only method that is available for exploiting direct cooling with cooling tower water that can work with direct-expansion (DX) cooling coils.

As a practical matter, waterside economizers are usually limited to DX air handling units that have their own compressors and condensers. This is because it is expensive to run water piping to numerous air handling units. If the units need water piping for condenser cooling, the additional piping cost for the economizer coils is relatively small. Typically, self-contained air handling units are installed to avoid the cost or space requirements of a central chiller plant. Figure 2 shows a typical air handling unit of this type that uses a waterside economizer.

This is primarily a method for new construction. Retrofitting economizer coils to existing air handling units would be difficult or impossible.

Comparative Efficiency Characteristics

The comparative efficiency characteristics of a waterside economizer system are shown in Table 1 of the Subsection introduction.

A unique efficiency disadvantage of the waterside economizer is that it requires a separate coil in the air stream. This coil has a significant amount of resistance, compared to other pressure losses in the air handling system, so it requires a corresponding increase in fan power. The coil is always present, so fan power is increased at all times, even when the waterside

Fig. 1 Waterside economizer system Water from the cooling tower is used to cool remote coils in the air handling units. These coils operate independently of the DX cooling coils operated by the compressors. A heat exchanger is usually needed to isolate the economizer coils and the condensers from the dirt picked up by the tower.

economizer is not operating. This makes it especially important to have weather conditions that favor a waterside economizer for a large fraction of the time.

A waterside economizer system may or may not provide a net saving in pump energy, depending on the cooling load profile. The system requires no chilled water pumps. The power required for pumping cooling tower water is increased. The amount of pump power depends on how the water is circuited inside the air handling units, as discussed below.

Installing an economizer system typically requires a heat exchanger for the cooling tower water. This is because the economizer coils cannot tolerate the dirt that exists in cooling tower water. The temperature differential in the heat exchanger wastes part of the cooling potential of the cooling tower. The heat exchanger also requires a separate pump, and the additional resistance in both water circuits increases total pump power.

Because the condensers in the air handling units are served by the same water circuit as the economizer coils, the heat exchanger also raises the condensing temperature, reducing the efficiency of mechanical cooling whenever the water temperature is higher than the minimum required by the compressor systems. In other words, the economizer system imposes an efficiency penalty on the compression cooling systems even when the economizer itself is not operating.

Figure 3 shows a typical plate heat exchanger for a waterside economizer. It is relatively small compared to the other components of the system.

How Waterside Economizer Coils are Connected

The economizer coil in each air handling unit is installed directly ahead of the main cooling coil. If a preheat coil is installed, the economizer coil is installed downwind of the preheat coil, since the latter is vulnerable to freezing.

In each air handling unit, the water flow to the economizer coils may be piped in parallel with the water flow to the condenser, or it may be piped in series. A parallel connection provides the lowest water temperature to both, but it increases pump power and pipe size. If the water is piped in series, it goes to the economizer coil first. The warming of the water in the economizer coil does not cost an efficiency penalty if the compressor must maintain a condensing temperature that is higher than the discharge temperature of the economizer coil. This is typically true with contemporary equipment, but it may not be true in the future, as equipment manufacturers become more aggressive about exploiting the efficiency benefit of lower condensing temperatures.

If the chiller requires an elevated condensing temperature, it also needs a recirculation circuit around the condenser. This maintains a constant flow rate through the condenser for proper heat transfer.

You can save pump energy by installing a separate pump for each air handling unit or group of air handling units that operates on a separate schedule.

An additional refinement for minimizing pump power is bypassing the water flow around the economizer coils when they are not needed. To exploit this fully, you need a variable-flow pumping system.

WESINC

Fig. 2 Self-contained air handling system that uses a waterside economizer The cooling water pipes coming from the left serve both the economizer coil and the condenser of the DX cooling unit.

This is relatively easy in an economizer system. Pump the water with a single distribution pump that is controlled to maintain a fixed pressure differential in the system. Also, install shutoff valves to stop the flow to condensers that are not in use.

How to Control a Waterside Economizer

Each economizer coil is controlled individually, as follows:

- the economizer coil and the primary cooling coil operate in sequence, with the economizer coil valve opening fully before the primary coil starts to operate
- when the cooling tower water temperature is higher than the temperature of the air entering the economizer coil, the economizer coil is shut off
- a signal to start the primary coil is generated whenever the economizer coil cannot satisfy the demand of the thermostatic control

There are differences in the control scheme that depend on the type of air handling system. In single-zone air handling units:

- control the coils in response to the space temperature or return air temperature, as appropriate
- to turn off the economizer coil when heating is desired, use the same control signal that turns off the primary cooling coil.

In air handling units that are controlled to maintain a specific supply air temperature (VAV and reheat units):

- control the coils to maintain the desired supply air temperature
- use supply air temperature reset aggressively to maximize the benefit of the economizer.

The cooling tower fans need special control, especially if the chillers are not designed to exploit minimum condensing temperatures. The economizer cycle needs as much cooling effect from the cooling tower as possible. Water in cooling towers evaporates more sluggishly at lower outside air temperatures, so the cooling fans must be controlled to produce the maximum evaporative cooling effect in this temperature range. Such fan usage is excessive for normal compressor operation. Design the fan controls to optimize overall system efficiency under both economizer and non-economizer modes of operation. See [Measures 2.2.2 ff](#) for details.

ECONOMICS

SAVINGS POTENTIAL: 10 to 30 percent of compressor energy, in appropriate applications.

COST: In new facilities, a waterside economizer costs \$50 to \$150 per ton of system capacity, typically. In retrofit, the cost of adding economizer coils to existing air handling units is probably prohibitive.

PAYBACK PERIOD: Several years or longer, typically.

TRAPS & TRICKS

DESIGN: Waterside economizers are fairly common. However, do not copycat existing designs, as they may be flawed or inefficient. Select cooling equipment that exploits the efficiency advantage of low condensing temperature.

EXPLAIN IT: Put a clear explanation of the system in the plant operating manual. Install placards at the economizer coils and the controls.

MONITOR PERFORMANCE: Record the outside air wet-bulb temperature and the supply and return temperatures of the economizer circuit in the chiller plant operating log. Review the log regularly to check performance, because failure or incorrect calibration of the controls is invisible.

MEASURE 2.9.5 Install a closed-loop atmospheric cooling unit in the chilled water circuit.

RATINGS

New Facilities	Retrofit	O&M
D	D	

You can use outside air to cool chilled water directly by using a conventional heat rejection unit. The heat rejection unit may be a closed-loop cooling tower, or even a dry cooler. This method is unusual. It is too expensive to compete with the other Measures in common applications, but it may be the best choice in some special cases. Figure 1 shows the arrangement.

Appropriate Applications

Refer to the Subsection introduction about the general application of free cooling and the various methods to consider.

Table 1 in the Subsection introduction shows that this method is relatively efficient compared to the other Measures. It can operate along with the normal chiller operation, providing free cooling as long as the outside air temperature (dry-bulb or wet-bulb, depending on the type of heat rejection unit) is lower than the return chilled water temperature.

The major disadvantage of this approach is high cost. In constant-flow chilled water systems, the heat rejection unit must be sized for the full flow of the chilled water circuit, but it operates with temperature differentials that are typically small. This requires a heat rejection unit that is large in relation to the quantity of the heat rejected. In chilled water systems that have cooling towers, all the other Measures of this Subsection are usually more economical.

The heat rejection unit can be much smaller if the chilled water system has variable-flow pumping, because the flow rate is much lower when the cooling load is low, as it usually is when the outside air is cold. Also, the efficiency of this Measure is higher with variable-flow pumping systems because the return chilled water temperature is higher.

This is the only Measure of this Subsection that can be used with air-cooled water chillers. However, its range of applications is still narrow. Air-cooled chillers are commonly selected for arid climates to avoid the need for cooling water, and these climates are typically too warm for this Measure. At the other temperature extreme, air-cooled chillers may be used so they can operate during cold weather without freezing the heat rejection unit. Liquid chilling during freezing weather is an uncommon application.

This Measure is relatively simple to accomplish, although expensive. The main physical limitation is finding a mounting location that can accommodate the size and weight of the heat rejection unit.

SUMMARY

An alternative that offers good efficiency, but is economical only in specialized applications. Most likely to be desirable in systems with variable-flow chilled water pumping, and with air-cooled water chillers that operate during cold weather.

Dry Cooler or Wet Cooler?

This Measure can be accomplished with either a closed-loop evaporative cooler or a dry cooler. A quick analysis with a psychrometric chart shows that an evaporative cooler provides much greater savings. The evaporative cooling effect lowers the chilled water temperature enough to greatly increase the number of hours of non-chiller cooling, especially in climates that are dry.

Furthermore, the heat exchange loss in a dry cooler keeps the chilled water at least 15°F warmer than the outside dry-bulb temperature. Thus, for example, making 50°F chilled water with this method alone would require an outside air temperature of about 35°F.

How to Control the System

The atmospheric cooling unit is turned on, and the transfer valves connect it into the chilled water circuit, whenever the cooling unit can reduce the temperature of the returning chilled water enough to justify its operation. A dry cooler can be controlled with a switch that senses the difference in temperature between the return chilled water and the outside air. With a wet cooler, the control should sense the outside air wet-bulb temperature. For best efficiency with a wet cooler, use a sliding scale of temperature differentials for different wet-bulb temperatures.

Controls are also needed for freeze protection, unless the system uses antifreeze or is drained before the onset of freezing weather.

The potential benefit of the Measure is influenced heavily by the chilled water temperature. Keep it as high as possible. This also improves the COP of the chiller. See [Measure 2.2.1](#) about chilled water temperature reset.

Freeze Protection

Chilled water systems are usually located entirely indoors, avoiding the need for freeze protection. However, the atmospheric cooling unit is exposed to outside conditions, where it may be damaged by freezing. A leak in this unit would shut down the entire cooling system.

The most efficient way to avoid freezing is to drain the exposed portion of the chilled water piping when freezing is a possibility. Freezing conditions come and go repeatedly, so install an automatic drain-down. Drain-down is activated when the water in vulnerable parts of the system approaches freezing temperature.

An alternative method of freeze protection is to use antifreeze solution with the chilled water system. A disadvantage of this method is that antifreeze solutions have poorer heat transfer than water. Using antifreeze reduces the efficiency of all the heat exchangers in the system.

Sump heaters are sometimes used to avoid freezing in heat rejection units. Avoid these because of their energy consumption.

ECONOMICS

SAVINGS POTENTIAL: 10 to 30 percent of compressor energy, in appropriate applications.

COST: \$300 to \$600 per ton of free cooling capacity.

PAYBACK PERIOD: Several years, to much longer, depending mainly on energy costs and the weather profile.

TRAPS & TRICKS

PLANNING AND DESIGN: Make sure that this is the best approach for your application. Do not let the simplicity blind you to the cost. The design is not particularly tricky, but it is unconventional. Efficient drain-down for freeze protection requires some cleverness. Be prepared to work out bugs in the installation.

EXPLAIN IT: Put a clear explanation of the system in the plant operating manual. Install placards at the heat rejection unit and the controls.

MONITOR PERFORMANCE: Include columns in the chiller plant operating log to record the outside air wet-bulb temperature and the supply and return temperatures of the heat rejection circuit. Review the logs regularly to check performance, because failure or incorrect calibration of the controls is invisible.

Fig. 1 Cooling the chilled water circuit with its own heat rejection unit This unusual arrangement works even with air-cooled cooling machines.

Heat Recovery From Chillers

The Measures in this Subsection recover the heat that is rejected by chillers, or increase the amount of heat that you can recover. When a chiller is working, it rejects an amount of heat that is equal to the cooling load plus the energy input to the compressors. In facilities that have a large cooling load, heat is discarded to the atmosphere in enormous amounts. This energy seems to cry out to be put to use.

Fortunately, recovering heat from chillers at their normal condensing temperatures is usually simple and free of trouble. However, the low temperature of the recovered heat is a fundamental limitation. To achieve maximum efficiency, chillers are normally designed to operate with condensing temperatures close to the temperature of the outside air. Most facilities cannot use much heat that is recovered at these low temperatures. Preheating domestic water is by far the most common application. Other applications are unusual, and they tend to be specialized to particular industries.

Increasing Heat Recovery by Increasing the Condensing Temperature

You can increase the temperature of the recovered heat as much as 20°F to 50°F (11°C to 28°C) by increasing the condensing temperature. This also increases the amount of heat you can recover. And, you may be able to find new applications for the recovered heat, including some space heating and industrial heating applications.

However, increasing the condensing temperature imposes a serious penalty on chiller efficiency. It also invites a host of complications and problems. Chillers are designed to produce a specified capacity at a specified maximum ambient temperature, which typically involves condensing temperatures in the range of 100°F to 110°F. In normal operation, the average condensing temperature is lower than this. It is usually safe to operate a chiller continuously at its design maximum temperature, or even at a somewhat higher temperature, but motor life may be reduced.

You can increase the heat recovery temperature further by using a chiller that is designed specifically for heat recovery. A heat recovery chiller is simply a conventional unit that is optimized for higher condensing temperatures.

INDEX OF MEASURES

2.10.1 Use condenser water directly for heating applications.

2.10.2 Use an auxiliary condenser or double-bundle condenser for heat recovery.

2.10.3 To recover large amounts of heat at elevated condensing temperature, install a heat recovery chiller.

2.10.4 To recover small quantities of heat at maximum temperature, install a desuperheater.

2.10.5 Improve the quantity or economics of heat recovery by adding or increasing heat storage.

■ The Effect of Higher Recovery Temperature on Chiller COP

If you increase the condensing temperature, balance the increased value of the recovered heat against the increased cost of cooling. Increasing the condensing temperature typically reduces the chiller COP by 1% to 2% per degree Fahrenheit.

Your best compromise depends on the relative value of chiller input energy and the heat that is recovered. The recovered heat is usually less valuable than the chiller input energy. The input energy for compression chillers is usually electricity or another expensive source. On the other hand, the heat pump effect of a chiller makes the amount of recovered heat several times greater than the amount of chiller input energy.

If you select a new chiller for higher condensing temperature, it will have a somewhat higher COP in heat recovery operation than a similar chiller that is selected for normal condensing temperatures. However, this “heat recovery” chiller will have a lower COP at normal condensing temperatures.

■ The Effect of Higher Heat Recovery Temperature on Cooling Capacity

Operating a chiller at increased condensing temperature reduces its capacity substantially. The effect of condensing temperature on capacity varies with the type of compressor. Centrifugal chillers suffer a more serious loss of capacity than other types because the refrigerant gas in a centrifugal compressor is not moved by positive displacement. As the gas flows through the chiller, it is slowed by the increasing discharge pressure caused by higher condensing temperature.

Whether the reduction of cooling capacity is important depends on the time relationship between the cooling and heat recovery applications. For example, preheating domestic water may have to be curtailed during periods of high cooling load. Typically, this does not reduce heat recovery much, because peak cooling conditions are occasional. You can avoid this limitation completely by using heat storage.

■ The Effect of Higher Condensing Temperature on Equipment Life

Increasing the condensing temperature for long periods of time may adversely affect compressor and motor reliability. The effect depends on the type of compressor, the type of refrigerant, and the details of the specific model. Check the chiller specifications before operating at elevated condensing temperature for long periods. Discuss the advisability of heat recovery operation with the chiller manufacturer’s engineering department.

The most serious long-term threat is to the motor insulation. The life of the insulation declines rapidly as its temperature increases. Motor temperature rises because motor current increases as the motor must produce greater condensing pressure. Failure of an

internal motor is especially bad because the burnout products are corrosive and travel throughout the refrigerant circuit, requiring a messy cleaning procedure. If the chiller motor is external, it may be advisable to replace it with a motor that has a higher temperature rating. See [Measure 10.1.1](#) for details of motor temperature and reliability.

Some refrigerants have exceptionally high discharge temperatures, or superheat. Increasing the condensing temperature may raise the discharge temperature enough to break down the lubricating oil that is carried along in the refrigerant. You can deal with this by selecting a lubricating oil suitable for the higher temperatures.

■ Unloading Limitations of Centrifugal Compressors at Elevated Condensing Temperatures

Centrifugal chillers have the highest peak efficiency of all contemporary chiller types. This makes them the most popular type in large sizes. Unfortunately for heat recovery, a centrifugal compressor is less tolerant of having its condensing temperature increased than other types of compressors. The most serious problem is that centrifugal chillers lose their ability to throttle capacity as condensing temperature is increased. This is because a centrifugal chiller “surges” at some point as its output is reduced. The load at which this occurs increases with condensing temperature.

Surge is a special problem of centrifugal devices (including centrifugal fans and pumps). In brief, the higher pressure in the perimeter housing (the “volute”) of the compressor tends to force gas back into the impeller, against the outward flow. The centrifugal force of the outward flow is reduced as the chiller output is reduced. When the centrifugal force can no longer overcome the discharge pressure, the outward flow stalls in the diffuser area leading to the volute, the capacity drops abruptly, and the unstable flow causes severe vibration.

Increasing the condensing temperature for heat recovery raises the discharge pressure. To avoid surge, the chiller must operate at higher load to increase the centrifugal force which drives the outward gas flow. Surge can occur even at full load if the condensing temperature is too high.

Centrifugal chillers offered as “heat recovery” models are not different from other centrifugal chillers in any basic way. They simply are designed to produce greater centrifugal force in the gas. The manufacturer does this by increasing the impeller diameter or by increasing the impeller speed.

Special Heat Recovery Modes of Certain Chiller Types

■ Oil Heat Recovery in Screw Compressors

Most screw compressors inject oil into the compression process to seal the gaps around the rotors. This oil absorbs a considerable amount of the heat of

compression, and this heat is removed from the oil at a temperature that is high enough to be useful for some applications. The quantity of heat removed from the oil is limited, but don't overlook it.

■ Recovery of Heat from Discharge Cooling of Ammonia Compressors

Ammonia is limited to reciprocating and screw compressors because of its high pressure differential. Ammonia has exceptionally high superheat, so the compressor may be designed for water cooling of the discharge passages to protect the machine. The quantity of heat in this compressor cooling water is a small fraction of the total heat rejection, but it is worth circuiting the cooling water so that this heat can be collected along with the condenser coolant. To recover the superheat at a temperature higher than condensing temperature, refer to [Measure 2.10.4](#).

■ Heat Recovery from Absorption Chillers

As a rule, do not try to increase heat recovery from absorption chillers by increasing their condensing temperature, especially if they are driven by steam or hot water. The COP of absorption chillers is low at best, and increasing the condensing temperature makes the COP even worse. Also, the operating temperatures of absorption chillers are critical. (See [Measure 2.2.2](#) for some of the reasons.) Read the operating manual carefully before making any adjustments.

Some direct-fired absorption chillers offer an option described as "heat recovery." This is a misnomer invented to boost sales. The chiller is powered by an internal burner. The "heat recovery" consists of diverting heat from the burner to an internal boiler. This saves the expense of installing a separate boiler. This feature is a convenience that does not increase overall efficiency.

How to Match the Heat Recovery Application to the Chiller Plant

■ Heat Recovery is Usually Supplemental

Consider chiller heat recovery to be a supplemental heat source. The chiller may not be able to provide the needed amount of heat or the maximum temperature at all times. Even if it can, you need a conventional backup source for times when the heat recovery chiller is taken out of service.

■ Match the Timing of Cooling and Heat Recovery

Recovered heat must be available at the time the application requires it. Therefore, the amount of heat that can be recovered depends on the relative timing of chiller operation and the heat recovery application. For example, domestic water heating may use chiller heat recovery on a supplemental basis whenever the chiller happens to be operating.

More energy is recoverable in a warm climate, where chillers operate continuously, than in a climate

where the chiller operates for only several months per year.

If you want to use chiller heat recovery for space heating, the facility must have a substantial cooling load during cool weather to provide the heat.

You can deal with short-term differences in timing, extending as long as several days, by using heat storage. This is covered by [Measure 2.10.5](#).

■ Match the Heat Recovery and Application Temperatures

In some applications, the amount of heat that can be recovered is proportional to the condensing temperature. If heat recovery cannot provide the maximum temperature of the application, then heat recovery is still valuable for preheating. For example, in heating domestic water from 55°F to 130°F, chiller heat recovery can preheat the water to 100°F, and a conventional water heater is used to complete the job.

In other applications, you would have to modify the application to exploit heat recovery at all. For example, to use heat recovery for space heating, the heating system must be designed for exceptionally low heating water temperature. Chiller heat recovery cannot work with conventional hydronic heating that has a typical supply water temperature of 160°F (71°C) and a typical return water temperature of 120°F (49°C). To use heat recovery, the system would have to operate with a supply temperature of 130°F (54°C) or less, and a return temperature of about 90°F (32°C). This would require special heating units, and the low supply air temperature may cause complaints about comfort.

■ Heat Exchanger Losses and Contaminant Isolation

Heat recovery usually requires a heat exchanger. Condensing temperatures are low, so the temperature drop that occurs in a heat exchanger may seriously reduce the amount of condenser heat that you can recover. Therefore, design the heat exchangers for minimum temperature loss.

If the condenser is water-cooled, you may be able to recover the heat simply by using the cooling water directly. But this is not always possible. If the system uses an open cooling tower to cool the condenser, the cooling water is dirty. Cooling towers wash pollutants out of the atmosphere and trap debris. Also, cooling tower water is usually treated with chemicals that are toxic. This may force you to use another heat exchanger to isolate the tower water from the application. For example, the dirt in the water may foul heating coils.

As an alternative, you may be able to recover heat without a heat exchanger by installing a strainer system in the cooling tower circuit. See [Measure 2.9.3](#) for this technique, which is not foolproof.

If the condenser is air-cooled, you have to install a heat exchanger to recover the heat of the compressed

refrigerant gas. In some applications, such as heating potable water, the heat exchanger may also have the purpose of blocking contamination. A leak in the heat exchanger may contaminate the heated medium with refrigerant. Halocarbon refrigerants combine with water to form hydrochloric and hydrofluoric acids, which are toxic and corrosive. Ammonia refrigerant combines with water to form window cleaner.

The most efficient way to protect against contamination is using a double-wall heat exchanger. In this type of heat exchanger, the heat transfer surface consists of two metal surfaces with a space between them that is vented to the outside. Thermal conduction between the two surfaces occurs across metal-to-metal contacts that are spaced at regular intervals.

With refrigerants having very low condensing pressure, especially R-123 and R-11 (which is being phased out for environmental reasons), you may be able to provide isolation by keeping the heated liquid at a pressure higher than the condensing pressure. For example, this may be possible in a domestic water system where pressure is maintained by a standpipe. Even with this arrangement, contamination may occur if the domestic water pressure is turned off during a period of time when a leak exists in the heat exchanger.

(Contamination in the other direction, from the water side into the refrigerant, is a serious problem that is faced by all water-cooled chillers that have single-wall heat exchangers. See [Measure 2.7.1](#) for details.)

■ Distribute the Load Efficiently Between Heat Recovery and Non-Recovery Chillers

Raising the condensing temperature costs a penalty in chiller COP and capacity. Therefore, you want to operate the minimum amount of chiller capacity at elevated condensing temperature. At the same time, you want to avoid operating any chiller at an inefficient load.

For example, assume that you have a chiller plant with two 1000-ton chillers and a single 500-ton chiller. At a particular moment, the total cooling load is 900 tons, and 300 tons of this load are needed to satisfy the heat recovery load. If you operate only a single 1000-ton chiller, it has to operate with elevated condensing temperature, so the entire cooling load is delivered with a COP penalty. On the other hand, you could operate the 500-ton chiller at a load of 300 tons to provide heat recovery, and one of the 1000-ton chillers at 600 tons to

provide the rest of the cooling load with low condensing temperature. In this case, both chillers are loaded near their points of peak efficiency.

You can shift the cooling load between the heat recovery chiller and other chillers in several ways:

- ***manually reset the chilled water temperature settings of the chillers.*** Standard chiller controls adjust their loading to meet a temperature setting for the chilled water supply or return. Lowering the temperature setting of one chiller in a group increases the load on that chiller and reduces the load on the others.
- ***install a chiller sequencing controller.*** Chiller sequencing controllers are automatic devices that start and stop chillers in a programmed sequence in accordance with the cooling load. They also distribute the load among the chillers. See [Measures 2.1.1 ff](#) for details.
- ***exploit the preferential load capability of variable-flow pumping.*** In variable-flow pumping systems, a selected chiller can be loaded preferentially by the manner in which it is installed in the chilled water piping system. Using this method, the selected chiller is loaded fully before any other chillers are loaded. This method is inflexible, but it has certain advantages. Refer to [Measure 2.5.2](#) for details of variable-flow pumping.

How This Subsection is Organized

The first three Measures of this Subsection recommend recovering heat from the condensers of chillers. They are presented in order of increasing cost and complexity. The fourth Measure captures the relatively small quantity of energy that is available at high temperature in the form of superheat. The last Measure recommends heat storage, primarily to increase the amount of heat that can be usefully recovered.

You can recover heat from cooling equipment in many ways. The Measures in this Subsection represent the basic and intermediate levels of complexity. Other techniques are more complex, such as two-stage heat recovery, combinations with heat pumps, etc. These methods require an advanced knowledge of refrigeration theory and practice, and they are more difficult to operate efficiently. These heat recovery techniques are usually specialized to particular industries, and they are likely to be integrated into the design of specialized processes.

MEASURE 2.10.1 Use condenser water directly for heating applications.

RATINGS

New Facilities	Retrofit	O&M
A	C	

The easiest way to recover heat from a chiller is simply to divert the condenser water through a heating application on the way to the cooling tower. The heat recovery temperature can be increased by raising the condenser water temperature setting, subject to the limitations of the chiller.

The simplest arrangement is shown in Figure 1. You can use this for an application such as tank heating, where the amount of heat available exceeds the requirement, and where the normal condensing temperature is adequate.

Another arrangement is shown in Figure 2. This one provides somewhat higher recovery temperature because it avoids the heat loss that would occur in an idle cooling tower. This advantage is most significant if heat is being recovered during cold weather.

Fig. 1 Condenser heat recovery This arrangement simply taps heat from the condenser cooling water as it leaves the condenser.

Energy and Cost Saving Potential

If you can recover heat at the chiller system’s minimum condensing temperature, this Measure saves energy in three ways:

- **heat recovery.** All the heat rejected by the chiller can be recovered by this method. The application determines how much of this heat is useful.
- **reducing compressor power,** due to the cooling of the condenser water in the heat recovery process. This cooling augments the cooling tower. This saving occurs as long as the cooling tower water would be warmer than the minimum allowable temperature without heat recovery. The efficiency improvement is greatest when the chiller is heavily loaded and the cooling tower has the highest temperature differential.
- **reducing cooling tower fan power.** Heat recovery leaves less heat for the cooling tower to discard, so the tower fans do not have to work as hard. The saving depends on how the cooling water temperature is controlled.

If you raise the condensing temperature to recover more heat, the chiller will consume more energy. The cooling tower fans will use less energy because they are rejecting less heat, and because the cooling tower is more effective at higher temperature. If you have a choice in selecting the condensing temperature, make a careful analysis to find the temperature that produces the greatest overall saving.

Protecting Against Contamination

The main limitation of this method is that the cooling tower water is contaminated by dirt and water treatment chemicals. The water may also become contaminated by refrigerant. Therefore, the application must be able

to tolerate the contaminants, or it must be isolated from them.

The simplest application is one in which the cooling tower water can be passed through a coil that is designed to operate with dirty water. For example, heating storage tanks for heavy oil is a good application. If the application needs protection against the possibility of a heat exchanger failure, refer to the Subsection introduction for various methods.

Fig. 2 Condenser heat recovery with option to bypass the cooling tower This arrangement maximizes the amount and temperature of heat recovery by avoiding heat loss from the cooling tower. This is especially useful in cold climates.

Controls

If you intend to recover heat only at normal condensing temperatures, no additional controls may be needed.

If you intend to raise the condensing temperature to increase heat recovery, install controls that limit the condensing temperature to the minimum needed to satisfy the moment-to-moment heat requirement of the application.

If the chiller must maintain a minimum condensing temperature, and the initial temperature of the substance you are heating is below this temperature, install a thermostatically controlled bypass to maintain the minimum temperature in the condenser.

ECONOMICS

SAVINGS POTENTIAL: The amount of heat that can be recovered is equal to the cooling load plus the energy input to the chiller. The energy consumption of the cooling tower fans is reduced. If the heat is recovered at minimum condensing temperature, the chiller COP is improved by the reduction of the condenser temperature. If heat is recovered at elevated condensing temperature, compressor power is increased.

COST: Varies widely, typically several thousand dollars for more. Most of the cost is for piping, and perhaps, for a heat exchanger.

PAYBACK PERIOD: Less than one year, to many years. The economics are better in larger systems, other factors being equal.

TRAPS & TRICKS

DESIGN: If you plan to increase the condensing temperature to increase heat recovery, design the controls to optimize the balance between heat recovery and reduced chiller performance. This requires a detailed knowledge of the chiller's efficiency characteristics.

MAINTENANCE: Cooling tower water is dirty, so schedule regular cleaning of any heat exchangers.

EXPLAIN IT: Put a clear explanation of the heat recovery system in the plant operating manual. Install placards on any unusual items.

MONITOR PERFORMANCE: Schedule periodic checks of control operation and heat exchanger cleaning in your maintenance calendar.

MEASURE 2.10.2 Use an auxiliary condenser or double-bundle condenser for heat recovery.

RATINGS

New Facilities	Retrofit	O&M
C	C	

If you don't want to recover heat directly from the cooling tower water (Measure 2.10.1) because of the dirt and chemical content of the water, consider using an auxiliary condenser. An auxiliary condenser is a second condenser. It is similar to the primary condenser, except that you size it for the amount of heat that you wish to recover. Clean water is circulated in a closed loop between the auxiliary condenser and the heat recovery application. Figure 1 shows a chiller with a large auxiliary condenser.

The compressor discharges freely to both the main condenser and the auxiliary condenser. The division of refrigerant flow between the main condenser and the auxiliary condenser depends on their relative temperatures and sizes.

Heat can be recovered at any temperature up to the temperature of compressor discharge. However, if the temperature of the main condenser is considerably lower than the heat recovery temperature, most of the heat will go into the main condenser. To increase heat recovery at maximum temperature, the flow of cooling water to the main condenser has to be throttled back.

A double-bundle condenser is a variation of this arrangement, in which a single condenser shell contains

SUMMARY

Requires an expensive special condenser. Avoids cooling tower water contaminants, but not the risk of refrigerant contamination. The economics are best in applications where heat recovery can occur at lower condensing temperatures. Can be used with air-cooled chillers.

two isolated tube bundles. One of the tube bundles is cooled by cooling tower water, like a normal condenser, and the other tube bundle is used for heat recovery, like an auxiliary condenser. Figure 2 shows heat recovery from a double-bundle condenser.

Trane Company

Fig. 1 Chiller with auxiliary condenser This chiller has two condensers of approximately equal size. One is connected to a cooling tower, and the other to a heat recovery application. An auxiliary condenser of this size can recover an enormous amount of heat at low temperature for applications such as pre-heating domestic water.

Double-bundle condensers are used in new chiller installations, while auxiliary condensers are used in both new and retrofit applications. The main differences are in cost and equipment layout.

Comparison to Measure 2.10.1

The energy and cost saving factors are the same as those of [Measure 2.10.1](#).

Heat recovery in [Measure 2.10.1](#) occurs in series with the condenser, whereas heat recovery in this Measure occurs in parallel with the main condenser. In [Measure 2.10.1](#), all the discharge heat enters the heat recovery process. In this Measure, a fraction of the heat bypasses the auxiliary condenser and is lost to the cooling tower.

For example, consider preheating domestic water that enters the auxiliary condenser at 55°F, while the water from the cooling tower enters the primary condenser at 90°F. If the two condensers are identical, most of the chiller's heat is rejected to the auxiliary condenser because it is colder, but some heat is lost to the cooling tower. This is not a problem if the amount of heat rejected by the chiller substantially exceeds the needs of the application.

Fig. 2 Heat recovery from a double-bundle condenser This arrangement has a throttling valve to regulate the heat recovery temperature. To maximize the heat recovery temperature, restrict the flow of water from the cooling tower to its tube bundle.

Contamination By Refrigerant or Leakage Into Refrigerant

The auxiliary condenser has its own closed water circuit, independent of the cooling tower water. This keeps the water clean, so it can be used in conventional heating coils.

A leak in the auxiliary condenser will contaminate the heat recovery water circuit with refrigerant, if a high-pressure refrigerant is used. Therefore, heating potable water and other critical liquids requires additional safeguards, which are explained in the introduction to this Subsection. If a low-pressure refrigerant is used, a leak in the auxiliary condenser will allow the water or other heated liquid to contaminate the refrigerant.

Control with Water-Cooled Primary Condensers

In the simplest cases, a water-cooled auxiliary condenser may require no controls. Preheating domestic water is such an application, provided that the incoming domestic water temperature is not too low.

To raise the heat recovery temperature, raise the temperature setting of the cooling tower. This causes more of the refrigerant to give up its heat in the auxiliary condenser.

The controls should optimize the system economics under all operating conditions, taking into account the value of heat recovery, chiller input energy, cooling tower fan energy, and energy consumption of heat recovery pumps. These controls may be simple or complex, depending on the heat recovery application and the amount of money at stake.

Stop the flow of liquid through the auxiliary condenser when the compressor is not running. Otherwise, the liquid may be cooled, rather than heated. As explained in [Measure 2.9.1](#), an idle chiller acts like a heat pipe, in which heat from warmer parts flow to the coldest part by refrigerant convection. For example, if cooling tower water continues to be circulated through the main condenser, the temperature there will approach the outside wet-bulb temperature. If the weather is cool, water flowing through the auxiliary condenser may lose heat to the main condenser.

Unless the compressor operates almost continuously, install an automatic valve to shut off the auxiliary condenser. This is an added complication, and another item to maintain.

Accessories and Control with Air-Cooled Chillers

In principle, you can use an auxiliary condenser with an air-cooled chiller. This is an odd arrangement, and it may take a great deal of skill to get it operating properly. The air-cooled condenser exposes refrigerant directly to outside air temperature. As a result, the relative temperatures of the two condensers cannot be used to regulate the amount of heat recovery. Instead, it would

be necessary to use backpressure valves in the compressor discharge line to distribute the flow of gas to the two condensers, along with check valves to control the flow of liquid refrigerant.

Another problem is that refrigerant would accumulate in the air-cooled condenser during cold weather. Therefore, the system would need enough extra refrigerant to make up for the refrigerant trapped in the air-cooled condenser during cold weather, and it would need a large receiver to hold the excess refrigerant during warm weather. In systems where oil travels with the refrigerant, piping technique would be critical.

ECONOMICS

SAVINGS POTENTIAL: *This arrangement can recover a large fraction of the heat rejected by the chiller system. The fraction depends on the relative size and recovery temperature of the auxiliary condenser (or bundle). The energy consumption of the cooling tower fans is reduced. If the heat is recoverable at minimum condensing temperature, chiller COP is improved by reducing the condenser temperature. If the temperature of the cooling*

tower condenser is increased to enhance heat recovery, the compressor input energy is increased.

COST: *\$10 to \$20 per thousand BTUH of heat recovery capacity.*

PAYBACK PERIOD: *Several years, or longer. Larger systems typically have shorter payback periods.*

TRAPS & TRICKS

PLANNING AND DESIGN: *Make sure that you can recover enough heat to justify the cost of the modification. As in all heat recovery methods, the tricky part of the design is the controls, which become more complex if you want to operate with elevated condensing temperatures. Provide safeguards against refrigerant contamination of the water, if this could be a problem. If you want to try this with an air-cooled system, treat it as a pioneering venture.*

EXPLAIN IT: *Put a clear explanation of the system in the plant operating manual.*

MONITOR PERFORMANCE: *Schedule periodic checks of control operation in your maintenance calendar.*

MEASURE 2.10.3 To recover large amounts of heat at elevated condensing temperature, install a heat recovery chiller.

RATINGS

New Facilities	Retrofit	O&M
B	D	

The main limitation of chiller heat recovery is the low temperature of the recovered heat. While conventional chillers can be operated at increased condensing temperature, they pay an increasingly severe penalty in COP, capacity, and service life as the heat recovery temperature is increased. If you have a potential heat recovery application and exploiting it would require a condensing temperature that is too high for your conventional chillers, consider installing a heat recovery chiller.

A heat recovery chiller is any type of cooling machine that is built to operate at a higher condensing temperature for the purpose of recovering its heat output at higher temperature. The difference is a matter of selection, not fundamental design. You select the condensing temperature to satisfy the temperature requirements of the heat recovery application. Typically, you select the capacity of the machine to satisfy the heating load, rather than the cooling load. By the same token, you may control the output of the machine to follow the heating load, rather than the cooling load.

A large cooling machine that is designed with a view toward recovering its heat output may be called a “heat pump,” although the term is commonly reserved for small units that are designed primarily as a substitute for other types of heating equipment. On the other hand, the more theoretical members of the HVAC trade use the term “heat pump” to cover all cooling machines, regardless of whether or not the heat output is exploited. Don’t be confused by the terminology. Regardless of what anyone calls the machine, the basic issues are the same.

Reasons to Install a Special Heat Recovery Chiller

A specialized heat recovery chiller may offer some or all of these advantages, when compared to chillers that are not selected specifically for heat recovery:

- it is capable of achieving higher recovery temperatures. In applications such as heating domestic water, this allows heat recovery to satisfy a larger fraction of the application’s energy requirement. In some cases, it allows heat recovery for applications that would not otherwise be possible.
- it achieves higher recovery temperature without sacrificing reliability
- it has a COP that is optimized for the heat recovery temperature (but it has a lower COP than conventional chillers when operating at conventional temperatures)

- in the case of a centrifugal chiller, it retains better unloading capability
- it is sized so that the COP penalty resulting from the high condensing temperature is limited to the smallest possible fraction of the cooling load
- it can be operated without a cooling tower, if all condenser heat is recovered
- in existing plants, it does not cause the chiller plant to lose cooling capacity because of operation at high condensing temperature.

Energy Saving Potential

The net saving provided by a heat recovery chiller is a balance between the value of the recovered heat and the cost of the additional energy required by the chiller.

The amount of recoverable heat equals the cooling load plus the motor input energy. The application determines how much of this heat is useful. If the chiller is sized properly, most of this heat is recovered.

On the debit side, the heat recovery chiller requires substantially more energy than a cooling-only chiller that produces the same amount of cooling at lower condensing temperatures. The compressor energy input typically increases from 1.0% to 1.4% per degree Fahrenheit (1.8% to 2.5% per degree Celsius) that the design condensing temperature is increased. If the application needs an intermediate heat exchanger to isolate it from possible refrigerant contamination, the temperature differential is increased, which increases energy input.

From the standpoint of energy alone, the increase in compressor energy is recoverable as heat. From an

economic standpoint, the compressor input energy usually has higher value than the recovered heat, unless the recovered heat is used to displace resistance heating. Electricity typically costs several times more, per unit of energy, than heat produced with common fuels.

The heat recovery process saves a fraction of cooling tower fan energy, because the recovered heat does not have to be rejected by the cooling tower. On the other hand, any pumps used in the intermediate heat transfer loop consume additional energy. These factors are usually minor in comparison with the first two factors.

Chiller Cost

In new construction, installing a heat recovery chiller may not add much to the chiller plant cost. The heat recovery chiller is typically a smaller unit, and it carries a part of the cooling load. The cost per unit of cooling capacity is somewhat higher because capacity drops at higher condensing temperatures.

In existing facilities, adding a specialized chiller to exploit heat recovery is expensive. To pay off, the potential heat recovery application must keep the chiller heavily loaded for long periods.

If the plant presently lacks a chiller that is small enough to handle low cooling loads efficiently, consider using a smaller heat recovery chiller to serve as a lead chiller. (See [Measure 2.8.1](#) about installing an efficient lead chiller.) This approach makes sense if there is a large heat recovery load during periods when the cooling load is low.

The economics of adding a heat recovery chiller to an existing plant are most favorable if the chiller satisfies a need for additional cooling capacity.

Sizing, Operating Schedule, and Heat Storage

The ideal heat recovery application is one that requires a steady input of heat at times that coincide with long periods of cooling. Such ideal loads are rare. Sizing the heat recovery chiller is usually a compromise between chiller cost and the amount of heat that can be recovered.

One way to level the heat recovery load is to store recovered heat until it is needed, as recommended by [Measure 2.10.5](#). This provides good utilization of the heat recovery chiller even with irregular heat loads, such as domestic water heating.

Electricity pricing schedules may affect the feasibility and operating schedule of a heat recovery chiller. See [Reference Note 21](#), Electricity Pricing, for details. The heat recovery chiller has higher demand for a given amount of cooling than conventional chillers, so it may not be desirable to recover heat during the time of day when electricity demand rates are high. If there is enough cooling load to produce useful amounts of heat outside the hours of high electricity prices,

consider heat storage as a way to satisfy the heat requirement during peak-price hours.

How to Distribute the Chiller Load During Heat Recovery

The heat recovery chiller normally is throttled to produce only enough cooling to satisfy the heat recovery load, because its higher condensing temperature gives it a lower COP. The introduction to this Subsection covers the ways of distributing the cooling load among chillers.

A subtle and serious problem may arise if a particular chiller is dedicated to heat recovery at high condensing temperature. The heat recovery chiller cannot share its cooling load with the next chiller that starts, so the next chiller may operate at low load for many hours, depending on the chiller sizing and the cooling load profile. This is especially serious with centrifugal chillers, and to a lesser extent, with screw compressor chillers. Correcting this situation may require sacrificing some heat recovery to provide higher cooling load for the cooling-only chillers. See [Measures 2.1.1](#) and [2.8.1](#) for more about this.

Operating the Heat Recovery Chiller at Reduced Condensing Temperature

If there are periods of time when no heat recovery is required, operate the heat recovery chiller at normal lower condensing temperatures, subject to any chiller design limitations. As with any chiller, cooling efficiency improves if you lower the condensing temperature.

A heat recovery chiller is less efficient at normal condensing temperatures than a similar chiller that is designed to operate at the lower condensing temperature. If you want the chiller to operate at both condensing temperatures, give the chiller manufacturer plenty of advance notice, as this may affect some design features.

Selecting the Type of Compressor

See [Reference Notes 32](#) and [33](#) for the characteristics of different types of chillers. See the introduction to this Subsection for chiller characteristics that relate specifically to heat recovery.

Screw compressor chillers are becoming attractive for heat recovery in all sizes except the largest and smallest. Certain models of screw compressors have variable discharge ports that allow them to adapt more efficiently to different pressure differentials. The advantage of these machines increases in applications where the cooling load and/or the heat recovery load varies widely, and also where the desired heat recovery temperature may vary.

Reciprocating chillers are well proven in heat recovery applications, and they continue to be the best

choice in many smaller applications. They have a great deal of flexibility in condensing pressure, throttling, and other characteristics. Their relatively low COP is less of a disadvantage in heat recovery applications, because their higher input energy is captured as heat.

For large heat recovery applications, a centrifugal heat recovery chiller offers the highest COP at its design condensing temperature. A big drawback of centrifugal chillers is limited ability to unload. Do not use a centrifugal chiller unless there is enough cooling load to keep the chiller above its minimum load during the period when heat recovery is useful. Centrifugal chillers have less ability than other types to increase their COP at condensing temperatures that are lower than their design condensing temperature. This is important if the chiller is needed for extended periods without heat recovery.

Centrifugal chillers with variable-speed drives are able to operate at reduced condensing temperatures without as much sacrifice of COP, and they are able to unload better. However, the variable-speed drive is an expensive feature that may not be justified in a dedicated heat recovery chiller.

■ Combinations of Chiller Types

In most cases, you can use any type of heat recovery chiller in combination with other types of chillers. For example, you might install a screw chiller for heat recovery in a plant where the other chillers are centrifugal.

You may have to deal with a control complication if you use a reciprocating chiller in combination with centrifugal or screw chillers. Reciprocating chillers use step control of capacity, so their output is usually controlled on the basis on return water temperature, while centrifugal and screw chillers typically control output on the basis of supply water temperature. Supply water temperature control is possible with a reciprocating chiller, but this requires special controls that anticipate the changes in supply chilled water temperature as the compressor unloads. This is a touchy method of control, especially where reciprocating chillers operate in parallel with other types.

Using the Same Chiller for Cooling Thermal Storage

The distinguishing feature of a heat recovery chiller is that it is designed for a larger difference between the evaporating and condensing temperatures. This same temperature differential may be appropriate for ice storage, which is covered in [Subsection 2.11](#). For example, a heat recovery chiller may be optimized for an evaporator temperature of 40°F and a condensing temperature of 110°F. A chiller optimized for ice storage, with an evaporator temperature of 20°F and a condensing temperature of 90°F, has about the same design temperature differential.

Thus, a chiller that is used for ice storage in summer to avoid peak electricity demand rates can also be used to recover heat at elevated temperatures during the rest of the year. This combination may greatly improve the utilization and economics of the chiller. For this to work well, the ice storage load and the heat recovery cooling load should be similar in magnitude.

The chiller cannot simultaneously recover heat at elevated temperature and store cooling at reduced temperature, because the increased temperature differential of the chiller can be used for only one application at a time.

Ice storage requires the chiller to cool an antifreeze solution as a medium for freezing the ice. Avoid using antifreeze solution when the chiller is used for conventional cooling, because all antifreeze solutions have poorer heat transfer characteristics than water. Switching the evaporator from chilled water to ice freezing solution requires draining the evaporator each time the chiller is changed from one function to the other. This is not too burdensome if done only on a seasonal basis. Some clever plumbing may ease the changeover.

ECONOMICS

SAVINGS POTENTIAL: *The amount of heat that can be recovered is equal to the cooling load plus the energy input to the chiller. The net saving is reduced by substantially increased compressor energy input, which usually has a higher value than the recovered heat. The net financial saving depends largely on the relative prices of electricity and heat.*

A minor bonus is that the energy consumption of the cooling tower fans is reduced. However, any heat transfer pumps require additional energy.

COST: *Heat recovery chillers cost between \$500 and \$1,000 per ton of cooling capacity. Because the cooling capacity is reduced at elevated condensing temperature, the cost averages about 20% higher than for chillers operating at minimum condensing temperatures. In terms of recovered heat, the cost of the chiller ranges from \$35 to \$70 per thousand BTUH.*

PAYBACK PERIOD: *One to three years, in new construction. Several years to much longer, in retrofit. The payback period is much shorter if the chiller is installed to satisfy a need for increased cooling capacity.*

TRAPS & TRICKS

PLANNING AND DESIGN: *Expect to spend time on this. A heat recovery chiller is one of the most complex ways to conserve energy. It can waste your investment or even waste energy if it is not planned properly, or if conditions change. Heat recovery design is complicated by interactions between the heat recovery chiller and the other chillers, by fluctuation in the value of the recovered heat, and by the variety of design options.*

SELECTING THE EQUIPMENT: Get your chiller from a manufacturer with experience in producing chillers for heat recovery applications. Check with other plant operators about the performance of the types of chillers you are considering.

EXPLAIN IT: Even though heat recovery should be controlled automatically, make sure that plant operators understand how heat recovery is supposed to work. Put

a clear explanation of the system in the plant operating manual. Otherwise, maintenance work or attempts to respond to cooling problems may sabotage the system.

MONITOR PERFORMANCE: Improper control operation is invisible, so schedule periodic checks of heat recovery efficiency. Include columns in the chiller operating log to record condensing temperature and other parameters related to the effectiveness of heat recovery.

MEASURE 2.10.4 To recover small quantities of heat at maximum temperature, install a desuperheater.

RATINGS

New Facilities	Retrofit	O&M
B	C	

With most refrigerants (but not all), the compression process raises the refrigerant gas temperature to a level higher than the saturation temperature in the condenser. This is why the compressor discharge pipe may be much hotter than the liquid refrigerant line from the condenser. The excess heating of the refrigerant over its saturation temperature is called “superheat.” The energy contained in the gas as superheat is a small fraction of the total heat rejected by the chiller.

A “desuperheater” is a heat exchanger that is installed between the compressor discharge and the condenser. The difference between the desuperheater and the condenser is that the heat removed in the desuperheater is only sensible heat, so no condensation occurs. Recovering the superheat at a temperature higher than the condensing temperature does not reduce the chiller COP, because this process does not affect the condensing temperature or the condensing pressure. (The compressor discharge pressure is determined by the condensing temperature of the refrigerant gas in the condenser, which is determined by the temperature of the cooling tower water.)

No control is needed on the refrigerant side of the desuperheater. The temperature of the liquid being heated is controlled by throttling its flow through the desuperheater. Alternatively, the liquid can pass through the desuperheater with no control, picking up as much heat as possible. Most commonly, the liquid is heated in the condenser first, and is then heated in the desuperheater to maximize its temperature.

Be aware that the term “desuperheater” may be used for any heat recovery heat exchanger that is installed in the compressor discharge line, regardless of how much it cools the gas. In this sense, a “desuperheater” is an

auxiliary condenser that is connected in series with the main condenser.

Applications and Energy Saving Potential

A desuperheater is useful where the desired heat recovery temperature is higher than the condensing temperature. Desuperheaters may deliver heat at a temperature that is useful for domestic water heating, for some space heating, and for some process applications. The recovered energy is sensible heat, so increasing the heat recovery temperature also increases the quantity of heat recovered.

If all the chiller’s rejected heat can be used at condensing temperature, a desuperheater cannot increase the total amount of heat that is recovered. If no desuperheater is installed, the condenser collects the

superheat energy, but at the lower condensing temperature.

Superheat comprises only a small fraction of the chiller's heat rejection. Most of the energy in hot refrigerant gas is contained as latent heat, not as sensible heat. Designers who are accustomed to recovering sensible heat from liquids and solids should not be fooled by the hotness of the compressor discharge pipe into believing that a lot of high-temperature heat is available.

Superheat is sensible heat, so the gas temperature drops as more heat is extracted. This forces you to compromise between the heat recovery temperature and the amount of heat that you recover in the desuperheater.

■ Common Refrigerants with High Superheat

With most common refrigerants, the amount of superheat is too small to be worth recovering. This is true of the common old refrigerants R-11 and R-12, and of the important replacement refrigerants R-123 and 134a. Of the common halocarbon refrigerants, only R-22 produces a substantial amount of superheat. The greatest amount of superheat among conventional refrigerants is produced by ammonia, which is notorious for its high discharge temperatures.

For example, consider a theoretical compression cycle from a 40°F evaporating temperature to a 120°F condensing temperature:

- with R-134a, the superheat energy is only about 4% of total heat rejection, and the discharge temperature is only about 12°F higher than the condensing temperature
- with R-22, superheat comprises about 11% of total heat rejection, and the compressor discharge temperature is about 155°F, which is about 35°F higher than the condensing temperature
- with ammonia, superheat is about 14% of total heat rejection, and the compressor discharge temperature is about 225°F, which is about 105°F higher than the condensing temperature.

These numbers apply only to "isentropic" compression, which is a theoretical situation. The temperatures in real equipment may be much lower, for the following reasons.

■ Effect of Compressor Features on Superheat

The numbers in the previous example assume that the gas is compressed without gaining or losing any heat between the evaporator and the condenser. This assumption is not valid with most compressors where compression occurs in stages, such as the common multi-stage centrifugal machines. Most of these machines use interstage cooling or refrigerant injection to improve efficiency, and these features reduce superheat considerably.

Most screw compressors use oil to seal the gaps between the lobes, and this oil acts as a coolant, reducing superheat.

Ammonia has a discharge temperature that is so high that reciprocating ammonia compressors commonly have water-cooled cylinder heads. The water cooling reduces the superheat. Screw compressors used with ammonia may also have water-cooled discharge components.

Before buying a new compressors, get information about its potential for recovering superheat from the manufacturer's engineering department.

To estimate the potential benefit of installing a desuperheater on an existing compressor, measure the superheat under different loads and condensing temperatures. To do this, you need to measure the temperature of the discharge line. You can do this easily by wrapping the sensing element of an accurate thermometer against the discharge line with a wad of any insulating material.

■ Limitations in Recovering Superheat from Air-Cooled Chillers

In an air-cooled chiller, the refrigerant discharge gas is in direct contact with the outside air temperature at the condenser. Therefore, the condenser pressure falls radically during cold weather. (Various features can be added to air-cooled condensers to maintain a higher condensing temperature, but these cannot maintain a high pressure under all loads.) The condensing temperature depends on the discharge pressure, so the high discharge temperature disappears during cooler weather. An air-cooled chiller is usually not eligible in applications where high temperature is needed during cold weather application, as in space heating.

Superheat could be maintained by installing a backpressure valve at the gas outlet end of the desuperheater. However, this would keep the chiller operating at reduced COP, even during periods when the condensing temperature can be reduced. Also, a backpressure valves adds potential failure modes. Failure of the valve in the closed position would shut down the chiller system, and failure in the open position would disable heat recovery.

Heat Exchanger Configuration

A desuperheater is relatively small. This is because the temperature differential is high and the amount of heat recovered is small. The gas passages must be large enough to pass full gas flow, since no condensation occurs. The desuperheater should allow free drainage of any refrigerant that condenses inside it. With refrigerants that carry oil, the desuperheater should allow proper return of oil to the compressor. The easiest way to satisfy these requirements is to install the desuperheater so that its discharge line drains toward the condenser.

To achieve the highest heat recovery temperature, the desuperheater should be a true counterflow heat exchanger. That means, the heated liquid should flow

in a direction opposite to the direction of the discharge gas. To achieve this, a coaxial unit is needed, rather than a shell-and-tube type.

How to Protect Against Contamination

If a leak in the desuperheater is a potential hazard, use a double-wall heat exchanger. These are readily available in desuperheaters.

ECONOMICS

SAVINGS POTENTIAL: Recoverable superheat is a few percent of the heat rejected by the chiller, the amount depending on the refrigerant and the features of the compressor.

COST: Double-wall desuperheaters cost from \$50 to \$100 per ton of compressor capacity, depending on size. Controls are additional, and may cost from several hundred to several thousand dollars. Installation typically requires one day to several days, depending on the complexity of the system.

PAYBACK PERIOD: Several years, or longer.

TRAPS & TRICKS

CHOICE OF METHOD: Don't let the high recovery temperature fool you into thinking that there is much heat available. Temperature is one thing, heat is another. Control the flow of liquid through the desuperheater so that the high temperature is not dissipated.

EXPLAIN IT: Although heat recovery should be controlled automatically, make sure that the plant operators understand it. Install a permanent placard with a diagram of the heat recovery system near the system controls. Placard the control valves and the controls.

MONITOR PERFORMANCE: Schedule periodic checks of heat recovery operation. Include a column in the chiller plant operating log to record the liquid discharge temperature from the desuperheater.

MEASURE 2.10.5 Improve the quantity or economics of heat recovery by adding or increasing heat storage.

In many potential applications for chiller heat recovery, the heat is available when it is not needed, and vice versa. In such applications, you can make recovered heat available when it is needed by installing heat storage as part of the heat recovery system.

You can use heat storage with any of the other Measures of this Subsection. The storage “technology” consists of an insulated tank. Liquid heated by the chiller condenser is stored in the tank. If that application already involves a tank, such as a domestic water heating tank, you can increase the storage effect by making the tank larger, or by adding another tank. Storage usually does not require any additional heat exchangers. The only energy penalty is heat loss from the storage tank, and perhaps the operation of a small additional circulating pump.

With some combinations of cooling and heating load profiles, using heat storage can reduce the size of the heat recovery chiller. This is important if you want to recover heat at an elevated condensing temperature. (Measure 2.10.3 explains why.)

Energy and Cost Saving Potential

The cost of heat storage equipment is high in relation to the value of the energy that can be stored at any one time. In order to be economical, the storage equipment must be needed to charge and discharge frequently, and to discharge fully during most cycles.

■ Applications that Benefit from Heat Storage

Heat storage for chiller heat recovery provides a benefit only if these timing relationships exist between the cooling load and the heat recovery application:

- there are periods of time when the amount of recoverable heat exceeds the immediate need for heat
- there are also periods of time when the need for heat cannot be satisfied by the available recovered heat
- these two periods alternate with each other. Recovered heat must be used fairly soon after it is stored. The stored heat continuously leaks out of the storage tank by conduction. With typical storage tanks, losses become excessive in time intervals ranging from one day to several days.

Figure 1 illustrates one typical day of operation with heat storage. On this day, heat storage is able to increase heat recovery only by a modest amount. By the same token, the storage capacity that is required to serve the heat recovery needs during this day is much less than the amount of heat that is recovered.

SUMMARY

Increases the amount of heat that can be recovered in applications where the cooling load is out of phase with the heat requirement on a daily cycle. May be able to reduce the size of the heat recovery chiller. The mechanical installation is fairly simple. Control may be complex if heat is recovered at elevated condensing temperatures.

■ An Example of Savings

Let’s look at an application in which condenser heat is used to preheat domestic water from a supply temperature of 55°F to an average final temperature of 85°F. The storage tank has a capacity of 10,000 gallons, and it costs \$10,000 to install.

Each gallon of water stores about 240 BTU, so the entire tank stores about 2.4 million BTU. If fuel-fired water heating costs \$5 per million BTU, then the value of the energy stored in the tank is \$12. In order to repay its cost, the storage tank must discharge completely 834 times (\$10,000 divided by \$12). The storage system operates on a daily cycle, and it discharges completely an average of 200 days per year. Therefore, the storage system breaks even about four and a half years after it goes into operation.

This example does not include a deduction for any additional pump energy required. Also, it assumes a very regular water usage pattern, which is unusual.

■ Effect of Electricity Demand Charges

Electricity rates do not affect your decision to use heat storage if you recover the heat at normal condensing temperatures.

If you increase the condensing temperature to recover more heat, this reduces the chiller COP and increases the demand cost of operating the chiller. Therefore, it may not be economical to recover heat during the time of day when electricity demand rates are high. (See Reference Note 21, Electricity Pricing,

for an explanation of demand charges. They are becoming an increasingly large part of electricity cost.)

Heat storage lets you operate the heat recovery chiller during hours when demand rates are low. However, this works only if there is enough cooling load at those times to produce the desired amount of heat. For example, this situation may occur in a hospital, but is unlikely to occur in an office building.

Electricity demand charges typically are seasonal. If you want to use heat recovery outside the months of highest electricity prices, then the effect of demand charges is less of an impediment to heat recovery during the daytime.

How to Estimate Storage Capacity

The chiller load varies from day to day, so estimating the most economical storage equipment capacity may be tedious. You need a series of graphs, similar to Figure 1, for your typical daily load profiles. From the number of days of each type, make a graph of the total annual heat recovery potential versus storage capacity and cost. From this, decide on the heat storage capacity. This is usually a compromise. The total savings increase as you increase capacity, up to the useful maximum, but the payback period gets longer.

An appropriate computer program may reduce the drudgery of this calculation, and it can model expected loads in new installations. See [Reference Note 17](#), *Energy Analysis Computer Programs*, for details.

In retrofit applications, you have the advantage that you can make your estimates with real data. Use a chart recorder or digital data logger to measure these profiles. Metering the chiller motor wattage is usually the easiest way to track the chiller load. You may have to install a

flow meter to measure the usage profile of hot water or other material that is to be heated.

The Heat Storage Equipment

The heat storage unit typically is a tank that has some additional hardware. The most important aspect of the tank design is keeping the heated liquid separate from the unheated liquid. Refer to the [Measure 2.11.1](#) for the ways that this is done in chilled water storage. The same methods apply to storing heated water.

The simplest, cheapest, and most common method of storing heated water is by exploiting the natural tendency of water to stratify in a tank. Compared to chilled water storage, hot water storage has the advantage that the change in water density with temperature is much greater, providing more reliable stratification. For example, water expands four times more in warming from 80°F to 100°F than it does in warming from 40°F to 60°F. Even so, be sure that the top and bottom connections are designed to limit water velocity and vertical mixing. This typically requires diffusers inside the top and bottom of the tank.

The major disadvantage of stratified storage is conduction of heat from the warmer water to the cooler water inside the tank. If water stands still inside the tank, the temperature of the water eventually becomes uniform. To maximize stratification and minimize the conduction problem, make the storage tank tall in relation to its width. Do not use a horizontal tank if you are depending on stratification. (A horizontal tank with a series of vertical siphon baffles is a more complicated method of storage.)

In some applications, you can exploit storage capacity that already exists. For example, if the

Fig. 1 Example of heat storage These are profiles of chiller heat rejection and water heating energy requirements for a large hotel on a typical day. By using heat storage, some of the excess heat produced during period "B" can be saved for use during period "C." Similarly, excess heat produced during period "A" can be saved for use during period "D." The required storage capacity is the larger of "C" or "D." To determine the storage capacity that provides the best economics, you need to make similar curves for all operating conditions.

application is fuel oil tank heating, the mass of the fuel oil itself acts as a storage medium.

Typical Domestic Water Preheating Systems

Domestic water preheating with chiller heat recovery is fairly simple. Figure 2 shows a typical installation. The heat exchanger recovers heat from the leaving condenser water, and a pump circulates water between the heat exchanger and the heat storage tank. Hot water enters or leaves the tank at the top, and cold water enters or leaves the tank at the bottom. An ordinary domestic water heater is used for final heating.

The final heating tank is typically much smaller than the storage tank, because it is sized only to provide for the maximum hot water usage rate. You can keep it small by increasing the capacity of the heater. But, if you use electricity for final heating, try to limit electric heating to periods of low electricity prices. This may require a larger final heating tank.

Control for this type of system is simple. In this example, the heat exchanger circulation pump runs whenever the condenser water entering the heat exchanger is more than a few degrees warmer than the temperature at the top of the storage tank. This single control performs these important functions:

- stops the pump when the chiller turns off. Otherwise, the flow of cooling tower water through

the heat exchanger would cool down the storage tank.

- stops the pump when the storage tank is fully charged
- prevents diluting the tank with colder condenser water if the condensing temperature is lowered to improve the COP after the tank is fully charged.

Typical Recirculating Heating Systems

If the application is a recirculating heating system, the heat storage layout is generally similar to the arrangement for domestic water heating. Although the layout is simple, some control complications are needed to match the characteristics of the storage equipment to the characteristics of the heating equipment. The design issues are similar to those described in [Measure 2.11.1](#) for cooling with chilled water storage.

In brief, the ability of the storage unit to provide heating energy is determined by the peak temperature of the heating system, and by the differential between the heating water supply and return temperatures. A major obstacle is that most heating systems operate at temperatures higher than typical heat recovery temperatures. To bring the two temperatures together, it is necessary to lower the system heating temperature and to raise the chiller heat recovery temperature. This complicates the design of the heating system, invites comfort problems, and sacrifices chiller COP.

Fig. 2 Heat storage for domestic water heating A small pump circulates water from the heat exchanger into the top of the storage tank, which depends on stratification to keep the warmest water near the top. Diffusers are installed at the top and bottom connections to preserve stratification. The pump operates only until the storage tank is filled with enough hot water to satisfy needs during the next discharge cycle. A diverting valve is installed in the condenser water line to avoid losing heat to the cooling tower when maximum heat recovery is desired.

Another obstacle is the very large storage volume needed to serve a typical space heating application. The amount of heat that can be stored in a given volume of water is directly proportional to the temperature differential in the heating system. To minimize the storage volume, design the heating system to maintain a large temperature differential between the supply and return water. This requires special heating coils, 2-way coil control valves, and variable-flow pumping, as in chilled water storage systems.

Balancing Storage Capacity with Heat Recovery Temperature

The amount of heat that can be stored in the form of hot liquid is directly proportional to the temperature differential that can be stored. Therefore, recovering heat at higher temperature reduces tank size and cost, even if the storage temperature is higher than the application requires. On the other hand, increasing the heat recovery temperature reduces the chiller COP. You need to calculate an optimum compromise between heat recovery and cooling efficiency.

Heat storage is most economical when it is used with a chiller that is optimized for heat recovery. The benefit is mutual. The higher recovery temperature of the chiller increases heat storage, and heat storage increases the utilization of the heat recovery chiller.

Minimize Operation at Increased Condensing Temperature

If you want to increase the condensing temperature at certain times to increase heat recovery, install time controls or other automatic controls to limit the duration of operation at elevated condensing temperature. These controls simply switch between two sets of condenser thermostatic controls, one for normal operation and the other for heat recovery operation.

The controls should limit operation at elevated condensing temperature to the minimum needed to provide for the estimated heating needs of the next heating cycle. If heat usage depends on weather, the day of the week, or other variables, intelligent logic is needed to estimate the heat requirement. Computer controls are available for this function, but manual input may still be needed to account for weather changes that the computer cannot foresee.

If demand charges are a factor in scheduling heat recovery, use either time controls or demand controls to minimize condenser temperature during periods of high demand charges.

If you install a specialized heat recovery chiller to operate at higher condensing temperatures ([Measure 2.10.3](#)), you need additional controls to distribute the load between the chillers to optimize overall plant performance.

Combining Heat Storage with Solar Collectors

In locations that are suitable for solar collectors, consider using them as a source of energy to charge the heat storage system. Combining the two may be favorable for these reasons:

- **complementary time schedules.** On a seasonal basis, solar collectors can continue to produce heat during cooler weather, when the chillers are operating at reduce load, or are not operating at all. Even during the cooling season, electricity demand charges make it undesirable to operate chillers at increased condensing temperature during peak daytime hours. Solar collectors are a daytime heat source, so they can increase the temperature of the liquid after initial heat recovery. If the system uses cooling thermal storage ([Measure 1.11.1](#)), the chillers do not operate during periods of high demand charges, which are typically summer days. Solar collectors are most effective at these times.
- **compatible temperatures.** Solar collectors can boost the temperature of water heated by the chiller condensers. Flat-plate collectors produce higher temperatures up to about 140°F, at useful flow rates. Focussing reflectors can produce temperatures that are much higher.
- **shared equipment costs.** The storage tank and piping of a heat storage system can also serve as part of an active solar system. Active solar systems have poor economics by themselves, largely because of the cost of these components. This is a way to get an active solar system at substantially reduced cost.

See [Reference Note 23](#), Non-Fossil Energy Sources, for more about solar energy systems.

ECONOMICS

SAVINGS POTENTIAL: *The saving consists of the additional heat that is usefully recovered by virtue of having the storage system.*

COST: *Insulated steel storage tanks cost about \$1 per gallon in large sizes, up to about \$4 per gallon in small sizes, including a moderate amount of piping. This translates to \$4 to \$20 per thousand BTUH stored, in typical applications. If storage is used to reduce the capacity of a new heat recovery chiller, the net cost of the storage equipment may be greatly reduced.*

PAYBACK PERIOD: *3 to 20 years, depending mainly on energy costs and the number of discharge cycles per year.*

CAREFUL DESIGN: *To calculate the optimum amount of storage capacity, make a range of estimates for*

reasonably foreseeable conditions. Design the storage tanks for effective separation of the heated water from the unheated water. Pay special attention to the control strategies if heat is recovered at elevated condensing temperature, or if final heating is done with electricity.

EXPLAIN IT: *Put a clear explanation of the storage tank in the plant operating manual as part of the*

explanation of the overall heat recovery system. Install a placard on the storage tank.

MONITOR PERFORMANCE: *Include a column in the chiller operating log to record storage tank temperature. Review the logs regularly to check that the system is operating properly.*

Cooling Thermal Storage

Cooling storage is an old technique that was originally employed to allow small cooling equipment to serve large cooling loads for short intervals. After a long period of dormancy, cooling storage experienced an explosion of interest in the 1980's that continues to the present. This time, the primary interest is in shifting the cooling load to times of day when electricity rates are lower. The difference in electricity prices between different hours of the day continues to widen. This suggests that cooling storage will continue to grow in popularity.

After a rocky start, storage equipment is becoming more reliable. Several types continue to evolve, and new types occasionally appear. The growing pains have not ended yet. Although the concept is simple, cooling thermal storage is a broad subject with many complications. A chiller system with cooling storage is a challenge to design, to install, and to operate. Many systems have failed. The initial phase of cooling storage has yielded a wealth of experience that can guide the designer who is wise enough to learn from the past.

This Subsection contains a single Measure that covers the contemporary applications and variations of this technology. It organizes the subject for you, and incorporates the important lessons of experience. It stresses planning and analysis, which were often neglected in enthusiastic haste to install systems. It will help you to decide whether to use cooling storage, and it will point you toward the best equipment for your application. Expect to do a lot of additional study and investigation before making a commitment to installing a system.

RATINGS

New Facilities	Retrofit	O&M
C	C	

This Measure helps facility owners to decide whether to acquire cooling storage, provides an outline for the designer of a cooling storage system, and guides facility staffs in operating cooling storage systems.

Deciding whether to install cooling storage is complex. Stated most generally, cooling storage is desirable in applications where the opportunities and benefits outweigh the disadvantages. Both the benefits and the disadvantages are explained below. Following that is a sequence of steps that lead you from the initial decision to consider cooling storage to successful operation of the installed system. This is followed by a comparative review of all contemporary types of cooling storage equipment. At the end is an introduction to the major engineering issues.

Overview

A cooling thermal storage system is like a conventional chiller system, with the addition of a large container that stores cooling in ice, chilled water, or some other material. A cooling storage system is analogous to the electrical system of an automobile. The chiller is like the automobile’s generator, and the cooling storage unit is like the automobile’s battery. At different times, the cooling load of the facility may be served by the chiller directly, by the cooling storage unit, or by both. (Not all systems can operate in all three of these modes.)

Cooling storage has two main advantages over a system without storage. One is that cooling can be available on any desired schedule, independently of the operation of the chillers (within limits). The other is that the cooling storage unit may be able to deliver cooling at a higher rate than the chillers, or to supplement the chillers.

Cooling thermal storage is not an energy conservation measure in the strict sense. On the contrary, all forms of thermal storage involve losses, and they require additional energy for the operation of the system. Some forms of cooling storage make the chillers operate less efficiently. Thermal storage exists primarily for the benefit of the electric utility. It allows the utility to generate more of its electricity with its most efficient generators. It may also allow the utility to generate electricity with fuels that are less scarce or less critical.

From the standpoint of the facility owner, thermal storage is a means of purchasing electricity at lower rates. The electric utility rewards the facility owner who uses cooling storage by offering lower electricity rates. All parties should understand that this is a business arrangement, not a matter of engineering. The electric

SUMMARY

Currently popular as means of purchasing electricity at lower rates. Sometimes used in new plants to reduce chiller cost. Bulky, expensive, and complex. Reliability has been poor, but performance will probably improve with time. Will not operate properly without continuous monitoring. Ice storage, the most common method, seriously reduces chiller efficiency. Economic feasibility depends largely on long-term considerations that are not under the user’s control.

utility attempts to persuade the facility owner to use cooling storage for its own purposes. In turn, the facility owner must have enough savvy to negotiate the best rates with the utility.

Less frequently, the facility owner may use cooling storage as a way of reducing the chiller capacity that is needed for a new facility. By itself, this yields an economic benefit for the owner only if the cooling load is concentrated in short time periods. In many applications, cooling storage can provide both types of benefit.

At the present time, cooling storage is partly a fad among facility owners who fail to understand the underlying purposes of the technology, and the business motives behind it. Be especially cautious that cooling storage will serve your purposes in the long term. Cooling storage requires the facility owner to understand the motives and needs of the electricity utility company, to understand the theory of electricity pricing, and to be able to negotiate effectively with the electric utility.

Cooling storage has long been used successfully in a variety of specialized cooling applications. It cannot yet be considered a success in air conditioning applications, where it has experienced a large number of failures. These have been caused by deficient design, installation flaws, neglected maintenance, and failure to understand the logic of the systems’ operation.

Cooling storage will undoubtedly become more successful, both technically and economically, as experience accumulates. Even so, cooling storage will always be risky. Long-term success depends largely on future conditions that cannot be predicted reliably and that the user does not control.

Benefits of Cooling Storage

The following are the benefits provided by cooling storage. The first two are the main reasons that cooling storage is usually installed. The remaining benefits are ancillary. They may improve the economics of cooling storage, but they generally do not justify it by themselves.

■ Reduced Electricity Cost

At the present time, most cooling storage is installed to reduce electricity costs. Review [Reference Note 21](#), *Electricity Pricing*, for an understanding of the electricity pricing issues that are involved. In brief, the price of electricity is related to the time period when the electricity is purchased. Electrically powered chillers typically account for a large fraction of a facility's energy consumption, and cooling storage allows the operation of the chillers to be shifted to time periods when electricity is cheaper.

The key issue in reducing electricity costs is the "demand" charge, which varies with the time of day, the day of the week, and the season. Make sure that you are comfortable with this concept before studying the following examples. In brief, the demand charge is a charge based on the maximum *rate* of energy consumption (measured in kilowatts), not for the *amount* of electricity consumption (measured in kilowatt-hours). In the following examples, the objective of cooling storage is the minimize the demand charge.

Figure 1 shows how cooling storage can reduce electricity cost in a facility where the non-cooling load (lights, air handling units, computers, etc.) are essentially constant during the period of high demand charges. For example, this is typical of office buildings and retail stores. In this example, cooling is provided by storage, rather than by chiller operation, during the periods of higher demand charges. There are three demand charge periods during the day, and the objective is to operate the chillers only during the period of lowest rates.

The cooling load to be avoided during periods of higher demand charges is marked "A." The cooling storage unit can be charged at any time during the off-peak rate period, but preferably during the coolest hours of the night (to maximize chiller efficiency). This cooling load is marked as "B." During off-peak periods, the chillers can also serve the cooling load directly, if a cooling load exists then. Direct cooling is more efficient than cooling with storage, as we shall see, so we try to use direct cooling as much as possible during the off-

peak period. In our example, this direct cooling load is marked "C."

Figure 2 shows how cooling storage can reduce electricity demand charges in a facility where the non-cooling load fluctuates widely during the demand charge period. For example, this is typical of colleges and manufacturing facilities. In this example, cooling storage is controlled so that it satisfies the portion of the cooling load marked "A." The purpose of this is to limit the maximum electric load during the peak demand charge period. The cooling storage unit is charged during off-peak hours. As in the previous example, this load is marked "B." Again, direct cooling is used during off-peak hours to the maximum extent possible. The off-peak direct cooling load is marked "C."

Unlike the example in Figure 1, direct cooling is used for a portion of the cooling load during the period of higher electricity rates. This is because the demand charge during this period is determined by the highest value of the non-cooling electrical load, which occurs at 6 PM in this example. This method of using cooling storage is called "peak shaving." In this case, the cooling unit can be charged at any time, provided that the cooling load never increases the demand above that determined by the non-cooling loads.

Demand charges typically are established on a monthly or seasonal basis. In Figure 2, the non-cooling demand that is shown represents the highest demand during the measurement period, not the highest daily demand, which may be much lower.

Don't blindly follow the example of Figure 2 when you are considering cooling storage for peak shaving. The electricity rates that you pay may have an important additional complication. Some utilities penalize high demand not only by a demand charge, but also by increasing the kilowatt-hour charge during periods of higher demand rates. This makes it desirable to shift as much of the cooling load as possible to the off-peak rate period, regardless of the demand profile of the non-cooling loads.

Reducing demand benefits the electric utility, so many utilities presently offer incentives for the owner to install cooling storage equipment. These incentives typically take the form of partial rebates of the cost of installing cooling storage. Where such rebates are offered, they may be a major factor in the overall economics. Unfortunately, such rebates tend to dazzle facility owners, making them careless in assessing the overall cost of the project or the long-term operating liabilities. It is foolish to burden a facility with inappropriate equipment for the sake of a rebate.

■ Ability to Reduce Chiller Capacity in New Plants

If you are building a new chiller plant, you can use cooling storage to reduce the chiller capacity, saving overall chiller plant cost. The price of storage equipment is only about 10% to 20% of the price of conventional

chiller equipment, per unit of cooling capacity. Therefore, storage may reduce equipment costs. However, the cooling load in your application must occur during predictable intervals that leave ample time for charging the storage unit. For example, cooling storage has been used to reduce the size of air conditioning equipment in churches, which need a large cooling capacity for only a few hours per week. Similarly, cooling storage has long been used in dairy operations, where rapid cooling of a large volume of milk is required for a few hours each day.

Figure 3 shows how cooling storage can be used to reduce chiller capacity. Here, the cooling load pattern is typical of an office building. In this example, the chiller is controlled on weekdays so that it operates at full output until the cooling storage unit is fully charged, at which time the chiller throttles back to handle the current cooling load. This method of control avoids the possibility of running out of cooling capacity during weekdays, although it may keep more energy in storage than necessary. During the weekend, the chiller does not store cooling until late on Sunday. This minimizes losses from the cooling unit. (Other possible control approaches are covered below.)

In applications where cooling storage can reduce chiller capacity, storage is likely to reduce electricity costs as well. Design the system to get the greatest combined benefit. In the previous example, you might wish to increase the size of the chillers and increase the storage capacity so that the chillers can be turned off during periods of higher electricity rates.

■ Ability to Exploit Lower Condensing Temperatures

Cooling storage operation usually shifts the operation of chillers into the night, when the outside air is considerably cooler. If the chillers are able to reduce their condensing temperatures to follow the night air temperature, their average COP improves considerably. (Many chillers cannot exploit reduced condensing temperature. See [Measure 2.2.2](#) for the reasons.)

This is a major bonus that tends to be overlooked. With chilled water storage, the chillers may actually be able to operate with higher net COP than in conventional daytime cooling. With ice storage, the reduced condensing temperature may substantially reduce the COP penalty caused by the low evaporating temperatures needed for freezing.

■ Reserve Capacity in the Event of Chiller Failure

Cooling storage buys time for the repair of a failed chiller, provided that the chiller fails when the storage unit has a substantial remaining charge. However, this bonus is offset by the fact that the storage system itself increases the probability that a failure will occur in the chiller system.

■ Smaller Water and Air Distribution Components

In attempting to make a virtue of the lower evaporator temperatures required for ice storage, systems are being developed that exploit the lower chilled water temperatures. The main advantage of these systems is smaller size for chilled water and air distribution equipment. These systems are a mixed blessing. They are discussed below.

Fig. 1 Using cooling storage to minimize electricity cost (case 1): the electrical loads other than cooling are fairly constant during the period of high demand charges. The load profiles are typical of an office building. This situation favors providing enough storage capacity so that all chiller operation occurs during off-peak hours. This method of control is simple and reliable.

■ Compensating for Capacity Loss with Replacement Refrigerants

Some common refrigerants used in the past must be replaced to satisfy environmental concerns. (See [Reference Note 34](#), Refrigerants, for details.) Converting existing chillers to use new refrigerants has a capacity penalty, typically 10% or less. Most chiller plants have enough reserve capacity to make up for the lost capacity. If not, you can use cooling storage to make up for the loss. However, before you do this, look for energy conservation measures to make up the difference. (You should exploit most of your other energy conservation opportunities before getting involved with cooling storage.)

■ Increasing Heat Recovery

Cooling storage may improve the potential for recovering condenser heat from chillers. This is because cooling storage causes the chillers to operate at steady loads for longer, predictable periods of time. On the other hand, cooling storage may make heat recovery more expensive by eliminating chiller operation during periods of time when recovered heat is needed. Refer to [Subsection 2.10](#) for details of chiller heat recovery.

Ice storage reduces chiller COP by lowering the evaporator temperature. Similarly, if you increase the condensing temperature to enhance heat recovery, this also reduces the COP. Therefore, you usually don't want to do both at the same time. On the other hand, a chiller that is designed for ice storage may also be effective for

heat recovery at elevated temperatures when it is used for direct cooling of chilled water.

Under some conditions, you can increase chiller heat recovery by installing a heat storage unit. See [Measure 2.10.5](#) for details. In some of these cases, which are discussed below, you can use the same storage unit for both heating storage and cooling storage.

Disadvantages of Cooling Storage

Cooling storage illustrates the maxim that engineering is compromise. Cooling storage systems can be designed in many ways, each with its own advantages and disadvantages. The following are the main disadvantages of cooling storage, which vary in importance among the different types.

■ Energy Losses

Cooling storage is not an energy conservation measure. Storage systems consume more energy at the facility than conventional cooling. In the least favorable applications, the increase in electricity consumption would negate the advantage of lower electricity prices. These are the main energy losses:

- *reduced chiller efficiency*, especially with ice storage. Ice storage pays a high energy efficiency penalty because the chillers need to operate at low evaporating temperature in order to freeze the ice. This lowers the chiller COP from 30% to 50%, compared to water chilling, for a given condensing

Fig. 2 Using cooling storage to minimize electricity cost (case 2): the electrical loads other than cooling vary widely during the period of high demand charges The load profiles are typical of a college campus. In this situation, there is no cost penalty if the chillers operate during the hours of high demand charges, but only up to a maximum total demand that is determined by the non-cooling electrical loads. (This part of the cooling load is marked "D.") This method of control allows the cooling storage unit to be smaller, and it exploits the fact that direct cooling is more efficient than storage cooling. However, you have to guess what the non-cooling loads will be. The chiller loading decision becomes more complicated if the kilowatt-hour charge (commodity charge) for electricity changes with the time of day.

temperature. Even storing chilled water as a liquid requires lower evaporator temperature.

A new chiller that is designed for both cooling storage and direct cooling of chilled water has reduced efficiency in both applications. Existing chillers may be especially inefficient if they are converted to ice storage, or they may not work at all.

The loss of chiller efficiency is partially compensated by the fact that the chiller spends more time operating at night, when the condensing temperature can be lower.

- **conduction loss.** All thermal storage loses energy by conduction from the storage unit. Storage systems for larger commercial applications typically lose several percent of their energy charge per day. The relative energy loss decreases as the storage vessel becomes larger. This is an important factor that weighs heavily against smaller storage systems.
- **loss of residual stored energy.** Energy that is left over in the storage unit at the end of an operating cycle suffers higher storage losses. Most types of ice storage require the storage unit to melt all ice completely at the end of the storage cycle. This energy is lost if it cannot be used during the off-peak period.
- **auxiliary equipment energy consumption.** Cooling storage also requires additional energy to put the cooling energy into storage and take it back out. This usually takes the form of energy needed to operate additional pumps. Depending on the type and design of the storage system, the additional pump load may be minor, or it may be several times greater than conventional chilled water pumping.

From a global perspective, the energy efficiency picture becomes more favorable when you consider the

reasons why electric utilities promote cooling storage. Utilities promote this technology primarily to delay expensive and troublesome power plant construction, and to generate electricity with energy sources that are less expensive and less critical. It also allows utilities to minimize the operation of less-efficient generators, especially gas turbines, to handle peak loads.

Delaying power plant construction also delays the large expenditure of energy that occurs in construction. However, this advantage is lost after several generations of plant construction, because later plants must be increased in size to provide the additional energy used by the early generations of storage systems.

■ Space Requirements

A large amount of space is needed by the storage container and its accessories. The volume of the storage container is roughly proportional to the volume of the space being cooled. Chilled water storage requires about 20 to 30 cubic feet per ton-hour, ice storage requires about 3 to 4 cubic feet per ton-hour, and eutectic salts require a storage volume intermediate between the other two types.

For example, a typical office building with a floor area of 100,000 square feet, operating on a daily storage cycle, requires a minimum of about 3,000 cubic feet of ice storage, or about 100,000 gallons of chilled water storage.

■ Operation and Maintenance Burden

Cooling storage technology burdens the operating staff with additional complexity. The storage equipment is not particularly mysterious, but the control needed to optimize the operation of the system is somewhat subtle. Even if cooling storage technology were mature, many facilities would be unable to maintain and operate it reliably.

Another problem is continuity of operation. Unless you negotiate special terms with the utility, you will

Fig. 3 Using cooling storage to reduce chiller size The load profile is typical of an office building. During weekdays, the chiller always operates at full load, long enough to keep the storage unit at full charge. On weekends, the chiller does not charge the storage unit until Sunday afternoon, to minimize storage losses. During months when the cooling load is lower, the chiller could be operated at lower output to reduce demand charges.

forfeit all or most of your savings in electricity prices if the plant fails even once during the high-demand period. Skilled staff must occupy the plant continuously during the months when peak demand occurs, and they must be able to immediately correct any failure of the storage system.

As a rule, do not install cooling storage in a facility where the system cannot be monitored continuously and repaired immediately. You may be able to relax this requirement somewhat if you can negotiate certain arrangements with the electric utility that are described below.

■ Economic Risk

Any saving in electricity cost that is provided by cooling storage is based entirely on the pricing policy of the electric utility. The willingness of the utility to continue providing favorable pricing will depend on the benefit that cooling storage provides to the utility. Both will change with time, depending on the factors explained in [Reference Note 21](#), Electricity Pricing.

Several growing issues presently place the commitment of utilities to thermal storage in greater doubt. One is utility deregulation, which eliminates the marriage of individual customers to a particular utility. This may kill utility support for thermal storage, except for the incentive provided by current rate schedules. Another issue is the renewed interest in electric vehicles. If electric vehicles become widespread, they will charge their batteries mostly during off-peak periods, eliminating the need for thermal storage to level the load.

To reduce the economic risk to reasonable proportions, you need to negotiate a long-term rate contract, as outlined below. If the utility will not agree to an acceptable contract, it would be economic folly to invest much money in cooling storage.

HOW TO APPROACH STORAGE COOLING

Although the concept of cooling storage is simple, success requires the proper execution of many steps, each of which may involve a great deal of detail and special expertise. The following are the main steps in the development of a cooling storage system, from conception to birth.

Step 1: Clarify Your Motives

Many cooling storage plants have been installed as a fad, or to reap utility incentives. Plants built for such reasons alone are likely to fail. Before investing substantial effort or expense, consider all the potential benefits and disadvantages discussed previously. Decide whether the potential economic saving is worth the long-term operational commitment.

Cooling storage systems are expensive. Decide whether the initial investment and the long-term operating cost might better be invested in other cost

saving measures, or in improving your product, or in the stock market. Don't get preoccupied with cooling storage until you have exploited all the possibilities for reducing your energy costs that are less expensive and more reliable.

Step 2: Consider the Facility's Ability to Operate Cooling Storage

A properly designed cooling storage plant does not require a great deal of extra labor to operate. However, it does require an operating staff with a high level of specialized skill and the ability to monitor the storage system continuously. If the plant fails for even a short time during the peak demand period, the utility rate advantage may be lost for a month, a cooling season, or an entire year.

Step 3: Develop the Facility's Cooling Load Profiles

The potential saving in electricity costs is determined by the peak cooling load that occurs during the utility's high billing periods. The capacity of the cooling storage system is determined by the duration of the peak cooling periods. High cooling loads of short duration provide the greatest saving in relation to cost, whereas high cooling loads that last all day require larger storage capacities to gain the same benefit.

In new construction, you need a sophisticated computer program to estimate future load profiles, as well as for analyzing the performance of candidate storage systems. See [Reference Note 17](#), Energy Analysis Computer Programs, for details.

In existing facilities, get the detailed load profiles for several past years and study them. You will need to contact the electric utility for this information, unless you have an in-house energy monitoring system that provides sufficient detail. Even the electric utility may not have the historical load information you need. In that case, either set up your own metering, or use a computer simulation program.

The load profiles help you to gauge the likelihood that the utility will maintain a long-term commitment to cooling storage. If only a few days of heavy cooling load occur each year, as in Minnesota, for example, it is cheaper for the utility to operate peaking generators to cover these loads than to maintain support for cooling storage. In such locales, a utility's interest in promoting cooling storage may be transient, making future operation of storage plants uneconomical. On the other hand, in a location such as Florida, where high cooling loads occur for many days each year, the utility is more likely to continue its interest in cooling storage.

If you are installing a new chiller plant, the simulated load profiles will tell you how much you can reduce your chiller capacity by using cooling storage. The greatest savings in chiller capacity are provided by cooling loads that are sharply peaked.

Step 4: Estimate the Long-Term Saving in Electricity Cost

Estimate the potential saving in electricity cost from the cooling load profiles and from the utility's rate schedules. See [Reference Note 21](#) for guidance in understanding rate schedules. The Big Question is whether the lower electricity rates for cooling storage will outweigh the increased consumption caused by reduced chiller efficiency. The Big Challenge is to estimate how these rates will change over the life of the cooling storage system.

It is foolhardy to assume that present electricity prices will continue, or even that they will change gradually. To convince yourself of this, review the pattern of electricity prices over the past twenty or fifty years. You can guess future rates intelligently only by assessing the utility company's future. This requires a crystal ball. The utility industry itself, with staffs of experts, has proven to be wildly wrong in predicting future conditions, even over time periods as short as a decade.

Furthermore, in the United States and some other countries, the structure of the utility industry is changing from a regulated environment to an environment in which some parts of the industry are regulated and others are not. There will be a period of chaos in which the long-term economic benefit of cooling storage is even more unpredictable.

To establish the range of possibilities, calculate for a best case and a worst case. If cooling storage looks potentially attractive, this exercise will help you to prepare for the rate contract negotiations recommended below. If cooling storage looks unrewarding or too risky at this point, forget about it and spend your money on reliable energy conservation measures. Unfortunately, the uncertainties of predicting the future are such that the best case is likely to make cooling storage look advantageous, while the worst case is likely to make cooling storage look unfeasible.

Step 5: Investigate Utility Ownership and Operation of the Cooling Plant

Most cooling storage is installed for the ultimate benefit of the electric utility, so consider a deal in which the utility operates the storage chiller plant. The cleanest arrangement is for the utility to build and operate the cooling storage plant at its own expense. It is also conceivable that the utility could own the plant while the facility operates it, or vice versa. However, splitting responsibilities invites poor performance and eventual litigation.

At present, this is not a common arrangement, but there is precedent for such arrangements. Cogeneration plants were installed and operated at customer sites by natural gas utilities during the 1960's and early 1970's.

Unfortunately, this precedent does provide a model for success, because most of those plants were abandoned before they were able to repay their costs. In that episode, the utility companies could not operate the satellite plants any better than their customers. However, the customer was not saddled with the full financial loss.

Step 6: Negotiate a Long-Term Rate Contract with the Electric Utility

By this point, it should be apparent that cooling storage is an unacceptable gamble unless you are assured of favorable electricity prices for the life of the storage plant. Electricity prices change. It is a fundamental mistake to assume that present electricity prices provide sufficient incentive for cooling storage, even if subsidies are also provided by the utility to offset the cost of construction. A storage system will cease to be profitable unless it continues to provide an electricity price advantage that compensates for the energy losses of the system, the additional operating costs, and amortization of the original investment.

Therefore, early in the development of a cooling storage project, negotiate a long-term rate contract with the utility. This is not an activity for the naive. To do it right, you need to understand rate structures. You need to tactfully investigate the utility's present motivations and to assess its future conditions. You need to assess the future of utility regulation in your jurisdiction. You need negotiating skill, along with the authority to negotiate. The negotiation should be headed by a senior facility manager who has studied the issues in depth.

Take the initiative to prepare a contract offer that protects your investment. After all, you will be the party taking the risk of owning and operating the system, or at least providing the space for it. Furthermore, even though utilities are primary sponsors of cooling storage, many are naive about the economic and technical aspects of operating these systems. Both for negotiating purposes, and to ensure the success of your system, you need to know more about cooling storage than the utility. The utility is more likely to respond favorably to a reasonable proposal than to originate an arrangement that is satisfactory to you.

Your contract proposal should cover these four critical issues:

- the specific rates
- the duration of the rates
- exemptions for demand peaks caused by occasional equipment failure
- which metered loads will be subject to the cooling storage rate.

■ The Rates

The structure of electricity rates is explained in [Reference Note 21](#). Review this material to understand how a utility is compensated for the electricity that it

produces, and how cooling storage reduces some components of the utility's costs.

The starting point for the customer is calculating the electricity price differential that is needed to make cooling storage attractive. This may require the utility to offer a more favorable price or a more favorable rate structure than it presently offers.

Remember how the utility views cooling storage. It is not a revenue producer like other electrical sales, but a means to solve a utility problem. When talking to the utility, focus on the aspects of cooling storage that help the utility. You will not get a favorable electricity rate unless your system helps the utility to satisfy its objectives. Don't be surprised if the utility itself is not clear about its objectives, especially in the long term.

■ The Duration of the Rates

As a minimum, the contract should guarantee that favorable rates will continue long enough to pay off the system and to compensate for the effort, investment, and risk involved in installing it. If the utility is unwilling to negotiate such a contract, you have no rational basis to install cooling storage. Without a long-term rate contract, all it takes is the future decision of a utility executive to turn your cooling storage plant into a white elephant.

Electricity prices depend on many factors that vary in unpredictable ways, as explained in [Reference Note 21](#). Do not expect the utility to commit to specific prices for a long term in the face of these uncertainties. Such an agreement would be a pure gamble for both parties. Perhaps the best way to deal with this uncertainty is to negotiate long-term rates that are expressed in terms of a discount from any future non-storage rates.

For example, agree that electricity for the chiller plant, purchased during off-peak hours, will be priced at a fixed percentage of the lowest non-storage rate offered by the utility to any customer.

■ Forgiveness Clause for Occasional System Failures

There is an economic hazard for the owner of a cooling storage plant that is not yet adequately recognized. The hazard is that a brief failure of storage could wipe out the saving in electricity costs for a long period of time. This is because demand charges are based on measurements that are made throughout a specified time period.

If the cooling storage systems fails for only one day during the peak period, the demand that occurs on that day becomes the basis for the demand charge for the entire demand billing period. The demand billing period may be a month, the entire cooling season, or the entire year. While demand peaks are almost always measured on a monthly basis, "ratchet" provisions in the rate schedule may extend a demand charge that is determined during one month into the months that follow.

For example, one utility bases its yearly demand charges on the highest demand that occurs during the months of July, August, or September. If the cooling storage system fails on a hot afternoon in July, the demand registered during that period becomes the basis of demand charges for the entire year. A failure that lasts one hour can wipe out most of savings that the storage system is supposed to provide for that entire year.

To avoid this risk, negotiate a forgiveness clause in your long-term rate contract. This clause exempts demand charges resulting from occasional failures of the cooling storage system. For example, the contract might stipulate that no demand charges will be levied for the three days of highest facility demand during the cooling season, provided that none of these days is coincident with the three highest days of the utility's demand. Thus, if the storage plant suffers a failure that requires two days to repair, the facility probably will not lose its savings in electricity cost.

At first glance, it might appear that this defeats the utility's purpose in having demand charges. This is not true. From the standpoint of the electric utility, rare failures of cooling storage by individual customers are not important. This is because a utility has many customers using storage or other demand-reduction techniques. Statistically, the utility can expect that only a few storage failures, at worst, will occur during a utility load peak.

This concept is novel, so be prepared to explain and persuade. Another problem is that the utility will probably have to modify the way it calculates demand. Be prepared to argue that most large utilities now calculate demand from a central computer, which can be programmed with modest effort to accommodate different rate arrangements.

■ Electricity Metering Configuration

The distribution of metering may have a profound effect on electricity cost. The chiller plant may be served by the same meter as the entire facility, or the chiller plant may have separate meter, or the chiller plant may be combined with selected other loads. Each of these arrangements produces a different total electricity cost.

For example, if storage is used for "peak shaving," the chillers should be served by the same meter that serves the variable non-cooling loads. On the other hand, if the rates include excess-consumption charges, it may be better to have a separate meter for the chiller plant.

You will have to negotiate a change in metering with the utility. If you think that rearranging the metering would produce lower electricity costs, be careful to consider the net effect on electricity cost for all the metered areas. Be clear about which meters are covered by your negotiations, and which continue to be governed by the utility's existing rate schedules, and their successors.

Step 7: Assess the Potential for Heat Recovery from the Storage Chillers

As discussed previously, cooling storage may increase the opportunity for recovering the heat rejected by the chiller plant. On the other hand, heat recovery may reduce the efficiency of cooling operation. If the facility presents an opportunity for heat recovery, refer to [Subsection 2.10](#) for the factors to consider.

Step 8: Select the Control Strategy for Minimizing Electricity and Equipment Cost

Controlling a cooling storage installation may be tricky. How you control storage depends on the purposes you hope to achieve. In turn, the control strategy largely determines the storage capacity that you need to install. Select the control strategy to satisfy these primary objectives:

- scheduling the chiller load to minimize electricity cost
- minimizing the amount of excess stored cooling that remains at the end of each discharge cycle
- minimizing total equipment cost. In new construction, you can reduce the cost of the chillers, and perhaps the cost of other facility cooling equipment.

You will have to compromise between these objectives.

A simple example is a typical large office building in which the non-cooling electrical loads are essentially constant throughout the working day. This example is illustrated in Figure 1. If the electric utility's demand period is from 0800 to 1800, then the chiller is controlled so that it does not run during these hours. At the end of each day, the control system estimates the amount of cooling that is needed for the next day. The chiller is operated during the coolest hours of the night to put this amount of cooling into storage, plus a reserve to cover the uncertainty in predicting the next day's cooling load.

A more complex case is one in which the electrical demand of non-cooling equipment varies widely throughout the day, as shown in Figure 2. In such cases, the chillers may operate during the demand period, but their output is limited to keep the overall demand of the facility within a set limit. Thus, chiller output declines as other electrical loads increase. Operating the chiller during the demand period allows you to reduce the storage capacity. If the demand charge changes from one month to another (which is typical), then the optimum amount of chiller operation during the demand period will vary from month to month. This particular control strategy is called "demand limiting," although all modes of chiller control should attempt to limit demand.

If the purpose of cooling storage is to minimize chiller capacity, then chillers operate as close to the usage

period as possible, but still during periods of lowest electricity prices. For example, a dairy operation may have two milking cycles per day, both of which occur during the utility's demand period. The chiller operates at night to provide enough stored cooling for both of the cooling cycles. If the utility does not have a demand charge on weekends, the chiller may operate during the day on Saturday and Sunday to store cooling only for the evening cycle.

Controls are covered in greater detail at the end of this Measure.

Step 9: Estimate the Cooling Storage Capacity

The cooling storage capacity that you need is determined by the purposes of the system and by the facility's cooling load profile. For example, an office building in a mid-latitude climate typically has an afternoon cooling peak lasting only a few hours. This profile requires less storage capacity for a given demand reduction than a hotel located in a warm, humid climate, where the cooling load may remain high all day.

It may not be economical to displace all chiller operation from the period of high electricity prices. For example, if a heavy cooling load occurs only for a few weeks a year, a storage system designed for those loads will have a large amount of idle capacity for the rest of the year. If the utility has no ratchet charges, the excess capacity provides little benefit.

The actual storage capacity needs to be somewhat greater than the amount of cooling load that is displaced. As with most equipment, provide some reserve for loads greater than expected, and for equipment performance poorer than expected.

With all cooling storage methods, the chilled water temperature rises as the storage unit discharges. This reduces cooling capacity at the end of the discharge cycle. If the cooling load remains high at the end of the discharge period, you may need additional storage capacity to account for this effect. On the other hand, you may be able avoid this problem by installing multiple storage units, and discharging them in sequence.

In ice storage units, the rise in chilled water temperature toward the end of the discharge cycle may be severe, and the effect increases with discharge rate. This may not be a problem in an ice storage system that distributes chilled water at normal temperatures, because ice storage produces water that is much colder than normal chilled water.

On the other hand, if the system uses low-temperature chilled water distribution, and the cooling load remains high near the end of the storage cycle, the rise in chilled water temperature may be unacceptable. The problem is least severe with ice shedders and ice slurry systems. Internal-melt systems and ice capsules suffer a large rise in temperature, unless the discharge

rate is low. (Individual types of storage units are described in greater detail below.)

If you compensate by increasing the capacity of the storage unit, this will increase that amount of cooling energy that remains in the storage unit at the end of the cooling storage period. Much of this energy is wasted. For example, if cooling storage is not needed over the weekend, some of the residual cooling left in storage at the end of Friday is lost by conduction over the weekend. Even worse, some ice storage units require all the ice to be melted at the end of each discharge cycle, whether the cooling is needed or not.

Step 10: Estimate the Heat Recovery Storage Capacity, If Used

If you want to recover heat from the chillers, installing a heat storage may substantially increase the amount of heat that you can recover. The heat storage capacity is determined largely by the chiller operating strategy. Refer to [Measure 2.10.5](#) for details of heat recovery storage.

Step 11: Estimate the Cooling Storage Chiller Capacity

The chiller capacity is determined by the control strategy and the storage capacity. If you rely entirely on storage cooling during the peak electricity price period, the chillers must be large enough to charge the storage unit during the period when electricity prices are lowest. If the chillers serve the cooling load in parallel with the storage unit, then the chiller capacity is determined by the storage load or the direct cooling load, whichever is larger.

When you select the chiller size for charging the storage unit, recall that the chiller's charging capacity is less than its capacity for direct cooling. This is because the chiller must operate at lower evaporator temperature when charging. In ice storage systems, chiller capacity is reduced by about 40% compared to direct cooling, for the same condensing temperature. This effect is compensated somewhat by lower nighttime condensing temperatures, provided that the chiller is able to exploit lower condensing temperatures.

In new construction, if storage is being used to reduce chiller capacity, consider future changes in the cooling of the facility. Leave space for more chiller capacity if the cooling load increases. For example, an office building in a warm climate may presently be cooled only eight hours per day, but it is conceivable that future conditions will require much longer periods of cooling.

Step 12: Select the Cooling Storage Technology

The various types of cooling storage are described below. Your selection of the type of storage unit has major effects on system size, cost, complexity, and efficiency.

The first selection step is deciding whether to use ice, chilled water, or eutectic storage. Under present conditions, ice appears to be preferable for most applications. Chilled water is rarely used unless there is an existing water tank of adequate capacity. Eutectic storage probably is not the best choice unless there has been a significant improvement in the technology by the time you read this. If you select ice storage, you have another major decision in selecting the type of ice maker.

A major part of this decision is figuring out where to put the storage vessel. The vessels used with the different types of storage vary considerably in volume, height requirements, and accessibility requirements. For example, underground tanks are acceptable for some applications and storage methods, but not for others.

Step 13: Select the Type of Cooling Storage Chiller

See [Reference Note 32](#), Compression Cooling, and [Reference Note 33](#), Absorption Cooling, for details of chiller selection factors. As in all chiller plants, high COP should be a dominant criterion.

You face additional selection issues if the chiller makes both ice (for storage) and chilling water (for direct cooling). This requires the chiller to operate at two different pressure differentials. These issues are similar to the ones related to selecting chillers for heat recovery at elevated temperatures. See [Measure 2.10.3](#) for details. In brief, screw compressors and reciprocating compressors are favored in this case because of their ability to adapt to different pressure differentials.

Be sure to select chillers that can exploit low ambient condensing temperatures, for the reasons explained previously.

Step 14: Select the Evaporator Configuration

The method of controlling refrigerant flow to the evaporator has a major effect on system COP. Storage systems have been built with each of the three major evaporator types: liquid overfeed, flooded evaporators, and expansion valve. These types are explained in [Reference Note 32](#), Compression Cooling. Expansion valve evaporators are inherently less efficient than the other two types.

In ice storage systems, expansion valve evaporators require additional complications to allow them to switch efficiently between making ice and chilling water directly. One way of doing this is to install an expansion valve that maintains a fixed superheat, regardless of the evaporator temperature. Such expansion valves have been available for a number of years. Another approach is to use two expansion valves, one for making ice and one for chilling water. Solenoid valves control which expansion valve is used, based on signals from the system controls.

Step 15: Design the Connections between the Chiller Plant, the Storage Unit, and the Facility Equipment

The type of storage unit dictates major aspects of the design. These include isolating the storage unit from the pressure of the chilled water system, reconciling the supply and return water temperatures, and switching from charging to direct cooling. These topics are covered at the end of this Measure. In general, keep the overall configuration as simple and reliable as possible, while providing for efficiency in all the modes of operation.

Step 16: Design the Controls and Alarms

Control is the trickiest aspect of the design, installation, and operation of a cooling storage system. Cooling storage may require a large number of control functions because a system changes its connections, running time, and chiller loading for different operating conditions. A peculiar difficulty of cooling storage is that the control system must predict load conditions from several hours to several days in advance. Details are given below.

Step 17: Design the Physical Layout

From the standpoint of long-term performance, the most important aspect of the physical layout is easy access for maintenance. Design the layout so that any component in the system can be replaced easily. *Make it easy to maintain the system for the life of the facility.* Don't design for the short lifetimes used in economic analysis. You don't want a system to be unrepairable just because it is paid off.

Many cooling storage systems are being installed today in a manner that makes it virtually impossible to repair them economically. Burying systems underground not only makes them inaccessible, but invites deterioration by ground water. Equally bad is stacking modular units inside a building in a way that makes it impossible to remove an individual unit or to replace the components in a unit. No system on the market is sufficiently well proven to justify these practices.

Step 18: Install the System

Installing cooling storage is similar to installing other complex HVAC equipment. Effective communication between the designer and the contractor is important. Selecting packaged equipment reduces installation cost, and it lessens the opportunities for installation problems.

Step 19: Train and Preserve a Skilled Staff

Among the many failures of cooling storage systems, failure to operate the systems properly looms large as a primary cause. Operating a cooling storage plant requires a high level of skill, unconventional

knowledge, and continuous monitoring. The staff must receive special training to operate the system. There can be no lapses in staff continuity as long as the system is operating.

This is a major management challenge. Staff turnover requires continual retraining. Furthermore, talented operating personnel tend to be diverted to tasks outside the chiller plant.

COOLING STORAGE EQUIPMENT

The various types of cooling storage differ markedly in size, efficiency, reliability, and other significant characteristics. Early cooling storage for HVAC applications focussed on liquid water as the storage medium. Within a few years, growing awareness of the huge volume required by water storage, along with its economic and practical problems, forced designers to switch their preference to ice storage. In turn, ice storage has posed a whole new set of challenges. The design compromises required in ice storage are stimulating development of a variety of storage vessels and system types. The following is an introduction to the types of cooling storage that are presently available, with emphasis on their comparative characteristics.

■ Common Considerations for Ice Storage Units

Using ice for thermal storage has two major advantages over using chilled water storage. One is that much more energy can be stored in a given volume. The heat required to melt ice is about 144 BTU's per pound, while liquid water can absorb less than 20 BTU's per pound in typical cooling storage applications. As a result, a typical ice storage unit requires only about one fifth the volume of a chilled water tank.

The other major advantage of ice storage is that ice always melts at a fixed temperature, regardless of the state of charge of the storage unit. This keeps the chilled water supply temperature fairly constant as long as ice remains, regardless of the return water temperature. Therefore, the cooling system served by the storage unit can be entirely conventional.

This advantage is lost in air conditioning systems that are designed to exploit the low chilled water temperature available with ice storage. This is covered in greater detail below.

The main disadvantage of ice storage is low energy efficiency. The evaporator temperature needed to freeze ice is about 12°F to 30°F (7°C to 17°C) colder than is needed to chill water in conventional applications. This imposes a severe reduction of chiller COP, typically in the range of 20% to 40%. Some types of ice storage require substantially lower evaporator temperatures than others.

A fundamental problem in ice storage design is that ice expands when it freezes. Freezing of water is one of nature's most destructive forces. Given sufficient

time, it destroys mountains. In much less time, it destroys man-made constructions, such as roads and thermal storage systems. Ice also exerts force by its buoyancy. Some types of ice storage accommodate these forces with a greater margin of safety than others. With types that require coils in the tank for freezing, use well proven packaged units, rather than run the risk of repeating past mistakes with a custom design.

Another challenge in the design of ice storage units is the relatively poor thermal conductivity of ice, which is about the same as for granite, and about 0.5% the conductivity of copper pipe. Lower evaporator temperatures are needed to freeze greater thicknesses of ice, so the storage unit should minimize the thickness. Some types do this better than others.

Another problem is non-uniform flow of the chilled water or heat transfer fluid as it flows through the melting ice. Where water flows freely in a tank, it tends to melt channels through the ice, reducing heat transfer during the discharge cycle. Some types of ice storage are very vulnerable to this problem, while at least one type is immune to it.

Ice Shedders

A simple method of cooling storage is making ice, dropping it into a tank, and circulating water through the ice. The ice making machines are similar to the ones that make the ice cubes for your drinks. These storage systems are called “ice harvesters,” or “ice shedders,” because the ice maker is usually mounted above the ice storage tank, where it drops the ice into the tank below. Figure 4 shows the equipment layout.

Ice shedder systems are popular because they offer several significant advantages, and they are free of some of the problems of other types of ice storage. A primary advantage is the simplicity of the system connections. Ice shedders average about the same overall efficiency as other ice storage systems.

A major advantage of ice shedder systems is that they are less vulnerable to flaws in the design of the site installation. The ice making machine is usually purchased as a complete package, ready to be installed on top of the tank. If the machine is derived from well proven standard equipment, it is less likely to have crippling flaws that appear the day after the warranty expires.

The ice maker itself is relatively expensive, although its cost per unit of capacity drops radically with increasing size. Therefore, ice shedders are favored for applications that require a large storage volume in relation to chiller capacity. The storage tank is relatively inexpensive because it is simple. Commonly used materials for the tank and tank circuit include plastic, fiber-reinforced plastic (fiberglass), and concrete.

Ice shedder systems may be several stories tall, because the ice maker is mounted on top of the tank.

Figure 5 shows a typical installation. The height can be reduced by using a conveyor to move the ice to the tank, but this sacrifices some of the elegant simplicity of the system.

■ Evaporator Features

Ice is formed on the evaporator from water that is circulated from the storage tank. Many contemporary units use flat plate evaporators, from which the ice sheds in the form of sheets or large flakes. The flat sheet form is favored because it shortens the path of heat through the freezing ice, allowing higher evaporator temperatures, and hence higher COP. However, ice can be made in many shapes. Figure 6 shows a typical unit in operation.

Ice tends to stick to the evaporator as it freezes, so the method of releasing the ice from the evaporator is a major issue with ice shedders. At present, the most popular method is similar to a defrost cycle, which operates about 5% of the time. The ice is released by periodically bleeding hot gas into the evaporator while the compressor is turned off. The hot gas typically comes from a compressor discharge manifold that links several compressors. Figure 7 is a diagram of the cycle.

Paul Mueller Company

Fig. 4 The basic components of an ice shedder system
An ice maker dumps ice into a tank, and chilled water is circulated through the ice.

Defrosting wastes a certain amount of energy, so manufacturers search for more efficient methods of releasing the ice from the evaporator. One method is scrapers, which come in various designs. Another involves freezing the water as it is carried by a carrier liquid that acts as a release agent. The latter type are called slurry systems. Two versions of slurry systems are described below.

Some models of ice shedders are incapable of cooling chilled water directly. Such units have expansion valve evaporators that are set to operate at only one temperature for freezing.

Other models have liquid overfeed evaporators, which can vary their evaporator temperature. These units cool chilled water by pumping it over the evaporator in the same manner as for ice making.

■ Storage Tank Features

Ice shedders avoid the trickiest problems of designing ice storage units, which is dealing with the expansion of water as it freezes. The ice tank is simply a bin. The equipment inside the bin is not exposed to expansion or buoyancy forces. The return chilled water distributors may be kept above the ice, and the headers that extract water from the bottom of the tank may easily

be designed to resist damage. Although the tanks are simple, tank shape and control of water level are important to keep large voids from forming in the ice. Voids can be eliminated by stirring the ice pile mechanically, but it is best to avoid the complication.

The chilled water is cooled by direct contact with ice in the form of small pieces, providing a large surface area. As a result, ice shedder systems have a high peak cooling rate. By the same token, if the water flow through the tank is well designed, the water discharge temperature is kept low until most of the ice has melted.

Short-circuiting of water flow poses somewhat less of a problem than with other methods of ice storage. Minimize it by careful design of tank shape and header configuration, by control of the water level in the tank, and perhaps by using mechanical agitators to redistribute the ice. Short-circuiting is more difficult to control if the ice is stored for long periods, because the ice pieces may fuse together, channeling water flow.

The independence of the storage bin from the ice maker allows you to select the size and shape of the bin to fit available space and to meet the owner's stylistic preferences. This flexibility is not unlimited. The ice falling from the ice maker forms a conical pile, which leaves some void space. If you need to minimize the

volume of the tank, make the tank round and tall. This shape also improves heat transfer and reduces heat loss.

■ Possible Need for Heat Exchanger

Ice shedders heavily aerate the water in the tank by virtue of pumping it continuously over the evaporator. The resulting high oxygen content makes the water especially corrosive to steel components. As a result, these systems commonly use a heat exchanger to isolate the tank water from the steel piping of the chilled water system.

Ice Freezing on Coil, External Melt

At first glance, the simplest way to make ice for cooling storage is to put a refrigerant coil in a tank of water and freeze the water around the coils. Cooling is recovered by circulating water around the frozen coils. This technique has been named “external melt” ice

storage, to distinguish it from another method in which the ice is melted by the coil. Figure 8 shows a cutaway of an external-melt ice storage unit.

The large ice surface area gives external-melt units a high discharge rate, if needed. Another virtue of external-melt systems is that their system connections are simpler than with some other types. Figure 9 shows the basic layout. This reduces the uncertainties of engineering and makes it easier for the facility staff to understand the operation of the system.

External-melt systems tend to have lower overall efficiency than other types of cooling storage systems. An inherent problem is the thickness of ice on the coils, which typically grows to several inches with reasonable coil spacing. This forces the chiller to operate at progressively lower evaporator temperatures as the ice accumulates. The average efficiency of the system is further reduced by inability to predict the exact cooling

load during the next cycle, the irregularity of ice formation, and other storage inefficiencies. The cost of the storage units is relatively high, because they are packed with coils, attachments, and accessories.

The simplicity of the concept made this method the first to be tried on a large scale. However, serious problems in the first generation of equipment almost led to the extinction of this method. Most of the problems have now been brought under reasonable control, and this type of ice storage has climbed back to a prominent position. External-melt storage units are now used in systems of all sizes. Figure 10 shows one module of a large system being installed.

A major failing of early external-melt storage units was that they failed to account for the enormous expansion force of freezing ice, which destroyed coils and tanks. Also, the buoyant force of the ice tore the coil assemblies loose from their attachments. These problems are now avoided by using packaged ice storage units that are carefully designed and heavily built. It would be folly to repeat the mistakes of the past by attempting to design external-melt storage units on a custom basis, unless the designer is very skilled and the customer has a large budget.

Paul Mueller Company

Fig. 7 Ice making and release cycle of an ice shedder Ice forms on the cold evaporator plates. To release the ice, it is partially melted by feeding hot gas from the compressor into the evaporator. This process involves some energy loss.

■ Direct-Expansion Storage Units

Ice can be formed on direct-expansion coils as well as on coils that are cooled indirectly by an antifreeze solution. Direct-expansion coils avoid heat transfer losses, but system design is more complex, mostly in the feeding of refrigerant to the coils. Coils have been made from various plastics, copper alloys, and steel. The strength of steel is probably needed for larger units. Steel coils make it possible to cool directly with ammonia, which is an excellent refrigerant for large ice storage units. (Ammonia attacks components containing copper.) Figure 11 shows a direct-expansion external-melt system that serves a small professional building.

■ Ice Bridging

Another fundamental problem of external-melt systems is ice bridging from one coil to adjacent coils. Bridging impedes the flow of chilled water in some parts of the storage unit, forcing short-circuiting through other parts. In order to minimize storage volume and cost, the coils are packed as close as possible. As a result, bridging will occur if the nominal ice capacity of the unit is exceeded.

Bridging also occurs if the ice is not completely melted between cooling cycles. Ice grows in a somewhat irregular manner, so bridging becomes probable after several cycles of incomplete ice melting. Therefore, the controls must ensure that the coils are melted completely at the end of every operating cycle, or perhaps after several operating cycles. This takes no special action if the cooling load continues into hours of low electricity prices. This allows the storage unit to operate until all the ice has melted. However, if cooling occurs mostly during hours of peak electricity cost, some ice may remain until the next charging cycle. In this case, energy may have to be expended to melt the remaining ice prior to charging.

■ Achieving Uniform Melting

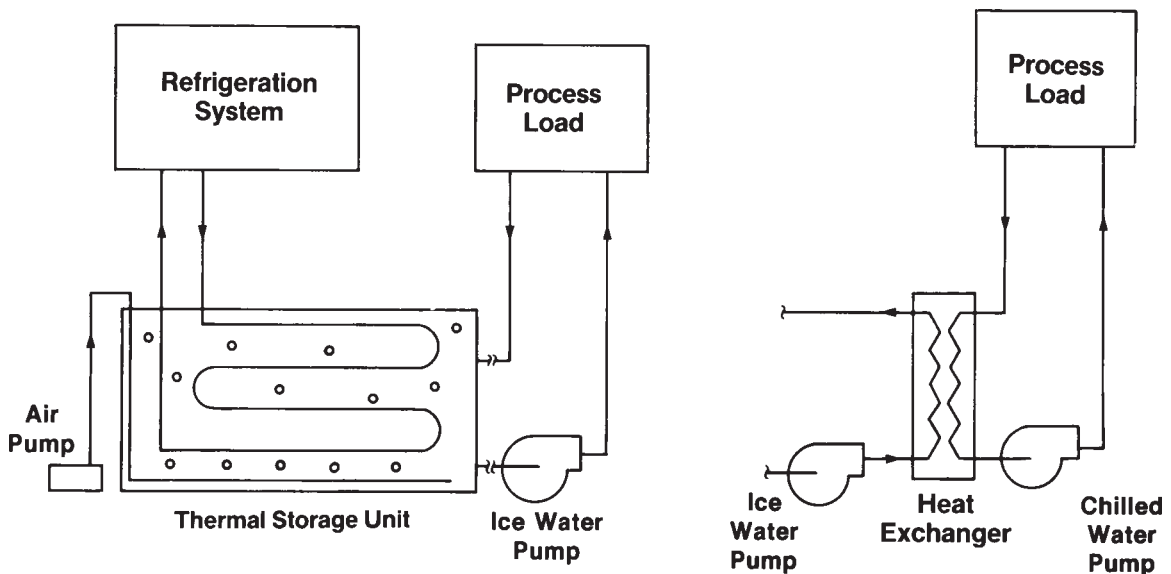

External-melt systems have difficulty maintaining low chilled water temperature as the ice melts, especially toward the end of the discharge cycle. There is a strong tendency toward short-circuiting, and this problem has not been solved entirely. If one path through the ice enlarges faster than others, the increased water flow will further hasten the enlargement, to the point that one part of the storage unit may melt completely while the rest of the unit still has considerable ice.

Various methods are used to encourage uniform melting, including careful coil design, baffles, and headers. One major manufacturer even uses an air bubbling system to keep ice melting uniform. A disadvantage of this method is that it aerates the chilled water, making it corrosive. This requires major corrosion protection features for the storage unit, and usually, a heat exchanger to isolate the aerated water from the chilled water system.

Baltimore Aircoil Company

Fig. 8 External-melt ice storage unit This is a tank full of water that is filled with freezing coils. The coils may be cooled by glycol from a chiller, or they may be cooled by direct expansion. Avoiding ice bridging between the coils and maintaining uniform water circulation are important challenges with this type of unit.

Baltimore Aircoil Company

Fig. 9 System connections with external-melt systems The chilled water can be pumped directly from the tank, or a heat exchanger can be used. A heat exchanger is needed to isolate the tank from pressure if portions of the chilled water system are located above it. This system includes an air bubbler to promote uniform water circulation. The bubbler saturates the water with oxygen, making it corrosive to steel. This is another reason to use a heat exchanger.

■ Alternating Use for Heat Storage

An interesting possibility is using the storage unit to heat and store hot water during the off-peak season. To do this, the evaporator coil connection is switched so that the coil becomes a second condenser bundle. This has been done in some small packaged systems.

Ice Freezing on Coil, Coil Melt

Another type of ice storage also freezes ice on coils, but the method of melting the ice is entirely different. Instead of melting the ice from the outside of the ice layer, the ice is melted by the same coil that freezes it. This system uses a heat transfer fluid, typically glycol, inside the coils. During the charging cycle, the glycol flows through the chiller to freeze the ice. During the discharge cycle, the ice is melted by circulating the heat transfer fluid with the chiller turned off. Figure 12 shows the system operating modes.

■ Advantages

Coil-melt systems avoid the most vexing problems of external-melt ice storage. Ice bridging is not a problem because the entire mass of water surrounding the coils can be frozen solid. This also increases the compactness of the storage unit. The water in the storage

tank does not circulate, so there is no need for headers, baffles, or other complications.

It is easy to protect the storage equipment from corrosion because the water that freezes in the storage unit does not circulate, and it is not aerated. There is no corrosion problem in the chilled water system, because it is a closed system.

■ Charging and Discharging Characteristics

The performance characteristics of coil-melt systems vary during the freezing and thawing cycle to a greater extent than with other ice storage methods. The charging efficiency and charging rate are greatest at the beginning of the charge cycle because ice was cleared from the coils by the previous discharge.

The temperature rises considerably throughout the discharge cycle, for a constant charge rate. This is due to the thermal resistance of the growing water layer that forms around the tubes as the ice melts. Liquid water has about four times the thermal resistance of ice when stationary, but convection currents in the water layer probably reduce the resistance considerably. This effect is not a major worry in chilled water systems that operate at conventional temperatures. However, it may disqualify this method of ice storage if you want to exploit low-temperature chilled water distribution.

Baltimore Aircoil Company

Fig. 10 An external-melt storage module for a district cooling system A large number of these modules are installed underneath a parking lot. The system serves a portion of downtown Baltimore.

By the same token, the maximum discharge rate also declines as the ice melts. This may be a problem if the cooling load remains high near the end of the discharge cycle.

■ Storage Unit Design

Packaged coil-melt storage units are available in a variety of sizes and shapes. The storage unit can freeze solid from one side to the other, so the tank must be designed to resist bursting or progressive leakage. (As an alternative, the system can be controlled to prevent complete freezing of the tank, but this method is less reliable.) Plastic pipe is typically used in smaller units, and steel pipe in larger units. Figure 13 shows a cutaway of a typical packaged storage unit.

Large storage systems can be assembled easily from any number of modular units. Figure 14 shows an example. Another approach is to use prefabricated coil arrays that are available for installation in large site-built tanks.

■ Connections to the Chilled Water System

The chiller and the ice storage unit can serve the cooling load individually or simultaneously, and the chiller can charge the storage unit while it serves the cooling load. It is challenging to design a system configuration that optimizes operating efficiency under all possible operating modes.

Some designs compromise by simply connecting the chiller and storage unit in series. This is fairly satisfactory, but sacrifices some efficiency or capacity, depending on whether the chiller is upstream or downstream of the storage unit.

Small systems may use the heat transfer solution directly in the chilled water system. This approach reduces heat transfer in the end-use equipment because glycol and other heat transfer fluids have worse heat transfer characteristics than water. An alternative is using a heat exchanger, which allows pure water to be used in chilled water circuit. This approach incurs a temperature rise in the heat exchanger. In larger systems, a heat exchanger becomes more desirable to reduce the quantity of glycol that is needed.

The heat exchanger, if one is used, needs freeze protection. This is because the glycol solution may be well below freezing temperature while the chilled water is unprotected. One method is to bypass the glycol around the heat exchanger when the glycol is below freezing temperature. Reliability requires multiple bypass valves and safety controls that stop glycol flow if the heat exchanger gets too cold.

Ice Capsules

In ice capsule storage systems, a tank is filled with sealed containers, or capsules, of water. The capsules are frozen by circulating a heat transfer fluid (generally glycol) through the tank. The storage unit is discharged simply by turning off the chiller and continuing to circulate the glycol through the tank, thawing the capsules.

The capsules are made of thin-walled plastic, typically polyethylene. They are shaped to survive the expansion of ice inside them. Some are dimpled spheres, typically a few inches in diameter. Others are shaped like large rectangular hot water bottles. These shapes

allow the glycol to flow between the capsules. Some shapes, especially spheres, may be held in place only by dense packing. Other shapes require an external framework, or they may be held apart by spacers that are molded into the capsules.

Ice capsules are the simplest form of ice storage. The tank can be of any type that has the appropriate volume and shape. Common materials are concrete, steel, and fiberglass. Tank design is fairly simple, because the ice capsules float freely in the tank, requiring no supporting structures.

Ice capsule systems are immune to overcharging problems. They are relatively foolproof, simple to install and control, and relatively inexpensive. Their particular failure modes, ruptured capsules and leaking tanks, are non-catastrophic and fairly easy to repair. Ice capsule systems have not received as much attention as they

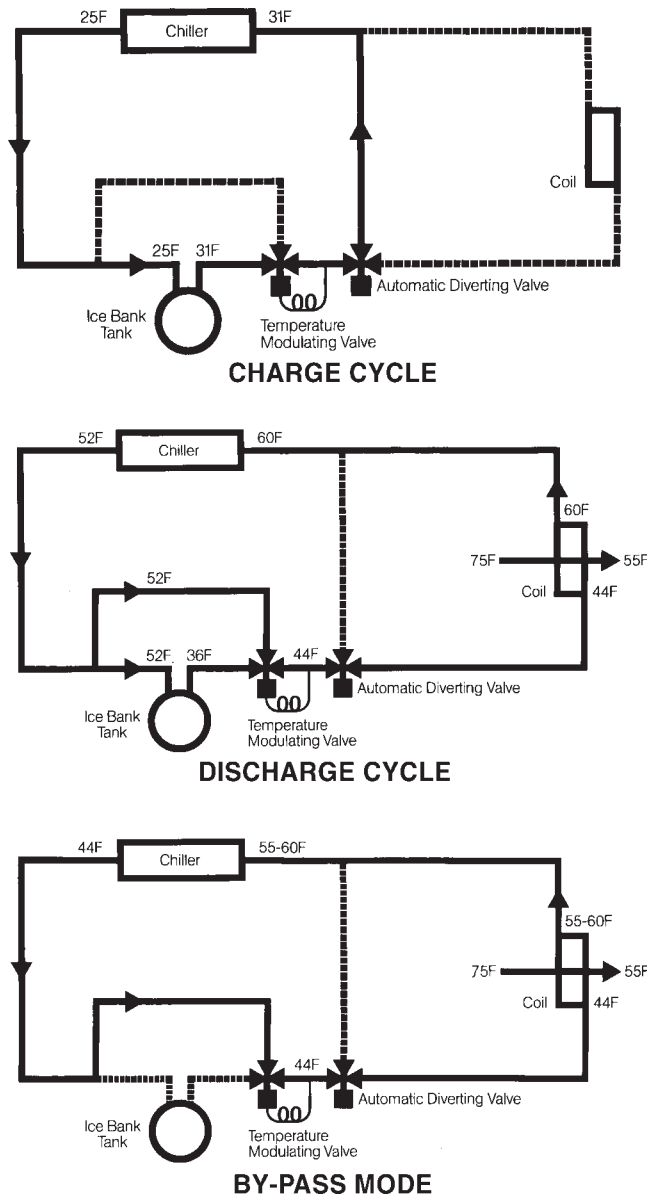

Fig. 12 Coil-melt cooling storage system operating modes

deserve, perhaps because their price is too low to finance advertising and technical support.

The storage unit is completely independent of the chiller. This makes it simple to operate the chiller separately from the ice storage unit, at normal chilled water temperatures. The chiller can also operate in parallel with the ice storage unit. The chillers are conventional, except that the evaporator temperature is selected for efficient freezing.

■ Discharge Characteristics

The surface temperature of each ice capsule remains near freezing until the ice melts completely, because the small volume of water inside each capsule stays in equilibrium with the remaining ice. As a result, the discharge temperature remains almost constant until some of the capsules thaw completely. Beyond that point, the discharge temperature rises rapidly.

To preserve full cooling capacity at the end of the discharge cycle, design the flow of glycol in the tank so that all the ice capsules melt evenly. During the discharge cycle, the first capsules to encounter the warm entering glycol are melted most rapidly. One solution is to install a pipe network that distributes entering glycol over all the ice capsules evenly. This requires a lot of pipe, takes up space, and complicates installation. Another solution is to oversize the storage tank for the load. Such steps may be unnecessary if chilled water is used by the facility at normal temperatures, and if the cooling load tapers off at the end of the cooling period.

■ Freezing Problems Inside the Capsules

Ice capsules have an odd problem that occurs at the beginning of the freezing cycle. If water is kept still and cooled slowly, it will cool to well below 32°F (0°C) before it starts to freeze. These conditions occur inside the sealed ice capsules. Therefore, the capsules must be cooled to about 25°F (-4°C) to be sure of freezing. Once freezing starts, the first ice triggers freezing of the rest of the water at normal freezing temperature.

Any residual ice inside a capsule prevents subcooling. However, this effect is not helpful. If some capsules are completely thawed at the beginning of the next charging cycle, and some are not, this only aggravates the problem of unequal freezing.

Ice capsules that are purchased with the water permanently sealed should contain an agent that stimulates freezing. If capsules are filled on site, add an appropriate agent for this purpose.

If the glycol temperature distribution in the tank is irregular, some of the capsules may never be cooled enough to freeze. To get a full cooling charge, you may have to operate the chiller at below-normal for a short time at the end of the charging cycle.

Stored Ice Slurry Systems

The stored ice slurry system is one of the newest entries in the cooling storage market. Figure 15 shows

a diagram of this type of system. It has several unusual features

One distinguishing feature of the system is a special evaporator that allows water to be frozen while combined with a carrier liquid. The carrier liquid is usually propylene glycol. The solution of water and glycol flows by gravity down a tall evaporator surface. The surface is agitated aggressively by a mechanical scraper, so that the water freezes in the form of microscopic crystals, forming a slurry with the glycol.

In one version of the system, the slurry is pumped to an insulated storage tank. The ice-bearing slurry floats to the top of the tank, leaving a solution of glycol and water at the bottom of the tank. Usually, the solution at the bottom of the tank is pumped to the application. The returning warmed liquid is sprayed over the slurry at the top of the tank.

Another version of the system pumps the slurry itself to the application. This can be a very efficient method of transporting cooling, because the ice crystals in the slurry have a high cooling energy content in the form of latent heat of freezing.

The stored slurry system should offer a high discharge rate because the ice crystals have a large surface area.

The system usually employs a heat exchanger. This isolates the glycol mixture, which has a poor heat

In this version of the system, a mixture of glycol and water settles out of the bottom of the slurry. This liquid is pumped to a heat exchanger to cool the chilled water system. transfer characteristics, from the pure water of the chilled water system. However, there are applications that do not need a heat exchanger.

The chiller, the evaporator, and the storage tank are independent of each other, except for pipe connections. This provides a great deal of flexibility in physical layout. The tank can be any shape or size, within broad limits, but it does require specialized design. The warm returning solution is sprayed uniformly over the top of the slurry mass in the tank. This is necessary to prevent channeling of flow.

Freezing the water on the surface of the evaporator avoids the heat transfer loss that occurs in ice storage systems that freeze water with glycol. However, mixing of the water with the carrier liquid reduces the freezing

temperature. Also, the various circulation pumps require energy.

The big question about stored slurry systems is their actual performance. They have only recently arrived on the market. As with any equipment that is supposed to last for decades, performance can be judged fairly only after years of operation in actual applications.

Separated Ice Slurry Systems

An older type of ice slurry system freezes ice in large flakes. Water that is mixed with a carrier liquid flows by gravity down a tall plate evaporator. Ice freezes out of the stream, but does not stick to the evaporator because it is carried along in the other liquid. The ice forms a slurry with the water, which is pumped to a

WESINC

Fig. 16 Separated ice slurry cooling storage system The system provides air conditioning for an elementary school. The storage equipment is surrounded by the brick enclosure in the foreground.

collecting bin. In the bin, the glycol falls free of the ice, which forms in a mass similar to a pile of snow. The separated glycol is then mixed with melt water to repeat the freezing process.

(Because water is combined with another liquid for freezing, slurry systems are sometimes called “binary” systems.)

The evaporator in a separated slurry system is much taller than the evaporator in a stored slurry system. The evaporator plate and ice collector is typically several stories high. This is necessary to allow the large flakes of ice to form. The ice bin also tends to be tall, because this is an efficient configuration for storing the ice, separating the glycol, and circulating chilled water through the ice.

Separated slurry systems are the most complex type of cooling storage, in terms of the number of large components and the complexity of piping. Figures 16, 17, and 18 show an ice slurry system used for air conditioning an elementary school in Florida.

The efficiency of a separated slurry system is probably better than the average for ice storage systems. Heat transfer on the evaporator is good, but mixing of the water with the carrier liquid reduces the freezing temperature. Distributing the chilled water efficiently with the ice mass is a challenge. Also, the additional pumps and conveyors require energy.

The system may not need a heat exchanger. If there is no heat exchanger, a certain amount of the carrier liquid will be carried along into the cooling distribution system.

The complexity of ice slurry systems outweighs their advantages in most applications. Initial cost is high. Slurry systems were never popular, and it seems that their niche in cooling storage is becoming narrower. Consider them for larger applications where the cost of custom fabrication is less of an economic penalty.

The original motivation for slurry systems was to freeze ice in such a way that it can be separated from the evaporator without a defrost cycle. In this regard, separated ice slurry systems can be considered a variation on ice shedder systems.

Liquid Chilled Water Storage

When electric utilities first started promoting commercial-scale cooling storage during the early 1980's, most designers envisioned storing the chilled water itself in large tanks. This method is conceptually simple. It also has a fundamental efficiency advantage over ice storage, namely, it does not require the chillers to operate at the low evaporator temperatures needed to freeze ice.

The storage tank is independent of the chillers, making it possible for the two to operate in parallel or separately. The connections between the chiller, the

storage units, and the chilled water system are relatively simple.

However, after a few years of analysis and experience, including some successful installations, it became clear that the enormous volume required to store water as a liquid is a serious economic disadvantage and a physical obstacle. The minimum temperature of liquid water is 32°F (0°C), and avoiding freezing in heat transfer forces the minimum temperature to be a few degrees warmer than this. In most HVAC applications, the chilled water is warmed to a temperature no higher than about 50°F (10°C). As a result, the cooling storage capacity of water is limited to about 15 BTU's per pound. This translates to about 100 gallons per ton-hour, an enormous amount of weight and volume that is difficult or impossible to accommodate in the layout of most facilities. Furthermore, the large surface area increases conduction losses.

In general, chilled water storage is not the best method of cooling storage unless storage is cheap or the storage volume is very large. Proponents of chilled water storage often pin their hopes on the availability of a large fire protection storage tank. Figure 19 shows

Fig. 17 Separated ice slurry system equipment The tall tower in the center is the evaporator. The ice storage tank is on the right. The chiller condensing unit is on the left.

a chilled water storage tank that also serves as a storage tank for fire protection.

Economy of scale benefits chilled water storage more than it benefits ice storage (except for ice capsule systems, which also have large economy of scale). The main reason is that tanks comprise most of the extra cost of chilled water storage, and the cost of the tanks per unit volume drops sharply with size. Also, relative heat loss drops substantially with larger tanks. Thus, chilled water storage may emerge as the best choice in very large applications.

■ Compatibility with the Chilled Water System

To achieve maximum storage capacity, the chilled water in the storage tanks is kept at the lowest possible temperature. This is lower than the usual chilled water supply temperature for HVAC applications, which is 42°F (6°C) or higher. Solving this problem is easy. Supply water from the storage tank is mixed with return water to produce the desired supply temperature.

A more critical problem is maintaining the highest possible chilled water return temperature. If the chilled water returns while it is still relatively cool, its remaining cooling energy will probably be unavailable for the remainder of the cooling cycle. This is because the water will be too warm to satisfy the cooling load if it is sent back through the chilled water system. If chilled water is wasted in this way, storage may be depleted before the end of the cooling cycle.

Keeping the return water temperature as high as possible requires special design of the user systems. The

application equipment, typically cooling coils, should have throttling control valves, rather than bypass valves. The coils or other devices should be designed to maximize the temperature rise of the chilled water. Expect to use variable-flow chilled water distribution. This adds cost, but it also improves pumping efficiency, a valuable energy conservation measure in itself. (See [Measure 2.5.2](#) for details.)

To keep the supply chilled water as cold as possible until the end of the storage cycle, the storage unit must keep the return water from mixing with the supply water. Any mixing dilutes the chilled water in the tank and poisons the ability of the storage unit to provide full cooling capacity. The need to separate the return chilled water somewhat increases the already huge volume requirement, and complicates the storage design. There are several methods of storing chilled water in a way that separates the return and supply water. Each of these methods, which are described next, has significant drawbacks.

■ Storage Using Multiple Tanks

One way to keep the supply water separate from the return water is to use a number of separate tanks. For example, use four tanks of equal size, three of which hold the initial charge of chilled water, while the fourth is empty. As chilled water is drawn from the first tank, return water is drained into the fourth tank. When the first tank is emptied, it becomes the return tank for the second tank, and so forth.

This method provides absolute segregation of supply and return water, which is especially valuable if chilled

WESINC

Fig. 18 Separated slurry system ice storage tank The returning chilled water is sprayed into the ice tank for cooling. The irregularity of the ice pile suggests that water distribution is less than ideal.

water is stored for longer periods, say, longer than one daily cycle. On the other hand, this method has several drawbacks. It requires extra volume. It increases tank cost per unit volume. The tanks have more surface for conductive heat loss. And, the piping and valve arrangements are somewhat complex.

■ Storage Tanks with Siphon Baffles

To avoid the disadvantages of multiple tanks, a single large tank may be divided into a labyrinth by partitions that form a series of siphon loops. Water is taken out of one end of the tank and is returned at the other end. At the point where the head of the return water stream contacts the tail of the chilled water stream, the area of contact is reduced by the baffles. Mixing is resisted by the difference in density of the supply and return water, especially in the downward flowing legs of the siphon loops.

Unfortunately, labyrinth tanks do not work as well in practice as it seems they should. The return water tends to overrun the chilled water, especially in the upward legs of the siphon loops. Also, the uninsulated steel baffles conduct heat from the return water to the chilled water. Experience teaches that a labyrinth tank should not be used unless its exact configuration has been tested and proven satisfactory.

■ Storage Tanks Using Stratification

“Stratification” is another method of keeping return water separate from the supply water. It allows water to be stored in a single large tank by exploiting the density differences of water at different temperatures. Water that is less dense floats on top of water that is denser. Cold water at supply temperature enters or leaves from the bottom of the tank, while return water enters or leaves from the top of the tank.

Water must enter and leave the tank gently, because the tendency to stratify is weak. The density difference between water at 39°F (4°C) and 50°F (10°C) is only about 0.03 percent. Therefore, the tank needs extensive diffuser trees in the top and bottom to reduce velocity and to control the flow direction.

The major disadvantage of stratified storage is its inability to separate supply and return water as the temperature approaches the point of maximum water density. The density of water is greatest at 39.2°F (4.0°C). If water is either warmer or cooler than this, it becomes lighter. If water colder than 39°F is pumped into the tank, it will float upward to mix with the water warmer than 39°F, destroying the stratification. Since a stratified tank cannot store chilled water below about 40°F, it needs more volume to compensate for the unusable temperature band.

There is much misunderstanding of this behavior, including a superstition that chilled water cannot be stored below 39°F. This is true only of tanks using stratification to separate the return and supply water. The other storage methods allow water to be stored at any temperature down to freezing.

Stratified storage has the advantage that the chillers operate at higher evaporator temperature, which increases COP. Also, using a single large tank has the advantage of minimizing the surface area for conductive heat loss.

An important efficiency drawback is that heat flows between the supply and return water by conduction within the tank. Any stratified tank has a region where the return water and supply water are of mixed temperature. This region, called the “thermocline,” is typically several feet thick, regardless of tank shape. It

WESINC

represents wasted cooling by the chiller, and it requires even more storage volume. You can minimize the thermocline problem by selecting a tank that is tall in relation to its diameter. For a system of any size, such a tank will be very tall.

You can achieve positive separation of the supply and return water within a single tank by using a moving diaphragm inside the tank. At the beginning of the discharge cycle, all the water is on one side of the diaphragm. As water returns, it enters on the other side of the diaphragm. The diaphragm itself adds some complexity, but it also eliminates the need for elaborate diffusers at each end of the tank. So far, this method has not become popular, perhaps because present diaphragm designs lack long-term reliability. Also, present diaphragm designs conduct heat from the return water to the supply water.

With stratified storage, the chillers operate at about the same temperature as they do when generating chilled water directly. Therefore, it is not necessary to make substantial efficiency compromises when selecting the chiller. For the same reason, stratified storage is usually compatible with existing chillers, except perhaps absorption units. With other types of chilled water storage, existing centrifugal chillers may seriously lose efficiency and capacity if chilled water is produced near freezing temperature. However, if charging is always done at night, the lower condensing temperature may avoid this problem.

■ How to Measure the Charge

With any of the previous types of storage, you can measure the amount of chilled water remaining in the tank fairly accurately. The usual method is installing a series of temperature sensors along the path of water flow in the storage unit. Systems with multiple tanks also need level sensors in each tank.

■ Combining Thermal Storage with Chiller Heat Recovery Storage

Chilled water storage offers the possibility of using the same tanks, at different times, for both chilled water storage and for storage of heat recovered from air conditioning condensers. This possibility becomes more attractive if the system has several storage tanks. For example, consider a system with four tanks. During hot weather, all four could be used for cooling storage. During cold weather, all four could be used for heating storage. During spring and fall, one or two of the tanks could be used for one purpose, and the rest used for the other purpose. See [Measure 2.10.5](#) for storage of heat recovered from chillers.

Eutectic Storage Media

Eutectic cooling storage seeks to combine the efficiency advantage of chilled water storage with the compactness of ice storage. The main efficiency disadvantage of ice storage is that ice freezes at a

temperature that is lower than necessary for most cooling applications, forcing ice storage chillers to operate at low evaporating temperatures. The desire to overcome this limitation has led to a search for materials that change in phase at a more desirable temperature. Such materials are called “eutectic.” (This word is based on Greek words that mean, approximately, “good freezing.”)

Ironically, the present eutectic alternatives to ice have phase change temperatures that are too high for optimum system performance.

■ Eutectic Materials to Date

Up to now, the best results for cooling storage have been obtained with hydrated salts, in which heat is absorbed in separating water molecules from salt molecules, a reaction that occurs at a fairly distinct temperature. (This is not a “phase change,” strictly speaking, but the term is used.) The material has a phase change temperature averaging about 47°F (8°C).

Formulations of salts with other melting temperatures are being tried. Unfortunately, the phase change in hydrated salts involves substantially less heat than the melting of ice. Commercial eutectic salt storage units require somewhat more than twice the volume of ice units. This is somewhat less than half the volume of chilled water storage.

Changes in the structure of organic polymers, especially the melting of waxes, have also been investigated, but these have relatively low heat storage potential. These materials also suffer from loss of storage capacity with cycling. The melting temperature may be different from the freezing temperature.

Other exotic materials have been investigated, such as clathrates, where the heat is given off when molecules of one type enter voids in the crystal lattice of a different type of material.

Eutectics are an evolving area. Newer materials may someday improve upon the shortcomings of the present materials. A phase change temperature in the range of 38°F to 42°F (3°C to 5°C) would be ideal. Even with this property, eutectic materials would need to increase their volumetric heat capacity by at least a factor of two to make them superior to ice in most applications.

■ Tank Configuration

Storage units using eutectic salt solutions are similar to those using ice capsules. Sealed containers of the eutectic material are stacked in a tank, and water is circulated through the tank. One major advantage is that glycol is not necessary, since water can be circulated through the tank without freezing.

The design of the storage unit is simplified by the fact that eutectic materials are heavier than water, so they do not tend to move around the tank by flotation. Also, eutectic materials do not change volume appreciably with the phase change, so there is no stress on the containers.

The lack of volume change makes it impossible to measure the charge by measuring the system water volume. So far, nobody has developed a reliable method of directly measuring the cooling charge in a eutectic system.

■ Dealing with the High Phase Change Temperature

The freezing temperature of present eutectic systems is too high to provide chilled water at normal temperatures. In addition, present eutectic materials do not maintain their low temperature throughout the discharge cycle, so the chilled water temperature may exceed 50°F (10°C) toward the end of the discharge cycle. Chilled water systems designed for conventional temperatures will not be able to provide full cooling capacity at these higher temperatures. If a system is designed to operate with the warmer chilled water, it may not be able to provide adequate dehumidification.

A eutectic system can be used for pre-cooling return chilled water in conventional chilled water systems, providing about half the cooling load, while the chiller further reduces the chilled water system. This may be satisfactory in some applications where only a partial reduction of the peak cooling load is required to satisfy the purposes of the system.

Present eutectic systems cannot use heat exchangers, because the temperature rise in heat transfer would worsen the problem of high chilled water temperature. Since eutectic storage cools the chilled water directly, the system does not need a heat exchanger unless there is excessive static pressure in the chilled water system. System pressure can be handled in a variety of ways that are suggested below.

■ Unusual Opportunities

Eutectic storage at these high temperatures offers several possibilities that are not available with other methods of cooling storage. One is operation with conventional absorption chillers. Another possibility is storing “free cooling” from the operation of cooling towers alone (see [Measures 2.9.2](#) and [2.9.3](#)). This can be done when the outside air temperature is below the phase change temperature.

GENERAL DESIGN ISSUES

The previous discussion outlined the steps needed to put a storage cooling system into operation, and gave a comparative overview of the types of storage cooling technology that are available. We will now examine in greater detail several important engineering aspects of installing the system. These apply to most types of systems.

How to Deal with Chilled Water System Pressure

The height of a chilled water system causes hydrostatic pressure. Unlike chillers, most cooling

storage units are not capable of resisting this pressure. Furthermore, most storage units are vented to the atmosphere. If they were directly connected to the chilled water system, portions of the system higher than the tank would overflow the tanks when the pumps are turned off. The following are methods of dealing with the static pressure of the distribution system.

■ Use a Heat Exchanger

The simplest method of isolating distribution system pressure is to use a heat exchanger. This method works well with ice storage systems that are designed to provide chilled water at normal temperatures. The low storage temperature easily makes up for the temperature drop in the heat exchanger. On the other hand, if an ice storage temperature is designed for low-temperature chilled water distribution, a heat exchanger would limit the minimum distribution temperature.

Heat exchangers are undesirable with chilled water storage, because their temperature loss would seriously reduce the effective storage capacity. By the same token, heat exchangers cannot be used with contemporary eutectic storage, which stores water at temperatures that are already higher than conventional chilled water temperature.

■ Elevate the Storage Unit

You can avoid the need for pressure isolation in open storage units by making the water level in the storage unit as high as the top of the distribution system. However, the enormous weight of water or ice is an obstacle to installing the storage unit high in the building structure. In existing facilities, it may be impractical to add sufficient structural support. In new construction, it may be easy to modify the structural design to provide adequate support. In fact, some huge ice storage systems have been installed in buildings above the level of the chillers, at the cost of heavily reinforced structures.

The weight of a storage system can be distributed to different parts of the structure by using a number of smaller storage modules. This practice is becoming common, especially for larger systems.

Chilled water storage is four to six times heavier than ice storage, making it generally impractical to install on the building structure. An exception is using fire protection tanks as storage units. These probably will not be large enough for a full-capacity storage system, but they may serve as valuable mini-storage units to reduce chiller size and reduce peak electricity costs.

■ Use a Backpressure Valve and Check Valves

Another approach is to install a backpressure valve at the bottom of the chilled water return leg. The valve is set to maintain a pressure somewhat higher than the hydrostatic pressure in the system. When the chilled water distribution pump turns off, the backpressure valve closes completely, trapping the water in the return leg.

Similarly, a check valve is used at the bottom of the supply leg to prevent water from draining out of the supply leg when the pump turns off.

Both backpressure valves and check valves tend to be leaky. One solution is to add a small pump to return any leaked water from the storage unit to the chilled water system. Another is to install automatic tightly closing valves to augment the backpressure and check valves when the pump turns off.

A backpressure valve may greatly increase the energy needed for pumping chilled water. In a closed system, the hydrostatic pressure in the return leg balances the hydrostatic pressure in the supply leg, so gravity plays no role in the pump power. However, using a backpressure valve effectively adds a gravity load that is equivalent to pumping all the water in the system to a height that corresponds to the pressure setting of the backpressure valve. Then, all the pumping energy is converted to heat in the return water, increasing the chiller load. This energy penalty will be imposed whether cooling is being provided from storage or by the chillers directly. In a tall building, a backpressure valve may cause pumping to absorb a large fraction of the energy consumption of the chilled water system.

■ Use a Pressurized Storage Unit

In principle, most types of cooling storage could be installed in closed tanks directly connected to the chilled water system. Expansion of ice would be accommodated by the expansion tank in the chilled water system.

The practical limitation is tank weight and cost. The wall thickness that a tank needs to withstand a given pressure is directly proportional to the tank diameter. Cooling storage tanks are large, so designing them to withstand pressure would require extreme thicknesses. In the United States, any vessel holding 15 PSI of pressure requires ASME pressure vessel certification, which further increases cost. This amount of hydrostatic pressure is produced by a height of merely three stories. Furthermore, tanks require access for inspection and maintenance. Large access panels are difficult to create and seal in pressurized tanks.

Coil-melt ice storage systems are a significant exception. In these systems, only the interior of the coils are subjected to system pressure. The coil diameters are small, so they can easily withstand large pressures. However, this is usually a moot point. The coils in coil-melt systems are filled with glycol. To avoid the need to fill the entire distribution system with glycol, it is common to use a heat exchanger with coil-melt systems. This by itself isolates the storage unit from system pressure.

Pressurized vessels cannot be used ice shedders, slurry systems, and multi-tank chilled water systems, because these types must be open to the atmosphere.

Chilled Water Supply and Return Temperature

Some cooling storage systems impose severe restrictions on chilled water supply and/or return temperatures. Using these types of storage systems requires you to modify the equipment that uses chilled water. Other types of storage systems impose no restrictions. The following are the major cases.

■ Ice Storage with Normal Chilled Water Temperatures

The simplest situation is using an ice storage system to provide chilled water to the facility at conventional chilled water temperatures. In this case, no change to the distribution system or user equipment is needed.

Using the chilled water at storage temperature would waste energy by excessive dehumidification, and might cause control instability at low cooling loads. To avoid these problems, control the chilled water supply temperature by using a mixing valve to dilute the cold water from the ice tank with return water.

■ Ice Storage with Minimum Chilled Water Temperatures

In attempting to salvage some benefit from the unnecessarily cold chilled water produced by ice storage systems, user systems are being developed that exploit the lower chilled water temperatures, especially in new construction. Colder chilled water carries more cooling energy, so pipes and pumps can be reduced in size, and the pump energy can be reduced correspondingly.

Where the low-temperature chilled water is used for air conditioning, air can be made colder. This can reduce the size of ducts, enclosures, and fans, and can reduce fan power consumption. These advantages have captured the attention of many designers. However, enthusiastic designers should be cautious of these potential problems of low-temperature air distribution:

- **cold air dumping.** Cold air “dumps” from overhead diffusers, causing serious localized discomfort. Overcoming this problem requires new types of diffusers that mix supply air with room air. It remains to be seen whether such diffusers will be satisfactory, especially in VAV applications. Terminal units with mixing fans may be required, adding cost, noise, and energy consumption.
- **duct sweating,** which may damage ducts, insulation, ceiling surfaces, and other equipment.
- **excessive dehumidification.** The low coil temperature increases dehumidification, which increases energy expenditure. Below normal air distribution temperature, the additional dehumidification usually does not improve comfort, and it may be an irritant.

Low-temperature air distribution is likely to provide more headaches than benefit, at least for the near future. This is a new area of comfort engineering, and it is likely

that lessons will be learned at the cost of expensive mistakes.

Low-temperature distribution marries the facility systems to the low evaporator temperatures required for ice storage. This may be an unwise commitment, because the low chiller efficiency may cause storage cooling, at least on a continuous basis, to be abandoned at some time in the future.

If the facility is designed to use low-temperature chilled water distribution, the ice storage system must be able to sustain low water temperature throughout the discharge cycle. Ice shedders and external-melt units are best in this regard, while internal-melt units are worst. Ice capsules suffer a serious rise in chilled water temperature in the second half of the discharge cycle.

■ Maximizing Efficiency with Liquid Chilled Water Storage

Refer to the description of liquid chilled water storage in the previous summary. The main design challenge is that you have to maximize the temperature differential between supply and return chilled water in order to preserve the cooling capacity of the storage unit. As explained previously, the way to do this is to use variable-flow chilled water pumping. In retrofit, this may require major modifications of the cooling equipment, including coils, control valves, and pumps.

■ Eutectic Storage with High Chilled Water Temperatures

Present eutectic storage systems produce chilled water that is warmer than normal. If the chilled water from the storage unit is not cold enough to satisfy the cooling load, it can be cooled further by a chiller before being distributed to the facility. This method is a hybrid of direct and storage cooling.

In any event, the return water temperature must remain high enough so that melting of the eutectic material does a large fraction of the cooling. Using variable-flow chilled water pumping and 2-way throttling valves on the coils helps to maximize the return temperature.

Keep Charging Separate from Direct Cooling

Chiller COP falls along with evaporator temperature, so operate the chillers at low evaporator temperature only for charging the storage unit. Try to operate the chiller separately, at the highest possible evaporator, for direct cooling. In other words, avoid using the same chiller for both storage charging and direct cooling simultaneously.

In principle, any kind of cooling storage system can be designed to allow the chiller to switch between charging and direct cooling. This is easier with some types of systems than with others. It is easiest with a liquid chilled water storage system. It is also fairly easy if the chiller cools a glycol solution. The glycol solution

can be sent either to the cooling storage unit or to a heat exchanger for direct cooling.

Using a heat exchanger forces the chiller to operate with lower evaporator temperature. In principle, the chiller could switch between chilling glycol (for ice freezing) and chilling water (for direct cooling), but the complications would not be justified by the reduced temperature loss.

There is another solution that is less conventional, but more efficient: add a second evaporator to cool the chilling water directly. The two evaporators cannot operate at the same time, because the evaporator temperatures are different. This solution may be fairly simple if the chiller system is designed for a separate evaporator, as with a liquid overfeed system. It may be difficult to accomplish with some packaged chillers. In any event, this is a job for someone who knows how to design unconventional chiller systems.

■ Separate Chillers for Storage and Direct Cooling

With any type of storage, a chiller that is optimized for one evaporator temperature is less than optimum at any other temperature. This is especially true of centrifugal chillers. Screw compressors with variable discharge ports can maximize their COP's at different evaporator temperatures. Reciprocating chillers are fairly tolerant of changes of evaporator temperature.

From the standpoint of efficiency alone, it would be desirable to install separate chillers for direct cooling and for charging the storage unit. However, this is generally not economical if it leads to duplication of equipment cost. Consider this approach if the facility has a large cooling load during the utility's off-peak periods. In this case, size one set of chillers to operate continuously during the off-peak period to charge storage, and size another set of chillers to satisfy the off-peak cooling load. For example, hospitals and hotels might benefit from this approach.

Controls and Alarms

Cooling storage systems require specialized control. You may have to do some or all of the control design separately, even with packaged storage systems. This is because the control sequences vary with the purposes of the system, with different electricity pricing structures, and with the load characteristics of the facility. You generally need a computer or a programmable logic controller (PLC) to control cooling storage for optimum efficiency. The control functions are too complex, too variable, and too repetitive for manual operation. The following is a guide to the control and alarm functions that the system may need.

■ Controlling the Amount of Storage for Each Cycle

The system controls must charge the storage unit based on the anticipated cooling requirement during the

next discharge cycle. Having too little capacity will either forfeit the electricity price saving or leave the facility without cooling at the end of the day.

On the other hand, storing too much cooling wastes energy, because more energy is required to produce stored cooling than to cool the space directly. Some of the excess stored cooling is wasted between discharge cycles by conductive loss from the tank.

With some types of storage, such as ice shedders, residual ice is melted if the chiller changes to direct cooling, wasting the ice. Even if the ice storage chillers are not used for direct cooling, the storage units require periodic melting of all the ice to prevent channeling or uneven ice accumulation. Exceptions are ice capsule systems and some slurry systems.

Unfortunately, the control system cannot predict the storage load for the next cycle accurately, because of changes in weather and internal loads. If the system wastes much energy as a result of leftover cooling storage, be ready to make manual control adjustments when a weather system is approaching or other changes in the load are foreseeable. Manual adjustment is an unreliable mode of operation in the long term, so try to avoid a system design that requires it.

■ Time Control to Conform to Electricity Rate Schedules

Electricity prices are usually related to the time of purchase. For example, the utility may charge its highest demand rate between the hours of noon and 8 PM. There may be a lower demand rate that applies for several hours before and after these times, respectively. Design the controls to limit chiller operation to the times of lowest electricity cost.

Optimum scheduling depends on the electricity rates for each period, the existence of ratchet provisions in the rates, the cooling load, the storage capacity, etc. Operate the storage system only at times when electricity costs are low enough to offset its efficiency disadvantage. The exception is when storage capacity is needed to augment chiller capacity.

■ Other Control to Conform to Electricity Rate Schedules

Electricity rates may not always be based on time. For example, excess-consumption charges and “hour charges” are based on consumption. Design your controls to get the most benefit from these rates, which involves measuring the total facility load. Some rates make it difficult to achieve optimum control. Expect to use a computer that you can program to follow changes in rates and rate schedules.

■ Facility Demand Limiting While Cooling Directly

If the electric utility’s demand charge is an important cost factor, balance direct cooling with cooling from the storage system to keep demand below a target level. If the non-cooling electrical load varies during the

demand period, as illustrated in Figure 2, this load usually determines the peak demand setting. A higher demand level is necessary if the storage capacity is not large enough to carry the entire cooling load. The arrangement of electric metering is a factor to consider, because different metering arrangements result in different total demand charges, as explained previously.

If the non-cooling load is unpredictable, limit chiller operation based on a conservative estimate of the non-cooling load. If the non-cooling load rises above this level, creating a higher demand charge for the period, raise the chiller load limit accordingly. Reduce the charging of the storage unit by a corresponding amount. Start all over again at the beginning of the next demand measurement period.

■ Time Control to Minimize Condensing Temperature

The controls should exploit the fact that condensing temperature has a major effect on chiller efficiency. Unless a weather system is moving through the area, the outside temperature drops continuously throughout the night. Therefore, charge the storage units as late as possible without running into a period of higher electricity rates. This control feature applies only to chillers that are able to exploit low ambient condensing temperatures.

■ Time Control to Reduce Storage Losses

The storage tank loses heat by conduction, so recharge it as late as possible. Charging at night provides an additional bonus of lower condensing temperature. If the storage tank is well insulated, small differences in the time of charging will not make much difference.

■ Control of Evaporator Temperature When Charging Storage

To save energy in charging, keep the evaporator temperature as high as possible. This requires control to correlate the evaporator temperature to the percentage of charge. An easy way to achieve this is to keep the compressor load constant throughout the charging period. With most types of storage units, this slows the rate of charging as the charge increases. Exceptions are ice shedders and some ice slurry systems, in which the charging rate is constant.

Increasing the evaporator temperature during charging lengthens the charging time. Therefore, coordinate this control function with the control function that determines the starting time for charging.

■ Maintaining Efficient Chiller Loading During Charging

The efficiency of a chiller may vary substantially with load. Set the chiller load during charging for maximum efficiency, whenever possible. The effect of loading on efficiency for different types of chillers is covered by [Reference Note 32](#), Compression Cooling.

Depending on the type of chiller, this control consideration may conflict with minimizing the evaporator temperature differential during charging. This is because the temperature differential increases with load.

■ Distributing the Load Among Chillers

See [Measures 2.1.1 ff](#) for the most efficient ways to distribute load among chillers. The storage system controls should determine which chillers serve the cooling load directly and which chillers charge the storage unit. If more than one chiller is used for charging storage, or if more than one chiller is used for direct cooling, try to use the same controller that distributes the load between the chillers, if there is one.

■ Safety Control to Prevent Overcharging

Install an independent override control to prevent overcharging. Overcharging may burst the tank with some types of ice storage. Also, energy is wasted in making more ice than the storage unit's design capacity. This control is a safety device, so it should be entirely independent of the operating controls. It should have a separate sensor that is triggered when the tank's ice capacity is exceeded.

■ Alarms

Install an alarm for each critical control function. For example, if a tank is not accumulating ice when it should be, an alarm should indicate this as early as possible, to avoid exceeding the demand limit during the next discharge cycle.

There should also be alarms for casualty conditions that are not related to controls. For example, open tanks should have high and low level alarms. The system should have all the conventional refrigeration alarms, such as high and low head pressure.

Alarms should be independent of the control system, and they should have their own sensors. Otherwise, a failure of the control system may disable the alarm. For example, the timing of chiller operation with respect to demand periods should be monitored by an independent alarm having its own clock.

ECONOMICS

SAVINGS POTENTIAL: *Cooling storage provides cost savings, not energy savings. The savings vary widely with circumstances, depending mostly on the pricing policies of electric utilities and your ability to negotiate with the utility. The cost savings provided over the life of the system are much less predictable than with most energy conservation measures.*

COST: *Coil-type thermal storage units and large chilled water storage tanks cost from \$50 to \$100 per ton-hour of storage, depending on size and type. This cost does not include the chillers themselves, piping connections, or controls. Heat exchangers, if needed, cost from \$100*

to \$200 per ton of heat exchanger capacity. The evaporator assemblies of ice harvester systems cost from \$500 to \$700 per ton of capacity, not including the compressors, insulated storage tank, piping, and pumps. Ice slurry evaporators cost from \$300 per ton in large sizes, to \$800 per ton in small sizes. At the present time, many electric utilities will defray part of the system cost.

PAYBACK PERIOD: *Several years, to much longer.*

TRAPS & TRICKS

MOTIVES: *One of the reasons that cooling storage units have a poor performance record is that they are installed as toys. When the charm wears off, the toy is abandoned. Before you install one of these big, expensive systems, make sure that you are ready to live with its operating and maintenance requirements. Understand that thermal storage exists for the benefit of the utility, and that you will benefit only to the extent that the utility provides a rate subsidy or other incentive for operating the system. Utility representatives will give you an optimistic pitch about this, but probably will not offer to provide a rate guarantee for a period that is long enough to protect your investment. You must learn enough about utility issues to judge whether a thermal storage installation is likely to be profitable in the long term. In particular, consider the effect of utility deregulation. Also, monitor the development of electric vehicles, which may abolish utility interest in thermal storage.*

DESIGN: *Designing an optimum thermal storage system involves a broad range of subjects, some of which are outside the realm of conventional HVAC design. A single detail that you overlook can cripple your system. Don't take the building design off on tangents to accommodate the storage system. In particular, be skeptical about low-temperature chilled water and air distribution.*

SELECTING THE EQUIPMENT: *Thermal storage equipment is still evolving, and performance is spotty. Favor equipment that has been in operation long enough to demonstrate good reliability. Shop the market thoroughly. Check with other users of the equipment you are considering. Remember that the equipment has to last for 20 years or longer if it is replaceable, and for the life of the facility if it is not replaceable.*

INSTALLATION: *Storage systems are heavy and require a lot of space. Make sure that structural support is adequate. Install the equipment so that it will survive. For example, avoid burying steel tanks. Provide easy access to all parts of the equipment for repair and replacement.*

ALERTNESS: *Maintaining a high level of skill and attention is an inherent part of operating a thermal storage system. During peak load conditions, the system must operate with total reliability to avoid losing the*

economic benefit. The system requires continuous surveillance during the peak load period. Install alarms to reveal all likely failure modes.

EXPLAIN IT: *The logic of the system can be confusing to the operators. Put up a well designed system diagram that explains how the system works, identifies its components, and spells out operating procedures. Install*

placards on all parts of the system that require action or inspection.

MONITOR OPERATING EFFICIENCY: *Make a continuous record of the charge status of the storage units and the loads on the chillers. Check the record often to make sure that the amount of energy stored is not too much or too little for the facility cooling load. Schedule periodic checks of controls operation.*

Section 3. SERVICE WATER SYSTEMS

INTRODUCTION

Service water systems provide cold and hot water for consumption. In residential and commercial facilities, service water is used in three main areas: (1) sanitary applications, including lavatories, showers, toilets, and urinals, (2) food and beverage applications, including food preparation, dishwashing, and drinking fountains, and (3) lawn and plant watering. Industrial uses of service water are even more varied. They include washing, cooling, and use of water as an ingredient in materials being manufactured.

Virtually all service water is recycled eventually. In many industrial operations, water is recycled within the facility. In most residential and commercial facilities, service water is not recycled within the facility. Instead, it is recycled through the environment, usually after being treated by a public sewage system. Water must be purchased to replace water that is discharged to the sewer, water that evaporates, and water that becomes part of products.

How to Use Section 3

This Section is organized by the major cost components of service water systems. These are:

- **water consumption.** The Measures of [Subsection 3.1](#) reduce water consumption by improvements to water fixtures and by helping users to conserve water.
- **water heating.** The Measures of [Subsection 3.2](#) improve the selection and operating efficiency of water heaters.
- **service water pumping.** The Measures of [Subsection 3.3](#) reduce pumping energy by improvements to pumps, piping, and storage.

Reducing Service Water Consumption

In many facilities, the cost of domestic water can be a surprisingly large fraction of total utility costs. Furthermore, the cost of water in many locations is rising rapidly. The Measures in this Subsection reduce consumption of service water with more efficient fixtures, more efficient use of fixtures, and better maintenance. Where the fixtures use hot water, these Measures also reduce energy consumption for water heating.

New fixtures are being developed for the purpose of using less water. However, newer fixtures are not necessarily better. Equipment that attempts to reduce water consumption may be unpleasant to use. Some items intended to conserve water, such as toilets with reduced tank capacity, may actually increase water consumption in practice. There is a place for new technology, but combine it with common sense in selecting fixtures and with motivating people to use water efficiently.

INDEX OF MEASURES

3.1.1 Repair water fixtures regularly.

3.1.2 Install efficient wash basin fixtures.

3.1.3 Install efficient shower heads.

3.1.4 Install shower valves that allow easy control of temperature and flow rate.

3.1.5 Provide instructions for efficient use of water in showers and lavatories.

RATINGS

The most common control devices for domestic water are valves, faucets, faucet aerators, toilet and urinal flush valves, and shower heads. All of these will eventually leak, fail, or get lost. Leaks can waste a large amount of water over the course of time because they are continuous. Repairing water control equipment is simple, important maintenance that should be accomplished continually.

Faucets and Valves

Stop leaks early to reduce the amount of maintenance required. If a faucet leaks for a long period of time, the valve seat will erode. Replacing the soft valve disk as soon as it wears out minimizes the need to replace valve seats.

Valve seats do wear out eventually, especially in environments with acidic or gritty water. Replacing them in faucets is usually easy. Use a thread sealant to prevent leakage between the valve seat and the body of the valve. Hose connection valves (“hose bibs”) may lack

removable seats, making it necessary to replace the valve body.

Adjust the valve stem packings to prevent leakage around the valve stem. Use a wrench that cannot mar the surface of the nut. When you need to apply too much force on the nut to stop leakage around the stem, it is time to replace the packing material. Valves commonly have a second packing that prevents leakage around the valve stem when the valve is fully open. Inspect this packing when replacing the primary packing.

Some types of valve disks last longer than others. Learn from experience which types provide the best service, and keep an ample stock of spares on hand. Also, keep on hand a stock of repair kits for your specialized faucets, such as single-lever types. Keep a few spare valve stems, as these wear out occasionally, especially in acidic water.

Faucet Aerators

Faucet aerators serve several purposes. They improve cleansing. They provide a sensation of vigorous flow that is desired by users. And, they conserve water by restricting flow. Figure 2 shows a typical aerator.

Aerators are screwed into the end of the spigot. They typically consist of a screen that breaks up the water flow. The screen is held by a fitting with air passages. This arrangement mixes air with the water stream as the stream is broken up by the screen.

Aerators must be removable to allow for occasional removal of debris that backs up behind the screen. The fact that they are removable allows them to work loose and be lost. For this reason, check faucets periodically to be sure that the aerators are present and installed tightly.

You may reduce loss of aerators by using thread locking compound when reinstalling them. However, this is not necessary if maintenance personnel are

careful, and it may cause more trouble than it avoids. If you do this, select a compound that does not grab excessively or harden with age.

Basin Stoppers

In lodging and residential facilities, leaking basin stoppers not only waste water, but they annoy users who need to fill the basin with water. See Figure 1. The annoyance may motivate the occupant to abandon the stopper and to keep a continuous stream of water running into the basin.

The usual problems with mechanical basin stoppers are improper adjustment, lack of lubrication of the linkage that drops the stopper into place, and clogging by hair and other debris. Basin stoppers need frequent, regular cleaning. Make this somebody's responsibility. You may have to train maids or cleaning crews how to do this. This will radically reduce the need for maintenance calls and increase occupant satisfaction.

Gravity Tank Toilet Valves

Toilets that use gravity tanks have two important valves. The flush valve is a large stopper in the bottom of the tank that is lifted by the flush handle when someone flushes the toilet. The fill valve refills the tank as soon as the tank starts to drain. It is operated automatically by a float,

The flush valve in the bottom of the gravity tank toilets will eventually start to leak. This allows water to leak out of the tank into the bowl, where it siphons into

the sewer. The flush valve has a large sealing area, so it can waste a lot of water when it leaks. A leak becomes progressively worse, and it will eventually start to destroy the valve seat. Replacing the valve seat is a messy job. It is easier in the long run to check for leakage and make repairs in a timely manner. At first, leakage of the flush valve is not obvious, so the trick is to identify it early.

Any easy test method is dropping a dye tablet into the tank. If the flush valve is leaking, the dye appears in the toilet bowl after several minutes. Dye tablets for this purpose are a standard hardware store item, but any dye can be used that does not stain the toilet. Food coloring works well.

Another foolproof method is to turn off the water supply to the tank when it is full. A leaking flush valve allows the tank to drain. You can usually tell that the water level has dropped within a fraction of an hour. A bonus of this method is that it exercises the shutoff valve, which typically freezes from lack of use.

A leak will start to become apparent if it is ignored too long. If the toilet is not used much, you may occasionally hear the tank valve open to refill the tank. If the water contains any staining agents, a stain may form in the bowl where water enters from the tank. But, don't wait for this. A leak may exist a long time before a stain becomes apparent. Also, the stains may be permanent.

The second important valve in a gravity tank toilet is the tank filling valve. Make sure that the fill valve shuts tightly after the tank refills. The float level needs to be adjusted properly. If the float cuts off the water supply at a level that is too low, the toilet does not flush properly. If the float is set too high, the incoming water drains continuously into the overflow pipe. If the fill valve leaks, the tank continues to fill slowly, and the excess water dumps into the overflow pipe. The operation of this valve is easy to check visually.

In time, the fill valve has to be replaced. The assemblies for most toilets are standard and inexpensive. Replacement takes about fifteen minutes with practice, if none of the coupling nuts are frozen.

Flushometer Valves

Flushometer valves on toilets and urinals eliminate the need for a gravity tank. They remain open for a fixed time interval, discharging the appropriate quantity of water into the bowl. The lack of a tank makes it difficult to test for valve leakage. In both toilets and urinals, you have to check visually for water flow into the bowl. Dry the sides of the bowl and inspect carefully.

Repairing a flushometer valve requires spare parts that are specific to the particular model.

Resources Conservation Inc.

Fig. 2 Faucet aerator This simple faucet part is important for water conservation and user satisfaction. It must be unscrewed periodically to clear out grit. As a result, it may get lost.

Shower Heads

Shower heads eventually clog because they act as strainers. To clean them, simply unscrew them and dump out the grit. High-efficiency shower heads need cleaning more often because they have smaller orifices.

Shower heads that have their own shutoff valves eventually leak. When they do, replace them with shower heads that do not have shutoff valves. See [Measure 3.1.3](#) for recommendations.

Shower valves that allow the user to adjust the spray pattern eventually wear out. Replace them with the most efficient type.

ECONOMICS

SAVINGS POTENTIAL: *Several hundred to several thousand dollars per year, in facilities of typical size and water consumption.*

COST: *Minor. Repair parts for common fixtures are inexpensive.*

PAYBACK PERIOD: *Short. The cost of the water saved is much greater than the cost of the repairs.*

TRAPS & TRICKS

SCHEDULING: *Inspect all water fixtures often enough to keep them from leaking for long periods. Make this a repetitive item on your maintenance calendar. If possible, train maids and cleaning crews to report defective fixtures.*

SPARE PARTS: *After you learn which repair items work best, keep an ample stock on hand. The bother of finding the right repair parts may deter maintenance more than the work itself.*

MEASURE 3.1.2 Install efficient wash basin fixtures.

RATINGS

New Facilities	Retrofit	O&M
A	C	

The use of water in wash basins is typically wasteful. The way you select faucets can reduce water consumption, although you can't expect the efficiency of a soldier shaving from his helmet. The key points are to select wash basin fixtures that minimize the flow rate and the duration of flow. This is especially important for hot water, where you are saving heating energy as well as the water itself.

In the United States, Federal law requires that faucets made after 1993 must limit water flow to these values, assuming a supply pressure of 80 PSI:

- lavatory faucets and aerators, 2.5 gallons per minute
- kitchen faucets and aerators, 2.5 gallons per minute
- self-closing faucets, 0.25 gallons per cycle.

Do not assume that all hardware will meet these criteria, or that they substitute for good judgement in selection. The flow rate of faucets may increase considerably if the aerator is lost or if the self-closing mechanism fails. Durability is an important selection factor.

Private-Use Wash Basins

Where wash basins are used for all purposes, as in private rooms and dormitories, follow these guidelines:

- **use single-spigot fixtures.** The basin should have a single spigot that mixes hot and cold water from separate taps. Using separate spigots for hot and cold water requires mixing the water in the basin to get the proper temperature. This wastes water and takes time.
- **provide effective stoppers.** The stopper should close the drain tightly. If the stopper leaks, the user must refill the basin continually. If leakage is severe, the user will leave the stopper open and use a continuous stream of water. Stoppers should resist jamming and should be easy to clean.
- **use aerators.** Aerators restrict the flow, make the stream effective for washing at a lower flow rate, and provide an increased sensation of flow.

Public-Use Wash Basins

Where wash basins are used mostly for hand washing, as in public lavatories, follow these guidelines:

- **use single-spigot fixtures,** for the same reasons as before
- **use aerators,** for the same reasons as before
- **use faucets that turn off automatically.** This feature is particularly important where wash basins are used by transients, as in airports and restaurants.

It is less important in facilities where the population is stable and responsible, as in office buildings.

A disadvantage of current types of automatic faucets is that they always operate with maximum faucet flow, which makes it especially important to maintain the aerators to limit flow. However, the full flow is tolerable if the faucets operate only when they are needed.

The older style of automatic faucet uses a dashpot that allows flow for a fixed time interval after a valve is depressed. This type is somewhat awkward to use, and it tends to stick.

Newer automatic faucets use infrared sensors that sense the presence of hands in the basin. This type allows water flow only when needed, and forces the user to be somewhat deliberate in hand washing. To date, this type of equipment is expensive and

somewhat temperamental, but it may improve in time. Figure 1 shows a typical unit. Do not use this type in open environments where the infrared sensor may be triggered by a heat source in the background, such as sunlight through a window.

- **use single-faucet fixtures with a fixed-temperature water supply.** To avoid the waste of energy that occurs when users attempt to mix hot and cold water, install fixtures that have a single valve. This approach is more expensive because it needs a separate branch of the service water system to serve the faucets. This branch has additional piping, a mixing valve, and probably an additional recirculation pump.

In general, avoid basin fixtures that are either awkward or unpleasant to use, even if they are efficient. Figure 2 shows faucets of this nature.

Soap dispensers are a continuing maintenance nuisance, and fiddling with the soap dispenser may cause users to waste water. Figure 3 shows a compact type of basin that combines soap dispensing, washing, and drying in the same location.

■ Avoid Communal Wash Basins

Avoid communal fountain-type lavatory fixtures with multiple nozzles or spigots. It makes no sense for an individual to wash his hands with a fixture that is

designed to provide water flow for a dozen persons. Also, the spray pattern of many models is particularly inefficient for hand washing.

In men's restrooms, these fixtures tend to be confused with urinals, especially by foreign visitors, sometimes leading to considerable embarrassment.

Reliability and Ease of Maintenance

Measure 3.1.1 emphasizes that maintenance is a major factor in water conservation. Select basin equipment for reliability and ease of maintenance. Some plumbing fixtures are much better in these respects than others.

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of the water and water heating energy used in wash basins.

COST: Self-closing single-temperature faucets cost about \$70 each. Single-temperature faucets controlled by infrared sensors cost about \$170 each, in small quantities.

PAYBACK PERIOD: Several years or longer.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Stick with simple, well proven fixtures. Stress reliability and ease of maintenance. You may want to gamble on new types of

equipment that can substantially reduce water consumption, such as faucets activated by personnel sensors. But don't make a big commitment to unproven equipment. Let others try the equipment first, and ask them about its performance.

MEASURE 3.1.3 Install efficient shower heads.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Ordinary shower heads flood the bather with much more water than is needed for efficient bathing. Figure 1 shows an example.

A variety of “high-efficiency” shower heads are available that you can use to limit water flow. These reduce water consumption by three methods: using smaller orifices, narrowing the discharge pattern, and mixing air with the water to increase the sensation of flow.

The sensation provided by the shower head is an important subjective factor for bathers. Experience shows that a particular shower head may be pleasing to one person and annoying to another. A partial solution to this problem is to select shower heads that let the bather change the spray pattern. However, this also forfeits part of the potential saving.

Savings Potential

Present types of high-efficiency shower heads use one to two gallons per minute if the user controls the water pressure to the shower head, and about two to three gallons per minute with full-flow valves. In contrast, common types of shower heads that are not designed for efficiency may pass 4 to 8 gallons per minute. The difference is starting to narrow as manufacturers increasingly design for water conservation. Even today, selecting a shower head for efficiency may reduce water consumption by half or better.

High-efficiency shower heads may cost less than conventional shower heads. This is because they are simpler. In new construction, this makes high-efficiency shower heads pay off immediately. Figure 2 shows a typical inexpensive high-efficiency shower head.

More expensive, “deluxe” shower heads have features that tend to be wasteful. Figure 3 shows an example. Of course, it is always possible for a manufacturer to jazz up an efficient unit and raise the price.

In retrofit, the payback period for replacing shower heads with high-efficiency units varies widely, depending on:

- **the average number of users per shower head per day.** High-efficiency units save more energy when installed in a busy gymnasium or in a communal dormitory shower than when installed in a hotel room or in a private residence.
- **the habits of the bathers.** The water consumption during each shower depends on the duration of the shower and the setting of the flow rate. This depends largely on whether the shower is used primarily for hygiene or as an esthetic experience. See [Measure 3.1.5](#) about showering behavior.
- **the type of valve.** See [Measure 3.1.4](#) about efficient shower valves.
- **the cost of water and water heating energy**
- **the characteristics of the shower head,** discussed next.

Control of Spray Characteristics and Flow Rate

Many high-efficiency shower heads are adjustable to accommodate user preferences. Some people prefer a needle-like spray, while others want a fuller flow at

lower velocity. In order for a shower head to work properly, the full pressure of the water system must be delivered to the orifices to break up the water into droplets.

Most adaptable shower heads adjust the spray pattern by varying the sizes of the orifices. The flow rate varies with the user's setting. With larger orifices, the stream is not broken into droplets. There is no way to avoid the fact that a coarser spray uses more water.

The least expensive models change orifice size by sliding one or more tapered plugs, or plugs with tapered grooves, to various positions in a nozzle plate. More expensive models use several sets of nozzles. Experience teaches that no single type is preferred by a majority of people.

Some models include a pulsing spray as one of the settings, as in Figure 3. This is an esthetic feature, not an energy conserving feature.

Select for Ease of Use

You will save more energy if you make it easy for bathers to use showers efficiently. If you install adjustable shower heads, select a type that is easy to use. The easiest adjustment is a large butterfly knob on the side of the shower head. Some cheap units have a knob in the center of the nozzle plate, forcing the user to reach through the spray to adjust it. This is annoying.

Shower heads that include several spray nozzles commonly require the bather to turn a large ring

surrounding the head, as in Figure 3. This can be confusing and awkward for unfamiliar users.

For those of European taste, high-efficiency shower heads are available in "telephone" style, installed on flexible hoses. They are awkward to use. If the shower space is confined, it is more convenient and more efficient to take "Navy" showers using a fixed shower head. See [Measure 3.1.5](#) about this.

Install User-Friendly Shower Valves

If the valve in the shower provides only full flow, the bather must adjust the spray at the shower head to modulate the flow. This is likely to produce a shower that is not as pleasing to the user. Simple shower valves are more efficient and more pleasing. See [Measure 3.1.4](#) about shower valves.

Avoid On-Off Valves on Shower Heads

Some high-efficiency shower heads include an on-off valve. Figure 4 shows an example.

In principle, this valve avoids the need to adjust the main hot and cold water valves. Once the main valves are set properly, the water is simply turned off at the shower head.

Don't use this type of shower head. In reality, it probably does not speed the process of getting the desired water temperature in the shower. The stagnant water must still clear out of the hot water supply line, and this takes longer if the user does not open the hot water valve to clear the line quickly.

Furthermore, this type of shower head may cause a continuous leak. If the main valves are left open with the shower head valve closed, the water line that connects the valves to the shower head is kept under pressure. This causes the valves to leak if they have leaky packings. If the shower is used with a tub, a diverter valve is installed, and this may leak. The valve in the shower head is a crude device that eventually starts leaking itself, so it has to be abandoned anyhow.

Fig. 1 Water waster This shower head has large orifices, which require a high flow rate to provide a satisfactory spray.

Resources Conservation Inc.

Fig. 2 Inexpensive water-saving shower head This unit saves water simply by having small orifices and a narrow spray pattern. The unit must be removed occasionally to clean out grit that backs up behind the orifices. For this reason, prefer units that have flats for a wrench instead of a knurled area.

Water Temperature Fluctuations

The bather adjusts the shower water temperature by adjusting the relative flow of hot and cold water. The hot water arrives by a separate pipe all the way from the hot water heater, which maintains the hot water pressure to the shower head. If someone turns on an adjacent cold water fixture, such as a faucet or toilet, the cold water pressure to the shower drops. This causes a sudden increase in the shower water temperature. In extreme cases, this may scald the bather.

High-efficiency shower heads may worsen this problem. If the existing shower heads are sensitive to water pressure, test this possibility before replacing them with high-efficiency units.

This problem occurs only if the cold water piping is too small, so that it cannot maintain water pressure when another fixture draws a large flow. In a well designed service water system, both the cold and hot water piping is of ample diameter to serve all fixtures. Individual fixtures are fed from lines of small diameter, to prevent them from bleeding too much pressure from the main pipe.

WESINC

Fig. 3 Versatile and amusing, but not highly efficient This shower head provides a variety of spray patterns, including a pulsating spray. Some of the patterns have higher flow rates. The pattern is selected by rotating the large outer ring, which is somewhat awkward.

Testing and Selecting Shower Heads

In the United States, Federal law requires that shower heads made after 1993 must limit water flow to 2.5 gallons per minute with a supply pressure of 80 PSI, but do not assume that this criterion will be met. Reliable data on the water consumption of individual models is usually not available. Consumer publications, such as *Consumer Reports*, occasionally review the efficiency and esthetic factors of currently available shower heads.

If you cannot find reliable information about the performance of different models, you can test samples yourself. Measure the length of time required to fill a bucket through the shower head with the water turned on fully. In retrofit applications, start by testing your existing shower heads.

The nature of the facility environment may be a major factor in your choice. Luxury hotels and private residences typically require greater adaptability than public showers, such as those in gymnasiums and swimming centers. Simple, non-adjustable shower heads may be quite satisfactory for the latter applications, and they are more rugged than the adjustable types.

Maintenance

Non-adjustable high-efficiency shower heads have tiny orifices. These trap particles behind the nozzle plate. The particles typically are too large to clog the orifices themselves, but enough of them may accumulate to choke flow through the entire unit. Correct these problems by unscrewing the unit and dumping out the grit. If the water supply is particularly gritty, you may have to do this often.

Do Not Use Flow Restrictor Inserts

Shower flow restrictors are simple orifices that are intended to reduce shower water consumption. They usually take the form of a plastic insert that is installed inside the shower head connector. These devices have been distributed widely by utility companies, government agencies, and others to promote conservation. Unfortunately, they do not work and they are a nuisance. In order for the flow restrictor to reduce water flow, it must dissipate most of the water pressure ahead of the shower head, so the shower head does not have enough pressure to work properly.

ECONOMICS

SAVINGS POTENTIAL: 40 to 70 percent of the water consumption and water heating energy used in showering.

Resources Conservation Inc.

Fig. 4 Shower head with integral shutoff valve This may seem like a good idea, but it isn't, for several reasons.

PAYBACK PERIOD: Immediate, in new facilities. One year to several years, in retrofit.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Be aware that people differ in their preferences for shower heads. Try to find a type that most bathers like. In residential facilities, keep a few good types in stock so that you can respond to complaints by installing a different type. Install a few samples on a trial basis before buying in quantity. Test their water consumption.

RATINGS

New Facilities	Retrofit	O&M
A	C	D

The old original style of shower valves, with separate valves for cold and hot water, is the most efficient for general use. Figure 1 shows a typical installation.

Separate valves allow the bather to quickly set the desired flow rate and temperature. They are simplest and easiest to maintain. Everyone knows how to use them. In new installations, they are usually the least expensive type.

Newer types of shower valves waste energy in several ways. The worst energy waste occurs with shower valves that operate only at full flow. High-efficiency shower heads (see Measure 3.1.3) typically use about 50% more water when operating at full pressure than when the bather is able to set the flow rate. Less efficient shower heads may double their water consumption with full-flow valves.

All non-standard types of valves waste water by forcing the bather to fiddle with the valve while attempting to figure out how it works. As the bather fiddles, water is being wasted. Also, a bather who is unfamiliar with a shower valve tends to set it to a higher flow rate than he would use with a familiar valve.

Again, the worst case is full-flow shower valves, which require the water to go to full flow before they control temperature. They also annoy users because they operate in a manner that is contrary to common

sense. They probably increase the risk of scalding. This type of valve is the stupidest development in the history of plumbing, an egregious case of spending extra money to irritate the user.

In facilities where inefficient shower valves are installed, try to replace them with conventional separate valves for hot and cold water.

It may not be economical to install double valves in showers where a full-flow valve is presently installed. In such cases, the best replacement is a combination valve in which total flow is controlled by moving the

knob in and out, and temperature is controlled by turning the knob. This type does not regulate flow as easily as separate valves, but it is fairly easy to use after a brief period of fumbling to figure out how it works.

The usual practices of showering and lavatory use in prosperous countries are very wasteful. A continuous stream of water is used where only brief wetting for lathering and rinsing is required.

In environments where it is possible to influence the practices of shower users, request bathers to use “Navy showers.” This procedure is used on ships where the fresh water supply is limited. It consists of turning on the shower briefly to wet the body, lathering with soap, and then turning on the shower briefly to rinse. The amount of water and water heating energy used in this way is a small fraction of the amount used in a normal shower.

In environments where it is not appropriate to request showering practices as strict as these, make a more general request to conserve water, which applies to all water usage in the lavatory.

Match the Instructions to the Environment

Strict “Navy” showering is appropriate in environments where showering is considered primarily as a hygienic measure, and to locales where water is considered a scarce commodity. Typical sites are military facilities, schools, prisons, and cities with acute water shortages.

Where showering may be considered an esthetic experience or a means of relaxation, as in hotels, it is more appropriate to post general requests to conserve water. If water is scarce, say so.

How to Convey the Message

Posting appropriate placards at the showers and lavatories is the most effective method of requesting users to conserve water. See [Reference Note 12](#),

The gravity tank toilet is the most common type in residential applications, while the flushometer type is the most common in commercial applications.

Typical older gravity tank toilets use five to seven gallons per flush. Figure 1 shows how this type of toilet works by siphon action. The amount of water required for effective siphoning has long been recognized as a problem. In response, a variety of toilet designs have appeared over the years that attempt to use less water. These include toilets that flush with positive pressure, toilets that grind the waste, etc. More recently, laws have been enacted that get politicians involved in designing toilets, with results that should not be surprising.

The reduction of water consumption in new toilets of conventional design has been marginal or illusory, so far. Any improvement is usually at the cost of increased annoyance. Some of the newer types of toilets do use substantially less water, but they may be complicated, messy, unreliable, or unpleasant. None of the newer types has yet proven to be clearly superior to the older types.

A problem in using less water for flushing is that the waste is not carried as far along the horizontal portions of sewage lines. The effect of this, and possible solutions, are still being debated.

Even so, if you are planning a new facility, you will have to select a new type of toilet, as the old reliable versions have been banned. The following are the main

American Standard, Inc.

Fig. 1 Conventional siphon toilet The water level in the bowl remains even with the top of the siphon elbow until flushing. When the water in the tank is released into the bowl, a siphon action is started that draws the waste into the sewer line, aided by the swirling of water into the bowl.

American Standard, Inc.

Fig. 2 Pressure-flushing toilet Compare this to Figure 1. The water for flushing is stored in a pressurized tank. Waste enters the discharge pipe by siphon action, and is then pushed through the discharge pipe by the pressurized water, which also increases the siphon effect.

points to consider. At this time, it is still too early to replace existing toilets for the sake of water conservation.

Be Skeptical of Ratings and Performance Claims

In the United States, Federal law requires that all types of toilets made after 1996 must use no more than 1.6 gallons of water per flush. A single exception is the blowout toilet, which is a pressurized flush toilet using a large trapway. This type of toilet, used only in special applications, may use 3.5 gallons per flush.

Government-mandated ratings are not a reliable guide to water consumption, because they only designate the amount of water consumed per flush. Several flushes may be required to get rid of waste. Some “water conserving” toilets flush more effectively than conventional toilets, and some flush less effectively. Some European designs appear to be intended more to allow examination of the waste than disposing of it. The ability of a toilet to get rid of waste also depends on the amount and characteristics of the waste.

How to Select Toilets

Select toilets for flushing effectiveness, esthetics, reliability, and ease of maintenance. Any toilet requires periodic maintenance, and it will waste water without it. Beware of the newer types of toilets that require mechanisms and seals in the path of the waste. When these fail, they become unpleasant to use and to repair.

At the present time, pressure-flushing toilets appear to offer a good compromise between water consumption, flushing effectiveness, and freedom from the more unpleasant types of maintenance. A typical pressure-

flushing toilet is shown in Figure 2. The distinguishing feature of this type is the pressure tank, which is shown in Figure 3. A significant disadvantage of this type is that the flushing action is very loud, although it is brief.

In facilities where toilet water consumption is substantial, be willing to consider novel types of toilets, but do your homework. In the United States, start with the Environmental Protection Agency information center on water conservation, but don't stop there. Investigate how the types that you are considering will work in a real environment. This may be challenging. The most novel units tend to be installed by enthusiasts who are blind to the practical and esthetic issues.

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of the water used in toilets.

COST: Toilets of conventional design, but improved allow flushing with smaller quantities of water, cost about \$70 each. Pressure-flushing toilets cost about \$170 each. More exotic types range widely in price.

PAYBACK PERIOD: Several years or longer.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: All toilets must meet the same standards for water consumption per flush. Therefore, when selecting new toilets, the main factor affecting efficiency is flushing effectiveness. Also, select for reliability, ease of maintenance, and esthetic factors. Put yourself in the position of the persons who must use and repair the unit.

MEASURE 3.1.7 Install efficient urinals or improve existing urinals.

RATINGS

New Facilities	Retrofit	O&M
A	C	

For disposal of urine alone, urinals have the potential of being much more efficient than toilets. If you have more than a few good men, install urinals adjacent to the toilets.

In the United States, Federal law requires that all types of urinals made after 1993 must use no more than 1.0 gallon of water per flush. This is a lax standard. It is easy to see that a urinal could be designed to operate with much less water than this, perhaps with only a cupful of water per use. Some designs use no water at all.

In existing facilities, consider replacing urinals if the existing ones are particularly inefficient. A urinal is not a major water user, provided that it does not flush continuously. Also, it uses only cold water. This makes urinal efficiency a relatively minor matter. Still, try to improve bad cases.

How to Select Urinals

More efficient urinals may cost little more than other types. Some types cost less. As with all equipment, shop diligently and examine actual installations.

The only efficiency issue with urinals is the quantity of water used. Urine, being a liquid, enters the sewage system without assistance. The only purpose of the water supply is to flush out the film of urine that remains on the surface of the urinal, for sanitary and esthetic reasons. Urinals should be designed to require the smallest amount of water for this simple flushing function.

In addition, the water should flow for the shortest possible time. The common flushometer valve works well for this. To eliminate the need for people to touch the flush handle, install urinals in which the flushing is controlled by a personnel sensor. These sensors are similar to the ones used in automatic faucets, covered by [Measure 3.1.2](#). Figure 1 shows a typical unit.

You may have to go to another country to find the best units, as fashion in urinals is national. In the United States, start with the Environmental Protection Agency information center on water conservation. In addition to efficient water usage, consider:

- *ease of use*
- *containment*, considering drippage and bad aim
- *effective rinsing* of the surface
- *ease of cleaning*, including removal of paper towels, cigarette butts, etc.
- *mechanical simplicity* and *ease of maintenance*.

SUMMARY

Current water consumption standards for new urinals are lax, so you have room to select more efficient types. Consider improving existing units, if possible.

■ **Waterless Urinals**

Some urinals require no water, except from the user. The simplest type is nothing more than a bowl with a

pipe that leads to the sewer. In most buildings, this arrangement is not acceptable, because any plumbing fixture requires a trap between the fixture and the sewer. (The purpose of the trap is to prevent gases in the sewage system from entering the space. The trap is usually a simple siphon loop. Look under a sink to see a typical example.) In a urinal with no water to flush the urine through the trap, the urine would linger in the trap, emitting odor into the space.

A refinement of the waterless urinal has a simple oil trap that controls odor. The urine passes through the oil, and then to the sewer by siphon action. The oil floats above the urine, preventing the odorous elements of the urine from evaporating into the space. Figure 2 shows a typical urinal of this type. Figure 3 is a detail of the oil trap.

The merits of this urinal, in addition to zero water consumption, are simplicity and low cost. The unit's

Waterless Co.

main disadvantage is that it does not flush the bowl surface. This allows more odor than a flushing urinal.

It appears that the best applications for waterless urinals are spaces that have a high ventilation rate or a rustic environment, such as restrooms in parks. They may also be appropriate for facilities, such as military bases, where esthetics is less of a concern and urinals are cleaned on a daily basis.

Waterless urinals require periodic replenishment of the oil in the siphon trap. They also require periodic replenishment of the filter cartridge, typically two to four times per year. The cartridge becomes clogged with small particulate matter, especially hair. Large debris, such as cigarette butts, does not pass into the cartridge, but must be cleaned out manually, as with conventional urinals.

Improve Existing Urinals that Lack Flush Valves

If existing urinals use a continuous stream of water, you may be able to eliminate most of the water consumption simply by installing a self-closing valve. A simple spring-return valve is inexpensive, reliable, and efficient. This type is satisfactory for most informal environments. For applications where a larger volume of water is required for flushing, install a flushometer valve that delivers appropriate volume.

For group urinals and for environments where users may not flush, consider using a personnel sensor to activate a flush cycle. Infrared sensors or light beams are effective for this purpose. Figure 4 shows an old communal urinal that could benefit from such a control.

Especially with urinals that were fabricated on site, you may be able to reduce water consumption by improving the distribution pattern of the flushing water.

ECONOMICS

SAVINGS POTENTIAL: 30 to 100 percent of the water used in urinals.

COST: Flush valves activated by infrared personnel sensors cost about \$200 each. The bowl itself costs \$100 to \$200, depending on size and style. Manual flushometer valves cost about \$100 each. Simple self-closing valves cost about \$50 each. All these prices are for small quantities. Waterless urinals with oil traps cost about \$300. Replacement cartridges for waterless urinals cost about \$6 apiece.

PAYBACK PERIOD: One to several years, when selecting more efficient units in new construction. Many years, typically, for replacing existing urinals. One to several years, for improving existing urinals.

SELECTING THE UNITS: When selecting new urinals, search for units that use substantially less water than prescribed by current government water consumption standards. Avoid designs that are complex or difficult to maintain.

Water Heating Systems

Water heating is a significant energy user in almost all facilities. In housing, food service establishments, and some industrial operations, water heating is a major part of total energy cost. Water heating systems usually operate continuously, so their losses are continuous. Inefficiency in water heating is caused primarily by inefficiency of the heating equipment, and by heat loss from water storage tanks and distribution pipe.

The Measures in this Subsection increase the efficiency of water heating units and systems. In addition, the last two Measures reduce the cost of electric water heating.

MEASURE 3.2.1 Minimize the hot water temperature.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
		

You can minimize energy losses by keeping the water temperature as low as practical. This a common opportunity because water heating systems are designed to produce water at a substantially higher temperature than is needed for most applications. For example, the typical domestic hot water heater is designed to produce water at temperatures as high as 180°F (82°C), but lavatory applications typically require water no hotter than 110°F (43°C).

Lowering the water temperature may reduce scalding hazard in some applications. On the other hand, be aware that lowering the water temperature may increase health hazards in certain situations. It also reduces the effective capacity of the hot water storage tank. Thus, water temperature is a compromise. You need to tailor the compromise to the particular application.

Energy Losses Related to Water Temperature

Energy consumption increases with water temperature in these ways, which are listed in approximate order of importance:

- **more heat delivered per unit of water.** In applications where the end-use water temperature is not regulated, as in residential clothes washers and dishwashers, lowering the water temperature reduces the amount of energy delivered. This is not true in applications where the end-use temperature is held constant by a thermostatic mixing valve.
- **more water consumed.** In lavatory and shower applications, excessive temperature increases the amount of water that is used at fixtures. This is because users must mix hot and cold water to achieve the desired temperature. For example, a bather who encounters high hot water temperature in a shower will spend time adjusting the mixed water temperature before stepping into the shower. Also, the bather will use a higher flow rate as a safety measure to provide good control of temperature.
- **increased surface loss.** Hot service water systems have a large amount of surface area in the tanks, distribution pipes, and recirculation pipes. Surface heat loss is directly proportional to the surface area and to the temperature difference between the water and the system environment. It is inversely proportional to the thermal resistance of the system insulation. Depending on the situation, some of the surface heat loss may be recovered as a form of

space heating, or it may increase the cooling energy requirement of the surrounding space.

- **increased standby loss.** In fuel-fired heaters, higher water temperature increases convective flue losses during periods when the burner is not operating.
- **increased combustion loss.** In fuel-fired heaters, higher water temperature increases stack losses by reducing the temperature differential between the combustion gases and the water.

Health Concerns Related to Low Hot Water Temperature

People are concerned that reducing domestic water temperature allows dangerous microorganisms to grow in the hot water system. This issue will continue to be the subject of research and conjecture for some time. Microorganisms are everywhere, and human beings have evolved resistance to infection. Nonetheless, be aware of the relevant safety issues for your application.

A variety of microorganisms found in hot water systems have been suspected of causing disease. These include, but are not limited to:

- **legionella pneumophila**, a widespread bacterium that grows in soil in all moderate climates. Legionella gained notoriety (and its name) in the Legionnaire’s Disease outbreak. Legionella may grow rapidly in water temperatures between 85°F and 113°F. They are killed by temperatures above 131°F. Some believe that algae must be present in the water supply to provide amino acids needed for growth.

Infection occurs by respiration of an aerosol containing the bacteria. The result is pneumonia. Showers appear to be a prime infection site. Only a small fraction of persons exposed to legionella develop symptoms. However, the mortality rate is high among those who do develop symptoms.

- **Pontiac fever bacteria** have characteristics similar to those of legionella. The result is a flu, and exposure almost always results in symptoms. The mortality rate is low.
- **salmonella** are common bacteria that cause illness by food poisoning. Drinking or eating is the usual route of infection. The principal protection is proper cooking of foods in which the bacteria can proliferate.

It is not practical or necessary to eliminate all microorganisms from domestic water supplies. The key is to prevent proliferation, because infection is related to the concentration of the microorganisms. Cold water is too cool for rapid growth.

Above 140°F, most infectious microorganisms are killed. Unfortunately, scalding becomes a hazard at this temperature. Even above this temperature, some bacteria may survive by being encapsulated inside amoebae that may be present in the water supply. However, bacteria cannot spread while in this state.

Whether disease occurs depends on the susceptibility of the people who are exposed. For example, “hospital-acquired pneumonia” is a serious health problem in hospitals, and legionella in the hospital water supply is suspected. Patients are assumed to be especially susceptible because of their weakened conditions.

Relationship of Health Hazard to Type of Water Heater and System

Some research has associated infections with certain types of water heaters. All water heater tanks and hot water storage tanks accumulate debris at their bottoms. This consists of dirt that enters along with the raw water. In water heaters, it also consists of fragments of scale that is formed by minerals in the water. The debris is presumed to serve as a breeding site for microorganisms.

Fuel-fired water heaters that are fired from the bottom appear to be immune to growth of microorganisms regardless of the water temperature setting. This is probably because the flame sterilizes the debris at the bottom of the tank.

Electric water heaters do not offer this protection, because the heating elements are installed well above the bottom of the tank. Incoming cold water typical enters the bottom of the tank, keeping the sediment relatively cool. The same applies to fuel-fired water heaters in which the flame does not cover the entire bottom of the tank.

In recirculating systems, this sterilization effect may protect the entire system provided that the circulating water is brought in contact with the fuel-fired surface on each pass. If the water heating system includes a storage tank without heating elements, the sterilizing

capability of the system depends on how the water flow is piped. If recirculated water is piped only through the storage tank and the storage temperature is low enough, the entire circulating water mass could grow microorganisms.

Water Temperature is a Compromise

From the standpoint of energy conservation, set the water temperature just high enough to satisfy the highest temperature requirement of the system. For example, if the system serves only wash basins, the temperature can be low, say 100°F (38°C). If you need higher water temperature for localized purposes, such as dishwashing, consider installing an auxiliary heater for those applications. See [Measure 3.2.2](#) for details.

High water temperature is the only reliable way of killing microorganisms in service water systems. Some microorganisms are very adaptable. For example, legionella survives throughout the range of pH found in domestic water supplies and also resists the

concentrations of fluorine and chlorine found in potable water.

This being said, keep the health aspect in perspective. Human beings do not require sterilized water, but rather water in which pathogens are kept at a safe level. All public water supplies contain a variety of pathogens. Prudent policy is to design and operate water systems so that pathogens are not allowed to multiply to dangerous levels.

The potential safety hazard from low water temperature depends on how the water is used. As discussed above, the hazard appears to lie primarily from inhalation of aerosols of heavily infested water. Water at reduced temperature may be safe for most applications if aerosols are not formed.

From a health standpoint, the water temperature setting at the heater can be deceptive. For example, in electric water heaters, the thermostat may be located immediately above the heater. The water that is below the heater may remain much cooler. For example, experimentation has shown that an electric water heater set at 140°F may contain many gallons of water at a temperature of less than 120°F.

Hot Water Thermometers

To provide an accurate guide to hot water temperature setting, install thermometers at both the tank outlet and the return end of the recirculation line. The outlet thermometer provides a direct reading of the tank temperature. You need one because the thermostat does not indicate temperature accurately. For example, see Figure 1. The return line thermometer provides a check on the effectiveness of recirculation.

Label the Thermostat

Install a placard at the thermostat of each water heater that states the temperature that should be set. State that the tank outlet thermometer should be used for temperature setting, not the indications on the thermostat itself. Include warnings about scalding hazards and growth of dangerous organisms in the water, as appropriate. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

Effect on Storage Capacity

Lowering the water temperature reduces the effective storage capacity of the hot water tank. For example, if water is needed at 100°F, hot water at 140°F is mixed with cold water at 60°F in even proportions. However, if the hot water storage temperature is reduced to 100°F, water is drawn from the tank at twice the rate, reducing its effective capacity in half.

This may not matter if the tank has a high “recovery rate,” which is the heating capacity of the heating element. However, if the recovery rate is low in relation to the tank volume, lowering the water temperature may cause the system to run out of hot water occasionally. This may happen if the capacity of the storage tank was selected to exploit load diversity.

In facilities that use electric water heaters, you can reduce electricity demand charges by storing hot water. (See [Measure 3.2.8](#) for details.) Lowering the water temperature interferes with this technique by reducing the effective storage capacity.

Relationship to Recirculation

In lavatory and shower applications, an effective recirculation system allows you to maintain lower hot water temperatures. It also makes the system more pleasant for users. See [Measure 3.3.2](#) for more about recirculation.

In some cases, the water temperature may be kept high to provided effective cleaning with detergents. For example, this is common in janitorial and laundry applications. You may be able to lower the water temperature if you substitute low-temperature detergents. Such detergents work well with the tepid temperatures needed for other domestic hot water applications, such as lavatories and showers.

Low-temperature detergents typically do not cost much more than conventional detergents. Even so, calculate whether any additional cost is justified by the increase in hot water system efficiency.

The effect of water temperature on the cleaning effectiveness of detergents is a matter of degree. You may have to experiment to find the lowest acceptable water temperature.

Be sure that high water temperature is not needed for its own sake, for example, for sterilization in the rinse cycle of dishwashers. If the application specifically requires high water temperature, consider installing an auxiliary heater. See [Measure 3.2.2](#) for details.

MEASURE 3.2.2 Install a separate high-temperature water heater for high-temperature applications.

RATINGS

New Facilities	Retrofit	O&M
C	C	

Some hot water applications require exceptionally high temperatures, which may be much hotter than needed by most users. For example, a dormitory that uses most of its hot water in showers and lavatories may have a cafeteria that requires much hotter water for dishwashing. The high dishwashing temperature increases heat loss throughout the hot water system. (See Measure 3.2.1 for the ways that energy is wasted.)

The solution is to install a separate water heater to serve the high-temperature application. This approach is worth considering if the high-temperature application is localized, while usage of water at ordinary temperature is dispersed. Install the high-temperature heater as close to the user equipment as possible, in order to minimize heat loss in the connecting piping.

There are two ways to provide a separate high-temperature water supply. One is to install an entirely separate high-temperature heater that draws water from the cold water system. This approach may be best if high-temperature usage is a large fraction of total usage, or if the equipment that uses high-temperature water is clustered in a particular area.

On the other hand, if high-temperature usage is a small fraction of total hot water usage, it is usually more economical to install a “booster” heater for each application. The booster heater draws water from the lower-temperature heating system. A booster heater can have a smaller heating capacity than a heater that draws from the cold water system. Booster heaters are offered as an integral part of some equipment, such as dishwashers.

Cost of the Energy Source

The cost premium that you can tolerate for separate high-temperature water heating depends on the losses that you can avoid. This Measure rarely provides a cost saving if the energy source for the high-temperature heater is more expensive than the energy source for the primary hot water system.

Some equipment may be equipped with an integral booster heater that requires a more expensive energy source. For example, a dishwasher may have an electric booster heater, while the primary water heater is fired by less expensive gas. In such cases, it may be economical to install an external booster heater that operates with the least expensive available energy source.

SUMMARY

Consider this for applications where a fraction of hot water is needed at especially high temperature. Must use an energy source that is no more expensive than the energy source used by the primary heater.

Control of Auxiliary Heaters

If the high-temperature water is needed on a predictable schedule, you may be able to save additional energy by turning off the high-temperature heater when it is not required. For example, you can use a timeclock to turn on the high-temperature heater one or two hours prior to the beginning of high-temperature water usage. This refinement is worth the effort and expense only in larger systems that have significant heat losses.

If the high-temperature heater is electric, its schedule of operation may have a significant effect on electricity cost. See Measure 3.2.8 for details.

RATINGS

New Facilities	Retrofit	O&M
A	C	A

There are substantial differences in the efficiencies of different models of water heaters. Be sure to select the most efficient models for new construction and when replacing failed units.

In existing facilities, it may even be worthwhile to replace a functioning heater with a more efficient unit.

The convenience of electric water heaters prompts people to install them even where a less expensive energy source is available. Figure 1 shows an example. Don't make this mistake. Install an electric water heater only if installing the flue and the fuel supply is too difficult, or if electricity is the least expensive energy source, taking all factors into account.

Efficiency Characteristics of Water Heaters

■ **Electric Water Heaters**

With electric water heaters, the efficiency of energy conversion in the water heater itself is virtually 100 percent. The only losses related to the heater itself are heat loss from the surface of the heater to the surrounding space.

As with all electrical equipment, there are large energy losses in the production and distribution of the electricity. (This is why electricity is usually expensive.) Within the boundaries of the facility, there are relatively minor losses within the transformers and power wiring.

Fig. 1 Going the wrong way This old gas water heater in a government building was replaced with an electric heater, even though gas is much less expensive than electricity in this location.

Not only for new facilities. Be ready to replace failed units with efficient models. It may even be economical to replace functioning units if they are especially inefficient. Consider converting to a less expensive energy source.

■ **Steam-Powered Water Heaters**

With steam-coil heaters, the efficiency of energy conversion in the water heater itself is also virtually 100 percent. Losses related to the heater are limited to heat loss from the surface of the unit.

There are substantial energy losses in the steam plant and the distribution system, including the condensate return. The latter includes leakage of the heater's steam trap. These losses are covered in [Section 1](#).

■ **Conventional Fuel-Fired Water Heaters**

Fuel-fired units are subject to the same combustion efficiency limitations as boilers. These are covered in the [Subsections 1.2](#) and [1.3](#). In summary, they are:

- **improper air-fuel ratio.** Setting the proper ratio is covered by [Measure 3.2.6](#).
- **flue losses due to fouling of the heat exchange surfaces.** Fuel-fired heaters lose efficiency as fouling accumulates on the heat transfer surfaces. Cleaning heat exchange surfaces is covered by [Measure 3.2.7](#).
- **flue losses due to unrecovered latent heat of water in the flue gas.** Water vapor is a combustion product of hydrocarbon fuels, especially of gas. If the water remains in the vapor state and escapes out the flue, it does not give up its latent heat.

Conventional water heaters may have much less effective heat transfer than boilers. This is because the heat transfer surface is limited to the bottom of the tank

and the flue pipe that rises through the tank. This limits the firing rate of a water heater, and hence its recovery rate. Some water heaters have several flue tubes, or flues of increased surface area, to increase the heat transfer area.

The portions of the tank surface that absorb heat from the flame and flue gases cannot be insulated. This creates standby losses when the unit is not firing. The heat of the water in the tank induces convection of cold air through the heater when it is not firing. If air is free to circulate, it carries away heat from the water, requiring additional firing.

You can reduce standby loss in existing water heaters by installing a flue damper, which is recommended by [Measure 3.2.5](#).

■ High-Efficiency Fuel-Fired Water Heaters

High-efficiency fuel-fired water heaters increase efficiency in two ways, by recovering the latent heat of the water vapor in the flue gas, and by minimizing standby loss. Figure 2 shows one type of unit.

WESINC

Fig. 2 High-efficiency water heater The exhaust is so cool that plastic pipe is used for the flue. This model uses pulsed combustion, an unusual feature of one manufacturer. The small muffler in the combustion air intake pipe and the very large muffler in the exhaust pipe minimize the noise.

To recover more heat from the flue gas, including both sensible heat and some latent heat, high-efficiency water heaters have heat exchangers with more surface area. At least the cooler end of the heat exchanger is made of stainless steel, to avoid corrosion by the condensed water vapor and acid.

High-efficiency water heaters may eliminate virtually all standby loss by using one or more of these methods:

- an integral flue damper
- heating the water in an external heat exchanger, so the storage tank has no uninsulated heat transfer surfaces
- using narrow combustion air passages that require a fan to move the combustion air. These passages allow minimal convection when the fan is not running.

■ Direct-Contact Fuel-Fired Water Heaters

Direct-contact water heaters are the most efficient kind of fuel-fired water heater. They eliminate most of the energy losses that relate to the exchange of heat between the combustion gases and the water. Figure 3 shows how a typical unit is constructed.

As the name implies, the water to be heated comes in direct contact with the combustion gases. Typically, the combustion gases flow upward through a stainless steel vessel, while the water to be heated is sprayed into the vessel from the top. Various kinds of filler material, such as clusters of stainless steel shells, distribute the water flow while allowing the combustion gas to heat the water.

This arrangement acts as a counterflow heat exchanger. As a result, the flue gases are reduced to a temperature almost as low as the temperature of the incoming water. The temperature difference may be as low as 10°F (6°C).

Direct-contact water heaters also recover most of the latent heat of the water vapor in the flue gas. With gas fuels, this accounts for more than 10% of the fuel's energy.

Direct-contact water heaters require expensive non-corroding materials, usually stainless steel, because the vessel and the filler material are exposed both to hot combustion gas and to incoming water that may be saturated with air. The units become economical in large sizes for applications that require large volumes of hot water, such as concrete plants, commercial laundries, and meat processing plants. Direct-contact heaters may provide a significant cost advantage in new applications where they avoid or reduce the need for boilers and related piping.

The cleanliness of the water depends on the fuel. The water will absorb whatever is in the flue gas. With gaseous fuels, the water is clear, even potable. It will dissolve the carbon dioxide in the flue gas, forming a

weak solution of carbonic acid, considerably less concentrated than in club soda. If other fuels are used, the water will not be potable, but it may be suitable for washing and for inclusion in products, such as concrete.

The exceptionally low flue gas temperature allows flues to be made of materials that cannot tolerate high temperatures, such as plastic pipe. However, the flue gas is saturated with water vapor and it picks up oxygen from the incoming water, so the flue material must be non-corroding.

Effect of Water Temperature on Efficiency

The water temperature has a major effect on the heat loss from all types of water heaters and from the rest of the hot water system. Therefore, keep the water temperature as low as practical. See [Measure 3.2.1](#) about this.

Water Heater Insulation

The surface area of a water heater is relatively small, but the unit's insulation is important because the water

Ludell Manufacturing Company

Fig. 3 Direct-contact water heater This is the most efficient type of fuel-fired water heater because it eliminates heat exchange losses and captures a large fraction of the latent heat of the water in the flue gas. If the fuel is clean gas, the cleanliness of the water is not significantly affected, except for a slight increase in acidity. If the fuel is dirty, the dirt will go into the water, which is still suitable for applications such as industrial washing and making concrete during cold weather.

temperature is high continuously. The best new water heaters may have insulation R-values five times higher than those of some older units.

If you are installing an engineered hot water tank, calculate the best compromise between insulation effectiveness and cost. Insulation is cheap. It is hard to overdo it.

Water Heater Efficiency Ratings

In the United States, smaller residential-type water heaters are rated by using an “energy factor.” This is defined as the ratio of the energy in the water to the input energy. It is measured under a standard set of usage conditions.

Contemporary electric water heaters have energy factors from about 0.80 to about 0.95. The only source of energy loss in an electric water heater is the insulation, so differences in the energy factors of electric heaters relate only to the insulation.

Contemporary gas-fired water heaters have energy factors from about 0.50 to about 0.70. These energy factors result from all the energy losses explained above.

Packaged water heaters are also rated by “R-factor”, which is the average thermal resistance of the unit’s insulation. Contemporary electric water heaters have R-factors ranging from 10 to 25. Contemporary gas-fired water heaters have R-factors ranging from about 6 to 18. The shape of a water heater has a minor effect on its surface heat loss. For a given R-factor, a more compact shape allows less heat loss.

Energy and Cost Saving Potential

The cost saving that you can gain by installing a water heater with better efficiency depends on the energy source, the cost of the energy source, and perhaps the amount of hot water consumption. In retrofit applications, it also depends on the efficiency of the existing equipment.

With electric water heaters, the amount of water consumption is not a factor in efficiency. The only loss is heat loss through the insulation, which depends only on the insulation and the water temperature. With an existing electric water heater, you can reduce heat loss by adding supplemental insulation, which is recommended by [Measure 3.2.4](#). In selecting a new electric water heater, consider the “energy factor,” as this takes into account both the insulation R-value and the shape of the tank.

With fuel-fired water heaters, energy losses depend on the amount of hot water that is used. If the water heater sits idle most of the time, its energy losses consist mostly of insulation heat loss and standby loss. If the unit has a high rate of water consumption, efficiency also depends heavily on the sophistication of the heat transfer surfaces. The “energy factor” covers all these

aspects. Use it as a selection guide, if it is available. If not, examine the design of the unit in light of the efficiency factors explained previously. If no hot water meter is installed, estimate consumption by recording the fuel input to the water heater.

To estimate the efficiency of an existing fuel-fired water heater, start by looking at its features, as discussed above. This is the best available indication of standby loss and insulation loss. You can do a combustion efficiency test to measure the unit’s efficiency of converting fuel energy to heat in the water. See [Measure 1.2.1](#) for details.

The value of improved insulation is reduced if heat lost from the water heater is a useful source of space heating. This happens only if the water heater is located in a heated space. Heat loss from the water heater is least important if the climate is predominantly cold, and if the energy used for space heating costs as much as the energy used for water heating. Conversely, the value of insulation increases if the water heater is located in an air conditioned space.

■ Electricity vs. Other Energy Sources

Do not assume that an electric water heater will cost much more to operate than other types. In water heating equipment, this is true less widely than with other types of heating equipment. The reason is that electric water heaters are more efficient than fuel-fired water heaters, for the reasons covered previously.

Furthermore, you may be able to improve the economics of electric water heating by installing a storage water heating system, or simply by allowing the electric utility to exercise interruptible control of your water heating. See [Measures 3.2.8](#) and [3.2.9](#) for the details.

As in other applications, your selection of the energy source for water heating should consider other pertinent factors, such as maintenance requirements, the reliability of the energy supply, ease of installation, the need for a flue, etc.

Significant Options

■ Access for Cleaning

With fuel-fired water heaters, select a unit that provides easy access for cleaning the heat transfer surfaces. Separate handholes for cleaning are available in water heaters above a certain size and price.

Some of the more exotic designs may have higher efficiency than other types when they are new, but inability to clean out scale will make them progressively less efficient throughout their lives.

■ Fast-Recovery Heaters

Some water heaters have extended-surface heat exchangers to provide a higher recovery rate. The increased surface area may or may not produce higher efficiency, depending on the firing rate.

■ Power Venting

Some water heaters have power venting, which means that the combustion gases are drawn through the unit by a small fan. Power-vented units have low flue gas temperatures and low standby losses, making them more efficient than average. The low flue gas temperature permits venting through an adjacent wall, without the need for a flue. Some units can use plastic pipe for venting.

This type saves money in new construction by avoiding the construction of a flue. In an existing facility, substituting a power-vented unit may be advantageous if it allows a flue leading from a heated space to be blocked off, reducing outside air infiltration.

■ Non-Metallic Tanks

Some electric water heaters have tanks made of fiber-reinforced plastic. This avoids the need for an anode rod in areas that have corrosive water. Anode rods cause odor problems with some water sources.

ECONOMICS

SAVINGS POTENTIAL: 10 to 40 percent of water heating energy.

COST: Typical residential-size water heaters cost several hundred dollars. The cost premium for more efficient models of conventional water heaters ranges

from 30 to 150 percent, depending on features and pricing policy. Many utility companies have rebate programs to defray the cost of smaller high-efficiency units. At the other end of the size range, direct-contact water heaters typically cost \$15,000 for a unit with a capacity of 1 million BTUH, to \$75,000 for a unit with a capacity of 25 million BTUH. If you change to a water heater with a different energy source, the cost of connecting to the new energy supply may be as much as the cost of the heater.

PAYBACK PERIOD: Several years, or longer, depending mainly on the quantity of water consumed.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Study the water heater market. There are many more choices than previously. Use the cheapest energy source that is readily available. Then, stress overall efficiency. Select a larger unit if this allows you to lower the water temperature. With units heated by fuel or steam, consider ease of cleaning the heat transfer surfaces. With complex high-efficiency units, check whether maintenance will be difficult. Check with others who have used your intended model for at least a few years.

TEMPERATURE SETTING: After installing a new water heater, minimize the water temperature. See [Measures 3.2.1 ff.](#)

MEASURE 3.2.4 Install supplemental insulation on water heaters.

RATINGS

New Facilities	Retrofit	O&M
	C	

Water heaters lose heat continuously through their insulation. The heat loss is independent of heater operation or water consumption. It depends only on the difference between the temperature of the water and the temperature of the surrounding space. If an existing water heater is poorly insulated, you can improve the insulation by covering the outside with a supplemental blanket of insulation. This activity is so popular that pre-cut insulation kits are available for the purpose. If a suitable kit is not available, you can do the job with batt insulation, a pair of scissors, and suitable tape.

Measure 3.2.3 points out that insulation heat loss is essentially the only source of energy waste in electric and steam-fired water heaters. Therefore, adding to the present insulation can make old heaters of these types about as efficient as new high-efficiency units.

How to Add Insulation

Insulation blankets for water heaters usually consist of glass fiber batt with an external covering. The covering may be thin plastic or fiber-reinforced foil. The insulation should have an insulation value of R-6 or more. This corresponds to a thickness of at least two inches.

Workmanship is important. The insulation should fit snugly at all points to avoid convective heat leakage between the heater and the insulation. Eliminate gaps. Tape the insulation at all edges and joints, and around pipes. Do not cover electrical connection boxes and thermostatic controls.

Fire safety is a concern. Keep the insulation and tape away from any hot areas. Be especially careful with fuel-fired heaters. Even glass fiber insulation includes a binder material that burns.

Alternative: High-Efficiency Water Heater

In fuel-fired water heaters, insulation heat loss is only one of several sources of energy waste, and it is usually not the most important one. Therefore, consider replacing a fuel-fired heater with a more efficient unit,

When Not to Insulate a Water Heater

This Measure is not economical if the water heater is installed in a space that is heated for a large part of the year. Also, the heat lost from water heaters may be useful for reducing humidity damage in basements and other humid areas.

ECONOMICS

SAVINGS POTENTIAL: 2 to 6 million BTU's per year, for water heaters of typical residential and commercial size.

COST: Materials cost about \$20. Installation typically takes an hour or two.

PAYBACK PERIOD: One year, to several years.

TRAPS & TRICKS

WORKMANSHIP: Proper installation matters as much as the amount of insulation. Fit all the insulation snugly against the heater surface. Seal edges and joints tightly.

MEASURE 3.2.5 Install automatic flue dampers on fuel-fired water heaters.

RATINGS

New Facilities	Retrofit	O&M
□	C	□

You can reduce the standby loss in a fuel-fired water heater by installing an external flue damper. Flue dampers apply to water heaters in the same way as to boilers. See [Measure 1.5.3.2](#) for the details.

The saving is typically smaller for water heaters because they burn less fuel than boilers, at least in typical applications.

Whether to Install a Flue Damper

External flue dampers are useful only with conventional water heaters that rely on convective circulation of flue gases. Modern high-efficiency water heaters have integral flue dampers or other means of reducing flue losses.

An external flue damper addresses only one of the sources of energy waste that occur in fuel-fired water heaters. If the present unit is old and/or inefficient, consider replacing it with a high-efficiency unit, as recommended by [Measure 3.2.3](#).

Is Installation Practical?

With many water heaters, installation may be difficult or impossible. The damper must be installed between the exhaust outlet and the draft hood. However, water heaters typically have an integral draft hood mounted on the heater casing. In order to install a flue damper, you would have to relocate the draft hood away from the heater. This may be too awkward to be practical.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Select a unit that looks well made. Flue dampers are made by many shops, and some are flimsy. Safety certification does not indicate reliability or efficient operation. Select a unit that closes as tightly as possible while satisfying safety requirements.

INSTALLATION: Install the unit so that it blocks the flow of gas from the heater, ahead of the draft hood. Be sure that the flue gas flows properly into the draft hood when the damper is open and closed. Get this right or flue gas will enter the space.

MEASURE 3.2.6 Clean and adjust the combustion systems of fuel-fired water heaters periodically.

RATINGS

New Facilities	Retrofit	O&M
		A

Fuel-fired water heaters are usually reliable, and they require only a modest amount of maintenance. To keep them at peak efficiency, give these maintenance items your attention at regular intervals:

- **burner cleanliness and air-fuel ratio.** Routine burner maintenance consists of (1) cleaning, followed by (2) readjusting the air-fuel ratio. Both of these functions require specialized equipment and techniques. Burner cleaning is covered by [Measure 1.4.1](#). Adjusting the air-fuel ratio is covered by [Measure 1.3.1](#).

Gas-fired heating units typically require burner maintenance only at long intervals. Inspect the flame visually on a routine basis. Make a combustion gas analysis at the beginning of each heating season. If the test indicates the proper efficiency, leave the burner alone.

The burners of oil-fired water heaters require periodic cleaning because the fuel oil tends to form sludge and coke on the burner. Clean the burner at scheduled intervals. Refer to the heater’s maintenance manual, or determine the appropriate intervals from experience.

- **fireside cleaning.** Accumulation of combustion products on the fireside surfaces of the heater increases flue losses. Clean the firesides of oil-fired heaters on the basis of soot accumulation. Typically, clean an oil-fired water heater about once a year.
- Gas-fired heaters that are adjusted properly may never require fireside cleaning. This is because soot burns off or spalls off faster than it can accumulate. If a heating unit accumulates soot or other fouling at an abnormal rate, the usual cause is a dirty or improperly adjusted burner.
- **automatic flue dampers** are important to efficiency. Failure of a flue damper can be a serious safety hazard, so they are made to be reliable. They require no routine maintenance. Check the operation of flue dampers visually at the beginning of the heating season.

MEASURE 3.2.7 Clean out scale from water heaters periodically.

RATINGS

New Facilities	Retrofit	O&M
□	□	A

Water heaters may accumulate prodigious amounts of scale if the water supply has a high content of dissolved solids. Scale forms because the solubility of most solids drops as the water temperature rises. When the water is heated inside the heating unit to the point that it is saturated with dissolved minerals, the minerals come out of solution and deposit on the hottest surfaces of the unit.

With fuel-fired heaters, the hottest surface is the bottom of the tank, where the flame heats the water. Unfortunately, scale is an effective insulator. With fuel-fired heaters, the insulating effect of the scale causes a larger fraction of the fuel energy to be forced into the flue. In addition to dissolved minerals, a certain amount of miscellaneous dirt enters with the water supply. The dirt to the bottom of the tank, increasing the insulation effect.

In water heaters heating tanks that have electric or steam-fired heating coils, scale forms on the heating coils. In electric resistance and electrode water heaters, scale has no effect on efficiency or capacity, because the electrical energy has no place else to go. (Extreme scaling may cause an electric heating element to burn out, but it does not reduce efficiency.) Steam-fired coils may suffer a reduction of capacity. This is not important, unless the tank needs rapid recovery.

How to Clean the Waterside

Virtually all fuel-fired water heaters have a drain connection at the bottom of the tank to remove scale and dirt. Scale breaks loose as a result of the expansion and contraction that occurs as the flame turns on and off, making it possible to blow out the scale chips.

Connect a hose to the drain connection, open the valve fully, and discharge the water to a bucket or drum. Look inside the bucket to see how much debris came out of the heater. Repeat the process until you have cleared out the heater.

Be careful to avoid scalding. Be ready to close the water supply valve that feeds the hot water tank if the blowdown valve breaks or fails to close completely.

Larger water heaters may have cleanout holes. If the heater has this feature, use it. Open it and clean the surfaces mechanically. Use a wire brush, water lance, or other appropriate tools.

Schedule this procedure often enough so that large amounts of debris do not accumulate between cleanings.

Label the Water Heater

A non-critical operation of this kind is easy to forget. Make it harder to forget by installing a placard at each fuel-fired water heater or group of water heaters. State the times when the heaters should be flushed, and when they should be mechanically cleaned. See [Reference Note 12, Placards](#), for details of effective placard design, materials, and installation.

Reducing Scale with Water Treatment

Hard scale consists mostly of calcium compounds. The tendency of water to form scale is described in terms of “hardness,” which is the quantity of dissolved minerals of calcium. You can reduce hardness by treating the incoming water supply in a water softener. This device passes the water through a bed of salt. It converts the dissolved calcium compounds into sodium

compounds. The sodium compounds are far more soluble, so they do not precipitate to form scale.

Water softeners are not economical just to reduce water heater scale. They are usually installed when the facility needs large amounts of soft water for purposes such as laundry, or to reduce stains in fixtures. If you are considering a water softener for one of these purposes, remember that keeping the water heater more efficient is a bonus.

A certain amount of “soft scale” can form in water heaters even with soft water.

Possible Health Benefit

Debris that falls to the bottom of the tank is suspected of being a breeding ground for dangerous microorganisms. See [Measure 3.2.1](#) for more about this. The problem is compounded by the fact that the water in the bottom of the tank may be much cooler than the

water above the heating elements. Therefore, cleaning out tanks periodically may reduce the health risk. But, don't depend on this.

ECONOMICS

SAVINGS POTENTIAL: *A few percent of water heating energy.*

COST: *Minimal, for routine flushing. Mechanical cleaning of larger units, in tanks where this is possible, may require several hours.*

PAYBACK PERIOD: *Immediate, for periodic blowdown. Other methods pay for themselves within a few months. Over the long term, the saving is many times the cost.*

TRAPS & TRICKS

SCHEDULING: *The only trick is to remember to do it. Put it on your maintenance schedule as a repeated item.*

MEASURE 3.2.8 Exploit interruptible or storage rates for electric water heating.

You may be able to get electricity at reduced rates by allowing the electric utility to install a remote control on your electric water heaters, as shown in Figure 1. The utility will turn off the heaters at certain times when they need to reduce their generating load. [Reference Note 21](#), Electricity Pricing, explains the utility's motivation for offering this deal.

In some cases, the utility offers the lower rate only for the electricity that goes to the water heater. In small facilities, the utility may extend the discount to all the electricity. This saves the utility the cost of installing a separate meter for the water heater.

The utility installs and maintains the control equipment. Control is reliable because the utility itself controls water heater operation.

During the period of time when the power to the water heater is interrupted, the facility must get by with the amount of water that is stored in the tank.

This customer option has been offered by many utilities for a long time. There are two common variations. One is called "interruptible" water heating. The other is called "storage" water heating. Both depend on the inherent storage capacity of typical water heaters.

Under an "interruptible" arrangement, the utility has the option of turning off the water heating element for a relatively short period, typically several hours. The utility typically exercises this option only a few times per year, during periods of especially high energy consumption. The interruptible arrangement typically is used by utilities serving areas that have only occasional high peak loads. Under this arrangement, a customer with a storage tank of normal size may suffer the inconvenience of rescheduling water usage for a few hours, but only a few times per year.

Under a "storage" arrangement, the utility typically turns off the water heating element for its entire period of high demand charges, which may last from six to eighteen hours per day. The interruption may occur every day, or only during certain extended periods, such as the summer or winter months. The customer must have enough storage capacity to satisfy hot water requirements for this entire period. Typically, reheating the tank takes two or three hours.

If the utility offers both "interruptible" and "storage" arrangements, the customer needs to consider two factors in making the choice. One is the relative electricity cost, and the other is the storage capacity requirement. Utilities usually offer more favorable rates for storage water heating because it provides more benefit to the utility.

SUMMARY

May provide substantial savings in electricity cost for water heating. The savings are foolproof because interruption is under utility control. Requires some discipline in scheduling water usage to avoid shortages, and may require additional storage capacity.

SELECTION SCORECARD

Savings Potential	\$ \$ \$
Rate of Return	% % % %
Reliability	✓ ✓ ✓ ✓
Ease of Initiation	😊 😊 😊

To exploit this opportunity, you need enough storage capacity to provide hot water during the periods when the power to the heating element is turned off. The amount of storage capacity depends on the length of time that the utility turns off the heating element, and it depends on the water usage pattern of the facility.

If your present water storage capacity is not adequate, you have two choices. One is to install a larger storage tank, or a supplemental tank. Many utilities provide discounts or rebates to encourage you to install more hot water storage capacity. The other approach is to reschedule the operations that require hot water. For example, a hotel could delay evening dishwashing to a time period when the water heating element is turned on.

Disadvantages

The main disadvantage is the possibility of running out of hot water during the interruption period. Deal with this by installing adequate hot water storage capacity. If you need to install a larger tank, or a supplemental tank, the additional space is typically not a problem. A modest increase in the dimensions of the tank provides much larger capacity.

How to Exploit This Opportunity

■ Step 1: Analyze the Utility's Rate Schedules and Incentives

Start by reviewing [Reference Note 21](#), Electricity Pricing. Then, ask your electric utility for all the current rate schedules that apply to your facility. Compare the cost of electric water heating under all the rates, including interruptible, storage, and conventional demand rates.

Also, be aware that many electric utilities offer specialty rates. For example, some utilities offer more attractive rates if you allow the utility to control other electric loads, such as dual-fuel space heating or electric storage space heating. If your facility has a large amount of interruptible electrical load, try to negotiate a special contract. Usually, it takes a minimum of several hundred kilowatts of interruptible load to entice the utility into a special arrangement.

■ Step 2: Analyze the Facility's Hot Water Storage Requirements

The facility must have enough storage capacity to provide hot water through the period of heating interruption. To estimate the amount of storage you need, analyze the facility's water consumption pattern, especially the amount needed during the interruption period.

For example, assume that the facility uses a maximum of 1,000 gallons of hot water per day. If the tank capacity is 1,000 gallons or more, the facility is completely unaffected by the interruption schedule of the utility, provided only that the water heater has a few hours to recharge.

Fig. 1 Interruptible water heating The arrow points to a small relay that the electric utility installed to interrupt the operation of the water heaters during periods of high electrical load. In return, the utility offers the electricity for the heaters at lower prices.

On the other hand, interruption may or may not be acceptable with the existing tank capacity. It depends on the length of the interruption and the pattern of consumption. If hot water consumption is distributed throughout the day and interruptions last only a few hours, hot water shortages will be rare. On the other hand, if an interruption extends all day, hot water shortages may occur too often to be acceptable.

Measure water consumption during typical days of high usage. You can do this by measuring the hot water flow with an external flow meter. (See [Reference Note 16](#), Measurement of Liquid, Gas, and Heat Flow, for details.) As an alternative, you can estimate water consumption from the energy input to the water heater. The simplest way to do this is to use a portable time recorder on each heating element. Or, if the heater has a number of heating elements, use a kilowatt-hour meter to measure the total electrical input.

A simple yes-or-no approach is to simulate interruption by turning off the power to the heating element during several days of heavy water usage. This tells you whether the present storage capacity is adequate.

Be cautious about utility claims that water heating power will be interrupted “only a few times” or “only for a short while.” This may be true at present, but interruptions are likely to get worse in the future, as the utility's load increases. Install enough storage to carry through the longest period of interruption stipulated in the rate schedule.

■ Step 3: Estimate Your Cost

The utility typically installs the control for your water heaters, and this part of the job costs you nothing.

If you have to add more storage capacity, the main item is the installed cost of the new tank. The utility may offer discounts or rebates for installing the additional capacity.

■ Step 4: Negotiate with the Utility

If the utility has a standard water heater control rate and your hot water consumption is not a major electrical load, simply request the standard arrangement. As stated before, if you have a large amount of demand that may be controlled, you may be able to negotiate more favorable terms.

■ Step 5: Install Additional Storage Capacity, If Needed

Install any additional hot water storage that you may need. Storage tanks are discussed below. Many utilities offer to handle the installation. Also, the utility may provide financing and charge time payments as part of the utility bill.

■ Step 6: Establish Appropriate Water Management Procedures

Do what you can to avoid water shortages during the period of interruption. In facilities that have a regular

water use pattern, no special action is necessary if you have planned properly. If an unusually high demand for water may occur during an interruption period, prepare to educate water users to the problem. You may be able to do this effectively with placards, as explained below.

Storage Water Heaters

Storage water heaters are the same as ordinary water heaters, except that the tanks are larger. The heating capacity is usually the same as for conventional heating. This is satisfactory because the elements operate during periods of low water consumption, when the tank can be reheated at leisure. For the same reason, you do not have to increase the capacity of the electrical circuits that serve the heaters.

Select storage water heaters that have exceptionally good insulation. Conductive heat loss from a well insulated water heater amounts to no more than a few percent per day. Heat loss does not increase much as you increase storage capacity, because surface area increases more slowly than volume.

You can also increase storage capacity by adding a second water heater in series with the original unit. To avoid increasing the total circuit amperage, recharge the downstream water heater first, and then the upstream heater. To do this, you have to power the two heaters in sequence. This is not a difficult control arrangement, but it is unusual.

In larger water systems, you can increase storage capacity by installing a plain tank, without a heater, ahead of the heating tank. Install a small pump to circulate hot water from the heating tank into the supplemental tank during the heating period.

Hot Water Temperature, Storage Capacity, and Safety

The amount of heat stored in water is directly proportional to the temperature of the water. Therefore, raising the temperature of the storage tank increases its effective capacity. This fact creates the temptation to limit the cost of storage heaters by raising the storage temperature. In principle, an ordinary water heater could store water almost at boiling temperature. In practice, the safety hazard is usually unacceptable if the water can come in contact with people, as in showering.

At first glance, it may appear that you can solve both the scalding hazard problem and capacity problem by using a tempering valve. A tempering valve is a mixing valve with an internal thermostat that mixes cold water with the hot water from the heater. The mixed water is then distributed within the facility.

This is probably a bad idea. The tempering valve is a mechanical device that may fail. If it fails, the water at the point of use may be much hotter than expected. In systems where the hot water is not recirculated, the

danger is more acute. When the user turns on the tap, cold water comes out first, causing the user to open the hot water tap fully. When the cold water clears out of the line, hot water follows. Tempering valves are not a solution to this problem, because they respond too slowly to stop the initial slug of hot water.

From a safety standpoint, the best approach is to install tanks that are large enough to store an adequate quantity of water at a safe temperature. Then, you may still want to use a tempering valve to lower the water temperature further for energy conservation. See [Measure 3.2.1](#) for details.

The appropriate temperature setting for human usage of hot water is bounded narrowly by two considerations. 140°F is commonly quoted as the maximum temperature to avoid scalding. You may want to use a tank discharge temperature almost this high to ensure that the temperature inside the tank is high enough to prevent proliferation of microorganisms. See [Measure 3.2.1](#) for more about this issue.

Higher temperatures are mandatory in sanitation applications, such as dairy barns and restaurant dishwashing, and in some other specialized applications. In such applications, the staff must be trained to deal with the hazards of the high water temperatures.

Equipment Placards and Interruption Indicators

The operating staff will not know about the purpose of interruptible water heating unless you tell them. Therefore, install a prominent placard at the hot water tank and/or at a location where hot water usage is controlled, which says:

- power to the water heating system may be interrupted as a cost saving measure
- the times and/or durations of interruption
- a signal will be activated when interruption is in effect
- restrict hot water use during periods of interruption.

There is a bonus in making all water users in the facility aware of heating interruptions, even though hot water continues to be available from storage. It reduces the chance that a water shortage will occur, and it motivates water conservation and energy conservation in general.

The utility should provide an indicator to show when water heating is being interrupted. This could be nothing more than a red light on the utility's control box that turns on when power to the water heater is interrupted. If this is not satisfactory, you can install a remote indicator anywhere that it will get the attention of the people who need to know. The control receiver that turns off the heating elements provides a signal voltage. Use this to trigger your indicator or alarm. As an alternative, use a relay to sense when power to the heating elements is turned off.

Understand the Utility's Motivation

A utility offers discounted rates for interruptible service because this provides a benefit to the utility. The value to the utility changes with time as the utility's load and generating resources change. The highest rate incentives are offered when the utility is most desperate to reduce its demand. However, when the utility is desperate, it will seek a variety of other solutions. The utility may eventually abandon the rate incentive.

A utility may reduce or abandon a discount rate at any time, subject to approval by the relevant regulatory agencies. Before making a substantial investment to gain a reduced utility rate, make an informed judgement about how long the utility is likely to continue the favorable rate.

This Measure shifts the utility's electrical load, but it does not reduce it. The water heating load that is deleted during the hours of interruption is added to the load during the other hours of the day. Only a few hours are needed for reheating the tank. The utility wants to move this load into the least-used off-peak nighttime hours. However, the need for the water heater to recharge extends the peak demand period. Eventually, there may be no more opportunity for transferring daytime load to nighttime.

This situation is most likely to arise in areas where electric space heating creates a peak load for the utility. Ironically, space heating can be a peak load in warm climates as well as cold climates, because the low cost of electric heating units makes them popular in warm locations.

What to Do if the Utility Does Not Offer a Storage Rate

Even if the utility does not offer an interruptible or storage rate for water heating, you can still reduce demand charges by controlling water heating on your own. See [Measure 3.2.9](#) for this alternative.

This Measure is similar to [Measure 3.2.8](#), except that responsibility for managing control of the water heater rests with the facility. This is a major difference. The activity is no longer foolproof, and the facility must pay for the necessary controls.

Give serious thought to whether your facility can manage interruption of water heating demand reliably. Although control is automatic, some discretion may be required. If the hot water storage capacity is marginal, interrupting water heating may sometimes create a hot water shortage. In that case, you must decide whether to forego the availability of the hot water or the savings in demand charges. A way out of this dilemma is to increase hot water storage capacity, but this is expensive.

How to Control Water Heating

The basic procedure is to install a demand controller to control the operation of the water heaters. A demand controller is a control device that senses the overall facility power consumption. When the facility load rises to a preset level, the controller turns off the water heater. The water heater is turned back on when the facility load drops below this level.

If the water heater has a number of heating elements, the demand controller should turn them off in sequence, so that water heating may continue to be available at a reduced level.

(Some electric water heaters have a pair of identical heating elements, one at the top of the tank and one at the bottom. These operate in sequence. The top element is intended to provide hot water quickly, after which the bottom element heats the rest of the water in the tank. This arrangement is used to limit the wiring capacity needed to serve the water heater. It also acts to limit demand.)

More sophisticated demand controllers “learn” from experience. If the facility load rises to a new high during a demand billing period, this level becomes the new threshold for demand control, reducing unnecessary interruption of water heating.

These functions can also be performed by many energy management computer systems, provided that you can program the computer to do it. See [Reference Note 13](#), Energy Management Control Systems, for details. A dedicated controller is more reliable, and it is usually cheaper in the long run.

Control Other Eligible Equipment at the Same Time

The facility may have other equipment that can be turned off on an elective basis. Use the same demand controller to control this equipment as well as the water heater. For example, the demand controller can sequence different air conditioners to limit the overall demand. Water heating is usually the only major controllable load in commercial and residential facilities. Some industrial facilities may offer other major opportunities.

Explain It!

The controls are automatic, but they will be sabotaged sooner or later if the staff does not understand their purpose. Failing to control water heating demand even once during a demand billing period will forfeit all savings during the billing period. Therefore, install an effective placard near the water heater controls that informs the staff of the purpose of the demand control. See [Reference Note 12](#), Placards, for details of effective placard design, materials, and installation.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely. Demand charges in the United States average several dollars per month per kilowatt of demand during the peak demand period.*

COST: *Several thousand dollars for the demand controls. The cost of adding more water storage capacity, if necessary, varies from hundreds of dollars to thousands of dollars.*

PAYBACK PERIOD: *Several years, or longer.*

TRAPS & TRICKS

PREPARATION: *Before you can do this successfully, you need to learn about electricity rates. First, request from your utility all the rate schedules that apply to your facility. Then, learn how to read them. After that, make an educated guess about the demand rates that the utility will offer in the future. [Reference Note 21](#) will guide you. See [Measure 3.2.8](#) about the possibility of increasing your water storage capacity.*

SELECTING THE CONTROL EQUIPMENT: *The most reliable approach, and probably the cheapest, is to install a single-purpose demand controller. Shop the market to see what is currently available. You can also use your energy management computer, but be prepared for programming headaches. Also, you will lose your control capability when the computer becomes obsolete in a few years.*

PUBLICITY: *Tell water users ahead of time when to expect water heating to be interrupted. See [Measure 3.2.8](#) for details.*

EXPLAIN IT: *Plant operators usually are not the people who pay the electric bill, so this activity could fail without anyone noticing. Therefore, describe the demand limiting control clearly in the plant operating manual. Install a placard at the control that explains how to tell whether the control is working.*

MONITOR PERFORMANCE: *Schedule periodic checks of the controls during periods of time when demand charges are affected. Also, periodically review the current rate schedules to verify the times and conditions under which interrupting water heating saves money. Utilities continually change their rate schedules.*

Service Water Pumping

The Measures in this Subsection reduce the energy consumption of service water pumps. Many facilities do not need their own pumps to provide service water pressure, because the public water utility provides adequate pressure. However, many facilities do need to provide or augment their own service water pressure, and the pumps for this function may be major consumers of energy.

Expect to find water pressurization pumps in facilities that have their own sources of water, typically from wells. Also, a facility needs to have its own pumps if the pressure provided by the water utility is not high enough, or if the public water supply is unreliable. The facility may have its own pumps for applications that need water at exceptionally high pressure. For example, tall buildings commonly have their own service water pumps to serve upper floors.

Most facilities have small pumps for recirculating hot water. These pumps typically consume only a small amount of energy. However, there are cases where the design of the service water system requires larger pumps for recirculation. You may be able to save a significant amount of energy by improving these arrangements.

MEASURE 3.3.1 In facilities that have their own service water pumps, configure the system to minimize pump energy consumption.

The purpose of this Measure is to improve the efficiency of pumping systems that provide pressure for service water. The pumps may be relatively small, perhaps a few horsepower. However, if the facility does not have a standpipe (water tower) or other type of storage tank that maintains pressure, the pumps consume a large amount of energy in relation to their size because they must operate continuously.

There are two general ways to improve pumping efficiency in such cases:

- **install pumps in increments of capacity**, so that pump power can increase in proportion to the flow rate demanded by the system. This approach is recommended by subsidiary [Measure 3.3.1.1](#).
- **install one or more standpipes or pressurization tanks**, to limit pump operation to brief periods of running at maximum efficiency. This approach is recommended by subsidiary [Measure 3.3.1.2](#).

Where to Consider this Measure

This Measure applies to facilities that employ their own pumps to provide service water pressure, or to augment the pressure provided by the water utility (“city water”). In-house pumps are used in tall buildings, in facilities that have their own water supply, and in locations where city water pressure is unreliable.

If an existing facility uses a standpipe for pressurization, your ability to make efficiency improvements is limited, because standpipe systems are inherently efficient. However, even if a standpipe is installed, you may be able to make improvements that are worth the effort.

The two subsidiary Measures offer a spectrum of possibilities that range from adding a single small pump to installing multiple standpipes. The more expensive changes are economical as retrofits only in facilities that have larger service water pumps.

An Example

To see how a service water system can waste pumping energy, consider the example of a large hotel in which service water pressure is produced entirely by in-house pumps. This is depicted in Figure 1. The hotel has a tall guest room tower. Meeting rooms are on the second floor. Kitchens, restaurants, laundry, ballrooms, offices, and lobby are on the first floor. The main mechanical equipment room is in the basement.

This system is inefficient because it must provide enough pressure to flush a toilet in the penthouse, even though most of the water flows to the large water-using equipment on the lower floors. The capacity of the

pressurization system must satisfy the requirements of all the showers, cooking facilities, laundry, and other water users. Even taking diversity into account, the pumping capacity must be much larger than the typical flow. If the entire system were pressurized by a single pump, the combined pressure and flow requirements result in the pump being vastly oversized.

We will return to this example in the subsidiary Measures to illustrate the various methods that we can use to reduce pump energy.

Fig. 1 How service water pressurization wastes energy
In this example of a worst case, service water pressure to a tall hotel is provided by a single pump. The pump must operate continuously. It must be sized for the maximum flow rate of the entire building, even though the average flow rate is a fraction of this amount. It must be sized to provide water pressure to the highest level in the building, even though most water consumption occurs at the lower levels.

Analysis of System Energy Consumption

(The following discussion requires an understanding of basic centrifugal pump characteristics. If you need a quick refresher, see [Reference Note 35](#), Centrifugal Pumps.)

The pump load in service water systems is created mostly by gravity and by the pressure requirements of the water-using equipment. These factors are constant. Therefore, the pump pressure requirement is fairly constant. On the other hand, the flow requirement typically varies over a wide range.

(The amount of pump energy dissipated by pipe friction is minor, especially because the average flow rate is low. However, the resistance caused by pipe

friction may become important at higher flow rates, requiring the pump pressure rating to be increased somewhat.)

These pump load characteristics cause a service water system to waste energy in several ways. Each of these has a different remedy. The following are the main causes of energy waste.

■ **Extended Operation at Low Flow Rate**

The key point is that a single domestic water pressurization pump spends much of the time operating at a very low fraction of its design maximum flow. Likewise, most of the energy that the pump consumes over the course of time is consumed while the pump is operating at such low flow rates. For example, in a hotel,

Fig. 2 Pump curve and system curve for a single pump providing service water pressure In a typical application, the pump spends most of its time operating at a very low fraction of maximum flow. The pump can operate only along its pump curve, so it produces more pressure than necessary at low flow rates. Also, the efficiency of the pump declines seriously when it operates at low flow rates.

a single pump might operate at less than 10% of maximum flow for a large fraction of the time. This wastes energy in two ways, which can be seen from the typical pump and system curves in Figure 2.

One cause of energy waste is that the pump operates at low efficiency for most of the time. Pump efficiency declines seriously when the pump operates far from its design pressure and flow rate. For example, in Figure 2, pump efficiency declines from about 85% at maximum flow to less than 50% at low flow rates.

The other cause of energy waste is that the pump can operate only along its pump curve. At low flow rates, the system curve is far from the pump curve, so the pump is producing much more pressure than needed to satisfy the flow requirement.

The graph in Figure 3 shows the overall effect of these two factors. It plots the pump power as a function of the flow rate. It also plots the power that would be required by a pump of the same maximum efficiency that is sized precisely for the pressure and capacity needed at each flow rate. There is a big difference between the two power requirements at lower flow rates. In fact, the pump power is several times higher than necessary to satisfy the system requirement during a large part of the time.

■ Differing Pressure Requirements in the Facility

The pumps in a service water system must produce the highest pressure needed anywhere in the system. Pump energy is wasted in delivering water at this

Fig. 3 Why a single pressurization pump wastes energy
The upper curve shows the actual power consumption of the single pump characterized in Figure 2. The lower curve shows the power needed to satisfy the system flow requirements by a pumping system that always operates at peak efficiency. The power differs enormously at low flow rates.

maximum pressure to portions of the system that need less pressure. This is a common problem in tall buildings, as in our sample hotel.

■ Systems with Pressure-Reducing Valves

Some buildings use pressure-reducing valves to keep system pressure within acceptable limits. This arrangement is typically found in tall buildings, where pressure-reducing valves might be installed in the lower portions of a tall riser. All the pressure that is dissipated by the valves must be produced by the pumps, wasting a considerable fraction of the pump's energy input.

■ Motor Efficiency

The efficiency of electric motors starts to decline rapidly when the motor is loaded less than about 50%. The motor is always somewhat oversized for the pump, so motor efficiency starts to decline before the pump load falls to half. See [Measure 10.1.1](#) for more about electric motor characteristics.

Factors That Determine Water Pressure Requirements

Excess pressure at any delivery point represents wasted energy. These factors determine the pressure that the facility's own water system must produce:

- **the height of the delivery point.** Hydrostatic pressure due to gravity is about 0.43 PSI per foot of height. For example, a 20-story building requires a pressure of about 100 PSI at the basement level to pump water to the top floor.
- **the types of fixtures served.** Most fixtures and appliances require minimum water pressures between 10 PSI and 20 PSI. Some shower heads may require as much as 30 PSI to perform well, but these are exceptional. Specialized appliances that need even higher pressures commonly have separate booster pumps.
- **the reliable pressure contribution of the city system.** The city water system may provide satisfactory pressure for the lower portion of a building, while supplemental pressurization is needed for the upper portions. If the city water pressure fluctuates, design to use the minimum reliable pressure. If reliability of water service is an issue, design to use city pressure whenever it is available, as explained next.

Exploit the Pressure Provided by the Water Utility

Don't spend your own money to create water pressure where the city water system already does this. Select your pressurization pumps to take suction at the lowest pressure that the city system normally provides.

Some facilities provide all their own water pressure from a vented tank at ground level that is filled from the city water supply. This arrangement may be used to ensure an adequate supply of water because the city water supply was considered unreliable at the time the

facility was built. Providing a reliable supply of water for firefighting may be one of the primary reasons for installing such a system. This arrangement duplicates the pressure of the city water system, wasting the corresponding pump energy. Figure 4 shows an example.

A solution is to connect the domestic water system directly to the city water supply, bypassing the storage tank. Fire protection pumps are separate from service water pumps, and these remain connected to the reservoir tank. Maintain a full tank of water for firefighting by using a float-actuated fill valve.

In retrofit, leave the original pumps in place for periods when the city supply fails. Install reliable controls to switch to the original pumps when needed. A simple method is to use the pressure of the city water supply to control a transfer switch that provides power to only one of the pumps. With a manual override on the transfer switch, the original pumps serve as a reliable backup for the new pumps.

With this arrangement, you have to be sure that the pump check valves do not leak. The check valves of both the new and the original pumps are under full supply pressure at all times. If the check valve of the new pump leaks, water will backflow into the city water supply. If the check valve of the old pump leaks, water will backflow into the vented tank, overflowing the tank into the sewer. Both leaks waste pump energy.

Pressurize Hot Service Water Efficiently

The hot water flow capacity is determined by the capacity of the cold water pumps. Therefore, remember the hot water requirements in each pressure zone when sizing the service water pumps for that zone.

In terms of pressure, the hot water system is connected directly to the cold water system through the water heater. In other words, hot service water is produced at the same pressure as the cold water system that feeds it. If the water system is divided into different pressure zones, the hot water usually is distributed to the same pressure zone as the cold water, even if not to

WESINC

the same physical space. Exceptions might occur if hot water is needed at a different pressure than cold water.

A separate water heater is needed for each separate pressure zone in which hot water is delivered. The cost and difficulty of installing additional water heaters is a major limiting factor in subdividing the water system for efficient pumping.

In all but the smallest facilities, hot water requires recirculation to maintain adequate temperature at the water-using fixtures. To avoid complications and waste of pump energy, each pressure zone should have its own recirculation system. If recirculation is designed properly, the recirculation pumps are very small.

MEASURE 3.3.1.1 Use multiple pressurization pumps.

RATINGS

New Facilities	Retrofit	O&M
B	C	

This subsidiary Measure explains the first of two approaches for minimizing service water pumping energy. This approach relies on using a clever combination of pumps.

There are two aspects to this approach. One is to install a group of several pumps in parallel to adapt to the changes in the water flow requirement. Another aspect is to install different groups of pumps that are matched to different pressure requirements within the facility.

The selection and grouping of pumps is largely a matter of judgement. There is a trend of diminishing returns in using larger numbers of pumps to match flow and pressure requirements more accurately. As you make the configuration more efficient, it becomes more complex and more expensive. Many pumps may be needed to efficiently match all the facility’s flow and pressure conditions.

How to Accommodate Changing Water Usage

To match pump power to the variations in flow requirements, install a parallel combination of pumps. Select the pump capacities so that some combination of pumps is reasonably efficient for all flow rates that may occur.

For example, consider our typical hotel, introduced in [Measure 3.3.1](#). Assume that the hotel has these water flow requirements:

- flow is maximum between the hours of 0600 and 0800, but never more than 200 GPM
- usually below 100 GPM during lunch and dinner hours
- usually below 50 GPM during the rest of the daytime and evening
- usually below 10 GPM during late night hours.

To meet these flow requirements efficiently, we will replace the present single pump and its standby unit with a parallel group of five pumps, as shown in Figure 1.

By using three pumps rated at 100 GPM each, we satisfy the maximum flow requirement, with one pump as a spare. Also, selecting this size allows a single pump to handle the lunch and dinner hours. A single pump of 50 GPM capacity is installed to handle the lower demand during the rest of the daytime. A single pump of 10 GPM capacity handles the minimal late-night requirements.

Obviously, other combinations are possible. The example makes it clear that there is a compromise between the number of pumps and the efficiency of pumping.

SUMMARY

Simple and reliable. Facilities with diverse pressure and flow requirements may require numerous pumps. Retrofit applications require piping changes, which may be modest. Requires a separate water heater and recirculation system for each pressure zone.

In parallel groups of pumps, select all of them to operate at the same pressure, since they may operate together. In principle, pumps operating individually at the lower system flow rates could be designed for a somewhat lower pressure, since they face less piping resistance. However, this refinement is not worth the extra complication.

■ **How to Control Pump Sequencing**

The best way to control the operation of the pumps is to sense the flow rate in the common discharge line. Remember that the flow rate is determined by the water users, not by the pumps. A specific pump or combination of pumps is turned on in each range of flow rates.

You cannot use pressure for normal control of pump operation, because the system pressure is supposed to remain constant at all flow rates. However, you might sense the pressure in the discharge line to start an additional pump in the event that one of the pumps fails.

■ **How to Select Reserve Pumps**

In systems designed to operate with only one pump, it is common practice to provide a reserve pump. However, in a system that uses multiple pumps, failure of one of the pumps may not be critical. In fact, a single pump failure may have no effect except during a peak consumption period. During a peak, the loss of pressure would be most noticeable in the highest portion of the building. Even then, the characteristics of centrifugal pumps allow them to “trade” pressure for increased flow.

If several pumps of mixed size are installed in parallel, a reserve unit equal in size to the largest pump usually provides a generous guarantee of performance.

■ **How to Minimize Pressure Fluctuations**

Starting or stopping a pump causes a small but fairly abrupt change in system pressure. You can smooth these fluctuations by installing a surge absorber in the discharge line from the pumps. This device is a small tank that is filled with air at system pressure. It is connected at the bottom to the water pipe. The pressurized air acts as a cushion that absorbs sudden increases in pump pressure, and it expands to compensate for small drops in system pressure.

How to Accommodate the Differences in Pressure Requirements

The previous technique, using a group of parallel pumps, reduces the waste of energy that results from excessive flow capacity. Additional steps are needed to

Fig. 1 Adapting efficiently to changes in water demand
The individual pumps are sized to satisfy the water demand at different times of day, minimizing excess flow capacity at any moment. Still, this arrangement does not account for the great differences in pressure needed to move water to different parts of the building.

minimize the waste of pump energy that results from differences in the pressure requirements of different parts of the facility. In tall buildings, pressurization pumps must provide enough pressure to serve the upper levels, resulting in unnecessary pressure at lower levels. Also, some branches of the service water system may have exceptionally high pressure requirements because they serve special requirements, such as dishwashers, high-pressure hosedown, or a decorative fountain. The following are two ways to solve this problem.

■ **Method A: Install Separate Pumps and Risers for Different Pressure Zones**

If cost were no obstacle, it would be desirable to provide separate pressurization for each area of a facility that has a different pressure requirement. The cost of piping and pumps determines how close to this ideal you should try to make the system. Even in retrofit applications, you may be able to cut apart existing risers and provide separate pumps, with little new piping being required.

The modification shown in Figure 2 illustrates this approach. In this case, three separate pressure zones have been created. One serves the higher portions of the building, a second serves most of the lower portions, and a third serves the higher pressure requirements of the dishwashing area. A short riser was added to connect the new guest room pumps to the existing guest room riser. Also, the piping in the equipment room had to be rearranged to provide a separate pressure zone for the dishwashing area.

The number of pumps has been increased further, compared to Figure 1. This is unavoidable, because each pressure zone must have a variety of pumps to accommodate different flow rates. However, the total pump energy consumption is reduced, because the pumps serving the largest flow requirements operate at lower pressure.

Remember that a separate hot water heater is needed for each pressure zone. In retrofit applications, this method allows the new pumps to be installed near the old ones, which makes it easier to install the additional water heaters in a cluster.

■ **Method B: Install Booster Pumps to Serve Zones with Higher Pressure Requirements**

Another way to provide increased pressure for certain areas or equipment is to install booster pumps. Figure 3 shows this approach being used in our hotel example to serve the upper guest room floors. Also, a single booster pump has been added to serve the high-pressure applications in the dishwashing area.

This method incurs no cost for additional piping, except for connections to the booster pumps. Compared to Figure 1, the number of pumps has been increased. This is necessary because each pressure zone needs a variety of pumps to accommodate different flow rates.

Booster pumps are most appropriate in cases where the city water pressure is sufficient for most of the facility. In such cases, using booster pumps eliminates the need to provide in-house pumps for the portions of the facility that can be served directly by city water pressure.

Each booster pump, or set of booster pumps, is usually controlled on the basis of the flow in its discharge line, as with the other pumps. However, a booster pump might be started by the operation of high-pressure equipment in the branch that it serves. For example, in Figure 3, the booster pump that serves the dishwashing area might be started by operation of the dishwashers. The check valve installed in parallel with the booster pump allows the primary pumps to provide other water requirements when the booster pump is not operating.

Installing additional hot water heaters may be cumbersome with this method. For example, you would

have to install the water heater for the upper floors in the same location as the booster pumps for the upper floors. This might require a water heater that uses a more expensive fuel than the main heater in the basement. If so, the increased fuel cost may largely offset the saving in pump energy.

Why You Can't Use a Variable-Speed Pump Instead

At first glance, installing a variable-speed pump drive seems to be a much simpler way of accommodating changes in water demand, instead of installing all those fixed-capacity pumps. Figure 4 shows that people have tried this. Unfortunately, it doesn't work. Slowing a centrifugal pump reduces the pressure output as well as the flow. Most service water applications need the water pressure to remain constant, regardless of the flow rate. Even a small reduction in pump speed would starve the system of water, starting at the highest points.

Fig. 2 Separate risers for different pressure zones This requires many pumps and extra pipe. Even so, the guest room riser still delivers water at greatly differing pressures.

Fig. 3 Booster pumps This arrangement achieves the same purpose as the one in Figure 2. It may require less pipe, and it is easier to retrofit. The number of pumps is the same, but one group must be installed at a remote location. The overall efficiency is about the same.

ECONOMICS

SAVINGS POTENTIAL: 40 to 80 percent of service water pumping energy.

COST: Several thousand dollars and up.

PAYBACK PERIOD: Less than one year, to many years. The payback period is best with large motors and easy piping.

TRAPS & TRICKS

DESIGN: This is basically a matter of balancing three variables: energy cost, pump cost, and piping cost. Sketch out all the configurations that make sense, then make a judgement call. Before installing pumps in remote locations, consider that pumps make a certain amount of noise, they may take up rentable space, they may leak, and they may be less accessible for maintenance.

EXPLAIN IT: Proper pump sequencing is the key to efficient operation. Describe the system, the sequencing scheme, and the control settings in the plant operating manual. Install a placard at the sequencing control that states the control settings.

WESINC

Fig. 4 Wrong application for a variable-speed pump

This variable-speed pump installation is intended to minimize the energy required to deliver service water in a tall hotel. However, the need to maintain a fixed pressure in the system dooms this approach to failure. The losses in this old hydraulic drive negate any small saving in pump power.

MEASURE 3.3.1.2 Install gravity tanks or pressurized storage tanks.

RATINGS

New Facilities	Retrofit	O&M
C	C	

This subsidiary Measure recommends another way to minimize the energy needed to pressurize the service water system. This approach relies on one or more tanks to maintain pressure on the system. The system’s pumps are used only to refill the tanks, so they operate only intermittently.

This is usually the most efficient method. The average rate of water usage in most facilities is much less than the peak consumption, so the pumps are stopped most of the time. The pumps can be optimized for the single pressure and flow rate needed to refill the tank. By the same token, the capacity of the pumps does not affect efficiency, unlike systems where the pumps provide system pressure directly.

SUMMARY

Allows the pumps to operate at their maximum efficiency. Provides stable water pressure. Requires a separate water heater and recirculation system for each pressure zone. In retrofit, structural support for the tank(s) may be a problem, but clever design can minimize tank size.

Fig. 1 Gravity tank and pressurized tank Using storage tanks eliminates excess pump operation. In addition, splitting the building into pressure zones improves pumping efficiency.

You have a choice of two types of tanks. You can install a simple gravity tank, which must be located above the highest water user in the system. Or, you can install a closed, pressurized tank at any elevation.

Figure 1 illustrates both types installed in the hotel that we have been using as an example in the previous Measures. The tall portion of the building is served by a standpipe located above the roof. The lower portions of the building are served by a closed pressurization tank located in the equipment room.

From the standpoint of energy efficiency, gravity tanks and pressurized storage tanks are essentially equal. The choice between the two usually does not affect the other components of the water system. The choice is guided mainly by relative cost and by the structural limitations of the building. Each tank requires only one pump, with perhaps a second reserve pump.

This method is likely to be more expensive than the methods of Measure 3.3.1.1, but this is not always true. This method adds cost for the tank(s) and supporting structure, but it may add relatively little piping cost. In new construction, the additional structural cost may be minor. However, structural support may be a large cost in retrofit, especially for standpipes on top of the building. In new construction, this method allows the pumps to be much smaller.

As in Measure 3.3.1.1, a separate hot water heater and recirculation system is needed for each pressure zone, i.e., for each pressurization tank.

Standpipes

A “standpipe,” or gravity tank, is an elevated tank that is intended to store water and to maintain a steady water pressure. In a standpipe system, water pressure is provided entirely by gravity and it is determined by the height of the tank above the user. The tank is vented and requires no accessories, except for a level switch to control the operation of the pump that fills it. Figure 2 shows a number of gravity tank installations.

WESINC

Fig. 2 Gravity tanks These buildings use gravity tanks for two purposes, pressurizing the domestic water system and providing a separate source of water for fire protection. In most of these buildings, separate tanks are used for the two purposes. The elevation of the tanks above the roofs provides adequate pressure for the upper floors.

Many buildings have gravity tanks for fire protection. The tank ensures both an adequate quantity of water and adequate pressure. A fire protection tank can also pressurize the service water system.

When considering a gravity tank, assess the ability of the building’s structure to carry the localized weight of the tank and its contents. In new construction, this may be a minor matter. A filled service water pressurization tank may weigh less than a boiler or a chiller. You can minimize the size of the tank by selecting the pump capacities carefully, as explained below.

A gravity tank must be located well above the highest level of water usage in order to provide adequate pressure. For example, if you need to provide 15 PSI to the top floor of a building, the water level in a gravity tank must be 35 feet above the tallest fixture.

If only a small amount of water is needed at the highest level in the building, it is more practical to use a small booster pump with a separate riser that serves just the upper floors of the building, as shown in Figure 3. This makes structural support easier. It also reduces the problem of freeze protection, which is discussed below.

The cheapest way to refill the tank is through the service riser. However, this causes pressure fluctuations at the user equipment when the pump starts or stops. You can damp these fluctuations by using a surge

Fig. 3 How to provide pressure to the upper floors

As a third approach, you could add a small pressurization tank just to serve the upper floors.

absorber, described previously. You can eliminate the fluctuations completely by installing a separate pipe to refill the tank.

Closed Pressurization Tanks

You can also store system pressure with a closed pressurization tank. This is simply a tank that has an air space to provide pressurization. A small air compressor replenishes the air occasionally as it is absorbed slowly into the water. Figure 4 shows an example.

A pressurization tank has the advantage that it can be installed anywhere in the service water system, provided that the piping is of adequate size at that point.

The tank wall thickness is proportional to the diameter of the tank, so it is desirable to keep the tank as small as possible. You can minimize the tank capacity by selecting the pump capacities carefully, as explained below. In a tall building, you can reduce the tank's pressure rating by installing it high in the system.

A pressurization tank acts as a surge absorber. The tank is most effective in this role if it is located near the pump discharge.

How to Select Tank Capacity and Pump Size

In a standpipe system, the pump turns on and off continually. The starting current of a motor is several times the normal full-load current, so frequent starting causes the motor to run hotter than normal. Calculate the maximum cycling rate that you can expect. Then, select the motor accordingly. See [Measure 10.1.1](#) for guidance in selecting motors.

The size of the tank is determined primarily by the need to limit pump motor cycling. Here is an example.

WESINC

Fig. 4 Service water pressurization equipment in the basement of a tall office building The closed tank on the right maintains constant water pressure. The three pumps on the left operate in sequence.

The peak flow rate is about 1,000 GPM, the pump has a capacity of 1,000 GPM, and the tank has a capacity of 2,000 gallons. The cycling behavior of the pump at different rates is:

This example shows that the number of motor starts per hour remains fairly constant throughout a wide range of water demand rates. A large tank capacity is needed to extend the period of time that the pump remains off. The number of motor starts per hour is inversely proportional to the tank capacity.

Greater pump capacity shortens the time needed to refill the tank, somewhat increasing the number of motor starts per hour. The pump capacity should be able to satisfy the maximum continuous flow requirement, but there is no merit in adding additional pump capacity, except to add a spare pump.

This analysis suggests a way of reducing the tank capacity. Namely, divide the pump capacity among several smaller pumps. Use a series of tank level switches to operate individual pumps, so that the minimum number of pumps are operated to satisfy the current demand flow rate. This slows the rate of filling and matches pump output to the flow requirement, allowing tank capacity to be reduced without excessive pump cycling.

For example, if the maximum expected flow rate is 1,000 GPM, install three pumps, each of 350 GPM. Install four tank level switches, at 100%, 30%, 20%, and 10% of full capacity. One pump is started when the tank level falls to 30%, a second when the tank level falls to 20%, and the third when the tank level falls to 10%. All pumps are turned off when the tank is filled to 100%.

Extending this example, a fourth pump can be installed as a spare. It is controlled with a level switch located at, say, the 5% level. It starts automatically if any of the other pumps fails, or if the maximum flow rate is greater than estimated.

Using Existing Pumps

If you add a standpipe or pressurization tank to an existing facility, consider using one or more of the existing pumps for refilling the tank. You may be able to save even more energy by trimming the pumps to

operate at the lowest practical pressure. See [Measure 10.2.1](#) for details of pump impeller trimming.

Freeze Protection of Exterior Tanks

Exterior tanks have been used for years in many cities with colder climates, such as New York City. A tank located outside the building in a cold climate should be insulated. The large mass of water keeps the tank from freezing, as long as some flow through the tank occurs on a daily basis. However, heat loss from the tank increases the energy required for heating the water. Exposed connecting pipe is vulnerable to freezing. Preventing this requires heat tracing of the pipe, which uses energy.

You can avoid the freezing problem entirely by keeping the tank within a heated space, such as an equipment penthouse. If you do this, provide adequate pressure for the upper floors with a small booster pump, as suggested previously.

MEASURE 3.3.2 Design hot water recirculation to minimize pump energy.

RATINGS

New Facilities	Retrofit	O&M
A	C	

The purpose of recirculation in a hot water system is to ensure that the temperature of the water at the fixtures does not vary, and to keep hot water available without a delay. Most hot service water systems in commercial and industrial facilities have recirculation.

Recirculation systems are needed because hot water cools quickly as it sits in the pipe. Water pipe has a large surface area in relation to its volume, so the water cools in a matter of minutes, even if the pipe is insulated.

Fig. 1 Little water heater, big recirculation pump This pump is probably much larger than needed, although it is still only a fraction of a horsepower. Note that the hot water distribution and recirculation lines are insulated.

Without recirculation, the first water drawn from the system by a fixture or appliance would be cooler than normal. Unless the hot water tank is close to the user, there would be a long delay in receiving hot water.

Recirculation is simple. Small pipes are installed in the hot water system at each area where hot water is used. These pipes draw water from the system continuously and return it to the water heater. This small flow keeps the hot water supply pipe warm. For example, each restroom typically has a recirculation line that draws from the common hot water line that serves the wash basins. A small pump operates continuously to recirculate the water.

Pump Energy Requirement

Recirculation requires little pump energy if it is designed properly. Only a low flow rate is needed to keep the pipes warm. Recirculation takes place in a closed loop, so there is no gravity load. A typical recirculation pump has a motor of one-tenth horsepower or less. However, recirculation pumps operate continuously, or at least for a large fraction of the time.

In existing facilities, recirculation systems typically have little potential for improvement. However, if a recirculation pump is larger than a fraction of a horsepower (or kilowatt), review the system layout. For example, Figure 1 looks suspicious. A design mistake is a possibility.

If you see that the recirculation pump is unusually large, consider the possibility that the pump is designed to overcome the resistance of a backpressure valve. Backpressure valves may be used in the return legs of recirculation lines at different levels in a tall building. Figure 2 shows an example. If this is the cause, consider redesigning the hot water distribution to eliminate the

need for the backpressure valve, as recommended by [Measures 3.3.1 ff.](#)

The flow capacity of a recirculation pump is determined by the flow velocity that is needed to keep the hot water supply line warm. A larger hot water supply pipe requires a larger recirculation pump and larger recirculation lines.

Insulate the Pipes Well

Recirculation keeps all the supply pipes and the recirculation pipes warm. Therefore, insulate the pipes to the economical maximum.

In addition to reducing heat loss, insulating the pipes also reduces the pump power that is needed. This is because the recirculation flow and pump power is directly proportional to the rate of heat loss from the system. Recirculation occurs in an open loop, so the pump power is proportional to the third power of the flow rate. Therefore, if you reduce the heat loss by a factor of two, you reduce the pump power requirement by a factor of eight.

How to Control Recirculation Pumps

You can save a modest amount of energy by installing a control to turn off recirculation pumps when they are not needed. The amount of energy at stake is usually small, so the method of control must be inexpensive to be economical.

There are two situations when recirculation is not needed. One is when there is no hot water usage. The other is when hot water usage is high, so that normal usage maintains the water temperature in the pipes.

You can easily minimize pump operation under both conditions by controlling the pump with a temperature sensor located at the remote end of the hot water system. If the system has several branches, install a temperature sensor at each end, and connect the sensors in parallel, so the pump starts if any branch gets cool. This may require long wiring runs to the temperature sensors. To keep the pump from cycling too much, set a reasonable difference between the turn-on and turn-off temperatures, say 10°F.

Thermostatic control is sometimes done incorrectly by installing the thermostat in the return portion of the recirculation pipe, perhaps at the pump. Figure 3 shows an example. This method is undesirable because it senses the water temperature in the recirculation pipe, rather than the supply pipe. The pump simply cycles as the water in the return pipe cools off, rather than responding to the actual water temperature at the application.

If safety is not an issue and no hot water is ever required outside normal hours of operation, consider controlling the recirculation pump with a timeclock. Think hard before you do this. Hot water may be needed at odd hours. For example, an office building may be

WESINC

Fig. 2 Large hot water recirculation pumps required by pressure reducing valves This steam-fired water heater serves a tall office building. vacated at night by the tenants, but cleaning crews may need hot water. See [Reference Note 10](#), Clock Controls and Programmable Thermostats, for guidance in selecting timeclocks. An alternative is using your energy management computer system, which is usually more expensive and less reliable. See [Reference Note 13](#), Energy Management Control Systems, for details.

Be especially cautious if turning off recirculation pumps may create a safety hazard. If the water in the supply pipes is allowed to cool substantially, there will be an abrupt rise in water temperature as the column of

freshly heated water reaches the appliances. This can be a safety hazard in showers and in other applications where people are in contact with the water. Some appliances, including some shower valves, include thermostatic mixing valves to regulate water temperature. Do not rely on such devices if safety is an issue.

If you decide to limit operation of a recirculating pump, install a placard that explains the controls. See [Reference Note 12](#), Placards, for details of effective placard design, materials, and installation.

WESINC

Fig. 3 Wrong way to control recirculation Here, thermostats are installed on the return ends of two recirculation lines. They control the operation of the recirculation pumps. This is incorrect. The temperature at this point bears no relationship to the temperature of the water supplied to the fixtures.

ECONOMICS

SAVINGS POTENTIAL: 40 to 70 percent of recirculation pump energy, which is usually a small amount. The saving may be larger if the recirculation design is extravagant.

COST: Several hundred dollars to several thousand dollars, typically.

PAYBACK PERIOD: Several years or longer.

TRAPS & TRICKS

RECOGNIZING PROBLEMS: The first thing to check is the size of the recirculation pumps. They should be small. If they are not, check for a pressure reducing valve in the system, and try to modify the system to get rid of it. To minimize pump operation, the only correct approach is to sense the water temperature at all the end users. Calculate whether the savings justify the cost of the wiring.

LABELING: If you install a control to limit the operation of the recirculation pump, its purpose will not be obvious to future maintenance personnel. Install a placard to explain it.

MEASURE 3.3.3 Trim pump impellers to eliminate excess system pressure.

In an existing facility, the service water pumps may develop more pressure than needed. This wastes energy, so consider adjusting the pump pressure to the minimum needed for proper operation of the water-using equipment. The only effective method, in most cases, is reducing the diameter of the pump impeller.

See [Measure 10.2.1](#) for the details.

This activity is limited in potential benefit. Service water systems, especially those in tall buildings, provide less potential for impeller trimming than other types of systems. This is because the pump must produce enough pressure to overcome the gravity requirement of the tallest parts of the system. Piping friction accounts for less of the pump pressure rating, so reduced friction at lower flow rates is less able to compensate for a reduction of the pump output pressure.

RATINGS		
New Facilities	Retrofit	O&M
	C	

Unless the pump has been selected with a much higher pressure rating than needed, trimming the pump impeller risks inadequate pressure at the highest fixtures, especially when the system flow is near maximum.

■ Why Pump Throttling Won't Work Instead

Another general method of reducing pump output is throttling the pump discharge. (This is covered by [Measure 10.2.2](#).) This method would produce little benefit in service water systems. The reason is that pump discharge throttling is effective mostly near the maximum system flow rate, whereas the typical service water system operates mostly at flow rates much lower than maximum. In other words, the fixtures in the system already throttle the pump most of the time.

MEASURE 3.3.4 Install power switching that prevents unnecessary operation of spare pumps.

It is common practice to install spare pump sets for the sake of reliability. These are often installed with no controls or instructions to avoid unnecessary operation of the spare units. A simple, foolproof way to avoid unnecessary pump operation is to install power switching

that denies power to the spare pumps as long as the regular pumps are operating.

See [Measure 10.4.1](#) for the details.

Before proceeding, check the flow requirements of the system to verify that the pumps really are spare units.

See [Measure 10.1.1](#) for the details. When designing new pump installations, make the small additional effort to specify efficient motors for the pumps.

In existing facilities, be prepared to replace a failed motor with a model that has the highest practical

efficiency. In some cases, you may even want to replace a functioning motor with a more efficient model.

Before replacing a pump motor, consider whether you can reduce the power requirement by any of the other Measures in this Subsection. If so, you may be able to reduce the size of the replacement motor.

Section 4. AIR HANDLING SYSTEMS

INTRODUCTION

Most larger buildings use centralized air handling systems to provide cooling, heating, and ventilation. Air handling systems are usually the largest user of energy in buildings that use them as their primary conditioning equipment.

Typical modern air handling systems expend much of their energy consumption for overhead functions, especially air delivery and reheat, that provide no useful heating or cooling of the spaces. Much of this energy consumption can be eliminated. As usual, the opportunities are greatest when designing new buildings, but major improvements are usually possible with existing systems that are wasteful. Make this excess energy consumption a prime target of your efforts to conserve energy. Many significant improvements to air handling systems can be made at modest cost. This Section shows how to do it.

What Air Handling Systems Do

Air handling systems may perform a surprisingly large number of functions, including these:

- ***heat and/or cool space air.*** Heating and cooling may be done entirely by coils contained within the air handling system, or in combination with localized heating and cooling equipment.
- ***control the humidity of space air.*** Most systems do this by cooling the air below its dew point. Some systems remove humidity directly by using desiccants.
- ***bring in outside air to reduce the concentration of internally generated pollutants.*** Most systems mix outside air with recirculated air. Some systems use outside air entirely, and exhaust all air in the first pass.
- ***bring in outside air for cooling.*** This function is limited to times when the outside air temperature is lower than inside temperature.
- ***provide cooling by evaporation of water.*** This function is limited to hot, dry climates.

4.9 INDUCTION SYSTEMS

- ***distribute air within the spaces*** in a controlled pattern. This may be done to provide effective distribution of heated and cooled air, to provide a sensation of air movement or to avoid such a sensation, to enhance cooling by perspiration, or to reduce concentrations of air pollutants by mixing air within the building.
- ***remove air pollutants by filtering*** incoming and/or recirculated air
- ***control the interior pressure of the building with respect to the outside pressure.*** Pressure differences may be minimized, to prevent drafts at windows and to avoid difficulty in opening exterior doors. Or, a positive pressure may be maintained to avoid infiltration of outside air through the envelope.
- ***control pressure relationships between different areas in the building.*** Pressure differences may be minimized to avoid difficulty in opening interior doors. Or, pressure differences may be created to prevent contamination of one space by the air from another.

An individual air handling system typically does not perform all these functions. Some of the functions may not be needed, or they may be overlooked in the system design. Some of these functions may be accomplished in a manner that wastes energy. As a result, many air handling systems offer opportunities both for improving functional performance and for saving energy. By the same token, when you set out to improve the efficiency of existing air handling systems, keep all these functions in mind, so you do not undermine any of the system's purposes. The Measures discuss these functions where appropriate.

Types of Air Handling Systems

It is useful to consider an air handling system as consisting of three groups of components. Figure 1 shows six different arrangements of components for the first group. We will call this group the "front end" of the air handling system. This part of the air handling system recirculates air from the spaces, controls the intake of outside air and the corresponding exhaust of space air, and largely controls the pressures inside the spaces that are served by the system.

The term "front end" is not standard, because the industry does not yet recognize the separate importance of these components, and of the need to give them distinct treatment in design and installation. This blindness to the front end is responsible for much inefficiency in air handling systems. [Measure 4.2.1](#) explains the differences between the six front end arrangements shown in Figure 1. Some of these configurations are much more efficient and versatile than the others.

The components on the left in each panel of Figure 2 represent the second group of air handling system components. These extend from the coils and supply fan to the spaces. They heat, cool, and control the humidity of the air, they move the air into the spaces, and they regulate space temperature. These components determine the name that is given to the system, such as "multizone," "terminal reheat," etc.

Figure 2, which extends over several pages, shows eleven principal types of air handling systems. These include all the common types, along with several less common types that are important. Some types have the potential to be much more efficient than others. However, variations within each type, as well as the adjustment of a system's controls, can cause major changes in their energy and comfort characteristics. Therefore, a more efficient type of air handling system may waste more energy than a less efficient type if it is badly designed or adjusted.

In principle, any of the front end arrangements in Figure 1 can be combined with any of the configurations in Figure 2. In fact, you can find examples of most such combinations.

The third group of air handling system components consists of fans that draw air directly from the spaces. Most buildings have a variety of these fans, serving applications such as toilets, kitchen hoods, laboratory hoods, etc. These fans are symbolized by a single fan on the right side of each panel in Figure 2. Treat exhaust fans as an integral part of air handling systems, even though they may have no mechanical connection to the rest of the systems.

Individual exhaust fans may remove air from spaces that are served by several air handling units. Be aware of their effects whenever you design or make any changes to an air handling system.

Why Air Handling Systems Waste Energy

Large buildings have been heated for several thousand years, using both central and distributed heating methods. Heating design regressed after the collapse of the Roman Empire, and remained primitive until the nineteenth century. The major advance of that century was replacing fireplaces with steam radiators, the steam being provided from a central boiler plant.

Ventilation of buildings, primarily for cooling, remained equally primitive. Thousands of years ago, some cultures in Mesopotamia developed effective convective ventilation systems, but these were exceptional and depended on special climatic conditions. Throughout the later centuries, large buildings could become brutally hot during warm weather. Relief was provided primarily by ventilation through windows, and by using tall ceilings that allowed stratification of warmer air above the people in the spaces.

Central ventilation systems using fans were introduced late in the nineteenth century. They became common in the period between the two World Wars, largely because they allowed buildings to be constructed with large core areas having no direct access to the outside for ventilation. This made space cheaper, and reduced the cost of heating. At the same time, mechanical air conditioning started to appear, first in the form of small units designed for individual spaces, and later as large central systems.

After World War II, a doctrine of comfort became popular that stressed cooling, air flow, and control of humidity. This doctrine, combined with the rising demand to cool entire buildings, caused central ventilation systems to evolve into central air handling systems. These systems combined the functions of heating, cooling, and ventilation. They promised economy of scale by using a small number of large components to serve a large area. They also made it possible to keep the noisy heating and cooling machinery at a distance from the occupied spaces.

Centralized air handling systems influenced the shape of modern buildings strongly by making it possible to design buildings with large core areas. In buildings of all sizes and shapes, central air handling systems motivated using windows that

cannot be opened. In turn, the non-openable windows made buildings dependent on air handling systems under all conditions.

After several decades of experience, it has become apparent that air handling systems waste energy in major ways that do not occur with smaller HVAC equipment that serves only individual spaces. The main areas of air handling system energy waste are:

- ***reheat***. This is used primarily to control the temperatures of individual spaces in a system that serves spaces with a diversity of loads. Reheat also provides control of humidity.
- ***increased fan power***. Central air handling systems require long duct systems. The cost of ductwork, and the need to fit it into small spaces, forces the design toward higher fan power.
- ***inaccurate control of outside air intake***. Conditioning outside air is especially expensive. It is possible to control outside air intake accurately, but many systems lack this capability.
- ***uneven distribution of ventilation air***. Central air handling systems that combine the function of ventilation with the functions of heating and cooling cannot distribute outside air accurately to individual spaces. If the system is to provide adequate ventilation to each space, it must provide too much ventilation to most of the other spaces.
- ***inability to turn off heating, cooling, and ventilation to individual spaces***. This problem could be solved by installing a shutoff damper at each space, but hardly any systems have this feature at present.

Energy waste from reheat can be enormous, and energy waste from the other causes is substantial. The variable-air-volume (VAV) type of air handling system was developed specifically to correct the first two of these of these problems. Unfortunately, lack of sufficient analysis led to serious comfort problems in VAV systems, and crude attempts to solve the comfort problems reintroduced a large amount of energy waste.

This is where the situation presently stands. The VAV concept has become dominant in all but the smallest air handling systems, but comfort and efficiency problems remain.

In a nutshell, the efficiency and comfort problems of central air handling systems occur because the designer tries to achieve too many purposes with a single type of equipment. We will venture the prediction that the energy and comfort problems of air handling systems will not be solved until outside air ventilation is handled separately from heating and cooling. The most comfortable and efficient buildings of the future will once again separate the heating and cooling functions.

How to Use Section 4

Section 4 is organized primarily by type of air handling system. Select the appropriate Subsection from Subsections 4.3 through 4.8 that applies to each type of air handling system that you have. The Measures in each Subsection are tailored to the type of system.

The first two Subsections, 4.1 and 4.2, have Measures that apply to all types of systems. The Measures in Subsection 4.1 recommend control practices that minimize unnecessary system operation. The Measures in Subsection 4.2 recommend improvements to the “front end” of all types of air handling systems. Subsection 4.9 includes Measures specifically related to motors and motor installations, which may apply to any type of air handling system.

As a general guide, each Subsection starts with the Measures that are least expensive and most widely applicable, and progresses to Measures that are more expensive and specialized. Measures providing exceptionally large savings are moved toward the front. Technically related Measures are grouped together.

Minimizing Duration of Operation

This is the place to start in reducing the energy consumption of air handling systems. The Measures in this Subsection tailor the running of air handling systems to actual need. These Measures often provide large savings at modest cost, and they are usually easy.

MEASURE 4.1.1 Turn off air handling systems when they are not needed.

Turning off unnecessary equipment is a fundamental principle of energy conservation. The subsidiary Measures control the running of air handling systems in response to a variety of conditions. You can combine these techniques to provide great flexibility in tailoring the operation of air handling systems to the usage of the spaces they serve.

Energy Saving Potential

Turning off air handling equipment whenever possible eliminates or reduces these causes of energy waste:

- **unnecessary conditioning.** Energy delivered by an air handling system changes space temperature and humidity. If the spaces are unoccupied, temperature and humidity usually can be allowed to drift within wide limits. Also, unoccupied spaces usually do not need outside air, which requires a lot of conditioning energy.
- **reheat losses.** Several common types of air handling systems consume energy for reheat, a method of temperature control in which heat is used to cancel cooling to regulate supply air temperature. Reheat provides no useful conditioning. It ceases when the air handling unit is turned off. (Measures that reduce reheat during system operation are in [Subsections 4.4](#) through [4.8.](#))
- **unnecessary system equipment energy consumption.** Fans typically account for a significant fraction of air handling energy consumption. You can usually turn off the system fans when conditioning is not required (but not always). In some systems, you can reduce the operation of the pumps that transport hot water and chilled water from the central plant to the air handling units.

Automatic Control is More Efficient than Manual Control

Human beings are not well adapted to starting and stopping equipment at precise times. In particular, physical plant operators are likely to neglect this function because they are diverted by a variety of other responsibilities. Human control is especially unreliable if the starting and stopping times vary with changing conditions, such as weather. For these reasons, use automatic controls wherever they are practical.

Nonetheless, you may have to start and stop some air handling units manually for reasons of safety or flexibility. For situations where automatic starting and stopping of air handling equipment is not advisable, [Measures 4.1.1.5](#) and [4.1.1.6](#) recommends methods that

improve control reliability while retaining human control.

Make Conditioning Available Whenever It is Needed

Controlling the running of air handling systems is not as simple as it may appear. Air handling systems provide comfort, so occupants will seek to disable any type of control that threatens to turn off conditioning when they may want it. For this reason, automatic controls for starting and stopping air handling systems have experienced a poor rate of survival.

Controls that merely turn off conditioning systems on a fixed schedule are not satisfactory. The challenge is making the system available during irregular or unexpected periods of space usage. The first step is to inventory the conditioning requirements of each space and application that is served by the air handling system. From this inventory, design a combination of controls that keeps the air handling system running as long as any space that it serves needs conditioning.

For example, the controls should accommodate individuals who work late, they should provide conditioning for cleaning crews who may arrive long after the facility has closed, and they should provide enough conditioning for security personnel who patrol at all hours. The subsidiary Measures provide a variety of techniques to respond to these needs.

Other Ways to Deal with Irregular Space Usage

Consider reducing conditioning levels for certain activities. For example, it is reasonable to require cleaning crews, who are physically active, to be clothed to work at lower space temperatures than are normal for sedentary daytime work.

Also, consider installing a separate small conditioning system for people who must remain within the building during normally unoccupied hours. For example, provide separate conditioning for guard stations.

Limit Temperature Extremes During Off Hours

If appropriate, include control provisions to restart the air handling system any time the spaces become too cold or too warm. The most common concern is freezing, but problems may be caused by less drastic temperature changes. Install safety thermostats that are set for the low and high temperature limits. Install them in the locations where temperatures first become critical. For example, install a freeze protection thermostat in a poorly insulated part of a space that has water piping.

Coordinate with Control of Other Systems

You can use similar techniques to control the facility's boiler plant equipment (Measures 1.1.1 ff), chiller plant equipment (Measures 2.1.2 ff), and individual conditioning units (Subsection 5.1). Coordinate all these controls to reduce cost and increase opportunities for conservation.

Comparison to Temperature Setback

Temperature setback is an energy conservation technique that consists of lowering the space thermostat settings during off hours, while the air handling system

continues to operate normally. Fans and other equipment continue to operate during the setback period, so setback is less efficient than turning off the air handling system entirely. Measure 4.3.2 gives details of temperature setback.

In any type of air handling system that uses reheat for temperature control, temperature setback may not save much energy. In fact, it may increase energy cost. The only types of air handling systems in which you can install temperature setback without careful analysis are non-reheat single-zone systems, non-reheat VAV systems, and triple-duct systems.

MEASURE 4.1.1.1 Where spaces operate on regular schedules, use timeclocks to start and stop air handling equipment.

RATINGS

New Facilities	Retrofit	O&M
A	A	

Where a facility operates on a regular schedule, timeclocks are usually the best way of automatically starting and stopping equipment, at least as a starting point. Timeclocks can be combined effectively with controls that respond to other inputs, such as outdoor temperature, occupancy, etc.

Where Not to Use Time Controls

Time control does not work in facilities that operate on an irregular schedule, such as conference rooms, auditoriums, and surgical suites. Unfortunately, one often encounters vain attempts to use timeclock systems in such spaces. In these misbegotten attempts, facility managers may publish periodic activity schedules that the operating staff is supposed to follow in resetting timeclocks. The staff invariably respond by ignoring the schedules and operating the air handling systems continuously.

How to Select Time Controls

Be careful in choosing from among the large selection of time controls that are available. Each application has its own requirements for reliability, ease of use, variety in scheduling, and override control. See Reference Note 10, Clock Controls and Programmable Thermostats, for equipment features and installation practices.

Where older timeclocks that lack desirable features are presently installed, consider replacing them with newer electronic models. This can provide capabilities

such as internal power backup, multiple schedules, cycling, automatic daylight saving time conversion, optimum-start, etc.

If you have an energy management computer system, consider using it to start and stop the air handling equipment. However, large-scale control systems tend to be unreliable, and the cost of connecting each air handling system is high. Simple localized controls are less expensive, they are individually much more reliable, and they are more adaptable to local conditions. The main advantage of a centralized system is its ability to re-schedule air handling systems from a central location. See Reference Note 13, Energy Management Control Systems, for details.

After-Hours Operation

In most applications, timeclocks should include a manual override feature. The primary purpose of the override is to allow conditioning in the event that the air handling system is needed during unscheduled times. This is essential to protect the time control, as well as for comfort. If an override is not easily accessible, irate occupants or operating staff will eventually disable the time control.

Overrides are not an efficient means of adapting to unscheduled operation. Overrides typically function to keep the equipment operating until the following “off” time. For example, if an air handling unit is scheduled to turn off at 6 PM and someone restarts the unit at 8 PM, the unit will continue to operate until 6 PM of the following day. Consider this type of override to be an emergency feature rather than a routine control function.

If an air handling system is needed often outside of normal hours, control it with an interval timer, a personnel sensor, or other control method that adapts to the duration of usage. You can install any of these controls as a supplement to timeclock control. They are covered in the following subsidiary Measures.

ECONOMICS

SAVINGS POTENTIAL: 10 to 70 percent of the air handling system’s operating cost.

COST: The price of electronic timeclocks ranges from less than one hundred dollars to several hundred dollars. Installation and training may cost from several hundred dollars to several thousand dollars per unit.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Get all the appropriate features. A timeclock soon becomes junk if it is difficult to use, or if it lacks any feature needed to adapt equipment operation to people’s needs.

INSTALLATION: Install the timeclock itself so that it is obvious and accessible only to those who should set it. Install a separate override in a location where it is conspicuous to occupants of the space.

EXPLAIN IT: Time controls invite tampering. Make sure that operators know how to use them properly, and that they are kept set properly. Provide clear setting instructions at the unit, if these are not included with the timeclock itself. In any event, install a placard at the unit that describes what the timeclock controls, the schedule that should be set, and any additional controls for the same air handling system.

MONITOR PERFORMANCE: Sooner or later, all time controls fail or get out of time. Schedule periodic checks of all time controls to verify proper operation and settings.

MEASURE 4.1.1.2 Install optimum-start controllers to adapt starting times to weather conditions.

Optimum-start control is a supplemental feature of timeclocks that automatically adjusts the equipment start time in response to weather conditions.

If air handling systems are started using simple timeclocks, facility operators typically set the start time to cover the worst weather conditions that may occur. This wastes conditioning energy, and also wastes the energy required to operate fans, pumps, and other equipment.

For example, consider a building that has been shut down over a weekend during very cold weather. This is a shutdown period of about 77 hours. The air handling systems of the building may have to operate for five hours prior to occupancy to warm the building to normal temperature. The next day, the same building may require only a one-hour warm-up period because the weather becomes warmer and the building has been shut down for only about nine hours. An optimum-start controller senses the differences and adjusts the start time accordingly.

How Optimum-Start Works

The time required for a building interior to reach normal temperature after a period of shutdown depends on the building’s thermal mass and on its rate of heat loss. Thermal mass soaks up conditioning energy during the start-up interval, increasing the time required to reach normal temperature. Heat loss diverts conditioning energy from the building interior, extending the start-up interval.

Optimum-start controllers take both of these factors into account. The time required to replenish heat lost from the internal mass of the building depends on the space temperature at start-up. The controller uses an inside thermometer to sense the space temperature. The controller calculates the rate of heat loss to the outside from the difference between the outside temperature and the desired inside temperature. The controller also has an outside thermometer for this purpose.

The controller must adjust for the building’s thermal storage and heat loss properties. In less sophisticated models, this is done by manual adjustments when the controller is installed. You may have to find the optimum settings by trial-and-error over a period of months. More sophisticated units can automatically “learn” an optimized schedule from experience.

Controller Options

Optimum start is a common feature of more sophisticated electronic timeclocks. Many models

provide optimum start for both heating and cooling, although some models function only for heating.

Don’t expect to add optimum-start capability to an existing timeclock. Instead, simply replace the timeclock with a model that has optimum-start capability. Fortunately, this equipment has become inexpensive. While you are at it, select the timeclock for the other important features that are described in [Reference Note 10](#), Clock Controls and Programmable Thermostats.

Most computer energy management systems include optimum start as a programming option. However, these large computer systems are less reliable than dedicated optimum-start controllers. Furthermore, the cost of a dedicated unit typically is lower than the cost of re-programming an existing centralized computer system and connecting it to the air handling systems. See [Reference Note 13](#), Energy Management Control Systems, for more about this approach.

How to Install the Outside Air Temperature Sensor

The placement and shielding of the outside air temperature sensor are critical. Install the sensor so that:

- it is exposed to the prevailing outdoor air temperature
- the penetration through the envelope is sealed so that positive pressure inside the building cannot force inside air over the sensor
- sunlight does not heat the sensor, either directly or by heating surrounding surfaces
- precipitation cannot reach the sensor, either directly or by splashing
- it is protected from physical impact.

Use One Controller for Several Applications

Time controls that offer an optimum-start feature typically offer several channels of control, each of which can be operated on a separate schedule. For example, a single controller could provide different turn-off times for different air handling systems. It could even be used to start different types of equipment, such as boilers and chillers. Using a single controller for different equipment simplifies installation, inspection, and maintenance. Inventory all your potential applications before selecting the controller.

Relationship to Temperature Setback Control

Temperature setback is an energy conservation measure that limits the temperature drop inside the building during unoccupied hours. In turn, this limits the time required to restore normal space temperature.

Optimum-start control is more efficient than temperature setback because it turns off the system completely. It also eliminates uncertainty about restoring space temperature on time. In most cases, optimum-start control is a better alternative than temperature setback.

However, one caution is to avoid possible damage from low temperatures during the off period. See [Measure 4.1.1](#) about avoiding this danger.

ECONOMICS

SAVINGS POTENTIAL: 1 to 10 percent of the cost of operating the air handling systems, compared to using ordinary timeclocks. The greatest savings occur with long shutdown periods and severe climates.

COST: Optimum-start is a feature that is available with many electronic timeclocks that are priced from \$100

up. Labor cost depends mainly on the difficulty of making connections to the controlled equipment and the difficulty of installing the outside air temperature sensor. Installation typically costs from several hundred dollars to several thousand dollars.

The cost of connecting and programming an existing computer energy management system for optimum-start is typically several thousand dollars.

PAYBACK PERIOD: Several months to several years, the period being shorter with larger systems and more severe climates.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: If you use a timeclock for optimum start, make sure to get all the appropriate features. A timeclock soon becomes junk if it is difficult to use, or if it lacks a critical feature.

INSTALLATION: Install the control so that it is accessible only to those who should set it. Install an override that is conspicuous to occupants of the space. A certain amount of patience may be needed to optimize the settings that account for the building's thermal characteristics. Make sure that the outside air temperature sensor is installed properly.

EXPLAIN IT: The purpose of the optimum-start controller is not obvious from its appearance. Install a placard to explain what the controller does, and the schedule of operation. The unit itself should have clear instructions. See [Reference Note 12, Placards](#), for tips on designing effective placards.

MONITOR PERFORMANCE: Improper operation is easy to overlook. Schedule periodic checks of all time controls to verify proper operation and settings.

MEASURE 4.1.1.3 In spaces with irregular usage, install rundown timer switches to provide user control of air handling system operation.

RATINGS

New Facilities	Retrofit	O&M
A	B	

Rundown timers are timing devices that turn on equipment immediately, and turn it off after a set amount to time. Rundown timers are appropriate for controlling conditioning in spaces that are used on an irregular basis, such as meeting rooms and auditoriums.

To control the air handling unit, install a rundown timer in each space that may need conditioning at odd hours. Connect the timers so that a signal from any one space will start the air handling system. Figure 1 shows a typical installation.

Fig. 1 Rundown timer used to control conditioning in a library function room This is very effective for the purpose. The space has no exterior exposure, so warm-up time is minimal. However, there is no placard to tell unfamiliar users what the timer does, or how to use it. Also, the locked cover on the thermostat is a bad idea.

SUMMARY

Inexpensive and fairly foolproof. Somewhat less efficient than personnel sensors (Measure 4.1.1.4). Limited in application by inability to anticipate occupancy for warm-up or cool-down.

Advantages

Rundown timers are inexpensive. In most applications, they are the most economical method of providing user control of conditioning.

Rundown timers are easy to use. They can be understood even by people who are unfamiliar with the space, provided that the timers are properly marked. This eliminates the need for members of the physical plant staff to get involved in scheduling the air handling systems.

Installation is usually easy. Just be sure that the timer is conspicuous and accessible to users of the space.

Limitations

The main limitation of rundown timers is that they cannot provide a warm-up or cool-down period prior to occupancy. Therefore, restrict rundown timers to applications where not much of a temperature change is required prior to occupancy. Rundown timers typically work well in interior spaces that are surrounded by other conditioned spaces.

A warm-up or cool-down period is acceptable if staff personnel are always available who can be assigned responsibility for starting the air handling system prior to occupancy. For example, rundown timers installed in hotel function rooms can be started by the staff who set up the spaces.

From an efficiency standpoint, rundown timers eliminate all system operation prior to occupancy, but they may leave the system running unnecessarily after occupancy. People have a tendency to set the timer for maximum duration. They may easily forget to turn the timer off when the space is vacated. This is relatively

unimportant if the space is used only occasionally, but it becomes a more serious limitation if the space is used often.

Likely Alternative Methods

In applications where you consider rundown timers, also consider personnel sensors, which are recommended by [Measure 4.1.1.4](#), next. Both types of controls may perform satisfactorily in a given application. Rundown timers are cheaper, simpler to comprehend, easier to install, and probably more reliable. On the other hand, personnel sensors tailor the operation of the system to occupancy more efficiently.

Types of Rundown Timer Switches

The most common type of rundown timer switch is the “dial timer,” which is a spring-wound mechanical timer that is set by twisting the knob to the desired time. These are available in a wide range of maximum times, up to about 24 hours.

This type of timer switch is vulnerable to damage. The shaft is weak, and the knob is usually not attached to the shaft securely. For this reason, dial timers may not last long in a hostile environment, such as a high school. Expect to replace units occasionally. Fortunately, they are inexpensive and easy to replace.

Mechanical rundown timers make a slight noise as they operate, which can be irritating in quiet environments.

Electronic switches are available that perform the same function as mechanical rundown timers. The best of these units are much more durable than mechanical timers. Some electronic timers offer too many options, which provides the opportunity for inefficient operation. For example, most electronic units do not limit the maximum running time sufficiently. Also, they may provide an override “on” position, which will be abused. Even the simplest electronic time control will baffle some space users.

Minimize the Time Intervals

For each space, select a timer that has the shortest time interval that is appropriate for the usage of the space. For example, the timer in a public library function room should probably have a duration no longer than three hours. For the sake of efficiency, err on the side of shorter intervals. If the timer runs down, the occupants can easily reset it.

Connections to the Air Handling System

Connecting timers to the air handling system controls is usually simple. You can connect an number of timers in parallel, so that a timer in any space can start the air handling system.

Explain It!

In most applications, the rundown timers will be operated by people who are unfamiliar with the conditioning system. Therefore, success requires instructions that are conspicuous and easily understandable. Install a placard adjacent to each rundown timer that states:

- that conditioning of the space is controlled by the timer switch in order to conserve energy
- that conditioning can be provided at any time by setting the timer to the desired duration
- that the switch should be turned to “off” when the space is vacated
- whom to contact in the event of difficulty.

See [Reference Note 12](#), Placards, for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: 80 to 95 percent of unnecessary operation of the conditioning unit. The fraction of total system energy consumption that is saved varies widely, depending on the occupancy of the space and its conditioning load.

COST: Mechanical rundown timers cost about \$20 apiece. Electronic units cost less than \$50 apiece. Wiring materials and labor typically cost several hundred dollars per space.

PAYBACK PERIOD: Several months to several years.

TRAPS & TRICKS

CHOICE OF METHOD: Do not use this method for initially warming up or cooling down a space over a large temperature range. It will take too long.

SELECTING THE EQUIPMENT: The timers will be subjected to abuse in almost any type of environment. Select them for ruggedness and ease of use.

MAKE IT OBVIOUS: The most important installation feature is locating the controls where they are accessible and obvious to transient occupants, while remaining well protected. Be sure to install an effective placard along with the timer. The activity will fail otherwise.

FOLLOW UP: Schedule periodic checks of the timers. Expect to replace broken units occasionally.

MEASURE 4.1.1.4 In spaces with irregular usage, install personnel sensors to control air handling equipment.

RATINGS

New Facilities	Retrofit	O&M
A	B	

In appropriate applications, personnel sensors match the operation of air handling systems to space occupancy more accurately than any other method. The distinctive advantage of personnel sensors is that they respond directly to occupancy. They start the conditioning system as soon as anyone enters the space, and they stop conditioning as soon as everyone vacates the space.

To control the air handling unit, install a personnel sensor in each space that may need conditioning at odd hours. Connect the sensors so that a signal from any one space will start the air handling system. Figure 1 shows a typical installation.

Installing personnel sensors is not difficult, but it is tricky. You need to select the right location and orientation for each unit individually. See [Reference Note 11](#), Personnel Sensors, for details of features and installation methods.

The hardware cost of the sensors themselves has become almost trivial. The main costs are for installation labor and wiring materials.

Sensor Types to Consider

With present technology, the best types of personnel sensors for HVAC control are those using either infrared or ultrasonic detection. See [Reference Note 11](#) for details of all contemporary types of personnel sensors.

Limitations Related to Occupancy Patterns

A fundamental limitation of personnel sensors is their lack of ability to anticipate occupancy. Therefore, personnel sensors are inappropriate in applications

Fig. 1 Ultrasonic sensor used to control conditioning in a conference room This, or an infrared sensor, might be installed with a turn-on delay to avoid turning on conditioning when someone passes briefly through the space.

SUMMARY

Very efficient, fairly foolproof. Limited to spaces that do not require extended warm-up or cool-down.

where a significant amount of warm-up or cool-down period is needed prior to occupancy.

If the start time of the air handling system is predictable but the stop time is not, use a time control to start the system and a personnel sensor to stop it. For example, this combination is appropriate for a restaurant, because operations always begin at a certain time but the staff may remain for an unpredictable length of time after the place closes.

Personnel sensors may start an air handling system unnecessarily by sensing the transient presence of security personnel, cleaning crews, etc. This may not waste much energy, because the system will stop shortly after the personnel leave the space. However, if there is a lot of transient traffic, personnel sensors may be less efficient than other types of control, such as interval timers.

Tailor Each Sensor to the Space

You have to tailor the installation of each personnel sensor. The reasons are explained in [Reference Note 11](#). In a given facility, you may need as many as a half dozen different types and models of personnel sensors, and many mounting configurations. You need to plan the installation of each sensor on a space-by-space basis to achieve satisfactory performance.

By the same token, personnel sensors are vulnerable to changes in space layout. Expect such changes to occur from time to time over the life of the facility. Seemingly minor changes to space configurations may force you to relocate the sensors within the space. For example, installing partitions can shield people from the view of the sensor. If a sensor is installed on a wall, placing a coat rack near the sensor may blind it to a large part of the space.

Personnel sensors are limited in range. In large spaces, you may have to install several units in order to provide adequate coverage of the space. You can reduce the number of units by being clever about where you place them. For example, install sensors near exits or near centers of activity.

Likely Alternative Methods

In applications where you consider personnel sensors, also consider rundown timers, which are recommended by subsidiary [Measure 4.1.1.3](#). Both types of controls may perform satisfactorily in a given application. Rundown timers are cheaper, simpler to comprehend, easier to install, and probably more reliable. On the other hand, personnel sensors tailor the operation of the system to occupancy more efficiently.

Connections to the Air Handling System

Connections to the air handling system controls are simple. You can connect any number of sensors in parallel, so that any sensor will start the air handling system.

Explain It!

Even though personnel sensors are automatic, let occupants know that conditioning is being provided. For example, if the space needs a warm-up or cool-down period, occupants need to be told that the space will reach the proper temperature in a short time.

In each space where you use personnel sensor control, install a placard at an appropriate location, e.g., adjacent to the space thermostat, stating that heating and cooling of the space is started automatically as soon as people enter the space. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

ECONOMICS

SAVINGS POTENTIAL: *A well tailored control system based on personnel sensors eliminates 70 to 95 percent of unnecessary operation of the air handling system. The cost saving varies widely among applications, depending on operating schedule, conditioning load, and other factors.*

COST: *A variety of satisfactory sensors are available for less than \$100 apiece. Installation cost is the major expense. Connections to a typical air handling system may cost several hundred dollars to several thousand dollars.*

PAYBACK PERIOD: *Several months to several years.*

TRAPS & TRICKS

CHOICE OF METHOD: *Do not use this method if the space may have to be warmed up or cooled down over a large temperature range. It takes too long. For warm-up or cool-down, consider combining this method with other Measures. Do not use personnel sensors if there is frequent transient traffic through the space outside of normal hours of occupancy.*

EQUIPMENT SELECTION AND INSTALLATION: *The type of sensor needs to be tailored to the space, along with the location and orientation of the sensors. Review [Reference Note 11](#).*

PUBLIC RELATIONS: *People need to be assured that they are getting heating or cooling. Install a prominent placard in the space telling occupants that heating or cooling started automatically when they entered the space, and that the space will soon be at the proper temperature.*

MONITOR PERFORMANCE: *Schedule periodic checks of the sensor controls, along with routine checks of all the thermostatic controls.*

MEASURE 4.1.1.5 Assign responsibility for operating air handling systems to the personnel who administer the spaces.

Although automatic control is usually more reliable than manual control, there are situations in which automatic control is not practical. For example, it may not be possible to design a satisfactory automatic controls for a hotel ballroom. The problem is that the ballroom is used on an irregular schedule, and it has transient traffic going through it during the hours when it is not used. These conditions would fool any conceivable combination of automatic controls.

In many such cases, specific people are responsible for the day-to-day “hands on” administration of the spaces. For example, the surgical suites in a hospital are administered by the chief surgical nurse, the ballrooms in a hotel are supervised by the banquet manager, etc. Such personnel can be assigned the responsibility of operating the air handling systems.

This method is reliable for turning on air handling systems, because failure to do so leaves the space uncomfortable. The big challenge is getting people to turn off the systems.

Make Controls Accessible and Explain Them

The only equipment change that may be needed is installing a large “on-off” switch in an area that is readily accessible to the manager of the space. Accessibility is a key point.

Install an effective placard at the switch that states its purpose and the desired manner of operation. See [Reference Note 12](#), Placards, for details of effective placard design and installation.

COST: Minimal, if existing switches are adequate. Installing more accessible switches may cost hundreds of dollars to thousands of dollars.

PAYBACK PERIOD: Immediate, if no physical changes are needed. Several months to several years, if you have to install switches that are more user-friendly.

TRAPS & TRICKS

ADMINISTRATION AND COMMUNICATION: This is primarily a matter of effective management and leadership. The physical plant department needs to communicate effectively with the other departments that are being asked to control the equipment. Back up the request with a well written memorandum. Show the people what needs to be done. Say please and thank you.

MAKE IT EASY: Make it easy and obvious for the people who are assigned to control the systems. The procedure is less likely to be forgotten if the switch controlling the system is located out in the open. Don't expect people to go looking for the switch in a locked room that is unrelated to their usual activities. Install an effective placard at the switch that explains which equipment is controlled, and when it should be started and stopped.

FOLLOW UP: The procedure will tend to fade away. Keep it refreshed by periodic contacts with the departments responsible. Schedule this in your maintenance calendar.

MEASURE 4.1.1.6 In applications where automatic starting and stopping of air handling units is undesirable and operators are on duty, use automatic controls to alert operators to turn systems on and off.

RATINGS		
New Facilities	Retrofit	O&M
B	B	

In some applications, it is not appropriate to control the running of air handling systems automatically. For example, automatic starting may be dangerous for personnel who may be working nearby. Automatic stopping could be dangerous in critical conditioning applications, such as a surgical suite. However, relying on individual initiative is an unreliable way of conserving energy.

A compromise solution is to use automatic controls to signal to system operators when equipment should be turned on and off, rather than operating the systems directly. For example, an optimum-start timeclock can be wired to flash an indicator light or sound a buzzer when the air handling units should be turned on. Use any combination of the automatic methods recommended previously, in Measures 4.1.1.1 through 4.1.1.5, as appropriate.

This method is less expensive than connecting the automatic controls directly to the equipment itself.

Staffing Requirements

For this Measure to work, equipment operators must be on duty at the times when equipment needs to be started and stopped. The most favorable situation is one in which operators are assigned to a specific location, such as a central control station or a security desk.

Use the Same Indicator Panel for Other Plant Equipment

In applications where this Measure is appropriate for controlling air handling systems, it is likely to be appropriate for controlling boiler plant and chiller plant equipment also. See Measure 4.1.1.6 for control of boiler plant equipment and Measure 2.1.2.5 for control of chiller plant equipment.

Outside Air Intake and Building Pressurization

The Measures in this Subsection deal with outside air intake and building pressurization. Outside air is taken into the building in large quantities, primarily to maintain air quality. Conditioning this air typically accounts for a large fraction of the energy consumption of air handling systems.

The movement of air through the building determines the pressure relationships inside the building, and between the inside of the building and the outside. In some types of buildings, these pressure relationships are important for safety, and in most buildings they have significant comfort effects.

The intake of outside air is controlled by two groups of air handling system components. One group comprises the “front end” of the air handling system. Various arrangements of these components are shown in Figure 1 in the [Section 4 Introduction](#). The other group consists of exhaust fans and relief fans that draw air directly from the spaces in the building. These components are symbolized on the right side of Figure 2 in the [Section 4 Introduction](#). While the space exhaust fans may be physically separate from the rest of the air handling system, consider them an integral part of the system. In many cases, a particular exhaust fan affects the operation of several air handling systems.

Air handling system design often fails to pay adequate attention to these components. The best time to initiate these Measures is when the facility is being designed. However, they can be retrofitted to existing facilities, in many cases. Many existing systems have defects in this area.

The first three primary [Measures, 4.2.1 ff through 4.2.3](#), are concerned with avoiding unnecessary intake of outside air. At the same time, these Measures emphasize indoor air quality, a serious concern that may conflict with energy conservation. One way of

RELATED MEASURES

- [Measure 1.5.2](#), boiler room ventilation

resolving this conflict is to use air cleaning, which is recommended by [Measure 4.2.4](#).

Under some weather and building load conditions, you can reduce the cost of cooling by exploiting outside air intake in a controlled manner. This principle is applied in [Measures 4.2.5](#) through [4.2.7](#).

Exhaust air heat recovery is a major technique for reducing the energy required to condition outside air. It is covered by [Measure 4.2.8](#).

The last three [Measures, 4.2.9](#) through [4.2.11](#), correct common defects in outside air intake that waste energy and cause discomfort.

MEASURE 4.2.1 Adjust outside air intake to the minimum needed to satisfy comfort, health, and code requirements, and to maintain proper building pressurization.

Conditioning outside air usually requires more energy than conditioning air that is recirculated from within the building. For this reason, reduce outside air to the minimum that is needed to maintain acceptable air quality. (An exception occurs when outside air can be used for cooling. The air handling system should be able to exploit this opportunity when it occurs. See Measure 4.2.5 for the details.)

Ventilation is presently a controversial issue. This Measure summarizes the current knowledge on the subject, tells you which ventilation standards prevail at the present time, and discusses the weaknesses of these standards.

Building pressurization is controlled by the same components of the air handling system that control outside air intake. Building pressurization is important because it affects energy consumption, comfort, and operation of doors. In some specialized facilities, creating differential pressurization between spaces is used as a primary method of preventing contamination.

To provide adequate control of the quantity of outside air and building pressure, you may have to make improvements to some parts of your air handling systems. This Measure describes the different methods that air handling systems use to control outside air intake, and it suggests improvements that you may need to make.

There are two subsidiary Measures. The first recommends special control procedures to minimize outside air ventilation during periods of reduced occupancy or activity. The second recommends controlling the outside air ventilation rate by sensing the concentration of air pollutants in the spaces.

Energy Effects of Outside Air Intake

Bringing outside air into the building increases all these classes of energy consumption:

- **heating.** Heating energy is directly proportional to the temperature rise required. For example, consider a situation in which the space temperature is 70°F, the outside temperature is 30°F, and the supply air temperature is 90°F. In this example, recirculated air is heated only 20°F, whereas outside air is heated 60°F, requiring three times more energy.
- **sensible cooling,** which is cooling that lowers the temperature of air. Sensible cooling energy is directly proportional to the temperature reduction required. For example, consider a situation in which the space temperature is 78°F, the outside

SUMMARY

Ease of Initiation	😊	😊		

temperature is 88°F, and the supply air temperature is 68°F. In this example, recirculated air is cooled only 10°F, whereas outside is cooled 20°F, requiring twice as much energy.

- **latent cooling or dehumidification,** which is energy that is required to remove moisture from air. Latent cooling energy is proportional to the amount of moisture removed. In dry climates, little or no energy is required for latent cooling. In humid climates, latent cooling may require as much energy as sensible cooling. In contrast, recirculated air typically requires little latent cooling.
- **humidification** of outside air while heating. This is energy intensive. For example, consider outside air at 30°F and 90% relative humidity that is heated to 70°F indoor temperature. If the air is humidified to 60% relative humidity at the indoor temperature, the energy requirement is increased by 70%.
Recirculating air within the building saves some of this energy, but not all of it. This is because building air continuously loses humidity by diffusion through the building envelope. The rate of moisture loss depends on the surface area and permeability of the envelope. (Building air loses humidity rapidly if it is exposed to envelope surface temperatures that are below its dew point. See Reference Note 42, Vapor Barriers, for more about this.)
- **fan energy.** Outside air intake has only a minor effect on fan energy in most types of air handling systems.

Effects of Building Pressurization

Positive pressure inside the building increases loss of conditioned air. The extent of leakage depends on

the tightness of the building envelope. For a given amount of envelope leakage, the savings that result from reducing building pressurization depend on the degree of recirculation. In a building that uses 100% outside air, leakage through the envelope does not reduce efficiency because the air will be discharged anyhow. On the other hand, a leaky building that recirculates a large fraction of conditioned air can lose a substantial amount of air through leakage.

Negative pressure inside the building causes outside air to leak into the building. This causes discomfort during cold weather, especially to people who are located near the leaking portions of the building envelope. It also wastes energy, because occupants increase heating to compensate for the discomfort. In leaky buildings, this can be a major problem.

Reducing the building pressure increases the flow of radon from soil into the building. The extent of the

radon problem depends on the local geology, the area of soil in contact with the building interior, and the effectiveness of measures to block the flow of radon into the building.

Either positive or negative pressurization can cause difficulty in opening or closing exterior doors. Differences of pressurization between different parts of the building make it difficult to move interior doors.

If the interior temperature of the building differs from the outside temperature, the relative pressure inside the building changes with height. This is called "chimney effect." If an air handling system serves several floors, this problem is unavoidable within the zone served by the system. Vertical passages in tall buildings, such as elevators, stairwells, and pipe chases, allow chimney effect of large magnitude to develop. Air handling systems generally cannot compensate for chimney effect. (A system could be designed to do so,

How Much Outside Air is Needed?

The pendulum of opinion has swung repeatedly regarding the question of how much outside air is necessary for occupant comfort and health. When modern conditioning systems started to evolve in the mid-1800's, there was concern that isolation from the outside environment would cause health problems. This concern receded quickly when no overt problems appeared. By the time of the first energy crises in the 1970's, outside air ventilation in excess of that provided by leakage and exhaust fans was considered largely unnecessary. The pendulum swung to the other extreme again during the 1980's, when the notion of "sick building syndrome" arose. Within a short time, many assumed that inadequate ventilation was a principal cause of this phenomenon. As a result, building codes were amended to require radical increases in ventilation rates.

To approach ventilation rationally, let's review the nature of indoor air pollution. Some pollutants are controlled by outside air ventilation, and others are not. Much of the controversy over the amount of outside air ventilation results from failure to distinguish between the various pollutant sources. Table 1 summarizes the major categories of agents that cause indoor air quality problems.

■ Where Increased Outside Air is Beneficial

The table makes it clear that outside air ventilation is desirable to clear out pollutants emitted from the building structure and furnishings (e.g., formaldehyde), user equipment (e.g., ozone from copy machines and laser printers), and people (e.g., carbon dioxide and body odor).

Increased outside air ventilation can also reduce the concentration of radon, in locations where this is a problem. The radon problem is serious but regional, and occurs because of natural discharge of radon from the soil underneath a building. In locales where radon emerges from the soil at dangerous rates, the extent of penetration into the building depends mainly on the building's subsurface and ground level architecture.

■ Where Increased Outside Air is Detrimental

Increasing outside air ventilation worsens the problem of pollutants that originate outside the building. Typical outdoor pollutants include nitrogen oxides and ozone derived from vehicle exhaust, and emissions from nearby industrial processes. In many locales, it is wrong to assume that the air outside a building is cleaner than the air inside. Especially where ventilation air is taken into the building at or below street level, the quality of outside air may be much worse than the quality of interior air. In fact, many buildings in urban areas limit outside air ventilation for this reason.

■ Where the Amount of Outside Air is Not a Primary Factor

The amount of outside air ventilation is only a secondary factor with two important categories of indoor air pollutants: microorganisms and fibers that originate inside the building. Biological air contaminants, which became notorious with the first diagnosed episode of Legionnaire's Disease, are characterized as pathogens (which cause disease) or allergens (which cause allergies).

It appears that most pathogens grow in the damp insides of cooling equipment, from which they migrate to any portions of the air distribution system that offer them food (dust is nourishing for many microorganisms) and sufficient moisture. Allergens typically consist of dust, the organisms and residue of organisms that grow in dust, and pollen (from outside the building). Allergies may also be caused by a host of non-biological materials.

Fibrous and porous materials used for insulation inside air handling systems act as a collection and breeding area for microorganisms. The same is true of air filters, if they are not kept clean.

At least some types of fibers cause lung diseases. Asbestos was the first fiber to be considered dangerous, and now other types of fibers are considered dangerous. How fibers cause disease is not well understood. Some researchers suspect that the shape of the fiber is as important as its chemical composition. Fiber hazards in most buildings are associated primarily with fibrous insulation inside air handling systems, including the exposed top surface of fibrous insulation inside ceiling plenums.

The principal defense against these latter types of hazards is to keep air distribution systems clean, a condition that is virtually impossible to achieve in many existing systems. The next best thing is to avoid knocking these contaminants loose into the air stream.

■ Relationship to "Stuffiness"

Lack of sufficient outside air ventilation is often mistakenly blamed for comfort problems, especially "stuffiness." Research in this area tends to show that such complaints are more likely to be the fault of inadequate air velocity within the space or of excessively high temperature and humidity. However, opinions will continue to differ about this subject.

Ventilation Standards

So, we see that the quantity of outside air ventilation is sometimes a matter of conflicting considerations. Code requirements serve only as a crude guide. They are usually better than no guidance at all, but they fail to provide the complete picture. Following them blindly may waste energy or fail to deal adequately with air quality. Standards for ventilation have been published by ASHRAE, building code agencies, and others.

At the present time, the dominant ventilation standard in the United States is ASHRAE Standard 62-89, which states specific ventilation rates, equipment requirements, and design practices. ASHRAE Standard 62-89 is still rudimentary, and it includes a large judgemental component that is controversial. Undoubtedly, it will continue to evolve. The basic research that supports the health issues is far from complete. Energy efficiency and health seem to pull ventilation requirements in opposite directions, and the equilibrium between the two will probably continue to shift.

ASHRAE Standard 62-89 has several different ways of defining the amount of outside air that is required, including:

- **a table of ventilation rates** that states ventilation rates for particular types of activities. For some environments, such as offices, dry cleaning shops, and theaters, the ventilation rate is stated on a per-person basis. Other environments, such as stores and garages, are covered on the basis of floor area. Bedrooms, living rooms, and baths are covered on a per-room basis.
- **control based on occupancy.** The Standard allows reduction of outside air during unoccupied periods or periods of low occupancy. (The details of reducing ventilation during unoccupied periods are covered in [Measure 4.2.1.1](#), below.)
- **control based on measured contaminant level.** The Standard lists a small number of contaminants, for which maximum allowable concentrations are given. These concentrations are controversial, but at least they provide a measurable basis for regulating outside air ventilation. (Control of outside air based on contaminant level is recommended by [Measure 4.2.1.2](#), below.)
- **reduction of outside air by air cleaning.** ASHRAE Standard 62-89 allows the quantity of outside air to be reduced by air cleaning, but the Standard is vague about how to determine the reduction. (Air cleaning is recommended in [Measures 4.2.4 ff.](#))

Ideally, the ventilation rate in a building should be controlled to keep any every pollutant in the building below a concentration that is objectionable. However, this approach is far from being feasible in the most general sense. To date, maximum safe concentrations have been defined for only a limited number of specific air contaminants, such as carbon monoxide and formaldehyde. Ventilation is often done in response to contaminants, such as cigarette smoke and body odors, for which objective standards are difficult to define. Furthermore, some researchers feel that only a fraction of the pollutants that cause air quality problems have been identified.

Air for Exhaust Fans

In many cases, the outside air requirement exceeds ventilation standards because of the need to provide sufficient air flow at exhaust fans. For example, in a restaurant where the kitchen draws air from the dining area, air flow through the dining room may greatly exceed the per-person ventilation standard because a large volume of air is needed to make the kitchen hood function properly.

Check all exhaust fans that draw from the spaces served by the air handling system to ensure that their flow rates are neither too high nor too low. Exhaust fans can be elusive, so make a careful search to find them all. Review the building drawings, and also look for any additional exhaust fans that are not shown on the drawings.

Exhaust requirements tend to be inflexible. For example, it can be dangerous to throttle kitchen or laboratory hoods below their rated flow. Several techniques can reduce the energy consumption related to exhaust while maintaining adequate flow rates:

- using **unconditioned makeup air** with exhaust hoods. Hoods are commercially available that have integral outside air makeup. These units are designed to avoid discomfort by keeping the flow of makeup air away from the people working at the hoods.
- installing **separate air handling systems for areas with high exhaust requirements.** For example, in a restaurant, install separate conditioning systems for the kitchen and dining area. Air handling systems in areas with a high exhaust flow may be candidates for air heat recovery ([Measure 4.2.8](#)), which reduces the amount of energy needed to condition outside air.
- **air cleaning**, which can be used to reduce exhaust requirements in many applications, such as toilet exhaust. This technique is covered in [Measure 4.2.4](#).

System Configurations for Controlling Outside Air

Before you start making adjustments, study your system and know its limitations. Figure 1 shows the common configurations that air handling systems use for controlling the intake of outside air.

System A in Figure 1 depicts the simplest type of air handling system, which has only a supply fan. In this system, the amount of outside air is determined almost entirely by exhaust fans that draw air from the spaces that are served by the air handling unit. The amount of outside air drawn into the system is equal to the exhaust from all the exhaust fans, plus any leakage through the envelope. Outside air usually enters through a damper located ahead of the air handling unit.

In this system, there is no way to increase the amount of outside air beyond the amount that is expelled by the exhaust fans. The amount of outside air can be reduced by partially closing the outside air damper at the air handling unit. This will also reduce the amount of air available to the exhaust fans, possibly causing problems.

In System A, the building pressure cannot be adjusted independently of the outside air quantity. The pressure in the building tends to remain negative because of the suction of the exhaust fan. Closing the outside air damper makes the building pressure more negative. The negative pressure induces infiltration throughout the building. Conversely, the intensity of the negative pressure depends on the leakiness of the building envelope.

The space pressure near the air supply may become positive under some conditions. This may occur if the outside air damper is fully open, the return air ducting has significant resistance, and the exhaust fans are turned off. In this situation, the space pressure near the air supply may become positive because the supply fan is pushing against the resistance of the return air ducting.

Systems B, C, D, and E in Figure 1 can control the outside air intake rationally. The minimum intake of outside air is determined by the needs of the space exhaust fans. In systems B, C, and E, the maximum outside air is 100% of the air handling system flow. In system D, the maximum outside air is determined by the space exhaust fans and by a relief fan.

The common feature of systems B and C is an arrangement of three dampers. One damper is in the outside air intake path, another damper is in the relief air path, and the third is in the path of the recirculated air. The recirculation damper creates resistance to the returning air, forcing some of it out the relief damper. The recirculation dampers also creates an area of reduced pressure in front of the fan, causing outside air to enter the system.

The three dampers are connected by a mechanical linkage or by a common control system. The relief and outside air dampers move in unison, while the recirculation damper moves in the opposite direction. I.e., when the relief and outside air dampers close, the recirculation damper opens, and vice versa.

In System B, both outside air intake and building pressure are controlled by the relative positions of the three dampers. For example, assume that you want to increase the pressure inside the building while taking in the same amount of outside air. First, close the recirculation and the relief dampers further to restrict the return of air from the space. This also reduces the supply fan's input into the space. To compensate for this, open the outside air damper wider.

A single-fan system, such as System B, is difficult to adjust properly because of the interaction between

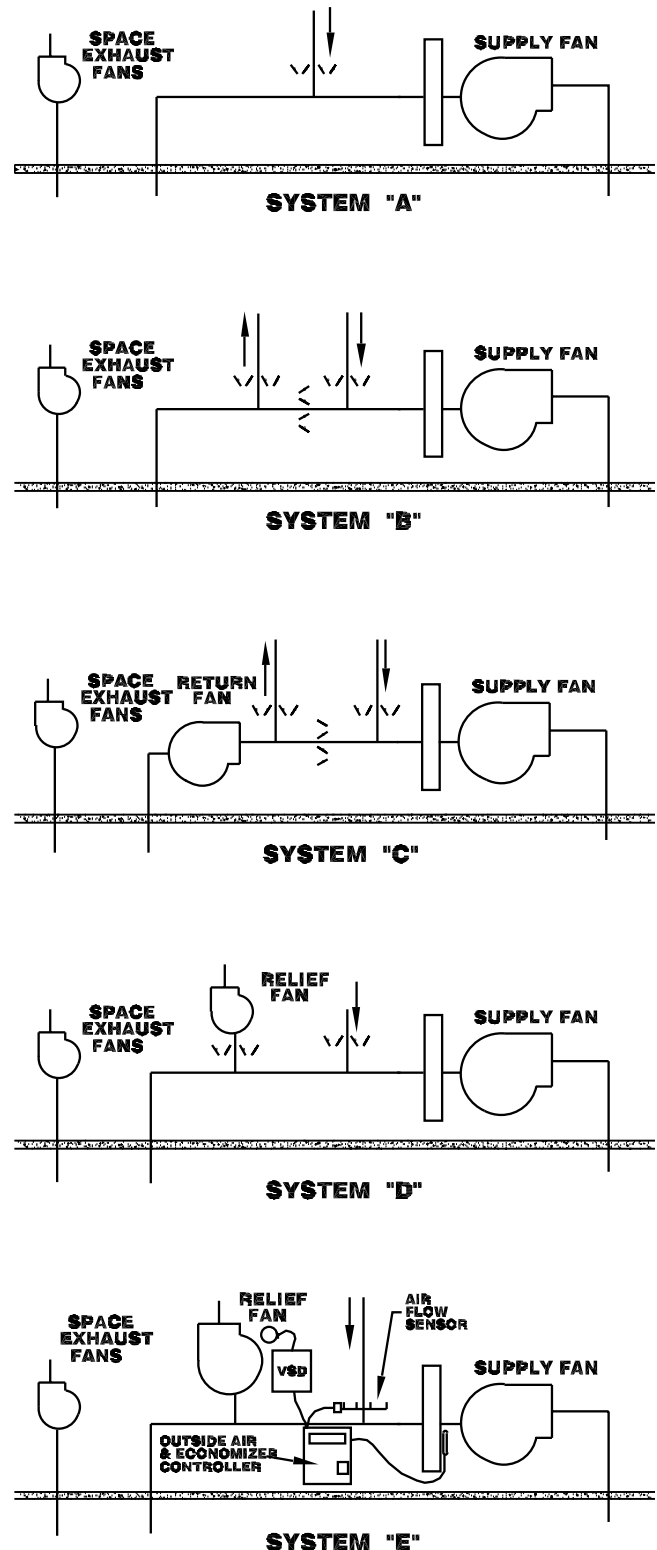

Fig. 1 Different arrangements for controlling outside air intake and space pressure All the fans and dampers are critical, including remote exhaust fans. The resistance of the return air path may also have a major influence. Some of these arrangements are much more effective than the others.

outside air quantity and building pressure. This configuration generally provides poor control of ventilation.

The distinguishing feature of System C is a return air fan. This fan is almost as large as the supply fan. Using a return fan allows the outside air flow and the building pressurization to be controlled more independently of each other. First, adjust the return fan capacity to provide the proper pressure in the spaces. Then, use the dampers to control outside air intake. If the dampers are selected and installed properly (often not the case), this system provides the most positive control of air flow and pressure.

System C is widely used in larger air handling systems, where the added cost of the return is a relatively small fraction of the total system cost. It is covered more thoroughly in [Measure 4.2.2](#).

System D in Figure 1 is a less common approach to controlling the outside air quantity. In this arrangement, a relief fan is installed in the air return. The relief fan is sized to make up the difference between the rate of outside air intake and the rate of exhaust from exhaust fans in the spaces. The fan helps to draw return air back to the air handling unit, reducing the positive pressure on the spaces. However, if there is a great deal of resistance in the return air path, this system will still produce positive pressure in the space.

In effect, System D uses an exhaust fan as an integral part of the air handling system. The primary advantage of this arrangement is that it provides accurate control of outside air intake. This is because a centrifugal fan provides more accurate regulation of relief air flow than typical dampers. If system operation never changes, no damper is needed ahead of this fan. However, a damper is needed to prevent infiltration when the air handling system is turned off.

System D does not need a recirculated air damper. At the maximum flow rate of the relief fan, the intake and relief dampers are fully open. Under this condition, no energy is wasted in moving air across the resistance of dampers.

The main disadvantage of System D is that it is inflexible. If the relief fan operates at a fixed flow rate, it cannot provide the large outside air flows needed for economizer cycle operation (see [Measure 4.2.5](#)) and for smoke clearance in the event of a fire. To accommodate these modes of operation, the relief fan would need the same maximum capacity as the supply fan (although a lower pressure differential). Also, it would have to

operate in variable-flow mode during economizer operation, and at a low fraction of its peak capacity at other times. The two dampers are poorly adapted to efficient and accurate operation over such a wide range of air flows.

System E of Figure 1 is an unusual configuration that offers advantages of efficiency combined with accurate control of outside air intake. It is now practical because of the availability of variable-speed fan drives that maintain high efficiency over a wide range of speeds. This system has no dampers, and hence it has no losses from dragging air through the resistance of dampers. It controls outside air precisely by using direct measurement of intake air flow to control the operation of a relief fan. It accommodates economizer cycle operation accurately and efficiently. It is covered more thoroughly in [Measure 4.2.2](#).

System E needs dampers in the intake and relief air path to block outside air infiltration during periods when the air handling system is not running. However, these dampers play no role in controlling air flow during normal operation.

(All the configurations shown in Figure 1 can control outside air intake by direct measurement of the intake air flow. However, the systems differ widely in their range of outside air intake, and in the way that changing the amount of outside air affects building pressure.)

If Necessary, Improve the Systems

The previous discussion shows that the air handling system layouts represented by Systems C, D, and E are the only ones that provide good control of outside air intake and building pressurization. Consider converting other configurations into one of these. This is especially important with larger systems. See [Measure 4.2.2](#), below, for details.

How to Measure Outside Air Quantity

You have to measure the outside air flow in order to set it. There are various methods that you can use.

You can easily measure the percentage of outside air with no equipment except a thermometer. Just use Formula 1.

To calculate the absolute quantity of outside air, multiply this percentage by the supply air flow rate. You can find the supply air flow rate in the building drawings. The actual supply air flow will differ somewhat from

FORMULA 1

$$\text{Percent outside air} = \frac{(\text{return air temperature}) - (\text{mixed air temperature})}{(\text{return air temperature}) - (\text{outside air temperature})} \times 100$$

the design figure because of variations in equipment and installation.

Stratification can cause an error in using Formula 1 by creating misleading temperature readings, especially in the mixed air stream. See [Measure 4.2.11](#) for details.

You can measure air flow directly by using a portable flow measuring device. This is satisfactory if you are adjusting the system on a one-time basis. Pitot tubes are moderately accurate for measuring air velocity. You can insert a pitot tube through small holes in ducts and air handlers. Irregularities in flow caused by bends and connections may seriously reduce the accuracy of the measurement. Correct for this by making a careful traverse of the duct with the pitot tube.

As an alternative, you can place a portable anemometer inside the duct. Expect some difficulty in placing the unit where it can read average air flow. Get an anemometer with a remote readout, because you cannot leave the access door open to read the unit while making measurements. In large systems, you may be able to stand inside the outside air intake. Don't let your own body interfere with the measurement.

In VAV air handling systems, and in some other systems where the flow requirement varies, the system controls need to measure air flow continuously. The control system needs to adjust the supply and return fans separately, because their air flow rates differ by the amount of outside air taken into the system. To control outside air intake most accurately, install a permanent flow measuring device to measure it directly. The system also needs a flow measuring device for either supply air flow or return air flow.

Air flow measurement devices actually measure air velocity. To calculate the actual volumetric flow, multiply the measured velocity by the cross section area of the duct at the point where the velocity is measured. Fixed flow measuring devices provide good accuracy if they are installed properly and kept clean.

How to Measure Building Pressure

You can measure building pressure by using a sensitive manometer, such as the type used to measure flue draft for boiler testing. To measure the difference in pressure between the inside and the outside of the building, you need to find a small hole in an exterior wall, door, or window. Leave the manometer on one side of the hole, and pass a probe through the hole to the other side. The main practical difficulty is finding a suitable small hole. You can't work through an open door or window, because the large opening kills most of the pressure differential in the vicinity of the manometer. If necessary, try feeding the probe through a wiring penetration.

You can easily get a rough idea of the strength of pressure differences by holding a door barely open. Doors are excellent indicators of pressure differential because they are large and balanced. If there is a pressure difference, it will tend to slam to door shut or push it farther open. For better sensitivity, disconnect the door closer.

If no exterior door is available, open a window slightly. Observe the strength of the draft by holding a lightweight piece of paper near the opening, or use a smoke pencil. This method is less satisfactory than using a door.

Measure building pressure when there is no wind. The velocity pressure of a moderate wind is as strong as a typical building pressure differential caused by air handling system adjustment.

If the air handling system serves spaces that differ in height by several floors, chimney effect can have a significant effect on the pressure measurements. Chimney effect is proportional to the temperature difference between the inside of the building and the outside. It may be very strong in a tall building on a cold day. It vanishes when the outside temperature equals the inside temperature.

Monitor the Dampers

The system's dampers are the Achilles heel of effective flow control. Many buildings were built with dampers that were junk when they were new. Even the best dampers allow a substantial amount of leakage because they have extensive mating surfaces. Damper leakage gets worse with time. Blades bend, seals wear out or fall off, and linkages work loose.

Furthermore, maintenance personnel are inclined to tamper with air flow settings in response to comfort complaints, and for other reasons. It is common to find outside air dampers blocked fully closed or fully open, with the damper linkages disconnected.

Improper ventilation air settings can persist indefinitely because they have no visible effect, other than increased energy bills. For these reasons, treat dampers as equipment that needs continual maintenance.

ECONOMICS

SAVINGS POTENTIAL: *May be a large fraction of the cost of heating and cooling energy. The savings are greatest in climates that have extremes of temperature or humidity.*

COST: *Small, in cases where only adjustments are required. The cost of air handling system modifications to allow precise regulation of air intake is covered in [Measure 4.2.2](#).*

PAYBACK PERIOD: *Less than one year.*

TRAPS & TRICKS

DECISIONS, DECISIONS: *Adjusting the percentage of outside air has become a lot more complicated than it used to be. Nowadays, you have to be familiar with legal requirements, you have to study many conflicting opinions, you have to examine evidence of air quality problems, and you have to avoid fooling yourself. In the end, the amount of outside air is a judgement call that you must make.*

ADJUSTMENT PROCEDURES: *Adjusting air flow seems to mystify a lot of people. There is no reason for this. Use common sense, understand the principles, and have good instruments. Be prepared for the possibility that your air handling systems may be so poorly designed that it cannot regulate air flow properly. In this case, you need to make hardware improvements, as recommended by [Measure 4.2.2](#). Be wary of dealing with “air balancing” services. This trade has gained a*

bad reputation for preaching hokum and faking work. At least the first time, adjust the outside air quantity yourself. It will be educational.

TRAINING AND COMMUNICATION: *Once you have figured out how to deal with outside air, train the operating staff. This will make them part of the solution, rather than part of the problem. Explain the air handling systems in the plant operating manual, and provide a list of the correct settings.*

MONITORING: *Because of air quality concerns and the high cost of conditioning outside air, outside air ventilation deserves continuing attention. Repeat air flow measurements and check the integrity of the system dampers and controls at scheduled intervals. Be alert to indications of air quality problems, but don't get hysterical. “sick building syndrome” is like many contemporary concerns. It probably exists, but it probably is not as common as generally believed. Keep yourself informed as this issue evolves.*

MEASURE 4.2.1.1 During periods of reduced occupancy, control outside air dampers and exhaust fans to reduce the quantity of ventilation air appropriately.

RATINGS

New Facilities	Retrofit	O&M
A	A	

Measure 4.2.1 provided guidelines for adjusting the outside air ventilation rate. When the facility is not operating, it may not need any ventilation, or it may need ventilation at a reduced rate. Control the air handling system to reduce outside air intake and building exhaust to match the requirements. Make sure that each air handling system has the appropriate controls to adapt ventilation to the area it serves. This includes controlling all those exhaust fans on the roof. See Figure 1.

Consider each of the following situations. Along with checking the controls, make sure that the dampers are capable of limiting the air flow to the required amount. See Measure 4.2.1 for details.

■ **When No After-Hours Ventilation is Needed**

The controls of most air handling systems are designed to close their dampers when the fans stop. This is important because the duct system still acts as an infiltration path. The fans themselves offer little resistance to air flow when they are idle, so the only positive obstacles to infiltration are the system dampers. Make sure that the dampers are controlled to close when the fans stop.

Also, take a good look at the dampers themselves, and repair them as necessary. See Figure 2. If the dampers are not designed to close tightly, consider improving them as recommended by Measure 4.2.2. Make sure that damper linkages are connected and adjusted properly. Figure 3 shows a common problem.

■ **When After-Hours Ventilation is Determined by Exhaust Fans**

After hours, the need for outside air may be determined by the need to keep some exhaust fans running, even though these fans are not explicitly part of the air handling system. For example, in a college chemistry building, the daytime ventilation rate is dictated by the occupancy of the classrooms, but night ventilation may be needed to feed the laboratory fume hoods at a reduced flow rate. Under these circumstances, the air handling unit may be turned off, unless it is needed to maintain space temperature.

Whether the air handling unit fans are running or not, the dampers should be set so that they do not force

WESINC

Fig. 2 These dampers need to be replaced They were too flimsy in the first place, a bad bargain.

air into the system. The controls should close the recirculation and relief dampers. The outside air damper should be opened completely or partially.

Provide controls to limit the running of all exhaust fans, such as toilet exhaust fans and kitchen hood fans, unless they must operate continuously. Provide separate controls for exhaust fans that operate on independent schedules.

Exhaust fans should be equipped with individual dampers. Make sure that dampers are installed, and that they close reliably when the fans turn off.

If any exhaust fans must continue operating, try to satisfy their air requirements with unconditioned air. For example, hoods are available with outside air connections directly to the perimeter of the hood.

■ When After-Hours Ventilation is Determined by People

A building may never be completely unoccupied. Typically, cleaning crews and security personnel are present during unoccupied hours. If people remain in the area served by the air handling system, then ventilation is subject to requirements that are given in ASHRAE Standard 62-89 or other relevant standards. See [Measure 4.2.1](#) for details.

The important point is that it may be satisfactory to reduce the ventilation rate during this time period. For

example, if the ventilation standard is expressed on a per-person basis, then provide ventilation for the number of people who are actually in the building.

If the ventilation rate is determined by the presence of people, then install controls that can sense when people are actually present. For example, you might install a personnel sensor (see [Measure 4.1.1.4](#)) to control the operation of the air handling system. A personnel sensor cannot tell how many people are present, so make a reasonable assumption in setting the ventilation rate.

Ventilation may be provided for after-hours occupancy by operating one or more exhausts fans, without running the air handling system fans. For example, operating the toilet exhaust fan may provide adequate ventilation for after-hours purposes.

On the other hand, it may be necessary to operate the air handling unit to maintain space temperature. In this case, the ventilation rate may be determined either by the air handling system dampers or by the exhaust fans. Select the method that most closely tailors the ventilation rate to the after-hours occupancy.

Don't Overlook Any Dampers or Exhaust Fans

Inventory all the ways that outside air is brought into the building. There may be several dampers that connect the air handling system to the outside. Most air handling systems have an outside air intake damper. Many larger air handling systems also have a relief damper at the air handling unit or nearby. Some air handling systems have air relief dampers located remotely in the building envelope, with no duct connections to the rest of the air handling system. Such remote relief dampers are easy to overlook.

(A note about terminology. "Relief air" is air that is discharged by an air handling system to make room for an equal quantity of outside air. Relief air carries away pollutants from the entire area served by the air handling system. "Exhaust air" is used to clear out pollutants that originate from a more localized source, such as a kitchen hood or a toilet. The distinction between the terms is not observed rigorously.)

In existing buildings, exhaust fans can be elusive. There are typically many of them, and not all of them may be shown on the original construction drawings. Make a careful search of the entire building envelope to find them all. If the building is large, it helps to use a camera in making your survey.

Provide Multiple Ventilation Rates as Needed

Ventilation requirements may vary in stages. For example, full ventilation may be required during weekdays, a lesser rate may be required during evenings and weekends, and no ventilation may be required after midnight. The system controls should accommodate

WESINC

Fig. 3 Common damper problem For some reason, damper manufacturers have not yet figured out how to keep a simple rod connected reliably. Therefore, you have to keep checking.

these changing requirements as closely as possible. This requires multiple stages of control.

The controls must have a way of “knowing” when to switch from one ventilation rate to another. If the ventilation rate is determined by time or occupancy, use one or more of the control methods recommended by [Measures 4.1.1 ff.](#) The ultimate refinement is varying the ventilation rate continuously as pollutant levels change. This approach is recommended by [Measure 4.2.1.2](#), next.

Anticipate the Beginning and End of Occupancy

The mass of air in a building dilutes contaminants, so it makes sense to cease outside air ventilation some time prior to the end of occupancy. By the same token, start ventilation prior to the beginning of occupancy to clear out accumulated contaminants. ASHRAE Standard 62-89 specifies permissible lead times for starting and stopping ventilation. These times are specified in terms of the air volume of spaces.

ECONOMICS

SAVINGS POTENTIAL: Typically, all or a large fraction of the energy used to condition outside air during unoccupied periods.

COST: Varies widely, depending on what needs to be done. Simple adjustments are cheap. Damper repairs, or even replacement, usually do not cost much in relation to the cost of conditioning energy. Adding control capabilities may cost thousands of dollars.

PAYBACK PERIOD: Less than one year, to several years.

TRAPS & TRICKS

DESIGN DETAILS: Design the air handling system controls to accommodate each mode of ventilation that may be needed. Consider all exhaust fans to be an integral part of the air handling system. Be sure to coordinate damper positions with the operation of exhaust fans.

EXPLAIN IT: Describe the after-hours ventilation controls in the plant operating manual. Install explanatory placards on fans and dampers that operate on special schedules. Inform the operating staff how the system is supposed to operate, even though the controls are automatic. This way, they will not try to start fans that are supposed to be off, or vice versa.

MONITORING: Fan and damper operation is vulnerable to tampering and control failure. Improper operation is not obvious, so schedule periodic checks.

MEASURE 4.2.1.2 Control outside air intake by sensing air contaminants.

RATINGS

New Facilities	Retrofit	O&M
C	C	

Measure 4.2.1 explained why it is important to minimize the outside air ventilation rate. An emerging method of doing this is to regulate ventilation air by sensing the concentration of specific contaminants within the spaces. In principle, this is the most efficient method of regulating ventilation, because it goes directly to the purpose of ventilation.

Identifying the Critical Pollutants

This method of controlling outside air is valid only if you can identify all the pollutants that determine the needed ventilation rate. For example, in an industrial operation where the dominant hazard is known to be formaldehyde, control ventilation on the basis of the formaldehyde concentration.

ASHRAE Standard 62-89 gives maximum allowable concentrations for a short list of contaminants. Government regulations and reference books on industrial hygiene give recommended maximum exposures for a much broader range of air contaminants.

This method is already popular for controlling the operation of garage exhaust fans, such as those in Figure 1. This method of control senses the carbon monoxide concentration in the air, because carbon monoxide is the primary concern in garages.

In buildings with clean environments that are intended primarily for human occupancy, such as office buildings and theaters, you may be able to control ventilation based on the carbon dioxide concentration in the air. Carbon dioxide is the main product of human respiration (along with water vapor), so its concentration can be used to indicate the density of people in the spaces

SUMMARY

In principle, the most efficient method of controlling ventilation. Still limited by the types of pollutants that can be sensed. Unproven, except in a few specialized applications. Requires sensor maintenance.

served by an air handling system. Carbon dioxide sensor systems for controlling ventilation are becoming available in the HVAC trade.

Control of ventilation by contaminant monitoring is not satisfactory in applications where there are non-specific air quality problems, commonly called “sick building syndrome.” This is because the causes of indoor air quality problems have not yet been adequately defined. Many substances found in air are suspected of causing discomfort and health problems, but few of these suspicions have been confirmed. Even where certain substances or classes of substances (such as “volatile organic compounds”) have been identified as likely culprits, rational concentration thresholds have not been established for them.

WESINC

Fig. 1 An application for control by carbon monoxide sensors These fans ventilate a garage. Similar technology that controls on the basis of carbon dioxide can be used to control ventilation in benign occupied spaces.

Design is Unconventional

Even if you can identify all the critical pollutants, you still have to find sensors for these pollutants that are suitable for control purposes. Sensors are available for many individual chemicals, for groups of substances, and for particulates in general. You may have a variety of choices. However, control of ventilation based on contaminant concentration is still a new concept in conventional air conditioning applications. For this reason, you may have to adapt sensors that presently are designed for non-HVAC industrial or research applications. This crosses the boundaries of established disciplines, so expect this to be a challenge.

Sensor Maintenance

Sensor systems for airborne contaminants require skilled maintenance and periodic calibration. Such equipment does not have an established track record in control of indoor air pollutants. You will have to develop an effective maintenance program from experience. You can expect satisfactory operation in the long term only in a disciplined maintenance environment where control of air quality is a concern of management.

The main exceptions are carbon monoxide and carbon dioxide. Newer types of sensors have been developed for these gases that require little maintenance or calibration, or none at all. Lack of maintenance is the major failure of unconventional systems, so be sure to select sensors that need a minimum of maintenance.

Get a Code Variance, If Necessary

Most codes that specify outside air ventilation are based on tables of ventilation rates for particular types of activities, as explained in [Measure 4.2.1](#). In jurisdictions that specify ventilation rates in this manner, request a variance from the code that allows you to control ventilation based on pollutant level.

Cost Components

The sensor systems themselves typically cost several thousand dollars. Installation costs vary widely, depending on the ease of interfacing the controls to the existing air handling system. After identifying the best type of sensor, try to find a model that provides standard

output signals for interfacing with your HVAC controls. Except in systems that are packaged specifically for ventilation control, design fees will comprise a major fraction of the installation cost.

Sensors for most pollutants, other than carbon monoxide and carbon dioxide, require continuing expenditure for maintenance and calibration. You also have to keep a stock of supplies, such as test chemicals or calibration gases.

ECONOMICS

SAVINGS POTENTIAL: 30 to 70 percent of the cost of conditioning outside air.

COST: Simple sensor systems that control ventilation on the basis of carbon monoxide or carbon dioxide content cost several thousand dollars. Custom controls that sense other pollutants would cost many times more.

PAYBACK PERIOD: Several years or longer, probably.

TRAPS & TRICKS

CHOICE OF METHOD: You will be a pioneer if you control by sensing anything other than carbon monoxide or carbon dioxide. Experimental and unusual equipment tends to be abandoned in operational environments, so don't do this unless your facility has a maintenance staff that is technically oriented.

PREPARATION: Expect to study the subject. Have the time and resources available for experimentation and working out details. Before getting started, verify that your method will satisfy local code requirements.

CHOICE OF EQUIPMENT: As always, try to use standard equipment, and check its reputation with other users. You will be entering a whole new world if you try to adapt pollutant and chemical sensing equipment that is not designed for HVAC control.

MAINTAIN IT: Sensor maintenance is the Achilles heel of this control method. The effort is small, but critical. Include sensor tests and maintenance in your maintenance calendar. To minimize the risk of tampering or improper operation, include a clear description in the plant operating manual. Install a placard at the sensor that identifies and explains it.

MEASURE 4.2.2 Provide accurate control of outside air intake and building pressurization by adding a return fan or relief fans and improving the damper configuration.

Poor design of the “front end” of many existing air handling systems prevents accurate control of outside air intake and building pressurization. The result is either waste of energy from taking in too much air, or health hazards and discomfort from taking in too little air. Lack of accurate control of outside air intake and air exhaust can also result in building pressurization problems. These issues are covered in [Measure 4.2.1](#).

The usual defects in “front end” design are the lack of a return air fan and ineffective damper arrangements. This Measure corrects these problems.

There are two approaches. The more satisfactory one is to improve the “front end” of the air handling system. The objective is to achieve either configuration “C” or configuration “E,” as shown in Figure 1 of [Measure 4.2.1](#). This is the approach to use in all new construction, and in retrofit wherever practical.

In retrofit, if neither of the previous approaches is practical, an alternative is to add relief fans in the spaces that are served by the existing air handling system.

The Best Fan and Damper Configurations

Figure 1 of [Measure 4.2.1](#) shows two front end configurations for air handling systems that provide good control of outside air intake along with good control of building pressure. These are systems “C” and “E.” The industry does not have standard names for these configurations, so we will call them systems C and E in this Measure.

System C has been used for a long time, and it has been well proven by experience. However, it is often installed with poor damper arrangements that void much of its benefit.

System E is an unusual configuration that offers advantages of efficiency combined with accurate control of outside air intake. It is now practical because of the availability of variable-speed fan drives that maintain high efficiency over a wide range of speeds. System E is novel. Therefore, you are pioneering if you use it. It deserves your attention because it avoids all the problems of control dampers, including their energy waste.

■ System “C” Front End Configuration

System “C,” in Figure 1 of [Measure 4.2.1](#), has become fairly standard in larger installations because it provides the best control of outside air intake and building pressurization. This configuration can induce outside air in any quantity, from a minimum that is determined by the space exhaust fans, up to 100% of system flow. It maintains fairly good regulation of

outside air quantity in the face of external forces, such as wind, opening exterior doors, etc. The main elements are three dampers and two fans. The three dampers are:

- an *outside air intake damper*
- a *relief damper*, which is needed to get rid of air in excess of the amount removed from the spaces by exhaust fans
- a *recirculation damper*, which creates resistance to the returning air, forcing some of it out the relief damper. The recirculation damper also creates an area of low pressure in front of the fan, which draws outside air into the system.

The three dampers are connected by a mechanical linkage or by a common control system. The relief and outside air dampers move in unison while the recirculation damper moves in the opposite direction. I.e., when the relief and outside air dampers close, the recirculation damper opens, and vice versa.

The return fan stabilizes the control provided by the dampers. The amount of air flowing through each of the three dampers is determined by the pressure difference across each damper. Using a return fan isolates the dampers from any pressure changes originating within the spaces. Such changes might be caused by opening doors and windows, or by turning exhaust fans on and off. Without a return fan, such changes could strongly affect the amount of air returning from the spaces, and hence, the amount of outside air intake.

The return fan also neutralizes the tendency of the supply fan to create excessive pressure inside the building. The return fan compensates for the resistance

of the return air path, which includes the recirculation and relief dampers. If only a supply fan is used, the pressure of the supply fan backs up against the resistance of the return air path to create a positive pressure within the building. As explained in [Measure 4.2.1](#), this wastes conditioned air through leakage, and may cause difficulty in door operation.

This combination of three dampers and two fans works well with any kind of air handling system: single-zone, multizone, dual duct, etc.

The main weakness of System C is its reliance on variable dampers (“control dampers”) to regulate air flow. These regulate air flow by creating resistance. Moving air across this resistance wastes energy.

Dampers also provide poor accuracy of control if the air flow varies over a wide range, especially near minimum flow. In many damper installations, the dampers are not capable of accurately maintaining the minimum air flow. Also, control dampers are so leaky in the closed position that they allow a considerable amount of infiltration into the building. These weaknesses can be overcome by careful damper selection, and by using combinations of dampers, as discussed below. However, you have to do much better than current conventional practice.

■ System “E” Front End Configuration

System E controls outside air intake entirely by changing the speed of a relief fan. It has no control dampers. For this reason, it avoids the energy waste caused by dragging air through the resistance of dampers. Air flow is controlled by fan output, which is based on measurement of actual air flow. Therefore, the control of air flow is accurate under all conditions.

System E does need shutoff dampers in the intake and relief air path to block outside air infiltration during periods when the air handling system is not running. However, these dampers play no role in controlling air flow during normal operation. To exploit this advantage, use low-leakage dampers to block infiltration, as discussed below.

System E has one important disadvantage, compared to System C. Because System E does not have a return air fan installed in the return air duct, it cannot compensate for the resistance of the return air path. As a result, the air pressure inside the spaces served by the air handling system is always positive. If the resistance of the return air path is high, the positive pressure may also be high.

To understand this, start with the fact that the pressure inside the air handling system is zero (equal to outside air pressure) at the outside air intake. It remains approximately zero at the inlet to the relief fan. Therefore, to return air from the space, the pressure in the space must be equal to the flow resistance of the return air path. For example, if the return air path has a resistance of 0.2 inches of water, then the pressure inside

the space (near the air return point) must also be approximately 0.2 inches of water.

Where to Use These Configurations

These front end configurations involve additional costs for the return fan, the dampers, connecting ductwork, and simple controls. In variable-air-volume (VAV) systems, an air flow measuring control system is needed for proper control.

In retrofit applications, another obstacle is the extra space required to properly install the return fan and the dampers. If this space is not available, you may be able to install space relief fans, as discussed below, instead of a return fan.

This Measure is not appropriate if the amount of air exhausted from the spaces by exhaust fans always exceeds the amount of outside air needed for ventilation. This situation exists commonly in facilities with large exhaust fans. For example, a restaurant may draw air through the customer area to be exhausted through the kitchen hood.

For example, consider a system in which the supply fan provides 100,000 CFM and the exhaust fans in the spaces remove 20,000 CFM. Only 80,000 CFM returns to the supply fan from the spaces, so 20,000 CFM of outside air is drawn into the supply fan inlet. If the outside air ventilation requirement is 20,000 CFM or less, there is no need for dampers to force air into the system. In this example, it is impossible to reduce the outside air flow to less than the exhaust flow.

Even if high exhaust flow makes the dampers unnecessary, it may still be desirable to install a return fan to keep the pressure in the spaces from being too high. However, the energy saving benefit would be minor, in most cases.

Design and Installation Issues

Despite the popularity of System C, it is commonly designed and installed with mistakes that cause poor performance. System E is novel, so it involves even more opportunity for mistakes. Work out the following issues.

■ Match Return or Relief Fan Capacity to Ventilation Requirements

The capacity of the return fan or the relief fan is selected to equal the capacity of the supply fan, minus the amount of air removed from the spaces by exhaust fans. For example, if the supply fan provides 100,000 CFM and the spaces have a number of exhaust fans totalling 15,000 CFM in capacity, then the return fan should have a capacity of 85,000 CFM.

If the supply fan has variable output, the return fan must also have variable output. In VAV systems, control the return fan to follow the supply fan. Also, if exhaust fans are turned on or off while the air handling system

is operating, the control system should adjust output of the return fan accordingly. Installing variable-flow fans is covered in the later Subsections that deal with the individual types of air handling systems.

■ Select Dampers for Low Leakage When Closed

Make sure the controls shut off outside air ventilation during periods when ventilation is not required. (See [Measure 4.2.1.1](#) for details of this control function.) The outside air and relief dampers are the hardware involved. Unfortunately, the cheaper type of opposed-blade dampers leak about 5 to 10 percent of their maximum flow, for a given pressure across the damper. Figure 1 shows this weakness dramatically. But this is not the whole story. If the air handling system continues to operate while the outside air and relief dampers are closed, increased pressure differential across the dampers increases their leakage.

For example, consider an air handling system designed to deliver 100,000 CFM to the spaces, with 20,000 CFM of outside air. With these requirements, the return fan is designed for only 80,000 CFM. There is low pressure in the damper area because the supply fan is trying to draw more air than the return fan provides. With ordinary dampers, the amount of leakage could be from 5,000 CFM to 10,000 CFM. The actual amount of leakage depends on the size and design of the dampers, their condition, and the fan characteristics.

There are two basic steps in minimizing damper leakage: (1) install dampers that are designed for low leakage, and (2) make the dampers as small as possible.

There is a large range of leakiness in conventional dampers. The damper industry in the United States has established a rating system for damper leakage. The best dampers for common applications have a “Class 1” leakage rating. This means that the damper has a leakage of less than 4 CFM per square foot at a test pressure of one inch of water gauge. Use dampers having a rating of Class 1 or better for blocking outside air infiltration.

Damper leakage tends to get much worse with age, especially with cheaper dampers. To minimize long-term deterioration of the damper’s sealing ability, spend the money to get these features (which are not inherently part of the Class 1 rating):

- a frame that is well reinforced to resist deformation
- extruded airfoil blades, which are very rigid and are shaped to improve air flow
- non-round blade shafts, and blades that are formed tightly to the shafts, to keep the blades in alignment
- good shaft bearings that do not bind or become sloppy with age
- strong linkages between blades, and between blades and actuators
- blade edge seals that are mechanically locked in place (not glued or clipped on)
- a method of easily replacing blade edge seals.

Good low-leakage dampers are significantly more expensive than the junk that is commonly installed, but the price premium is minimal in comparison with the energy savings.

Air leakage through a closed damper is proportional to its surface area, or more precisely, to the total length of blade edges. Conventional opposed-blade control dampers tend to be leaky because of the large ratio of blade edge length to surface area. Therefore, make intake and relief dampers as small as possible, subject to admitting the rated amount of ventilation air when the dampers are open. With typical outside air intake percentages, this area is small. The intake and relief dampers typically should be smaller than the cross section area of the return duct.

An important exception to the last statement is systems using an economizer cycle. (See [Measure 4.2.5](#) for an explanation of economizer cycles.) In these systems, both the intake and exhaust dampers must be large enough to pass the entire system air flow. This aspect of economizer operation is discussed below.

Special low-leakage dampers have been designed that block almost all air leakage. Figure 2 shows an installation. Unfortunately, most low-leakage dampers cannot modulate air flow effectively over a wide range. One solution is to use a combination of damper sizes, as in Figure 2. Another is to install a combination of damper types. One type is selected strictly to provide positive shutoff of outside air, and the other type, which is installed in series, modulates the air flow.

■ Select Dampers for Accurate Control of Outside Air

Conventional opposed-blade dampers are crude in their control of air flow. They fail to provide reliable control accuracy at both ends of their range of motion, and they are non-linear in the middle range of travel. For a given damper position, a small change in the pressure differential across the damper has a large effect on flow.

If you decide to install System C, the basic solution is to keep the outside air intake damper as small as possible, so that the damper will operate in the portion of its operating range where it can provide accurate control. This is the same solution suggested above for minimizing leakage when the damper is closed.

Trouble arises when the amount of outside air varies over a large range. This occurs with economizer cycle operation, and perhaps in other applications. In such cases, the outside air and relief dampers must be so large that they cannot provide accurate control at low flow rates. Solutions are offered below.

■ Control by Flow Measurement and Feedback

For the reasons given previously, damper position is not an accurate indication of the amount of outside air being drawn into the building, especially in systems that have changing outside air requirements, variable

exhaust fan requirements, and economizer cycles. To control outside air with any degree of accuracy, both System C and System E need controls that measure the actual air flow.

In System C, if the fans operate at fixed speeds, the dampers can be controlled with a single air flow measurement device located in the outside air intake. This simple arrangement can compensate for changes

Blender Products, Inc.

Fig. 1 Large damper array An installation like this cannot control low air flow rates reliably, and it cannot prevent major infiltration when the facility does not need outside air. Note the large unit heaters, probably installed for freeze protection. Such a high-energy alternative to good dampers is a very bad bargain.

in exhaust fan operation and changes in building pressure. Flow measurement and control become more complex if the supply and return fans have variable output, or if accurate control of building pressurization is an issue. In these cases, the system requires several flow measuring stations.

In System E, the speed of the relief fan is controlled with a single air flow measurement device located in the outside air intake. The flow measuring station responds to controls that determine the need for outside air. These might be a timeclock, an economizer cycle thermostatic control, etc. The output of the supply fan may be constant, or it may be controlled independently of the relief fan.

One of the advantages of System E, compared to System C, is that control of the relief fan's output is entirely independent of control of the supply fan's output.

■ Avoid Stratification

Eliminating stratification is a major aspect of good front end design. It is a challenge to mix the air streams in the damper section of an air handling system as damper positions and fan speeds change over a wide range. See [Measure 4.2.11](#) for details.

■ Access to Equipment

Provide easy access to all equipment that may need maintenance or adjustment. This includes access to fans, motors, fan drives, dampers, actuators, thermostats, flow measurement devices, and other control components.

Economizer Cycle Operation

Economizer cycles are covered in detail by [Measure 4.2.5](#). In brief, an economizer cycle is an energy conservation measure in which a large volume of outside air is taken into the building for cooling during cool weather. For the economizer cycle to function properly,

M&I Heat Transfer Products

Fig. 2 Low-leakage dampers These can seal almost hermetically, and they retain their tightness over the long term. They have the minimum possible edge length in relation to their area. However, they cannot modulate air flow over a wide range. To deal with this limitation, the array combines a variety of damper sizes. For example, this array can operate efficiently with both minimum outside air requirements and with an economizer cycle.

the air handling system must be able to take in outside air in quantities ranging from zero to 100% of system air flow.

Air infiltration during system shutdown is a common problem of economizer cycles, because a conventional damper large enough to handle 100% outside air may leak badly when it is fully closed. Also, the large outside air and relief dampers have poor control at low outside air intake rates, when the economizer cycle is not in use.

An unconventional solution is to use two sets of dampers. A large set of modulating dampers is used for economizer operation. When the economizer cycle is not in use, these large dampers are isolated by a special airtight damper. Ventilation air is then controlled by an appropriately sized smaller damper.

Flow measurement may be a problem with economizer cycles because most flow measurement devices are not accurate over a wide range of flows. One solution is to size the flow measurement devices to control outside air intake during non-economizer operation. During economizer operation, control the quantity of outside air with a thermostat that senses space temperature (in the case of single-zone systems) or supply air temperature (in the case of other types of systems).

Alternative: Space Relief Fans

An alternative to installing a return fan is installing one or more relief air fans that draw directly from the conditioned spaces. The fans draw an amount of air from the spaces equal to the amount of outside ventilation air desired for the spaces, minus any amount required by exhaust fans (for toilets, hoods, etc.). Relief fans should be controlled by the air handling system's controls in the same way as a return fan.

Relief fans may be the only choice in buildings where you cannot install a return fan and a full complement of dampers. They can also be used in buildings that lack a return air duct system. Relief fans have these disadvantages:

- **more expensive to modulate air flow.** Each relief fan serving a space with variable ventilation requirements requires dampers or a variable-flow drive.
- **more expensive control and wiring.** In a system that uses flow sensors, each relief fan requires a flow sensor. The distance of the relief fans from the supply and return fans increases wiring cost.
- **usually impractical to accommodate economizer cycle operation.** For an economizer cycle to work in a system that uses relief fans, the fans would have to be much larger than otherwise, and they would need the ability to modulate their output.

- **usually impractical to accommodate exhaust air heat recovery.** An exhaust air heat recovery system would need a connection to each relief fan.

The design and installation precautions in a relief fan system are generally the same as those discussed previously for a return fan system.

Coordinate with Other "Front End" Measures

This Measure involves the same part of the air handling system as the other Measures of this Subsection. To avoid wasting money and opportunity, decide which of the Measures is appropriate for each air handling system, and accomplish all of them together.

ECONOMICS

SAVINGS POTENTIAL: *Conditioning outside air typically accounts for a major fraction of heating and cooling cost. This Measure may reduce the cost of ventilation by 20% to 70%, compared to installations that control ventilation poorly.*

COST: *It is much cheaper to provide effective control of outside air in new construction than in retrofit. In either case, the cost varies widely, depending on the building and system configuration. For example, an array of tight-closing dampers costs about \$500 to \$1000 per square meter, for the equipment.*

PAYBACK PERIOD: *Usually short, in new construction. One year to many years, in retrofit.*

TRAPS & TRICKS

DESIGN: *The reason that so many air handling systems fail to control ventilation properly is lack of attention to detail in the design. The layout may be simple on paper, but the actual physical arrangement of the fans and dampers is critical. Use some imagination here. The method of damper and fan speed control is also important.*

SELECTING THE EQUIPMENT: *Good equipment is available, but you have to find it among the junk, and pay the higher price. It doesn't cost much extra.*

INSTALLATION: *Work with the contractor. Don't expect him to work out the design details. His job is sheetmetal, not engineering. Don't let the contractor substitute cheaper equipment.*

MONITOR PERFORMANCE: *The front end of an air handling system contains moving machinery that must be maintained. Damper linkages come loose and controls get out of calibration. Blades warp, and blade seals wear out. Tampering occurs in response to comfort complaints, to save energy, to avoid coil freezing, or for other reasons. Schedule periodic checks of the damper section, including air flow measurements.*

MEASURE 4.2.3 Where once-through air handling systems are installed unnecessarily, modify them to provide recirculation.

Once-through air handling systems are required in applications where recirculation of air is hazardous or undesirable, as in kitchens, surgical suites, and medical laboratories. However, once-through systems are sometimes found in applications where they are not needed. Conditioning outside air requires a lot of energy, so failing to recirculate air when it is possible to do so is a major waste. Examine each non-recirculating air handling system to decide whether it can exploit air recirculation for at least part of the time.

Air handling systems that could use recirculation may lack it for a variety of reasons. Sometimes, an air return is omitted to reduce installation cost. Recirculation is commonly omitted in spaces that require a high outside air ventilation rate at certain times, but not at other times. For example, 100%-outside-air systems are common in gymnasiums and locker rooms, even though they are unoccupied, or have minimal occupancy, most of the time. Sometimes, a space that originally required 100% outside air was changed to a function that does not require it.

This modification involves two main additions. One is a return air path from the conditioned spaces back to the air handling unit. The other is a set of dampers, and perhaps an additional fan, to regulate the intake of outside air.

Providing the Air Return Path

You can add an air return path in a variety of ways. The choice is governed by a variety of considerations, including fire safety, noise isolation, isolation from lighting heat gain, avoiding air quality problems, limitations in the space available to install ducts, isolation from perimeter infiltration, isolation from other air handling systems, and cost. Consider these possibilities:

- **ducted returns.** These are the most foolproof because they isolate the air handling system from external factors. They are also the most expensive. If you cannot find a way to install a return air duct inside the building, consider installing it outside the building, e.g., on the roof. Pay special attention to sealing and insulating external ducts.
- **plenum return.** This is satisfactory in many applications. Problems may arise if other air handling systems use the same plenum space as a return, or if the plenum space is in contact with a larger exterior surface. Making holes in partitions to create a plenum return increases the transfer of noise across the partitions. Also, the holes are a path for fire and smoke, although this problem can be limited with fire dampers. Plenum return picks

up the heat of light fixtures laid in suspended ceilings. Whether this makes a difference in the conditioning load, compared to ducted returns, depends on the layout of the building.

- **corridor air return.** This method is inexpensive, and it is used in many older buildings. It is least desirable from a fire safety standpoint because the air handling system circulates smoke through the corridors in the event of a fire. For this reason, corridor returns are now prohibited in many jurisdictions. If you want to use a corridor return, you have to install grilles of adequate size in the doors or walls of all the spaces that are served by the system, unless these spaces are permanently open to the corridor.
- **return through a void space** is sometimes possible. Be careful to avoid air quality problems. Expect problems if the space contains moisture, bare soil, animal residue, or dust that is light enough to be picked up by the air stream.

Design and Installation of the Outside Air Intake

The challenging part of the modification is designing the system to provide good control of outside air intake. See [Measure 4.2.2](#) about these aspects.

Satisfying Ventilation Code Requirements

Refer to [Measure 4.2.1](#) for ventilation requirements. If the original once-through air handling system results from a ventilation code requirement, providing air return may require a variance from the code. The designer is likely to get a variance if he can demonstrate that the system is capable of tailoring ventilation to requirements. Note that ASHRAE Standard 62-89, the basic ventilation standard for many jurisdictions, provides for reducing ventilation during periods of reduced occupancy.

Coordinate with Other “Front End” Measures

This Measure involves a major addition to the air handling system. When planning it, review the other Measures of this Subsection to see whether you can save money or effort by accomplishing any of them at the same time.

ECONOMICS

SAVINGS POTENTIAL: Possibly a large fraction of the total heating and cooling cost of the air handling system.

COST: Modifying a system to provide rational recirculation is much cheaper, and more satisfactory, in new construction than in retrofit. In either case, the cost varies widely, depending on the building and system configuration.

PAYBACK PERIOD: A few years, or less, in new construction. Longer, in retrofit.

TRAPS & TRICKS

CHOICE OF METHOD: Moving air through a building is subject to a variety of factors, including structural, fire safety, noise, conflict with other systems, etc. Take the broad view and consider all your options.

OPERATION AND MAINTENANCE: The result of this Measure is a conventional recirculating air handling system. See [Measure 4.2.1](#) about efficient adjustment and operation of the system.

MEASURE 4.2.4 Use air cleaning to reduce the need for outside air ventilation.

RATINGS

New Facilities	Retrofit	O&M
C	D	E

You may be able to save a lot of energy by cleaning and recirculating the indoor air, rather than replacing it with outside air. A variety of air cleaning methods are available. Individually or in combination, they have the capability of removing most types of indoor air pollutants.

Filtration to improve air quality is widely used in applications that are critical to health, such as surgical suites. Other air cleaning methods are less common. The idea here is to expand the application of air cleaning to take advantage of its energy saving potential. Most of the methods require specialized equipment and maintenance. Therefore, they tend to be limited to facilities with more sophisticated maintenance staffs.

(The ordinary filters used in air handling units do little to improve air quality for occupants. These filters, which are called “low efficiency” filters, serve mainly to protect the coils from becoming clogged. They trap mainly fibers and large particles. They cannot trap more than a small fraction of the dust, pollen, microorganisms, and gases that exist in building air.)

Energy Saving Potential

[Measure 4.2.1](#) estimates the amount of energy that you can save by reducing outside air quantity. The ventilation rates specified by guidelines such as ASHRAE Standard 62-89 depend on the usage and

conditions of the facility. By improving air quality conditions in the occupied spaces, you may be able to reduce the ventilation rates that are required.

■ Fan Power Penalty

Most air cleaning equipment adds considerable resistance to air flow. Additional fan power is needed to overcome this resistance. The additional fan energy substantially reduces the potential saving in conditioning energy, perhaps severely enough to make air cleaning uneconomical.

■ An Example

Consider an air handling system that has a flow rate of 100,000 CFM. Without air cleaning, 30,000 CFM of outside air is needed. With air cleaning, outside air can be reduced to 10,000 CFM.

Outside air is heated by an average of 30 degrees Fahrenheit for a duration of 3,000 hours per year. Air cleaning results in a saving in air heating of 1,950 million BTU per year. Air heating energy costs \$5 per million BTU, resulting in a heating cost saving of \$9,750 per year.

The filtering medium creates an additional air flow resistance of 2" of water gauge, which is imposed on the entire air flow of the air handling system. Fan power is approximately 0.25 horsepower per thousand CFM per inch of water gauge resistance. Thus, the total system fan power is increased by 50 horsepower, and the fans operate for a duration of 5,000 hours per year. At an electricity cost of \$0.05 per kilowatt-hour, the additional fan power costs \$9,320 per year.

Thus, in this example, the saving in air heating energy is almost entirely cancelled by the cost of the additional fan power. In addition, the cost of the air cleaning equipment must be paid off. In this example, the cost of the air cleaning equipment might range from \$6,000 to \$100,000, depending on the equipment selected.

Available Methods of Air Cleaning

Each type of air treatment technique is effective only for certain classes of pollutants. Therefore, identify all the pollutants that need to be controlled. The current state of research and testing does not allow this to be done with complete certainty. Many substances found in air are suspected of causing discomfort and health problems. Many of these are lumped into broad categories, such as "volatile organic compounds."

In existing facilities, only a small fraction of identified pollutants will be a problem. To identify which, start by analyzing occupant complaints, or noting their absence. If occupant complaints suggest the presence of a specific pollutant, get an expert to check for it. The expert should check for noxious sources within the spaces and within the air handling systems. Test for chemical or biological pollutants, or both, depending on the nature of the symptoms.

In principle, any kind of air pollutant could be removed by some process. A practical criterion is that air cleaning should be less expensive than increasing outside air ventilation, while being reasonably reliable and free of serious disadvantages. For example, it is too expensive to remove carbon dioxide by chemical treatment in typical HVAC applications, even though this is done routinely aboard submarines.

The following discussion covers the application and limits of available air cleaning methods. These methods

are presently used in HVAC applications, or they may become appropriate for HVAC applications within the foreseeable future. You may need to combine several pollutant removal techniques in your application.

■ HEPA Filters

HEPA filters are passive filters that pass essentially no particulate matter. (HEPA stands for "high efficiency particulate air.") They are used routinely in applications, such as surgery and microelectronics manufacture, which require removal of all biological and inorganic matter from the air. HEPA filtration is necessary to remove particulate matter below 10 micrometers (microns) in size. Particles of this size are particularly dangerous because they are retained in the lungs. Also, HEPA filtration is necessary to remove the small particles that are most responsible for soiling and dirt streaks.

The designation "HEPA" implies a specific filtering efficiency. There are filters that provide even higher filtering efficiency ("ultra" filtration), but these are unnecessary for dealing with ordinary particles. On the other hand, some purposes of this Measure can be served by filters that are less efficient than HEPA filters, such as "medium efficiency" filters. To keep the discussion simple, we will use the term "HEPA" for filters that clean air effectively enough to allow you to reduce outside air ventilation.

HEPA filters work by an entirely different principle than low-efficiency filters. The passages in HEPA filters are much smaller than those in conventional filters, but they are still much larger than the microscopic particles that they capture. Particles are trapped because they are attracted to the filter material by the localized electric charges on their surfaces.

(Conventional low-efficiency filters work by virtue of having passages that are smaller than the air flow passages in the coils they are designed to protect. Large particles straddle the fibers of filter material and are unable to pass through, while smaller particles pass through both the filter and coil. The principle of action is purely mechanical.)

The efficiency of a HEPA filter remains essentially constant throughout its service life. Photographs taken through the microscope show that the small particles collected by the filter grow into tree-like structures on the filter material, somewhat as a crystal grows. The electric charge on the surface of the dirt particles attract other particles, so that the captured particles in effect become part of the filter medium.

HEPA filters may perform satisfactorily for several years or longer, provided that they are isolated from large particles by prefilters. The open area of the filter is vast compared to the size of the tiny particles that the filters are designed to capture, so resistance to air flow increases only very slowly.

HEPA filters have virtually no ability to remove contaminants that are in the gaseous state. The electrons of gas molecules are too closely bound to serve as “hooks” to attach the molecules to the filter. Thus, HEPA filters are not effective against such major classes of indoor air pollutants as carbon monoxide, partially burned hydrocarbons, and the increasingly notorious class of “volatile organic compounds.”

The resistance of HEPA filters to air flow may total several inches of water column or more. Therefore, adding HEPA filters may double or triple the fan load. This major increase in energy consumption seriously offsets the energy saving derived from reducing the intake of outside air.

While HEPA filters themselves do not require frequent replacement, they do require prefilters. The prefilters are similar to conventional coil protection filters. They must be changed or cleaned at regular intervals.

■ Adsorbents

Adsorption is a process of capturing atoms, molecules, or particles on a surface. The basic mechanism is one of electrical attraction. The electron distribution on the surfaces of particles and large molecules can distort easily, forming clumps of charge that induce “image charges” of opposite polarity on the surface of the adsorbent material. Attraction between the opposite charges causes the molecule or particle to stick.

Adsorbents require a vast surface area at the molecular level, which is achieved by using materials of extreme porosity, such as carbon, alumina, and silica gel that have been processed (“activated”) to make them porous. The most common adsorbent is activated carbon. This material is often called “activated charcoal” because it is commonly made by partial combustion of coconut shells and other woody material.

The effectiveness of adsorbents in trapping smaller molecules varies widely. If the pollutant molecule has ionic bonds, i.e., if it has charges bulging out, it will stick to an adsorbent surface by electrical attraction. On the other hand, if a small molecule is formed by covalent bonds, it may easily pass through the filter.

Adsorbents have the advantage that they tend to trap all molecules and particles above a certain size, which corresponds to a molecular weight greater than about 80. Thus, adsorbents trap most incompletely burned hydrocarbons, and they trap many of the molecules included in the general class of “volatile organic compounds.”

Fortunately, activated carbon is effective in trapping ozone, which has become a major indoor air pollutant. Ozone is generated in copiers and laser printers, and to a lesser extent in the high voltage circuits of computer monitors and in cigarette smoke. Activated carbon not

only traps ozone, but induces its chemical breakdown into ordinary oxygen. Activated carbon also traps radon.

A disadvantage of adsorption is that it is reversible, except where the trapped material (notably ozone) is chemically changed. When pollutants accumulate on the surface of the adsorber, they are less tightly bound. At the molecular level, they may escape the surface because of thermal agitation or impact from other molecules. At a visible level, the pollutants may be knocked loose by vibration or impact. Therefore, you need to replace adsorbent filters periodically. The interval depends on the concentration of contaminants in the air.

In order for adsorbent filters to be effective, they must be thick enough so that the air passes through a substantial amount of the filter medium. As a result, adsorbents have high resistance to air flow. Effective activated carbon filters have a flow resistance of several inches of water column. (The thin layer of carbon used in cheap carbon filters is not fully effective and does not last long.)

Because of their porous structure, adsorbents also capture particles by mechanical trapping. Adsorbents stop all particles that are bigger than the passages in the adsorbent. For this reason, adsorbents need prefilters to keep them from becoming clogged.

Adsorbent filters are often combined with HEPA filters. This is an effective combination because the two remove different types of pollutants, and because both require supplemental fan power and prefilters.

■ Chemical Treatment

Air cleaning by chemical treatment converts pollutants to harmless substances, or converts them to a form that can be trapped permanently. Chemical treatment has the advantage of being irreversible, unlike adsorption. A disadvantage is that chemical methods are specific to certain pollutants or classes of pollutants.

In principle, any chemically active pollutant material can be rendered benign by attacking it with an appropriate chemical reaction. However, there are too many pollutants to tailor a chemical antidote to each one. Instead, the most common approach is to use strong oxidizers against pollutants. Oxidizers used in air cleaning include potassium permanganate, potassium hydroxide, and sodium hydroxide. This approach assumes that the oxidation products of pollutants are harmless, or that they are trapped in the filter medium.

To be practical, a chemical treatment process should be inexpensive and it should not create a large amount of resistance to air flow. Mixing air and chemicals in a water spray is one method that satisfies these criteria, but it is messy and hence it is disliked by operating personnel.

An alternative is dry chemical treatment. One of the leading dry systems uses potassium permanganate,

a strong oxidizing agent, contained in beads of activated alumina. Air is forced through a bed of these beads.

The effectiveness of chemical air cleaning depends on a number of factors that should be considered in selecting the equipment. These include:

- **temperature.** All chemical reactions are dependent on temperature, so install the chemical medium in a part of the system where the air temperature is appropriate to the chemicals being used.
- **contact effectiveness.** The effectiveness of pollutant removal varies radically with the length of time that the pollutant remains in the vicinity of the chemical medium. This can be done by making the filter larger in surface area or by making it thicker. The former reduces fan power, and the latter increases it. So, favor the approach of making the filter larger. Contact effectiveness also depends on the characteristics of the chemical bed. For example, in chemical processes that use media in the form of beads, the diameter of the beads is a major factor.
- **humidity.** Some dry treatment media, such as potassium permanganate, require a certain amount of moisture in the air. Normal humidity is usually sufficient, but it is conceivable that effectiveness could suffer in dry climates.

■ Electrostatic Filters

Electrostatic filters work by ionizing contaminant particles and then using electrostatic attraction to pull them out of the air stream. The process works with any kind of particle, although some types and sizes of particles are removed more effectively than others.

An electrostatic filter operates in two stages. At the upstream end of the unit, high electric fields are created by applying a positive potential of several thousand volts to electrodes located in the air stream. The strong positive field pulls electrons off air molecules and off small particles that pass close to the electrodes, giving them a positive charge. The charged particles are called "ions." Other particles in the air stream collect these ions and become charged also. The charged particles then pass between positive and negative (grounded) plates. The positively charged particles are attracted to the negative plates, where they stick. Adhesion of the particles may be enhanced by treating the surface of the plates with oils or adhesives. This type of device is often called a "precipitator."

"Ionizers" are less expensive electrostatic devices that ionize the particulates in air, but do not collect them on metal plates. Instead, the particles are allowed to collect on any nearby surface. The charged particle induces an opposite charge in the surface, so the two stick. In some designs, the charged particles are collected on filter media downstream of the electrode wires.

Electrostatic filters can create a serious problem of their own, namely, ozone. Ozone is a molecule consisting of three oxygen atoms, in contrast with normal atmospheric oxygen, which is a molecule consisting of two oxygen atoms. Ozone is an extremely strong oxidizer because it wants to get rid of the third oxygen atom. Ozone harms biological tissues and many other materials.

An electrostatic precipitator does not generate much ozone if it is functioning properly and if it is perfectly clean. A clean unit does not create electric fields strong enough to break down atmospheric oxygen to single atoms, which is the first stage in the formation of ozone. However, as the unit operates, fine dust fibers collect on the electrodes. These act as lightning rods, creating localized electric fields that are strong enough to generate ozone.

The rate of ozone generation rises rapidly as dust collects on the electrodes. This makes it important to keep electrostatic filters clean. Similarly, an apparently minor defect, such as a nicked electrode or a loose strand of wire, can create an area of high field strength in which ozone will form. Electrostatic filters should have effective prefilters to block the dust that causes ozone formation.

Fortunately, activated carbon is effective in neutralizing ozone, so a carbon filter may be installed downstream of the precipitator. The added resistance of the carbon filter increases the fan power requirement.

Dirt also reduces the filtering efficiency of an electrostatic filter, which is another reason why these units need regular maintenance. The maintenance consists of periodic cleaning of the electrodes and collecting plates. Maintenance is a major pitfall of electrostatic units, with the result that many are found abandoned. To ease maintenance, acquire electrostatic filters that have integral, automatic cleaning systems. These typically consist of detergent spray washers. Oil may be added to the plates as part of the cleaning process. The prefilters must be cleaned or replaced periodically.

Electrostatic filters require low air velocities, typically below one meter per second (200 feet per minute), to allow particles time to be trapped. Therefore, the unit must be large in cross section. By the same token, the air flow resistance of electrostatic filters is low. The prefilters serve to distribute air uniformly through the electrostatic unit. Prefilters are typically large in area, matching the size of the electrostatic filter, so they add only a modest amount of air resistance.

Electrostatic filters need energy to operate. They typically consume 20 to 40 watts for each 1,000 CFM of rated capacity.

■ Ultraviolet Radiation

Ultraviolet radiation is a method of killing microorganisms. It may prove to be increasingly important in air handling systems. In principle, ultraviolet radiation alone cannot reduce the outside air requirement, because biological contamination in an air handling system is not directly related to the rate of outside air ventilation. However, if a system is contaminated, a high rate of outside air ventilation may reduce the problem. By eliminating the growth of biological contamination, an ultraviolet system may make it possible to reduce outside air ventilation to a minimum level that is determined by other factors, such as the carbon dioxide level.

Ultraviolet radiation is a form of light that lies beyond the short wavelength end of the visible spectrum. The photons of ultraviolet light have enough energy to break the weak bonds that hold biological molecules together. Therefore, ultraviolet light will eventually kill any organism that it can penetrate. For example, bacteria and fungi are vulnerable. Larger microorganisms, such as amoebas, are not susceptible to ultraviolet at the levels of exposure that present equipment can produce.

The ultraviolet used for sterilizing applications lies in the “C” band of the ultraviolet spectrum, which is far from the visible spectrum. This radiation is produced by special lamps that are similar to fluorescent lamps, but without the phosphors. The lamps require special tubes to pass the radiation, which is absorbed by ordinary lamp glass.

(For those who are interested, the primary source of “C” band radiation in ultraviolet lamps is the 254-nanometer emission line of mercury. This is also the primary source of light in fluorescent lamps, before the phosphors convert it to visible light.)

Some ultraviolet lamps can operate in standard fluorescent fixtures. If the fixture needs a cover to protect the tube from moisture, dirt, or cold, the cover material must be made of a special material that is transparent to the ultraviolet radiation. As a practical matter, the output of present ultraviolet lamps is so weak that they should be installed bare wherever possible.

Extravagant claims of effectiveness have been made by advocates of ultraviolet sterilizing, including medical researchers. Nonetheless, ultraviolet has not yet been proven in HVAC applications. Research still needs to be conducted regarding the intensities and exposure times required, the appropriate wavelengths to be used, how different organisms respond, the best methods of installation, and other questions.

There are two separate problems in killing microorganisms. One is killing organisms that enter from outside the system, such as tuberculosis bacilli. The other is killing microorganisms that grow inside the system itself, or preventing them from growing.

A major limitation in both cases is the weak radiation output of the lamps. The killing ability of an ultraviolet lamp depends on the exposure time. In an air handling system, organisms in the air are carried past the lamp rapidly. For this reason, attention is being given to

Pure Water / Clean Air Group

Fig. 1 Ultraviolet air cleaner This unit is designed to recirculate the air within a space. Note the large array of tubes that is required. A similar type of unit could be installed in areas of air handling systems where growth of microorganisms may occur.

increasing the output of the lamps. To kill transient organisms, you have to set up arrays of lamps in such a way that an organism anywhere in the air stream is exposed to the ultraviolet radiation for a sufficiently long time. Figure 1 shows a commercial ultraviolet air filtering unit that is used to recirculate air within a small space.

It is becoming increasingly clear that cooling coils, their drain pans, and related hardware, are the primary site for the growth of microorganisms within air handling systems. The organisms, which may be of many types, grow in the water that condenses from the cold surfaces of the cooling equipment. The primary solution to this problem is to locate the ultraviolet lamps where they can irradiate the wet areas continuously.

Irradiation is hampered by several factors. One is that the radiation is effectively line-of-sight, at least at the low intensities presently available. Therefore, organisms may continue to grow inside crevices of equipment. C-band ultraviolet radiation typically reflects from surfaces much less than visible light. This is especially true of rough surfaces, such as duct liner. It reflects moderately well from aluminum, and less well from stainless steel. Another limitation is that C-band ultraviolet does not penetrate deeply into water.

Ultraviolet air treatment may prove to be inexpensive, easy to install, noiseless, and undemanding of space. In contrast to other methods, it does not increase the power requirement or noise of the fans.

Do not install ultraviolet sources where people may be exposed to them. Moderate exposure to ultraviolet light causes eye inflammation. Extended exposure can cause cataracts, skin cancer, and other damage to exposed tissue. Ultraviolet radiation is energetic enough to break weak chemical bonds, so it harms all organic materials, such as wood, fabrics, and paper. The metal casing of an air handling system is immune to ultraviolet damage and it isolates the radiation completely, so it appears to be an ideal installation site.

■ Unproven Air Cleaning Methods

Various other types of air cleaning have been used, such as water baths, but none of these have gained the attention of building designers. Cleaning space air is likely to be a rapidly evolving field because of the intensity of concern about indoor air quality. When selecting an air treatment method, study the current status of developments. As in other aspects of energy conservation, be wary of any technology that is not well proven in installations similar to yours.

Trapping of Pollutants by Normal System Operation

Some air pollutants are reduced significantly just by passing through the air handling system. Contaminants such as cigarette smoke are trapped by sticking to the interior surfaces of the entire system. Highly reactive chemical pollutants, such as ozone,

combine with the first thing they touch, so they tend to disappear in traveling through a long air distribution system. Large particulates settle out throughout the system. A look inside the ducts of a typical air handling system is enough to make you try to stop breathing, but this confirms that contaminants are trapped there.

Once pollutants settle out inside the air handling system, they tend to stay there. However, they are jarred loose by mechanical impact or vibration, causing a short burst of intense contamination in the space. This can be a potential health hazard.

Cooling coil surfaces that are wetted by condensation trap particulate material, such as pollen, that is too small to be removed efficiently by conventional filters. (This is unrelated to the growth of microorganisms in stagnant cooling coil condensate.)

The drying of the air that occurs during heating operation kills some microorganisms. On the other hand, alternating wetting and drying may hasten the growth of some microorganisms.

Ventilation standards make no allowance for removal of pollutants by normal system operation.

Where to Install Air Cleaning Equipment

You can install most types of air cleaners anywhere in the supply air stream that is convenient. You can install them in the air handling unit, in the ducts, or within the spaces themselves. The choice depends primarily on whether the air cleaner is supposed to serve all the spaces connected to the air handling system, or only certain areas. If you want to clean the air to all the spaces, it is usually least expensive to install a single filtration unit at the air handling unit. This approach also simplifies noise attenuation and maintenance.

On the other hand, if only a fraction of the space served by the air handling system requires special air treatment, it is usually more economical to install equipment only to serve that space. As we have seen, most types of air cleaners substantially increase fan power requirements. Therefore, try to avoid installing air cleaning equipment where it imposes an added fan power requirement on spaces that do not need air cleaning.

In most cases, the best way to compensate for the added resistance of the air cleaner is to install a supplemental fan at the unit, if the unit does not have its own fan. Otherwise, it would be necessary to increase the pressure of the air handling unit fan. This would increase duct leakage and might require heavier ductwork.

A disadvantage of integral fans is that they are closer to the occupants. The large dissipation of energy across the filter creates noise. Design the air cleaner to minimize the noise that enters the space.

Packaged in-space filtration units are available that recirculate the air within a space. All the types

mentioned above, except wet processes, are available in in-space versions and even in portable versions. An advantage of localized units is that they can be turned on and off to conform to the occupancy of the space, minimizing fan energy consumption.

If a pollution source is localized, installing an air cleaner at the source is more efficient than letting the pollutants disperse before capturing them. Install the air cleaner as close to the pollution source as practical, and between the pollution source and the air return. If appropriate, install a hood or flexible duct to collect the emissions before they disperse into the space. (If the pollutant source is localized and intense, such as welding, exhausting the source to the outside is more economical than air cleaning.)

Another advantage of localized units is that you can control them individually. Control their operation automatically with a pollutant sensor in the space, as recommended by [Measure 4.2.1.2](#), or with one of the control methods recommended by [Measures 4.2.1 ff](#).

Increasing the Pressure of Air Handling System Fans

If you depend on the air handling system fans to overcome the resistance of the air cleaning equipment, expect to increase the pressure of the fans considerably. This will radically increase the pressure requirement of the fans. In retrofit applications, you may not be able to increase the pressure of the existing fans enough to do the job.

Ordinary coil protection filters add a resistance of 0.1 inch to 0.5 inch of water column, depending on air velocity, filter size, and the state of cleanliness of the filter. In comparison, HEPA and adsorbent filters offer much greater resistance to air flow, up to about 10 inches of water column in combination units.

In retrofits, you can usually increase fan pressure by increasing the fan speed. However, the potential increase is limited. Fan impellers have maximum rated speeds, and noise output rises rapidly with speed. Even a small increase in pressure may require a larger fan motor. As a result, you may have to replace the fan impeller or the entire fan assembly.

If a backward-inclined fan is presently installed, you can get a large increase in pressure at the same fan speed by substituting a forward-curved fan. However, the latter type is somewhat less efficient, and it is inherently noisier (for a given speed).

The air cleaning device will absorb some of the additional noise, but only in the direction of the device. Also, the noise level will increase in the space surrounding the air handling unit. Unless the air handling system was very quiet originally, you will probably have to redesign the air handling system to keep fan noise within acceptable limits.

Hazard to Occupants if Air Treatment Fails

Failure of the air treatment equipment will expose occupants to the pollutants that the equipment is supposed to remove. Consider the severity of this hazard in deciding whether to use air treatment as a substitute for higher ventilation rates.

The danger posed by an equipment failure depends on the nature of the pollutant and the rate at which its concentration builds up. With some pollutants, a brief increase in exposure is not harmful. For example, the U.S. Environmental Protection Agency specifies a long-term limit for sulfur oxides of 0.03 parts per million, but a short-term (24-hour) exposure limit of 0.14 parts per million. With other pollutants, even short-term exposure must be avoided.

In any environment where special air treatment is required, the application is serious enough to merit careful monitoring. The method of monitoring depends on the nature of the air cleaning methods. For example, mechanical filters can be monitored by sensing the pressure drop across them. On the other hand, adsorbent filters may become saturated with pollutants without exhibiting a marked rise in resistance. Monitor adsorbent filters on the basis of duration of usage, or by other means.

Where health is an issue, install alarms to indicate failure of the air cleaning equipment. In critical applications, make the alarms self-testing.

Alternatives to Air Cleaning

There are several ways to improve air quality, in addition to air cleaning. One is to minimize the generation of indoor pollutants. The most notable success of this type has been eliminating cigarette smoke from many environments. Increased attention is being given to reducing the hazard of pollutants emitted by structural materials and furnishings, especially when these are new. More needs to be done. It is becoming clear that chemicals brought into the building by people, such as cleaning materials and cosmetics, are significant pollutants. Unfortunately, there are presently no alternatives to ventilation in dealing with these pollutants.

Mechanical equipment that fosters biological hazards, such as condensate drain pans and duct insulation, can be redesigned to reduce these hazards. The HVAC industry is becoming more educated about this aspect of design, but no one has yet developed a comprehensive doctrine for the design of HVAC equipment to avoid these problems.

Isolating localized pollutant sources is another important technique. The most common way to do this is to install hoods over pollutant emitters. These should draw only enough air from the space to direct pollutants to the outside. Hoods are a good idea that can be used

much more widely than they are at present. For example, they can be used with ordinary copy machines in spaces where the copy machine is the main source of pollution. Other forms of isolation, such as installing copying machines and laser printers in a separate room, are also effective. Integrate the design of hoods and isolation spaces with the overall design of the air handling system.

Another approach is to maintain conventional (i.e., high) outside air ventilation rates and recover the energy from the exhaust air. This approach is covered by [Measure 4.2.8](#).

ECONOMICS

SAVINGS POTENTIAL: A large fraction of the cost of conditioning outside air, in many cases. Deduct the cost of increased fan power from these savings.

COST: Varies widely. For example, HEPA filtration costs about \$60 per thousand CFM. Oxidizing chemical filtration costs about \$1,000 per thousand CFM, in large sizes, and much more in smaller sizes. Electrostatic air cleaners cost several hundred dollars per thousand CFM, the cost varying widely with size and features. Additional fan power needed to overcome the resistance of the filtering media is a major additional cost. Maintenance is a significant continuing cost with all air cleaning equipment. For example, replenishing chemical media may cost thousands of dollars per year.

PAYBACK PERIOD: One year to many years.

TRAPS & TRICKS

CHOICE OF METHOD: All air cleaning systems need unfailing maintenance. This is their biggest weakness. If you are not sure that the equipment will be maintained reliably for the life of the facility, pass up this Measure.

DESIGN AND EQUIPMENT SELECTION: The design of air cleaning systems is an extensive, specialized topic. Make sure that adequate talent is brought to the job. Selecting the best type of equipment is the biggest challenge. Some types of equipment, such as HEPA filters and adsorbents, are well proven. The quality of electrostatic equipment varies widely among models. The materials and maintenance costs of chemical systems are high. Any new or unusual type of equipment is suspect. Do your homework, and don't let vendors make this choice for you. Check with others who have used air cleaning systems of the types you are considering.

INSTALLATION: Make it easy to replace filters and filter materials, or the systems will be neglected. If potential pollutants may be dangerous in small concentrations, make sure that the installation does not allow the pollutants to leak around the cleaning units.

EXPLAIN IT: Establish and follow a rigid maintenance schedule. Keep the staff trained. Describe the system in the plant operating manual. Install placards on all parts of the system that require attention, stating what needs to be done.

MONITOR PERFORMANCE: Schedule periodic checks of equipment condition in your maintenance calendar. If the air cleaning system has observable characteristics that can indicate its state of maintenance, such as air pressure differential across filters, include appropriate columns in the plant operating log to record these conditions.

MEASURE 4.2.5 Provide outside air economizer cycle operation of air handling units.

RATINGS

New Facilities	Retrofit	O&M
A	C	

An economizer cycle is a method of providing free cooling during periods when the outside air is cooler than the indoor temperature, typically, when the outside air temperature is below about 60°F. The economizer cycle is a damper control sequence that increases outside air intake just enough to meet the cooling requirements of the air handling system. If outside air cannot provide sufficient cooling, mechanical cooling makes up the difference.

In order for an economizer cycle to work properly, the air handling system must be able to control the amount of outside air intake accurately. Also, the air intake and relief passage must be large enough to allow large volumes of air to be brought into the building. In new construction, these features can be included at modest cost.

In many existing facilities, the outside air intake capacity is ample and the necessary dampers are already installed in the system. In such cases, you can retrofit an economizer cycle without major mechanical modifications, and the additional controls are the only major expense. In other retrofit applications, you may have to make major modifications to the “front end” of the air handling system to handle the large volumes of outside air and relief air.

Energy Saving Potential

The savings potential of an economizer cycle is determined by three factors: (1) the climate at the time the air handling system is operating, (2) the net internal heat load in the spaces, and (3) the design of the air handling system.

■ The Weather Profile is a Primary Factor

An economizer cycle can save cooling energy only when the outside air temperature is less than the indoor temperature. To satisfy the entire cooling load, the outside air temperature must be as cool as the air distribution temperature that would be produced by mechanical cooling. Typically, this is about 55°F to 60°F. (This assumes that the system is capable of taking in 100% outside air. This point is discussed further below.)

Therefore, a critical issue is the number of hours each year that the ambient air is cool enough and dry enough to be used for cooling *while the facility is operating*. To calculate the saving potential with reasonable accuracy, you need temperature and humidity data grouped by time of day. It does little good for the outside air to be colder than inside while the air handling systems are shut down. For example, cold night

temperatures are of little use to facilities that operate only during the day.

Most energy analysis computer programs include hourly weather data. If you want to make a manual estimate, a good source of weather data grouped by time of day is the publication *Engineering Weather Data*, available from the U.S. Government Printing Office. This covers many locations in the United States and major locations in other countries.

■ Internal Heat Gain Increases the Savings

The net heat load, i.e., the internal heat gain of a space minus the heat losses, determines the cooling requirement during cold weather. Interior zones have no envelope heat loss, and therefore have net positive heat loads under all weather conditions. Therefore, an economizer cycle can save energy in cooling interior zones any time the outside air temperature is lower than the indoor temperature.

Perimeter spaces may also have a considerable net heat gain, especially if they have large windows that are exposed to direct sunlight. For example, if windows are double- or triple-glazed, a perimeter space may have a net heat gain at an outside temperature of 40°F or 50°F. In typical mid-latitude climates, this results in many hours that an economizer cycle can save energy.

Heat gain may be increased substantially by user equipment, such as computers, photographic lighting, and sterilizers, increasing the value of an economizer cycle. On the other hand, other energy conservation measures reduce heat gains, making an economizer cycle less valuable.

■ Savings in Reheat Energy

In air handling systems that use reheat as a method of temperature control, the bulk of the cooling load that occurs during cool weather may be to chill air prior to reheating it. It may be economical to install an

economizer cycle just to reduce the cost of reheat under this condition. But, a better alternative is to modify the system to eliminate or reduce reheat. In some cases, use both approaches. Refer to [Subsections 4.4](#) through [4.8](#) for the methods that apply to specific types of systems.

■ Limitations with Multizone and Dual Duct Systems

Economizer cycles usually are not practical with conventional multizone or dual duct systems. In these systems, outside air is fed into both the heating and cooling coils of the system. Increasing the amount of cold outside air reduces the cooling load, but it increases the heating load. Therefore, an economizer cycle is valuable only if the cost of heating energy is always less than the cost of cooling energy.

This limitation does not apply if the dual duct or multizone system is designed so that outside air flows only into the cold air side of the system. This design feature is unconventional. It is likely to be too expensive for most retrofit applications.

Don't Use an Economizer Cycle with Polluted Outside Air

This Measure radically increases the quantity of outside air at certain times. This makes the Measure undesirable if the outside air is polluted or smelly. For example, an outside air economizer is not a wise choice near a paper mill or a fish processing plant.

Air Handling System Front End Configuration

An economizer cycle needs positive control of outside air intake. This is a function of the “front end” of the air handling system, as defined in the [Section 4 Introduction](#). Not all air handling system designs are capable of controlling the amount of outside air intake over the wide range of flow rates that is needed by an economizer cycle. Refer to [Figure 1](#) in [Measure 4.2.1](#) for the different methods of controlling outside air intake. Systems B, C, and E in that [Figure](#) provide adequate control of outside air intake. There are several important issues that distinguish these three systems.

One issue is control of pressure inside the spaces. Only System C allows you to control space pressure independently of supply air flow and the outside air flow. This is important if the return air path has a significant amount of resistance to air flow. The pressure in the space with System B or E is always positive, and it is approximately equal to the flow resistance of the air return path. (See [Measure 4.2.2](#) for details about this.) If the air return path has only minimal resistance, the space pressure will remain approximately neutral.

With an economizer cycle, the amount of air flow in the return air path changes over a wide range. Therefore, if the return path has high resistance, the

pressure inside the spaces will vary with Systems B and E.

Another important issue is energy efficiency. In this regard, System E has a clear advantage because it does not require control dampers. It avoids the waste of fan power that is needed to move air past the resistance of the control dampers.

A third important issue is damper leakage, and the ability of the dampers to control flow accurately at low flow rates. Again, System E has a clear advantage in this regard because it has no control dampers. If you use System B or System C, the quality and characteristics of the air handling system dampers are important. The outside air damper should present only minimal resistance to air flow at maximum outside air intake. It should provide accurate control of outside air when the economizer cycle is not operating. And, it should close tightly when the facility is unoccupied. The return air damper should close tightly while the economizer cycle is in operation, and it should control air flow accurately at other times. These are stringent requirements that most existing air handling systems cannot meet without improvements. See [Measure 4.2.2](#) for tips on improving damper performance.

System A cannot work with an economizer cycle because it has no means of modulating the intake of outside air. With such systems, there are two solutions: (1) convert the system to the configuration of System B, C, or E; or, (2) increase exhaust from the spaces using an exhaust fan that can handle full system flow. The second approach is rarely used. It would need a variable-output exhaust fan. It would also cause pressure variations inside the space, although these would usually be minor.

System D usually cannot work with an economizer cycle, because the relief fan limits the amount of relief air. The best way to adapt this system to economizer cycle operation is to convert it to the configuration of System C or System E. Converting to System E means installing a relief fan that is much larger, and providing it with a variable-speed drive and appropriate controls.

In summary, consider System E as your best choice, from the standpoint of energy efficiency and freedom from damper problems. However, if you need positive control of space air pressure, your only choice is System C. See [Measure 4.2.2](#) for details of converting an air handling system to the configurations of System C or System E.

Air Intake and Relief Passages

In order for the system to fully exploit outside air cooling, the outside air intake ducting must be large enough to allow the entire system air flow to be drawn from the outside. Similarly, the relief air passages must be able to exhaust the entire system air flow.

If an air handling unit does not presently have the capability of taking in a large fraction of outside air, consider enlarging the outside air intake and relief to accommodate an economizer cycle. If the air handling unit is installed next to an exterior wall, this may be relatively inexpensive. If the air handling unit is located far inside the building envelope, enlarging the ducting may be expensive. Sometimes, air flow is limited by duct features, such as a succession of sharp bends, that increase flow resistance.

Consider an economizer cycle even if the outside air intake is too small to handle the full system air flow, especially if there is a substantial amount of cold weather. Any amount of cold outside air reduces the amount of mechanical cooling that is required.

You may be able to increase outside air intake through the existing system by installing an intake fan. The fan is needed to overcome the resistance of the intake passage. It will consume additional energy. However, if it is controlled properly, it will consume much less energy than would be needed to provide a corresponding amount of mechanical cooling.

Control Sequences

Although the economizer cycle concept is simple, making it work efficiently requires thought. The major goal is to control the economizer so that mechanical cooling operates no more than necessary. The control sequence for an economizer cycle depends on the type of air handling system. These are the control sequences for different system types, in summary form:

- **single-zone systems with variable discharge temperature.** These systems typically use hydronic coils with throttling valves. The space thermostat initially opens the outside air damper instead of the cooling coil valve. After the outside air damper opens fully, the cooling coil valve starts to open to provide supplemental cooling. When the outside air temperature rises to equal the return air temperature (or space temperature), the outside air damper closes to minimum position.
- **single-zone systems with on-off or staged cooling.** These systems typically use direct-expansion refrigerant coils. The space thermostat initially opens the outside air damper instead of turning on the cooling compressor. After the outside air damper opens fully, the thermostatic control allows the compressor to operate to provide supplemental cooling. When the outside air temperature rises to equal the return air temperature (or space temperature), the outside air damper closes to minimum position.
- **single-duct reheat systems.** These systems maintain a constant cooling coil discharge temperature, which typically is 55°F. The coil discharge thermostat initially opens the outside air

damper instead of turning on the cooling compressor. If the outside air temperature is not able to maintain the coil discharge temperature, the coil discharge thermostat opens a hydronic cooling valve or starts a cooling compressor to provide supplemental cooling. When the outside air temperature rises to equal the return air temperature (or space temperature), the outside air damper closes to minimum position.

Dry-Bulb or Enthalpy Control?

The preceding control sequences are based on measuring ordinary (dry-bulb) temperature. The economizer cycle provides greater energy savings if the controls sense the enthalpy of the outside air instead of its temperature. Enthalpy controls can also be used to avoid discomfort from excessive intake of humid outside air. Enthalpy controls are explained in [Measure 4.2.6](#), next.

Control Equipment Precautions

Many economizer cycle controls that are designed on a custom basis are installed incorrectly, or they fail to provide the full potential benefit. In addition, maintaining custom controls requires special training for plant operators.

The failure potential of economizer cycle controls is reduced by buying them as a dedicated control package, which is available commercially. Also, economizer software is available for energy management computer systems, although this is less desirable because of the reliability weaknesses of these systems. Even packaged economizer controls are vulnerable to failure from incorrect selection or installation.

Coordinate with Other “Front End” Measures

This Measure involves the same part of the air handling system as the other Measures of this Subsection. To avoid wasting money and opportunity, decide which of the Measures are appropriate for each air handling system, and accomplish all of them together.

Other Methods of Augmenting Mechanical Cooling

There are many ways of using outside air for cooling. This Measure is usually the best choice for sealed buildings of the modern type, provided that the mechanical installation is feasible and that the quality of the outside air is satisfactory.

An important class of alternatives consists of using the existing chilled water system, the condenser water system, or both for bringing outside cooling into the building. These methods are covered in [Subsection 2.9](#). They exploit evaporative cooling to increase the cooling effect, so they can operate with somewhat warmer outside air than the outside air economizer cycle. This is a significant advantage in dry climates.

Here are some simpler methods of bringing outside air directly into spaces, or of augmenting mechanical cooling:

- **ventilate the space directly**, by installing openable windows, by using existing windows more effectively, or by installing ventilation openings and fans
- **use circulation fans inside the space**. They work well alone, and they increase the effectiveness of mechanical air conditioning.
- **in dry climates, use evaporative space coolers**.
- **in humid climates, use room dehumidifiers**. They reduce the need for mechanical cooling in humid climates. They can be used in combination with mechanical cooling to reduce overall energy consumption.

ECONOMICS

SAVINGS POTENTIAL: An economizer cycle can eliminate the need for mechanical cooling during periods when the outside air temperature is below about 60°F. The savings depend on the cooling loads that exist during these periods.

COST: Varies widely. An economizer control package typically costs several thousand dollars. If modifications of the intake ducting or fans are required, the cost may be much higher.

PAYBACK PERIOD: Less than one year, to many years.

TRAPS & TRICKS

CHOICE OF METHOD: Compare this approach to all possible alternatives. In retrofit applications, consider an economizer cycle even if you do not have enough intake capacity to provide 100% of system air flow. Be careful in estimating the potential benefit, which varies widely with the type of air handling system.

SELECTING THE CONTROLS: You may be able to find a packaged control system for an economizer cycle, but make sure that it can control your type of system in an optimum manner. If the climate is humid, consider enthalpy control for the economizer cycle.

EXPLAIN IT: The system operates automatically, but air handling system controls are vulnerable to tampering, which may be prompted by comfort problems. The system will be reliable only if maintenance personnel are properly trained. Describe the system clearly in the plant operating manual.

MONITOR PERFORMANCE: Schedule periodic checks of the economizer cycle during periods of time when it is operating. If your plant has an operating log that covers air handling systems, include a column for the percentage of outside air. If you use enthalpy controls, schedule inspections and calibration at appropriate intervals.

MEASURE 4.2.6 Install enthalpy control of economizer cycles.

If humid outside air is used for cooling, the cooling coil may need to expend energy to reduce the air’s humidity. The additional energy needed to dehumidify the outside air reduces the energy saving potential of an economizer cycle. For example, outside air at 65°F is useful for cooling if it is dry. But, if air at this temperature is humid, the cost of dehumidifying the air may exceed the saving in sensible cooling that it provides.

For this reason, an economizer control operating in a humid climate can be more efficient if it is controlled to sense humidity as well as temperature. (To emphasize that temperature indicates only sensible heat, the HVAC industry uses the redundant terms “sensible temperature” or “dry-bulb temperature.”) The total energy content of air is the sum of its sensible heat and its latent heat. This total heat content is called “enthalpy.” Economizer cycle controls that respond to both temperature and humidity are called “enthalpy controls.”

Enthalpy controls are standard components. An enthalpy control consists of a temperature sensing element and a humidity sensing element calibrated so that the sum of their two signals provides an indication of the total enthalpy of the air. If an energy management computer system is being used to control economizer cycles, the computer can calculate enthalpy from the outside air temperature and humidity.

Where to Consider Enthalpy Control

If the outside air is often humid when the temperature is in the range of 40°F to 65°F, enthalpy controls can provide a significant improvement in economizer operation. For example, enthalpy controls are valuable in cities like New Orleans and London. On the other hand, humidity is almost irrelevant to economizer cycle operation in dry climates, as in the American Southwest.

Comfort Considerations

In conventional cooling design, humidity is controlled by adjusting the temperature of the cooling coil. In chilled water systems, this is done by controlling the chilled water temperature. However, economizer cycles shut down or reduce the output of the cooling coils, so they allow higher space humidity to occur. As a result, economizer cycles may be inappropriate for humid climates. Enthalpy controls partially avoid this problem, because they reduce the intake of outside air as it becomes more humid.

A refinement of economizer control that improves efficiency in humid climates. Also avoids comfort problems caused by high humidity.

If you decide to use enthalpy control, be aware that comfort does not correlate closely to enthalpy. For example, most people consider a combination of 76°F and 40% relative humidity to be comfortable. Air has the same enthalpy at a combination of 60°F temperature and 100% relative humidity, but people feel clammy under those conditions. Going the other way, air has the same enthalpy at a condition of 90°F and 10% relative humidity, and this would feel arid.

Human comfort is related to temperature, humidity, air flow, interior heat radiation, clothing, the nature of the activity, and other factors. Enthalpy deals only with the first two of these. In humid climates, even using an enthalpy control to optimize efficiency may produce interior conditions that are considered too humid for comfort.

Within the narrow range of space temperatures that are considered acceptable with mechanical cooling, relative humidity is a reliable criterion for comfort. Therefore, when using an economizer cycle in humid climates, sense the relative humidity in the spaces. Use this signal as an override on the economizer cycle to limit the amount of outside air taken into the system when the outside air is humid.

Maintenance Requirements

Humidity sensing is the Achilles heel of enthalpy control. In the past, the humidity sensing elements used in HVAC controls were neither accurate nor stable. Inaccuracy in the enthalpy sensor causes the economizer cycle to operate inefficiently. An accurate dry-bulb temperature control is preferable to a miscalibrated enthalpy control. Do not use enthalpy controls unless you are reasonably sure that skilled personnel will

maintain them throughout the life of the facility. Figure 1 shows what happens otherwise.

Factor skilled maintenance into the cost of using enthalpy controls. Contemporary enthalpy controls require periodic recalibration, although the best types of enthalpy sensors have much longer calibration intervals than earlier types.

Although enthalpy measurement technology is improving, the cheap unreliable varieties of sensors will probably remain in the market. When selecting enthalpy sensors, stress accuracy, reliability, and stability.

Don't expect the maintenance staff to do a good job with equipment that they do not understand. The concept of enthalpy is not widely understood. This makes it especially important for you to train maintenance personnel in calibrating enthalpy controls.

ECONOMICS

SAVINGS POTENTIAL: Depends on weather conditions. In humid climates, enthalpy controls may improve the efficiency of an economizer cycle from 10 to 30 percent. This may translate to approximately 2 to 10 percent of the total cooling load. In dry climates, enthalpy control provides little benefit.

COST: Several hundred dollars to several thousand dollars more than sensible temperature controls.

PAYBACK PERIOD: One year, to many years.

TRAPS & TRICKS

SELECTING THE EQUIPMENT: Your choice of the sensor type will determine the long-term reliability and accuracy of the enthalpy control. Investigate current offerings thoroughly. Some newer types of sensors may be able to operate for long periods without calibration. Older types are no longer acceptable. You may have to go outside the HVAC field, to "industrial controls," to get the best equipment.

INSTALLATION: Details are important. Install the enthalpy sensor near the center of the outside air intake duct, where it is not influenced by sunlight, motor heat, humidifiers, or other influences.

MAINTAIN IT: Provide maintenance training. Explain the control system in the plant operating manual. Schedule regular sensor inspections and calibration.

MEASURE 4.2.7 Install a purge cycle for overnight cooling.

RATINGS

New Facilities	Retrofit	O&M
D	D	

A purge cycle is a ventilation control technique that applies to buildings that are unoccupied at night. The concept is to operate the air handling system fans at night to “sweep” heat out of the building, without operating the cooling coils. Typically, the system fans are operated for an hour or two just before sunrise, when the outside air is coolest. You might think of a purge cycle as an economizer cycle that operates during off-hours.

From a control standpoint, a purge cycle is fairly simple. It needs a time control, some temperature sensors, and damper control modifications.

Where to Consider a Purge Cycle

Purge cycles were widely advocated during the energy hysteria of the 1970’s, when people were grasping for new ways to save energy. Like many energy conservation concepts that arose at that time, it promised greater savings than it can deliver. The main shortcoming of a purge cycle is that it works only within a narrow set conditions.

Most weather conditions do not allow a purge cycle to provide much benefit. The daytime temperature must be hot, but the outside air must cool to a temperature substantially below indoor temperature for a few hours during the night. In the United States, such conditions are typical of the Southwest, but they occur infrequently in the rest of the country.

A purge cycle is effective only with buildings that are occupied during normal daytime working hours, and are unoccupied the rest of the time. In this situation, the chillers are turned off at the end of normal occupancy, a few hours before sunset. After shutdown, the heat absorbed by the building exterior during the day soaks into the interior of the building. After sunset, the building exterior loses heat by conduction and radiation, but the interior may continue to warm up from the heat entering through the structure. Late at night, the outside air may become much cooler than the building interior. At this point, the air handling unit fans are operated to circulate outside air through the building.

This scenario describes the behavior of buildings that have a massive structure. Lightweight buildings, such as those using curtain walls, tend to cool off quickly as the outside air temperature drops, reducing the benefit of a purge cycle.

The building interior cannot be used to store much cooling for the daytime, because this would require the interior to be uncomfortably cool during the first few hours of occupancy.

SUMMARY

A control technique that may save a small amount of cooling. For a purge cycle to be useful, the building must be massive, it must be vacated at night, it must be located in a dry climate, and it must need cooling in the early morning.

The net effect of these factors is that a purge cycle provides only a limited ability to reduce cooling load. Where suitable weather conditions exist, an air purge cycle is useful mostly on the last night after an extended period of shutdown, such as Sunday night after a weekend.

Possible Humidity Problems

A purge cycle raises the humidity inside the building because the outside air is not dehumidified before it is brought into the building. This brief period of high humidity may cause problems if anything within the building is sensitive to humidity. However, condensation is unlikely to occur because the interior of the building is warmer than the air. The humidity level is reduced quickly once the cooling coils are turned on. In the dry climates that are most favorable for purge cycles, humidity is unlikely to cause problems.

If you are concerned that a purge cycle may cause humidity problems, you can avoid problems by sensing the relative humidity inside the space. Use this signal to turn off the purge cycle if the relative humidity becomes too high.

How to Control a Purge Cycle

When the purge cycle is operating, the outside air intake dampers and relief air dampers should open fully, and the recirculation dampers should close. The objective is to provide maximum exposure to the low outside air temperature.

When to turn on the fans, and for how long, depends on the outside air conditions and the inside temperature.

To minimize fan operation, the purge cycle should not start too early. Wait for the outside air to cool as much as possible. Then, the fans should operate long enough to reduce the inside temperature to the minimum acceptable daytime temperature. Purge cycle control is similar to economizer cycle control ([Measure 4.2.5](#)) in that both are controlled on the basis of the difference in temperature (and perhaps humidity) between the inside and outside.

■ Complications in VAV Systems

VAV systems with “shutoff” terminals have an additional complication. In these systems, the terminal units shut off air flow when the inside temperature falls below the normal daytime setting. You can work around this problem by modifying the thermostatic controls.

If the VAV terminals have pneumatically operated normally-open dampers, the controls can keep them open during the purge cycle by turning off control air pressure. You can do this from a central point, so the modification should be inexpensive. If the thermostats have a temperature setback feature that can be activated from a central point (e.g., by changing the pressure provided to pneumatic thermostats), you may be able to use this feature to open the terminals.

Some energy management control systems (EMCS's) have purge cycle control as a standard feature. The EMCS will open the VAV terminals as necessary. If you have an EMCS without this feature, you may be able to program it to provide a purge cycle. However, custom programming is difficult to do properly, and the cost may not be justified.

In VAV systems that use “minimum-CFM” terminals, the terminals cannot close beyond a certain fraction of maximum air flow, which is typically about 40% of maximum. The minimum-CFM position of the terminals may provide enough air flow to operate a purge cycle.

Outside Air Intake Capacity

The typical outside air ventilation capacity of most air handling systems is adequate for a purge cycle. The quantity of outside air that must be circulated in a purge cycle is relatively low because the quantity of heat being removed is much less than during maximum cooling conditions.

Coordinate with Other System Control Measures

Coordinate this Measure with other Measures involving control of air handling system dampers, including night shutdown control ([Measure 4.2.1.1](#)) and economizer cycle control ([Measure 4.2.5](#)).

ECONOMICS

SAVINGS POTENTIAL: 0.1 to 2 percent of cooling energy.

COST: In new construction, adding a purge cycle to the system controls costs little. Modifying existing controls may cost several thousand dollars.

PAYBACK PERIOD: Short, if you can use an existing EMCS. Several years or longer, otherwise.

TRAPS & TRICKS

CHOICE OF MEASURE: First, make sure that a purge cycle will provide a significant saving. Only a small fraction of buildings can benefit from it.

DESIGN: Although the concept seems simple, purge cycle control is an added complication in the “front end” controls of the air handling system. Make sure that it is done right.

EXPLAIN IT: This control feature is another source of confusion for maintenance personnel. Describe it clearly in the plant operating manual.

MONITOR PERFORMANCE: Failure of a purge cycle is easy to overlook, so schedule periodic checks. Somebody will have to get out of bed early to do this.

MEASURE 4.2.8 Install an exhaust air heat recovery system.

When air is exhausted from a building, it carries away a large fraction of the energy that was consumed to heat, cool, humidify, or dehumidify it. One method of reducing this energy waste is to recapture the useful energy from the exhausted air and to use this energy for conditioning the incoming air. In the most favorable applications, exhaust air heat recovery can save a large amount of energy.

This simple concept has been exploited for a long time. Still, it can be tricky to accomplish successfully. Several types of heat exchangers are used for exhaust air heat recovery. Each has its own limitations and quirks. All the types of systems are expensive, and estimating the savings potential can be subject to large uncertainties.

To avoid being tedious, we use the term “exhaust” in this Measure to mean both relief and exhaust, unless we need to make the distinction. “Relief air” is air that is vented from the air handling system to make room for incoming outside air. In the strictest sense, “exhaust air” is air that is vented directly from spaces, typically spaces that have major sources of contamination.

Consider Heat Recovery from Both Relief Air and Exhaust Air

Consider recovering energy from all the exhausts of the building, not just from the main air relief of the air handling system. A large amount of conditioned air may be dumped by toilet exhausts, hood exhausts, and other exhausts. Heat recovery from exhausts is more likely to be economical if the air streams are large, or if you can combine small streams before they enter the heat exchanger. Only one type of heat exchanger, the runaround loop, allows heat to be collected from several air streams.

Not all types of heat exchangers can be used safely with contaminated exhaust air.

Recovery of Sensible Heat

All common types of exhaust air heat exchangers are designed to recover sensible heat primarily. Sensible heat is the heat that changes the temperature of the air. Conversely, the flow of sensible heat is driven by a temperature difference. Therefore, the potential benefit of a sensible heat exchanger depends mainly on the average temperature difference between the exhaust air and the incoming air. In typical mid-latitude climates, much more heating energy can be recovered than cooling energy, because of the larger temperature differentials.

For example, a typical winter day may produce a 50°F temperature differential between exhaust air and

incoming air. In the same location, a typical summer day may produce only a 15°F differential.

In some sensible heat exchangers, heat flows directly from the warmer air to the cooler air through the conducting material of the heat exchanger. In other types of heat exchangers, the heat from the warmer air stream flows into a heat transfer medium that moves between the warmer and cooler air streams.

Recovery of Latent Heat

Latent heat is the heat that is associated with changing water vapor to liquid, or vice versa. Latent heat is important in cooling, except in dry climates. This is because cooling systems typically provide a substantial amount of dehumidification as well as cooling. Latent heat is removed from incoming air when water vapor is condensed out of the air at the cooling coil. In typical mid-latitude climates, latent cooling (i.e., dehumidification) consumes less energy than sensible cooling on an annual basis, but it is still a large energy user. In a humid location, such as Houston or New Orleans, the cooling load during the winter months may consist mostly of dehumidification.

Water vapor is the carrier of latent heat in air. Therefore, recovery of latent heat consists of removing the water vapor from one air stream and putting into the other. The difference in moisture concentration is what drives the transfer of water vapor. Some equipment allows the moisture to migrate directly through heat transfer surfaces that are permeable to water vapor. Other equipment uses a hygroscopic material that shuttles between the incoming and outgoing air streams.

In principle, all sensible heat exchangers have the capability of dehumidifying incoming air by

condensation, provided that the dew point of the incoming air is lower than the temperature of the exhaust air. For example, consider a muggy day in Houston when the outside air dew point is 85°F and the exhaust air temperature is 78°F. The surfaces of the heat exchanger, cooled by the exhaust air, would condense a certain amount of moisture out of the incoming air.

Weather data shows that this process can yield little dehumidification in most climates. Even in the most humid climates, this condensation process would salvage only a small fraction of the latent heat energy in the exhaust air stream. This is because the incoming air must be cooled to a temperature much lower than the temperature of the exhaust air. (Typically, the air is cooled to about 55°F). Thus, the cooling system must do most of the dehumidification. Furthermore, heat exchanger inefficiency reduces even the small amount of condensation that can occur.

Latent heat is not a factor in recovering energy for heating, because heating does not involve any evaporation or condensation of water vapor. A possible exception might be the recovery of humidity from humidified air, but this is not practical. If a latent heat exchanger were used for this purpose, it would load up with frost and stop the process (as well as creating other problems) whenever the outside air temperature drops below freezing temperature.

Heat Exchanger Types

The following are the air-to-air heat recovery methods that deserve your consideration at the present time. Most of these are well established. This is not to say that they are free of problems.

■ Plate Heat Exchangers

Plate heat exchangers consist of a stack of plates that are separated so that the entering and leaving air

Fig. 1 Plate heat exchanger The core of a real unit is no more complicated than this. Accessories include washers and preheat coils.

Trane Company

Fig. 2 Cross section of heat pipe The heat transfer rate is high because the vapor travels much faster than heat conducts through a solid.

streams pass between alternate plates. Heat is transferred between the air streams by conduction through the plates, which usually are metal. Figure 1 shows how they work.

Plate heat exchangers have been commercially available as packaged units for HVAC applications since the 1970's. Units are available with accessories, such as self-contained fans, washing systems, and preheaters for preventing freezing.

■ Permeable Medium Heat Exchangers

This type of heat exchanger is similar in construction to the previous one, except that a permeable material is used for the heat transfer plates that separate the intake and exhaust air streams. Molecules of water vapor are able to pass through the permeable material, driven by the difference in moisture concentration. Paper is one material that is used as a separator material.

Permeable medium heat exchangers are sold as packaged units for heat recovery in air handling systems. Originally commercialized in Japan, they have not been used extensively in the West. It seems reasonable to suspect that the permeable material is fragile, and that cleaning the material is a problem.

Because the heat exchange material is both permeable and fragile, it is not well suited to applications where it is important to prevent contamination of incoming air by the exhaust air.

■ Heat Pipe Heat Exchangers

A heat pipe is a sealed tube that contains a liquid that evaporates and condenses rapidly at the heat exchange temperatures. For example, halocarbon liquids, normally used as refrigerants, are commonly used as the fluid in heat pipes. When one end of the pipe is warmer than the other, the liquid at the warmer end evaporates and the vapor travels to the cooler end, where it condenses. Heat moves much faster in this way than it would by conduction through a solid. Figure 2 shows the interior of a typical heat pipe.

A typical heat exchanger consists of a bundle of heat pipes encased in fins and mounted in an enclosure, as shown in Figure 3. A partition in the middle of the

Trane Company

Fig. 3 Heat pipe heat exchanger One air stream flows through the near end, and the other air stream flows through the far end. The heat transfer capacity of the unit can be regulated by tilting the unit slightly, draining the liquid in the individual tubes toward one end or the other.

enclosure separates one end of the pipes from the other end. Exhaust air passes through one side of the enclosure, and entering air passes through the other side.

Heat transfer is sensitive to small angles of tilt of the tube bundle. If the cooler end is lower, the refrigerant all condenses there and heat transfer stops. If the warmer end is lower, pooling of the refrigerant at the warmer end reduces the evaporative surface, reducing heat transfer. Maximum heat transfer occurs when the warm end is slightly lower than the cold end.

Adjusting the tilt of the heat exchanger is the primary means of modulating heat transfer. Modulation is needed in exhaust air heat exchangers for reasons explained below. If the air handling system is used for both heating and cooling, the heat exchanger is mounted so that it can tilt in both directions. The range of tilt angle is typically only a few degrees.

To accommodate the changes in tilt, the heat exchanger needs flexible connections where it is connected to the intake and exhaust ductwork. These connections are prone to cracking, allowing air leakage to or from the space surrounding the heat exchanger. Careful installation can greatly extend the life of the flexible connections. Use an accordion-type material, and install enough material so that the connection is not stretched excessively.

Heat pipe heat exchangers are commercially available as packaged units for use in air handling systems. They have been sold for this purpose since the 1970's.

■ Sensible Heat Wheels

A heat wheel is a rotating cylinder of material that is honeycombed with air passages that run parallel to the axis. Exhaust air flows through one side of the cylinder, and incoming air flows through the other. The wheel is rotated slowly, transferring heat from one air stream to the other. The heat storage material of sensible heat wheels is usually thin sheetmetal. Figure 4 shows how the unit works.

The rotation rate of heat wheels must be matched to the velocity of the air streams. If the wheel rotates too slowly, heat is not transferred from one side to the other quickly enough. If the wheel rotates too rapidly, the warm portion of the wheel does not linger in the cool air stream long enough to lose its heat. By the same token, the rotation of the wheel can be slowed or stopped to modulate heat transfer.

A major shortcoming of heat wheels is transfer of contaminants from the exhaust air into the entering air. This occurs because each portion of the wheel alternately comes in contact with both air streams. Contaminants from the exhaust air may adhere to the heat wheel, and then be blown free into the entering air.

To minimize this problem, a purge section may be added to the heat wheel casing. This is a segment-shaped portion of the intake passage where the wheel first arrives

Trane Company

Fig. 4 Heat wheel One air stream heats half of the wheel. Slow rotation of the wheel moves the heated portion into the other air stream. The pie-shaped segment in front is the purge section, which reduces contamination from exhaust to intake, but it also wastes recovered heat.

after coming from the exhaust side. The passages in the casing are arranged so that the incoming air in this part of the wheel is diverted directly into the exhaust air stream. The reverse flow in this portion of the wheel dislodges contaminants. Unfortunately, the air passing through the purge section also carries away a significant portion of the heat being carried by the wheel.

Another source of cross contamination in heat wheels is the gap that exists between the wheel and the stationary casing. These gaps are closed by seals, but the seals wear out.

Heat wheels have a long history as combustion air preheaters in boilers. They were adapted for use in air handling systems before the other types of packaged heat exchangers were developed, and they experienced a great deal of popularity in the 1970's. Latent heat wheels, covered next, have always been more popular than sensible heat wheels. Sensible heat wheels have now faded away under competition from types that are simpler and less bulky.

■ Latent Heat Wheels

Latent heat wheels are similar to sensible heat wheels, except that the rotating cylinder is coated with

a hygroscopic material (a material that has a strong attraction for water in the vapor state). In warm weather, moisture in the outside air is captured on the wheel and is released into the drier exhaust air. In cold weather, moisture is recovered from the exhaust air and added to the intake air.

(With a hygroscopic material, moisture transfers from one air stream to another because of the difference in moisture concentration, not because of a temperature difference. Condensation plays no role in this process.)

The problem of cross contamination between the exhaust air and the incoming air is even more severe with latent heat wheels than with sensible heat wheels. The hygroscopic material used in latent heat wheels has a rough texture, so it is more likely to catch contaminants. More seriously, it is difficult to clean the hygroscopic material because it cannot tolerate being wetted or scrubbed. As a result, latent heat wheels have the most serious cross contamination problem of any type of heat exchanger.

Latent heat wheels experienced a surge of popularity in the 1970's. Ironically, many were installed in medical and research facilities, applications where their tendency

Trane Company

Fig. 5 Runaround loop Heat from one air stream is picked up in a coil, and the heat is transferred to another coil by a water loop. Heat can be transferred to and from any number of air streams in this way. There is no risk of contamination, and no fire hazard. However, the pump consumes energy, and the coils increase the fan power requirement.

toward cross contamination is most detrimental. This is a classic example of how fascination with new technology can overpower common sense.

■ Runaround Loops

A runaround loop is a system that uses water to transfer heat between air-to-water coils that are installed in the incoming and exhaust air passages. Figure 5 shows the operation of a typical system.

Runaround loops have several significant advantages over other types of heat exchangers:

- the intake and exhaust locations can be widely separated
- heat can be transferred from any number of exhaust locations to any number of intake locations. A single loop can even serve different air handling and ventilation systems.
- the intake air is completely isolated from the exhaust air, even in the event of equipment failure
- water coils are less bulky, and hence easier to install in tight spaces, than the other types of heat exchangers. However, installing the pipe may be difficult in retrofit applications.

On the negative side, the sensible heat recovery efficiency of runaround loops is somewhat lower than that of other sensible air-to-air heat recovery methods. This is because the two heat transfer steps absorb some of the temperature differential that drives the heat recovery.

Coil design is a major aspect of the design of runaround loops. The coils must provide efficient heat transfer, but they must also minimize resistance to the flow of air and water. You need to compromise between face size, fin configuration, and coil circuiting to achieve good efficiency at acceptable cost.

Modulate heat transfer in a runaround loop either by changing the pumping rate or by bypassing water flow around coils.

Freeze protection is a major factor in the design of runaround loops. A basic step is to use a heat transfer fluid having a low freezing temperature, such as glycol. Frosting of the exhaust air coil can be avoided by limiting the heat transfer.

Install the system pump(s) upstream of the coils that are installed in the cooler air stream. This recovers the heat that is added to the liquid by the pumps. If the air handling unit accomplishes both heating and cooling, the pump location will be wrong for one of the two applications. Therefore, locate the pump for the dominant usage.

Runaround loop systems are not available as standard packages. They are designed and assembled from individually selected coils, pumps, piping, and controls. Design is trickier than the simplicity of the concept may imply. A sloppily designed system may work, but it will be significantly less efficient than one

that is designed by someone who takes the trouble to deal with all the issues. Certain manufacturers of HVAC equipment have developed expertise with these systems. They offer design support, including computer simulation programs.

Heat Recovery Efficiency

Table 1 gives nominal ranges of efficiencies for the common types of heat exchangers. Consider the following points when referring to this table.

■ Sensible Heat

All types of sensible heat recovery equipment claim efficiencies in the range of 50 to 70 percent, when used to recover heating. When used to recover cooling, claimed efficiencies are somewhat lower because of the lower temperature differentials. Efficiency increases with greater heat transfer surface, but heat exchanger size is a major cost factor. Therefore, efficiency is largely a matter of how much heat exchanger you can afford. For a given heat exchanger, efficiency is better in more severe climates.

■ Latent Heat

With units specifically designed to recover latent heat, calculated latent heat recovery efficiencies of 30 to 60 percent are claimed. Like sensible heat recovery, latent heat recovery is sensitive to weather conditions, being better in more humid climates. The features that allow latent heat recovery increase cost and maintenance problems. Because of these factors, many heat recovery systems do not include latent heat recovery.

■ Fan and Pump Energy Penalty

All types of air-to-air heat recovery incur a penalty of increased fan power, which is required to drive both the intake air and the exhaust air through the heat exchanger. In systems that use a liquid as a heat transfer medium, pump power is also required. If the control of the system is sloppy, or if the system is not well matched to the application, the additional fan and pump power may negate a large part of the savings from recovered heat energy.

■ Be Skeptical about Claims

You may have trouble finding objective data on the efficiency of specific types and models of heat recovery equipment. There are no independent organizations that rate these systems. Suspect that the efficiency claims of equipment manufacturers are optimistic, and that the claims of newer companies are based more on hope than on experience. It is prudent to purchase heat recovery equipment only from manufacturers with extensive experience. Request certified performance data.

How the Application Affects the Savings Potential

The amount of energy that you can save with exhaust air heat recovery depends on the application. The most important factors are:

- **the type of air handling system.** Single-zone air handling systems derive the greatest benefit from exhaust air heat recovery. Other types of systems are unable to exploit much of the energy saving potential of heat recovery.

In dual-duct and multizone systems, the benefit of heat recovery is reduced because one part of the incoming air is warmed and the other part is cooled. Thus, recovering heat saves heating cost but increases cooling cost. Likewise, recovering cooling energy reduces cooling cost but raises heating cost. This makes it unlikely that heat recovery would be economical in these types of systems.

In single-duct reheat and VAV systems, air is first cooled at the cooling coil regardless of the outside air temperature or the conditioning requirements of individual spaces. For example, if outside air enters at 60°F, it is first cooled to 55°F before being distributed to the spaces, where it is reheated to various temperatures. Increasing the temperature of the outside air with recovered heat would have the adverse effect of increasing the cooling load on the coil.

This behavior of reheat and VAV systems reduces the outside air temperature range in which heat recovery is useful. In the previous example, heat recovery is useful only when the outside air temperature is well below 55°F. Heat recovery cannot be economical with these types of systems unless the climate is very cold.

- **the required ventilation rate.** The savings potential is greatest in facilities that require a large amount of outside air ventilation, such as health care facilities.
- **the hours of operation of the facility.** The saving is roughly proportional to the number of hours during which outside air is used.
- **the weather profile.** Mild weather renders heat recovery uneconomical, both because conditioning

energy requirements are reduced, and because the efficiency of heat recovery equipment declines.

- **heat gains.** If the facility has large heat gains, it is unable to benefit from heat recovery during the milder portions of the heating season. This is because the coolness of the incoming cold air is desirable to offset the heat gains, down to a certain temperature. In other words, heat gains reduce the outside air temperature range in which heat recovery is useful. There is no compensating improvement in the efficiency of cooling recovery.

Evaporative Cooling of Heat Exchangers

When the air handling system is providing cooling, the benefit of exhaust air heat recovery can be boosted by wetting the exhaust air side of the heat exchanger surfaces. This cools the heat exchanger surface by evaporation. During heating operation, the surfaces are not wetted.

This technique can be used with any type of heat exchanger that is not damaged by water and that confines the water to the exhaust passage. At least one manufacturer of plate heat exchangers offers a wetted version. In runaround loops, the exhaust air coil surfaces could be wetted.

A distinctive advantage of this method of evaporative cooling is that it works well even in humid climates. This is because the evaporation is caused by exhaust air, which has been dried by the action of the cooling system. Wetting the surfaces allows the heat exchanger temperature to approach the wet-bulb temperature of the exhaust air.

Furthermore, this lower temperature gives evaporative heat exchangers some ability to extract moisture from humid outside air, although not as much as the types of heat exchangers that provide direct vapor transfer between the air streams.

For example, consider air that has been cooled in the air handling unit to 55°F. By the time it becomes exhaust air at a temperature of 78°F, it has a dew point of about 55°F. (This assumes that the air is not saturated as it emerges from the cooling coil, but that it picks up some moisture in the building.) Air in this condition has a wet-bulb temperature of about 64°F. Evaporation may cool the incoming air surface of the heat exchanger to, say, 70°F. In a climate that is warm and humid, this process might accomplish as much as 50% of the dehumidification. (On the other hand, it will not accomplish any dehumidification as long as the incoming air has a dew point lower than 70°F.)

Evaporative cooling equipment needs frequent cleaning of the wetted surfaces, which accumulate the material dissolved or carried in the water. Anticipate problems with scale, dirt, and biological growth similar to those found in cooling towers and cooling coils. An automatic cleaning cycle is very desirable.

The cost of water for evaporative heat exchangers is significant. Design the equipment, and control the water flow, so that the minimum amount of water is needed to keep the exhaust passages wetted.

How to Select the Heat Exchanger

Here is a summary of the criteria to consider when selecting the general heat recovery method and the specific equipment:

- **efficiency** of heat recovery, as discussed previously
- **additional power** required for fans and auxiliary equipment, as discussed previously
- **ability to control** heat exchange. There may be times when heat exchange is not desirable. For example, during cool weather, it may be desirable to keep the incoming air at the outside temperature to offset high internal heat gains.

In a single-duct reheat or VAV system, it is undesirable to increase the incoming air temperature as long as it is higher than the cooling coil discharge temperature. Lack of control, or sloppy control, of heat recovery in a single-duct reheat or VAV system will increase cooling energy requirements during mild weather.

In extremely cold weather, you may need to limit heat transfer to keep ice from forming in the exhaust air passage of the heat exchanger. This is most likely to be a problem if the building is humidified. Plate heat exchangers (including permeable plate units) cannot modulate their heat exchange. They need external bypasses and dampers for this. Runaround loops and heat wheels can modulate heat exchange precisely. Heat pipe units can reduce heat transfer almost to zero.

- **need to bring the intake and exhaust air streams together** at the heat exchanger. This may require major modifications of the intake and exhaust duct systems. A runaround loop requires less sheetmetal work, but more piping.
- **ability to transfer heat between multiple air streams**, including the discharge from remote exhaust fans. Joining several air streams together at a heat exchanger is a clumsy proposition. In many cases, a runaround loop is the only practical way to recover heat from several exhaust air streams.
- **cleaning capability**. The heat transfer surfaces in all types of heat exchangers must be cleaned periodically. Some types of heat exchangers are easier to clean than others. Some manufacturers are more clever than others in providing cleaning capability for a particular type of heat exchanger. Automatic washers are desirable. They are mandatory if heat is recovered from especially dirty exhaust, such as kitchen or laundry exhaust. Cleaning is a major problem in all types of latent

heat recovery equipment. Take a close look at the methods used by the equipment you are considering.

- **contaminant recirculation** between the exhaust and intake air in normal operation. Heat wheels inherently have this problem. Permeable plate heat exchangers may allow recirculation of microscopic contaminants.
- **risk of contaminant transfer in the event of failure** of a component, such as the heat transfer surfaces or seals. Heat wheels are worst in this regard, because of the continuous wear on seals. Permeable plate heat exchangers appear vulnerable to plate rupture. Only runaround loops are completely immune from the possibility of cross contamination.
- **spread of fire** from exhaust to intake. Runaround loops are immune from fire spread. Metal plate heat exchangers will heat the incoming air, but will not pass flame and smoke (unless they burn out). Heat wheels will leak smoke around the seals, especially if they burn out. Latent media will probably burn out quickly, leaving a large passage for recirculation of smoke.
- **freeze protection**. Any type of heat exchanger can form frost in the discharge air passages. Whether this will occur depends on the outside air temperature and on the humidity of the exhaust air. Frosting can be prevented by reducing heat transfer, by bypassing the incoming air around the heat exchanger, or by preheating the incoming air.
- **maintenance requirements**. Some heat exchangers require considerably more maintenance effort and skill than others. Have a strong bias in favor of systems that require little maintenance, and that are easy to maintain.
- **design risk**. Consider how well proven the equipment is. Consider the amount of design support offered by the manufacturer. Favor equipment that is packaged to include auxiliary equipment, such as fans, washers, heaters, and controls.
- **installation difficulty**. This depends on the bulk of the equipment and the extent to which it is packaged.

First, Minimize Outside Air Intake

The cost and bulk of exhaust air heat recovery equipment is proportional to the volume of air that is handled. This makes it important to reduce the amount of outside air intake to the minimum that is required. [Measure 4.2.1](#) covers ventilation requirements.

Exhaust air heat recovery is especially attractive in 100%-outside-air systems. But, consider the alternative of converting the system to recirculation, which reduces the outside air requirement. [Measure 4.2.3](#) recommends such modifications.

Air cleaning may be used economically in some facilities to reduce outside air ventilation. This option is recommended by [Measures 4.2.4 ff.](#)

Accommodating an Outside Air Economizer Cycle

Outside air economizer cycles (see [Measure 4.2.5](#)) ingest large volumes of incoming air while they are operating. It is not economical to increase the size of an air-to-air heat exchanger to accommodate the intake requirements of the economizer cycle. Fortunately, this is not necessary, because the economizer cycle and the heat recovery system operate under different conditions. The heat recovery system operates when the weather is cold, and the conditioned space has a net loss of heat. In contrast, the economizer cycle operates during cool weather when the conditioning zone has a net heat gain. The economizer cycle never operates during warm weather.

Install a bypass around the heat exchanger to handle the large air flow during economizer operation. Either install controls to turn off the heat exchanger during economizer operation, or install an isolation damper for the heat exchanger that closes during economizer operation.

ECONOMICS

SAVINGS POTENTIAL: 10% to 50% of the energy used to condition outside air, depending on the climate, the type of air handling systems, the type of heat exchanger, and other factors. The savings are partially offset by higher fan energy consumption. Runaround loops also require additional pump energy. Systems that enhance cooling by evaporation in the exhaust air stream have a water cost.

COST: The heat exchange equipment itself costs several dollars per CFM of capacity. Connecting ducts, piping, other materials, and labor add additional cost, which may vary over a wide range.

PAYBACK PERIOD: Several years, to much longer.

TRAPS & TRICKS

ESTIMATING THE SAVINGS: Don't fool yourself. The energy saving potential is not the same as the heat exchanger efficiency. If the air handling systems have any kind of reheat, the potential saving is greatly reduced. The best applications are large, single-zone systems in extreme climates.

DESIGN AND EQUIPMENT SELECTION: The subject is more complex than it appears. Each type of heat exchanger has its own design lore. Talk with others who have years of experience with the types of equipment you are considering. Some types are well proven, while others require the owner to be a guinea pig.

MAINTAIN IT: Cleaning is a continuing requirement. It is easy to ignore, causing efficiency to decay invisibly. Schedule it in your maintenance calendar. At the same time, check the condition of the equipment, such as the integrity of the seals on heat wheels and heat pipe units.

EXPLAIN IT: Describe the system clearly in the plant operating manual. Install placards to identify the heat exchanger(s), controls, and pumps.

MONITOR PERFORMANCE: Schedule checks of the operation of the controls and systems temperatures to make sure that the system is really recovering as much energy as it should be. If you have a plant operating log, include columns to record all four air stream temperatures.

MEASURE 4.2.9 Improve the envelope penetrations of air handling systems to minimize air quality problems, wind problems, and energy requirements.

The openings in the building envelope where outside air is drawn into the air handling system and where air is exhausted are important parts of the air handling system. They deserve design attention, but they are commonly treated as mere holes in the wall. These neglected holes may cause significant problems, including:

- large variations in outside air intake
- building pressure fluctuations
- excessive preheat to prevent coil freezing
- intake of contaminated air from outside the building
- recirculation of building exhaust air back into the building.

This Measure suggests improvements to avoid these problems. In addition, by locating intakes to exploit local differences in ambient air temperature, you may be able to reduce heating and cooling costs by a modest amount. Consider all these factors together when planning modifications, because the solutions are interrelated. For example, beware of possible wind effects when relocating an air intake to avoid recirculation of exhaust air.

Design the Intakes to Avoid Pollutant Sources

A primary reason (in many cases, the only reason) for introducing outside air is to improve air quality inside the building. Therefore, it makes no sense to tolerate the intake of pollutants through the outside air. ASHRAE Standard 62-89, the primary ventilation standard in the United States, requires that “makeup air inlets and exhaust air outlets shall be located to avoid contamination of the makeup air.” In some cases, problems arise from the location of the intakes, as implied by the Standard. However, problems may also be caused by the design of the intake and by conditions outside the building. The following are the most common sources of outdoor air pollution, and the ways to deal with them.

With respect to all the following pollutants, note that the location of the intake openings has a strong effect on the amount of pollutants that enter the air handling system. In addition, the velocity of the air intake has a strong influence on the tendency of the intake to ingest solid and particulate matter. High intake velocity creates a vacuum cleaner effect that can lift solid material. You can reduce intake velocity simply by increasing the free area of the intake.

■ **Vehicle Exhaust**

Vehicle engine exhaust is the most common serious pollutant that is brought into a building along with outside air. Vehicle exhaust fumes are heavy, so an outside air intake that is located at street level or in a pit will ingest exhaust from nearby vehicles. Figure 1 shows a typical vulnerable location.

The problem of vehicle exhaust becomes much worse if the air intake is located in an area where vehicle exhaust is confined, as at a loading dock or garage. (Yes, there really are designers careless enough to locate outside air intakes in such areas.) For example, a diesel truck may idle for hours at a loading dock, poisoning the air throughout the area served by the air handling unit.

The only practical solution to this problem is to locate the outside air intake as high as possible. Vehicle exhaust is substantially warmer than the outside air at first, so it may tend to rise. For this reason, do not install the intake directly above vehicle traffic or loading areas. From the standpoint of minimizing pollution from ground-level sources, the roof is the best location for the air intake.

■ **Vegetation and Botanical Chemicals**

Decaying vegetation is a rich growth medium for molds and fungi. These are potential health hazards if they enter the air handling system in any concentration. This may occur if air intakes are located at or below grade level, especially if they are surrounded by soil or nearby vegetation. If trees are growing nearby, decaying leaves can be a problem. Figure 2 shows an example.

Consider these solutions:

- **relocate the intake** to a position where there is no rubbish to be ingested. This is generally to a position well above ground.
- **increase the surface area** of the screen. If necessary, install an extension of the intake opening that has a larger screen. This reduces the air velocity through the screen, along with the vacuum cleaner effect. This does not mean that you should increase the damper size. Dampers that are too large cause leakage and control problems.
- **mount the intake screen horizontally**, with air flow upward, so that gravity will keep the screen clear of material, such as leaves, that is large enough to block the screen.

A related problem is the use of herbicides, insecticides, fertilizers, and other chemicals that are applied to lawns, shrubbery, and other vegetation. Many such chemicals are volatile or dusty, and they are drawn into the facility, where they may cause health problems. One expedient is to ban the use of chemicals in the vicinity of air intakes, but this solution is unreliable in the long term.

■ Animal Debris

Serious health problems can be caused by microorganisms that grow in animal debris. For example, histoplasmosis is a serious fungal infection that originates in bird feces. Other debris includes feathers, nest material, and dead bodies. Birds can be a problem at any elevation. The solution is to install screens at the outermost intake point, blocking any sites where birds could perch between the screens and decorative louvers or grilles.

Pick the most effective place to install the screens. For example, one hospital had an attic containing all the air handling units for the surgical suites. All intake air for the spaces was drawn from the attic. The attic and everything in it was covered to a depth of several centimeters with pigeon excrement. The attic was cleaned out, but the problem immediately started to recur. It was not solved until all the entrances to the attic were effectively blocked.

■ Evaporative Heat Rejection Equipment

All equipment in which water is stagnant or recirculated is a potential breeding ground for microorganisms. Some of these organisms are lethal,

WESINC

Fig. 1 Outside air intakes below grade Vehicle exhaust fumes from the adjacent street readily enter here, along with grass clippings, lawn chemicals, etc. Note the leaves accumulated behind the louver at right. On the positive side, easy access to the pit makes it easy to clean out. The large area keeps the entering air velocity low, which minimizes the tendency to pick up debris. Still, it would be better to install these intakes on the roof.

as in the case of Legionnaires' Disease. Others cause serious transient illness, such as Pontiac fever, and others cause long-term health problems, such as "hypersensitivity pneumonitis." Cooling towers, evaporative condensers, and evaporative space coolers convert contaminated water into a mist that may be breathed by occupants. (After the mist evaporates, most microorganisms that were carried by it die quickly.)

Mist is not the only potential danger. If the outside air intake ducting is in a vulnerable location, drippage from evaporative equipment may leak into the outside air intakes through leaks in the ductwork. This process was suspected of causing the original Legionnaires' Disease outbreak.

The only satisfactory protection against contamination by evaporative equipment is physical isolation. Install the equipment where cooling tower spray or water drippage cannot come in contact with people, either directly, through the air handling system, or by other paths.

Conventional water treatment chemicals kill most of the organisms found in evaporative equipment. However, do not depend on this. Expect that water treatment will be neglected at times.

■ Radon

Radon is a radioactive heavy element that exists in the form of an inert gas. Radon is a decay product of uranium, so it originates in the ground. The amount of uranium, and hence radon, varies radically from one geographic location to another. The concentration is very dangerous in some locations, and minimal in others. An expensive test can quickly measure the concentration of radon that is present in a building.

The primary danger of radon comes not from the gas itself, but from its radioactive decay products, which are radioactive isotopes of heavy metals. These metal atoms attach to small particles in the air that become lodged in the lungs. These radioactive materials decay further by emission of alpha particles, which are especially potent in creating cancerous changes in cells.

Excessive intake of radon is the result of certain construction features, such as an unvented area in contact with the soil.

Radon is also released from well water that originates in uranium-bearing soil. For example, showers act to release radon from the water, exposing bathers to radon. Cooling towers act in the same way. An outside air intake exposed to the discharge from a cooling tower would take in the radon.

■ Emissions from Outlying Sites

If the source of contamination is distant from the facility, or if it is large in size, such as a landfill, the contaminated air will envelope the facility. In such cases, local changes to the outside air intakes cannot solve the problem.

WESINC

Fig. 2 Air intakes for a public library The intakes are below grade, surrounded by small bays that accumulate debris. The bay at right is located behind bushes, where leaves, soil, and other matter fall directly into it.

Shield Intakes and Exhausts from Wind

Wind can cause significant changes in outside air intake and building pressurization. The kinetic energy of wind that strikes the upwind side of a building is partially converted into static pressure. If there is an opening in the building envelope, such as an air intake or relief, this increased static pressure is transmitted throughout the air handling system. Wind pressure can radically change the percentage of outside air that enters the air handling system.

The effect of wind on an outside air intake is minimized if the intake and relief dampers face in the same direction, because the wind pressure is balanced in the two. However, this same configuration maximizes building pressure effects caused by wind.

The positive pressure created by wind on the upwind side of the building is stronger than the negative pressure created on the downwind side. Buildings are poor airfoils, so the velocity of wind on the downwind side is mostly converted to turbulence rather than to negative static pressure.

Try to install air intakes, reliefs, and exhausts in shielded locations where the effects of wind pressure are averaged out. A shielded enclosure located on the roof approximates neutral pressure.

If you have to install an intake or discharge on the side of a building, reduce the effect of wind by installing a deflecting hood. A simple hood that faces downward or upward may not do the job. When air strikes a wall, it must turn and flow along the surface. The direction of the flow may be up, down, or sideways, depending on the wind direction and the location on the wall. Therefore, if you have to install an intake or exhaust in a wall, try to install a hood that shields in all directions.

The hoods used by restaurant exhaust fans are a good example. These have the shape of large mushrooms. They are not an elegant addition to the decor. If

appearance matters, you can hide them with a porous decorative screen of some kind.

Design to Avoid Recirculation of Building Exhaust

A facility's own exhaust air is likely to be recirculated to some extent, perhaps from one air handling system to another. If the building exhaust does not contain dangerous contaminants, the small amount of recirculation that occurs in a typical facility is harmless.

The amount of recirculation depends on the air discharge and intake velocities, on the relative locations of the grilles, and on wind. The amount of recirculation may vary radically from moment to moment. Certain conditions can greatly increase recirculation. It is common practice to run both the intake and relief ducts to the closest point in the building envelope, often right next to each other. This sloppy practice allows exhaust air to short-circuit from the relief air grille to the adjacent air intake.

Approach a recirculation problem by studying the geometry of the situation. The best approach is to move either the outside air intake or the exhaust to a location where wind or convection cannot cause recirculation. In retrofit, this is likely to be expensive.

A less effective, but cheaper, approach is to install deflectors over the intake and relief that face in different directions. For example, if both are at the same level, the relief might have a deflector that directs the exhaust upward, while the intake is equipped with a hood that draws air from below. Design upward-facing deflectors to shed the rain water and debris that they will collect. For the reasons stated previously, deflectors that point in a particular direction are undesirable if wind can blast against the wall where the deflectors are installed.

If the exhaust air may be dangerous, a common solution is to discharge the exhaust from the roof with a high-velocity stack. Figure 3 shows examples. This requires exhaust fans of higher power to provide the necessary velocity. This solution is satisfactory only if the dangerous contaminants are decomposed or diluted sufficiently before they get back to earth. Wind and convection may defeat the protective action of high velocity exhaust.

For example, in one tall laboratory building where lethal microorganisms may have been discharged from the roof exhaust, it was found that the exhaust was being recirculated into the air intakes of the same building. The intakes were located below ground level. In summer, the cool exhaust air was heavier than the ambient air, and it fell to the ground on days when there was little wind.

If dangerous materials may be exhausted from the building, exhaust alone may not be the answer. Safety may require sterilizing the exhaust before releasing it into the environment. If you have a potentially dangerous situation, get an expert to help you solve it.

Exploit Local Differences in Ambient Air Temperature

The temperature of the air that surrounds a building is not uniform, especially during the daytime. For example, the air next to a wall exposed to sunlight may be 10°F warmer than the air next to a shaded wall. In a cool climate, it would be desirable to capture this thin layer of heated air. Conversely, in a warm climate, it would be desirable to avoid taking in this warmer air.

If you want to exploit this opportunity, understand how the air is heated and cooled. For all practical purposes, air itself does not gain or lose heat by radiation. Air cannot be warmed directly by the sun, and it cannot lose heat directly into the sky.

WESINC

Fig. 3 High-velocity exhaust stacks These exhaust stacks on a laboratory building reduce recirculation into the building. This method cannot completely eliminate recirculation. If the exhausted air is cooler than the surrounding air, it will fall back to the surface. Under such conditions, wind is needed to carry away the exhaust.

Instead, the differences in air temperature result from contact with the building or its surroundings. The solid surfaces of the building absorb solar radiation, which warms the surfaces, and the surfaces warm the adjacent air by conduction. Shaded portions of the buildings and its surroundings lose heat by radiation, become cooler, and cool the adjacent air by conduction.

The warmed or cooled air exists in a thin layer that is difficult to capture. For example, even though a black roof can become very hot, the heated air layer next to the roof is thin, and it escapes by convection and is blown away by wind.

To maximize useful air heating, you could cover the roof with glazing to channel the air on the way to the air intake. This exploits the greenhouse principle. Doing the same to a sunlit wall creates a so-called Trombe wall. You could pass the air through a glazed box, which is called a solar air heater. All these methods are expensive because they require a lot of expensive glazing material. (This is one of the fundamental problems of solar energy. See [Reference Note 23](#), Non-Fossil Energy Sources, for more about solar collectors.)

Specialized circumstances are needed to exploit the cooling of air by shaded surfaces. Air that is cooled by conduction becomes heavier and falls off the surface. The cooled air will not accumulate enough to be useful unless it is confined to an area where it can be collected, such as a shaded courtyard.

Exploiting natural cooling is limited by the volume of cooled air available. Typical ventilation guidelines call for the air in a building to be completely replaced one to three times per hour. Most facilities do not have an outside reservoir of cool air that is large enough to replenish the building air throughout the day.

In climates where both heating and cooling are significant loads, you would need one outside air intake for cooling and another for heating, along with foolproof controls to ensure that the proper intake is selected. With dual duct and multizone air handling units, an intake in

a warm location might be used for the hot deck and an intake in a cool location for the cold deck.

In summary, if you have flexibility in locating your air intakes, try to find locations that exploit localized temperature variations. But, don't expect to save a lot of energy this way unless exceptional circumstances exist.

ECONOMICS

SAVINGS POTENTIAL: *Varies widely. In the worst cases, wind effects may increase outside air intake severalfold, wasting the energy needed to condition this air. Effective shielding of intakes and exhausts can eliminate most of this waste, but not all of it.*

Bad intake design may cause air quality problems. This can waste energy by motivating the staff to increase the amount of outside air in response to the bad air quality.

Conversely, ingenious methods of capturing air heat at the intake may save as much as 10% in outside air heating energy.

COST: *In new construction, optimizing the design of envelope penetrations may not cost much. The cost of modifying existing penetrations varies widely.*

PAYBACK PERIOD: *Several months, to many years.*

TRAPS & TRICKS

TURN PROBLEMS INTO OPPORTUNITIES: *Look at your mechanical system drawings and catalog all the places where air enters and leaves the facility. Then, walk around and check them all for potential problems, such as intakes close to exhausts, openings facing into a prevailing wind, a truck dock adjacent to an air intake, heavy debris on screens, etc. Be aware of complaints about indoor air quality, but don't instigate them. Problems can often be fixed in a variety of ways. Look for ways to draw heating air off a hot roof, cooling air from a shaded courtyard, etc. Don't create eyesores.*

MEASURE 4.2.10 Minimize the use of extra heat for freeze protection.

RATINGS

<small>New Facilities</small>	<small>Retrofit</small>	<small>O&M</small>
A	B	

Air handling systems are vulnerable to freeze damage if they contain water (hydronic) or steam coils. Water coils used for either cooling or heating are vulnerable. When the system fans are running, the main hazard is entry of cold air through the outside air intake. When the fans are not running, cold air may be able to leak into the system through any of the entry or exit points.

When cold weather comes, facilities may waste energy in the methods they use to prevent coil freezing. The most wasteful practice is keeping the air handling system in operation just to prevent freezing. The freeze protection features of the air handling system may also waste energy throughout the rest of the year.

This Measure explains the methods that you can use to protect the system from freezing without wasting energy. These include changes to design, improvement in installation details, and better operating practices. Select the method, or combination of methods, that is most effective for your systems.

How to Protect Water (Hydronic) Coils from Freezing

■ **Use Antifreeze**

The most reliable method of protecting hydronic coils from freezing is using an antifreeze solution in the hydronic system. The only failure mode is neglecting to replace antifreeze that is lost through leakage or maintenance.

Antifreeze is relatively inexpensive. If it is removed from the system for maintenance, it can be reused.

Antifreeze solutions have two efficiency disadvantages. Both of them result from characteristics of the liquid that are shown in Figure 1. One characteristic is that ethylene glycol has less effective heat transfer than pure water. As a result, all the coils in the system must operate with higher temperature differentials. This effect is insignificant with heating systems. With cooling systems, it forces the chiller to operate at a somewhat lower evaporator temperature. This lowers the chiller efficiency. (Measure 2.2.1 explains why.)

The reduced heat transfer also reduces the heating or cooling capacity of the system.

Another efficiency disadvantage is that antifreeze solutions require more pump power to deliver a given amount of heat. This is primarily because glycol has a lower specific heat than water.

In new construction, design the system to account for these factors. If an existing system was not designed for use with antifreeze, it is still likely to have enough reserve capacity to handle it.

The common antifreeze solution for hydronic systems is ethylene glycol, the same antifreeze used in automobiles. (The ethylene glycol used in HVAC systems has different additives than the ethylene glycol used in automobiles. Don't substitute these products for each other.) In unusual applications where the toxicity or environmental effects of ethylene glycol may be a problem, use propylene glycol. It is non-toxic. In fact, it is used as a food additive.

Antifreeze can be added to most water systems, including chilled water and heating water systems. An exception is systems where the water is exposed for evaporative cooling, such as "waterside economizer" systems that use an open cooling tower.

■ **Drain the Coils**

If the cooling coil is hydronic, the coil can be protected by draining it during periods of the year when freezing is a possibility. In most applications, it is practical to do this only on a seasonal basis. The main failure mode with this method is forgetting to drain the coil.

This method is desirable for applications where mechanical cooling is never needed during the period of the year when freezing may occur. Cooling can still be provided by an outside air economizer cycle (see Measure 4.2.5) even if the cooling coil is drained.

If the air handling system has water coils that are used for heating, other methods are needed to protect those coils.

How to Protect Steam Coils from Freezing

Protecting steam coils from freezing is a bigger challenge. If the flow of steam to a steam coil is throttled, condensation of the steam causes the pressure inside the coil to fall below atmospheric. The pressure of the atmosphere outside the coil then keeps condensate from draining. As a result, water may accumulate in the coil, the condensate piping, and steam traps. The condensate may freeze in parts of the equipment and rupture it, even though the coil is operating.

The most reliable way to protect the steam coil itself from freezing in extreme cold conditions is to eliminate the inlet valve, so the entire coil remains at full pressure and temperature. Heat output from the coil usually is controlled by face-and-bypass dampers.

This arrangement is susceptible to energy waste from air leakage because the dampers are large and the wide-open steam coil is very hot. Design the system controls to shut down the coil and drain it whenever it is not needed. Make sure that the dampers cannot leak enough hot air to exceed the heating requirements of the system under any operating condition. If the dampers leak excessive heat into the system, some form of cooling (either mechanical cooling or free cooling) is needed to cancel the excess heat.

If a throttling valve is used with a steam coil, freeze protection can be accomplished by installing vacuum breakers on the coil and on the steam traps to allow condensate to drain, as shown in Figure 2. This method is less reliable. Throttled steam coils must operate in cycles to allow condensate to drain. As a result, the temperature of the air through the coil fluctuates continually. For this reason, throttling a steam coil is inadvisable if the system cannot tolerate large temperature fluctuations.

You have to protect the condensate piping using different methods. The first step is to install the condensate piping so that all of it drains easily. In colder climates, keep the condensate lines warmed. Insulation may be sufficient for this purpose. However, insulation may not be completely reliable, because a low rate of condensate drainage may allow the condensate pipe to cool enough to freeze. If the incoming air is especially cold, or if the condensate pipe is long, install heat tracing on the condensate pipe.

Select steam traps with an eye toward their resistance to freeze damage. Unfortunately, all efficient types of traps are vulnerable to freezing to some extent, and other selection factors may conflict with freeze protection. See [Measure 1.10.3](#) for the characteristics of steam traps.

How to Use Preheat Coils for Freeze Protection

Many air handling systems have a preheat coil installed in the outside air intake. Typically, the preheat coil is used only to bring the outside air up to a modest temperature, while the main heating coil in the air

handling unit warms the return air and finishes the heating of the outside air in response to heating requirements. The usual reason for installing a preheat coil is to prevent freezing of the main air handling unit coils (both heating and cooling coils). Using a preheat coil for freeze protection provides a number of advantages:

- the preheat coil is sized only for the outside air flow, rather than the total system flow. Therefore, a preheat coil can be smaller and less expensive than a coil installed inside the air handling unit.
- the preheat coil offers resistance only to intake air, which reduces the fan power required to draw air through the coil
- system design is simplified by eliminating large variations in temperature at the main coils, and by eliminating the need to include freeze protection measures in the main coils
- by bringing the temperature of the outside air closer to the temperature of the return air, preheating minimizes the adverse effects of stratification. The preheat coil itself may reduce stratification by acting as a baffle to disperse the entering air stream. (Stratification is covered in [Measure 4.2.11](#), next.)

Preheat coils are specially designed to resist freezing. They typically have short steam or hot water circuits consisting of straight tubes or U-bends, rather than long serpentine coils. This reduces the chance of overcooling the outlet ends of the circuits. With steam coils, the short tubes allow better condensate drainage. Steam or hot water is admitted to the air inlet side of the coil face, so that the air is warmed before it comes into contact with the outlet end of the coil. This is called “parallel flow,” which is less efficient from a heat transfer standpoint than the “counterflow” pattern that is used

in conditioning coils. Steam preheat coils may have steam distributor tubes installed inside the heating tubes to ensure uniform temperature across the entire coil surface.

Adding a preheat coil on a retrofit basis is too expensive, unless the system has a major freeze protection problem that cannot be solved by the methods given previously.

■ Optimize the Preheat Temperature

In systems where a preheat coil is installed, energy may be wasted if the preheat temperature is set too high. This possibility occurs when the coolness of the outside air is useful for cooling the building, whether or not the cooling coil is operating. In other words, you are trying to keep the preheat coil from interfering with the operation of an outside air economizer cycle. (See [Measure 4.2.5](#) for the details of economizer cycles.)

In this case, energy waste may occur even if the preheat temperature is much lower than the supply air temperature. The reason is that a relatively small amount of outside air may be mixed with a relatively large amount of return air. The return air is warmer than the supply air, so the outside air would have to be much colder than the supply air to make the mixed air cooler than the supply air.

In single-zone systems and terminal reheat systems, you can avoid or minimize this energy waste by setting the preheat temperature as low as possible. See Figure 3. If possible, set the preheat coil thermostat to keep the entering air temperature just above freezing during normal system operation.

In dual-duct and multizone systems, follow the same practice of keeping the preheat temperature as low as possible. There is an exception if the preheat coil uses a cheaper fuel than the heating coil in the air handling unit. In that case, you have to calculate the preheat coil discharge temperature that yields the lowest overall operating cost. The answer depends on the magnitudes of the heating and cooling loads of the spaces served by the system.

The preheat coil may have to operate when the air handling unit is turned off in order to provide makeup air for exhaust fans. During that mode of operation, the controls must allow the preheat coils to produce an air temperature that is suitable for keeping the spaces warm.

■ Using Unit Heaters as Preheaters

Unit heaters are sometimes installed in the space between the outside air dampers and the cooling coil to provide freeze protection. In order for this method to work reliably, the unit heaters must be able to circulate warmed air throughout the space in front of the coil. Otherwise, a portion of the coil may freeze. If the fans are operating, the strong flow of air into the system may not allow adequate mixing to occur.

Unit heaters are fairly reliable as a method of preventing coil freezing when the fans are not running. If the dampers are leaky, the unit heaters will consume a lot of energy in attempting to heat the outdoors. A preheat coil that is installed intelligently will waste less energy in this way.

Don't Depend on Exhaust Air Heat Recovery for Freeze Protection

You may see exhaust air heat recovery promoted as a method of freeze protection. The idea is that heat removed from the exhaust air stream warms the incoming outside air. (See [Measure 4.2.8](#) for details.) Unless the outside air is extremely cold, the heat recovered in this way is sufficient to prevent coil freezing. However, the heat recovery system provides freeze protection only as long as the fans are operating. Therefore, this benefit is useful only in applications that operate continuously, such as hospital wards and hotel lobbies.

Furthermore, the heat recovery system can fail, or it can be turned off. Therefore, if you plan to exploit the system for freeze protection, stress reliability in selecting it.

Efficient Freeze Protection When the System is Shut Down

When the main fans of the air handling system are running, the freeze hazard is limited to entry of cold air through the outside air intake. When the fans are not running, cold air may be able to leak into the system through any of the entry or exit points of the system. Every entry and exit point in the system, including exhaust fans throughout the building, should have dampers that close tightly.

Tightly closing dampers are an important energy conservation feature, but do not rely on dampers as a primary method of freeze protection. All dampers leak, and the leakage gets worse with time. Also, dampers are vulnerable to defects that keep them from closing fully. The best defense is to make the coils themselves freeze-proof.

If the air handling unit has a heating coil, keeping the coil warm protects all the coils on the downstream side of the heating coil. If there are exhaust fans that continue to operate, the heating coil warms the air entering the building.

One weakness of this method is that it does not protect the interior of the building from infiltration that occurs through the return portion of the air handling system. With the main fans turned off, the return duct is another avenue for air to enter the building. This makes it important to have exhaust air dampers and recirculation dampers that close tightly when the main fans turn off.

Keeping the heating coil active is not entirely reliable as a method of freeze protection. It fails if the source of steam or hot water fails, or if the coil itself is turned off. Also, in some configurations, enough cold air may bypass the heating coil to freeze the cooling coil. The heating coil itself may freeze at the discharge end if it has no antifreeze, because of the low flow rate through the coil.

WESINC

Fig. 3 Air handling system temperature controls These settings can have a major effect on system energy consumption. In single-zone and reheat systems, do not raise the preheat coil discharge temperature higher than needed to avoid freezing and stratification.

■ Damper Improvements

See [Measure 4.2.2](#) for the characteristics of good dampers. As suggested there, consider a combination of dampers. In addition to normal control dampers, which have a certain amount of leakage, another set of tightly closing dampers is used when the system is shut down. This arrangement is unusual and it involves extra cost. In new construction, it may pay for itself quickly. It may be difficult to retrofit.

■ Wind Protection

Wind is the main force that drives leakage through outside air dampers when the fans are turned off. As an adjunct to effective dampers, install wind deflecting hoods over the envelope penetrations where air enters and leaves the air handling system. Protection against wind is covered by [Measure 4.2.9](#).

If the system is vulnerable to freezing, wind deflectors are important even if high winds occur only rarely. Wind pressure is proportional to the square of wind speed. A high wind velocity that occurs only once in several years may be able to force enough cold air past closed dampers to freeze vulnerable coils.

■ Effect of Duct Configuration on Air Leakage

The fact that a coil is installed far from the building envelope may provide less protection than your intuition may suggest. The duct connecting the coil to the outside provides virtually no resistance to air flow. Good dampers are the only effective barrier to air flow.

A difference in height between the coil and the envelope penetration may have some effect on air entry. If the penetration is above the coil, convection tends to force warm interior air through the damper to the outside. If the penetration is below the coil, convective force tends

to oppose the flow of outside air into the system. Convective force is much weaker than wind, unless an air passage is very tall.

■ Control of Space Exhaust Fans

The outside air damper cannot be closed if exhaust fans are kept running anywhere within the portion of the building served by the air handling system. Whenever exhaust fans operate, the heating coils must operate to warm the outside air that replaces the exhausted air. Exhaust fans, such as toilet exhausts, may be operated unnecessarily during off hours. Refer to [Measure 4.2.1.1](#) for methods of minimizing the operation of exhaust fans.

Avoid Unnecessary Energy Use for Freeze Protection

Don't expend energy for freeze protection when there is no need for it. During warm weather, unnecessary heating for freeze protection can waste cooling energy as well as heat.

■ Prevent Coil Valve Leakage

Leaking throttling valves on steam and hydronic heating coils cause them to lose heat continuously, even during periods when heating is not needed. This energy waste may remain undetected for years. Throttling valves on preheat coils tend to develop leakage because they operate for long periods at low output. This hastens erosion of seating surfaces ("wire drawing") that occurs when a valve is barely open.

You can detect valve leakage when the valve is supposed to be turned off by feeling the temperature of the pipe that connects the valve to the coil. This is a matter of good routine maintenance.

Most coils are fitted with isolation valves for maintenance purposes. Turn these valves off during periods when the coils are not needed. This reduces erosion of the control valves, and prevents energy loss if the control valves leak. This function is easy to forget, so install effective placards on the isolation valves to

get the attention of the operating staff. See [Reference Note 12, Placards](#), for placard design and installation procedures.

■ Minimize Stratification

Stratification of the air flow through the air handling unit may cause unnecessary preheat by confusing the freeze protection thermostats. If the cold portion of a stratified air stream passes over the thermostatic element of a freezestat or preheat control, this increases coil heat output.

The adverse effects of stratification are covered in [Measure 4.2.11](#), along with remedies. Make a point of minimizing stratification whenever you modify the outside air intakes.

ECONOMICS

SAVINGS POTENTIAL: 0.5 to 5 percent of conditioning energy.

COST: Varies widely, depending on the nature of the repairs or modifications required.

PAYBACK PERIOD: Less than one year, to many years.

TRAPS & TRICKS

RECOGNIZE PROBLEMS: Check all the places where preheat is used. Don't be surprised if what you see does not match the drawings. Carry a thermometer to check that preheat is not being used excessively. Check for dampers that are poorly designed, poorly selected, or poorly installed. If you have steam coils and you are not a steam heating expert, get help.

EXPLAIN IT: Describe preheat controls in the plant operating manual. Install placards at controls that explain what they do, and state the correct settings.

MONITOR PERFORMANCE: Schedule periodic checks of your freeze protection equipment and controls during the heating season.

In air handling systems, “stratification” means that the air entering the coils of the air handling unit is not at a uniform temperature. Stratification is caused by failure of the incoming outside air to mix thoroughly with the recirculated air. As a result, air enters different parts of the coils at different temperatures. Stratification in an air handling unit is a simple phenomenon, although it may not be easy to fix. It is depicted in Figure 1.

In many air handling systems, stratification is serious enough to cause coil freezing, to reduce comfort, and/or to reduce system efficiency. Stratification is likely to occur unless the air handling unit, and the duct connections leading to the air handling unit, are designed specifically to prevent it.

Stratification occurs because air is a viscous fluid that does not mix easily. You can see this behavior in airplane condensation trails, which remain distinct from the surrounding air. There is a common misconception that stratification is caused by convection that results from the temperature differences. This is not true. The air moves through the system too rapidly for convection to be significant. (Convection does cause stratification of air within a space, which is an entirely different process.)

Stratification occurs most commonly at the coils in the air handling unit. However, in the worst cases, it may extend all the way to individual ducts in the conditioned spaces. This Measure tells you how to avoid stratification, and separately, how to keep it from causing problems.

Problems Caused by Stratification

How serious a problem is stratification? It depends on the climate, the type of air handling system, and whether a preheat coil is used in the outside air intake. In general, stratification causes damage only during freezing weather. In some cases, it can cause discomfort before it causes damage. It can waste energy in invisible ways whenever the weather is cold or hot by making supply air temperatures less than optimum.

Stratification is most troublesome in cold weather, when the temperature difference between outside air and return air is greatest. The most dramatic effect of stratification is coil freezing. The desire to avoid this hazard motivates excessive heating for freeze protection. (See Measure 4.2.10 about freeze protection methods in general.)

A related problem is nuisance tripping of freezestats, which are protective devices that turn off the fans if a temperature is sensed that is low enough to freeze the

SUMMARY

Stratification is a common problem that wastes energy indirectly, and may cause comfort problems. It can be tricky to eliminate.

coils. Freezestats err on the side of safety, causing unnecessary shutdowns if stratification exists during cold weather.

Another effect is inaccurate system temperature control. This results from the temperature sensor being located either on the warm or cold side of the stratified air stream. Depending on the type and layout of the air handling system, inaccurate temperature control can result in discomfort, energy waste, or both. For example, the cooling coil discharge temperature in a terminal reheat system has a major effect on the amount of energy wasted by reheat.

Discomfort results if stratification can extend to the spaces. The discomfort is bad in its own right, and it motivates desperate corrective actions by occupants and staff that typically increase the waste of energy.

Blender Products, Inc.

Fig. 1 Stratification in an air handling system This is simply the tendency of air streams to maintain their individual identities. It may cause trouble when one air stream is colder than the other.

Stratification Problem or Thermostat Problem?

Stratification always occurs when two air streams join, as in Figure 1. If it causes trouble, the question is whether they are caused by the stratification itself, or by the way that the thermostatic controls in the air handling unit respond to the stratification. For example, a particular coil may not be in danger of freezing, even though a portion of the coil is exposed to freezing temperature by stratification. However, if the sensor of the thermostat is located where the incoming air is coldest, the air handling unit may be shut down by the thermostat.

There are two basic configurations of thermostat sensors used in air handling systems. One is a short probe that extends into the air stream. This type senses the air temperature only at the point where it is mounted. If a temperature sensing problem is caused primarily by the probe location, you can usually find a satisfactory place to relocate the probe.

Another common type of thermostat uses a long capillary that is stretched across the face of the coil. Contrary to appearances, this type of sensor does not average the temperature across the face of the coil. Instead, it responds preferentially to the lowest temperature on the capillary. This is because the capillary contains a liquid in equilibrium with a vapor. The coldest point on the capillary removes vapor by condensation, reducing the pressure that actuates the thermostat.

How to Visualize the Problem

You normally can't see directly how the air flows through an air handling system, but you need to have a clear picture of stratification problems to plan your corrective measures. In designing new facilities, you have to learn from experience with existing systems. The methods of avoiding stratification that are given below summarize this experience.

In existing facilities, you can visualize stratification by taking temperature measurements around the perimeter of the duct. You can take measurements from outside the duct by drilling holes to insert a thermometer. (Seal the holes afterwards.) The pattern of stratification is easier to visualize during colder weather, when the temperature differences in the stratified air stream are greatest.

Make temperature measurements upstream of the coils to determine whether there is a freeze problem. Make temperature measurements downstream of the coils to determine whether the coil discharge temperature is uniform. Make temperature measurements in different zone ducts to determine whether stratification is causing space temperature variations.

A smoke streamer can provide a dramatic visual clues to stratification. However, inserting the smoke and seeing it may take some effort. To see the smoke pattern, cover access panels or doors with transparent

plastic. Make sure to announce the smoke tests to the occupants of affected spaces.

You can get a general impression of the potential for stratification by looking at the configuration of the system. In general, mixing occurs best when the geometry of the air handling system causes separately entering air streams to slam into each other. For example, in Figure 1, the return air enters the air handling unit perpendicular to the outside air stream, tending to mix the streams.

Stratification is greatly affected by the velocities of the air streams. Stratification tends to be severe when both air streams are moving at low velocity, regardless of the system configuration. If an air stream moves slowly, it hugs the side of the passage on which it enters.
