The following articles are U.S. government works in the public domain:

- “Abundance Estimates” by Anne E. York
“Age Estimation” by Aleta A. Hohn
“Albinism” by Patricia E. Rosel
“Australian Snubfin Dolphin” by Kelly M. Robertson
“Beaked Whales” by James G. Mead
“Blue Whale” by William F. Perrin
“Bowhead Whale” by David J. Rugh
“Bryde’s Whales” by William F. Perrin
“California, Galapagos and Japanese Sea Lions” by William F. Perrin
“Cetacean Ecology” by Lisa T. Ballance
“Cetacean Life History” by Susan J. Chivers
“Climate Change” by Sue E. Moore
“Coloration” by William F. Perrin
“Common Dolphins” by William F. Perrin
“Crabeater Seal” by John L. Bengtson
“Cuvier’s Beaked Whale” by James G. Mead
“Elephant Seals” by William F. Perrin
“Endangered Species and Populations” by Douglas P. DeMaster,
Richard Merrick and Gregory K. Silber
“Gastrointestinal Tract” by James G. Mead
“Genetics for Management” by Phillip A. Morin
“Geographic Variation” by William F. Perrin
“History of Marine Mammal Research” by William F. Perrin
“Humpback Whale” by Phillip J. Clapham
“Indo-Pacific Beaked Whale” by Robert Pitman
“Krill and Other Plankton” by Roger Hewitt and Jessica D. Lipsky
“Management” by Jay Barlow
“Mating Systems” by Sarah L. Mesnick and Katherine Ralls
“Melon-headed Whale” by Wayne L. Perryman
“Mesoplodont Whales” by Robert Pitman
“Minke Whales” by William F. Perrin and Robert L. Brownell, Jr.
“Museums and Collections” by James G. Mead
“North Atlantic Marine Mammals” by Debra L. Palka and Gordon T. Waring
“Ocean Environment” by Paul C. Fiedler
“Pantropical Spotted Dolphin” by William F. Perrin
“Population Dynamics” by Paul R. Wade
“Population Status and Trends” by Jay Barlow
“Pygmy Killer Whale” by Meghan A. Donahue and Wayne L. Perryman
“Ribbon Seal” by Peter Boveng
“Right Whale Dolphins” by Jessica D. Lipsky
“Rookeries” by George Anthony Antonelis
“Sexual Dimorphism” by Sarah Mesnick and Katherine Ralls
“Shepherd’s Beaked Whale” by James G. Mead
“South American Sea Lion” by William F. Perrin
“Species” by William F. Perrin
“Spinner Dolphin” by William F. Perrin
“Stock Assessment” by Jeffrey M. Breiwick and Anne E. York
“Stranding” by William F. Perrin
“Striped Dolphin” by Frederick I. Archer, II
“Surveys” by Karin A. Forney
“Sustainability” by Charles W. Fowler
“Tuna-Dolphin Issue” by Tim Gerrodette
“Whaling, Modern” by Phillip J. Clapham
“Whaling, Illegal and Pirate” by Robert L. Brownell

		Dusky Dolphin (<i>Lagenorhynchus obscurus</i>) Koen Van Waerebeek and Bernd Würsig	335

E

Eared Seals (<i>Otariidae</i>) Roger L. Gentry	339
Earless Seals (<i>Phocidae</i>) Mike O. Hammill	342
Echolocation Whitlow W.L. Au	348
Ecological Effects of Marine Mammals James A. Estes	357
Ecology, Overview Bernd Würsig	361
Elephant Seals (<i>Mirounga angustirostris</i> and <i>M. leonina</i>) Mark A. Hindell and William F. Perrin	364
Endangered Species and Populations Richard Merrick, Gregory K. Silber, Douglas P. DeMaster, and John E. Reynolds, III	368
Endocrine Systems Shannon Atkinson, David St. Aubin, and Rudy M. Ortiz	375
Energetics Daniel P. Costa	383
Entrapment and Entanglement Jon Lien	391
Estrus and Estrous Behavior Daryl J. Boness	392
Ethics and Marine Mammals Marc Bekoff	396
Extinctions, Specific Deborah A. Duffield	402

F

False Killer Whale (<i>Pseudorca crassidens</i>) Robin W. Baird	405
Feeding Morphology Christopher D. Marshall	406
Feeding Strategies and Tactics Michael R. Heithaus and Lawrence M. Dill	414
Female Reproductive Systems R.E.A. Stewart and B.E. Stewart	423
Filter Feeding Donald A. Croll, Bernie R. Tershy and Kelly M. Newton	429
Fin Whale (<i>Balaenoptera physalus</i>) Alex Aguilar	433
Finless Porpoise (<i>Neophocaena phocaenoides</i>) Masao Amano	437
Fisheries, Interference With Dagmar Fertl	439
Fishing Industry, Effects Of Simon Northridge	443
Folklore and Legends Rochelle Constantine	447
Forelimb Anatomy Lisa Noelle Cooper	449
Forensic Genetics C. Scott Baker and Merel L. Dalebout	453
Fossil Sites, Noted R. Ewan Fordyce	459
Franciscana Dolphin (<i>Pontoporia blainvillei</i>) Enrique A. Crespo	466

Fraser's Dolphin (<i>Lagenodelphis hosei</i>) M. Louella L. Dolar	469	Harbor Seal and Spotted Seal (<i>Phoca vitulina</i> and <i>P. largha</i>) John J. Burns	533
G			
Gastrointestinal Tract James G. Mead	472	Harp Seal (<i>Pagophilus groenlandicus</i>) David M. Lavigne	542
Genetics for Management Phillip A. Morin and Andrew E. Dizon	477	Health Joseph R. Geraci and Valerie J. Lounsbury	546
Genetics, Overview Per J. Palsbøll	483	Hearing Sirpa Nummela	553
Geographic Variation William F. Perrin	492	Hind Limb Anatomy Peter J. Adam	562
Giant Beaked Whales (<i>Berardius bairdii</i> and <i>B. arnuxii</i>) Toshio Kasuya	498	History of Marine Mammal Research Bernd Würsig, William F. Perrin and J.G.M. Thewissen	565
Gray Seal (<i>Halichoerus grypus</i>) Ailsa Hall and David Thompson	500	Hooded Seal (<i>Cystophora cristata</i>) Kit M. Kovacs	569
Gray Whale <i>Eschrichtius robustus</i> Mary Lou Jones and Steven L. Swartz	503	Hourglass Dolphin (<i>Lagenorhynchus cruciger</i>) R. Natalie P. Goodall	573
Group Behavior Alejandro Acevedo-Gutiérrez	511	Humpback Dolphins (<i>Sousa chinensis</i> and <i>S. teuszii</i>) Guido J. Parra and Graham J.B. Ross	576
H			
Habitat Pressures Peter G.H. Evans	521	Humpback Whale (<i>Megaptera novaeangliae</i>) Phillip J. Clapham	582
Habitat Use Alejandro Acevedo-Gutiérrez	524	Hunting of Marine Mammals Randall R. Reeves	585
Hair and Fur Pamela K. Yochem and Brent S. Stewart	529	Hybridism Martine Bérubé	588
Harbor Porpoise (<i>Phocoena phocoena</i>) Arne Bjørge and Krystal A. Tolley	530	I	
		Identification Methods Randall S. Wells	593

Minke Whales (<i>Balaenoptera acutorostrata</i> and <i>B. bonaerensis</i>) William F. Perrin and Robert L. Brownell, Jr.	733	O	
Molecular Ecology A. Rus Hoelzel	736		
Monk Seals (<i>Monachus monachus</i> , <i>M. tropicalis</i> , and <i>M. schauinslandi</i>) William G. Gilmartin and Jaume Forcada	741		
Musculature J.G.M. Thewissen	744		
Museums and Collections John E. Heyning and James G. Mead	747		
Mysticetes, Evolution Annalisa Berta and Thomas A. Deméré	749		
N			
Narwhal (<i>Monodon monoceros</i>) M.P. Heide-Jørgensen	754		
Neoceti R. Ewan Fordyce	758		
New Zealand Sea Lion (<i>Phocarctos hookeri</i>) Nicholas J. Gales	763		
Noise, Effects Of Bernd Würsig and W. John Richardson	765		
North Atlantic Marine Mammals Gordon T. Waring, Debra L. Palka and Peter G.H. Evans	773		
North Pacific Marine Mammals Sergio Escorza-Treviño	781		
Northern Fur Seal (<i>Callorhinus ursinus</i>) Roger L. Gentry	788		
			The Ocean Environment Paul C. Fiedler 792
			Odobenocetops Christian de Muizon 797
			Omura's Whale (<i>Balaenoptera omurai</i>) Tadasu K. Yamada 799
			Osmoregulation Daniel P. Costa 801
			Otters, Marine J.A. Estes, J.L. Bodkin, and M. Ben-David 807
P			
			Pacific White-Sided Dolphin (<i>Lagenorhynchus obliquidens</i>) Nancy A. Black 817
			Pantropical Spotted Dolphin (<i>Stenella attenuata</i>) William F. Perrin 819
			Parasites J. Antonio Raga, Mercedes Fernández, Juan A. Balbuena and F. Javier Aznar 821
			Parental Behavior Janet Mann 830
			Pathology Daniel F. Cowan 836
			Peale's Dolphin (<i>Lagenorhynchus australis</i>) R. Natalie P. Goodall 844
			Pilot Whales (<i>Globicephala melas</i> and <i>G. macrorhynchus</i>) Paula A. Olson 847
			Pinniped Ecology W.D. Bowen, C.A. Beck, and D.A. Austin 852

Pinniped Evolution Annalisa Berta	861	Pygmy Right Whale (<i>Caperea marginata</i>) Catherine M. Kemper	939
Pinniped Life History Ian L. Boyd	868		
Pinniped Physiology Daniel E. Crocker and Daniel P. Costa	873		
Pinnipedia, Overview Annalisa Berta	878		
Playful Behavior Bernd Würsig	885		
Polar Bear (<i>Ursus maritimus</i>) Ian Stirling	888		
Pollution and Marine Mammals Peter J.H. Reijnders, Alex Aguilar and Asuncion Borrell	890		
Popular Culture and Literature Paul H. Forestell	898		
Population Dynamics Paul R. Wade	913		
Population Status and Trends Jay Barlow and Randall R. Reeves	918		
Porpoises, Overview Andrew J. Read	920		
Predation on Marine Mammals David W. Weller	923		
Predator–Prey Relationships Andrew W. Trites	933		
Pygmy and Dwarf Sperm Whales (<i>Kogia breviceps</i> and <i>K. sima</i>) Donald F. McAlpine	936		
Pygmy Killer Whale (<i>Feresa attenuata</i>) Meghan A. Donahue and Wayne L. Perryman	938		
		R	
		Remoras Dagmar Fertl and André M. Landry, Jr.	942
		Reproductive Behavior Michael A. Fedak, Ben Wilson and Paddy P. Pomeroy	943
		Ribbon Seal (<i>Histiophoca fasciata</i>) Lloyd Lowry and Peter Boveng	955
		Right Whale Dolphins <i>Lissodelphis borealis</i> and <i>L. peronii</i> Jessica D. Lipsky	958
		Right Whales (<i>Eubalaena glacialis</i> , <i>E. japonica</i> , and <i>E. australis</i>) Robert D. Kenney	962
		Ringed Seal (<i>Pusa hispida</i>) M.O. Hammill	972
		Risso’s Dolphin (<i>Grampus griseus</i>) Robin W. Baird	975
		River Dolphins Randall R. Reeves and Anthony R Martin	976
		River Dolphins, Evolutionary History and Affinities Christian de Muizon	979
		Rookeries George Anthony Antonelis	986
		Ross Seal (<i>Ommatophoca rossii</i>) Jeannette A. Thomas and Tracey Rogers	988

Rough-Toothed Dolphin (<i>Steno bredanensis</i>) Thomas A. Jefferson	990	South American Aquatic Mammals Enrique A. Crespo	1071
S			
Scrimshaw Stuart M. Frank	993	South American Sea Lion (<i>Otaria flavescens</i>) Humberto Luis Cappozzo and William F. Perrin	1076
Sea Lions: Overview Daryl J. Boness	998	Southern Fur Seals (<i>Arctocephalus</i> spp.) John P.Y. Arnould	1079
Sei Whale (<i>Balaenoptera borealis</i>) Joseph Horwood	1001	Species William F. Perrin	1084
Sensory Biology: Overview J.G.M. Thewissen	1003	Spectacled Porpoise (<i>Phocoena dioptrica</i>) R. Natalie P. Goodall	1087
Sexual Dimorphism Katherine Ralls and Sarah Mesnick	1005	Sperm Whale (<i>Physeter macrocephalus</i>) Hal Whitehead	1091
Shepherd's Beaked Whale (<i>Tasmacetus shepherdi</i>) James G. Mead	1011	Sperm Whales, Evolution Guram A. Mchedlidze	1097
Signature Whistles Laela S. Sayigh and Vincent M. Janik	1014	Spermaceti Dale W. Rice	1098
Sirenian Evolution Daryl P. Domning	1016	Spinner Dolphin (<i>Stenella longirostris</i>) William F. Perrin	1100
Sirenian Life History Daniel K. Odell	1019	Steller's Sea Cow (<i>Hydrodamalis gigas</i>) Paul K. Anderson and Daryl P. Domning	1103
Skeleton, Postcranial Sentiel Rommel and John E. Reynolds, III	1021	Steller Sea Lion (<i>Eumetopias jubatus</i>) Thomas R. Loughlin	1107

ORGANISMS AND FAUNAS

Amazon River Dolphin (*Inia geoffrensis*)
 Antarctic Marine Mammals
 Antarctic Fur Seal (*Arctocephalus gazella*)
 Arctic Marine Mammals
 Atlantic Spotted Dolphin (*Stenella frontalis*)
 Atlantic White-Sided Dolphin (*Lagenorhynchus acutus*)
 Australian Sea Lion (*Neophoca cinerea*)
 Australian Snubfin Dolphin (*Orcaella heinsohmi*)
 Baiji (*Lipotes vexillifer*)
 Baleen Whales (Mysticetes)
 Beaked Whales, Overview (Ziphiidae)
 Bearded Seal (*Erignathus barbatus*)
 Beluga Whale (*Delphinapterus leucas*)
 Blue Whale (*Balaenoptera musculus*)
 Bottlenose Whales (*Hyperoodon ampullatus* and *H. planifrons*)
 Bowhead Whale (*Balaena mysticetus*)
 Bryde's Whales (*Balaenoptera edeni* and *B. brydei*)
 Burmeister's Porpoise (*Phocoena spinipinnis*)
 California, Galapagos, and Japanese Sea Lions (*Zalophus californianus*, *Z. wollebaeki*, and *Z. japonicus*)
 Caspian and Baikal Seals (*P. caspica* and *P. sibirica*)
 Cephalorhynchus Dolphins (*C. heavisidii*, *C. eutropia*, *C. hectori*, and *C. commersonii*)
 Cetacea, Overview
 Clymene Dolphin (*Stenella clymene*)
 Common Bottlenose Dolphin (*Tursiops truncatus*)
 Common Dolphins (*Delphinus delphis* and *D. capensis*)
 Crabeater Seal (*Lobodon carcinophaga*)
 Cuvier's Beaked Whale (*Ziphius cavirostris*)
 Dall's Porpoise (*Phocoenoides dalli*)
 Delphinids, Overview
 Dugong (*Dugong dugon*)
 Dusky Dolphin (*Lagenorhynchus obscurus*)
 Eared Seals (Otariidae)
 Earless Seals (Phocidae)
 Elephant Seals (*Mirounga angustirostris* and *M. leonina*)
 False Killer Whale (*Pseudorca crassidens*)
 Finless Porpoise (*Neophocaena phocaenoides*)
 Fin Whale (*Balaenoptera physalus*)
 Franciscana (*Pontoporia blainvillei*)
 Fraser's Dolphin (*Lagenodelphis hosei*)
 Giant Beaked Whales (*Berardius bairdii* and *B. arnuxii*)
 Gray Seal (*Halichoerus grypus*)
 Gray Whale (*Eschrichtius robustus*)
 Harbor Porpoise (*Phocoena phocoena*)
 Harbor Seal and Spotted Seal (*Phoca vitulina* and *P. largha*)
 Harp Seal (*Pagophilus groenlandicus*)
 Hooded Seal (*Cystophora cristata*)
 Hourglass Dolphin (*Lagenorhynchus cruciger*)
 Humpback Dolphins (*Sousa chinensis* and *S. teuszii*)
 Humpback Whale (*Megaptera novaeangliae*)
 Indo-Pacific Beaked Whale (*Indopacetus pacificus*)
 Indo-Pacific Bottlenose Dolphin (*Tursiops aduncus*)
 Indo-West Pacific Marine Mammals
 Irrawaddy Dolphin (*Orcaella brevirostris*)
 Killer Whale (*Orcinus orca*)

Leopard Seal (<i>Hydrurga leptonyx</i>)	Shepherd's Beaked Whale (<i>Tasmacetus shepherdi</i>)
Manatees (<i>Trichechus manatus</i> , <i>T. senegalensis</i> , and <i>T. inunguis</i>)	South American Aquatic Mammals
Melon-Headed Whale (<i>Peponocephala electra</i>)	South American Sea Lion (<i>Otaria flavescens</i>)
Mesoplodont Whales (<i>Mesoplodon</i> spp.)	Southern Fur Seals (<i>Arctocephalus</i> spp.)
Minke Whales (<i>Balaenoptera acutorostrata</i> and <i>B. bonaerensis</i>)	Spectacled Porpoise (<i>Phocoena dioptrica</i>)
Monk Seals (<i>Monachus monachus</i> , <i>M. tropicalis</i> , and <i>M. schauinslandi</i>)	Sperm Whale (<i>Physeter macrocephalus</i>)
Narwhal (<i>Monodon monoceros</i>)	Spinner Dolphin (<i>Stenella longirostris</i>)
New Zealand Sea Lion (<i>Phocarctos hookeri</i>)	Steller's Sea Cow (<i>Hydrodamalis gigas</i>)
North Atlantic Marine Mammals	Steller's Sea Lion (<i>Eumetopias jubatus</i>)
Northern Fur Seal (<i>Callorhinus ursinus</i>)	Striped Dolphin (<i>Stenella coeruleoalba</i>)
North Pacific Marine Mammals	Susu and Bhulan (<i>Platanista gangetica gangetica</i> and <i>P. g. minor</i>)
Omura's Whale (<i>Balaenoptera omurai</i>)	Toothed Whales, Overview
Otters, Marine	Tucuxi and Guian Dolphin (<i>Sotalia fluviatilis</i> and <i>S. guianensis</i>)
Pacific White-Sided Dolphin (<i>Lagenorhynchus obliquidens</i>)	Vaquita (<i>Phocoena sinus</i>)
Pantropical Spotted Dolphin (<i>Stenella attenuata</i>)	Walrus (<i>Odobenus rosmarus</i>)
Peale's Dolphin (<i>Lagenorhynchus australis</i>)	Weddell Seal (<i>Leptonychotes weddellii</i>)
Pilot Whales (<i>Globicephala melas</i> and <i>G. macrorhynchus</i>)	White-Beaked Dolphin (<i>Lagenorhynchus albirostris</i>)
Pinnipedia, Overview	
Polar Bear (<i>Ursus maritimus</i>)	RESEARCH METHODOLOGY
Porpoises, Overview	Abundance Estimation
Pygmy and Dwarf Sperm Whales (<i>Kogia breviceps</i> and <i>K. sima</i>)	Age Estimation
Pygmy Killer Whale (<i>Feresa attenuata</i>)	Biogeography
Pygmy Right Whale (<i>Caperea marginata</i>)	Forensic Genetics
Ribbon Seal (<i>Histiophoca fasciata</i>)	Fossil Sites
Right Whale Dolphins (<i>Lissodelphis borealis</i> and <i>L. peronii</i>)	Genetics for Management
Right Whales (<i>Eubataena</i> spp.)	History of Marine Mammal Research
Ringed Seal (<i>Pusa hispida</i>)	Identification Methods
Risso's Dolphin (<i>Grampus griseus</i>)	Mark–Recapture
River Dolphins	Museums and Collections
Ross Seal (<i>Ommatophoca rossii</i>)	Paleontology
Rough-Toothed Dolphin (<i>Steno bredanensis</i>)	Stock Assessment
Sea Lions, Overview	Stock Identity
Sei Whale (<i>Balaenoptera borealis</i>)	Surveys
	Telemetry

PREFACE TO THE SECOND EDITION

Seven years have gone by since the first edition of the Encyclopedia of Marine Mammals was published. The field of marine mammalogy has continued to move at great speed, and significant changes have occurred, even in the roster of our subject animals with the discovery of new species (e.g., Omura's whale), and the disastrous extinction of another (the baiji). One conspicuous difference between the new and the first edition is the use of color throughout the volume, hopefully making it easier and more enjoyable to use. A number of illustrations of marine mammals, kindly provided by Brett Jarrett, are reproduced as they appeared in Jefferson *et al.* "Marine Mammals of the World" (2008) Academic Press.

In addition, authors were given the opportunity to update their chapters, and nearly all took advantage of this to include the latest

research results. Several new chapters have been added, covering areas of marine mammal science that have changed significantly, such as those related to climate change and the interface of ecology and conservation. The editors also decided to add conjoined chapters on subjects that were somewhat fragmented in the first edition (e.g., Aerial Behavior) and new chapters to make the volume more comprehensive (e.g., Sense of Balance). We hope that the new edition will get the same positive reception that the first edition enjoyed.

—The Editors

PREFACE TO THE FIRST EDITION

Marine mammals are awe inspiring, whether one is confronted with the underwater dash of a sea lion, a breaching humpback, or simply the sheer size of a beached sperm whale. It is no surprise that we are fascinated and intrigued by these creatures. Such fascination and curiosity brought us, the editors, to the study of marine mammals at the beginning of our careers, and they keep us excited now. To share the excitement and feed the curiosity of others, scientists or laypersons, we here attempt to summarize the field of marine mammalogy; in a very broad sense, including aspects of history and culture. This was the first reason to compile this encyclopedia.

The science of marine mammals goes back at least to Aristotle, who observed in 400 BC that dolphins gave birth to live young which were nursed with the mother's milk. Observations on the biology of marine mammals expanded throughout the Middle Ages, usually mixing freely with imagination and superstition. Konrad Gesner's *Historia Animalium* (1551), for instance, is a pictorial guide to the animals known in his time. Next to rhinos and seals, it also depicts the unicorn, the fabled mix of a horse and a narwhal. Interest greatly increased with the advent of hunting marine mammals on a large scale. Herman Melville's *Moby Dick* (1851) chronicles nineteenth century Western whaling and displays a curious mix of accurate natural history observations on whales with stubborn misconceptions (such as "whales are fish"). The great whaler/naturalist Charles Scammon accurately described the behavior and aspects of natural history of many species, albeit of necessity from his view behind gun and harpoon.

From these roots, marine mammal science has grown exponentially, especially since the Second World War. Unlike in earlier days, most contemporary research on marine mammals is carried out by observing living animals. Modern marine mammal studies combine aspects of mammalogy, ethology, ecology, animal conservation, molecular biology, oceanography, evolutionary biology, geology, and—in effect—all major branches of the physical and biological sciences, as well as some of the social sciences. This enormous breadth unfortunately necessitates that most marine mammalogists specialize, concentrating on one or a few aspects of marine mammal science and limiting the number of species that they study. Therein lies the second reason for compiling this encyclopedia: we aim to present a summary of the entire field for the scientist who needs information from an unfamiliar subfield.

As editors, we constrained what authors wrote as little as possible, applauding diversity and keeping to minimal guidelines. We consider modern marine mammals to include the mammalian order Cetacea (including whales, dolphins, and porpoises), the order Sirenia (dugongs and manatees), and many members of the order Carnivora: the

polar bear, the sea otter and marine otter, and the pinnipeds (true seals, sea lions, fur seals, and walruses). We asked the authors to follow Rice (1998) for the species-level taxonomy and nomenclature of the modern marine mammals (with certain exceptions, as noted in the Marine Mammal Species list), as his work is an excellent, generally accepted listing of diversity.

There is some overlap among the articles. This is not an accident. As in every scientific field, different workers in marine mammalogy have different perspectives on many technical issues and disagree strongly on some of them. We urge the reader to use the cross-indexing to peruse different accounts relating to the same question; on some matters the jury is still very much out, and the range of views is interesting and important.

Ours is an encyclopedia, an alphabetically arranged compilation of articles that are independent and multiauthored, the only such work on marine mammals. However, some other recent books form excellent complements to our work. For example, *Handbook of Marine Mammals* (S. H. Ridgway and R. J. Harrison, Academic Press, 1985–1999) is a series of compendia presenting descriptions of the marine mammal species. *Biology of Marine Mammals* (J. E. Reynolds III and S. A. Rommel, Smithsonian Institution Press, 1999) presents an overview of marine mammals based on a number of long review chapters. *Marine Mammals: Evolutionary Biology* (A. Berta and J. L. Sumich, Academic Press, 1999) presents a current review of the evolutionary aspects of marine mammal science in a textbook format. There are many other authored and edited books, monographs, and research papers, often on more specific topics or particular species. These are listed here in the bibliographies that follow each entry, and the interested reader is encouraged to make use of university libraries, major research libraries (such as in the Smithsonian Institute in Washington, DC, for example), and World Wide Web search engines to find out how to obtain specific reference works. In our modern computer-accessible information era, it is hardly ever appropriate to use the excuse "I cannot find the reference," and we hope that this encyclopedia serves as a text to help point the way.

We hesitated before agreeing to edit this encyclopedia. Marine mammalogy is an exceptionally broad field, ranging across many taxa and across disciplines from molecular genetics and microstructure to whaling history and ethics. We three are all cetologists: we study the evolution and biology of whales, dolphins, and porpoises, and we personally know relatively little about seals, sea cows, or whaling. But we rub shoulders with those who do know much about these things, in our laboratories and universities, in advisory bodies, and at conferences, so we were considered to be in a good position to elicit and edit articles from our colleagues. The project has been fatiguing

and sometimes exasperating but elevating nonetheless. We have learned a lot along the way. We owe a great deal to many people. First we thank our editors at Academic Press: Chuck Crumly (the Encyclopedia was his concept and owes its existence to his drive), Gail Rice, and Chris Morris, who all put up bravely with our editing and publishing amateurism and endless missteps and interventions. A very large number of colleagues acted as anonymous peer reviewers for the articles. But the most credit must go to the authors, who gave so freely of their time and expertise. The Encyclopedia is appropriately an international project: articles were authored by scientists in Argentina, Australia, Brazil, Canada, China, Denmark, France, Georgia, Germany, Japan, Mexico, The Netherlands, New Zealand, Norway, Peru, Russia, South Africa, Spain, the United Kingdom, and

the United States. The difficulties of such wide participation were eased by the Internet.

We and the authors have engaged in our tasks as a labor of love of our field. We hope that you find not only information in these pages, but also a sense of the excitement of the known and the mystery of the yet-to-be-explored. If this work so affects you, it will have been successful. We also hope that it will help stimulate our growing cadres of young colleagues, naturalists, conservationists, and citizens of earth to contribute to the efforts to save and protect these marvelous creatures of the seas.

GUIDE TO THE ENCYCLOPEDIA

The *Encyclopedia of Marine Mammals* is a complete source of information on the subject of marine mammals, contained within a single volume. Each article in the Encyclopedia provides an overview of the selected topic to inform a broad spectrum of readers, from researchers to students to the interested general public.

In order that you, the reader, will derive the maximum benefit from the *Encyclopedia of Marine Mammals*, we have provided this Guide. It explains how the book is organized and how the information within its pages can be located.

SUBJECT AREAS

The *Encyclopedia of Marine Mammals* presents articles on the entire range of marine mammal study. Articles in the Encyclopedia fall within seven general subject areas, as follows:

- Anatomy and Physiology
- Behavior and Life History
- Ecology and Population Biology
- Evolution and Systematics
- Human Effects and Interactions
- Organisms and Faunas
- Research Methodology

ORGANIZATION

The *Encyclopedia of Marine Mammals* is organized to provide the maximum ease of use for its readers. All of the articles are arranged in a single alphabetical sequence by title. An alphabetical Table of Contents for the articles can be found beginning on p. v of this introductory section.

As a reader of the Encyclopedia, you can use the alphabetical Table of Contents by itself to locate a topic. Or you can first identify the topic in the Contents by Subject Area and then go to the alphabetical Table to find the page location.

So that they can be more easily identified, article titles begin with the key word or phrase indicating the topic, with any descriptive terms following this. For example, “Noise, Effects Of” is the title assigned to this article, rather than “Effects of Noise” because the specific term *Noise* is the key word.

ARTICLE FORMAT

Each article in the Encyclopedia begins with an introductory paragraph that defines the topic being discussed and summarizes the

content of the article. For example, the article “Baculum” begins as follows:

The baculum (os penis) is a bone in the penis that occurs in small insectivorous placentals (orders Afrosoricida, Erinaceomorpha, and Soricomorpha), Chiroptera, Primates, Rodentia, and Carnivora. The corresponding element in females is the little-studied clitoris bone (os clitoridis), which has been documented for polar bears and several pinniped species, but presumably is present in all pinnipeds, and in marine and sea otters (it is present in the northern river otter, *Lontra Canadensis*).

Major headings highlight important subtopics that are discussed in the article. For example, the article “Intelligence and Cognition” includes the topics “Brain Size and Characteristics,” “Learning,” and “Behavioral Complexity in Nature.”

CROSS-REFERENCES

The *Encyclopedia of Marine Mammals* has an extensive system of cross-referencing. References to other articles appear in two forms: as designations within the running text of an article; and as indications of related topics at the end of an article.

An example of the first type, a cross-reference within the running text of an article, is this excerpt from the entry “Baleen Whales:”

External parasites, particularly WHALE LICE (cyanid crustaceans) and BARNACLES (both sessile and stalked) are common on the slower-swimming more coastal baleen whales such as gray, humpback, and right whales.

This indicates that the items “whale lice” and “barnacles,” which are set off in the text by small capital letters, appear as separate articles within the Encyclopedia.

An example of the second type, a cross-reference at the end of the article, can be found in the entry “Forensic Genetics.” This article concludes with the statement:

See Also the Following Articles:

Classification ■ Molecular Ecology ■ Stock Identity

This reference indicates that these three related articles all provide some additional information about forensic genetics.

BIBLIOGRAPHY

The Bibliography section appears as the last element of an article, under the heading “References.” This section lists recent secondary sources that will aid the reader in locating more detailed or technical information on the topic at hand. Review articles and research papers that are important to a more detailed understanding of the topic are also listed here.

The Bibliography entries in this Encyclopedia are for the benefit of the reader, to provide references for further reading or additional research on the given topic. Thus, they typically consist of a limited number of entries. They are not intended to represent a complete listing of all the materials consulted by the author or authors in preparing the article. The Bibliography is in effect an extension of the article itself, and it represents the author’s choice of the best sources available for additional information.

RESOURCES

The final pages of the *Encyclopedia of Marine Mammals* contain three important resources for the reader.

- *Species List*: This section provides a complete list of living and extinct marine mammal species.

- *Biographies*: This section provides biographical information for more than 50 noted scientists who made important contributions to the field of marine mammal study.

- *Comprehensive Glossary*: This section provides definitions for more than 1000 specialized terms that are used in the articles.

INDEX

Within the subject index entry for a given topic, references to general coverage of the topic appear first, such as a complete article on the subject. References to more specific aspects of the topic then appear below this in an indented list.

ENCYCLOPEDIA WEB SITE

The *Encyclopedia of Marine Mammals* maintains its own editorial Web Page on the Internet at:

<http://www.apnet.com/narwhal/>

This site gives information about the Encyclopedia project and features links to many related sites that provide information about the articles of the Encyclopedia. The site will continue to evolve as more information becomes available.

A

Abundance Estimation

STEPHEN T. BUCKLAND AND ANNE E. YORK

Abundance estimation covers the range of techniques by which the size of a population of marine mammals can be estimated. Such population size estimates are often referred to as “absolute” abundance estimates. When it is difficult to estimate absolute abundance with an acceptably low bias, relative abundance indices are often used instead. These are indices that are believed to be proportional to population size, apart from stochastic variation, allowing trends in the population in space and/or time to be assessed. The main techniques for abundance estimation (relative or absolute) are distance sampling, mark–recapture, migration counts, and colony counts.

I. Distance Sampling

Distance sampling (Buckland *et al.*, 2001, 2004) is the most widely used technique for estimating the abundance of cetaceans. The method is particularly suited to populations of animals that are readily detectable (at least at close quarters) and sparsely distributed over a large area.

The two primary methods of distance sampling are line transect sampling and point transect sampling. The latter method has seldom been applied to marine mammal populations, and we therefore concentrate mostly on line transect sampling. Another distance sampling method is cue counting, which was developed specifically for populations of large whales and the theory for which is closely similar to that for point transects. Distance sampling data may be analyzed using software Distance (Thomas *et al.*, 2006).

A. Line Transect Sampling

1. Survey Design In line transect sampling, the survey design comprises a set of straight lines, randomly or more commonly, systematically spread through the study area for which an abundance estimate is required. For marine mammal surveys, the lines are covered by a team of observers on a ship or boat, or by one or more observers in an aircraft. Because efficiency is improved if lines are placed perpendicular to density contours, a common design for inshore surveys is to have a series of parallel lines as far as possible perpendicular to the coastline. The study area is often divided into geographic blocks or strata, allowing different orientations of the grid of lines in different strata and allowing effort to be greater in high-density strata. For shipboard surveys especially, systematic zig-zag designs are often used because there is then no loss of expensive

Figure 1 The observer records an animal at detection distance r and detection angle θ , from which the perpendicular distance is calculated as $x = r \sin \theta$.

ship time in traversing off-effort (i.e., not searching for marine mammals) from one line to the next (Buckland *et al.*, 2004). The ship can then be continuously searching for marine mammals during day-light hours.

2. Assumptions The following three assumptions should hold:

- (1) Animals on or very close to the line are certain to be detected (see later).
- (2) Animals are detected before they respond to the presence of the observer, and nonresponsive movement is slow relative to the speed of the observer.
- (3) Distances are measured accurately (for ungrouped distance data), or objects are correctly allocated to distance interval (for grouped data).

Bias from nonresponsive movement is generally negligible, provided that the average speed of the animals is less than one-half of the speed of the observer. A fourth assumption is made in many derivations of estimators and variances: whether an object detected is independent of whether any other object is detected. Point estimates are robust to the assumption of independence, and robust variance estimates are obtained by taking the line to be the sampling unit, either by bootstrapping lines or by calculating a weighted sample variance of encounter rates by line.

We do not need to assume that animals are randomly distributed throughout the survey area, provided that lines are placed randomly with respect to the animals. This ensures that objects in the surveyed strip are uniformly distributed on average with distance from the line.

3. Estimation Perpendicular distances x are measured from the line to each detected animal. (We will consider the case that animals occur in groups later.) In practice, for shipboard surveys, detection distances r and detection angles θ are usually recorded, from which perpendicular distances are calculated as $x = r \sin \theta$ (Fig. 1). Suppose there are k lines of lengths l_1, \dots, l_k , with $L = \sum l_j$, and n animals are detected, at perpendicular distances x_1, \dots, x_n . Suppose that animals farther than some distance w from the line are not recorded. Then the “covered area” is $a = 2wL$, within which n animals are detected. However, not all animals within the surveyed area are detected. Let the effective half-width of the strip be $\mu < w$ (so that the proportion of animals within the covered area that are detected is μ/w). Then animal density (number of animals per unit area) is estimated by:

$$\hat{D} = \frac{n}{2\hat{\mu}L} \quad (1)$$

Abundance is estimated as $\hat{N} = A\hat{D}$, where A is the size of the study area. We therefore need an estimate $\hat{\mu}$ of μ . The software Distance provides comprehensive options for these analyses.

Animals often occur in groups, which we term “clusters.” If one animal in a cluster is detected, it is assumed that the whole cluster is detected, and the position of the cluster is recorded. Equation (1) then gives an estimate of the density of clusters. To obtain the estimated density of individuals, we must multiply by an estimate of mean cluster size in the population $\hat{E}(s)$:

$$\hat{D} = \frac{n\hat{E}(s)}{2\hat{\mu}L} \quad (2)$$

Because the probability of detection is often a function of cluster size, the sample of cluster sizes exhibits size bias. In the absence of size bias, we can take $\hat{E}(s) = \bar{s}$, the mean size of detected clusters. Several methods exist for estimating $\hat{E}(s)$ in the presence of size bias (Buckland *et al.*, 2001).

These methods assume that once a cluster of animals is detected, it is possible to record the size of that cluster accurately. For ship-board and aerial surveys, this often dictates that at least part of the survey is conducted in “closing mode.” After detection, search effort ceases, and the vessel closes with the detected cluster, to allow more accurate estimation of cluster size. This strategy also eases the difficulties of species identification. If “passing mode” is adopted, then underestimation of the size of more distant clusters might be anticipated. Regression methods for correcting size bias also correct for this bias, provided that the sizes of clusters on or close to the transect line are estimated without bias. Where cluster size estimation is problematic, observer training is usually necessary to ensure that bias is not large.

4. Multiple-Covariate Distance Sampling Whether an animal is detected is a function of many factors apart from distance of the animal from the line. Sea state, glare, observer, animal behavior, observation platform, cluster size are a few of the possible factors. When detection on the line is certain, we do not need to model the dependence of detection probability on all these factors, because estimation is pooling robust. However, it is often of interest to estimate how detectability is affected, and the methods to address this issue are available in chapter 3 of Buckland *et al.* (2004) and in Distance (Thomas *et al.*, 2006).

5. Modeling Density Surfaces There is an increasing interest in modeling density surfaces, so that animal density can be related to habitat or environmental variables, or so that abundance for a section of the survey region can be estimated with greater reliability and precision. Figure 2 was obtained using the methods of chapter 4 of Buckland *et al.* (2004) and shows density of minke whales (*Balaenoptera acutorostrata*) in the North Sea, estimated from the 1994 SCANS survey data (Hammond *et al.*, 2002).

6. Uncertain Detection on the Transect Line The standard line transect method assumes that animals on the line are certain to be detected. Double-platform methods in which observers search simultaneously from two platforms are therefore becoming commonplace. This allows extension of the standard methods to the case that animals on the line are not certain to be detected and also, given appropriate field methods, allows adjustment for responsive movement of animals prior to detection by the primary observers. The methods described in chapter 6 of Buckland *et al.* (2004) are available in Distance (Thomas *et al.*, 2006). To reduce the bias arising from unmodeled heterogeneity in the detection probabilities, these

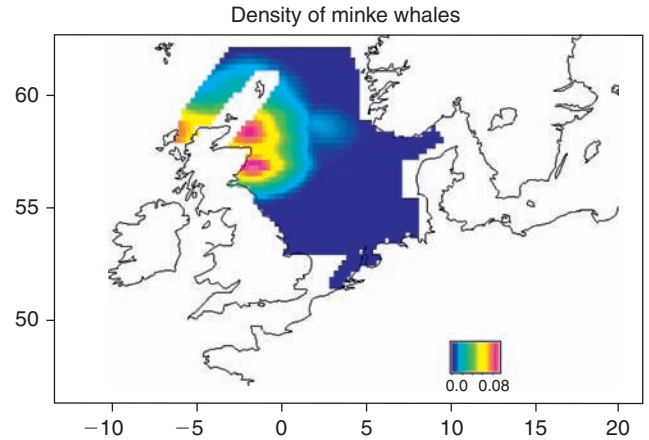

Figure 2 Estimated density of common minke whales in the North Sea.

methods do not assume full independence between observers, but instead use the weaker assumption of point independence: detections (conditional on recorded covariates) are assumed independent on the line only, as dependence can be expected to be weaker here than away from the line. Double-platform surveys are used widely in cetacean surveys, and have also been used for estimating the abundance of polar bears (*Ursus maritimus*) and seals.

7. Automated design algorithms and GIS Increasingly, survey designs are being developed within Geographic Information Systems (GIS). Automated design algorithms allow the user to avoid the need for designing surveys by hand and allow identification and implementation of more efficient designs. Chapters 7 and 8 of Buckland *et al.* (2004) cover these issues, and Distance (Thomas *et al.*, 2006) has GIS functionality together with a selection of automated design algorithms.

B. Strip Transect Sampling

Strip transect sampling is a special case of line transect sampling in which it is assumed that all animals out to the truncation distance w are detected. This simplifies analysis, and distances of detected animals from the line need not be measured, except to ensure that they are within distance w of the line. However, the method is seldom efficient for marine mammals; if the strip is narrow enough to ensure that all animals out to w are detected, then many animals are detected beyond w , and these observations must be ignored. Abundance of sirenian populations has traditionally been obtained by strip transect methods.

C. Cue Counting

In cue counting, observers on a ship or in an aircraft cover a sector ahead of their observation platform and record all cues detected within the sector and the distances of the cues from the platform. In principle, the method can be used for any marine mammal, but in practice, it has been used primarily for large whales, for which the cue is the blow. The same design considerations apply as for line transect sampling, although the analysis is essentially the same as for point transect sampling.

If the cues are well defined, such as blows of large whales, then cue counting has the advantage over line transect sampling that the recording unit is the individual cue. Observers need not identify whether different cues are from different animals or how many

animals are in a cluster. It also does not matter if some whales stay down so long that they will be undetectable even if they are on the transect line, provided that all cues within the recording sector and very close to the observation platform are detected. Another advantage is that the method requires observer-to-animal distances, which are easier to estimate than perpendicular distances of animals from the line. The main disadvantage is that the method yields estimates of cue density per unit time, which can only be converted into whale density by estimating the cue rate (cues per animal per unit time) from additional costly surveys. The estimated cue rate is prone to bias, both because animals may behave differently when a survey ship is close by and because it is easier to monitor animals that cue frequently, thus biasing the cue rate upward. Additionally, if animals cue more frequently when a ship is bearing down on them, an excess of short distances will be observed in the distance data, biasing the estimation of cue density.

The number of cues per unit area per unit time is estimated by:

$$\hat{D}_c = \frac{2n}{\phi \hat{\rho}^2 T} \quad (3)$$

where n is the number of cues detected in time T , ϕ is the angle of the sector in radians, and $\hat{\rho}$ is the estimated effective radius of detection. Estimated density is then,

$$\hat{D} = \frac{\hat{D}_c}{\hat{\lambda}}$$

where $\hat{\lambda}$ is the estimated number of cues per animal per unit time (the cue rate). As before, abundance is estimated as $\hat{N} = A\hat{D}$, where A is the size of the study area.

Because cues may be from the same whale, or the same pod of whales, they cannot be assumed independent. This is not a major problem given the robust variance estimation methods provided by software Distance, although model selection tools such as AIC and goodness-of-fit tests are unreliable.

If cues immediately ahead of the vessel might be missed, double-platform methods similar to those for line transect sampling may be used. This has the advantage over those analyses in that it is easier to identify whether a single cue is seen from both platforms, e.g., by recording exact times of cues, than to identify whether a single animal or animal cluster is seen by both platforms, as the two platforms may see different cues from the same animal.

II. Mark–Recapture

MARK–RECAPTURE tends to be more labor-intensive and more sensitive to failures of assumptions than distance sampling. However, it is applicable to some species that are not amenable to distance sampling methods and, if the marks are long lasting, can yield direct estimates of survival and recruitment rates, which distance sampling cannot do. Mark–recapture methods can be useful for populations that aggregate at some location each year, whereas distance sampling methods are more effective on dispersed populations. The two approaches should therefore be seen as different tools for different purposes. Among marine mammals, mark–recapture has been used most often to estimate the abundance of pinnipeds, usually for the estimation of young of the year. Polar bears have also been the subject of mark–recapture studies. Perhaps the most comprehensive software currently available for analyzing mark–recapture data is MARK (White and Burnham, 1999).

A. Estimation from a Tagged Subset of Animals

1. *The Petersen Estimator* In its simplest form, mark–recapture consists of marking a sample of M animals from a population of unknown size N , returning the animals to the population and then removing, capturing, or observing a sample of n animals. Suppose that, of these n animals, m were marked. We assume that the proportion of marked animals in the second sample is a valid estimate of the proportion of marked animals in the population, giving the following “Petersen” estimator of population size:

$$\hat{N} = nM/m$$

2. *Chapman’s Modified Estimator* Inference for the Petersen model is complicated by the fact that the variance of \hat{N} is infinite unless $n + M > N$, in which case m cannot be zero. Chapman’s estimator $\hat{N}_c = (n + 1)(M + 1)/(m + 1) - 1$ has finite variance. It also has lower bias (and no bias for $n + M > N$), provided that the assumptions of the estimator are satisfied.

Many variations on this theme have been developed, including extensions to multiple samples, extensions to open populations, “single release” methods, and “single recapture” methods (particularly suited for when the mark is recovered from a dead animal). See “Mark and Recapture Methods”, this volume.

3. *Assumptions* The assumptions required for \hat{N} to be a reasonable estimate of population size are that the population of interest is closed over the survey period and that animals are marked and resighted or recaptured at random. In using the ordinary Petersen estimate, it is also assumed that marks are not lost during the survey period and that marking does not affect the probability of resighting or recapturing the animal. Methods have been developed to circumvent these restrictive assumptions and the literature for this topic is rich (see reviews by Pollock, 1991 and Buckland *et al.*, 2000). For most wildlife populations, probabilities of recapture or resighting tend to vary among animals for a variety of reasons. This heterogeneity can be problematic to model and can lead to large bias in abundance estimates, so that the design of a mark–recapture survey should be carefully addressed to minimize heterogeneity.

4. *Estimation of Pinniped Numbers by Mark–Recapture* Mark–recapture techniques have been successfully used to estimate the abundance of young of the year for several species of fur seals. Chapman and Johnson (1968) described the first successful application of this technique for the population of northern fur seals (*Callorhinus ursinus*) on the Pribilof Islands. They marked seals by shearing some hair from their heads and later went back to the colony and counted numbers of marked and unmarked animals within groups of animals. They calculated the Petersen estimate of abundance, which they verified on small colonies where direct counts of young of the year could be made. Resighting was replicated on each colony and several procedures for estimating the variance of the total population size were investigated. These included (1) an empirical estimate calculated as the variance of the mean of replicated estimates for each colony, and the variance of the total calculated by summing the individual colony variances, and (2) a variance for each replicated colony estimate assuming the hypergeometric distribution, with the variance of the mean count for each colony estimated from the variances of the individual counts. They also discussed the use of interpenetrating subsamples to estimate the variance. This procedure is similar in flavor and intent to the bootstrap procedure.

5. *Mark-Recovery Methods* Before the development of line transect methods for estimating the size of populations of large

baleen whales, mark-recovery studies were carried out in which “Discovery” marks were fired into whales, a proportion of which would later be recovered by whalers. Disadvantages of this approach included a requirement for very large sample sizes to ensure an adequate number of recaptures; a long delay before sufficient data accumulated to allow abundance to be estimated; and strong sensitivity of abundance estimates to failures of assumptions. The methods were largely unsuccessful. For a review of the mark–recapture models that are potentially relevant to such data, and of the numerous sources of potential bias in the abundance estimates, see Buckland and Duff (1989). Before the development of mark–recapture or mark–resight techniques for northern fur seal pups, there were many attempts to estimate the population size by tagging pups at birth and recovering the tags in a commercial harvest. This application failed for similar reasons that the use of Discovery tags failed to properly estimate the size of cetacean populations.

B. Use of Natural Markings

Studies that use natural markings to identify individual animals in a population have become widespread in recent years. These usually rely on photo identification of individuals. A significant milestone in the use of such methods was Hammond *et al.* (1990), which comprises an edited collection of papers from a workshop on the topic. While the technique is undoubtedly of great value, it is important to be aware of its limitations.

Natural markings data can be very effective for estimating survival rates of marine mammals. Abundance estimation is more problematic, as this involves extrapolation from the identified sub-population. If a high proportion of the population (>80%) can be identified, then abundance estimates are likely to have small bias, especially as there is a tendency to underestimate population size. It is possible to achieve such high rates, e.g., for small coastal populations of bottlenose dolphins (*Tursiops* spp.) and pinniped colonies, provided individuals have distinct markings. The method is then useful because it allows enumeration of almost the whole population without fear of double counting individuals or of seriously underestimating population size. When smaller proportions of animals are identified, estimates of population size can be badly compromised for a variety of reasons. Severe heterogeneity in the “capture” probabilities is common, e.g., because some natural markings are identified much more readily than others or some individuals are more approachable than others. It is notoriously difficult to model such mark–recapture data reliably. Another problem is that the population being estimated is not always well defined, with some animals from elsewhere temporarily entering the population and others temporarily absent. A severe problem for large populations, in which only a small proportion can be identified, is that false positives in the matching procedure, even if they occur only rarely, can lead to a substantial underestimation of population size.

Genetic fingerprinting, if feasible, can reduce this problem substantially. Natural markings studies are invaluable for estimating survival and birth rates, for identifying migration routes, and for detailed studies, including abundance estimation, of a small population. However, they are rarely a cost-effective or reliable method for estimating the size of large populations of marine mammals.

III. Migration Counts

Many populations of large whales conveniently file past coastal watch points on migration, allowing observers to count a large proportion

of the population. This count can then be corrected for animals passing outside watch periods to estimate population size. In practice, further corrections are needed, e.g., to adjust for pods that pass undetected during watch periods, for biased estimation of pod size, for different rates of passage between day and night, and for a component of the population that fails to pass the watch point. Despite the need for various correction terms, migration count data yield very precise estimates of abundance with low bias, provided that the more significant correction factors are estimated reliably. This is unsurprising given that typically 30–40% of the population might be seen by the observers, a much higher fraction than is normal in a distance sampling survey.

The methods usually used for modeling migration counts were developed for the analysis of surveys of the California gray whale (*Eschrichtius robustus*). To estimate the numbers of undetected pods passing during watch periods, two count stations operate independently, and these double-count data are modeled using logistic regression. A polynomial model is used to estimate the rate of passage as it varies through the season, from which numbers of whales passing outside watch periods are estimated. A Bayesian approach is used for analyzing similar data on bowhead whales (*Balaena mysticetus*).

IV. Colony Counts

Many populations of pinnipeds gather for breeding and pupping at certain times of the year. Researchers often make counts of these populations from cliffs above the colonies, from planes flying overhead, or sometimes from ships passing the colony. Often photographs are taken of the colonies. These are brought back to the laboratory for analysis and form a permanent record of the population. In most pinniped populations, it cannot be assumed that all the animals are on shore at any given time, although in fur seal populations there is a time window in which almost all of the young of the year and breeding males are present, and in certain phocid populations all the young of the year and breeding females are present. Thus, colony counts alone cannot be used to determine absolute abundance of the population size, except for certain classes of animals, and this depends on the reproductive patterns of the population of interest, which must be taken into account when the survey is designed. Serial colony counts can be used to determine the rate of increase of the population if the same proportion of animals is present each year at the colony when the counts are made. This assumption is most likely valid for young of the year. For other segments of the population, this assumption fails if the timing of reproduction changes or if conditions at sea change so that animals need to spend a different amount of time at sea feeding and consequently a different amount of time at the colony.

The size of the harbor seal (*Phoca vitulina*) population in the state of Washington is estimated by combining colony counts made during aerial surveys and mark–recapture to account for animals not present during the aerial surveys. Transponder tags with unique frequencies are attached to animals before the surveys. During the flyovers, animals on shore are counted and radio searches are made to determine the proportion of animals that is ashore. The total population is estimated as $\hat{N}_{tot} = \bar{N}/\hat{p}$ where \bar{N} is the average count of animals on shore and \hat{p} is the estimated fraction of marked animals on shore. The total harbor seal populations in the Gulf of Alaska (Boveng *et al.*, 2003) and in England (Thompson *et al.*, 2005) are estimated from corrected colony counts from aerial surveys. In both cases, the correction factors are estimated from a regression analysis of observed counts on factors that affect the propensity to haul-out on land, such as time of day, tide level, or weather.

A corrected count method is also used to estimate the numbers of southern elephant seal (*Mirounga leonina*) and Antarctic fur seal (*Arctocephalus gazella*) pups on South Georgia. In those surveys, counts of adult females are made from shore or ship along the whole coastline during the pupping season. The counts made at any particular site are then used to estimate the total production for that site based on the adult female haul-out curves and pregnancy/pupping rate estimates from sites that are monitored regularly (twice daily in the case of fur seals) through the breeding season. Similarly, the abundance of northern fur seal pups on the Pribilof Islands is sometimes estimated from mark-recapture estimates on sample colonies coupled with counts of breeding males on all colonies (York and Kozloff, 1987). The ratio of pups to breeding males, estimated on the sampled rookeries, is multiplied by the total count of breeding males on all colonies. Total population size of the stock of northern fur seals has been estimated by multiplying estimated pup numbers by a correction factor derived from a life table assuming a stable age distribution. This method is a very rough tool for estimating the total population and usually no estimates of its bias or variability are computed. In the case of UK gray seals (*Halichoerus grypus*), population dynamics models are fitted to the time series of pup counts, to allow estimation of population size, while accounting for the major sources of uncertainty: observation error, demographic and environmental stochasticity, and model uncertainty (Thomas *et al.*, 2005).

The sizes of colonies of pinnipeds can also be determined using estimates of the area of all colonies coupled with estimates of the density of animals on those colonies. Although this method is often used to estimate the sizes of bird colonies, it has only been used occasionally to estimate pinniped population sizes. The estimates of the areas of the colonies were made from maps of the colonies. Counts or corrected counts, or mark-recapture estimates of the population of interest, are determined on a subsample of colonies. It is assumed that the density of animals in the sampled colonies is representative of the density on all colonies and the total population is estimated by multiplying the total area by the estimated density. Researchers attempted to use this method to estimate the size of the Pribilof northern fur seal population in the late 1940s. At that time, it was thought that the variability of the estimates was too large and efforts were begun to design mark-recapture studies.

Counts, or more often corrected counts, are also sometimes attempted on other marine mammals. For example, because sea otters (*Enhydra lutris*) are difficult to survey by other means, they tend to be counted from a boat. Such counts typically underestimate population size, sometimes substantially (Udevitz *et al.*, 1995). Such counts may be useful as indices if the methods are consistent from survey to survey and if the behavior of animals does not vary in a way that would affect the survey count.

Aerial Behavior

BERND WÜRSIG AND HAL WHITEHEAD

Dolphins and whales (and some pinnipeds, at times) are aerially acrobatic in seemingly exuberant displays of sheer joy. While play may at times be a cause of leaping and other surface activities, there are multiple aerial behavior types and reasons, not all totally understood. We here discuss mainly leaping and breaching, but also mention lunging, spy-hopping, slapping flukes and flippers onto the water surface (lobtailing and flipper slapping), porpoising, and lifting the flukes clear of the water, or fluking.

When large whales leap, the activity is generally termed breaching; when the smaller toothed whales leap, it is generally termed leaping. While the terms can be used interchangeably, we here attempt to stick to those general uses. The breach of a large whale is almost certainly the most powerful action performed by any animal; that of a leaping

dolphin rising many body lengths above the surface is one of the most breathtaking. But most breaching and leaping are not immediately functional activities for an aquatic animal, and a question of “Why?” is still only partially answered.

I. Whale Breaching

Breaching is defined as a jump in which at least 40% of the animal leaves the water. This is distinct from lunging, when less than 40% of the body leaves the water; and lunges are often part of other activity, such as a whale lunging toward another as a part of aggressive display (humpback whale, *Megaptera novaeangliae*, males). The breach (and dolphin leap) may be thought of as an intentional act—leaping out of the water for that express purpose. Dolphins porpoising, to be discussed below, do so as apart of their forward locomotion, and in this special case, the reason for leaping while high-speed swimming is reasonably well understood.

When breaching, sperm whales (*Physeter macrocephalus*) tend to approach the surface vertically from depth (Waters and Whitehead, 1990). Other animals swimming in water less than a few body lengths deep, e.g., humpback and right whales (*Eubalaena* spp.), make a horizontal approach to the breach, gaining speed until, at the last moment, they raise their heads and flukes, pivoting on their flippers, so converting horizontal momentum into vertical motion, and thus rising through the surface (Whitehead, 1985a). To make a full breach, a humpback whale must break the surface at about 15 knots (about 8m/s), close to its maximum speed. It is likely that some of the most spectacular breaches of other species also represent the full power of the animal.

After breaking the surface, whales have many styles of breaches. In the classic breach of a large whale (such as a humpback or right) the animal emerges from the water at about 20° to 30° from the vertical, twisting so as to land on its back or side, having shown about 90% of its body above the surface at peak emergence (Fig. 1). However, about 20% of the breaches of sperm and humpback whales are “belly flops,” with the animal landing ventrally. Breaching whales produce large splashes upon reentry into the water, which can be visible at many kilometers. Frame-by-frame analysis of high-speed photography shows that there are actually two splashes: one is created as the animal falls onto the water surface and initiates a crater of water underneath it, and the other is the secondary splash (and slap sound) produced as the crater collapses on itself, in an act of cavitation.

Figure 1 A killer whale (*Orcinus orca*) performs a classic breach typical of large whales. The Killer whale is the largest of the dolphins but is not as great a breacher as some of the baleen whales, Photo by Bernd Würsig.

Breaches are often performed in bouts. Extreme is 130 breaches in 75 min, probably all breaches are performed by the same humpback whale on Silver Bank, West Indies. As such sequences progress, animals tend to show less and less of their bodies, visibly appearing fatigued.

Quantitative breaching rates are only available for a few species and are usually not comparable. However, it is clear that there are substantial differences between species in the rates of this and other forms of aerial activity (Whitehead, 1985b). Frequent breachers include the humpback, right, and sperm whales, as well as virtually all offshore dolphins. In contrast, balaenopterids (blue, *Balaenoptera musculus*; fin, *B. physalus*; sei, *B. borealis*; Bryde’s, *B. edeni*; minke, *B. acutorostrata*, *B. bonaerensis*), and most beaked whales (except the northern bottlenose, *Hyperoodon ampullatus*) breach much more rarely.

Breaching rates, then, are not related to size and, at least in the large whales, are inversely related to speed—stouter, slower animals tend to breach more. Instead, interspecifically the best correlate of breaching rate is sociality. Animals found in larger groups, and for whom social structure seems more important, breach more frequently. In sperm whales, the gregarious females breach more often than the much larger, and more solitary, males. Calves of many species breach more frequently than adults.

The circumstances in which breaches occur can provide important clues as to their purpose or function. In some species, different segments of the population breach more frequently than others. For instance, calves of many species breach more frequently than adults. In sperm whales, the gregarious females breach more often than the much larger, and more solitary, males.

Most baleen whales have pronounced seasonal cycles, feeding in winter at high latitudes and breeding in winter nearer the equator. Humpbacks in the western North Atlantic breach about seven times more frequently on their winter breeding grounds in the West Indies than when feeding off Newfoundland.

In a number of species (including humpback, right, and sperm whales) breaching is observed more frequently when groups are merging or splitting. Male humpback whales may breach when they stop singing on the Hawaiian breeding grounds. Breaching is often observed together with lobtailing and/or flipper slapping, with different animals performing different activities at the same time, or one animal switching between the different activities. Studies of humpback and right whales have also shown that breaches by one animal seem to trigger breaches by neighbors. On Silver Bank, breaching humpbacks form clusters about 10km across. One of the most interesting, and in some ways unexpected, findings that has emerged from several studies of different species is that breaching rates of large whales increase with wind speed. There is currently no generally accepted explanation for this widespread pattern, although it has been postulated that the sound of the breach may serve for better communication in all directions in a surface-noisy ocean.

II. Dolphin Leaping

The act of dolphins leaping clear of the water is always an energetic and at times a highly acrobatic feat. Just as in large whales breaching, to clear the water the dolphin needs to attain a rapid forward speed and momentum, near the limit of its swimming capability. It generally bends its body abruptly to exit the water and then twists the body mid-air to reenter the water in some structured fashion. Even a noisy “belly flop” after a leap has been designed as such, as multiple similar leaps of the same animals demonstrate. Reentering the water can be head first (unlike in breaching large whales, where it is never

head-first), creating minimal splash and noise. It can consist of a side, back, or belly splash, resulting in a welter of white water and foam and a considerable percussive (splash) noise in-air and underwater. Finally, there is the “showy” acrobatic leap that consists of spins, somersaults, and various in-air twists. Frame-by-frame analysis of high-speed photographs shows that dolphins control these acrobatics to within split-second timing, affecting muscle movements that allow them to perform the same leap and reentry onto the water again and again. In human terms, a well-trained gymnast or pool diver comes to mind. Dolphin leaps tend to last for 1–2 s, depending on the acrobatics being performed and the size of the leaping individual.

There are three main variations of this leap that tend to create little water disturbance or noise upon reentry. One consists of a “stationary” leap, where the animal comes steeply from depth, usually greater than three body lengths. It leaps in-air, breathes, and tucks its body into a bend to reorient the head downward, then rapidly descends into depth at or very near the original exit point. This leap appears to be executed for the animal to leave whatever it is doing at depth for a minimal time, breathe, and use the in-air weight of its body to regain its position. The need for such an efficient mechanism to breathe becomes clear when we consider that dolphins feeding or mating at depth, e.g., essentially need to interrupt these activities to obtain life-sustaining air. If they can do so rapidly, all the better. The stationary leap is performed singly by dolphins herding food fish below the surface (Würsig, 1979), but often in twos or threes during socializing (Norris *et al.*, 1994) (Fig. 2).

A second head-first reentry leap consists of rapid swimming just below the surface, a very abrupt bend of the body to exit the water, and then a long arcuate in-air leap that may propel the dolphin forward by up to three times of its own body length. While the reentry is head first, there is nevertheless some splashing of water due to the rapidity of the action, kicked up by the body as it exits and again as it enters. This is the “running leap” of dolphins moving at speed, a form of high porpoising. Dolphins propel themselves underwater with several powerful but rapid tail beats and then “sail” through the air, a medium 800 times less dense than water. There is considerable drag generated by crossing the air–water interface, but for an animal that needs to come to the surface to breathe anyway (such as penguins and dolphins), travel efficiency increases above a particular

speed by leaping rather than swimming (Fig. 3). For a 2.5-m-long dolphin, the crossover speed from swimming to leaping is about 4.6 m/s, or 16.6 km/h (Au and Weihs, 1980). Above about 4 m body length (and concomitant body weight), high porpoising is no longer as easy, although killer whales (*Orcinus orca*) moving very rapidly may leap in this manner for short periods of time.

The third head-first reentry leap is designed to gain height. Dolphins, often in twos or threes, leap as high as three times their own body lengths above the surface of the water, usually but not always reentering the water head first. A 2.5-m male pantropical spotted dolphin (*Stenella attenuata*)—spotted dolphins are the champion high leapers—thus leaps about 7 m into the air, or the equivalent of over two apartment stories high. While these leaps may be performed largely for “fun,” they may also serve the function of seeing to greater distance by gaining height. Dusky dolphins (*Lagenorhynchus obscurus*) leap in this fashion just before high porpoising toward feeding aggregations with flocking birds some kilometers away (Würsig and Würsig, 1980) (Fig. 4).

Dolphins that noisy leap exit the water in similar fashion as in head-first reentry leaps, but twist the body to reenter with back, side, or belly first. Many noisy leaps end with the dolphin merely falling back onto the water surface. Others are particularly designed to have the animal reenter in a predetermined fashion, and high-speed photography shows subtle tail, flipper, head, or other body readjustments even split seconds before reentering and appearing to be structured to force the body onto the water with a maximal intensity of splash. These

Figure 2 Two dusky dolphins (*Lagenorhynchus obscurus*) perform stationary, or headfirst re-entry, leaps while socializing. Photo by Heidi Pearson.

Figure 5 A southern right whale (*Eubalaena australis*) performs a percussive tail slap.

Figure 6 A spinner dolphin (*Stenella longirostris*) spinning.

observations have led to speculation that noisy leaps are structured for omni-directional communication among dolphins and whales. Indeed, noisy leaps tend to occur more often in higher wind states (when near-surface ambient noise greatly increases), and this observation fits with the hypothesis of communication. Noisy leaps also occur around the periphery of near-surface schools, and in that case, the percussive slaps, as well as the underwater bubble clouds formed by dolphins reentering the water, may serve to frighten fish and cause them to school or aggregate more tightly. Dolphins may at times also stun or debilitate fish prey with the slaps of noisy leaps (as well as with tail slaps), but there is no detailed information on this possibility (Fig. 5).

Some dolphins are especially showy for at least some of their leaps, with spins, somersaults, combinations of flips, head twists, extra tail kicks in-air, and so on. These leaps are almost always associated with an obviously high level of social activity in a school or pod, as evidenced by social rubbing, sexual activity, and a cacophony of whistle and other sounds. Acrobatic leaps usually occur in bouts, with one dolphin (or whale) leaping at least several times. The more social the group, the more leaping dolphins and the longer the individual bouts. These leaps appear graceful to our human eyes and appear particularly structured to be enjoyed in the making and the viewing, like art. However, this may not be the case; we simply do not know.

Spinner dolphins (*Stenella longirostris*) spin by rotating their body rapidly around the long axis up to seven times (usually two to four times) before falling back into the water (Fig. 6). They do so in both

vertical spins and horizontal fashion (Norris and Dohl, 1980; Norris *et al.*, 1994). While twisting of the body in-air may effect some small change in the spin, the angular momentum appears to be almost entirely generated by subsurface corkscrewing in the more dense medium (880 more dense than air!) of water (Fish *et al.*, 2006).

Members of the genus *Lagenorhynchus*, such as Pacific white-sided (*L. obliquidens*) and dusky dolphins, are probably the most aerially acrobatic of all dolphins and whales, with somersaults, twists, and various inventive bends and contortions (Brownell and Cipriano, 1999). Individuals also have the longest bouts of any of the dolphins (some whale breach bouts are as long, and longer; discussed earlier), with up to 36 somersaults having been counted in one dolphin in one about 5-min duration. Interestingly, *Lagenorhynchus* spp. individuals will “never” change leap type during a bout. If a dusky dolphin begins a backward somersault with a half twist to the left and a tail kick just before reentering the water, it will continue this same leap, with no noticeable variation, during that leap bout. Toward the end of the bout, it will tire, muscle action will slow, and the leap will be slightly imperfect. It then quits and breathes while resting at the surface for several minutes. Later, in a different bout, the same individual will leap differently, demonstrating that it knows more than one leap type.

Acrobatic leaps tend to be noisy, but are not structured specifically to make noise. They are structured to be acrobatic, and it is difficult to imagine that they occur for anything but the “fun” (or the art) of it. A more scientifically acceptable explanation may be that acrobatic leaps are not merely an outgrowth of a high level of social activity, but are themselves a call for social activity. Acrobatic leap types may thus serve a social facilitation function that helps to coordinate members of a school or pod. Such facilitation may be especially useful to animals that coordinate finding and aggregating of food and that may need to establish and maintain delicate balances of social and sexual hierarchies. One argument against this stands out: dolphins leaping acrobatically are not being watched by others. They perform their show above the surface while, at any one time of a leap, most or all others are below. Acrobatic leaps may create somewhat different splash sounds from other more simple leaps, but this is not known (Fig. 7).

III. Other Active Aerial Behaviors

Lunging can be a low form of a would-be breach, and may therefore at times indicate a lowered form of alertness or sociality. But, lunging in whales can also be directed at another individual or individuals, and can signal aggression. Dolphins that play around the eyes and mouths of whales at times apparently do so to elicit lunging from the whales, so that they can ride the “bow-wave” of the lunging behemoth (see Playful Behavior, this volume).

Spy hopping is practiced by both whales and dolphins, and consists of the animal usually quite slowly lifting the head out of the water almost or fully vertical, usually just to the level of the flippers. The term “eye out” might be better for this activity, as we do not know whether the animals are indeed “hopping” out in order to “spy” or look around in-air. At times, spy hopping is attended by a slow rotation of the body, and it does, indeed, appear that the whale or dolphin may be surveying its in-air environment.

Lobtailing or tail slapping consists of forcefully slapping the tail onto the surface of the water (Fig. 5), either ventrum or dorsum up. Large whales are usually oriented more or less vertically in the water column, and the tail stock is sharply bent at the surface in order to produce the tail slap. Smaller toothed whales and dolphins, however, tend to have their bodies oriented parallel to the surface with the

Figure 7 A dusky dolphin performing an acrobatic leap. Photo by Jody Weir.

tail stock not as strongly bent. The slapping action can propel them forward slowly, usually in a semicircle. While the beat frequency in large whales can be quite slow, on the order of several to as many as 10s between slaps, in dolphins it can be up to one or slightly more per second; it is then at times termed “motorboating”. Lobtailing produces a loud “crack” sound in air but is not all that loud underwater, and certainly not as loud as many of the vocalizations made by whales and dolphins.

There is high variability of which whale species lobe tail and which do so less or not at all. While our review does not pretend to be complete, sperm, right, bowhead (*Balaena mysticetus*), humpback, and gray whales (*Eschrichtius robustus*) are “frequent” lobe tailers; but members of the genus *Balaenoptera* tend to lobe tail little or not at all. For the smaller cetaceans, Delphinids are champions at lobe tailing and other aerial behaviors, but Phocoenids (the porpoises) and river dolphins lobe tail (and flipper slap) rarely.

Flipper slapping by whales and dolphins (and by sea lions and fur seals), occurs, as in lobe tailing, with both ventrum and dorsum (of the flipper) striking the surface. It also produces a percussive sound in air, and a less loud one underwater.

IV. Potential Reasons for Aerial Behaviors

It is of course difficult to succinctly summarize our thoughts on reasons for many and diverse gradations of aerial behaviors. Much of the time, especially active behaviors are associated with high levels of alertness, or high levels of sociality. Especially percussive signals may have direct COMMUNICATION function.

A number of authors have suggested that breaching, leaping (when in “noisy” fashion), lobe tailing, and flipper slapping may help cetaceans feed by scaring, stunning, herding, or trapping fish or other prey. Although many, probably the majority, of breaches of most species occur in nonfeeding circumstances, the closely related activity of lobe tailing is known to sometimes assist feeding, so a direct benefit to food capture cannot be ruled out as a function for some breaches, perhaps especially the “clean-entry leaps” of dolphins.

Figure 8 A sperm whale (*Physeter macrocephalus*) in the act of diving and fluking off the coast of New Zealand. Initiation of the dive (top), as the back curves just before lifting the flukes. This fluking sequence shows a particularly high “fluke out” before a fully vertical descent. Photo by B. Würsing

Similarly, we cannot completely rule out some rather prosaic potential benefits of breaching and leaping such as stretching, looking above the water, or inhaling water-free air in rough weather. However, these too are unlikely to be important functions of most aerial activities.

One proposed benefit of breaching/leaping that is more consistent with at least some of the evidence is ectoparasite removal. Among the baleen whales, the more heavily infested species tend to be the most frequent breachers, and in Hawaiian spinner dolphins, 44% of spinning dolphins had remoras attached. However, spinners without remoras also breached, and much of the circumstantial evidence points to a very different function—communication.

As noted earlier, the more social species of cetaceans tend to be more aerially active. As sociality is based on communication between members of the same species, the strong inference from these results, then, is that especially percussive aerial activity is a form of communication.

However, there is a paradox in that while breaches, e.g., are excellent at conveying information to visually based human observers above the surface; they are far less prominent for the potential or actual social companions of the breacher. Other whales and dolphins cannot generally see the breacher's body arcing above the surface, and while the reentry makes a noticeable underwater sound, it seems to be less loud than the natural vocalizations of the animals. The paradox may be resolved by considering the theory of "honest signaling": signals are especially useful in animal communication if they convey some important attribute of the signaler that cannot be faked. The distinctive underwater sound or bubble pattern produced by a full breach, while not especially prominent in its own right, is an honest signal of the physical abilities of the breacher (which often seems to leave the surface at close to its maximum speed) and its desire to communicate this by using a significant amount of energy (about 1% of a humpback whale's estimated daily resting metabolic expenditure per breach).

Thus the breach may be a useful signal to nearby potential or actual social companions. What might it be signaling? Suggestions for large whales include aggression, "extreme annoyance" (perhaps with a nearby vessel), an "act of defiance," courtship, or a display of strength by males. Some scientists have suggested that a breach may be used to add emphasis to some other signal, perhaps a vocalization or visual display. By showing the extent of its physical prowess, and expending a significant amount of energy, the whale accentuates the importance of a companion signal. For dolphins, leaps have mainly been considered signals concerning schooling. For instance, it has been suggested that leapers may be used to define the deployment of a school, to recruit dolphins to a cooperative feeding event, or as social facilitators that reaffirm social bonds.

Finally, there is a play. This is probably the most commonly attributed function of breaching, leaping, and much other aerial activity by the general public, but it is also seriously considered by scientists who recognize play as a valid, but hard to define, type of BEHAVIOR. Biological definitions of play usually focus on its lack of immediate biological function, resulting in play becoming a "garbage can" into which activities without an obvious function, such as breaching, get placed in a haphazard fashion. It is likely that many aerial activities described by human observers as "playful" actually function as important signals. However, it is also likely that some, especially those by young animals, provide no immediate benefit, instead, like other forms of play, help to equip the aerially active animal with abilities that may be beneficial in later life.

A discussion of leaping and other aerial activities would be incomplete without mention of other than cetacean marine mammals. Indeed, otariid pinnipeds also high porpoise (probably for the

same hydrodynamic efficiency consideration as for dolphins), and especially fur seals and sea otters (*Enhydra lutris*) leap at the surface by rapidly rolling around their own axes. This activity serves to aerate the extremely fine, long, and dense pelage of these marine mammals that use air for insulation. Leaping in pinnipeds and sea otters at times may also consist of play activity, but there is no further information on this point. Especially otariids occasionally flipper slap, at times in apparent play, at times in alarm.

V. Fluking

Fluking is the act of a whale, dolphin, or porpoise [very rarely, a manatee (*Trichechus* spp.) or dugong (*Dugong dugon*)] raising its tail, or flukes, above the surface of the water during the beginning of a dive (Fig. 8). Usually, whales fluke when diving steeply in water deeper than at least two of their own lengths, although fluking can also occur during shallow submergences. There is great variability in fluking behavior by species: humpback and sperm whales almost always fluke or "fluke out" during the dive; minke and fin whales do so rarely (Leatherwood and Reeves, 1983). Right, bowhead, and gray whales are known to vary the amount and type of fluking depending on whether they are feeding near the surface (no fluking), at moderate depth (occasional fluking), or at depths of 60 m or more ("always" fluking). These species also generally fluke on migration, during the final dive after a series of "near-surface" dives between respirations. Even smaller toothed whales, such as bottlenose dolphins (*Tursiops truncatus*) and pilot whales (*Globicephala* spp.), at times fluke during deep or at least steeply angled dives (Carwardine *et al.*, 1998).

Large whales fluke as a part of bending their bodies as they angle downward, and the fluke out becomes a natural extension of the animal "rolling" forward and down. In smaller delphinids, however, fluking probably has a distinct advantage during the initiation of the dive: the tail and tailstock (or caudal peduncle) held above the surface provide in-air weight to the body and help propel it downward. The effect of this action is quite similar to human skin divers kicking their feet and legs out of water while bending at the waist as they initiate a dive.

Bowhead whales about to dive steeply often stretch their entire bodies so that head and flukes are at the surface, and the belly or mid-part of the body hangs much further below. The spine, in other words, is curved downward. Such a "pre-dive flex" takes about 2 s and occurs just before the last blow before a dive. The pre-dive flex is usually predictive of a fluke-out dive, and pre-drive flex and the flukes out indicate steep, generally deep, diving for feeding or migrating (Würsig and Clark, 1993).

A final form of "flukes out" consists of raising the flukes above water and keeping them there for some time. Dolphins wave their flukes about for at times over 1 min, "headstanding" in apparent play; right, bowhead, and gray whales do so for at times over 10 min. It has been suggested that southern right whales are purposefully sailing by holding their large tails in air during a stiff breeze, but this recreational use of their tails has not been substantiated (Payne, 1995).

Flukes of whales and dolphins have thin trailing edges (similar to the trailing edges of dorsal fins) and are therefore easily tattered or marked by conspecific interactions, getting entangled in lines, or touching other objects. These marks make individual recognition of the flukes possible in those species that habitually fluke out, and fluke-based photographic identification is being practiced for sperm, humpback, and gray whales. In the latter two species, an additional bonus is variable spot or mottling patterns on the flukes (Hammond *et al.*, 1990).

Age Estimation

ALETA A. HOHN

I. Introduction

Age estimation is a tool for obtaining a numerical value of age for animals for which the actual age is not known. Currently, age is estimated primarily from counts of growth layers deposited in several persistent tissues, primarily teeth, less often bone, and in some cases from other layered structures or from chemical signals. Growth layers in the persistent structures are similar in concept to growth rings in trees. Until the use of growth layers became a feasible means of age estimation, relative measures of age, such as tooth wear, pelage or skin color, or fusion of cranial sutures allowed individuals to be placed in age groups; these techniques largely have

been replaced with methods that allow for estimation of absolute age by counting growth layers. Marine mammalogists pioneered age estimation from counting growth layers in teeth, initially in pinnipeds (Laws, 1952); this discovery was followed by widespread use for terrestrial mammals as well. Much of the development of this field has focused on how to ensure that age estimates are accurate and precise. That focus has been directed toward verifying the amount of time represented by a growth layer (i.e., calibration or validation), developing increasingly better ways to prepare samples for optimizing counts, and standardizing methods to ensure that growth layer counts are consistent among studies.

Age is fundamental to interpreting and understanding many aspects of the biology of marine mammals. The traditional and most obvious use of age is for estimating parameters used in population dynamics models. Age-specific estimates of fecundity or mortality can be used in these models to project population growth, for example. Estimates of age at sexual maturation are used in absolute terms in population models, while changes in this parameter have been interpreted to reflect changes in population abundance or resource availability and, therefore, indicate a density-compensatory response. Population age structure would also be a useful parameter, although it is rarely known. It is possible, however, to determine the age structure of individuals removed from a population intentionally, such as through directed fisheries, or incidentally, such as in bycatch. This information then can be used to refine estimates of the impact of fisheries on those populations.

The need for accurate and precise estimates of age does not end with traditional population modeling. Of late, there has been increasing concern about the effects of contaminants on the health of marine mammals. Because many of these contaminants bioaccumulate, interpretation of the measured levels of organic or inorganic compounds must be taken as a function of the age, and reproductive condition, of the individual. Furthermore, because indices of health such as blood parameters change naturally with age, understanding the effects of contaminants or other factors on the health of individuals also requires knowing their age. With the recent epizootic events involving morbillivirus (Tautenberger *et al.*, 1996), the ages of individuals infected as well as those with titers indicating previous infections become important in understanding the epidemiology of these outbreaks.

II. Growth Layer Terminology

In the context of age estimation, the term growth layer is ambiguous. That is because annual increments, as a rule, comprise more than the minimum two growth layers, e.g., a broad layer and a fine layer, needed to differentiate one annual increment from the next. Other layers are usually present; these layers are often referred to as accessory or incremental layers. In the context of age estimation and identifying annual increments, the presence of subannual incremental layers can cause errors and confusion, and have resulted in semantic controversies with regard to the term “growth layer.”

To help remedy confusion in terminology, a more descriptive phrase, growth layer group (GLG), was coined at a workshop held in 1977 on estimating age in toothed whales and sirenians (Perrin and Myrick, 1980), predominantly in reference to dentine. Its use has expanded, however, to other marine mammal species and to cement as well as dentine. GLG is a group of layers which occur with cyclical and predictable repetition. Strictly speaking, GLG is a generic term and does not automatically imply deposition that occurred over a 1-year period. It needs to be defined for each species and each

use. For practical purposes, however, GLG generally is defined by authors to represent 1 year's deposition, i.e., "annual" is implied. Below, the term "annual layer" is equivalent to "annual GLG."

III. Calibration of Annual Layers

Verification that annual layers exist within the complement of visible layers derives from validation or calibration studies. Notably, the first confirmation of annual layers in pinniped teeth occurred soon after teeth were examined for the possibility of age estimation; Scheffer (1950) found external layers (ridges) in the canines of fur seals, *Callorhinus ursinus*, that corresponded to the known age of seals branded as pups and recovered up to 8 years later. Further studies to validate annual layering patterns and to show that patterns are consistent among individuals and species have involved three approaches: (1) examining teeth or bone from animals of known age or known history; (2) examining teeth or bone marked with tetracycline; and (3) comparing growth layers in teeth that have been removed at known intervals (multiple extractions).

For cetaceans, animals of known age or with a known history most often were captive for all or much of their lives. In the latter situation, support for annual layers then hinges on counts of the number of presumed annual layers corresponding to the known age or to the known approximate age of the animal given the length of time it spent in captivity and other data, such as its body length when removed from the wild. Initial encouragement that growth layers in dolphin teeth were annual was from three captive bottlenose dolphins, *Tursiops truncatus* (Sergeant, 1959). Teeth obtained from free-ranging *Tursiops* of known age and known history were significant for confirming and identifying annual layering patterns and determining that annual layers in free-ranging bottlenose dolphins were similar to those in their captive conspecifics (Hohn *et al.*, 1989). Within the pinnipeds, sirenians, and sea otters, numerous studies of free-ranging tagged or individually identified animals have compared the number of growth layers in tooth sections to known ages (e.g., Bowen *et al.*, 1983, and Arbom *et al.*, 1992). In many of these studies, as in cetacean studies, the actual age of individuals is greater than the "known age" because animals were captured or tagged some time after their birth. Thus, the number of growth layers counted is compared to that minimum age plus an additional number of years estimated as a function of the size of the animal at the time it was first tagged or identified. The most recent and rigorous studies counted growth layers without knowledge of the known ages of specimens in the sample, which eliminates a bias in counting. What is notable about all of these studies is that the authors concluded that they were able to identify annual growth layers (annual GLGs) that correspond to known ages or known approximate ages of the individuals in their samples at least up to some minimum age.

True calibration of growth layer deposition over extended periods of time relative to the lifespan of an animal has not been attempted. To do so would require direct marking of layers, such as through administration of tetracycline, preferably at the same time each year and ideally on the animal's birthday. Tetracycline binds permanently to actively growing mineralized tissue and fluoresces when a bone or tooth section is viewed under ultraviolet light, hence its ability to serve as a marker. Two tetracycline treatments or one treatment followed by extraction have been used to unambiguously identify growth layer deposition over the period of time between the marks, providing a limited calibration; annual layers were determined from this method for several dolphin species, most extensively for spinner dolphins, *Stenella longirostris*, (Myrick *et al.*, 1984) and bottlenose

dolphins (Myrick and Cornell, 1990). Alternatively, multiple extractions of teeth from an individual allow for calibration, but with much restricted sampling opportunities. This method has been used with free-ranging bottlenose dolphins, where two teeth were extracted and growth layer deposition between extractions compared (Hohn *et al.*, 1989). Limited opportunities exist for extensive direct calibration, although captive animals could be used for such studies as could free-ranging populations where individuals are resighted each year and could be caught, administered tetracycline and released.

New techniques continue to be developed as technology becomes increasingly sophisticated. Recently, mass spectrometry was used to identify isotopic signatures of radiocarbon from atomic bomb testing that had been incorporated into teeth of beluga whales (*Delphinapterus leucas*) from Canadian waters (Stewart *et al.*, 2006). Results helped resolve a controversy regarding the number of growth layers deposited annually in beluga teeth.

IV. Tissues Commonly Used to Obtain Absolute Age Estimates

Given the importance of obtaining age estimates, various tissues and methods have been investigated for elucidating growth layers (Perrin and Myrick, 1980; McCann, 1993; Klevezal', 1996). The most commonly used tissue has been teeth, as they have been for terrestrial mammals (Klevezal' and Kleinenberg, 1967). Fortunately, odontocetes (Figs. 1–3), pinnipeds, sea otters (Fig. 5), and polar bears have teeth that are suitable for use in estimating age. In contrast, teeth cannot be used for baleen whales and manatees, therefore other tissues or methods have been investigated. As alternatives, incremental layers have been found in bone, baleen, and ear plugs. Teeth have several advantages over these other tissues. The normal process of remodeling (resorption and reconstruction) in bone results in resorption of all but the most recent growth layers. For young animals, the number of bone layers may accurately reflect age; otherwise, the number of layers will be less than the age of the animal. The most useful bones are those that show negative allometry, i.e., growing more slowly than the skeleton as a whole (Klevezal', 1996). Growth layers also have been identified in baleen. Unfortunately, baleen abrades fairly quickly during normal use, and relatively few growth layers accumulate. Ear plugs are restricted to just a few species of whales and are challenging to collect.

In the normal course of events, teeth do not remodel, and growth layers continue to be deposited throughout the life of the individual. Teeth are easy to collect, store, and section and have become the preferred means of age estimation for most species with teeth. Within a tooth, two tissues have been used for aging: dentine and cement. New dentine is deposited on the internal surface, i.e., from the pulp cavity side, so that layers deposited when the animal was youngest are found on the outer edges of the tooth or at the crown (Figs. 1–3). Cement or cementum wraps around the outer dentine and functions in anchoring the tooth to its alveolus. In contrast to dentine, new cemental layers are deposited on the external surface (Figs. 3 and 4). In most species of cetaceans, the cemental layer is very thin and the resulting growth layers are so fine that they can be difficult to differentiate. As a result, dentine is primarily used for estimating age. Notable exceptions include the franciscana, *Pontoporia blainvillei*, and the beaked whales, family Ziphiidae, where dentine is useful only for the first few years and then cement, which is extensive, must be used. In addition, for sperm whales, family Physeteridae, and the beluga whale both cement and dentine are well developed and can be used. Because most cetaceans have homodont dentition (the teeth are all approximately the

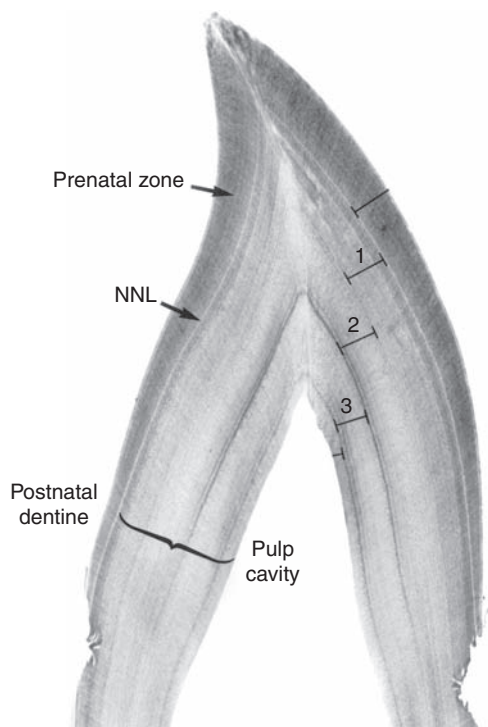

Figure 1 Decalcified and stained mid-longitudinal section in the buccal–lingual plane from a free-ranging bottlenose dolphin known to be 3 years of age. This view shows only the upper half of the section. The neonatal line (NNL) represents the time when the animal was born and, therefore, is age “0” for the purpose of estimating age. Dentine external to the neonatal line was deposited before birth and is known as prenatal dentine while the neonatal line and dentine internal to it is postnatal dentine. A thin layer of enamel covered the prenatal dentine but was removed when the tooth was decalcified. The first three complete presumed annual growth layers or GLGs are marked in the sequence they were deposited. Teeth from young dolphins have very little cement and none can be seen in this photograph. Photograph from Hohn et al. (1989).

same shape), each tooth contains the same layering pattern, except for the underdeveloped teeth found most anteriorly and posteriorly in the tooth rows.

For pinnipeds, sea otters, and polar bears, cement is most frequently used for age estimation (Garlich-Miller *et al.*, 1993; Bodkin *et al.*, 1997; Figs. 4 and 5), similar to what is done for most terrestrial mammals. For many species, dentine can give accurate age estimates for young animals, but the pulp cavity either becomes occluded or the dentine deposited is too irregular to resolve additional growth layers. Notable exceptions occur in some of the phocids, such as the ringed seal (*Pusa hispida*), Caspian seal (*Pusa caspica*), and the harbor seal (*Phoca vitulina*), where more than 15–20 dentinal layers can be found (Stewart *et al.*, 1996). For these species, which have heterodont dentition, canines are best for counting dentinal layers while the postcanines are better for counting cement.

Although dentine and cement do not remodel like bone, teeth do wear down. When this occurs, generally it is not a problem for age estimation for species whose teeth show limited growth, i.e., do not continue to grow from the root but reach a maximum length when the animal is still relatively young. That is because an important

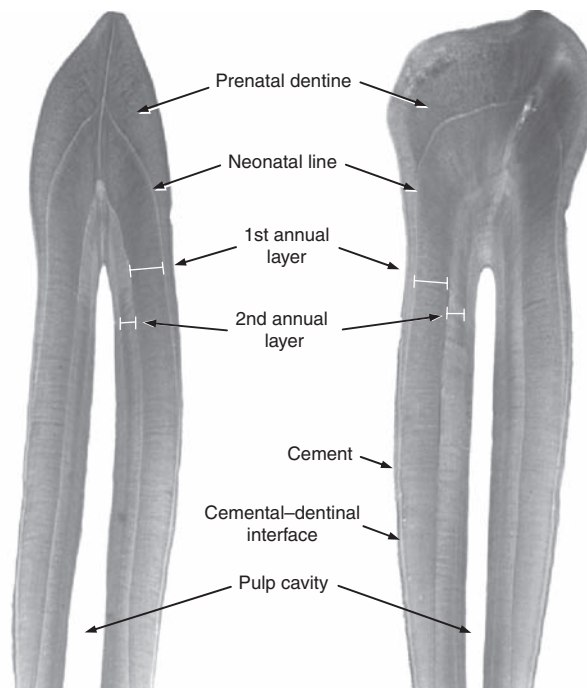

Figure 2 Decalcified and stained mid-longitudinal sections of teeth from a harbor porpoise. Porpoise teeth are spatulate. When sectioned along the buccal–lingual plane, they appear similar to dolphin tooth sections; when sectioned sagittally, the spatulate shape is apparent. The results are comparable in both orientations for this group. A narrow layer of cement occurs externally to the dentine in the part of the tooth that was below the gum line.

marker for accurate age estimates is the neonatal line, which is deposited at birth and represents time zero for the purposes of counting growth layers (Figs. 1 and 2). As long as the neonatal line is visible, it is possible to obtain a complete count of growth layers. Initially, the neonatal line extends below the gum line. In species for which tooth growth is limited, even when the tooth wears down above the gum line the neonatal line remains visible in the remaining tooth that was below the gum. In species with continuously growing teeth, such as the walrus (*Odobenus rosmarus*) (including mandibular teeth), bearded seal (*Erignathus barbatus*), beluga whale (*Delphinapterus leucas*), members of the sperm whale family (Fig. 3), and the dugong (*Dugong dugon*), wear continues as the tooth grows up from the root and eventually the neonatal line is worn away. When this occurs, the count of growth layers of dentine or cement is only a minimum. In some species, such as the beluga whale, tooth wear is not uniform and the best estimates of age are made from the least worn tooth.

Manatees (*Trichechus* spp.) present an unusual case for age estimation. In the related dugong, tusks (incisors) and other teeth provide a means for aging using techniques similar to those used for teeth from other species. Manatees lack tusks. Furthermore, they have an indeterminate number of molars that are constantly lost and replaced throughout the life. Therefore, except in young animals, the number of growth layers in a tooth will reflect the age of the tooth but not the age of the individual manatee. As an alternative, it has been demonstrated in manatees that growth layers in tympano-periotic (auditory) bones are annual (Fig. 5) and that resorption occurs at a much slower rate than in other bones, meeting the requirement of a bone with negative allometry. More than 20 annual

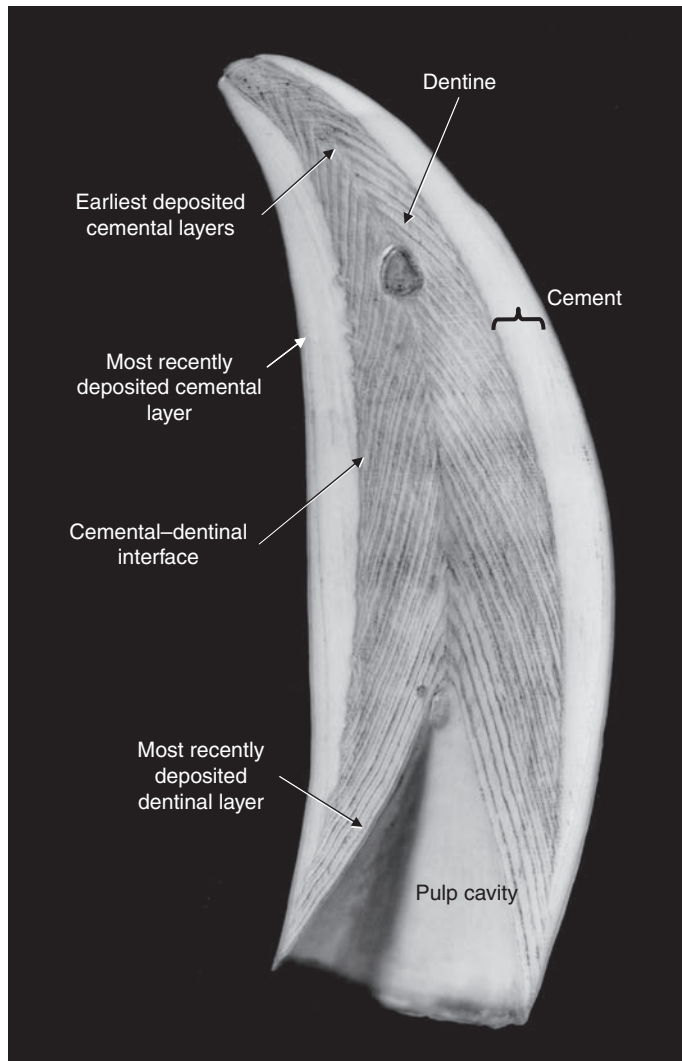

Figure 3 Mandibular tooth from a sperm whale, cut mid-longitudinally in the buccal-lingual plane, etched in acid, then rubbed with pencil to highlight growth layers in the dentine. Sperm whales have thick cement which from which age can be estimated. In contrast to cement in the dolphin or porpoise tooth, here cement covers all of the dentine. In sperm whales and other species with continuously growing teeth, the tooth adds layers at the bottom (root end) and pushes upward. The cement was deposited when the dentine was still below the gum line. Erupted teeth continuously wear, and in older animals the earliest deposited layers are no longer present. The circular structures are pulp stones that form at the edge of the pulp cavity as globular masses of secondary dentine. Pulp stones are common in some species. Photograph courtesy of the International Whaling Commission.

layers were found in many specimens and 59 found in a single animal (Marmontel *et al.*, 1996).

Baleen whales also present a special case for age estimation, because they lack teeth. The rorqual whales (family Balaenopteridae) have ear plugs that are deposited in an annual layering pattern throughout life (Laws, 1961; Fig. 6); these are considered accurate for obtaining age estimates. These structures are more difficult to collect and more fragile than teeth or bone. An advantage of ear

plugs is that they are not resorbed and do not wear. Other methods of aging have been investigated for balaenopterids as well as the other species of baleen whales. As in manatees, layers occur in the tympanic bullae (auditory bones) in bowhead (*Balaena mysticetus*), gray (*Eschrichtius robustus*), and common minke (*Balaenoptera acutorostrata*) whales (Christensen, 1995), often with no concomitant layers in other cranial or skeletal bones (Klevezal, 1996). Use of tympanic bullae is challenging because extensive effort is required to determine where exactly within the bullae the least amount of resorption and greatest resolution of growth layers will occur. When this region is located, the maximal number of layers will be found. Otherwise, ages will be underestimated. Chemical signals, specifically amino acid racemization, have been used for dolphins and small and large species of whales (Bada *et al.*, 1980), including fin (*Balaenoptera physalus*) and bowhead whales (George *et al.*, 1999). Age is estimated as a function of the proportion of D- and L-isomers of aspartic acid in the lens of the eye.

V. Collection and Preparation of Tissue for Age Estimation

When the primary tissue to be examined is dentine, especially for old animals, it is critical that a full mid-longitudinal section be obtained. Otherwise, the very fine layers deposited in old animals will be missed. In toothed whales and dolphins (the odontocetes), the possibility of obtaining this mid-longitudinal section is greatly increased if a tooth that is straight in the buccal-lingual plane (cheek to tongue) is used. Generally the largest and straightest teeth occur near the center of the tooth row, and generally teeth are sectioned in the buccal-lingual plane. In some species, sections in the anterior-posterior plane are comparable (Fig. 2). It has become a convention for studies on small odontocetes to use teeth from the center of the left mandible when possible (Perrin and Myrick, 1980). When using specimens from museum collections, often the teeth will have fallen out of the alveoli and so the straightest, largest (in that priority) teeth will be optimal. For studies using cemental layers, post-canines or molars are the generally preferred tissue. In terrestrial mammals, some differences in counts of cemental growth layers among tooth sections from the same individuals have demonstrated that the thickness of the cement influences the deposition pattern, either because the cement is so thin that layers are not readily distinguishable or because the cement is so thick that other incremental layers are apparent and may appear as annual layers (Klevezal, 1996). Differences in cemental thickness can occur both within a molar and between molars (Fig. 4). Ideally, a full investigation of the best site for sectioning can be made to select the optimal tooth and location within that tooth. When that selection has been made, mid-longitudinal sections are more likely than cross-sections to show all of the cemental layers, although cross-sections are commonly used (Klevezal, 1996). As noted above, there is also variability in compact bone thickness in tympanic bullae, resulting in variability in number of growth layers visible; an investigation of the optimal site for sectioning is required. The bone is then cross-sectioned at that site. Ear plugs are sectioned centrally along the long axis of the plug.

Because growth layers are integral to bone and tooth structure, growth layer counts are not sensitive to most of the common ways of storing bones and teeth: cleaned of soft tissue and stored dry such as in museum bone collections, or in alcohol, formalin, or glycerin. It has been suggested that long-term storage in formalin will affect growth layer counts if formalin degrades to formic acid (Perrin and Myrick, 1980). Some teeth will crack at the tip when stored dry, making

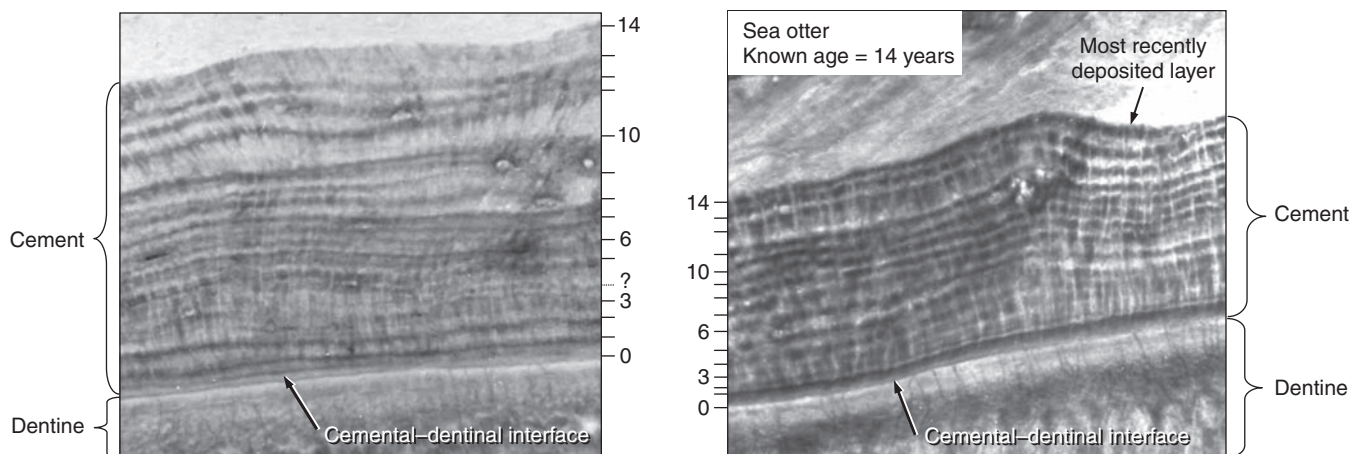

Figure 4 Growth layer deposition in cement of a known-age sea otter (14 years). Images are from the same tooth section at different locations. In one location (right image), 14 well-defined, presumably annual layers are visible. These layers are exceptionally clear. In another location (left image), growth layers split and merge: on the right side there appear to be fewer layers, on the left side there appear to be more layers. Presumed annuli are marked on the two images, with the marks on the left image being more subjective and a particularly uncertain layer marked with a dashed line. Counts begin at the interface where the dentine meets the cement; that represents time zero for counting growth layers. Positive identification of annual layers is made by carefully following layers along the tooth to watch for splitting and merging. Photographs of decalcified and stained thin sections courtesy of James Bodkin, USGS, and Gary Matson, Matson's Laboratory, 250X.

Figure 5 Growth layer deposition in the tympano-periotic bone of a manatee that was maintained in captivity for 9 years. Eleven to twelve growth layers can be seen. These layers are primarily on the outer surface of the bone. Even at this age, the bone tissue is being resorbed and beginning the remodeling process. sectioning a bit more difficult but not affecting the growth layers. Earplugs are stored in 5–10% buffered formalin (Lockyer, 1984). For amino acid racemization, eye lenses must be collected fresh and immediately frozen (George *et al.*, 1999).

Many creative methods have been tried to obtain the best resolution of growth layers (Perrin and Myrick, 1980). Two of these methods have persisted and become the most widely used: untreated sections (i.e., not decalcified and stained) and decalcified and stained thin sections. The former method generally involves using a low-speed saw with diamond blades to cut a section ranging from 50 to 200 μm thick, depending on the species and tissue, and counting layers directly from that section. The section may or may not

be permanently mounted on a microscope slide. This method was initially the most prevalent one for age estimation from teeth, a little less so for bone, and continues to be widely used because it is fast, easy, and requires little specialized equipment. The increasingly used alternative, decalcified and stained thin sections, requires additional preparation. For this method, whole teeth or thick sections from teeth or bone are decalcified in acid, sectioned on a microtome at from 6 to 25 μm , depending on the species, tissue, and microtome used, then stained in hematoxylin and sometimes counterstained with eosin, two routinely used histological stains. Sections are mounted on a microscope slide. It has become increasingly evident that using the easier method produces inaccurate results

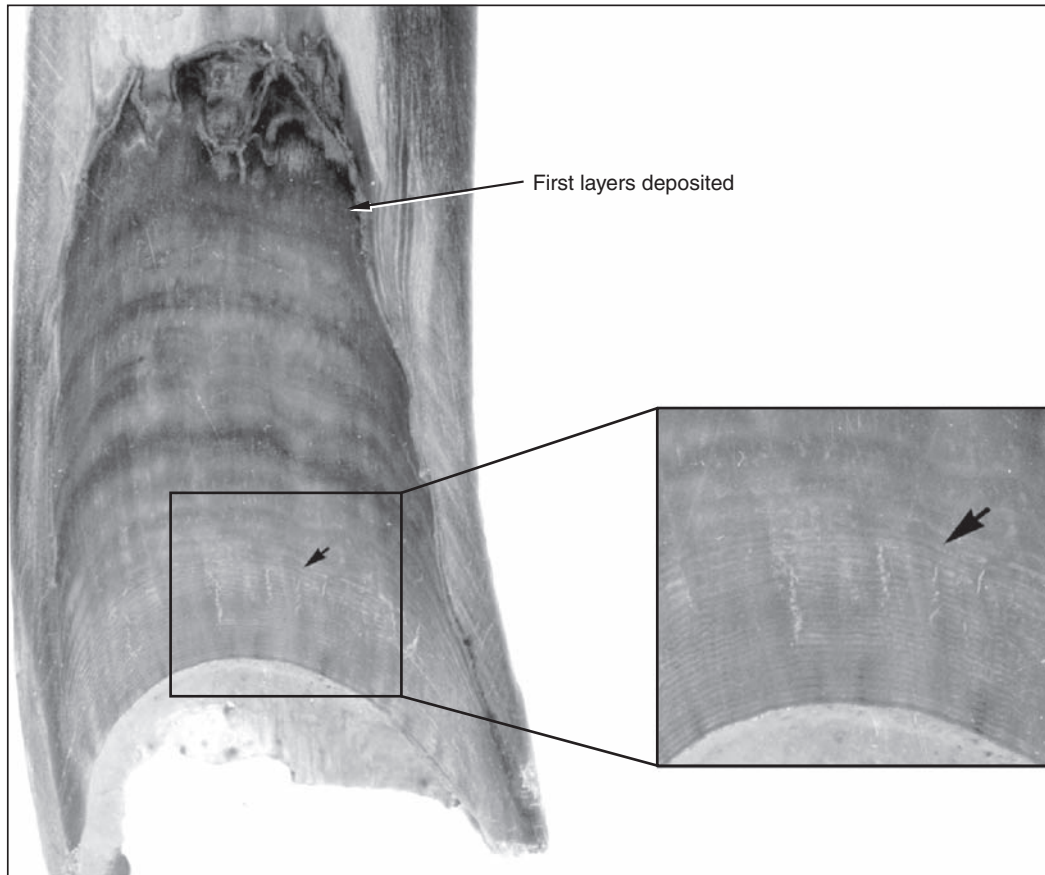

Figure 6 Ear plug from a fin whale, cut mid-longitudinally to expose the growth layers. The arrow denotes a significant and abrupt change in growth layer characteristics that coincides with the transition of the animal from sexually immature to sexually mature. It is called the transition phase. Photograph from Lockyer (1984) and provided courtesy of C. Lockyer and the International Whaling Commission.

for both bone and tooth sections (Stewart *et al.*, 1996; Hohn and Fernandez, 1999). Stained thin sections allow for much better resolution of growth layers in dentine, cement, and bone to the extent that many layers not apparent in untreated sections are visible and countable in stained sections. This difference is especially apparent in older animals where growth layers become increasingly thinner; staining is required to separate adjacent fine layers. As a result, many estimates of age using untreated sections are underestimates.

VI. Consistency and Repeatability of Age Estimates

Because annual layers are not the only growth layers present, interpretation of layers is often subjective. Misinterpretation of annual layers or differences in interpretation between investigators or studies leads to errors. For example, is one population but not another actually responding differently to exploitation, or is an apparent difference simply caused by differences in age estimation? Is a population failing to recover because a growth model is incorrect or because the parameters used in that model were incorrect due to misinterpretation of annual layers?

Accuracy and precision are, in large part, influenced by the species being examined. For some species, growth layers are well defined and easily identified, while for other species growth layers are inherently indistinct. Annual layers in polar bear (*Ursus maritimus*)

cement are notably difficult to interpret, at least during the first few years of life. Different areas in the cement have more or less distinct annual layers and accessory layers. Furthermore, different populations within a species may have different growth layer characteristics. For example, harbor porpoise (*Phocoena phocoena*) from the Bay of Fundy have very distinctive growth layers while those from California do not. Within studies it is common to conduct multiple readings of sections by one or more researchers to test the differences between readers or between readings for an individual reader. Measures of precision can be incorporated in models or can be used to evaluate the reliability of ages estimated for a sample.

Consistency and repeatability of age estimates can be increased if the tooth or bone sections are well prepared. Preparing these sections is a multistep process, and at each step the potential for error exists. If the end product is not well done, then the age estimate may be inaccurate or imprecise. For counts using dentine, a large source of error is using a section that is not mid-longitudinal. For all sections, the incorrect stain or degree of staining (light or dark) and under- or over-decalcification also affect the final product in ways that prevent optimal resolution of all growth layers.

Even when sections are perfect, the subjective nature of counting growth layers still results in varying age estimates. Descriptive models of the appearance, size, and complexity of annual layers have been developed to increase consistency, particularly between investigators. These models include photographs with the growth layers

interpreted to be annual clearly marked (Hohn, 1990). Such photographs are equally valuable in individual studies to allow other investigators to determine whether the age estimates were obtained using comparable annual layering patterns. To date, such descriptive models have been prepared for bottlenose dolphins (Hohn *et al.*, 1989) and the franciscana (Pinedo and Hohn, 2000). Development of models for other species would increase the accuracy and precision of age estimates. Such models are particularly important and valuable when known-age specimens are available.

VII. Growth-Layer Tissues as Recording Structures

The annual layering pattern likely is endogenously controlled, while individual subannual growth layers represent events that have a systemic effect on the animal and therefore influence the deposition of the matrix or mineral in teeth, bone, teeth, earplugs, or other tissue. In essence, the annual increments themselves, as well as any layers formed within the annual increments, are recording structures that reflect the physiology of an individual at the time of deposition (Klevezal', 1996). For example, a decrease in thickness of growth layers has been shown to coincide with a general decrease in body growth with age, as well as with maturation, in cetaceans and seals. Following maturation, changes have been shown to occur in the characteristics of growth layers, or in various types of irregularities or anomalies in dentine, reflecting changes in hormone levels associated with maturation, pregnancy, or lactation in females. The appearance of distinctive lines within growth layers (marker lines) has been suggested to indicate parturition in cetaceans and feeding bouts in pinnipeds. Marker lines, as well as anomalies and other tooth characteristics, have demonstrated value in distinguishing animals from various geographic areas, suggesting a means of stock identification (Lockyer, 1999). A decrease in mineral density in growth layers in teeth from Peruvian dusky dolphins (*Lagenorhynchus obscurus*) was found to correspond to an El Niño year (Manzanilla, 1989). Interpreting these structures can serve as another tool for reconstructing life history events for individuals, including changes in growth rates, reproductive events, including number of births, effects of changes in the environment, and distinguishing stocks.

Aggressive Behavior, Intraspecific

CLAUDIO CAMPAGNA

The heterogeneous phenomena considered as intraspecific, aggressive, or agonistic behaviors represent a conglomerate of social responses, including male disputes over territorial boundaries, female fights to protect an offspring, female harassment and forced copulations, and infant abuse and killing. Agonistic encounters

- (a) mediate competition for limited resources economically defensible and valuable to the fitness of an individual (Bartholomew, 1970). Finite resources that can be monopolized would lead to social conflict between individuals of different sexes and generations and of the same sex and similar age class and status. Most often, agonistic confrontation (at least the most conspicuous interactions) involves sexually mature males.
- (b) are more common in some social contexts, such as breeding on land in a polygynous mating system, in which competition for resources is typically solved via aggressive disputes. Size and strength (but also agility) correlate positively with winning a contest through exerting dominance over individuals subdued by the costs of rebellion.
- (c) have a broad range of costs for actors and recipients, from simple rejection after a ritualized threat display to injury or even death after an overt physical encounter.

The form and frequency of agonistic behavior partially reflect the sophistication of social systems. Aquatic mammals vary widely in the complexity of their societies, thus in the manifestation of agonistic behaviors. The most openly competitive societies characterize the otariids, the walrus, *Odobenus rosmarus*, and phocids that live in crowded conditions (e.g., elephant seals, *Mirounga* spp., and gray seals, *Halichoerus grypus*), a fertile ground for aggressive social interactions (Riedman, 1990). Conversely, polar bears, *Ursus maritimus*, all the mysticetes and river dolphins and some other phocids (e.g., Ross, *Ommatophoca rossii*, and leopard, *Hydrurga leptonyx*, seals) are mostly solitary, except for the mother–calf bond and short periods during reproduction in which breeding males engage in scramble competition over receptive females (Berta and Sumich, 1999). The most complex social systems in the aquatic mammals would characterize some of the odontocete cetaceans such as killer whales, *Orcinus orca*; pilot whales, *Globicephala melas*; bottlenose dolphins, *Tursiops* spp.; or sperm whales, *Physeter macrocephalus* (Connor *et al.*, 1998). These species live in stable social units and show coordinated, cooperative behaviors. The long-term, shared history among individuals of the group would have ritualized many of the overt aggressive responses typical of the polygynous pinnipeds.

I. Male–Male Competition for Mates

Competition over limited resources to maximize reproductive success would be the most common origin of agonistic encounters. In all the aquatic mammals, males compete for access to reproductive females, either by direct monopolization or, indirectly, through achieving the best place for reproduction or the highest status in a dominance rank. The social and ecological contexts associated with the alternative forms of defense systems would set the stage for the evolution of sexually selected traits, such as dimorphism in size and

in special morphological structures (e.g., tusks, manes, elongated snouts).

The behavioral manifestation of conflict directed toward the intimidation of rivals is often referred to as agonistic displays or agonistic social signaling. Behavioral displays include vocal signals, facial expressions, and stereotyped postures and movements, such as static open-mouth threats, open-mouth sparring, foreflipper raise or waving, oblique staring, etc. Overt fighting is commonly a last-resort solution to conflict.

A. Pinnipeds

The form of male agonistic encounters and its outcome have been described in detail for several pinnipeds. Within the highly polygynous otariids and phocids, there are examples of resource-defense (territorial) and female-defense polygynous systems (Riedman, 1990, and references cited therein). Both types of polygyny may occur in the same species, such as in the South American sea lion, *Otaria flavescens*, as a function of different ecological conditions (Campagna and Le Boeuf, 1988).

The establishment and defense of a territory involves vocal displays, stereotyped postures and movements, and fights. During territorial displays, contenders may rush toward each other with the mouth open or vocalizing, weave heads from side to side, puff out the chest or perform the “oblique stare” posture at one another, but physical contact is carefully avoided. Much of the fighting between otariid males takes place early in the breeding season, when territorial boundaries are being established. When physical contact occurs, it typically lasts a few seconds but may be violent, particularly in the largest sea lions. Fights involve chest-to-chest pushing, vigorous biting of the neck and face, lunging, and slashing at the opponent’s flippers, chest, and hindquarters.

In female-defense polygyny, females cannot be sequestered or attracted to a particular place. Males then compete to achieve a position among the females in the breeding colony, and move with the shifting population of females (see Boness and James, 1979, for gray seals and Campagna and Le Boeuf, 1988, for South American sea lions). Association with a particular group of females is not fixed and may change even during the same day due to female redistribution related to the physical environment (high temperatures, variable space due to tidal movements) or to social behaviors (e.g., group raids of ousted males into the colony; Campagna *et al.*, 1988a).

In phocids such as the elephant seals, males aggressively establish a dominance hierarchy, rather than a resource or female defense system. Only the highest ranking individuals have undisturbed reproductive access to females (Le Boeuf and Laws, 1994). During the establishment of hierarchies, males attempt to intimidate each other with vocal displays. If none of the contestants retreat, then a chest-to-chest fight takes place. Fights in elephant seals are violent confrontations and may last half an hour. Each bull throws his weight against the other and slashes at his opponent’s face, neck, and back with long canines. Most fights end with multiple lacerations and bloody wounds or even a broken canine tooth; death of one contender does occur on rare occasions.

Vocal threats are a common component of agonistic encounters. Pinnipeds vocalize both in air and underwater (Riedman, 1990). Harp, *Pagophilus groenlandicus*; ringed, *Pusa hispida*; Weddell, *Leptonychotes weddellii*; and bearded, *Erignathus barbatus*; seals and the walrus have a rich underwater vocal repertoire. Males maintain underwater territories and vocalizations seem to be a part of territorial displays. Vocal displays are often complex enough to be called

songs, meaning that they occur in predictably similar patterns again and again, as in bird (and human) song. Otariid males, particularly among the fur seals, have a rich variety of airborne threat vocalizations associated with boundary display postures. The California sea lion, *Zalophus californianus californianus*, vocalizes both in air and underwater (several phocids also produce airborne and underwater sounds). The strong airborne calls or barks of California sea lions occur during the breeding and nonbreeding seasons and may serve to advertise dominance. In elephant seals, airborne threat displays consist of loud and directional pulsed sounds that always precede fights.

B. Cetaceans

There is comparatively little description of agonistic encounters in the rest of the aquatic mammals. Agonistic behaviors to establish dominance relationships were described among dolphins in captivity. Observations of free-ranging cetaceans described a range of behaviors interpreted as agonistic, such as lobtailing, tail, and flipper slaps to the body of other individuals, open-mouth postures, jaw claps, forceful exhalations, chases, body charges and leaps and body slaps, and vocal threat displays (see Wells *et al.*, 1999). Escalated agonistic displays involve striking with flukes, biting, and jousting with tusks.

The scar pattern of some odontocetes has been interpreted as the consequence of tooth marks and violent interactions. Several odontocetes have a conspicuous scar pattern. In Risso's dolphins, *Grampus griseus*, narwhals, *Monodon monoceros*, and in several of the beaked whales, most of the body is covered with scars. At least for the narwhal, scars were associated with intraspecific agonistic encounters (discussed later). Scrape marks are also common in baleen whales. It has been suggested for the southern right whales, *Eubalaena australis*, that males may use the thorny callosities during scramble competition over females.

Males of the humpback whale, *Megaptera novaeangliae*, escort receptive females and vigorously rebuff other males by threatening displays such as thrashing of the flukes. Males also at times violently interact with each other in apparently direct "fights," in so-called social active groups at the surface. The underwater songs of humpback whales on Hawaiian breeding grounds are performed by males, and may serve as communication signals in the context of male competition.

A particularly striking example of male–male competition involves Australian bottlenose dolphins (Connor *et al.*, 1998). Males of this population form stable alliances of 2–3 individuals that cooperate to obtain and control reproductive females. Two alliances occasionally combine efforts to sequester or defend females from another alliance. Alliances in dolphins and group raids in sea lions (discussed later) represent special cases in which competition involves the participation of several individuals simultaneously. Posturing and acoustic threats are common but serious injuries are rare during these male agonistic interactions. One episode of a bottlenose dolphin being rendered unconscious by repeated physical blows to his head was observed during an interaction of a male alliance with a "solo" male, suggesting that some aggressive interactions may be severe (Parsons *et al.*, 2003).

C. Other Aquatic Mammals

Sea otters, *Enhydra lutris*, polar bears, and sirenians are solitary or live in low-density societies with few direct and prolonged interactions among individuals (Berta and Sumich, 1999). Male sea otters are polygynous, establish breeding territories, and mate in the water.

Females live in low-density areas chosen in relation to the distribution and abundance of food.

During the mating season, polar bear males rove to locate receptive females that are dispersed and solitary. Males access one female at a time. Competition involving physical interactions has been rarely observed but can be inferred from broken teeth and scarring on the head and neck.

Manatees, *Trichechus* spp., form mating groups in which several males compete for access to a receptive female by pushing and shoving each other. Physical competition for females also occurs in dugongs, *Dugong dugon*, with some males presenting scars probably made by the tusks of other males.

II. Tusks as Special Structures for Aggression?

Two species of marine mammals have extraordinarily developed tusks: the walrus and the narwhal. The two upper canines in both male and female walrus are extraordinarily elongated (Riedman, 1990). The massive tusks of a male can weigh up to 10 pounds and be almost 1 m long. Both sexes use tusks in squabbles, to threaten one another and, perhaps, to establish dominance. Males may force their way to selected places in crowded colonies by pushing and jabbing other walruses with their tusks.

The tusks of narwhals are even more exceptional morphological traits. As a general rule, the left canine in males extends anteriorly into a spiraled tusk to a length that may exceed 2.5 m. Some males have two tusks and a few females also develop one or even two shorter and less robust tusks. It has been suggested that narwhal tusks may be used to disturb or pierce prey, to open-breathing holes in the ice, as defense weapons against predators or as organs of sexual display. Although tusks may be used in more than one context, there is evidence that they largely serve in aggressive encounters (Silverman and Dunbar, 1980; Gerson and Hickie, 1985). Evidence includes direct observations of males crossing tusks and striking them against one another, scar patterns (with adult males having more and larger scars on the head after attaining sexual maturity), a significantly higher incidence of broken tusks in mature males compared to immature individuals or to females, and embedded splinters and tusk tips found in the heads of males. Tusks are also used to spear individuals of other species or, apparently, at rare times even female narwhals.

III. Sexual Selection and Special Morphological Traits

Pronounced sexual dimorphism in the direction of males being heavier and larger than females is common in all the otariids, the walrus, and some phocids (e.g., elephant and gray seals). This kind of dimorphism often indicates direct physical confrontation among reproductive males involving pushing or strength contests. Dimorphism is not apparent; is slight, or even reversed in most other phocids. Lack of even reverse dimorphism is often accompanied by defense of aquatic territories, aquatic mating, and serial monogamy. Females in these species are often dispersed and breeding occurs over a protracted period. The social and ecological conditions of the latter do not favor frequent direct physical confrontations, but competition does occur and may select in this case for more agile rather than larger individuals.

Among other aquatic mammals, males are much larger than females in some odontocetes, such as killer and sperm whales, whereas dimorphism is reversed in all the mysticetes, possibly due to the female needing as large a body as possible to gestate and nurse

her very large calf. Mysticetes may have promiscuous mating systems in which competition for insemination may take place at the level of males displacing each other from the vicinity of a female and of sperm cells displacing or diluting sperm of other males. Gray, *Eschrichtius robustus*, right and bowhead, *Balaena mysticetus*, whales have larger testes than expected based on their body weight, suggesting selection for sperm competition.

Besides dimorphism in body size, males of some species evolved special secondary sexual features that may function in the context of competition for mates. Examples are the enlarged snouts of male elephant seals and gray seals, and the inflatable nasal cavity of hooded seals, *Cystophora cristata*. Hooded seal males can blow a red, balloon-like sac from one nostril that is similar in shape to the long proboscis of elephant seals. These organs may have visual or acoustic effects, and may allow other males and females to judge the quality of a contender or a sexual partner. The developed neck and mane of sea lions with long and thick guard hairs may also have visual effects and serve as a shield that protects internal organs from bites.

IV. Avoiding Fights

Competition for resources by direct aggression may be a costly experience in species capable of inflicting serious injuries that could lower future fitness of the contestants. Thus, contenders with low chances of success should avoid physical confrontations. Theory predicts that assessment of fighting ability of competitors and of resource value before an escalation of violence, may allow differential adaptive responses on the basis of the perceived asymmetries (Maynard Smith and Parker, 1974). Once a territory or a social hierarchy is established, disputes are asymmetric contests in which territory owners or high-ranking males almost always win. Threat displays may then serve as indicators of quality and motivational state of a contender. Other mechanisms, such as a concept of “dear enemy recognition” in territorial species, have been proposed to prevent escalated contests between neighbors. Individual variation in vocal displays may help territorial males to recognize one another.

In female-defense systems, the proportion of sexually receptive females accessible to a male is variable in space and time. Thus, the level of the asymmetry varies sometimes during the same day within the breeding season. This social context would favor behaviors that are unusual in strict territorial or hierarchical systems, such as group raids in South American sea lions.

V. Group Raids and Other Forms of Male Harassment of Reproductive Females

Violent behavior toward females that leads to injury and death is common in sea lions and some phocids (e.g., South American sea lions: Campagna *et al.*, 1988a; northern, *Mirounga angustirostris*, and southern, *M. leonina*, elephant seals: Le Boeuf and Mesnick, 1990, Galimberti *et al.*, 2000; New Zealand sea lions, *Phocarctos hookeri*: Chilvers *et al.*, 2005; gray seals, Boness *et al.*, 1995; monk seals, *Monachus* spp., Hiruki *et al.*, 1993).

In the South American sea lion, losers in male–male competition raid the breeding colonies in groups of dozens of individuals (Campagna *et al.*, 1988a). Raiders abduct females from the harems of established males and attempt to mate with them. A male may seize a female in his jaws and hurl her in the air to a spot where he may hold his ground against other males while aggressively keeping her in place. In the process, females are often wounded and can be killed. Group raids may represent a primitive stage of a male alliance or coalition.

Harassed females are injured and sometimes killed by males during mating attempts. Le Boeuf and Mesnick (1990) suggested some social conditions that increase mortality risks to a female during mating: (a) marked male sexual dimorphism, (b) males outnumbering females, (c) use of force or potentially dangerous weapons in mating, and (d) monopolization of mating by a few individuals through direct or indirect control of resources (space, females, food, etc.), with forcible exclusion of the majority of the competitors. All the above traits are common in the majority of polygynous mating systems.

The chief cause of female deaths during the breeding season of elephant seals, the most sexually dimorphic of all the pinnipeds, occurs by traumatic injuries inflicted by males during mating attempts as the females depart the harems for the sea at the end of lactation. Male South American sea lions and elephant seals are 3–5 times heavier than females, have large canines and often bite the neck of the female when copulating. Breeding colonies in the early and late season have a high number of males that intercept departing females and attempt to mate with them. Since the early work by Le Boeuf and Mesnick (1990), increased evidence supports the suggestion that male aggression toward females may be a selective force in shaping female behavior, female choice, maternal performance, and reproductive synchrony (Boness *et al.*, 1995; Galimberti *et al.*, 2000; Chilvers *et al.*, 2005).

VI. Female Agonistic Behavior

In the polygynous pinnipeds, females are aggressive toward one another and rarely tolerate neighbors close by, which contributes to the regulated density of a site (e.g., Fernández-Juricic and Cassini, 2007). A common context of female agonistic encounters is that of the protection of a pup in a crowded breeding colony. Alien pups are often bitten by females. Aggressive mothers react rapidly and intensively to a threat of their pup originated in a neighbor, and enhance chances of pup survival by decreasing risks of mother–pup separation and pup injury (Christenson and Le Boeuf, 1978).

Females sometimes threaten transient males when the latter approach, or they protest vocally when males mount them. As a result, a harassing male is more likely to be challenged by another male. These challenges generally interrupt a male’s approach or mount, and hence a potential copulation. By resisting male copulatory attempts, females can increase the likelihood of mating with a dominant individual, which may be viewed as an indirect form of mate choice.

VII. Abuse and Killing of the Young

Infanticide is the killing by conspecifics of the young, still dependent on their mothers. Infant or young refers here to a lactating or recently weaned pup, calf, or cub. Infant abuse implies injury of a young either via active violent behaviors or passive neglect. Infant killing and abuse by conspecifics represent a widespread phenomenon in nature. Parental and nonparental infanticide have been reported in almost 100 species of mammals, most of which are terrestrial (Hausfater and Hrdy, 1984; Parmigiani and vom Saal, 1994). Infant killing is the direct outcome of a violent interaction or can result from the indirect neglect of a young or an accident.

This review will focus on violent, nonparental forms of infanticide in aquatic mammals. Parental killing in this group is apparently restricted to the indirect effects of maternal neglect (see Le Boeuf and Campagna, 1994), and will not be treated. Infant abuse is a much more common behavioral occurrence than infanticide. It may imply active violence or passive neglect, and it does not necessarily involve the intended death of the victim. Death in the context of abuse is usually

perceived as accidental, a by-product that often follows a process of infection and starvation (Le Boeuf and Campagna, 1994).

Except for otariids and phocids, data on killing and abusing the young are sparse in aquatic mammals. Infanticide is an event that may pass unobserved or unreported. Spotty research coverage, with some species being well known and others virtually unstudied, suggests that the relevance and diversification of abuse and killing of the young may be more widespread than reported here. Explanations of the well-documented cases of abuse and infanticide in aquatic mammals rarely support the adaptive hypotheses that would account for similar episodes in terrestrial species.

A. Abuse and Killing of the Young by Males

Violent behavior toward young has been described in four of five sea lion species (California and Galapagos, *Zalophus californianus wollebaeki*, sea lions being the exception). Subadult and juvenile males of the South American sea lion abduct (seize), abuse, and kill pups during the breeding season (Campagna *et al.*, 1988b). The behavior was observed in coastal Patagonia (Campagna *et al.*, 1988b), Uruguay (Vaz-Ferreira, 1965), Chile (H. Paves Hernandez and C. Espinoza, pers. comm.), Peru (Harcourt, 1993; Soto *et al.*, 2004), and the Falkland-Malvinas Islands (C. Duck and D. Thompson, pers. comm.). At Punta Norte, Península Valdés, Argentina, 163 successful abductions were recorded in four breeding seasons. More than 20% of the 400 pups born each season were abducted by males. In a typical abduction, a juvenile or subadult male approached the breeding area alone or as part of a group raid (Campagna *et al.*, 1988b), dashed toward a pup and grabbed it. The pups were then abducted away from the breeding group, some were carried out to sea (11% of the abductions), whereas others were released and held close to the abductor. Pups that attempted to escape were shaken violently from side to side, tossed in the air, held crushed against pebble substrate, or submerged. Males defended their abducted pups from other males. Some abductors mounted pups, fully covering them with their massive bodies. About 6% of the pups abducted and 1.3% of the pups born during a season died as a consequence of physical abuse. Dead pups show tooth puncture wounds and extensive hematomas.

Australian, *Neophoca cinerea*, and Hooker's (i.e., New Zealand), *Phocarctos hookeri*, sea lions abduct and abuse pups in a similar fashion described for South American sea lions, with the important difference that adult Hooker's sea lions cannibalize the killed pups. Adult male Australian sea lions grab pups that may be alone or with the mother, and bite, shake, and toss them several times (Higgins and Tedman, 1990). Eight attacks recorded in two breeding seasons resulted in four dead pups (5% of the pups observed) and accounted for 19% of pup mortality in the rookery (Higgins and Tedman, 1990). Adult and subadult male Hooker's sea lions grab pups by the neck, violently thrash them from side to side, and sometimes drown them at sea (Wilkinson *et al.*, 2000). Adult abductors were also observed eating pups. Opportunistic observations on Hooker's sea lions report males abducting pups on two occasions and eating them on nine occasions (Wilkinson *et al.*, 2000). After thrashing the victim repeatedly from side to side, males bit the flesh off the carcass and consumed it. This is the only otariid species for which cannibalism has been described. Immature males apparently do not kill pups, although they may try to keep them under control and occasionally mount them.

Steller sea lions, *Eumetopias jubatus*, may trample, crash into, or push pups over a cliff as an indirect consequence of territorial disputes. In some instances, however, pups are killed as a direct violent action by males.

Episodes of violent behavior toward pups are rare among fur seals, except for the northern fur seals, *Callorhinus ursinus*, (Kiyota and Okamura, 2005). Juvenile, subadult, and adult males of the species may enter the breeding area and sniff, bite, grab, or mount pups. Males also abduct pups of both sexes to other places on land or to sea. Pups are killed by drowning, skull damage, or separation from the mother, the latter leading to emaciation. The behavior closely resembles that of the infanticidal sea lion species.

Among the other pinnipeds, infant abuse and killing have been described in at least four phocids and the walrus. Male northern and southern elephant seals of different age classes kill suckling pups and weanlings (Le Boeuf and Campagna, 1994). Pups are accidentally trampled by bulls in the context of male–male competition and may then die of internal injuries. Weaned pups are abused by pubertal males that attempt to mate with them and, in the process, injure and kill individuals of both sexes (Rose *et al.*, 1991). At the time of first departure to the sea, 30–50% of northern elephant seal weaned pups show signs of having been mounted by a male that range from neck bites, scrapes, cuts, and puncture wounds to deep gashes exposing blubber and profuse bleeding. An adult southern elephant seal male from the Patagonian colony of Península Valdés killed and apparently ate pups. He grabbed weaned pups from the beach, dragged them to sea, kept them underwater until struggling ceased, and then tore off chunks and consumed them. The cannibal returned to the same place at least during two consecutive breeding seasons and killed dozens of weanlings. Male gray seals occasionally shake, toss, bite, mount, and kill pups. There is also evidence of cannibalism in this species (Bédard *et al.*, 1993; Kovacs, 1996). An adult male was involved in killing and eating of pups during three breeding seasons. In a similar modality to the southern elephant seal cannibal, the gray seal male grabbed his victims by the hind flippers, dragged them into the water and drowned them. He later tore off chunks of the pup's body with a biting–shaking action and consumed the blubber, skin, and muscle. Hawaiian monk seal, *Monachus schauinslandi*, males mount pups, and then suffocate or drown them (Hiruki *et al.*, 1993; M. Craig, pers. comm.). Some seals persist in this behavior and may kill many pups. Finally, adult male, female, and immature walruses can jab a pup with their tusks and cause lethal injuries.

In summary, adult, subadult, and juvenile males of several pinniped species injure, abuse or kill suckling and recently weaned pups in the following contexts: (a) accidentally, often as an indirect outcome of trampling and crushing during dominance, female-defense, and territorial disputes; (b) as a direct or indirect consequence of a misdirected sexual assault, such as during abductions and abuse by pubertal males; (c) as a direct or indirect consequence of misdirected aggressive behavior with no clear sexual component, such as attack of pups by territorial males not associated to mounting, herding, or harassing; and (d) as an apparent source of food (cannibalism). The age class involved in the abuse and killing varies with the species. In the Australian and Hooker's sea lions, adults are most aggressive toward pups, but subadult and juvenile males also sequester pups and engage in biting, mounting, and holding them underwater. In the South American sea lions, subadult and juvenile males do most of the abductions; adults are rarely involved in pup abuse. Among phocids, young males seem to be more often involved in abuse than adults; adults may cause pup death or injury as an epiphenomenon of male–male competition.

Reports of violence toward young in the rest of the aquatic mammals are rare. Male polar bears occasionally kill and eat cubs, a behavior that is apparently generalized throughout the Arctic (Taylor *et al.*, 1985). There is indirect evidence suggesting infanticide in the

common bottlenose dolphin, *Tursiops truncatus* (Patterson *et al.*, 1998). Stranded dolphin calves were found with internal injuries that included contusions around the head and thorax, bone fractures and lacerated organs compatible with violent behavior. The interactions that may have caused the death of the calves were not observed. However, an adult dolphin was observed to interact violently with a dead conspecific calf, and dolphins were also seen to chase and hit harbor porpoises, *Phocoena phocoena*, hard enough to toss them into the air. Stranded harbor porpoises had evidence of trauma similar to that reported for the stranded dolphin calves. Additional indirect evidence of conspecific killing in common bottlenose dolphins is available for the population of the southeast Virginia coast (Dunn *et al.*, 2002). Nine bottlenose dolphins within their first year of life, and thus still dependent upon their mothers, were stranded with multiple skeletal fractures, hematomas, organ lacerations, contusions, and hemorrhages, indicating multidirectional trauma. External signs of trauma were absent, an observation incompatible with predation, boat strike, and fisheries interactions. Lesions were, however, similar to traumatic injuries reported for stranded harbor porpoises and bottlenose dolphins elsewhere and attributed to violent dolphin interactions (Patterson *et al.*, 1998).

B. Abuse and Killing of the Young by Females

Adult pinniped females repel alien young in the context of aggressive protection of resources intended for their own pup. In the northern elephant seal, females aggressively reject alien pups that approach them (Le Boeuf and Campagna, 1994). They shake, throw, and viciously bite unrelated pups. Attacks may be violent enough to cause extensive wounds or fractures, with subsequent infection and death. Orphan pups that attempt to be nursed from any female are thus particularly vulnerable to attack and injury.

An unusual behavior involving females and resulting in the death of unrelated pups was described for the South American sea lion rookery at Islas Ballestas (Peru; Soto *et al.*, 2004). During the 1997–1998 El Niño (warm water and little food availability) breeding season, virtually all pups starved to death. The following year, only about one-quarter of the females gave birth. These mothers had to defend their newborn pups from the sustained attempts of neighboring females to abduct the latter. It often occurs that otariid females close to parturition attempt to bring alien pups near them. However, the particular breeding context of the post-El Niño year resulted in an unusually high incidence of a behavior that may be related to confusing alien pups with their own pup. Females did not nurse the abducted pups, which were later abandoned. Those that failed to reunite with their mother died from starvation or were killed by young males. In the same El Niño context, a behavior was reported for females who in groups of 4–6 animals abducted and killed pups from other females. The pattern is reminiscent of young male group raids but was considered aberrant and related to low pregnancy rates after the El Niño (Soto *et al.*, 2004).

C. Male Violent Behavior toward Mature Females and Interspecific Pups

From a behavioral standpoint, abuse and killing of conspecific young by male pinnipeds resemble male violent behaviors directed toward mature females of the same species and toward females and pups of other species. Attributes that allow males to physically overpower competitors would also promote aggressive sexual behaviors

related to achieving access and maintaining control of breeding females. For example, adult and subadult South American sea lion males abduct females from established harems (Campagna *et al.*, 1988a). Abductions involve grabbing, tossing, herding, mounting, and biting. Some females are badly injured and killed in the process. Male harassment of conspecific females may be relatively common in phocids; it was reported at least for both species of elephant seals, the Hawaiian monk seals and the gray seal (Mesnick and Le Boeuf, 1991; Hiruki *et al.*, 1993; Boness *et al.*, 1995).

Strong and large pinniped males with an indiscriminate sexual urge often injure and kill females of other species. Males killing interspecific females during mating attempts were reported in all the sea lions (Miller *et al.*, 1996). South American sea lion males injure and kill South American fur seal, *Arctocephalus australis*, females, and Northern (i.e., Steller) sea lions kill California sea lion females, and even males. Mating attempts with dead females of the same and of a different species occurs in some otariids and phocids, such as the South American sea lion and elephant seals. Abnormal escalation of aggressive sexual behaviors may lead to instances such as one Steller sea lion male killing at least 84 California sea lion females and 12 males over three seasons (Miller *et al.*, 1996), and one southern elephant seal male killing more than 100 Cape fur seal, *Arctocephalus pusillus pusillus*, breeding females over successive breeding seasons (Best *et al.*, 1981).

Sea lion predation of pups of other otariid species typically involves grabbing a pup by the neck, shaking it from side to side, tossing and recovering it, dragging it to sea, submerging and drowning it, biting off flesh, and consuming it. This was described for at least three species. Steller sea lions prey upon northern fur seal neonates (pups under 5 months of age; Gentry and Johnson, 1981). Adult South American sea lions prey on South American fur seal pups (Harcourt, 1993). Hooker's sea lions, a species for which cannibalistic behaviors have been described (Wilkinson *et al.*, 2000), prey on New Zealand fur seals, *Arctocephalus forsteri*, and on Antarctic, *A. gazella*, and subantarctic, *A. tropicalis*, fur seals.

South American sea lions may also injure, abduct, or kill South American fur seal pups without consuming them. Interspecific pup abduction was observed in Peru (Harcourt, 1993), Chile (H. Pavés, pers. comm.), and Uruguay (Vaz Ferreira and Bianco, 1987; Cassini, 1998), where sea lions and fur seals live sympatrically. Males grab a fur seal pup, take it to neighboring beach, and toss and shake the pup, often to death. Young males also defend pups from other sea lions, a behavior that closely resembles the pup abductions within their own species. Fur seal pups may be killed as an indirect consequence of violent treatment, but are not consumed by their abductors. Mothers that attempt to protect their abducted pups typically fail to overpower young males.

In summary, pup killing in some species (e.g., Steller sea lions) is more common in the context of interspecific predation, whereas in others (e.g., South American and Australian sea lions) it occurs more often in a sexual or aggressive social context. In general terms, pup abuse follows a similar pattern to female abuse, with the most aggressive species toward pups being also violent toward conspecific and interspecific females.

D. The Adaptive Meaning of Infant Abuse and Killing

Several hypotheses have been proposed to account for infanticide in mammals (Hausfater and Hrdy, 1984; Ebensperger, 1998): (1) exploitation or predation, young are killed for nutritional benefits;

(2) resource competition, adult kill unrelated young to increase access to food or breeding space for themselves or their offspring; (3) sexual selection, males kill unrelated offspring to achieve reproductive access to females; (4) parental manipulation, a parent reduces litter size by eliminating all or part of a litter; and (5) social pathology, a maladaptive behavior. Adaptive explanations for the killing of young in aquatic mammals have been suggested for bottlenose dolphins (sexual selection, Connor *et al.*, 1996) and Hooker's sea lions (cannibalism; Wilkinson *et al.*, 2000).

Cannibalism is exceptional among aquatic mammals, and social pathology would be involved in cases such as the cannibal adult male gray seal and the subadult male southern elephant seal described earlier. However, cannibalism in Hooker's sea lions was suggested to fit the food resource hypothesis. Several males kill and eat pups in a fashion similar to that described for the same species preying on fur seals. Pups are easy targets for males and may supply calories in excess of the daily energy requirement of a male, as has been suggested to explain predation of South American sea lions on South American fur seals (Harcourt, 1993). Cannibalism in polar bears appears to occur as carrion feeding and as attacks by males on cubs. There is also evidence of a polar bear male feeding on an adult female, but this is a rare observation of difficult interpretation.

Most instances of infant abuse and killing in pinnipeds are better understood as epiphenomena of indiscriminate sexual and aggressive behaviors (Le Boeuf and Campagna, 1994). Social context, sexual dimorphism, and sexually selected behaviors may set the context for the occurrence of injury and death of the young. Pinniped colonies are often dense, parental investment is limited to females, males are large relative to pups and females, and male movements are frequent in the vicinity of pups. At times during the breeding season, pups may be the most abundant age class in a rookery, increasing the opportunity of social interaction. Reproductive females are aggressive toward conspecifics in general and alien pups in particular. Female aggressive behavior in this context may be explained by the cost of producing milk for individuals that are fasting while nursing. A large proportion of the breeding males do not have sexual access to females, and males have indiscriminate sexual behavior. Pups, particularly those close to be weaned, may be almost as large as young mature females, and are often confused as females. South American sea lion and northern and southern elephant seal males kill pups in the context of misplaced sexual behavior. Abducted South American sea lion pups, e.g., are treated as female substitutes, perhaps as a practice of herding or harem keeping (Campagna *et al.*, 1988b). Pups born in a harem are not likely to be the offspring of the dominant male, since they were sired the previous season. Behavioral mechanisms that can protect pups from direct and indirect violence (e.g., being crushed during male fights) are not then under selective pressure. Infanticide in the Australian sea lions may be the consequence of misdirected aggression. It has been suggested that territorial males may perceive pups as a threat. After killing a pup, males return to their usual position in the territories (Higgins and Tedman, 1990).

It is not yet clear to what extent the abuse and killing of conspecific pups may have a common evolutionary substrate with violent behaviors directed to mature females of the same or other species, and toward the young of other species. Examples among the otariids suggest that a circular gradation may exist from simple predation to infanticide to cannibalism. Steller sea lions kill pups of other species as predators but rarely or never abuse conspecific pups as abductors; South American sea lions prey on pups of other species when adults, and abduct (but do not eat) pups of the same and other species when young; and Hooker's sea lions abduct, abuse, kill and eat conspecific

and interspecific pups. It remains to be determined if this progression is actual. It is possible, however, that the behavioral similarities among these phenomena may indicate a key to understanding the evolutionary origin of abuse.

Albinism

DAGMAR FERTL AND PATRICIA E. ROSEL

Albinism refers to a group of inherited conditions resulting in little or no pigment (hypopigmentation) in the eyes alone or in the eyes, skin, and hair. In humans, all types of albinism exhibit abnormalities in the optic system, including incorrect connections of the optic fibers between the retina and the brain, and incomplete development of the fovea, the area of the retina where the sharpest vision is located (Oetting and King, 1999). It is the presence of these types of eye problems that are best used to define albinism rather than the abnormalities in pigmentation. Inheritance of an altered copy of a gene that does not function correctly is the cause of most types of albinism, and mutations in at least 12 different genes have been identified in different types of albinism in humans (Oetting *et al.*, 2003). Albinistic people most often have white or light skin and hair, and eye color varying from dull gray-blue to brown. In one kind of albinism, only eye color is affected. The “pink” eyes often associated with albinism are due to the reflection from choroid capillaries behind the retina. With pigment lacking in the iris of the eyes, this reflection is visible, similar to red-eye in a flash photograph.

I. Pigmentation

Mammalian color is almost entirely dependent on presence (or absence) of the pigment melanin in the skin, hair, and eyes. Melanin is produced through a stepwise biochemical pathway in which the amino acid tyrosine is converted to melanin. The enzyme tyrosinase plays a critical role in this pathway, and alterations or mutations in the tyrosinase gene can result in a defective enzyme that is unable to produce melanin, or does so at a reduced rate. Currently, as many as 100 different mutations in this gene have been found associated with albinism (Oetting *et al.*, 2003). At the other end of the spectrum, overproduction of the pigment melanin results in melanism—overly dark animals (Visser *et al.*, 2004). Albinism is differentiated from piebaldism (body pigmentation missing in only some areas) and leucism (dark-eyed anomalously white animals) (Fig. 1). Pigmentation patterns should not be the only criterion used to define albinism, as some mutant phenotypes (pseudualbinism) may be due to the action of genes at other loci.

Figure 1 Leucistic Antarctic fur seal (*Arctocephalus gazella*) at the isolated subantarctic island, Bouvetøya. Photo by Greg Hofmeyr.

II. Albinism and Marine Mammals

Albinism is known to affect mammals, birds, fish, reptiles, and amphibians. In marine mammals, anomalously white individuals have been reported for 21 cetacean species (Fertl *et al.*, 1999; Fertl *et al.*, 2004) and 7 pinniped species (e.g., Rodriguez and Bastida, 1993; Bried and Haubreux, 2000) (Fig. 2). No reports are known of anomalously white sea otters (*Enhydra lutris*) or sirenians. Anomalously white individuals are often presumed to be true albinos. Some of those individuals match the description of true albinism [e.g., there are well-documented reports of albino sperm whales (*Physeter macrocephalus*) and bottlenose dolphins (*Tursiops truncatus*)], but many do not. “Chimo,” an anomalously white killer (*Orcinus orca*) captured for display in Canada, was diagnosed postmortem with Chédiak–Higashi Syndrome, (Fig. 3), a type of albinism (Taylor and Farrell, 1973). This inherited disorder is characterized by diluted pigmentation patterns that appear pale gray, eye and white blood cell abnormalities, and a shortened life span. Whales and dolphins also may appear white if extensively scarred, or covered with a fungus, such as Lobo’s disease (also known as lobomycosis) (Migaki *et al.*, 1971).

III. Problems Associated with Albinism

Humans with albinism are often sensitive to light, have limited visual acuity and may display other vision impairments, such as extreme farsightedness, nearsightedness, and astigmatism. There

are unpublished reports of apparent vision problems for albino seals, when they are on shore (King, 1983). Costs of this aberrant pigmentation for marine mammals may include reduced heat absorption in colder waters, increased conspicuousness to predators, increased skin and eye sensitivity to sunlight, and impaired visual communication (Hain and Leatherwood, 1982). Despite the costs, some individuals do reach adult age and breeding status.

Amazon River Dolphin

Inia geoffrensis

VERA M.F. da SILVA

I. Characteristics and Taxonomy

The Amazon River dolphin is known as boto or boto-vermelho in Brazil; bufeo colorado in Colombia, Ecuador, and Peru; and toninha and delphin Rosado in Venezuela. It is also known in English as pink dolphin and internationally as boto.

It belongs to the family Iniidae (Mead and Brownell, 2005). The genus *Inia* is currently considered monospecific, with three recognized subspecies: *Inia geoffrensis geoffrensis*, *I. g. boliviensis*, and *I. g. humboldtiana*. However, skull morphology (da Silva, 1994) and genetic analysis (Banguera-Hinestroza *et al.*, 2002) suggest that *I. g. boliviensis* could be a separate species.

The boto (Fig. 1) is the largest of the river dolphins with a maximum recorded body length of 255 cm and body mass of 207 kg for males and 225 cm and approximately 153 kg for females. It is also the most sexually dimorphic of the river dolphins, with males 16% longer and 55% heavier than females (Martin and da Silva, 2006). The body is corpulent and heavy but extremely flexible. Nonfused cervical vertebrae allow movements of the head in all directions. The flukes are broad and triangular; the dorsal fin is long, low, and keel-shaped, extending from the mid-body to the strong, laterally flattened caudal peduncle. The flippers are large, broad, and paddle-like and are capable of separate circular movements. Although most of these characteristics restrict speed during swimming, they allow this dolphin to swim backward and to maneuver between trees and submerged vegetation to search for food in the flooded forest. The rostrum and mandible are prominent, long, and robust. Short bristles along the top of the rostrum persist into adulthood. The melon is small and soft, and the shape can be altered by muscular control. The small, round eyes are functional and the vision is good, both under and above water (Best and da Silva, 1989a,b).

Body color varies with age. Fetuses, neonates, and young animals are dark gray. This pigmentation diminishes in intensity through adolescence to a light gray color. Adult botos become pinker as a consequence of severe scarring on the body surface. Males are pinker than females and more heavily scarred due to intermale aggression (Martin and da Silva, 2006). Adult botos can be dark on the dorsum, but the flanks and underside are pinkish. One albino was captured and maintained in captivity for more than a year in an aquarium in Germany.

II. Distribution and Abundance

The boto has a wide distribution, occurring almost everywhere it can physically reach without venturing into marine waters. It occurs in six countries of South America—Bolivia, Brazil, Colombia, Ecuador, Peru, and Venezuela—in an area of about 7 million km². It can be found along the entire Amazon River and its principal tributaries, smaller rivers, and lakes, from the mouth near Belém to its headwaters in the Ucayali and Marañon Rivers in Peru. Its principal limits are impassable falls such as those of the upper Xingú and Tapajós Rivers in Brazil, and very shallow waters. A series of rapids and falls along the Madeira River up to the Abuña falls has isolated a population of boto (*I. g. boliviensis*) in the Beni/Mamoré basin in Bolivia, in the southern part of the Amazon Basin. The boto is also found throughout the Orinoco River basin, with the exception of the Caroni and upper Caura Rivers above Para falls in Venezuela. The only connection between the Orinoco and Amazon River Basins is the Cassiquiare Canal, where botos have been sighted. The boto is the most abundant river dolphin. Its current distribution and abundance apparently do not differ from those in the past, although local relative abundance and density are highly seasonal and appear to vary between rivers. During the dry season the dolphins are concentrated in the main channels of the rivers, whereas during the flooded season they disperse into the flooded forest (igapó) and river floodplains (várzea).

Differences in survey methodology used by various workers make comparisons between the results of the different surveys of abundance

difficult. Long-distance surveys were carried out on the Solimões–Amazon River, from Manaus to Santo Antonio do Içá–Tabatinga, over a total of 1200 km. The number of sightings averaged 332 ± 55 botos per survey ($n = 9$), and the estimated density was 0.08–0.33 botos/km in the main river and 0.49–0.93 botos/km in the smaller channels. Another boat survey along 120 km of the Amazon River bordering Colombia, Peru, and Brazil carried out by Vidal *et al.* (1997) estimated 345 ($CV = 0.12$) botos in the study area with a density per km² of 4.8 in tributaries, 2.7 around islands, and 2.0 along the main banks. In the central Amazon, six multiday visual surveys covering a total track-line distance of 1402 km in strip transect and 810 km in line transect mode were performed throughout the flooding cycle in the Japurá and Amazon Rivers (Martin *et al.*, 2004). The estimated density along river margins across all surveys was 3.7 botos per km². The density was higher at the river margin, declining with distance toward the center of the river, where the density was lower than for any edge-type habitat along the river margins. In floodplain channels, where a cyclical pattern of boto density followed the water level, Martin and da Silva (2004) estimated peak densities of 18 botos per km², whereas in rivers and large lakes margins the mean density varied from 1.8 to 5.8 km⁻². These figures suggest that the boto occurs at higher densities than any other cetacean.

III. Ecology

The boto is active day and night. The greatest fishing activity occurs between 0600–0900 and 1500–1600 h. It feeds on over 43 species of fish belonging to 19 families. Stomach content analysis has revealed up to 11 fish species in one animal. The mean size of consumed fish is 20 cm (range 5–80 cm), with large fish torn to pieces. In captivity, food sharing has been recorded. Daily consumption is about 2.5% of body weight. The botos diet is unique among cetaceans in that its heterodont dentition allows it to tackle and crush armored prey (da Silva, 1994).

IV. Behavior and Physiology

The boto is mostly solitary and is not commonly seen in cohesive groups. Group size is generally from one to four individuals. Most groups of two are mother–calf pairs, but mixed groups and groups of males are also common. Large loose aggregations may be seen at confluences and bends of rivers and canals due to large concentrations of fish, or for resting and social purposes. Spatial segregation of the sexes occurs among botos, where the proportion of adult males, at mid-rising and high water, is higher on the main rivers and lower toward the innermost parts of the flood forest, where most females and calves are found. During low water, all habitats available are equally used by both sexes. Mark–recapture studies carried out in Central Amazon, Brazil, have shown that some individuals are resident in a particular area during the entire year (Martin and da Silva, 2004).

The boto is a slow swimmer with a normal speed of 1.5–3.2 km/h, but bursts of >14–22 km/h have also been recorded. It is capable of strong swimming for some length of time. When surfacing, the melon, tip of the rostrum, and long dorsal keel are out of water simultaneously in a very conspicuous way. The boto does a high-arching roll in which these parts appear sequentially thrust well out of the water. The tail is rarely raised out of the water before a dive. Botos also wave a flipper, show the head or tail above the surface, lob-tail, spy hop, and ‘rarely’ jump clear of the water.

Studies in captivity indicate that botos are less timid and show less social contact, aggressive behavior, play and aerial behavior than

bottlenose dolphins. They are very curious and playful, rarely showing fear of strange objects. However, captivity may not show their true range of behaviors. Wild botos grasp fishermen’s paddles, rub against canoes, pull grass under water, throw sticks, and play with logs, clay, turtles, snakes, and fish. They are known to react protectively to injured or captured individuals. Several observers have reported seeing botos in a stationary position, often upside down, with the eyes closed.

V. Life History

Males attain sexual maturity much later than females at about 200 cm in length. In females, sexual maturity occurs at around 6–7 years of age at body lengths between 175 and 180 cm. Reproductive events are seasonal, and the mating season coincides with low water levels. Gestation time has been estimated at about 11 months, and the calving season is apparently long, with most births occurring at the peak of the river’s flood level. The boto’s length at birth is about 80 cm. Lactation lasts for more than 1 year and the birth interval is from 2 to 3 years.

VI. Interactions with Humans

The boto is part of the folklore and culture of Amazonian people, and several legends and myths are commonly known throughout its distribution. Because of these legends, often involving supposed supernatural powers; the boto was protected and respected in the past, although old records mention the use of its oil for illumination. Body parts of incidentally captured animals have been used by local people for medical purposes and as love charms. Recent molecular analysis has revealed that most of the eyes sold in markets in different parts of the Amazonian region, today, as being of *I. geoffrensis* are in reality from *Sotalia guianensis*, which is also known along the coast of Pará and Amapá States as “boto.” With increased use of nylon gill nets, machine-made lampara seines, and other fishing techniques, the incidental catching of botos has become more common. Since the mid-1990s a direct catch for use as bait to catch a scavenging catfish, known in Brazil as “piracatinga” (*Callophrys macropterus*), has become the most severe threat to the species. Other threats are the construction of hydroelectric dams on major tributaries affecting the abundance and presence of some species of fish. Dams separate and isolate populations and may reduce the gene pool, thereby increasing chances of local extinction.

I. geoffrensis is listed in Appendix II of the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) and is classified by the IUCN as Vulnerable because of serious threats throughout its range.

Ambergris

DALE W. RICE

Ambergris is a substance that forms only in the intestines of the sperm whale (*Physeter macrocephalus*). The word comes from the Old French *ambre gris* or “gray amber,” as opposed to *ambre jaune*, “yellow amber,” which refers to the true, resinous amber. Most ambergris is found in the large intestine or rectum. Probably most lumps of ambergris are eventually voided during defecation, unless they grow too large to pass through the anus. Ambergris is rather rare and may be found in only a few sperm whales. The only fishery in which every whale landed was thoroughly searched for ambergris was that which operated from the island of San Miguel in the Azores from 1934 to 1953; there ambergris was found in only 19 of 1933 whales, or 0.98% (Clarke 2006) (Fig. 1).

Ambergris forms as concretions that usually weigh 0.1–10.0 kg, but rarely much bigger pieces have been recovered; the largest on record, weighing 420 kg, was removed from a 14.9 m bull sperm whale killed in the Southern Ocean on December 21, 1953 (Clarke, 1954). Such huge masses greatly distend the whale’s large intestine. Most pieces of ambergris are in the form of an irregular roundish lump, somewhat resembling a potato. Their specific gravity is 0.73–0.95. In consistency they are solid and friable, similar to nearly dry clay. Internally they usually show no laminations, but when broken apart they tend to fracture along concentric cleavage surfaces. In color they are pale yellowish to light gray on the inside, while the outer surface is dark brown with a varnished appearance. The chitinous beaks of cephalopods may almost invariably be found imbedded in the lumps. Fresh ambergris has the highly distinctive pungent odor of sperm whale feces, but aged pieces have an almost pleasant odor or even musky smell.

Figure 1 Lump of ambergris recovered from the rectum of a male sperm whale 16.5 m long (specimen no. DWR 19600189) killed near the Farallon Islands off central California on 11 May 1960. Note the smooth spherical cleavage surface partially exposed on the upper left where several chunks have been broken off. Scale in centimeters.

Chemically ambergris is a nonvolatile solid consisting mainly of a mixture of waxy, unsaturated, high molecular-weight alcohols. The principal components are epicoprosterol and an ester of ambrein. Epicoprosterol and coprosterol have been found in the feces of other mammals. Ambrein ($C_{23}H_{39}OH$) is the substance which gives ambergris its peculiar properties and odor (Gilmore, 1951). One analysis gave the following chemical composition: ambrein, 25–45%; epicoprosterol, 30–40%; coprosterol, 1–5%; coprostanone, 3–4%; cholesterol, 0.1%; pristane, 2–4%; ketone, 3–4%; free acids, 5–8%; residues insoluble in ether, 10–16% (Berzin, 1971; this analysis was mistranslated in the 1972 English edition of Berzin’s book).

The circumstances that induce the production of ambergris are poorly understood. Clarke (2006) hypothesized that the formation of ambergris begins when a mass of indigestible material—mainly squid beaks, which the whale normally vomits—manages to pass through the duodenum. If this mass blocks the intestine, the intestinal wall reacts by absorbing water from the feces-impregnated mass, thus causing it to solidify. As this process continues the mass increases in size by the accretion of additional solid layers.

Contrary to the prevalent notion, ambergris is hardly ever found on beaches; most is recovered directly from whale carcasses. Through the years many people have brought me malodorous globs that they picked up on the seashore in hopes that it was ambergris; none of it ever was. If a suspected specimen of ambergris fits the physical description, the simplest way to confirm its identity is to heat a wire or needle in a flame and thrust it into the sample to a depth of about a centimeter; if the substance is really ambergris it will instantly melt into an opaque fluid the color of dark chocolate. When the needle is withdrawn, the ambergris will leave a tacky residue on it.

Ambergris was known throughout the Moslem world as early as the ninth century. There it was highly valued as an incense, an

aphrodisiac, a laxative, a spice, an ingredient in candles and cosmetics, and as a medication for treating a diversity of ailments. Its reputation soon spread around the globe. In those days ambergris was picked up on beaches or found floating on the sea, and its origin remained a complete mystery, thus giving rise to many fanciful and hotly debated theories. In 1574 the Flemish botanist Carolus Clusius was the first author to deduce from the inclusions of squid beaks in ambergris that it was the product of the digestive tract of whales. It was not until after the commencement of the American sperm whale fishery in 1712 that it became generally recognized that ambergris was produced solely by the spermaceti whale (Beale, 1839; Dannenfeldt, 1982). In the ensuing years ambergris was prized mainly as a fixative for fragrances in perfumes. In the twentieth century synthetic chemicals replaced it, so it no longer has much value.

Anatomical Dissection: Thorax and Abdomen

JOHN E. REYNOLDS, III AND SENTIEL A. ROMMEL

The general organization of the posterianal soft tissues does not vary appreciably among mammals. Factors that may influence the relative proportions or positions of organs and organ systems include phylogeny and adaptations to a particular environment or trophic level.

The structure and function of specific organs or organ systems are described in other articles of this encyclopedia. This article provides a "road map" that orients a prosector to the organs and organ systems of marine mammals. For comparative purposes, we focus on the California sea lion (*Zalophus californianus*), Florida manatee (*Trichechus latirostris*), harbor seal (*Phoca vitulina*), and common bottlenose dolphin (*Tursiops truncatus*). Our descriptions are at the gross anatomical level.

To recognize variations on a theme, one must first recognize the theme. Although there is no "typical" mammal, we shall use our own species and the domestic dog as the norms against which to make comparisons. To appreciate human and dog anatomy, we suggest

Hollinshead and Rosse (1985) and Evans (1993), respectively. Anatomy of internal organs of domestic mammals is covered by Schummer *et al.* (1979). For discussions of the anatomy of various types of marine mammals, consult Fraser (1952), Green (1972), Herbert (1987), Howell (1930), King (1983), Murie (1872, 1874), Pabst *et al.* (1999), von Schulte (1916), Slijper (1962), and St. Pierre (1974). Whenever possible, anatomical terms follow the *Nomina Anatomica Veterinaria* as illustrated by Schaller (1992).

I. Mammalian Postcranial Landmarks

Marine mammals are generally dissected either ventrally or laterally, but some large, stranded animals must be examined in whatever position they are found. For consistency, we provide figures that describe anatomy in terms of a lateral view, and we discuss organs and organ systems in the order in which they are revealed during necropsy. Although this approach may take some getting used to if one is accustomed simply to the ventral approach, the lateral orientation approximates the living condition more closely.

A. The Diaphragm

The diaphragm of most marine mammals is generally similar in orientation to that of the diaphragm in both the human and the dog. It lies in a transverse plane and provides a musculotendinous sheet to separate the heart and its major vessels, the lungs and their associated vessels and airways, the thyroid, thymus, and a variety of lymph nodes (all located cranial to the diaphragm) from the major organs of the digestive, excretory, and urogenital systems (all typically caudal to the diaphragm). The diaphragm is generally confluent with the transverse septum (a connective tissue separator between the heart and the liver) and, thus, attaches medially at its ventral extremity to the sternum.

Although the diaphragm separates the heart and lungs from the other organs of the body, the diaphragm is traversed by nerves and other structures such as the aorta (crossing in a dorsal and medial position), the caudal (inferior) vena cava (crossing more ventrally than the aorta, and often slightly right of the midline, although appearing to approximate the center of the liver), and the esophagus (crossing slightly right of the midline, at roughly a midhorizontal level). This approximately transverse orientation exists in most marine mammals, although the orientation of the diaphragm may be more or less diagonal, with the ventral portion being more caudal than the dorsal portion.

The West Indian manatee's diaphragm differs from this general pattern of orientation and attachment. The diaphragm and the transverse septum are separate, with the septum occupying approximately the "typical" position of the diaphragm and the diaphragm itself occupying a horizontal plane extending virtually the entire length of the body cavity (Fig. 1B). This apparently unique orientation contributes to buoyancy control (Rommel and Reynolds, 2000). Additionally, there are two separate hemidiaphragms in the manatee (Figs 2B, C). The central tendons attach firmly to the ventral aspects of the thoracic vertebrae, producing two isolated pleural cavities. The position of the manatee diaphragm stands in contrast with the curved, oblique diaphragm (DIA, Fig. 3) of the sea lion, seal, and dolphin.

B. Regions and Structures Cranial to the Diaphragm

The region cranial to the diaphragm is typically compartmentalized into three sections (1) the pericardium (containing the heart),

Figure 1 Schematic arrangements of mammalian diaphragms (modified after Rommel and Reynolds 2000). (A) The typical mammalian diaphragm extends ventrally from the dorsal midline to attach to the sternum. The typical diaphragm is a separator between the heart and lungs in the front and the liver and other abdominal organs in the back. (B) The manatee diaphragm extends dorsal to the heart and does not touch the sternum. There is a mechanical barrier between the heart and the liver and other abdominal organs but it is a relatively weak barrier called the transverse septum.

(2) the pleural cavities (containing the lungs), and (3) the mediastinum (Figs 3 and 4).

The pericardium is a fluid-filled sac surrounding the heart (HAR, Fig. 3); in manatees, it often contains more fluid than is found in the pericardia of the typical mammal or in those of other marine mammals. The heart occupies a ventral position in the thorax (immediately dorsal to the sternum), making it easy to see when the overlying muscles, ribs, and sternum are separated. The heart lies immediately cranial to the central portion of the diaphragm (or just the transverse septum in the manatee). Some lungs may embrace the caudal aspect of the heart, separating the heart from the diaphragm. As do the hearts of all other mammals, marine mammal hearts have four chambers, separate routes for pulmonary and systemic circulation, and the usual arrangements of great vessels (vena cavae, aorta, coronary arteries, and pulmonary vessels). Cardiac fat is commonly found in manatees but is typically absent in pinipeds and cetaceans.

The pleural cavities and lungs of mammals are generally found dorsally and laterally to the heart and are separated along the midline by the heart and mediastinum (discussed later). In the manatee, the lungs are unusual in that they extend virtually the length of the body cavity and remain dorsal to the heart (Rommel and Reynolds, 2000). Lungs of some marine mammals (cetaceans and sirenians) often lack lobes. The size of the lungs of marine mammals varies according to each species' diving proficiency. Marine mammals that make deep and prolonged dives (e.g., elephant seals, *Mirounga* spp.) tend to have smaller lungs than expected (based on allometric relationships) whereas shallow divers (e.g., sea otters, *Enhydra lutris*) tend to have larger than expected lungs.

The mediastinum is typically considered to be the area between the lungs, excluding the heart and pericardium. The mediastinum contains the major vessels leading to and emanating from the heart, nerves (e.g., the phrenic nerve to the diaphragm), and lymph nodes. The thymus, which is larger in younger individuals, is found on the cranial aspect of the pericardium (sometimes extending caudally to embrace almost the entire heart) and may extend into the neck in some species. The thyroid gland is located in the cranial part of the mediastinum along either side of the distal part of the trachea, cranial to its bifurcation into the bronchi (in sea lions, but not in other marine mammals, the bifurcation is cranial to the thoracic inlet).¹ In most marine mammals, the mediastinum is generally not remarkable; in the

manatee, however, the unusual placement of the lungs and the unique diaphragm change how one must define the mediastinum (Rommel and Reynolds, 2000).

One additional structure, located on the cranial aspect of the diaphragm in seals and sea lions, is an atypical mammalian muscular feature associated with the heart. This is the caval sphincter (CAS, Fig. 3), which can regulate the flow of oxygenated² blood in the large hepatic sinus to the heart during dives (Elsner, 1969).

C. Structures Caudal to the Diaphragm

Easy to find landmarks caudal to the diaphragm include a massive liver and the various components of the gastrointestinal (GI) tract. The urogenital organs are generally found only after removal of the GI tract (note that the exception is the uterus of the pregnant female).

1. *The Liver*. Typically, the liver is located immediately caudal to the diaphragm. It is a large, brownish, multilobed organ positioned so that most of its volume/mass is to the right of the midline of the body. Although marine mammal livers are generally similar to the livers of other mammals, in manatees, the organ is displaced somewhat to the left and dorsal relative to its location in most other mammals. The size, color, and "sharpness" of the liver margins can be used to assess the nutritive state and health of individual animals. Bile may be stored in a gallbladder (often greenish in color) located ventrally between the lobes of the liver, although some species (e.g., cetaceans, horses, and rats) lack a gallbladder. Bile enters the duodenum to facilitate the chemical digestion of fats.
2. *The GI Tract*. Most of the volume of the cavity caudal to the diaphragm (the abdominal cavity) is occupied by the various components of the GI tract: the stomach, the small intestine (duodenum, jejunum, and ileum), and the large intestine (cecum,

¹The thoracic inlet is the cranial opening of the thoracic cavity and is bounded by the vertebral and sternal ribs and sternum.

²Diving mammals with abundant arteriovenous anastomoses (shunts between arteries and veins that bypass capillary beds) can have high blood pressure and highly oxygenated blood in their veins. One such venous reservoir of oxygenated venous blood is the hepatic sinus of seals (King, 1983).

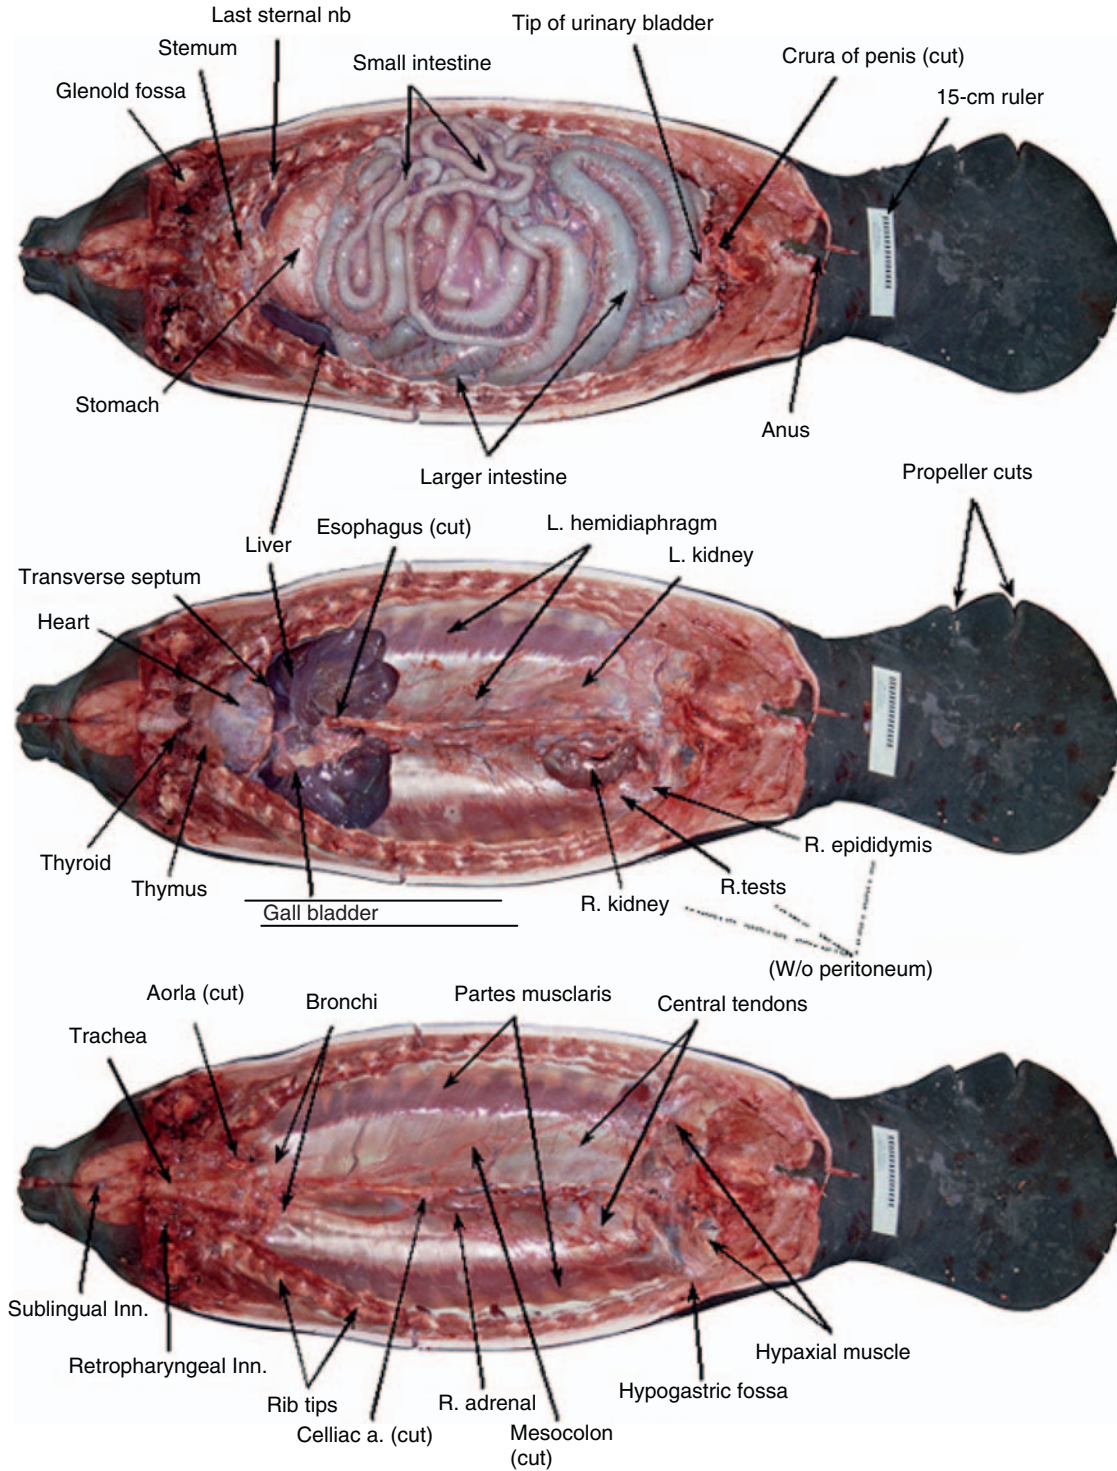

Figure 2 Photographs of ventral views of the Florida manatee (modified after Rommel and Reynolds 2000). The ruler is 15-cm long. (A) After removal of the ventral skin, fat, and musculature, the small and large intestines are exposed; the large intestine (with contents) may account for 10% of the total body weight and can measure 20-m long. Portions of the stomach and ventral margins of the liver are visible caudal to the sternum. (B) Removal of the sternum and GI tract reveals the heart, transverse septum, liver, hemidiaphragms, and right kidney (the left kidney was removed to expose that portion of the hemidiaphragm). (C) The two central tendons of the hemidiaphragms attach medially to the ventral aspects of the vertebral column. The diaphragm muscles attach laterally to the ribs. The lungs are flattened, elongate structures dorsal to the hemidiaphragms; when fully inflated, the lungs extend almost the entire length of the region dorsal to the hemidiaphragms. Note the junctions of the central tendon and the pars muscularis of each hemidiaphragm; this approximates the lateral margin of each lung.

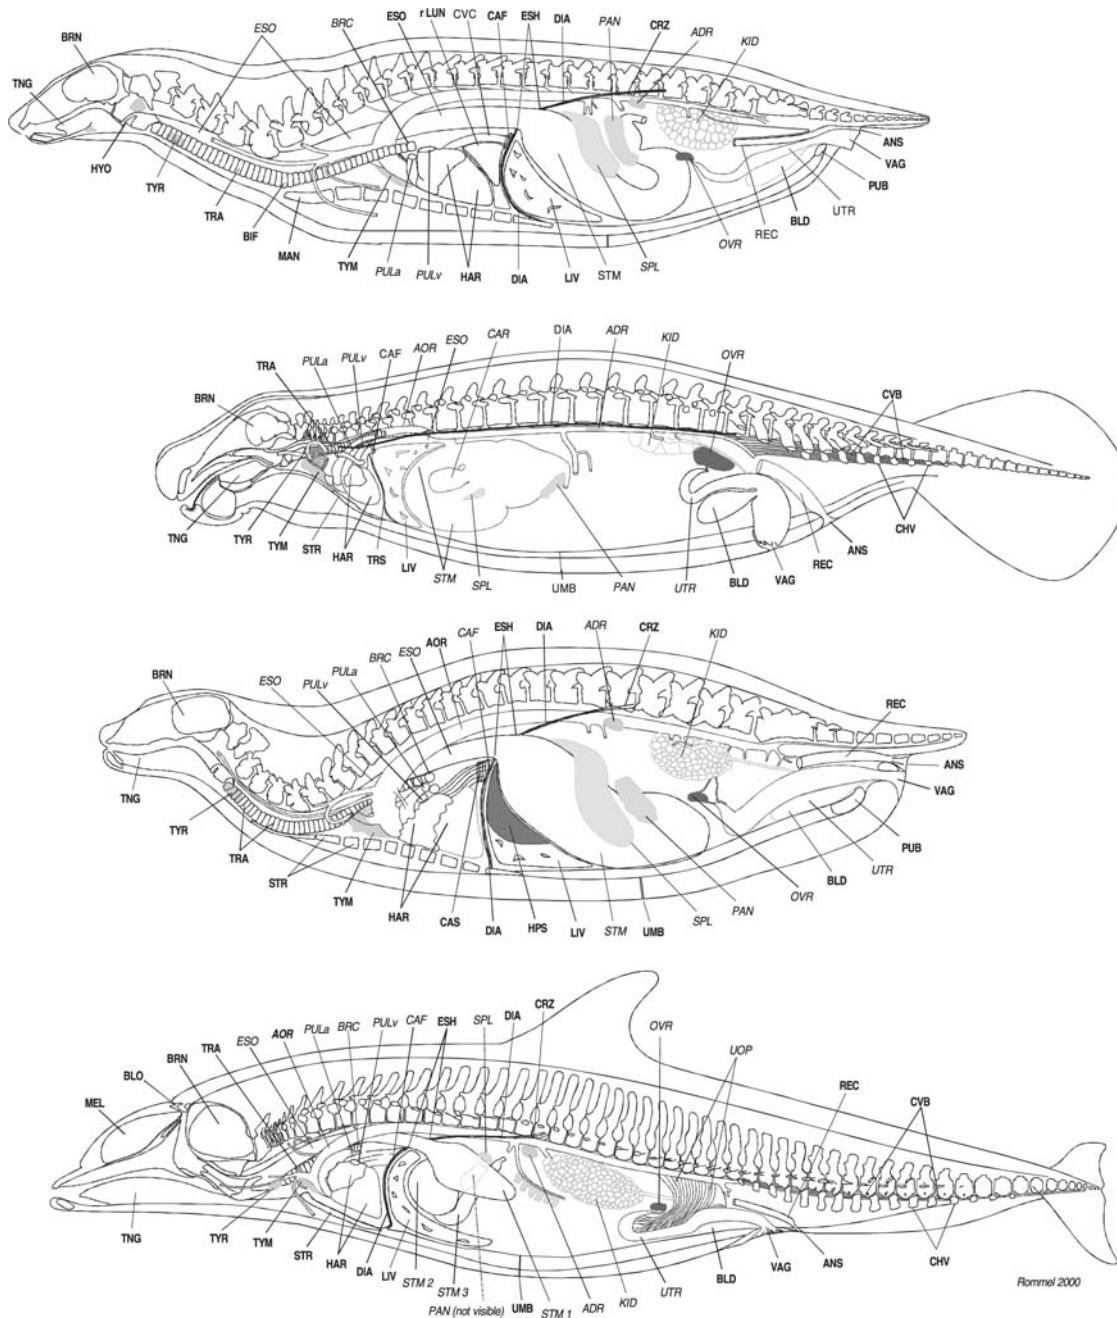

Figure 3 Left lateral illustrations of the superficial internal structures and “anatomical landmarks” of the California sea lion (*Zalophus californianus*), Florida manatee (*Trichechus manatus latirostris*), harbor seal (*Phoca vitulina*), and bottlenose dolphin (*Tursiops truncatus*) with the skeleton (minus the distal appendicular elements) superimposed for reference. Our view is a left lateral view, focused on relatively superficial internal structures (labeled in bold) visible from that perspective; the other important bony or soft “landmarks” are not necessarily visible from a left lateral view but they are useful for orientation and are labeled in italics. Skeletal elements are included for reference, but not all are labeled—for these details, consult the figures in the skeleton postcranial and skull chapters. Each drawing is scaled so that there are equivalent distances between the shoulder and the hip; thus, the thoracic and abdominal cavities are roughly equal in length. The shoulder joints are aligned. The left kidney (not visible from this view in the manatee) is illustrated. The relative sizes of the lungs represent partial inflation—full inflation would extend margins to distal tips of ribs (except in the manatee). The following abbreviations are used as labels (structures on the midline are in bold, those off-midline are in italics): **ANS**, anus; **BLD**, urinary bladder; **BLO**, blow hole of dolphin; **DIA**, diaphragm, midline extent (except manatee); **EYE**-eye (note small size in manatee); **HAR**, heart; **ILC**, iliac crest of the pelvis; **INT**, intestines; note the large diameter of the large intestines in the manatee; **KID**, left kidney (not visible from this vantage in the manatee); **LIV**, liver; **LUN**, lung (note that in this illustration, the lung extends under the scapula except in the seal); **MEL**, melon, dolphin only; **OLE**, olecranon of ulna; **OVR**, left ovary; **PAN**, pancreas (in this view visible only in seal and sea lion); **PAT**, patella; **PEL**, pelvic vestige; **REC**, rectum; **SCA**, scapula; **SPL**, spleen; **STM**, stomach; **TRA**, trachea (not visible in this view of the manatee); **TYM**, thymus gland; **TYR**, thyroid gland; **UMB**, umbilical scar; **UOP**, uterovarian plexus in dolphins; **UTR**, uterine horn; **VAG**, vagina. © S.A. Rommel.

Figure 4 A view slightly to the left of the midsagittal plane illustrates the circulation, body cavities, and selected organs of the California sea lion (*Zalophus californianus*), Florida manatee (*Trichechus manatus latirostris*), harbor seal (*Phoca vitulina*), and bottlenose dolphin (*Tursiops truncatus*), with the skeleton for reference. The left lung is removed. Note that the diaphragm separates the heart and lungs from the liver and other abdominal organs. Each drawing is scaled so that there are equivalent distances between the shoulder and the hip; thus, the thoracic and abdominal cavities are roughly equal in length. The shoulder joints are aligned. Note that the manatee's diaphragm is unique and that the distribution of organs and the separation of thoracic structures from abdominal structures require special consideration in these beasts. The following abbreviations are used as labels (structures on the midline are in bold, those off-midline are in italics): **ADR**, adrenal gland; **ANS**, anus; **AOR**, aorta; **BLD**, urinary bladder; **BLO**, blowhole; **BRC**, bronchus; **BRN**, brain; **CAF**, caval foramen; **CAR**, cardiac gland, in manatee only; **CAS**, caval sphincter, surrounding the vena cava in the seal and sea lion; **CHV**, chevron bones; **CRZ**, crus (plural crura) of the diaphragm; **CVB**, caudal vascular bundle, in manatee and dolphin; **DIA**, diaphragm, cut at midline, extends from crura dorsally to sternum ventrally (except in manatees); **ESH**, esophageal hiatus; **ESO**, esophagus (to the left of the midline cranially, on the midline caudally); **HAR**, heart; **HPS**, hepatic sinus within liver, in seals only; **KID**, right kidney; **LIV**, liver, cut at midline; **LUN**, lung, right lung between heart and diaphragm; **MEL**, melon, dolphin only; **PAN**, pancreas; **PUB**, pubic symphysis (seals and sea lions only); **PULa**, pulmonary artery, cut at hilus of lung; **PULv**, pulmonary vein, cut at hilus of lung; **REC**, rectum, straight part of terminal colon; **SPL**, spleen; **STM1**, fore stomach; **STM2**, main stomach (**STM** in non-cetaceans); **STM3**, pyloric stomach; **STR**-sternum, sternabrae; **TNG**-tongue; **TRA**-trachea; **TRS**-transverse septum; **TYM**-thymus gland; **TYR**, thyroid. © S.A. Rommel

colon, and rectum). The proportions and functions of these components reflect the feeding habits and trophic levels of the different marine mammals. Therefore, the gastrointestinal tracts of marine mammals vary considerably.

Food and water travel from the mouth, through a muscular pharynx, and into the esophagus. As noted earlier, the latter pierces the diaphragm to join the stomach, which is typically a single, distensible sac. The distal end of the stomach (the pylorus) is marked by a strong sphincter before it connects with the small intestine (duodenal ampulla in cetaceans). The separation between jejunum and ileum of the small intestine is difficult to distinguish grossly, although the two sections are different microscopically. The junction of the small and large intestines is often (but not in cetaceans) marked by the presence of a cecum (homologous to the human appendix). In manatees, the midgut cecum has two blind pouches called cecal horns. In some marine mammals, the large intestine, as its name implies, has a larger diameter than the small intestine.

The gastrointestinal tracts of pinipeds and other marine mammal carnivores follow the general patterns outlined earlier, although the intestines can be remarkably long in some species. Cetaceans, however, have some unique specializations (Gaskin, 1978). Cetaceans can have two or three stomachs (usually three) depending on the species being examined. The multiple stomachs of cetaceans function in much the same way as the single stomach found in most other mammals. The first stomach of cetaceans, called the forestomach (essentially an enlargement of the esophagus), is muscular and very distensible, and it acts much like a bird crop, i.e., as a receiving chamber. The second or glandular stomach is the primary site of chemical breakdown among the stomach compartments; it contains the same types of enzymes and hydrochloric acid that characterize a “typical” stomach. Finally, the “U-shaped” third or pyloric stomach ends in a strong sphincteric muscle that regulates the flow of digesta into the duodenum (the duodenal ampulla is sometimes mistakenly called a fourth stomach) of the small intestine. The cetacean duodenum is expanded into a sac-like ampulla. The only other remarkable feature at the gross level is the lack of a cecum, which makes it difficult to tell where the small intestine ends and the large intestine begins. The intestines of some cetaceans may be extremely long (especially in the sperm whale, *Physeter macrocephalus*; Slijper, 1962), but they are not especially long in many other marine mammal species.³

Among marine mammals, sirenians have the most remarkably developed gastrointestinal tract. Sirenians are herbivores and hindgut digesters (similar to horses and elephants) so the large intestines (specifically the colon) is extremely enlarged, enabling it to act as a fermentation vat (see Marsh *et al.*, 1977; Reynolds and Rommel, 1996). In horses, the cecum is the region of the large intestine that is enlarged, but in sirenians, the cecum is relatively small and has two “horns.” The sirenian stomach is single chambered and has a prominent accessory secretory gland (the cardiac gland) extending from the greater curvature. The duodenum is capacious and has two obvious diverticulae projecting from it. The GI tract and its contents can account for more than 20% of a manatee’s weight.

The length and mass of the gastrointestinal tract are impressive and create three-dimensional relationships that can be complex. Simplifying the organization is the fact that tough sheets of connective tissue called mesenteries suspend the organs from the dorsal part of the abdominal cavity and shorter bands of connective tissue (ligaments)⁴ hold organs close to one another in predictable arrangements (e.g., the proximal spleen is always found along the

greater curvature of the stomach and is connected to the stomach by the gastrosplenic, or gastrosplenic ligament). Also suspended in the mesenteries are numerous lymph nodes and fat.

Accessory organs of digestion include salivary glands (small in most marine mammals but very large in the manatee), pancreas, and liver (where bile is produced and then stored in the gall bladder). The pancreas is sometimes a little difficult to locate because it can be a rather diffuse organ and it decomposes rapidly postmortem; however, a clue to its location is its proximity to the initial part of the duodenum, into which pancreatic enzymes flow. Another organ that is structurally, but not functionally associated with the GI tract is the spleen, which is suspended by a ligament, generally from the greater curvature of the stomach (the first stomach in cetaceans) on the left side of the body. The spleen may be a single organ accompanied by accessory spleens in some species. The spleen is bluish in color and varies considerably in size among species; in manatees and cetaceans it is relatively small but is more massive in some deep-diving pinipeds (Zapol *et al.*, 1979) in which it acts as a storage region for red blood cells.

3. *Urogenital Anatomy.* The kidneys lie in a retroperitoneal position, typically against the musculature of the back (epaxial muscles) at or near the dorsal midline attachment of the diaphragm (crura). In the manatee, the unusual placement of the diaphragm means that the kidneys lie against the diaphragm, but not against the epaxial muscles. All mammals have metanephric kidneys (i.e., containing cortex, medulla, and calyces). In many marine mammals, the kidneys are specialized as reniculate (multilobed) kidneys, where each lobe (renule) has all the components of a complete metanephric kidney. Why marine mammals have reniculate kidneys is uncertain, but the fact that some large terrestrial mammals also have reniculate kidneys has led to speculation that they are an adaptation associated simply with large body size (Vardy and Bryden, 1981).

The renal arteries of cetaceans enter the cranial poles of the kidneys, whereas in other marine mammals, they enter the hilus (typical of most mammals). Additionally, in manatees, there are accessory arteries on the surface of the kidney. The kidneys are drained by separate ureters, which carry urine to a medially and relatively ventrally positioned urinary bladder. The urinary bladder lies on the floor of the caudal abdominal cavity and, when distended, may extend as far forward as the umbilicus in some species. The pelvic landmarks are less prominent in fully aquatic mammals. In the manatee, the bladder can be obscured by abdominal fat.

Pabst *et al.* (1999) noted that the reproductive organs tend to reflect phylogeny more than adaptations to a particular niche. If one were to examine the ventral side of cetaceans and sirenians before removing the skin and other layers, one would discover that positions of male and female genital openings are different, permitting rather

³Assessing the length of intestines is fraught with potential bias because it is extremely difficult not to stretch the intestines to unnatural lengths after they are freed from the mesenteries and straightened. Linear measurements of gastrointestinal tract are, therefore, highly subjective.

⁴Ligament has several meanings in anatomy: a musculoskeletal element [e.g., the anterior (cranial) cruciate ligament], a vestige of a fetal artery or vein (e.g., the round ligament of the bladder), the margin of a fold in a mesentery (e.g., broad ligament), and a serosal fold between organs (e.g., gastrosplenic ligament).

easy determination of sex in some species without dissection. In all marine mammals, the female urogenital opening is more caudal than the opening for the penis in males. One way to approach dissection of the reproductive tracts is to follow structures into the abdomen from their external openings.

The position and general form of the female reproductive tract in marine mammals are generally similar to those of the female reproductive tracts in terrestrial mammals. The vagina opens cranial to the anus and leads to the uterus, which is bicornuate in marine mammal species. The body of the uterus is found on the midline and is located dorsally to the urinary bladder (the ventral aspect of the uterus rests against the bladder). Although the body of the uterus lies along the midline, it has bilaterally paired, relatively large diameter projections called uterine horns (cornua), which extend laterally. The relatively small-diameter oviducts conduct eggs from the ovaries to the uterine horns where implantation of the fertilized egg and subsequent placental development occur. The dimensions of the uterine horns vary with reproductive history and age. Often the fetus may expand the pregnant horn to the point that it fills a substantial portion of the abdominal cavity. The horns terminate abruptly, narrowing and extending as uterine tubes (fallopian tubes) to paired ovaries. The uterus and the uterine horns are held in place in the abdominal cavity by the broad ligaments. Uterine and ovarian scarring may provide information about the reproductive history of the individual.

The ovaries of mature females may have one or more white or yellow-brown scars, called corpora albicantia and corpora lutea, respectively. Although ovaries are usually solid organs, in sirenians they are relatively diffuse.

Mammary glands are ventral, medial, and relatively caudal in most marine mammals, but they are axillary in sirenians. Many marine mammals have a single pair of nipples; sea lions and polar bears, *Ursus maritimus*, (DeMaster and Stirling, 1981), have two pairs of nipples, and cetaceans have mammary slits (note that some male cetaceans have distinct mammary slits).

The male reproductive tracts of marine mammals have the same fundamental components as the tracts in “typical” mammals, but positional relationships are significantly different. This difference is due to the testicond (ascrotal) position of the testes in most marine mammal species. Sea otters are scrotal (J. Bodkin, personal communication); polar bears are seasonally scrotal (I. Stirling, personal communication); and sea lion testes become scrotal when temperatures are elevated. The testes of some marine mammals are intraabdominal, but in phocids, for example, they lie outside the abdomen, partially covered by the oblique muscles and blubber. The position of marine mammal testes creates certain thermal problems because spermatozoa do not survive well at body (core) temperatures; in some species, these problems are solved by the circulatory adaptations mentioned later.

The penis of marine mammals is retractable and it normally lies within the body wall. The general structure of the penis relates to phylogeny (Pabst *et al.*, 1999).

4. *Adrenal Glands.* The term “suprarenal gland” is often used interchangeably with “adrenal gland.” Although the suprarenals often lie immediately atop or very close to the kidneys of terrestrial mammals, adrenals of marine mammals may lie several centimeters cranial to the kidneys, along either side of the median. Adrenal glands can be confused with lymph nodes, but if one slices the organ in half, an adrenal gland is easy to distinguish grossly by its distinct cortex and medulla.

5. *Circulatory Structures.* Blood vessels are often named for the regions they feed or drain. Thus, the fully aquatic marine mammals (cetaceans and sirenians) lack femoral arteries that supply the pelvic appendage. However, most organs in marine mammals are similar to those of terrestrial mammals so their blood supply is also similar. Therefore, readers who want to learn details of typical circulatory anatomy should consult one of the anatomy references cited earlier. The thoracic aorta leaves the heart and lies ventral to the vertebral column, giving off segmental arteries to the vertebrae and epaxial muscles (and in the case of cetaceans and manatees to the thoracic retia). The aorta continues through the aortic hiatus of the diaphragm (between the crura) and into the abdomen as the abdominal aorta and lumbar aorta, which give off several paired (e.g., renal and gonadal) and unpaired (e.g., celiac and mesenteric) arteries. The caudal aorta follows the ventral aspect of the tail vertebrae. In the permanently aquatic marine mammals, there are robust ventral chevron bones that form a canal in which the caudal aorta, its branches, and some veins are protected.

Some of the diving mammals (e.g., seals, cetaceans, and sirenians) have few or no valves in the veins (Rommel *et al.*, 1995); this adaptation simplifies blood collection.⁵ Other exceptions to the general pattern of mammalian circulation are associated with thermoregulation and diving. Countercurrent heat exchangers abound, and extensive arteriovenous anastomoses exist to permit two general objectives to be fulfilled (1) regulating loss of heat to the external environment, while keeping core temperatures high and (2) permitting cool blood to reach specific organs (e.g., testes, uteri, and spinal cord) that cannot sustain exposure to high body temperatures (see reviews by Rommel *et al.*, 1998; Pabst *et al.*, 1999).

In mammals, several paths for supplying blood to the brain exist: via the internal carotid, the external carotid, and the vertebral/basilar arteries. Some species use only one, others use two, and manatees use all three pathways. In cetaceans, the path for supplying blood to the brain is unique. The blood destined for the brain first enters the thoracic rete, a plexus of convoluted, small-diameter arteries in the dorsal thorax. Blood leaves the thoracic rete and enters the spinal rete where it surrounds the spinal cord and enters the base of the skull (McFarland *et al.*, 1979). There are two working explanations for this convoluted path of blood to the brain: (1) the elasticity of the retial system allows mechanical damping of the blood pulse pressure wave (McFarland *et al.*, 1979) and (2) the juxtaposition of the thoracic retia to the dorsal aspect of the lungs may provide thermal control of the blood entering the spinal retia. Combined with cooled blood in the epidural veins, the spinal retia may provide some temperature control of the central nervous system.

II. Overview

Marine mammal postcranial soft tissue anatomy is, in many regards, similar to that of “typical” mammals. However, the relative proportions of and, to some extent, the positions of organs may be somewhat different from the norm.

⁵The near absence of valves in the veins of seals and dolphins allows two-way flow to occur, increasing the blood available when venipuncture is used; in contrast, sea lions have numerous valves in the hind flipper veins.

We close with a reminder about orientation: namely the orientation of the prosector relative to the orientation of the specimen and the orientation of the specimen to the orientation of that animal when it was alive. The position of animals during necropsy may be belly-up, obviously not the usual position of the living animals. Thus, gravitational forces make the positional relationships we may observe during necropsy somewhat artificial; we assess “dead anatomy” rather than “living anatomy.” We suggest that people examining marine mammal postcranial anatomy bear this fact in mind and try to constantly picture how the structures being observed during necropsy might be arranged in a free-ranging animal. The more the latter perspective can be maintained, the easier it will be to envision dynamic relationships among organs and systems and to relate function (physiology) to structure (anatomy).

Antarctic Fur Seal *Arctocephalus gazella*

JAUME FORCADA AND IAIN J. STANILAND

I. Characteristics and Taxonomy

The genus *Arctocephalus* (G. Saint-Hilaire and F. Cuvier, 1826) derives from the Greek words *arctos* (bear) and *kephale* (head), meaning bear-headed. The species *Arctocephalus gazella* (Peters, 1875) is thought to be named after the German vessel SMS *Gazelle* by Theophil Studer, a zoologist of the Venus Transit Expedition. The species was described from a young female specimen collected at the Kerguelen Islands during the expedition, between 1874 and 1875. The other common name, Kerguelen fur seal, is seldom used. Antarctic fur seals are part of the group Arctocephalinae and evolved to their present form in the past 2–3 million years. There are many similarities between Antarctic fur seals and the other Arctocephalinae, and they can be confused with most other southern fur seals, particularly females.

Both sexes have thick bodies and relatively long necks, which make the head look small (Fig. 1). The snout is smooth and relatively pointed and appears to be flat from the forehead to the nose, especially in males. The skull has a convex forehead and broad and short rostrum, with short nasal bones and a broad flattened palate. There are nine pairs of teeth in the upper jaw and eight pairs in the lower jaw. The tooth rows diverge posteriorly, with a wide diastema between upper postcanines 4 and 5, and 5 and 6. This is a major difference from the other Arctocephalinae, which lack the diastemas. The teeth are small and unicuspid, and the maxillary shelf is long. The upper canines in bulls have obvious external bands that correspond well with single annual growth layers. The lower canines are

Figure 1 Antarctic fur seal territory with a dominant bull defending females and their pups at Bird Island, South Georgia.

Figure 2 Different coloration patterns of fur seal pups observed at Bird Island, South Georgia. Approximately 1–2 in 1000 pups are born white, and less than 1 in 5000 have mixed coloration.

laterally compressed and large; they are used in fights with other bulls for breeding territories.

At birth, mean standard length for pups is 67.4 cm (58–66). Males are born heavier at 5.9 kg (4.9–6.6) compared to females at 5.4 kg (4.8–5.9). This sexual dimorphism is pronounced in adults, with bulls being almost 1.5 times longer and 4 times heavier than females. Bulls' mean standard length is 180 cm (170–200) and mean weight 133 kg (90–197). In females these are 129 cm (117–140) and 34 kg (20–51), respectively. Males have a well-developed scrotum and testicles are external, although they can be concealed, making it especially difficult to distinguish young males from adult females. Younger males lack the heavy manes of bulls but have heavier and larger body foreparts and teeth than females. Long facial vibrissae can extend beyond the pinnae and are usually white. In bulls these can grow up to 48 cm, longer than in any other pinniped.

The body is covered by hair except for the rhinarium, ear tips, and palmar surfaces of the flippers. The hair extends to the base of well-developed nails at the top of the hind flippers, which are often used to groom the hair. The nails on the fore flippers are less well developed. On land the pelage is grizzled dark brown, shading paler below. Color differences are partly due to the length and structure of three different types of hair. From the skin to the outside, the pelt has a dense underlayer of fine fur, which provides thermal insulation, and two distinct types of guard hairs, stouter, and more obvious in the bulls' mane (Bonner, 1968). The pelage of pups is black until the first molt, after which the pelage has the adult coloration. In pups, adult-type guard hairs with white tips may protrude, giving paler coloration, especially in the facial area. Approximately 1–2% of the pups are born white, with lack of pigmentation in the guard hairs and much paler underfur and exposed skin, but these are not albinos. Their coloration remains whitish for life. White individuals have only been reported at South Georgia, with incidental records at Bouvetøya Island, King George Island, and Marion Island (De Bruyn *et al.*, 2007). Intermediate colorations, with clumps of black among predominantly white guard hair, are rarer still but are observed in high-density areas (Fig. 2).

II. Distribution and Abundance

Antarctic fur seals have a very wide distribution and breed primarily in subantarctic and Antarctic locations of the South Atlantic and

Indian Ocean sectors of the Southern Ocean. In the South Atlantic, the main breeding populations are south of the Antarctic polar front, on South Georgia Island, South Sandwich Islands, South Orkney Islands, South Shetland Islands (these four archipelagos belong to the Scotia Arc), and Bouvetøya Island. In the Indian Ocean, they are south of the polar front on Heard Island and McDonald Islands and north of the polar front on the Prince Edward Islands, Crozet Islands, Kerguelen Islands, and Macquarie Island. The distribution range widens after the breeding season, when animals can leave the main breeding rookeries. Most records of seals instrumented with telemetry devices suggest unstructured movements or individual dispersal. Bulls can travel very long distances, from the breeding islands to the ice edge and north of the polar front. Seals from South Georgia travel to the Antarctic Peninsula, the Falkland Islands, and southern Argentina, including the Juan Fernández Islands, Tierra del Fuego, and Mar del Plata. A group of Antarctic fur seals were seen at Gough Island, which is mostly populated by subantarctic fur seals, also north of the Polar Frontal Zone (Wilson *et al.*, 2006). Bulls from Kerguelen, Heard and Crozet Islands travel to the ice edge and north of the polar front. During the winter, females disperse at sea with individuals traveling south to the marginal ice zone and north, crossing the polar front and reaching as far as the Mar del Plata region of the Patagonian shelf. Females returning to breed at South Georgia often carry pendunculate barnacles, indicating that they can spend extended periods at sea between their breeding events. Juveniles and bulls are often seen around the breeding beaches throughout the winter. Post-weaning pups remain close to the natal beaches but move to oceanic waters (>500 m) as the winter progresses.

Available population estimates are South Georgia 2,700,000 and pup production (pp) 269,000 (season 1990–1991); Bouvetøya Island 66,000 and pp 15,523 (2001–2002); South Shetland Islands 21,190 and pp 10,100 (2000–2001); Marion Island 3821 and pp 796 (2003–2004); Heard Island 4100 and pp 1278 (2000–2001); Prince Edward Island 2000 and pp 400 (2001–2002). Additional minimum pup production is 6500 at Kerguelen Islands, 295 at Crozet Islands, 350 at South Sandwich Islands, and 1000 at South Orkney Islands. The population of South Georgia probably comprises more than 95% of the world population. However, the total estimate was extrapolated from an estimate of 379,302 (287,363–471,240) breeding females in 1990–1991 (Boyd, 1993) obtained from beach counts and assumed a rate of population increase from 1977 to 1991 of 9.8%. Many females

did not return to breed in 1990–1991 because of poor environmental conditions (Boyd, 1993; Forcada *et al.*, 2005) and as a result the counts were low and unrepresentative of the true number of females alive. Since 1990, the number of breeding females at a study site, used to estimate population correction factors and rates of increase, has been significantly declining, whereas circumstantial evidence suggests that seal numbers at other locations of South Georgia have increased. Therefore, reliable recent population estimates and trends are unavailable. Most Antarctic fur seal populations are thought to be increasing at rates well above 5%, although these estimates are not robust and most likely are positively biased.

Modern genetic population structure is known in detail from mitochondrial DNA control region sequences, with 26 haplotypes, including 16 represented in more than one individual, in a study of 145 seals from eight populations (Wynen *et al.*, 2000). The relationship between haplotypes suggests little lineage structure but two genetically distinct regions: a western region including the islands of the Scotia Arc, Bouvetøya, and Marion Islands, and an eastern region including Kerguelen and Macquarie Islands. Seals from Crozet Islands and Heard Island show mixtures of haplotypes from both regions. South Shetland and Marion would have been recolonized by seals from South Georgia and Bouvetøya, and Macquarie by seals from Kerguelen. The severe reduction of the world population by sealing in the eighteenth and nineteenth centuries could have caused population bottlenecks in most locations. However, present molecular data suggest higher levels of genetic variation at the nuclear and mitochondrial DNA loci than expected from the estimated remnant population levels.

III. Ecology

The diet of Antarctic fur seals is highly dependent on local prey availability, and comparative differences between sites probably reflect

regional differences in prey assemblages rather than differing foraging strategies. For example, the distance from the coast to the shelf break, a proxy for the available shelf habitat, is negatively correlated with the proportion of pelagic fish in the diet of fur seals. In addition, the diet mostly reflects the prey within the seal's narrow depth range. Females are particularly shallow divers and depend on prey migrating into the surface waters, usually at night. Their diet is likely biased toward epipelagic and diurnally migrating mesopelagic species.

The density of Antarctic krill (*Euphausia superba*) is very high in the productive waters of the Atlantic sector of the Southern Ocean, and it dominates in the diet of the seals in this area. In the Indian Ocean sector, euphausiids are of minimal importance and are often absent from the diet, which is instead dominated by fish. Other than krill, Antarctic fur seals principally eat myctophids, icefish, and notothenids, although skates and rays are also taken. Squid, a very minor (<1%) part of the diet at South Georgia, can play an important role in some areas, occurring in half the winter diets at Heard Island.

Seasonal differences in diet are reported at most sites where studies have been undertaken, but these are difficult to interpret because prey preference varies with age and sex of fur seals and the composition of the population in an area is very different within and outside of the breeding season. Interannual differences in diet relate to differences in local oceanographic conditions. At South Georgia, increases in myctophid occurrence are closely linked to sea surface temperatures, whereas changes in the consumption of icefish (*Champsocephalus gunnari*) are more closely linked to abundance of krill, its principal prey.

Although normally a very small component of the diet, penguins, especially during fledging, can be an important food source for fur seal bulls, and this may be a significant source of mortality where it occurs. At Marion Island, in a unique situation, the bulls take king penguins on land (Hofmeyr and Bester, 1993).

The dependence on land-based breeding strongly influences the distribution of Antarctic fur seals and their foraging ecology. Females

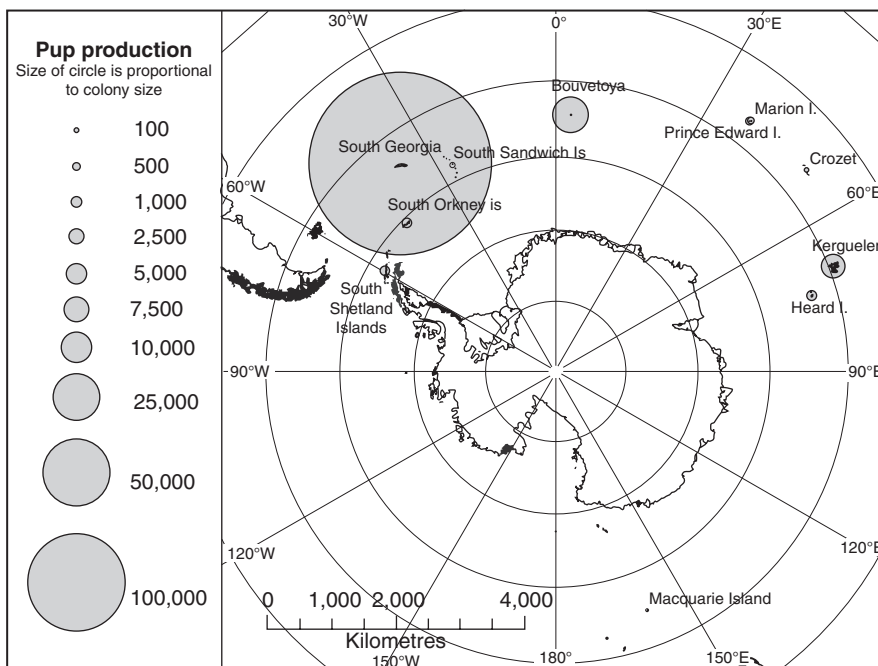

Figure 3 Antarctic fur seal breeding distribution and pup production. Size of circles is proportional to colony size. All named locations have breeding colonies.

during lactation act as a central place foragers and are thus restricted to foraging in the waters immediately surrounding the breeding beaches, usually around 150 km from the pupping location. However, tracking studies have shown that there is large individual variation in the time spent at sea and the distance traveled. Generally female foraging is associated with areas of high gradient, i.e. shelf breaks, in the immediate vicinity. The bathymetry preferences associated with observed foraging patterns are ultimately determined by prey distribution.

Antarctic fur seals preferentially breed on shale and pebble beaches, but they are found on almost all seashore environments, from sandy beaches to exposed rock platforms, and also in areas with vegetation behind landing beaches, such as in the Prince Edward Islands. A few weeks after giving birth, females suckle their pups in the relatively quieter areas behind the breeding beaches. They are generally faithful to a suckling location, which can be quite distant from the water and up to 100 m above sea level.

At South Georgia, Antarctic fur seals lay on tussock grass clumps to avoid the often wet and muddy ground. This behavior erodes the top of these clumps and, in areas of high density, kills the tussock, leaving a mound of earth and roots. The destruction of vegetation by recovering populations of fur seals has been a cause of concern, but it may well reflect the return of the environment to its pre-sealing state. This is clear in many areas where sealing artifacts (e.g. try-pots and shelters) are being uncovered by such erosion.

Away from land males are observed hauling out on sea ice and feeding in the marginal ice zone. However they are ill adapted to extreme cold, and if entrapped they can experience blindness through the freezing of their basal tears, often leading to death.

Killer whales are probably the only predator of Antarctic fur seals of all ages, but pups and yearlings are also vulnerable to leopard seal predation. Such predation can be significant, and leopard seals are thought to limit the population growth during winter at Elephant Island, South Shetland Islands. Leopard seals visit Bird Island, South Georgia. Their main prey is pups, although the estimated kill is less than 1% of the island's annual production. Large otariid bulls of other species may also prey on pups where the species co-exist. At Macquarie Island, a single subadult male Hooker's sea lion (*Phocarctos hookeri*) was believed to have killed a total of 54 Antarctic and subantarctic fur seal pups, 43% of the total production.

Antarctic ecosystems are often considered to be isolated and pristine, but Antarctic fur seals regularly cross the polar frontal zone and are therefore a potential vector for diseases. Little is known on the diseases of Antarctic fur seals, but given their similarity to, and mixing with, other fur seal species they are likely to share similar bacteriology and pathology. During the breeding season, the scale of fur seal bull mortality fluctuates between years. The main causes appear to be infections from fighting wounds and pneumonia. Studies have isolated various *Streptococcus* sp., *Staphylococcus* sp., *Bordetella* sp., and *Corynebacterium phocae* from dead animals. Anti-bodies of *Brucella*, which can impair female reproduction, have been found in individuals on the Antarctic Peninsula.

The most obvious external parasitic/commensal organism of Antarctic fur seals is the goose barnacle (*Lepas australis*), typically found on females returning to breeding after extended periods at sea (Setsaas and Bester, 2006). The average infestation of 10 barnacles reported on 4% of returning females has little effect on swimming performance. However, individual seals have been recorded with over half of their fur colonized by the barnacle, which would severely increase the individual's hydrodynamic drag. The barnacles die and drop off within a few days of the seal being ashore. Gastric

nematodes are prevalent, and tapeworms have been recorded, but no ticks have been observed.

Antarctic fur seals and elephant seals often breed in the same areas, but the difference in their timing of breeding means that their interactions are limited. Elephant seals occasionally crush fur seal pups and in turn elephant seal weaners are observed with superficial wounds inflicted by fur seals.

Despite penguins being preyed on by fur seals, on land they often breed side by side with the seals. Although fur seals generally ignore their avian neighbors, seal disturbance, usually an individual rushing through a penguin colony, can lead to egg loss and chick mortality.

Fur seals provide resources to many flying birds. At South Georgia, seal carcasses are consumed by giant petrels and skuas and also provide food for pintail ducks and sheathbills. Placentas provide food at the beginning of the breeding season, whereas dead or dying pups provide a steady source of food for scavengers. Increases in the skua and northern giant petrel populations at several subantarctic sites have been attributed to increases in seal carrion, in particular at South Georgia where the species is highly abundant, although this may not be the case in other areas (De Bruyn *et al.*, 2007).

The destruction of tussock stands could potentially impact birds that nest or burrow in this habitat, but this is unlikely to be a major problem, especially compared to the impact of predation from rats and cats where these pests have been introduced. Although Antarctic fur seals share the tussock habitat with larger birds, like wandering albatrosses and giant petrels, there is little evidence of any negative impact on these species.

IV. Behavior and Physiology

Antarctic fur seal bulls begin to arrive on the breeding beaches in numbers during early November and fight to establish territories. The first females arrive a few weeks later and give birth within a few days of hauling out. The perinatal period lasts 5–8 days, at the end of which the females mate before heading out to sea. Antarctic fur seals are highly polygynous, with bulls on average having "harems" of nine females. However, females exhibit mate choice, and genetic studies have revealed that females from a given male-associated group can travel through a number of neighboring territories in order to mate with a bull who is both heterozygous and unrelated (Hoffman *et al.*, 2007). After mating, males migrate to higher latitudes in January, and their numbers increase on the more southerly islands, on the Antarctic Peninsula and around the ice edge.

Females are income breeders, spending periods ashore nursing the pup (1–2 days) interspersed with foraging at sea (2–11 days). Pups wean in April only after 4 months, the shortest lactation period of any otariids. Only northern fur seals (*Callorhinus ursinus*) have a comparably short lactation.

Extended dives usually relate with feeding or attempts to locate food. Females dive predominately during the night, to shallow depths (0–40 m), exploiting diurnally migrating prey within the mixed surface layer. The great sexual dimorphism and the constraints imposed on females by pup rearing lead to obvious sexual segregation. Because of their larger size, males can dive deeper and longer. Maximum dive durations are around 5 min for females and 10 min for males, reaching maximum depths of 210 and 350 m, respectively.

Males foraging around South Georgia prior to breeding are segregated from females both horizontally and vertically. However, their foraging trips are very similar in length to those of breeding females, despite being unconstrained by any offspring demands. Whilst female foraging is concentrated at the shelf break, males mostly forage closer

to the breeding colony on the continental shelf. In these shallower waters males dive throughout the day and night and undertake benthic dives (mean depth 200 m), which are not observed in females.

Diving behavior is strongly influenced by prey behavior and differs between foraging locations. Females foraging in shelf waters have a higher proportion of daytime dives and dive deeper than they do in oceanic waters. When males forage in oceanic waters they follow a similar pattern to females foraging there, diving nocturnally within surface waters, but with a deeper dive range (0–60 m).

Bulls perform two main vocalizations. A threatening roar (full-throat call) is generally used in direct aggression against other males or in response to a specific threat. The second type is a “huff-chuff” sound generally used when moving around a territory, interacting with females, or within the area of other seals. This sound appears to act as a display of status, as its use by subordinates can provoke aggression. Females and pups are occasionally heard vocalizing in this way either in aggression toward conspecifics or during play. Although females will huff-chuff and roar, their main vocalizations occur in mother–pup interactions. Mothers and pups establish a bond through both smell and vocalization immediately after birth that is constantly re-enforced throughout the postnatal period. When mothers return from a foraging trip or when they are separated from their pups ashore, the two locate each other by call and response, and once in close proximity identity is confirmed by smell.

Females molt in February–March when clumps of hair can be seen trapped in the nails on their hind flippers. They are still suckling pups at this time and they can continue foraging at sea throughout the molt. Pups begin to molt from their natal coat to adult pelage around early February at about 1–2 months of age. The timing of the bulls’ molt is unclear, although identifying paint marks on the fur from behavioral studies can last up to 2 years or more on some individuals, suggesting that any annual molt may only be partial.

V. Life History

Extreme sexual dimorphism and the species’ breeding biology determine completely different life histories for females and males. Mean female age at maturity is 4 years, although first conception occurs as early as 2 and as late as 7 years. By age 6 most females have attained full adult size. Variability in primiparity is largely dictated by body mass, density dependence, and environmental stress. Early age at primiparity may affect survivorship of physically immature females, although this is difficult to observe, because the survival of all young females is highly affected by environmental stress. Reproductive rates increase rapidly from age 2, peak at 0.80 yr at age 8, and remain high, on average 0.75 (0.68–0.77), until the onset of a senescent decline, around age 11. Weaning success increases with age and experience, although it relies heavily on food availability and the ability of mothers to provide. Trauma and lack of food are usually the most common causes of early pup mortality in densely populated areas.

Female longevity is around 20 years; the oldest known female was 24. The mean adult female survival is 0.87 (0.68–0.93); variation is mainly caused by fluctuation of the biological environment. In years with severe climate anomalies, it can be reduced by as much as 15–20%. Female fitness, measured as the asymptotic population growth rate, is most sensitive to changes in the survival of breeders and their propensity to breed. Therefore, with adverse environments, females’ body condition may decrease, and they defer or alter breeding rather than put their life at risk. Breeding can be altered by not implanting or resorbing the blastocyst, abortion, or by pup abandonment.

The female breeding cycle is highly constrained by their income breeding system and the extreme seasonality of high latitudes. Females can only breed during the short austral summer when suitable pupping habitat is available and the local environment is sufficiently productive to supply constant nourishment for maintenance and pup rearing. This requires a high breeding synchrony that concentrates the birth of 90% of the pups in a 10-day window. This synchrony is highly consistent across the different breeding locations in the Southern Ocean, with only small differences in median birthdate (Hofmeyr *et al.*, 2007) and is mostly affected by local environmental influences.

Despite these constraints, most females breed annually, investing greatly in pupping. They conceive and carry a new fetus although still lactating and are constantly foraging. Because their gestation lasts between 8 and 9 months, annual breeding is achieved by having (1) a diapause period of 3–4 months between conception and implantation of the blastocyst and (2) the shortest lactation among otariids, which is required to cope with the highly seasonal productivity typical of high latitudes. The advantage of diapause is that the pupping interval can be very close to 365 days and is thus adjusted to seasonal breeding; mothers only start investing on the new gestation when the previous pup is weaned or close to weaned. Lactation is arguably the highest breeding cost. Given its heavy reliance on the biological environment, the rapid and successful recovery of the once almost extinct South Georgia population can be explained by the high abundance of its main prey, Antarctic krill. However, the current increased frequency in climate anomalies is reducing the krill supply in the Scotia Sea more regularly, rendering the environment less predictable for breeders. Their vital rates are affected by this fluctuation that reduces the carrying capacity of the environment. This instability is unlikely to support the high rates of breeding success and the population expansion previously seen.

Males reach sexual maturity at ages 3–4, but they are not reproductively active until they reach their adult body size, usually between ages 7 and 8, when they start competing for territories. Territory tenure is highly variable, and with high population density only a few bulls gain access to receptive females. These are the bulls more likely to mate successfully and father most (up to 60%) of the pups born on dense breeding beaches. Higher heterozygosity has been associated with higher bull success, in terms of longer territory tenure and competitive ability. Territory tenure implies greater competition with other bulls and a higher chance of mortality. On average, most bulls live for 8 years, which suggests a high mean mortality rate, possibly 30% higher than that of females. However, reliable estimates are not available for any population.

Antarctic fur seals and subantarctic fur seals (*Arctocephalus tropicalis*) breed sympatrically in at least six locations. At Marion Island hybrids make up at least 0.02% of the island population. At Possession Island, Crozet Islands; Heard Island; and Macquarie Island, Antarctic and subantarctic fur seals occur in breeding groups where New Zealand fur seals (*Arctocephalus forsteri*) also occur. Recent analysis indicates the presence of hybrids involving the three species (17–30% of the pups) and some degree of hybrid reproductive success. Hybrid bulls can hold territories, but their reproductive success is low, with a great proportion of pure-species females in their territories conceiving extra-territorially with conspecifics. This suggests the presence of reproductive isolating mechanisms that limit the frequency of hybrids (Lancaster *et al.*, 2007). The overlap in breeding areas of the different fur seal species is thought to result from recent colonization and the increase and spreading of populations after recovery from intense exploitation.

VI. Interactions with Humans

Antarctic fur seal populations suffered intense commercial exploitation during the eighteenth and nineteenth centuries, mainly for their pelts. This led to a dramatic reduction of populations worldwide. Large-scale sealing began in the Southern Hemisphere in 1775. Antarctic fur seals were known to be abundant on South Georgia during the eighteenth century; Captain Cook discovered the island in 1774 and found that the beaches “swarmed” with seals. The first record of Antarctic fur seals taken from South Georgia is from 1786. Sealing reached a peak in 1800–1801, when 17 British and American vessels took 112,000 skins. A single ship had a recorded catch of 57,000 seals for that particular season. By 1821 near-extinction was recorded by James Weddell, who calculated a total take of 1.2 million seals. A few more seals were taken in 1838–1839, in the 1870s, and in 1908. Fur-sealing on South Georgia continued until just one seal was found and killed in 1915 (Bonner and Laws, 1964; Headland, 1984). Sealing efforts on the South Shetlands began as soon as they were discovered in 1819, and fur seals were almost completely exterminated in just three seasons. James Weddell calculated that 320,000 were taken during 1821 and 1822.

On South Georgia, the population recovered very rapidly and has now reached very high numbers. A small breeding colony was discovered in 1930s on Bird Island, west of South Georgia, where the recolonization is thought to have started. From 1958 to 1972, the annual rate of increase on that small island was estimated as 16%, with pup production increasing from 10,000 per year in the early 1960s to 90,000 in 1975. The current annual production is thought to be no higher than 60,000 pups per year. The numbers and recovery rates were different at other locations. At Bouvetøya, historical accounts suggest that there were significant numbers of seals present toward the end of sealing (Hofmeyr *et al.*, 2005). At other locations, numbers after sealing are thought to be very small. At Heard Island the first recorded breeding after sealing was in 1963; since then the population is thought to have increased by 12–20% per year (Page *et al.*, 2003). At the South Shetlands, recovery also was fast, with a possible rate of pup production increase of 20% (Hucke-Gaete *et al.*, 2004).

The Antarctic fur seal conservation status is listed as lower risk and Least Concern by the IUCN. However, a number of threats exist. Direct interactions with fisheries have been reported, particularly in the South Georgia area. The problem has not had a significant impact because of good regulation and the use of mitigation measures. A common problem is entanglement in man-made debris, mostly from the fishing industry (Fig. 4). This has been documented since the 1980s, but the effort of removing and reporting entanglements is variable, and there are no good assessments for most areas. The most thorough published study is from 1989 to 1990 on Bird Island, which suggests that 0.1% of the population is affected. Most entanglements were by young males, in polypropylene straps (packaging bands), nylon string, fishing nets, and other materials (Croxall and Boyd, 1990). Up to 30% of the entanglements caused physical injury and less than 20% could be removed easily. The rate of entanglements appears to be increasing, possibly linked to illegal fishing operations, especially in longlining. Entanglements have also been reported on Bouvetøya Island and Marion Island (Hofmeyr *et al.*, 2002), although the rate of occurrence is very low, indicating that it is not a real threat to the current population.

Antarctic Marine Mammals

IAN L. BOYD

The Southern Ocean is the ocean subregion surrounding the continent of Antarctica. Its southern boundary is defined by the narrow coastal continental shelf of Antarctica itself. To the north the boundary is defined by an oceanic frontal feature known as the Antarctic convergence or southern polar frontal zone. The zone marks the boundary between cold southern polar waters and temperate northern waters. The ocean temperature can change by as much as

10°C across the front, which may be only a few miles across. The polar front is an important physical feature that determines marine mammal distributions. It defines the normal southern extent of the distributions of most tropical and temperate marine mammals (Fig. 1).

A second feature that is important to marine mammals in the Antarctic is the annual sea ice. The seasonal change in sea ice cover can lead up to 50% of the Southern Ocean being covered in ice during late winter, but by late summer this can have contracted to 10% of the winter maximum. These large seasonal fluctuations in the sea ice have profound implications for the ecology of the Southern Ocean, including that of marine mammals. Many marine mammals, including most cetaceans, migrate north across the polar front in winter.

I. Antarctic Species

This section deals with true Antarctic species defined as those species whose populations rely on the Southern Ocean as a habitat, i.e., critical to a part of their life history, either through the provision of habitat for breeding or through the provision of the major source of food. Species that inhabit the subantarctic, which is generally seen as including the islands that circle Antarctica in the region of the polar front or the polar frontal zone itself, are not included.

The Southern Ocean accounts for about 10% of the world's oceans but it probably supports >50% of the world's marine mammal

Figure 1 Antarctica and the Antarctic Convergence, where waters of warmer northern seas meet colder Antarctic waters. This confluence of waters of different temperatures occurs in some of the roughest seas known.

biomass, including six species of pinnipeds, eight species of baleen whales, and at least seven species of odontocete whales. Therefore, in terms of the diversity of species, the Antarctic is host to only one-fifth of the world's pinniped and a little less than one-fifth of the world's cetacean species. This low diversity may be attributed partly to the lack of land masses to cause isolation and speciation and also because, although large in its total area, the Southern Ocean does not have the diversity of habitats and prey species seen in other ocean basins.

Among the pinnipeds (Laws, 1984), there is one species from the family Otariidae (eared seals, which include fur seals and sea lions) and there are five species from the family Phocidae (earless or "true" seals), but all of these come from a single subfamily, the Monachinae. This list is as notable as much by its absences as it is for those that are present. For example, there is no representative of the phocid subfamily Phocinae, which contains a diverse collection of species of Northern Hemisphere seals. There are also no representatives of the subfamily Otariinae, which includes all of the sea lions, and there is only one representative of the diverse Southern Hemisphere subfamily Arctocephalinae, which includes the southern fur seals.

Where pinnipeds are concerned, evolutionarily it would appear that there have been only two or three species immigrating into the Antarctic. The main immigration was of an ancestral phocid, possibly related to the nearly extinct tropical phocids of today known as monk seals which gave rise to the four most closely related Antarctic phocids: the crabeater seal (*Lobodon carcinophaga*), Weddell seal (*Leptonychotes weddellii*), Ross seal (*Ommatophoca rossii*), and leopard seal (*Hydrurga leptonyx*). At some later date it is likely that elephant seals (*Mirounga leonina*) arrived. Although these seals extend their distribution into south temperate latitudes, as much as 90% of the world population relies on the Southern Ocean as a critical habitat. These were likely to have been followed, or perhaps preceded, by Antarctic fur seals. The taxonomic status of Southern Hemisphere fur seals, a group within which eight species are currently recognized, is uncertain and it seems probable that many of these are not true species but are instead subspecies. Therefore, the Antarctic fur seal (*Arctocephalus gazella*) may simply be an Antarctic race or subspecies of the southern fur seal.

Among cetaceans (Brown and Lockyer, 1984), there are only three Antarctic species within the highly diverse family Delphinidae, which includes all of the dolphins and porpoises. These three are the hourglass dolphin (*Lagenorhynchus cruciger*), long-finned pilot whale (*Globicephala melas*), and killer whale (*Orcinus orca*). The beaked whales are represented by only three species, because these species are very difficult to identify in the field; it is possible that among the very large number of these individuals that are found in the Southern Ocean, several other species could be present.

II. Distribution and Abundance

Antarctic marine mammals can be divided ecologically among those associated with fast ice, pack ice, or found in the open ocean. Weddell seals are mostly associated with fast ice, Ross seals with open water or pack ice. Leopard seals are animals mainly of the pack ice zone, but they may also be found feeding at penguin and seal colonies north of the pack ice zone. Crabeater seals travel extensively within the pack ice zone and individuals may have a potential range that extends to the total area of the Antarctic pack. The same may be true for Ross seals, although relatively little is known about the biology of these animals. They have been recorded to migrate north of the pack ice zone. Weddell seals appear to be relatively sedentary, forming more or less isolated populations around the coast of Antarctica.

Elephant seals are known to feed within the pack ice zone on occasion, but they are mainly animals of the open oceans north of the pack ice zone. Antarctic fur seals are sometimes found along the boundary between the pack ice and the open ocean but, again, they are mainly animals of the open ocean. Perhaps up to half of both the Antarctic fur seal and southern elephant seal populations migrate north of the polar front during the winter.

Toothed whales have a stratified distribution within the Southern Ocean relative to the polar front and the edge of the pack ice (Fig. 2). Some species, such as long-finned pilot whales and hourglass dolphins, are more closely associated with the polar front, whereas others, such as killer whales, are more often present close to the pack ice. Bottlenose whales (*Hyperoodon planifrons*) and killer whales are the only cetaceans regularly associated with a distribution within the pack ice zone, but they are also present within the open ocean. Bottlenose whales appear to be able to survive comfortably among almost continuous sea ice cover. Killer whales have been recorded in pack ice in winter, but the only baleen whale found regularly in the pack ice zone is the minke whale (*Balaenoptera bonaerensis*). Other larger species, including the sperm whale (*Physeter macrocephalus*), are restricted to the open ocean, but during the summer they may feed along the boundary between the pack ice and the open ocean. In general, these species are absent from the Southern Ocean during the winter. In the case of the sperm whale, only males are found within the Southern Ocean as females remain north of the polar front throughout the year.

Marine mammal distributions are also affected by bathymetric and oceanographic conditions. Southern right whales (*Eubalaena australis*), which are possibly from the same population that winters at Peninsula Valdes, Argentina, and along the coast of South Africa, spend the summer foraging over the continental shelf of South Georgia within the Southern Ocean. Baleen whale and Antarctic fur seal abundance around South Georgia is also influenced by the local oceanography so that there are regions of predictably high abundance of these marine mammals at specific points along the edge of the continental shelf. Southern elephant seals also appear to migrate from breeding and molting grounds on subantarctic islands to shallow regions along the coast of Antarctica. Most of these types of preferences for different locations are assumed to reflect the distribution of food so that marine mammals migrate to the areas of greatest food abundance.

Figure 2 Distribution of odontocete whales in the Southern Ocean relative to the southern polar front and the edge of pack ice. Reprinted from Kasamatsu and Joyce (1995) with permission from Cambridge University Press.

The crabeater seal is probably the most abundant seal in the world, with population somewhere between 7 and 14 million. There are considerably fewer Weddell seals and leopard seals. Ross seals are rarely seen and the total number is very uncertain, but it is probably the least abundant Antarctic pinniped. The Antarctic fur seal population is more than 3 million and is increasing at about 10% each year. In contrast, the southern elephant seal population within the Antarctic appears to have been relatively stable since the early 1960s, even though the number of elephant seals breeding at sites outside the Antarctic has declined steadily over the same period. The elephant seal population at South Georgia is estimated at 470,000, which probably represents 58% of the world population of the species.

In general, whale populations are in a highly depleted state. Blue whales (*Balaenoptera musculus*) are numbered in the hundreds for the whole of the Antarctic, and the sighting of a blue whale is a rare event. The number of fin whales (*Balaenoptera physalus*) appears to be increasing, as are humpback whales (*Megaptera novaeangliae*) and southern right whales.

Within the Antarctic, there are no significant threats to pinniped species. However, some cetacean populations have been depleted to such a high degree that several are endangered. In particular, blue whales are so rare in the Antarctic that they are possibly close to extinction from the area. Similarly, severely depleted southern right whale and humpback whale populations have very specific migratory routes between summering grounds in the Antarctic and winter grounds in temperate and tropical regions, which make them more vulnerable to threats such as disturbance, habitat loss, and reduced genetic diversity.

III. Ecology

The presence of a large biomass of marine mammals in the Antarctic is probably a result of the unusual food chain structure of the Southern Ocean. The marine mammals of the Antarctic with large numbers, such as crabeater seals and Antarctic fur seals, rely on krill as their main food source (see Section IV). This is in contrast to marine mammal communities elsewhere that rely mainly on a fish-based diet. Energy enters the food chain through photosynthesis and carbon sequestration by phytoplankton. The relative efficiency with which this energy is passed up the food chain to predators with a krill- or fish-based diet is illustrated in Fig. 3. The efficiency of energy transfer at each step in the food chain can be as low as only a few percent. The fewer steps there are between phytoplankton and marine mammals, the more the energy will be transferred more efficiently to marine mammals. In the Antarctic, there is on average one less step than there is in other oceanic ecosystems, which has led to the very large biomass of marine mammals found in the Southern Ocean.

IV. Diet

Among seals, there is a progression of dietary specialization from those that mainly eat krill to those that mainly eat fish (Fig. 4). The leopard seal has seabirds and other seals as a major component of its diet, and it is probable that some individuals specialize in feeding on other seals or penguins instead of krill, fish, or squid. Among whales, dietary specializations are divided along taxonomic lines between odontocetes that mainly eat squid and mysticetes that forage primarily on zooplankton.

The crabeater seal is one of the most ecologically specialized of all seals because it feeds almost entirely on Antarctic krill that it

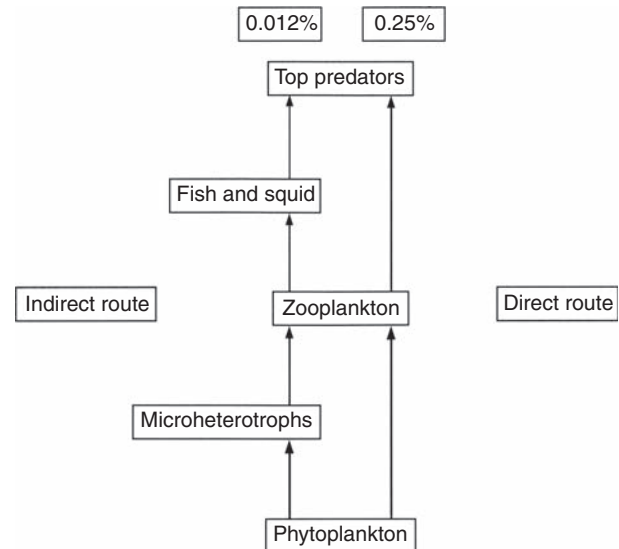

Figure 3 Simplified diagram of energy flow to marine mammals as top predators in marine food chains. This diagram shows the more direct route of energy transfer in the southern ocean, vs the more indirect route elsewhere. The percentage of the energy taken in by phytoplankton that subsequently reaches the top predators is shown at the top of the diagram.

gathers from the underside of ice floes where the krill themselves feed on the single-celled algae that grow within the brine channels in the ice. Antarctic fur seals also feed on krill to the north of the Antarctic pack ice edge, and many of the other Antarctic seals rely, to varying degrees, on krill as a source of food. Antarctic krill probably sustains more than half of the world's biomass of seals and also sustains a substantial proportion of the biomass of the world's seabirds and whales.

Although the dentition of crabeater seals is modified to help strain krill from the water, the feeding apparatus of the baleen whales is the most highly modified for a diet of plankton. Krill is the major component in the diet of most of the Antarctic baleen whales, although copepods may also be strained from the water, especially by right whales. The Antarctic krill, *Euphausia superba*, often occurs in dense swarms in the open ocean, and the baleen whales have probably evolved to exploit these dense patches of food. Baleen whales eat 30–50 million tons of krill in the Antarctic each year and seals probably eat a similar or slightly lower total amount as whales. Consumption of squid by beaked whales and sperm whales is estimated to be about 14 million tons each year. Killer whales prey on fish and squid but also hunt seals and penguins. Pods of killer whales have been observed tipping over ice floes to push crabeater seals into the water in an effort to catch them.

V. Exploitation

Throughout the nineteenth and early twentieth centuries, the Antarctic was viewed as an almost limitless source of marine mammals to be hunted for skins, oil, and other products that found expanding markets in Europe and North America. However industrialization of whale and seal hunting brought both greater efficiency and the inevitability that the resources would be exhausted, much to the detriment of the ecology of the Antarctic and its populations of marine mammals.

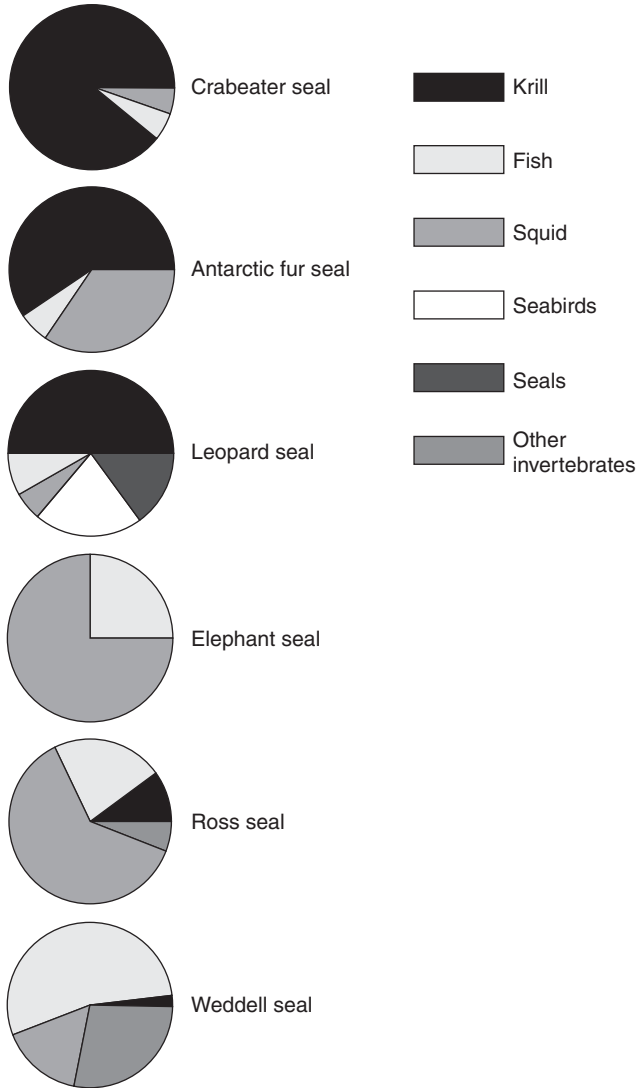

Figure 4 Pie charts showing the composition of diets of Antarctic seals.

There were three phases of exploitation: exploratory sealing (late eighteenth and early nineteenth centuries), preindustrial sealing and whaling (nineteenth century), and industrial whaling (twentieth century). There are very few records of the exploratory sealing and the preindustrial era. During the exploratory sealing era, exploitation was mainly targeted at fur seals to supply skins for the Chinese market, where there were turned into felt to supply the European market. By about 1830, fur seals in the Antarctic and elsewhere in the Southern Hemisphere had been all but extinguished. In 1825, James Weddell, himself the captain of a sealing vessel, noted that “the number of skins brought from off Georgia cannot be estimated at fewer than 1,200,000.” He was referring to South Georgia, where more than 95% of the current world population of Antarctic fur seals resides. This species was considered to be extinct until the early 1920s when whalers saw several individuals at South Georgia. Since then, the numbers have increased rapidly and the population is conservatively estimated to now be on the order of 3 million. The preindustrial era was mainly targeted at whaling and the larger seals, particularly elephant seals for their oil. This activity was mainly undertaken from

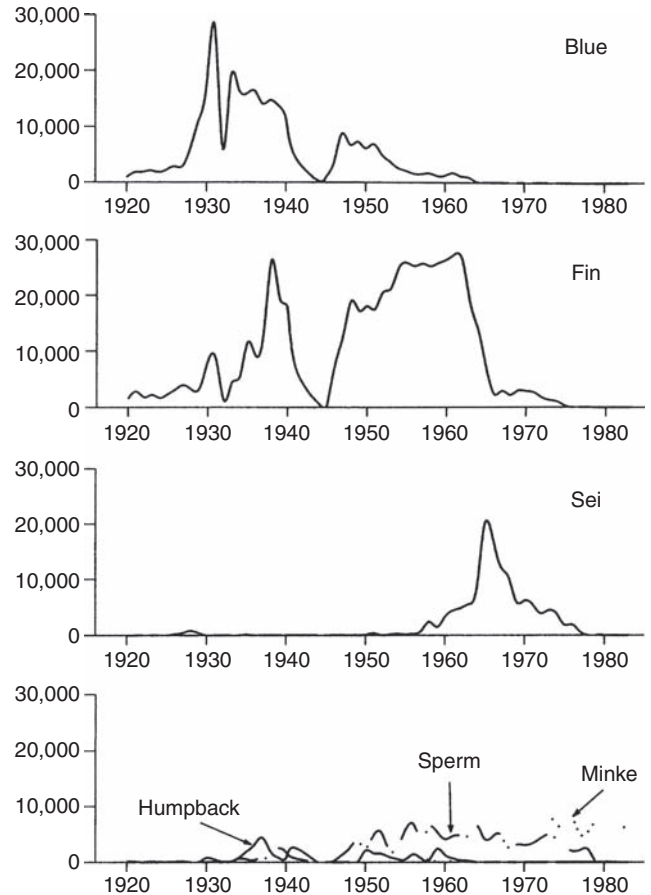

Figure 5 Numbers of whales caught in the industrial whale harvest in the Southern Ocean.

sailing vessels. The introduction of steam power to the Antarctic was largely responsible for the transition to industrial whaling.

Industrial whaling began in the early years of the twentieth century. This industry operated for more than 60 years and in that time it removed about 71 million tons of whale biomass involving 1.4 million individual whales from the Antarctic; about 10% of these were taken at South Georgia. Antarctic fur seals feed on krill (Fig. 4), and may have benefited by the reduction in numbers of krill feeding whales and therefore had less competition for their food.

The industry was selective about which species of whales it targeted. The largest and most profitable were selected first, followed by progressively smaller species (Fig. 5). Eventually, the industry became unprofitable because only minke whales were left to exploit and these were too small to be profitable.

VI. Conservation Measures

Concerns about the effects of industrial whaling on the populations of whales began early in the industrial era. By the early 1920s, the “Discovery Investigations” had been established to determine whale populations mainly around South Georgia. These were funded by a levy on the industry, but they were free from control of the industry. They are one of the first examples of the fledgling field of ecology being used to solve a wildlife management problem. Even though the “Discovery Investigations” made ground-breaking scientific progress and were influential in the introduction of some

conservation measures, they came too late to influence the power of the industry and the fate of the populations of whales in the Southern Ocean.

The story of overexploitation of a marine resource in the Southern Ocean repeated itself in the 1960s and 1970s when industrial fisheries targeted the fin fish populations and reduced them to uneconomic levels. This stimulated a renewed effort to ensure that there was proactive conservation of marine living resources in the Southern Ocean. The result was the Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR) and the Convention for the Conservation of Antarctic Seals (CCAS), which came into effect in 1982 and 1978, respectively. One of the unique features of the CCAMLR convention is that it accepts that exploitation has effects on components of the ecosystem far beyond those that are being targeted for exploitation (Kasamatsu and Joyce, 1995). This means that any proposals for the exploitation of living resources in the Antarctic must consider the effects that such exploitation is likely to have on marine mammals, whether or not they are the target species. Therefore, even though marine mammals enjoy legal protection in the Antarctic from unregulated exploitation under the environmental protocol within the Antarctic Treaty, they are also protected from other activities within the Southern Ocean ecosystem. Only time will tell if this is sufficient to ensure their long-term survival.

Archaeocetes, Archaic

J.G.M. THEWISSEN

Archaeocetes is the common name for a group of primitive whales that lived in the Eocene Period (~55–34 million years). Archaeocetes are important because they represent the earliest radiation of cetaceans and because they include the ancestors of the two modern suborders of cetaceans, the Mysticeti (baleen whales) and Odontoceti (toothed whales). Archaeocetes are also the main source of information about the great morphological changes that were associated with the acquisition of aquatic features in cetaceans (Zimmer, 1998). The first archaeocete whales (*Pakicetus* in Fig. 1) looked, externally, nothing like modern whales, instead their bodies resemble wolves with long snouts and powerful tails. Later archaeocetes look more like crocodiles, otters, or sea lions, and it is not until about 39 million years ago that basilosaurid cetaceans

Figure 1 Five cetaceans that lived in the Eocene. Clockwise from top: the basilosaurid *Dorudon* (~39 million years old); the ambulocetid *Ambulocetus* (~49 million years old); the pakicetid *Pakicetus* (~50 million years old); the remingtonocetid *Kutchicetus* (~45 million years old); and the protocetid *Rodhocetus* (~45 million years old). Note the increase of aquatic adaptations from *Pakicetus*, the earliest whale, to *Dorudon*, one of the last archaeocetes. Illustration from Thewissen and Williams, 2002.

can easily be recognized as whales. The archaeocete families document that Eocene cetacean evolution is characterized by increasing aquatic adaptations, documenting amphibious stages that preceded obligate aquatic life in the late Eocene whales (basilosaurids).

Five families of cetaceans are commonly included in archaeocetes: Pakicetidae, Ambulocetidae, Remingtonocetidae, Protocetidae, and Basilosauridae (Williams, 1998). Basilosaurids (also called zeuglodonts) are discussed separately in this volume, and the remaining four families are treated here.

Pakicetidae are only known from the early-to-middle Eocene and lived approximately 50 million years ago in India and Pakistan. Many parts of the skeleton of pakicetids are known, including a number of skulls (Thewissen *et al.*, 2001). Basically, pakicetids varied from fox-to-wolf-size. The nasal opening of pakicetids was near the front of the head, and the eyes faced dorsally, similar to crocodiles. Pakicetids had small brains flanked by enormous chewing muscles. The skull and dentition of pakicetids do not resemble those of modern whales and dolphins, but the ear of pakicetids clearly shows that they were cetaceans: there is thick internal lip of bone on the middle ear (the involucrum), and the ear ossicles are pachyostotic and oriented differently from those of other mammals. The limb bones of pakicetids were also very dense, probably as a means to counteract buoyancy, and allow them to wade in water (Gray *et al.*, 2006). Pakicetid fossils are only found in freshwater deposits and most are known from deposits that represent shallow ephemeral streams in an arid climate, it is unlikely that pakicetids were good swimmers. Three genera are included in Pakicetidae: *Pakicetus*, *Ichthyolestes*, and *Nalacetus*.

Ambulocetids are known from middle Eocene rocks in northern India and Pakistan. There are fewer than 10 described ambulocetid fossils, but one of these consists of a nearly complete skeleton of a single individual of *Ambulocetus natans* (Thewissen *et al.*, 1994, 1996). *Ambulocetus* resembled a crocodile in some respects, with short limbs, and a powerful body and tail. It had a large head, with a long snout and eyes that were dorsal on the skull, but faced laterally. The teeth are robust and strongly worn. Skull and vertebrae

indicate that the muscles of the head and neck were strong, indicating that *Ambulocetus* was a powerful animal. The shape of the lower jaw of *Ambulocetus*, unlike that of the pakicetids, shows that there was an unusual soft tissue connection between the back of the jaw and the middle ear. In modern odontocetes, this connection consists of a large fat pad that functions as part of the sound-receiving system. This connection is small in *Ambulocetus* and was probably not as important functionally as it is in modern cetaceans. It does show that hearing adaptation arose early in cetacean phylogeny (Nummela *et al.*, 2004). The hindlimbs were relatively short, but the feet were long, and there were four toes. The long paddle-shaped feet indicate that it swam like a modern otter, by swinging its hindlimbs through the water and creating additional propulsive force with its tail (Thewissen and Fish, 1997). The forelimbs were short, with five fingers that each terminated in a short hoof. The hands were much shorter than the feet. The skeleton of *Ambulocetus* indicates that it was probably slow on land. *Ambulocetus* was probably an ambush hunter, attacking prey in or near shallow water. This method of hunting is used by modern crocodiles.

Ambulocetus is only known from nearshore marine environments, including estuaries or bays. Geochemical analyses of ambulocetid bones indicate that it drank a mixture of fresh and seawater and that different individuals may have inhabited different microenvironments (Roe *et al.*, 1998). Genera included in Ambulocetidae are *Ambulocetus*, *Gandakasia*, and *Himalayacetus*.

Remingtonocetids are only known from India and Pakistan, from sediments approximately 46 to 43 million years old (Kumar and Sahni, 1980; Bajpai and Thewissen, 1998). Dozens of remingtonocetid fossils have been described, but most of these document only the morphology of skull and lower jaw. Dental and postcranial remains are scarce. The smallest remingtonocetids may have been as small as *Pakicetus*, and the largest may have been close in size to *Ambulocetus*. All early cetaceans had long snouts, but those of remingtonocetids are proportionally even longer than those of other archaeocetes. Skull shape varied between different remingtonocetid genera and possibly reflected different dietary specializations. In *Andrewsiphius* the snout is very narrow and high, and the chewing muscles are weak, suggesting that it may have eaten small, slippery fish. In *Remingtonocetus*, the snout is rounded and robust, and the chewing muscles are large, as would be expected in an animal that attacks larger, struggling prey. No remingtonocetid displays the robust masticatory morphology of *Ambulocetus*. The nasal opening of remingtonocetids is near the front of the skull, similar to pakicetids. The eyes are small, unlike ambulocetids and protocetids. The ear of remingtonocetids is larger than that of pakicetids and ambulocetids, and the connection between the lower jaw and the ear is larger than in ambulocetids. The ears are also set far part, possibly to increase directional hearing. These features are consistent with an increased emphasis on underwater hearing in remingtonocetids. Behind the skull, the remingtonocetid skeleton indicates that the neck was long and mobile and that the hindlimbs were large. Remingtonocetids were certainly able to support their body weight with their limbs, similar to ambulocetids.

The most primitive and oldest remingtonocetid is *Attockicetus*. It is found in the same deposits as *Ambulocetus*. The other remingtonocetids are known from marine, nearshore deposits and may have lived in bays and saltwater swamps. Stable isotope geochemistry indicates that remingtonocetids ingested seawater (Clementz *et al.*, 2006). Remingtonocetid genera include *Remingtonocetus*, *Andrewsiphius*, *Attockicetus*, *Dalanistes*, and *Kutchicetus*.

Protocetids are found in middle Eocene rocks in Indo-Pakistan, Africa, Europe, and North America. Protocetids have never been

found at localities with pakicetids or ambulocetids, they are a later radiation, overlapping, partly with remingtonocetids. Protocetids are the oldest whales to disperse across the oceans, although they probably only inhabited the warm seas near the tropics. Many protocetid genera are known, and several of these include several partial skeletons (Gingerich *et al.*, 1994, 2001; Hulbert, 1998). Protocetids are diverse, their average size was similar to that of *Ambulocetus*.

Protocetids had long snouts, large eyes, and their nasal opening was farther caudally than in earlier archaeocetes. This suggests that protocetids could breathe while holding much of their head horizontally, similar to modern cetaceans and foreshadows the origin of the cetacean blowhole. The teeth of protocetids vary between genera, with some showing specializations for crushing hard prey, and others for shearing meat. It is likely that protocetids were active hunters of marine animals, possibly similar to modern pinnipeds. Protocetid locomotor morphology was varied. In general, the tail is well developed and was probably involved in creating propulsive forces. The hind limbs are reduced, and in some species the innominate (pelvis) is not connected by bone to the vertebral column, suggesting that the hind limb did not support the body weight. There are no fossils that document all of protocetid hind limb morphology, but some preserved elements suggest that the hind limbs were short. Indo-Pakistani protocetids inhabited the same environments as the remingtonocetids, and protocetids from other continents are known from shallow marine environments. Known genera of protocetids are *Protocetus*, *Babiacetus*, *Eocetus*, *Georgiacetus*, *Indocetus*, *Natchitochia*, *Pappocetus*, *Rodhocetus*, *Takracetus*, *Artiocetus*, *Rodhocetus*, *Qaisracetus*, *Gaviacetus*, and *Carolinacetus*.

Arctic Marine Mammals

JOHN J. BURNS

I. Northern Ice-Covered Marine Environments

Traditionally the Arctic is viewed as an ill-defined region around the North Pole that was further subdivided into the high arctic and the low arctic. We are here concerned with much broader, although still poorly defined, areas within which ice-associated bears, pinnipeds, and cetaceans occur. Some freshwater seals are included. It is useful to think in terms of regional climate, oceanography, annual ice dynamics, and life history strategies. For most marine environments, the definitions advanced by Dunbar (1953) are particularly useful. The arctic seas are those in which unmixed polar water from the upper layers of the Arctic Ocean occurs in the upper 200–300 m. A large portion of this zone is ice covered throughout the year. The maritime subarctic includes those seas contiguous with the Arctic Ocean in which the upper water layers are of mixed polar and nonpolar origin. There are, however, some non-contiguous subarctic seas (no water of polar origin) adjacent to terrestrial ecosystems that lie in the subarctic zone. Examples include the Okhotsk Sea, the northern part of the Sea of Japan (Tartar Strait), the Bohai Sea, Lake Baikal in Siberia, and Cook Inlet in Alaska (Fig. 1). In the subarctic, there is a complete annual ice cycle, from formation in autumn to disappearance in summer. Finally, there are areas in the temperate zone where unique climate conditions produce a winter ice cover of relatively short duration. Such areas include the Baltic Sea, the northern Yellow Sea, and the western Sea of Japan.

An estimate advanced in 2005 indicated that over the period 1979–2001, in September, the average annual minimum extent of sea ice was 8 million km², restricted mainly to the Arctic Ocean. The average maximum extent in March was 15 million km², including all of the subarctic seas (or parts thereof), and parts of some in the temperate zone. Most species of the so-called arctic marine mammals

are associated with the seasonal ice during the breeding period. They cope with the annual expansion and contraction of the ice cover in a variety of different species-specific ways. Clearly, there are many kinds of ice-dominated habitats formed in response to factors such as regional climate, weather, latitude, currents, tides, winds, land masses, proximity of open seas, and others.

II. Sea Ice Habitats

Sea ice in the Arctic and subarctic occurs in more complex forms than ice in the Antarctic. This is because of the central location of the Arctic Ocean with its perennial drifting ice, its partially landlocked nature, and the complexity of the subarctic seas encircling it. The annual expansion and contraction of the ice cover provides conditions ranging from the thick and relatively stable multiyear ice of the high latitudes to the transient and highly labile southern pack ice margins that border the open sea. Marine mammals must have regular access to air above the ice, as well as to their food in the ocean below it. During the breeding season, the ice on which pinnipeds haul out must be thick enough and persist long enough for completion of the critical stages of birth, nurture of their young, and, in many cases, completion of the annual molt. Additionally, by virtue of location, behavior, reproductive strategies, and/or physical capabilities, they must be able to avoid excessive predation on dependent and often nonaquatic young. All of the marine mammals must also cope with the great reduction or complete absence of ice during the open water seasons.

There are many different features of the varied types of ice cover that provide marine mammals access to air and allow the pinnipeds to haul out. There are also some features, characteristics, or types of ice that exclude most marine mammals. Important ice features or types include stable land-fast ice (excludes most marine mammals); annually recurring persistent polynyas (irregular shaped areas of open water surrounded by ice); recurrent stress and strain cracks, coastal and offshore lead systems (long linear openings); zones of convergence and compaction (as against windward shores or in constrictions such as narrow straits); zones of divergence (where boundary constraints are eased); the generally labile pack ice of the more southerly seas; and the margins or front zones of broken ice, the characteristics of which are strongly influenced by the open sea (Fig. 2). Ice margins are particularly productive in that ice-edge blooms of phytoplankton and the associated consumers extend many tens of kilometers away from them.

III. The Role of Sea Ice

There are great differences in how marine mammals exploit ice-dominated environments (Fig. 2). Many are a function of evolutionary constraints imposed on the different lineages of mammals. Polar bears (*Ursus maritimus*) are the most recent arrivals in the high-latitude northern seas, having evolved directly from brown bears (*U. arctos*). They utilize relatively stable ice as a sort of *terra infirma* on which to roam, hunt, den, and rest (Fig. 3). Like their contemporary terrestrial cousins, they are generally not faced with the problem of ice being a major barrier through which they must surface to breathe. Cetaceans are at the other extreme. They live their entire lives in the water and have limited (though differing) abilities to make breathing holes through ice and are therefore constrained to exist where natural openings or thin ice are present. Pinnipeds spend most of their time in the water, but they must haul out to bear their young. Most of them also haul out on ice to suckle their young, to molt, and to rest.

Figure 1 Map of the Arctic Ocean and adjacent seas depicting the average maximal (March) and minimal (September) annual extent of sea ice over the period 1979–2001. Courtesy of M. C. Serreze, NSIDC, Boulder, CO).

Figure 2 Typical sea ice of the southeastern Bering Sea front zone in March/April. An aggregation of spotted seals is present.

Figure 3 Tracks of a polar bear (*Ursus maritimus*) roaming on land-fast ice of the central Beaufort Sea in early spring.

For cetaceans, obvious benefits are protection from predators, access to ice-associated prey without competition from other animals, and a less turbulent winter environment shielded from perpetual and often storm force winds.

Pinnipeds have flourished in ice-dominated seas both in terms of the number of different species and the number of individuals. All are obliged to haul out either on land or on ice for at least part of the year. As noted by Fay (1974), ice has several special advantages over

land, including *isolation* from many predators and other disturbing terrestrial animals; vastly increased *space* away from seashores; a *variety* of different habitats that accommodate more species than does land; easy access to their *food supply*, especially for those that are benthic feeders, or that utilize concentrations of prey associated with ice fronts and polynyas; passive *transportation* to new feeding areas and during migrations; *sanitation* resulting from the ability to avoid or reduce crowding and to haul out on clean ice; and *shelter* among pressure ridges or in snow drifts.

IV. Ice-Breeding Marine Mammals

Ice-breeding marine mammals in the Northern Hemisphere include eight pinnipeds: gray (*Halichoerus grypus*) (some populations), harp (*Pagophilus groenlandicus*), hooded (*Cystophora cristata*), bearded (*Erignathus barbatus*), ringed (*Phoca hispida*), spotted (*Phoca largha*), ribbon seals (*Histiophora fasciata*), and the walrus (*Odobenus rosmarus*); three cetaceans: narwhal (*Monodon monoceros*), beluga (or belukha) (*Delphinapterus leucas*), and bowhead whale (*Balaena mysticetus*); and one fissiped—the polar bear.

A. Pinnipeds

A common theme in the ecology of ice-breeding pinnipeds is that of an obligatory, or nearly obligatory, association with ice during the breeding season, which occurs during or shortly after the period of maximal ice extent and relative stability. Seal pups become independent during the spring onset of ice disintegration and retreat. Most species also molt on the ice, after which they disperse to a variety of habitats during the open water season, a few continuing to remain with the diminishing cover. They resume their increasing association with ice during autumn, as it again forms and expands. They haul out on the ice in all seasons during which it is present, although with highly variable frequency depending on species and weather. The maximum number of species and the greatest total number of seals are associated with ice when it is most extensive, and vice versa.

The soft natal fur, or lanugo, of most seals born on ice or in snow lairs, and remaining in one place for long periods of time, is primarily an adaptation for maintaining body heat. Such pups tend to be small, have little insulating blubber, and have a relatively large surface area to body volume ratio at birth. White-coated pups presumably also benefit from the cryptic coloration it provides during the period before they are weaned and begin to enter the water. Prenatal molting occurs in those ice-breeding pinnipeds that are relatively large at birth and can enter the water within hours or days. Detailed discussions of northern ice-breeding seals are presented in the following species accounts, although general comments are noted below.

Gray seals are usually not included in the ice-associated marine mammals category. However, some populations breed on the ice. Gray seals largely inhabit the temperate zone in the North Atlantic region. Their distribution is coastal, often in association with harbor seals (*Phoca vitulina*). There are three populations: those in the Baltic Sea, the eastern North Atlantic, and the western North Atlantic. There is a very wide range in timing of the breeding season. In the eastern Atlantic, pups are born on shore during late autumn to early winter. In both the Baltic and the western Atlantic, however, pups are born during mid- to late winter on ice near shore, or on shore when ice is absent. At birth, gray seals weigh about 15 kg. In all populations almost all pups are born with a silky, whitish coat of lanugo that is retained during the nursing period. They remain on ice or land until after weaning. The late pupping season of the marginally ice-associated breeding populations is thought to be an adaptation to that environment. Grey seals move extensively, although

they are not considered to be migratory. None are associated with sea ice during late spring through autumn.

Spotted seals (or large seals) occur in continental shelf waters of the Pacific region that are seasonally ice covered. During winter and spring they mainly inhabit the temperate/subarctic boundary areas, occurring in the southern ice front (mainly) of the Bering and Okhotsk seas or in the very loose pack ice of the northern Yellow Sea and Sea of Japan. The birth season is from January through April, depending on latitude. All populations give birth and nurture their pups on the ice, although pups are occasionally born on shore. Newborn pups weigh about 10 kg and have a dense, whitish, woolly lanugo, which is shed toward the end of the month-long nursing period. Seals older than pups usually haul out on the ice to molt, although they also use land when the ice disappears early. As the seasonal ice disintegrates and recedes, all spotted seals disperse, moving to the ice-free coastal zone where they use haulouts on land. The seasonal dispersal can be extensive: in the Okhotsk Sea to its entire perimeter and from the central Bering Sea to most of its perimeter, as well as northward into the northern Chukchi and Beaufort seas. Therefore, some spotted seals reside in the higher latitudes of the subarctic zone during the open water season. They range widely over the continental shelves. There is a close association with sea ice during autumn through spring.

Ribbon seals are animals of the temperate and temperate/subarctic boundary zones in the North Pacific region. Breeding populations are in the Bering and Okhotsk seas and Tatar Strait. During the open water season, they live a completely pelagic existence in the cold temperate waters along and beyond the continental shelves, often far from the locations of their winter habitat. The breeding cycle is similar to that of the spotted seal, and the two occur in relative close proximity to each other during late winter and spring. At the time of pupping and molting, ribbon seals utilize ice of the inner ice front where floes are larger, thicker, more deformed, and more snow covered than in the adjacent ice margin favored by spotted seals. They are noted for hauling out on very clean ice. They pup in late March and April. At birth the pups weigh about 10.5 kg and have a coat of dense, white lanugo. During the nursing period the pups remain on the ice and gradually shed their lanugo. They remain on the ice for some time after they are weaned. In the opinion of this writer, the preference for heavier ice of the inner front, which persists longer than that of the spring ice margin, is because it permits all age classes of these otherwise pelagic seals to haul out until the molt is completed. Ribbon seals do not come ashore unless debilitated. They appear to be the pinniped analog of the Dall's porpoise (*Phocoenoides dalli*) during the pelagic phase of their annual cycle (June through late autumn), dispersing near the shelf breaks and the deeper waters beyond. They have the morphological and physiological attributes of a seal that can dive to great depths and remain submerged for a long time. In the Bering Sea, relatively few move north of their breeding range, except during years of minimal spring ice cover.

Harp seals occur in the North Atlantic region. There are three breeding populations: those of the White Sea, the Greenland Sea and the Gulf of St. Lawrence. They are a gregarious and highly migratory species that lives primarily in the subarctic zone during winter and spring and is broadly distributed in the open sea from the coastal zone to near the ice margin during the open water season. The birth period extends from late January to early April, depending on the region. During the pupping season they form large aggregations in which pups are born in close proximity to each other (often closer than 2.5 m). They prefer large ice fields within the ice front, usually at some distance from the pack ice margins. Here the floes are extensively deformed and ridged, providing shelter to the otherwise

exposed pups. At birth the pups weigh about 11.8 kg and have a coat of dense white lanugo. The nursing period lasts from 10 to 12 days and they fast, remaining on the ice floes, for some time after weaning. Mating, which occurs after pups are weaned, is followed by the molt. As with the ribbon seal (which is also pelagic after the molt) it seems that the preference of harp seals for the thicker and more stable ice of the inner front zone is because it provides the selective advantage of persisting until the molt is completed. Harp seals make one of the longest annual migrations of any pinniped; some travelling more than 3000 miles from wintering to summering areas. Part of the spring migration is passive as the seals drift on the receding ice.

Hooded seals are a high subarctic, strongly migratory, deep water species that occur in the North Atlantic region and have pups, or whelps, in four different areas: near Jan Mayen, in Davis Strait, off the Labrador coast, and in the Gulf of St. Lawrence. Shifts to heavier ice in the more northerly whelping areas reportedly occur during periods of warmer climate and diminished ice (drift ice pulsations). Pups are mainly born on thick heavily ridged ice floes well within the subarctic pack during late March and early April. At birth, the pups weigh about 22 kg (relatively large) and are comparatively precocious. Their lanugo is shed *in utero* and their birth coat (the blue-back stage) does not resemble the pelage of adults. The nursing period is amazingly brief, averaging 4 days, during which the mothers remain on the ice with their pups. Pups enter the water shortly after weaning, although they spend considerable time on the ice during the postweaning fast. Mating occurs after lactation, and molting after mating. They migrate, both passively on the drifting ice and by swimming, and disperse widely in the open sea (to the Grand Banks), near high latitude shores, and along the edge of the summer pack ice. Extralimital occurrences are common, even to the North Pacific region.

Bearded seals are primarily benthic feeders that have a circumpolar distribution in arctic and subarctic seas. They have evolved in the face of heavy predation pressure by polar bears. Their range broadly overlaps that of all the other ice breeding pinnipeds. They are the least selective of the seals with respect to ice type, provided that it generally overlies water of less than about 200 m deep. Bearded seals are usually solitary and occur from the southern ice margins and fronts (few) to the heavy drifting pack around the rim of the arctic basin, although infrequently in landfast and multiyear ice. Within the heavier pack ice they occur mainly in association with those features that produce open water or thin ice (polynyas, persistent leads, flaw zones, etc.). They are capable of breaking holes in thin ice (<10 cm) and can make or at least maintain breathing holes in thicker ice, with their stout foreclaws. The large pups (about 34 kg) are usually born on the edges of small detached, first year floes very close to the water. The lanugo is shed *in utero*. The pups can swim from birth if necessary, and usually do so, at least in order to move away from the afterbirth. Beyond that they remain on the ice for a day or so. Nursing, which is usually on the ice, lasts 12–18 days, during which time the pups spend a considerable amount of time in the water and begin independent feeding prior to the end of the nursing period. Mating occurs after pups are weaned. The main period of molt is during May and June, and the greatest numbers of all age classes haul out on the ice during that time. However, molting seals are encountered throughout the year. In some areas, such as the Bering and Chukchi seas, the adults and most juveniles migrate to maintain a loose year-round association with ice. They haul out on it throughout the year, although infrequently during winter. In areas where ice disappears during summer (i.e., the Okhotsk Sea) or recedes beyond the continental shelf, they occur in the open sea, in near shore areas, in bays and estuaries, and sometimes haul out on land.

Ringed seals have a circumpolar distribution that includes the arctic and subarctic seas. They have evolved in the face of heavy predation pressure, primarily by arctic foxes, which take pups, and polar bears, which take all age classes. Unique species and subspecies of the subgenus *Pusa* also occur as landlocked populations in Eurasia and include the seals of lakes Baikal, Ladoga, and Saimaa, as well as the Caspian Sea. Ringed seals are the most numerous and widely distributed of the northern ice-associated pinnipeds. During winter to early summer they utilize all ice habitats from the drifting ice margins and fronts (relatively few) to thick stable shore-fast and multiyear ice. Their range extends farther north and includes areas of heavier ice cover than that of any other marine mammal except the polar bear. They occur from shallow coastal waters to the deep of the Arctic Basin. During winter through late spring the adults tend to be solitary and territorial and are most abundant in moderate to heavy pack and shore-fast ice. Ringed seals can make and maintain holes through the ice and crawl out to construct snow lairs above them. In regions where conditions permit, they migrate and maintain a year-round association with ice. In some regions where the pack ice completely or mostly disappears during summer (i.e., the Okhotsk Sea, Baffin Bay, Lake Baikal) they move to nearshore areas and sometimes haul out on land.

Pups are born during late March through April, in snow lairs or cavities in pressure ridges. The pups are small, averaging about 4 kg at birth, and have a thick woolly lanugo, which is usually shed by the end of the nursing period. Lactation lasts 4–6 weeks. Pups mostly remain in the birth lair for the first several days but are soon capable of entering the water and periodically returning to a lair. Mating occurs after the nursing period and is followed by the molt. The peak period of molt in nonpups is during May and June, when the seals haul out above collapsed (melted) lairs, at enlarged breathing holes, or next to natural openings in the ice. Ringed seals are extremely wary when hauled out. During the open water season, depending on the region, they occur in the much reduced pack ice and in open water over a broad area. In some regions they haul out on land.

Walruses are the largest and most gregarious of the ice-breeding northern pinnipeds. They have a discontinuous although nearly circumpolar distribution around the perimeter of the Arctic Ocean and the contiguous subarctic seas. They are benthic feeders mainly restricted to foraging in waters less than 110 m deep. In all areas, their distribution is limited by water depth and in some (i.e., the East Siberian, Laptev, and Kara seas) it is further constrained by severity of ice conditions. In most regions, walruses haul out on ice in preference to land. However, during the open water season, they (mainly males) use land haulouts near the wintering grounds and, in more northerly areas, most come ashore to rest when ice drifts beyond shallow water, as occurs frequently in the Chukchi Sea. During autumn, walruses that migrate southward ahead of the advancing ice also come ashore to rest. All populations are associated with seasonal pack ice during winter to spring/early summer. They mainly use moderately thick floes well into the winter/spring ice cover. The combined requirements for floes low enough to haul out on, but thick enough to support these large animals (usually herds of them) and that are also over shallow productive continental shelves, make walruses particularly dependent on regions within which persistent natural openings are present. They make (batter) holes through ice as thick as 22 cm, using the head, and sometimes maintain them with the aid of their tusks.

Calves are born mainly in early May, which for the Bering Sea population is during the northward spring migration of females, calves, subadults, and some adult males (Fig. 4). Walruses shed their lanugo *in utero*. Calves are born on the ice. They weigh about 60 kg and enter the water from birth, although they haul out frequently.

Cows with young calves often form large nursery herds and migrate passively on the drifting ice, as well as by swimming (Fig. 5). The nursing period lasts more than a year. Walrus haul out in all months of the year.

B. Cetaceans

The ice-associated cetaceans include two odontocetes (toothed whales), the beluga and the narwhal, and one mysticete (baleen whale), the bowhead. None have a completely circumpolar distribution. Morphological adaptations to ice seem minimal and include the lack of a dorsal fin in all three and the high “armored” promontory (also termed a “stack”) atop which the blowholes of the bowhead are situated. In winter all three species occur in drifting ice where there are persistent natural openings or where the ice cover is thin. Polynyas, shear zones, and leads are important features for them in the regions of heavy pack ice.

The narwhal is a North Atlantic species of the high subarctic and low arctic, which, in winter, consistently occurs in regions of heavy drifting ice over deep water or shelf edges. Adult males have a unique,

Figure 4 Small herds of walrus (*Odobenus rosmarus*) including females, calves, and subadults on scattered mid-summer ice floes in the eastern Chukchi Sea.

long unicorn-like tusk which is presumably used in male sexual display. The largest population is that in Davis Strait and Baffin Bay. Seasonal movements of narwhals are directly tied to the advance and retreat of ice. During summer they move to high-latitude, ice-free coastal and nearshore areas, which are often penetrated by deep fjords. Calves are born during the summer, reportedly during July and August, and are nursed for more than a year. This whales' preference for heavy pack ice during winter and spring makes them particularly vulnerable to entrapment during periods of rapid ice formation or when the pack becomes tightly compressed. Most episodes of entrapment are probably brief, though prolonged confinement and rapid ice formation sometimes result in death either by drowning or by polar bears, for which entrapped whales are easy and plentiful prey. Confined whales are also harvested by Inuit hunters whenever they are found.

Beluga whales have a nearly circumpolar distribution that extends from roughly 48°N (the Gulf of St. Lawrence and the northern Sea of Japan) into the summer multiyear pack of the Arctic Ocean. During winter, they are most abundant near the southern ice margins and fronts and as far into the seasonal pack as conditions permit. Again, polynyas, flaw zones, persistent leads, and other features that permit belugas to surface for air are important in the more northerly regions. Belugas often make holes through thin (to about 10 cm) newly formed ice by pushing it up with their head and back. They also surface in openings made by bowheads, with which they often associate during spring migration.

DISTRIBUTION during the open water season is quite variable depending on region. In most cases these whales move into the coastal zone in May to July or early August, where they enter lagoons and estuaries to feed, bear calves in warmer water, and molt. They frequently ascend rivers to feed on seasonally abundant fishes. Telemetry studies have shown that belugas in the Beaufort Sea and the Canadian high arctic spend slightly less than 2 weeks in lagoons, and spend most of their summer feeding in offshore waters (unlike belugas farther south). Some males from the eastern Chukchi and Beaufort Sea stocks are now known to penetrate much farther into the pack ice of the Arctic Ocean during summer than was previously supposed (to beyond 80°N). Other belugas range widely throughout Amundsen Gulf and the Beaufort and northern Chukchi seas during summer and early autumn.

Figure 5 Part of a huge nursery herd of walrus (*Odobenus rosmarus*) during the northward spring migration through Bering Strait.

The larger populations include multiple stocks. In the Bering Sea population, the largest of the stocks migrates north through the disintegrating ice cover in spring, and uses both ice-free coastal waters and the summer pack of the Arctic Ocean, ranging from northwestern Canada to northeastern Russia, as the open water season progresses. Most belugas leave the coastal zone by September, although some remain or revisit areas where food is abundant. This habit has resulted in some large and fatal entrapments. Smaller entrapments at sea are not uncommon. All move with the advancing ice in autumn, either migrating southward with it, or moving into it as it forms and expands.

Bowhead whales occur in subarctic waters during winter and spring and, depending on the population, in productive marginal arctic waters during the open water season. These large whales are highly specialized zooplankton feeders and seek areas of high prey abundance. Bowheads may be the slowest growing and latest maturing mammal on earth. Females are thought to become sexually mature between their late teens to mid-twenties (later than humans or elephants). They may live to be well over 100 years old.

The range of bowheads includes the North Atlantic region (three stocks) and North Pacific region (two stocks), with extensive gaps between the two. During winter through early spring they occur from the southern margins of the pack ice to as far into it as persistent natural openings in the ice permit. Large polynya systems are of great importance during winter and spring. In the Pacific sector, the Okhotsk sea stock remains there after the ice has completely disappeared. Most whales of the other stocks migrate northward during spring and southward during autumn. Most whales of the Bering Sea stock maintain a loose association with the summer ice margin, mainly feeding in the open waters south of it. The northward migration begins in late March or early April when they move from the Bering Sea into the eastern Chukchi, and then across the Beaufort Sea through heavy ice in a very long corridor cleaved by a linear system of stress cracks, polynyas, shore leads, and flaw zones. Some migrate into the western Chukchi Sea. Beluga whales commonly migrate with bowheads. Bowheads can stay submerged for long periods and push up through relatively thick ice. These abilities allow them to reside and travel in waters where natural openings in the ice are continually forming and refreezing. Calves are born mainly during April to early June, during the spring migration.

C. Fissipeds

Two fissipeds roam the high-latitude ice-covered seas: the polar bear and the arctic fox (*Alopex lagopus*). The latter, which rarely enters the water and pups in dens on shore, is not usually considered to be a marine mammal.

Polar bears have a circumpolar distribution in the Arctic and contiguous high subarctic. They are not “marine” in the sense that whales or seals are, but occupy a marine environment in which ice is the substrate on which they live. They prey on other marine mammals, particularly the ringed seal. Depending on the region, they remain with the ice and hunt year round or, where it completely disappears, they come ashore and usually fast or utilize carrion. Exceptions to the latter are some islands (i.e., Wrangel and Herald) where they hunt animals that haul out on shore, particularly walrus, and also feed on the numerous marine mammal carcasses that occur there. On the ice, availability (access) of prey seems to be a more important factor affecting the distribution of bears than is maximum prey abundance. It is difficult for bears to catch marine mammals, except pups, when there are unlimited escape routes and places to surface in a very labile ice cover (cf. Fig. 2). For example, few polar bears range south of the northern Bering Sea during winter, even though the majority of other

marine mammals (except ringed seals) are south of there. Also, polar bears are not present in the Okhotsk Sea.

Pregnant females make and enter snow dens in early November. These maternity dens can be on the heavy pack ice, on shore-fast ice (relatively few), or on land. The altricial cubs are born in late December or early January, during the arctic winter, and do not emerge with their mothers until late March or early April. Sows that bore their cubs on shore go back to the drifting sea ice after the young emerge from natal dens (Fig. 6). Ringed seal pups, born in lairs beneath the snow starting in late March, are important prey for the sows with cubs.

V. Possible Effects of Climate Change

It is now well recognized that we are in a phase of accelerated global warming and that the multiyear and seasonal ice cover is being affected. During the period 1979–2006, the average sea ice extent has declined for every month. In September, the usual time of minimal annual extent, the trend of decline is estimated to have been at the rate of -8.6% per decade. The seasonal ice cover is becoming generally less extensive and thinner, and it is forming later and disintegrating earlier than at any time in recorded history. In the Arctic Ocean the multiyear ice cover is also contracting and thinning. Similar changes have occurred in the geological past. The current warming trend, however, seems to be either driven or strongly intensified by anthropogenic inputs (carbon and greenhouse gases) to earth's oceans and atmosphere. In addition to a diminished ice cover, warming conditions also produce rising sea levels, increased ocean circulation, and increased nutrient flow into the northern seas. These changes are likely to have varying effects on the different species of ice-associated marine mammals. At present, we cannot reliably forecast complex changes of the various interacting natural systems that extend from the northern part of the temperate zone to the Arctic.

For some species or populations, e.g., the bowhead whale and spotted seals of northern Beringia, ameliorating conditions might be positive as they would result in more favorable habitat over a broader area than at present. The number of bowhead whales of the Bering Sea population has been increasing steadily and has recently shown a

Figure 6 NOAA pilot William Harrigan at a temporary snow den on land-fast ice, used by a female polar bear (*Ursus maritimus*) and her cub, as they traveled from land toward the drifting pack ice in the central Beaufort Sea.

remarkable annual increase in calf production. For others, especially those dependent on currently marginal seasonal sea ice habitats, or on heavier and more stable ice habitats of the far north, the changes are likely to have negative impacts. Spotted seals in the Yellow Sea and the Sea of Japan are likely to be negatively affected and, for the true arctic species, there is particular concern about polar bears and their primary prey, ringed seals. At a minimum, global warming will likely result in significant geographic shifts of the seasonal centers of abundance of all ice-associated marine mammals, and populations of some species may decline.

Atlantic Spotted Dolphin

Stenella frontalis

WILLIAM F. PERRIN

I. Characters and Taxonomic Relationships

This sturdy spotted dolphin (Figs 1 and 2) is found only in the Atlantic and is commonly seen around the "100-fathom curve" along the southeastern and Gulf US coasts, in the Caribbean, and off West Africa.

The Atlantic spotted dolphin is not always spotted. A large heavy-bodied form found along the coast on both sides of the Atlantic (formerly called *Stenella plagiodon* along the US coast) may be so heavily spotted as to appear white from a distance, but a smaller more gracile form occurring in the Gulf Stream and out into the central North Atlantic can be lightly spotted or entirely unspotted as an adult (Perrin *et al.*, 1987; Viallelle, 1997). A constant diagnostic external feature of *S. frontalis* is a spinal blaze sweeping up into the dorsal cape; this distinguishes it from the very similar pantropical spotted dolphin, *S. attenuata*, also found in the tropical Atlantic. In addition, the peduncle does not exhibit the division into darker upper and lighter lower halves present in *S. attenuata*. The calf of the heavily spotted form is born unspotted, with a three-part color pattern of dark dorsal cape, medium-gray lateral field, and white ventral field. Spots first appear at 2–6 years and increase in size and density up to 16 years (Herzing, 1997). Genetic analyses in correlation with morphology indicate that at least three populations occur in the western Atlantic and the Gulf of Mexico (Adams and Rosel, 2006).

The beak is of medium length (intermediate between those of *Tursiops truncatus* and *S. attenuata*) and sharply demarcated from the melon. The dorsal fin is tall and falcate. Measured adults range from 166 to 229 cm in body length ($n = 106$) and weigh up to 143 kg ($n = 37$) (Perrin *et al.*, 1994a; Nieri *et al.*, 1999). Weight at length is greater than for *S. attenuata* (Perrin *et al.*, 1987).

As in *S. attenuata*, *T. truncatus*, and *T. aduncus*, the skull is characterized by a long rostrum, distal fusion of maxillae and premaxillae

Figure 1 Young Atlantic spotted dolphin in the Gulf of Mexico, just developing spots. Spots and blaze below dorsal fin are diagnostic for the species. Photo by R. L. Pitman.

Figure 2 Heavily spotted adult Atlantic spotted dolphin in the Gulf of Mexico. Spinal blaze is still visible. Photo by R. L. Pitman.

in adults, convergent premaxillae, large rounded temporal fossae, and arcuate mandibular rami. Tooth counts are 32–42 in the upper jaw ($n = 115$) and 30–40 in the lower ($n = 107$) vs 35–48 ($n = 315$) and 34–47 ($n = 315$) *S. attenuata* (Perrin and Hohn, 1994; Perrin *et al.*, 1994a; Nieri *et al.*, 1999). This species and *S. attenuata* overlap in all skull measurements as well as in tooth counts (Perrin *et al.*, 1987). Both species vary greatly geographically. Some specimens of the two species can be identified only with multivariate analysis. However, vertebral counts for the two species do not overlap [67–72 ($n = 52$) in *S. frontalis* vs 74–84 ($n = 75$) in *S. attenuata*].

Taxonomy of the spotted dolphins was long confused, with specimens of this species and the pantropical spotted dolphin (*S. attenuata*) classified or identified under various permutations of the nominal species *S. attenuata*, *S. frontalis*, *S. plagiodon*, *S. froenatus*, *S. pernettyi*, and *S. dubia* (see Hershkovitz, 1966). A revision (Perrin *et al.*, 1987) recognized one pantropical species (*S. attenuata*) and a second species endemic to the tropical Atlantic (*S. frontalis*), both highly variable geographically in size, tooth size, and color pattern. Although the skull of the Atlantic spotted dolphin shows close affinities with that of the pantropical spotted dolphin, the two species did not emerge as sister taxa in a cladistic phylogenetic analysis based on cytochrome *b* mtDNA sequences (LeDuc *et al.*, 1999). *S. frontalis* was imbedded in a strongly supported polytomic clade with *S. coerulealba* and *S. clymene* (sister taxa), *Tursiops aduncus*, and *Delphinus* spp. *T. truncatus* was a sister taxon to this clade, with the resulting higher clade imbedded in the five-part polytomic delphinine clade with *S. attenuata*, *S. longirostris*, *Sousa chinensis*, and *Lagenodelphis hosei*. Despite a high degree of cranial similarity, this wide phylogenetic separation suggests that the similarity represents either convergence (homoplasy) or retention of primitive character states (plesiomorphy). The interspecific relationships in color pattern may accord better with the molecular phylogeny, e.g., the pattern of head stripes in *S. frontalis* is closer to those of *T. truncatus* and *T. aduncus* than that of *S. attenuata* (Perrin, 1997). In any case, the existing genus-level taxonomy of the group badly needs revision; *Stenella* is presently polyphyletic and *Tursiops* paraphyletic (LeDuc *et al.*, 1999). A cladistic analysis of morphology (not yet attempted) is in order.

II. Distribution and Abundance

This species is endemic to the tropical and warm-temperate Atlantic; it is not known to occur in the Pacific or Indian Oceans. The range extends from about 50°N to about 25°S (Jefferson *et al.*, 2007). A discontinuity exists in the range in the western South Atlantic (Moreno *et al.*, 2005). In the western Atlantic, the large heavily spotted form inhabits shallow, gently sloping waters of the continental shelf and the continental-shelf break, usually within or near the 200-m curve but occasionally coming close to shore in pursuit of prey (Perrin

et al., 1994a; Davis *et al.*, 1998; Würsig *et al.*, 2000). In the Southwest Atlantic, they are found within the 1000-m isobath (Moreno *et al.*, 2005). It is usually replaced in nearshore waters by the coastal form of the bottlenose dolphin, *Tursiops truncatus*. There are few estimates of abundance. About 31,000 were estimated to inhabit the northern Gulf of Mexico, but this is thought to be an underestimate (Waring *et al.*, 2006). About 14,000 were estimated from a survey of waters from Maryland to Central Florida (Mullin and Fulling, 2003).

III. Ecology

Shallow water (6–12 m) over sand flats is utilized as habitat in the Bahamas (Herzing, 1997). A wide variety of prey items has been recorded, including small-to-large epipelagic and mesopelagic fishes and squids and benthic invertebrates; diet may differ between coastal and Gulf Stream forms. Sharks are the only known predators, but it is probably also preyed on by killer whales (*Orcinus orca*) and other small toothed whales.

IV. Behavior and Physiology

Dives to 40–60 m and lasting up to 6 min have been recorded, but most time is spent at less than 10 m (Davis *et al.*, 1996). Behavior of this dolphin has been studied extensively in the Bahamas (Herzing, 1997; Herzing and Johnson, 1997), where it associates closely with bottlenose dolphins during foraging and traveling. Schools may be segregated by age and sex and fluctuate in size and composition, consisting of up to 100 individuals (Perrin *et al.*, 1994a). In the Azores, Atlantic spotted dolphins join large temporary mixed-species feeding aggregations with tuna, other cetaceans, and seabirds (Clua and Grosvalet, 2001). Echo-location signals in the species recorded in the wild resemble those of other delphinoids in captivity (Au and Herzing, 2003).

V. Life History

Little is known of the life history of this species. Maximum age in 44 specimens from Brazil was 23 years with maximum length attained by about 20 years (Siciliano *et al.*, 2007). Age at sexual maturation is estimated at 8–15 years in females (Herzing, 1997). First parturition is associated with the mottled phase of spotting development. The average calving interval is about 3 years, with a range of 1–5 years. Nursing has been observed to last up to 5 years. Average first-year natural mortality in a study in the Bahamas was 24%.

VI. Interactions with Humans

This species does not do well in captivity; most captive animals have died within a year or less, many refusing to eat (Perrin *et al.*, 1994a). It is killed incidentally in fisheries in Brazil, the Caribbean,

the western North Atlantic, and West Africa (Perrin *et al.*, 1994b; Nieri *et al.*, 1999; Van Waerebeek *et al.*, 2000).

Atlantic White-Sided Dolphin

Lagenorhynchus acutus

FRANK CIPRIANO

I. Characteristics and Taxonomy

Atlantic white-sided dolphins are robust and powerful, impressively patterned, and more colorful than most dolphins. A narrow, bright white patch on the side extends back from below the dorsal fin and continues toward the flukes as a yellow-brown blaze above a thin dark stripe (Fig. 1). The back and dorsal fin are black or very dark gray, as are the flippers and flukes, while the belly and lower jaw are white, and the sides of the body a lighter gray. A black eye ring extends in a thin line to the upper jaw, and a very thin stripe extends backward from the eye ring to the external ear. A faint gray stripe may connect the leading edge of the flipper with the rear margin of the lower jaw. The beak is short and grades smoothly into the “melon” (forehead). The upper jaw contains 29–40 and the lower jaw 31–38 small, conical teeth. Molecular analysis has recently been used to examine the evolutionary relationships of *Lagenorhynchus acutus* and the five other currently recognized members of the genus *Lagenorhynchus*. Although formal taxonomic revision awaits a comprehensive review of morphological and molecular characters, the molecular evidence suggests that some of the five are actually more closely related to the right whale dolphins (genus *Lissodelphis*) and some Southern Hemisphere dolphins (genus *Cephalorhynchus*) than they are to *L. acutus* (LeDuc *et al.*, 1999; Harlin-Cognato and Honeycutt, 2006).

II. Distribution and Abundance

Inhabitants of the cold-temperate North Atlantic, Atlantic white-sided dolphins are usually encountered in waters over the continental shelf and slope, extending into deeper oceanic waters and occasionally into coastal areas (Fig. 2). The southern limit in the western Atlantic is Cape Cod and the submarine canyons south of Georges Bank in the west and Brittany in the east. Groups of Atlantic white-sides are often seen by fishermen and deep-water sailors off the coasts of New England, Nova Scotia and Newfoundland, the western British Isles, Northern Europe and in the Norwegian Sea. There are no records of this species from the inner Baltic Sea, although some sightings and strandings are known from the straits between Denmark, Norway,

Figure 1 The Atlantic white-sided dolphin (C. Brett Jarrett).

Figure 2 Known distribution limits of the Atlantic white-sided dolphin. The patterned area indicates areas of regular occurrence; question marks indicate uncertainty about occurrence in particular areas.

and western Sweden. The northern distribution limits are poorly known but extend at least to southern Greenland, southern Iceland, and the south coast of Svalbard Island (Reeves *et al.*, 1999).

Censusing oceanic dolphins is a difficult task, requiring extensive aerial surveys or long observation tracks from survey ships (or both), and then extrapolation of the densities observed to immense ocean areas. Given the wide distribution of Atlantic white-sided dolphins across the northern reaches of the Atlantic, rather wide confidence limits on abundance estimates are to be expected. The best estimate for the western Atlantic is around 50,000 animals (NOAA, 2006), but there is not enough survey coverage for good estimates in the eastern or central Atlantic. For the entire Atlantic there are perhaps 150,000–300,000 (Kaschner, 2004).

III. Ecology

Analysis of the stomach contents of mass-stranded, incidentally entangled, and drive-caught dolphins is used to assess their diet,

since diagnostic “hard parts” (crustacean shells, fish ear bones, and squid beaks) accumulate in stomach chambers. A general indication of the importance of particular prey items can be inferred from the percent contribution of each type, although the number of meals represented by such traces is usually unknown and there may be bias in the retention of different types. Major prey species of Atlantic white-sided dolphins include herring, small mackerel, gadid fishes (codfish and their relatives), smelts and hake, sand lances, and several types of squid (Reeves *et al.*, 1999). Different prey species may predominate at different times of year, representing seasonal movements of prey, or in different areas, indicating prey and habitat variability in the environment. For example, different species of squid are eaten by these dolphins on opposite sides of the Atlantic, while in spring and autumn, sand lance and dolphin distributions in the Gulf of Maine appear to mirror each other. Atlantic white-sided dolphins are probably not deep divers—the maximum dive time recorded from a tagged dolphin was 4 min and most dives were less than a minute in duration.

IV. Behavior and Physiology

The number of Atlantic white-sided dolphins observed in a group ranges from a few individuals to several hundred, and mean group size appears to vary with location. In Newfoundland inshore waters 50–60 dolphins in a group are typical; in inshore waters of the British Isles and near Iceland, groups usually contain less than 10 individuals; and off the New England coast group size ranges from a few to around 500, but the usual group size is around 40. Some segregation by sex and age has been suggested from mass stranding records—larger juveniles were absent from some mass-stranded groups that contained many calves, adult males, and pregnant females. Mass strandings involving up to a hundred or more animals at one time are common for this species in the Western North Atlantic (NOAA, 2006).

V. Life History

Male Atlantic white-sided dolphins are known to reach a maximum body length of about 270 cm and a weight of 230 kg, while adult females reach a maximum size about 20 cm shorter and 50 kg lighter. This is smaller than that well-known oceanarium inhabitant, the common bottlenose dolphin *Tursiops truncatus* (around 380 cm/270 kg maximum) and a bit longer and a lot heavier than the short-beaked common dolphin, *Delphinus delphis* (around 230 cm/75 kg).

Females reach sexual maturity at 200–220 cm, at ages from 6 to 12 years. Males reach sexual maturity at lengths of 215–230 cm, corresponding to ages of 7–11 years. Maximum ages recorded were 22 and 27 years, for males and females, respectively. At birth, Atlantic white-sided dolphins are around 120 cm long, after an approximately 11-month gestation period, and weigh about 25 kg (Perrin and Reilly, 1984). In the western Atlantic, the calving season peaks in mid-summer, while in the eastern Atlantic the calving season may extend several months longer (Weinrich *et al.*, 2001). The lactation period lasts around 18 months, and some stranded individuals were observed to be both pregnant and lactating, suggesting that some individuals may breed annually (Sergeant *et al.*, 1980).

VI. Interactions with Humans

This species is not currently hunted on a large scale anywhere in its range, although historically many were killed in drive fisheries in Norway and Newfoundland and smaller numbers were taken off Greenland and the Faroe Islands. Incidental mortality has been documented in many areas; these dolphins may be particularly susceptible to entanglement in trawl nets. Recent large catches in pelagic trawl nets have been reported in the Atlantic Frontier off Ireland (Berrow and Rogan, 1997). Within US waters, small numbers of white-sided dolphins have recently been observed caught in sink gillnet, bottom trawl, mid-water trawl, and the Gulf of Maine/Georges Bank herring trawl fisheries (NOAA, 2006). Comprehensive genetic studies and abundance estimates off western Europe are needed to determine the potential impact of mortality in particular areas, since this species seems vulnerable to bycatch from a wide variety of fishing gear types.

Australian Sea Lion

Neophoca cinerea

JOHN K. LING

I. Characteristics and Taxonomy

The endemic Australian sea lion (Fig. 1) is one of the world’s rarest and most unusual seals: rare in terms of very small numbers and unusual in its having a sesquiennial reproductive cycle. It is also a temperate species whose range lies between latitudes 28°S and 38°S around much of the southern part of the island continent (Ling, 1992).

At birth the pups are a dark chocolate-brown to charcoal-gray in color, which changes to the smoky gray (hence the specific name *cinerea*) and cream adult color after the post-natal molt (Walker and Ling, 1981; Ling, 1992). Females retain this coloration throughout life, but males gradually develop a brownish-black coat with increasing age. Males of breeding age have a cream patch on the back of the head and nape of the neck. This species has flattened guard hairs but no underfur—the pelage apparently being adapted to a temperate environment. It also has a relatively thin layer of blubber beneath the skin, about 2 cm thick. Pups measure 62–68 cm in length (nose–tail) and weigh 6.4–7.9 kg at birth, males tending to be heavier than females. Adult females range in length from 132 to 181 cm and weigh between 61 and 105 kg (for a pregnant specimen); males measure up to 200 cm in length and attain weights well in excess of 200 kg.

Marlow and King (1974) summarized the history of the taxonomy of *Neophoca* and concluded that it and the New Zealand sea lion,

Figure 1 Australian sea lions: adult male (white “cap” on head not visible), two adult females and juvenile (ca. 4 months old) suckling, at North Casuarina Island, off Kangaroo Island, South Australia. Photo courtesy of P.D. Shaughnessy.

Phocarcos hookeri, rightly belonged in different genera, based on skull characteristics. Some common names applied to *Neophoca* are Australian sea lion (preferred), counsellor (“wigged”) seal, white-necked or white-capped hair seal or simply hair seal (particularly in early Australian historical times).

II. Distribution and Abundance

The breeding range of the Australian sea lion extends from Houtman Abrolhos (29°S, 114°E) in Western Australia to the Pages Islands (36°S, 138°E), just east of Kangaroo Island, South Australia, with stragglers reaching central New South Wales on the east coast (Fig. 2).

The most recent study (McKenzie *et al.*, 2005) estimates that there are only 9794 Australian sea lions occupying their wide geographic range in 73 scattered colonies (47 in South Australia and 26 in Western Australia), of which only six produce more than 100 pups in a breeding season. Four-fifths of the population resides in South Australia and a fifth occurs in Western Australia, where more than half the breeding colonies are located, all of which are small. The largest breeding colonies are on Purdie Islands (32°S, 133°E), Dangerous Reef (35°S, 135°E), Seal Bay (36°S, 137°E) on Kangaroo Island, and the two islands of The Pages. Australian sea lions once ranged as far as the eastern end of Bass Strait, but today only stragglers occur there and beyond. The various sea lion colonies are to some extent genetically isolated and members maintain a strong attachment to their respective birth places, particularly adult females.

Australian sea lions were ruthlessly hunted during the sealing era from the late eighteenth to the mid-nineteenth century for their skins and oil, when only a few thousand skins were reported to have been harvested. It is not possible to estimate the number killed for oil, because “seal oil” included fur seal oil and sea lion oil in the cargos. However, there may not have been many sea lions to be taken anyway, compared with the large fur seal populations, which are increasing today after having been almost exterminated by early sealers. Because the first census over most of the sea lion’s entire breeding range was carried out only recently (Gales *et al.*, 1990; Dennis and Shaughnessy, 1996), it cannot be determined at this stage whether colonies are growing or declining, except at Seal Bay, where

numbers are decreasing. Future surveys of all breeding colonies will need to be undertaken, since counts of live and dead pups provide the most accurate estimates of the size of the total population.

III. Ecology

After they are weaned, sea lions feed on cephalopods, crustaceans, and fish (Ling, 1992). It is not known how far offshore they forage, but diving appears to begin as soon as females leave the rookery and this takes the sea lions out over the continental shelf. Large prey are generally seized in the mouth and shaken violently at the surface to remove cuttlefish bones, skin or skeletons before swallowing. Depending on size, experimental markers take from 5 to 48 h to pass through the alimentary tract. Australian sea lions are infected by the usual array of external and internal parasites: lice and mites, and acanthocephalans, nematodes, cestodes, and trematodes. Dissections often reveal heavy infestations. Many carry up to several kilograms of pebbles in the stomach, which are thought to aid digestion.

IV. Behavior and Physiology

The protracted pupping season, during which mating is effected, ensures that there is a high turnover of territories and a breakdown of any harem system (Ling and Walker, 1978; Higgins, 1993; Gales *et al.*, 1994; Gales and Costa, 1997). In contrast to many otariids in which dominant males control small to large numbers of females, *Neophoca* practices what is known as sequential polygyny which still allows males access to several females in a season, but, in general, one at a time. Nevertheless, aggressive encounters do take place between rival breeding males and are a significant cause of mortality among young pups that are unfortunate enough to be attacked or trampled by rampaging bulls. Their lumbering gait resembles something of an ungainly gallop a little above a fast human walking pace and punctuated by frequent rests. Females are most solicitous of their young, and several tourist visitors to Seal Bay and other breeding colonies have received nasty bites when they approached too closely a cow with her pup. When returning from a foraging trip, a female will call from the sea with a soft “moo” and wait for her

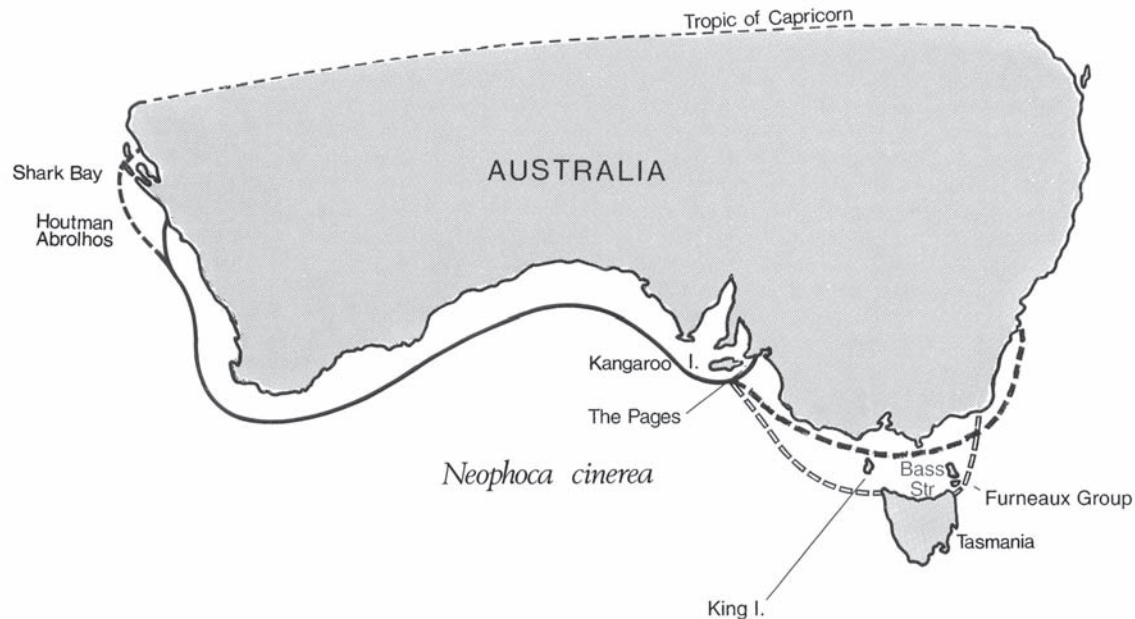

Figure 2 Present and past distribution of Australian sea lions. Unbroken solid line depicts current known breeding range, broken solid line depicts seasonal stragglers, and broken open line depicts extent of former breeding range. Courtesy of the Royal Zoological Society of South Australia Inc.

pup's answering call which resembles a lamb's bleat. When pups are small and site fidelity is very strong, so little searching for each other is necessary. Once the two are reunited, recognition is confirmed by smelling. Sea lions are powerful and skilful swimmers, using their large front flippers to propel them rapidly through the water. They are also excellent surfers and can often be seen riding the waves right into the shallows or "porpoising" along wave crests and troughs farther out to sea.

Large males tend to lie apart from other sea lions, but females and immature animals often lie close together, wriggling, squirming, and scratching constantly. On hot days when the sun temperature may exceed 45°C they will occasionally go into the sea and return a short while later to allow evaporative cooling to take effect. Sea lions may also venture some distance inland to lie under bushes or up steep slopes to find a shelter; they are quite agile on land.

There is a marked increase in concentrations of the hormones progesterone and oestradiol about 3–5 months after the probable mating date, and they reach their highest levels after another 2 months. This suggests that the blastocyst reactivates and implants 3.5–5 months into pregnancy, a similar free blastocyst stage to that of other seals. It also means, however, that post-implantation gestation lasts up to 14 months to fit with the 17.5-month reproductive cycle.

The lipid content of Australian sea lion milk is lower during all stages of lactation than that reported for other middle- and high-latitude eared seals. This may be correlated with the extended lactation period—15–17 months and even longer for some pups—of this species. Lipid and energy content do increase during lactation but the composition varies greatly between and within individuals.

At-sea metabolic rates of Australian sea lions are comparable with those of other eared seals and are up to 6.8 times the predicted basal metabolic rate for terrestrial mammals of similar size. Compared to California sea lions, *Neophoca* works hard during its foraging dives that last from about 3 to 8 min for adult females, at average depths of

67 m and an average maximum depth of 92 m. These are longer dive durations than for other eared (but not true) seals.

V. Life History

The life history of *Neophoca* is unique in a number of aspects: the approximately 17.5-month aseasonal reproductive cycle, a protracted (i.e. 5 month or longer) pupping season, prolonged (14 month) post-implantation gestation, and lactation lasting almost until the next pup is born or even longer (Ling and Walker, 1978; Gales *et al.*, 1997). In addition, because many of the sea lion colonies are genetically isolated, breeding across their range is asynchronous. Until recently, this unusual reproductive cycle was thought to be an adaptation to the sea lion's environment that was characterized as a nutrient-poor, low-energy, stable *milieu* associated with the eastward flowing Leeuwin Current on the southern coast of Australia. Recent ocean studies have demonstrated significant upwelling in the waters of western Victoria and South Australia as far west as Eyre Peninsula in summer and autumn, which makes this region quite rich in nutrients; this is where about three-quarters of the Australian sea lion population resides.

Pups are born a few days after the females have moved to their breeding sites, to which they are known to return for successive birthings. Viable twins have never been observed, but two aborted fetuses, believed to be twins and estimated to be about 3 months post-implantation, were found on Kangaroo Island in 1985.

Mating takes place 7–10 days post-partum; there is a 3–4-month-free blastocyst (embryonic diapause) stage, followed by a gestation period of up to 14 months duration. The pup is suckled for the next 15–17 months and during this time it learns to forage for food that it will consume in later life. The milk is low in energy (fat) compared with other pinnipeds and its quality may vary according to the foraging success of the mother and stage of lactation. While the pelage is

unlikely to be involved in thermoregulation, the flattened hairs overlap each other and provide a smooth but flexible outer surface that reduces turbulence when swimming. Periodic renewal of the hair coat ensures that it functions efficiently in whatever role it has. The timing of pelage renewal or molt is variable. Immature sea lions molt during the breeding season, females begin their molt up to 4 months after parturition (which is about when implantation occurs) and adult males do not start their molt until about 9 months after the breeding season.

The Australian sea lion's unusual life history enables it to survive as a very small population scattered over a wide, in places nutrient-poor longitudinal range. The longer than normal (pinniped) gestation and lactation periods allow the female to nurture a developing fetus and growing pup whilst having to forage. Normal growth rates can also be achieved despite the low energy content of the milk. At the same time, the long maternal association confers many learning and protective advantages on the young sea lion. The protracted, asynchronous pupping season spread out over the wide geographic area again means that food resources can be better shared and there is not a sudden influx of newly independent sea lions, such as occurs with more highly synchronized species that occupy nutrient-rich, higher latitudes.

VI. Interactions with Humans

At Seal Bay Conservation Park on South Australia's Kangaroo Island humans can approach Australian sea lions quite closely, and could approach even much closer before stricter guidelines were introduced to prevent disturbance to both animals and humans! Sea lions at other island colonies are much less tolerant of humans and scatter quickly into the sea when disturbed.

Older males, in particular, occasionally haul out onto Adelaide and other beaches: apparently having left or being driven out of their former breeding colonies. They are sometimes taken into animal care or, more often than not, return to the sea and go elsewhere.

There is some conflict between fishermen or fish-farmers and Australian sea lions which take fish from nets and pens, respectively, rather than having to chase prey themselves. Various scaring devices have been tried in an effort to avoid having to shoot at a species that is threatened with extinction. The main method now uses seal fences consisting of wire strung on stanchions about 1.8 m high.

The Australian sea lion colony on Kangaroo Island is internationally famous because of its proximity to the large city of Adelaide and the public being able to view the animals at close quarters (Robinson and Dennis, 1988). There is also a smaller breeding colony on the mainland at Point Labatt on Eyre Peninsula to the west, which may be viewed from a lookout high above the beach. In February 2005 *Neophoca* was listed as a *Threatened* species, *Vulnerable* category under the Commonwealth of Australia *Environment Protection and Biodiversity Conservation Act 1999* (Shaughnessy, 1999). In view of this and the species' importance to the tourist industry on Kangaroo Island (no other colonies are so easily accessible), the South Australian Government has embarked on an intensive management strategy. The whole Seal Bay area has been designated a *Conservation Park*. Public access is limited to the main beach and only in the company of authorized personnel, but there are also viewing platforms overlooking the beach and other restricted areas. The principal pupping sites in sheltered coves adjacent to the main beach have been declared *Prohibited Areas*. Regular classified censuses are conducted to monitor the status of the Seal Bay colony and enhance its chances of survival and value to tourism.

However, some Australian sea lion colonies appear to be suffering very high pup mortality (30–40%) and decreasing pup production.

Only with a widespread and cooperative research and management effort will the species be perhaps more secure.

Australian sea lions have adapted well to captivity, where there have been at least 45 births around the country since 1981 (Ling *et al.*, 2006). One female produced 8 pups in 11 years. Birth intervals are approximately 17.5 months or multiples thereof, thus mirroring reproduction in the wild. A female, estimated to have been about a year old when caught, lived for 25 years in captivity, and a male, aged approximately 1–2 years when captured, has been captive for more than 22 years. These figures agree closely with maximum ages of tagged sea lions in the natural state. The oldest surviving captive-bred specimen (in January 2007) was aged 21 years 3 months. There have been no attempts to introduce captive-bred Australian sea lions into the wild.

Australian Snubfin Dolphin

Orcaella heinsohni

KELLY M. ROBERTSON AND PETER W. ARNOLD¹

I. Characteristics and Taxonomy

The Australian snubfin dolphin is a coastal dolphin species that occurs throughout northern Australia with some evidence for occurrence in Papua New Guinea. This species was previously considered to be a population of Irrawaddy dolphins (*O. brevirostris*). Clear and consistent differences between Asian and Australian *Orcaella* specimens in coloration, cranial and external morphometrics, postcranial morphology, and molecular data are consistent with species-level differences. The Australian snubfin dolphin was formally proposed as a separate species in 2005 (Beasley *et al.*, 2005).

Recent morphological and genetic studies place the genus *Orcaella* in the family Delphinidae, with the closest relative possibly being the killer whale *Orcinus orca*. The Australian snubfin (Fig. 1) dolphin, resembles the Irrawaddy dolphin in appearance and is closely related to it genetically.

Figure 1 Australian snubfin dolphin (*Orcaella heinsohni*) from Cleveland Bay, Queensland, Australia. Courtesy Guido J. Parra.

Figure 2 Australian snubfin dolphin displaying neck crease and lack of dorsal groove. From Beasley *et al.*, 2005.

The name “snubfin dolphin” was first suggested as an alternative common name for Irrawaddy dolphins in 1981. This name highlights a diagnostic external character, is appropriate to all populations, and has been included in lists of common names and general field guides. The proposed common name for this species, the Australian snubfin dolphin, further reflects the fact that the majority of known specimens and morphological work are based on Australian populations.

The species was named for George E. Heinsohn, recognizing his pioneering work on northeastern Australian odontocetes, including the collection and initial analysis of Australian snubfin dolphin specimens.

Total length reaches 230 cm in females and 270 cm in males. Mass of three adults (2.14–2.25 m long) was recorded as 114–133 kg (Arnold and Heinsohn, 1996). The head is rounded in lateral view and lacks a beak. It is usually bounded by a distinct neck crease (Fig. 2) situated about half way between the eye and the anterior insertion of the flipper. The species lacks the dorsal groove that is present on the Irrawaddy dolphin, a distinct indentation from the base of the skull to the anterior edge of the dorsal fin. The body has a subtle three-tone color pattern: a distinct dark brown dorsal cape, light brown lateral field, and white abdominal field. The small variably shaped dorsal fin (from rounded to slightly falcate) is situated in the latter half of the body. A mid-ventral crease runs along the belly from the flippers to the genital slit. The flippers are broad, paddle-like, and highly mobile.

The adult skull retains neotenic features. The number of nasal bones/depressions on each side of the skull vertex varies from 0 to 6, with a mean of 2.9. The nasal bones are nodular in appearance, often with at least two nasals on each side of the vertex. The mesethmoid plate is thin and poorly developed, leaving much of the frontal bone on the anterior face of the vertex exposed. The shallow postnarial pit is filled by a supernumerary bone. The temporal fossa height is greater in the snubfin dolphin than in the Irrawaddy dolphin, with a mean of 61.2 mm vs 45.8 mm (Fig. 3). There are 11–22 teeth in each half of the upper jaw and 14–19 teeth in each lower row.

II. Distribution and Abundance

The species is confirmed to occur from Broome, Western Australia, north to the Northern Territory and along the Queensland coast as far south as the Brisbane River. Cranial morphological

¹A posthumous contribution.

Figure 3 Skulls showing differences in temporal fossa height between the Australian snubfin dolphin (top) and the Irrawaddy dolphin. From Beasley *et al.*, 2005.

features of one Papua New Guinea specimen from Daru were consistent with those of the Australian snubfin dolphin, and it is likely that the species occurs in localized areas around Papua New Guinea. Further study is needed on *Orcaella* in Papua New Guinea and neighboring regions (particularly Indonesia) to confirm the species' respective ranges.

Based on the current known distribution, the Australian snubfin dolphin occurs on the Sahul shelf of Australia/Papua New Guinea, whereas the distribution of the Irrawaddy dolphin corresponds to the Sunda shelf of South and Southeast Asia. These areas are separated by deep oceanic waters and remained separate even during periods of lowered sea levels in the Pleistocene Ice Ages.

Little is known about the current population status of the species. An estimate of about 1000 animals was calculated in 1989 (Freeland and Bayless, 1989) based on aerial survey records. However, the low number of sightings from surveys conducted along the Queensland coast from 1987 to 1995 indicates that the estimate may be high (Parra *et al.*, 2002).

III. Ecology

Sighting records indicate that the Australian snubfin dolphin occurs mainly in protected, shallow (<15m deep), coastal waters, especially adjacent to river and creek mouths, with a preference for sea grass beds. It has been observed to co-occur with the Indo-Pacific humpbacked dolphin (*Sousa chinensis*) throughout most of its range in Australian waters. Shark wounds have been observed on individuals in the field (Parra, 2006).

Australian snubfin dolphins have an opportunistic diet, taking a wide range of fishes as well as cephalopods (squid, cuttlefish,

octopus) and shrimps. Fish from the following families have been identified as prey: Clupeidae, Engraulidae, Apogonidae, Chirocentridae, Anguillidae, Pomadasyidae, Sillaginidae, Hemirhamphidae, Terapontidae, and Leiognathidae.

IV. Behavior and Physiology

Australian snubfin dolphins are generally found in small groups of 2–6 animals; however, groups of up to 14 animals have been observed (Parra *et al.*, 2002). Surfacing is generally unobtrusive, with a low roll showing little of the back. Given this, the dolphins' shy behavior, and the small size of the dorsal fin, it is often easy to miss in the field.

Interactions with Indo-Pacific humpback dolphins have been observed to be aggressive and sexual in nature with the humpback dolphins demonstrating dominance. Vocalizations have been recorded by Van Parijs *et al.* (2000) and include broadband clicks (>22kHz), three or more types of pulsed sounds (>22kHz), and two types of whistles (1–8kHz). These vocalizations occur during both socializing and foraging.

V. Life History

Very little is known about the life history of the species. Most of the information available on the life history of *Orcaella* is based on the Asian species, the Irrawaddy dolphin. It is thought that the life history parameters of the Australian snubfin dolphins and Irrawaddy dolphins are probably very similar. Reproductive seasonality of the snubfin dolphin is unknown. It is thought that gestation may be approximately 14 months. One record of a near-term fetus exists from Townsville, Australia, collected in the month of August. A small number of snubfin dolphins from northeastern Australia were aged using dentinal growth layer groups in teeth. It was estimated that dolphins reached adult size (2.1m) at 4–6 years, and maximum life span was considered to be about 30 years.

VI. Interactions with Humans

The current conservation status of the snubfin dolphin in Australia is listed as “Insufficiently Known” by the Action Plan for Australian Cetaceans and “Near Threatened” in the IUCN Red List of Threatened Species.

Previously, the major known threat to the species was accidental capture in nets used to control the number of sharks off popular swimming beaches. Currently, nearshore fishery gillnets are a threat, as they are set in creeks, rivers, and estuaries, the preferred habitat of the snubfin dolphin. Rezoning of the Great Barrier Reef Marine Park in 2004 has provided areas where gillnetting is banned, limited by permit, or allowed for only several months of the year. However, these areas provide very little coastal coverage; many areas outside the Marine Park are not regulated, which is a concern for the conservation of this species.

Concern has also recently been raised about habitat reduction and degradation that may be caused by human population growth. Suggested effects include reduced food supplies (from habitat degradation and overfishing), increased industrial and urban pollution of coastal sites and disturbance from increased vessel traffic. Such potential threats are largely unquantified; it is hard to predict whether they will cause or have already caused fragmentation of dolphin populations leading to potential decline of the species. More research is needed throughout the range in order to help determine proper management decisions to ensure the conservation of the species.

Azorean Whaling

RICHARD ELLIS

They called it the “Western Islands” Grounds because it was an island-group west of Europe, closer to Europe than America. These islands were among the earliest areas visited by the sperm whalers of New England in the eighteenth century. Early in the history of fishery that was to dominate much of New England’s commercial history, it was discovered that the waters around the Azores were among the favorite haunts of sperm whales. It soon became apparent that there were other attractions in these islands: food and water could be obtained, and more importantly, men willing to sign aboard could be expeditiously recruited.

From his observatory at Sagres at Cape Saint Vincent in Portugal, the westernmost point in continental Europe, Henry the Navigator (1394–1460) inspired the explorers who would extend the boundaries of the known world. Infante Dom Henrique (as he is known to the Portuguese) was the patron of Gil Eannes, the first man to round the previously untried Cape Bojador on the western hump of Africa, opening the South Atlantic for the voyages of such heroes as Bartolomeo Dias, Vasco da Gama, and Ferdinand Magellan. The pilot Diogo de Sevilha, possibly on a return voyage from Madeira, reached the islands that would eventually be named the Azores, but it was Goncalo Vetho Cabral who is credited with the official discovery of the islands in 1431. Cabral first claimed Santa Maria, then So Miguel, Terceira (“third”), Sao Jorge, Graciosa, Pico, and Faial. The seven islands were named 11-has dos Acores (“Isles of Hawks”), and within a year the Portuguese had settled in. While searching for the nonexistent island of Antilia, Diogo de Tieve discovered the remaining two islands in 1452.

The peaks of submerged volcanoes rising from the Mid-Atlantic Ridge, the nine islands of the Azores archipelago, sizzled out of the North Atlantic some 900 miles east of Portugal. The water around these islands can be over a mile deep; a perfect locale for the deep-feeding sperm whale, or cachalot. After Cabral found the islands, the whales would have only another three centuries—the blink of an eye in cetacean history—to swim unmolested in Azorean waters. The whalers were coming.

As they extended their horizons, the Yankee whalers sailed first to the Bahamas and the West Indies, then out into the Atlantic. The currents of the North Atlantic circulate in a roughly clockwise fashion, but there are enough subcurrents, drifts, and gyres to make sailing less than easy. The same surface ocean movements that allowed Columbus to sail in a south-westerly arc to reach the Caribbean also assisted the whalers as they hitched a ride onto the northerly segment of the Atlantic gyre which pushed them toward Spain and Portugal, and eventually south to Africa. (Although Ponce de Leon is believed to have been the first to describe the Gulf Stream during the early sixteenth century, the whalers recognized its benefits early in the eighteenth century only. These benefits were illustrated and published in 1786 by Benjamin Franklin, the cousin of a Nantucket whaler named Timothy Folger.) Perhaps the whales were not in evidence when they first explored Azorean waters, but the Nantucket whalers first sighted the West African whales in 1773, and 5 years later, they discovered the Western Islands Grounds.

The usual route for whaling in the Atlantic—only the broadest of generalizations, since the whales rarely appeared where or when they were supposed to—would consist of a southward bearing in the spring, to the Carolinas and the West Indies, thence to the Azores, the Cape Verdes, and the coast of Africa in the summer. Eventually, the whalers would re-cross the South Atlantic, and work the Brazil Banks or the Falklands. The ships would return to New England in July and after refitting, sail for the Grand Banks to the north. “Plum-pudding” whaling was the way these short, relatively safe Atlantic voyages were described. It would not be until 1789 that the British whaler *Emelia* would round the Horn and initiate the era of round-the-world whaling voyages.

Because the British whaling fleet was active in Greenland waters, the Atlantic was available to the colonists. During the mid-eighteenth century, French and Spanish privateers and pirates roamed the Atlantic, adding yet another threat to an already hazardous pursuit. The dogged Yankee whalers persevered, however, and continued to visit the Western Islands for sperm whales, because the islands had the reputation of being the home of particularly large whales. (In an account of Azorean whaling, Trevor Housby (1971) describes the capture of a 61-footer, one of the largest bull sperm whales ever measured.) Even though there were large whales to be found there, however, the Azores were only a way-station on the way to such places as the Cape Verde Islands and the whaling grounds of southern Africa.

During the height of square-rigged whaling, the whalers would plunder the waters of the Western Islands for whales and the lands for whalers. Since the days of Vasco da Gama, Portuguese sailors have demonstrated an inordinate desire to go down to the sea in ships. While the Portuguese proved to be brave and competent whalers, however, early New England chauvinism relegated the Azoreans to the same class as anyone who was not a “full-blooded Yankee”—whatever that was supposed to mean in 1820. In later years, Hohman (1928) would write, “as the better type of American forsook the forecastles, their bunks were filled by criminal or lascivious adventurers, by a motley collection of South Sea Islanders known as Kanakas, by cross-bred

negroes and Portuguese from the Azores and the Cape Verdes, and by the outcasts and renegades from all the merchant services of both the Old World and the New.” When Clifford Ashley, the writer and painter, shipped aboard the *Sunbeam* in 1904, he described the crew in detail, concluding, “The South Sea Islands, East Indies, Cape Verdes, Azores and Canaries, all were liberally represented on our list. Profane, dissolute and ignorant they were, yet, on the whole, as courageous and willing a lot as one could desire.”

Most narratives of Atlantic whaling include a visit to the Azores; among the arrivals was the *Bruce*, which J. Ross Browne named *Styx* in his *Narrative of a Whaling Cruise*. Here he describes his first sight of the islands in 1842:

Terceira is a remarkably picturesque island, beautifully laid out in farms, which at this season of the year have a rich golden hue that bespeaks abundant crops. The coast is broken and rugged, and in many places so steep as to preclude the possibility of ascent. Part of the island seems to have been engulfed by an earthquake, which accounts for the rugged appearance of the coast. It is visited at certain seasons of the year by heavy gales and rains, especially in October and November, when there is frequently danger in approaching it. While we lay off and on, awaiting a suitable opportunity of running in, we had hard, shifting winds, and it rained almost incessantly. Mount Brazil, and other elevated portions of the island, were covered most of the time with white, misty clouds.

Browne describes the Azorean whalers as wearing “sennet hats with sugar-loaf crowns, striped bed-ticking pantaloons patched with duck, blue shirts, and knives and belt. They were all barefooted...”

It is impossible to determine when the Azoreans began whaling on their own, but the Portuguese seemed to have maintained a sperm whale fishery, which “they had learned from the New Englanders and carried on upon the coast of Brazil” as early as 1785. The islands sustained international fishery for perhaps a 100 years, but by 1870, the only whalers operating out of the Azores were the Azoreans themselves.

They fitted out their own whaleships, but they were never particularly successful. Their first attempt was the *Cidade da Horta*, a brig that had been abandoned in the islands by the French as not being seaworthy. They probably never sent out more than 10 of their own vessels because their economy was never strong enough to lay out the considerable sums required to build, pay for and man a full-rigged ship. Instead, the Azoreans would sign aboard foreign vessels. Nevertheless the islands later developed a technique that would not be duplicated anywhere else in the world: shore whaling for sperm whales.

In shore whaling, which involves spotting whales from lookouts, the prey has almost invariably been the relatively placid right whale and less frequently the humpback. The reasons for these choices are obvious. Both the right and the humpback are inshore creatures; slow-swimming, passive animals that, more often than not, rolled over and died when they had been lanced. The cachalot, however, is a dangerous threat, given to smashing whaleboats in its death-throes, and less frequently to attacking whaleships and sinking them. It was indeed a courageous whaler who chose to approach the most fearsome of all the great whales in a fragile little cockleshell.

It is possible that the Azoreans learned shore whaling from the Basques, who may have called at the islands as they extended their right-whale fishery to Newfoundland in the sixteenth century. (The Basque term *vizãa*, which means a lookout, is still in use in the Azores today, and the word *cachalote* is also of Basque origin.) The village of

Horta (also known as Porto Pim) on the island of Faial is believed to have been the site of the first shore station in the Azores, sometime around 1832. The Azorean records are scanty, but it is known that the American consul, a man named Dabney, set up a tryworks at Horta in 1850. From Faial, the industry spread to the other islands, and soon there were stations on São Jorge, Graciosa, Terceira and São Miguel. The Pico islanders began whaling around 1853, following an outbreak of phyloxera that almost totally wiped out the vineyards which had been their main source of revenue. By 1898 there were no less than 29 whaling companies working in the Azores.

Originally, the whaleboats had been imported from New Bedford, but around the turn of the century, a whaleman named Machado built the first boat at Pico. Shortly thereafter, the laborious method of rowing or sailing out to the whaling grounds was abandoned in favor of motorboats, which towed the killing boats out to sea. Although this greatly improved the Azoreans’ efficiency by allowing them to go to the whales without the endless hours of backbreaking rowing or time-consuming tacking, the innovation was one of the few attempts at modernization that the Azoreans made. Curiously, at the same time that they adopted motorized launches, the Azoreans abandoned the hand-held harpoon guns which they had been using—somewhat uneasily—since around 1885. They also introduced two-way radios to facilitate communication between the *canoas*. With the exception of the radios and the towing boats, which replaced the whaleship in putting the whalers close to the whales, Azoreans continued to kill and process cachalots in a manner that almost precisely replicated that of the Yankee whalers. Despite the anachronistic nature of the fishery, its economy allowed the technology to be exported. (By 1900, most of the world’s whaling was being conducted with exploding harpoons and steam- or diesel-powered catcher boats.) Open-boat whaling was introduced to Madeira in 1941, and although they had only a brief time there, Azorean whalers established a similar fishery in Brazil in 1950.

From the *vigias* on the cliffs, the lookouts stood watching from dawn to dusk, every day of the year. They used powerful binoculars, which they claimed enabled them to spot whales at a distance of 30 miles. When blows were sighted, a rocket was set off to alert all the whalers, who then set out in pursuit. (Another vestige of the Yankee whaling industry was the introduction of English terms into Portuguese. They cried *bloz!* or *baleia!* when a whale was sighted, called the bull whale a *brilo*, the boom a *bâme*, and the junk the *janco*.) The whaleboats, known as *canoas*, were 38-ft long (10ft longer than the average American whaleboat), and as graceful and seaworthy as the Yankee whaleboats that Clifford Ashley had called “the most perfect water craft that have ever floated.” They were smooth-sided, or carvel-built, unlike the Yankee boats, which were clinker-built (Fig. 1). (The Azoreans believed that the acute hearing of the sperm whale enabled it to hear the slap of the water on the strakes.) Where their Yankee predecessors employed a crew of six, the Azorean double-enders shipped a crew of seven. The Azorean harpooner and the steersman did not make the dangerous and awkward change of places after the whale had been struck, so that the harpooner both made fast to the whale and lanced it. Like almost everything else in the Azorean fishery, the harpoons employed followed the New England fashions of the mid-nineteenth century, with a “Temple” toggle head that pivoted to a right angle when plunged into the whale. The boats were equipped with a gaff mainsail and a jib, and if possible, the boat was sailed tight onto the whale for the harpooning. Often the Azorean whalers would paddle up to the whale under sail, using canoe paddles that Robert Clarke described as “betraying their Red Indian origin by their shape and

Figure 1 In the swallows, Azorean whalers section a sperm whale before winching the pieces onto shore. The small rowboat is used only for this cutting; the canoas (whaleboat) were more than 30-ft long. Photography courtesy of William Dawbin.

Figure 2 The harbor at Horta on the Island of Fayal in the Azores, with American sperm whalers picking up provisions. Credit: New Bedford Whaling Museum.

the way they were used.” The rowing oars were 16–18 ft long, and the steering oar was about 23 ft in length. Clarke wrote, “In the history of seafaring trades there can scarcely be a more remarkable survival than the present use in the Azores of hand weapons to take and kill great whales.” The harpoon was not the killing instrument, but was used to make the whale fast to the boat. After the whale towed the boat (which might consume several hours), the whalers threw the lance, a spearlike projectile which was driven deep into the body of the exhausted whale. A towing strap was inserted into the whale’s upper jaw so that it could be brought back to shore, sometimes a distance of 25 or 30 miles. The toggle was reeved into the head rather than the tail because a whale normally moves forward through the water (Fig 2).

When John Huston was filming *Moby Dick* in 1955, he sent a crew to film actual whaling in Madeira. The early scenes depicting

whalers chasing and harpooning sperm whales show better than any text the process and the excitement of the chase. The white whale, unavailable for *filming*, was represented by several 90-foot steel, wood, and latex models that were eventually lost at sea off Ireland to the bewilderment of cruising sailors. Whaling in Madeira, some 500 miles southeast of the Azores, is a smaller version of the Azorean fishery and was founded by Azoreans. From 1941 to 1949, almost 1000 whales were taken by 102 Madeiran whaleboats. The last factory was closed in 1981.

Dead whales were usually brought to the stations in the late afternoon and processed the following day. Before the steam-powered whaling station was built at Lages do Pico in 1950, the whales were beached on the rocks at the entrance to the harbor and worked up there. First the head was cut off with a razor-edged blubber spade, then the carcass was stripped of its blubber. Formerly, only the teeth

and the blubber were saved, but in later years, the meat was used in the manufacture of fertilizer and livestock feed.

The statistics of the number of whales obtained are not available, but from 1895 to 1897 some 480,000l of whale oil were exported from the Azores. Up to the opening years of the twentieth century, the Azorean fishery had flourished, but by the time of World War I, it had begun to flag. Sperm oil had been used in England and the United States primarily for the manufacture of fine candles, but by 1910 paraffin was substituted and candles became cheaper. Sperm oil had only a limited application in the manufacture of cosmetics and medicinal salves, and because the market was diminishing, the catches decreased as well. In 1910, the Azores accounted for some 73% of all sperm whales caught in the world, but by 1915, the figure had fallen to a depressing 3.8%. World War II saw the return of the factory fleets to the high seas, and their pursuit of sperm whales in the North Atlantic reduced the Azorean catch. In 1949, there were only 125 *canoas* operating out of 19 stations, and the total catch was some 500 whales. As the whaling industry declined and the economy of the islands plummeted, there was a mass evacuation. Whaling was perceived as a dangerous occupation (in 1974 two men were killed when a whale smashed a *canoa*), and it became increasingly difficult to interest young men in this line of work. Many Azoreans crossed the Atlantic to take up residence in New England, and the large Portuguese-speaking enclaves in Massachusetts and Rhode Island are the results of that emigration.

Sperm whale teeth, stored in the Azores, have been finding their way to New England where they are carved into scrimshaw and sold illegally to unsuspecting collectors. There is still a cottage scrimshaw industry in the Azores, but with the passage of the Marine Mammal Protection Act in 1972, it has become illegal to bring whale products into the United States, and the European Economic Community has also imposed strict prohibitions on the import of whale products. With the disappearance of the Azorean markets, the whaling industry has ground to a halt.

Although Portuguese observers attended the meetings of the International Whaling Commission for many years, the country never applied for membership in the commission, perhaps because the government realized that participation would result in sanctions against her whaling. By 1966 sperm whales had been placed in the “protected” category, which meant that they could not be legally killed anywhere. The Azoreans continued to fish in a sporadic fashion, but like so many other whaling operations, theirs was an ecological and economic anachronism, doomed to obsolescence.

In a 1976 *National Geographic* article, Don Moser (1976) wrote that “whaling is dying out in the Azores,” and quoted harpooner Almerindo Lemos as saying he can make more money working on a tuna boat. “But I have a craving,” says Lemos, “I have an addiction.” In 1976, only 200 whales were killed, and since then the number has dropped. In 1982 the boats were still visible, and there were huge piles of dried-out skulls and bones, but it was obvious that the industry, if not over, was on its last legs.

Although commercial whaling officially ceased in 1984, the Azorean Department of Fisheries issued a permit for five male sperm whales to be taken in 1987 in an attempt to stimulate the Azorean economy. Three whales were harpooned and brought to shore, but since the whaling factories had closed down, there were minimal facilities for processing them. A tractor was used to strip off the blubber, and some of the meat was sold for fish bait and fertilizer.

The rest of the carcasses were towed out to sea and discarded, and the teeth were made into scrimshaw trinkets. In their 1988 IWC report, Deimer *et al.*, (1988) wrote:

The killing of whales led to a debate and protest both inside and outside the Azores. The member of the European Parliament for the Azores, Prof. Vasco Garcia, was prominent amongst those opposing the whaling and proposed that other ways, such as whale-watching, should be found to exploit the region’s cetacean resources. The Azores’ position as a semi-autonomous part of a new member of the EEC added a further complication to the situation. It appears that whaling is still permitted within the archipelago.

The idea of initiating a whale-watching business in the islands as a means of “exploiting the region’s cetacean resources” was a brilliant one, and a decade after Azorean whaling officially ended, a number of companies are offering voyages to the whales. Sperm whales, the very creatures that formed the basis of Azorean whaling, are now the prime attraction there, because, as one website puts it, “the archipelago of Azores is one of the best sites in Europe for the observation of cetaceans. It is one of the few places on earth where it is possible to meet sperm whale pods of females with their offspring.” Off São Miguel and Pico islands, watchers might spy blue whales, fin whales, humpbacks, sei whales, and many different species of dolphins including killer whales (which are really large dolphins), false killer whales (ditto), common dolphins, bottlenoses, and Atlantic spotted dolphins. Whaling has ended in the Azores, after a century of intensive exploitation, and the *Museu dos Baleeiros* in Lages do Pico, with its whaleboats, harpoons, and scrimshaw, exists as a reminder of the glorious days of Azorean whaling. The switch from whale-killing to whale-watching shows that it is possible for a society to recognize that whales do not have to be killed to provide jobs and income for locals.

B

Baculum

EDWARD H. MILLER

The baculum (os penis) is a bone in the penis that occurs in small insectivorous placentals (orders Afrosoricida, Erinaceomorpha, and Soricomorpha), Chiroptera, Primates, Rodentia, and Carnivora (Burt, 1960). Among marine mammals, it is present in Ursidae (polar bear, *Ursus maritimus*), all Mustelidae

[including the marine otter, *Lontra felina* (undescribed but presumed) and the sea otter, *Enhydra lutris*], and Pinnipedia. The baculum is absent in Cetacea and Sirenia. The corresponding element in females is the little-studied clitoris bone (os clitoridis), which has been documented for polar bears and several pinniped species, but presumably is present in all pinnipeds, and in marine and sea otters (it is present in the northern river otter, *Lontra canadensis*; Mohr, 1963; Fay, 1982).

The baculum is one of several so-called heterotopic bones in mammals, like the kneecap (patella), which form through ossification in connective tissue. In rodents, the bacular shaft is true bone, and includes hemopoietic tissue in the enlarged basal portion. In the caniform Carnivora (which includes bears, otters, and pinnipeds) bacular development has been detailed only in the dog (*Canis familiaris*) but is probably similar in other Caniformia. The dog baculum develops in the proximal portion of the penis, in association with the fibrous septum between the paired corpora cavernosa penis, or in their fibrous non-cavernous portion; centers of ossification on left and right sides fuse early in development. The developing baculum grows dorsally above the urethra, and thickens. The bacular base becomes firmly attached to the corpora cavernosa and to the fibrous tunica albuginea which surrounds them.

The urethral groove in the baculum is deep in the dog but is shallow to absent in bacula of marine mammals (Fig. 1A lower, 1B lower),

Figure 1 Bacula of marine mammals are large, but most are morphologically simple: (A) polar bear (*Ursus maritimus*); (B) subantarctic fur seal (*Arctocephalus gazella*); (C) Mediterranean monk seal (*Monachus monachus*); (D) crab-eater seal (*Lobodon carcinophagus*); (E) Weddell seal (*Leptonychotes weddellii*). All scale bars, 5 cm (no scale bars for E2, E3). Bacula in (A)–(D) are shown in right lateral (upper) and ventral (lower) views. E1: Baculum in right lateral view (note cross-sectional shapes at the indicated points). E2: Oblique view (right side) of the bacular apex (same specimen); dashed line indicates how much growth occurs in the crest (above the line), following sexual maturity. E3: Apical view (dorsal surface above; same specimen). A from R. Didier (1950; *Mammalia* **14**, 78–94); B from R. Didier (1952; *Mammalia* **16**, 228–231); C from P. J. H. van Bree (1994; *Mammalia* **16**, 228–231); D from R. Didier (1953; *Mammalia* **17**, 21–26); E from G. V. Morejohn (2001; *Journal of Mammalogy* **81**, 877–881).

Figure 2 The bacular apex is morphologically complex and interspecifically diverse in Otariidae. The apex is shown in apical view (dorsal surface up) for (A) unknown species of *Arctocephalus fur seal*; (B) northern fur seal (*Callorhinus ursinus*); (C) California sea lion (*Zalophus californianus*); (D) Australian sea lion (*Neophoca cinerea*); and (E) Hooker's sea lion (*Phocarcos hookeri*). From G. V. Morejohn (1975; Rapports et Proces-verbaux des Reunions, Conseil International pour l'Exploration de la Mer **169**, 49–56).

although is likely present terminally in the undescribed baculum of the marine otter, because this is the pattern in the northern river otter (Baryshnikov *et al.*, 2003). Bacula of polar bears and phocid seals are fairly simple, being more or less straight or slightly curved (arched dorsally) structures, and lacking elaborate apices (Fig. 1). In at least some phocids, the bacular apex has a prominent cartilaginous cap (e.g., hooded seal, *Cystophora cristata*). Cross-sectional shapes of phocid bacula vary considerably among species, and a prominent crest develops on the anterior dorsal surface in some Antarctic seals (Fig. 1E). The bacular apex is larger and more elaborate in otariids than phocids, in keeping with the close proximity of the apex to (beneath) the glans penis in otariids where apical size and shape may be functionally important during copulation (Fig. 2). Mustelids possess some of the most diverse and morphologically elaborate bacula within the Caniformia, although that of the sea otter is relatively simple (Fig. 3; Baryshnikov *et al.*, 2003). Within species, bacula are variable in size, shape, cross-section, and specific structural features, even among individuals of the same age. For example, a dorsal keel may be present or absent in southern elephant seals (*Mirounga leonina*); processes on the shaft near the apex are variably present in California sea lions (*Zalophus californianus*); and bacula may be bilaterally asymmetrical or slightly twisted (Fig. 1D).

Bacula of Carnivora are fairly large (Dixon, 1995; Larivière and Ferguson, 2002; Ramm, 2007). Bacular length is approximately 6% of body length in otariids, but relatively longer in polar bears (~8%) and phocids (8% in hooded seals; 10% in harp seals, *Pagophilus groenlandicus*); the baculum is also much thicker in phocids than otariids (Mohr, 1963; Scheffer and Kenyon, 1963). In pinnipeds, and indeed among all mammals, the walrus (*Odobenus rosmarus*) has the largest baculum both absolutely (to 62.4 cm in length and 1040 g in mass) and relatively (18% of body length; Fay, 1982). Interspecific differences in bacular size in mammals have been linked to diverse selective pressures: reproductive isolation between species; aquatic vs terrestrial copulation; copulatory duration or pattern; sexual selection and mating system; climate; and risk of fracture (Scheffer and Kenyon, 1963; Eberhard, 1985; Dixon, 1995; Larivière and Ferguson, 2002; Ramm, 2007). Fractures result from accidents (e.g., falls in walruses), sudden movements during intromission (e.g., in aquatically mating Caspian

Figure 3 The baculum of the sea otter (*Enhydra lutris*) is fairly simple, except for the apex (to the right). Top: dorsal view; center, ventral view; bottom, right lateral view. Scale is in centimeters. From K. W. Kenyon (1969; North American Fauna **68**, 1–352).

Figure 4 Developmental changes in bacular size and shape, illustrated by representative specimens from northern fur seals (*Callorhinus ursinus*), ranging in age from newborn (left) to 8 years of age (right). Specimens are shown in right lateral view, with bacular apex at the top. Scale is in centimeters. From V. B. Scheffer (1950; *Journal of Mammalogy* **31**, 384–394).

seals, *Pusa caspica*), and aggressive social interactions (e.g., fights in adult male sea otters). Healed fractured bacula have been documented for several species. Bacula likely serve several functions: as a mechanical aid in copulation (especially in the absence of full erection), or maintenance of intromission, in aquatic copulations; and to initiate or engage neural or endocrinological responses in females. Bacular size may be limited by adverse effects on females: a female sea otter and a harbor seal (*Phoca vitulina*) pup died from perforation of the vagina during forced copulations with male sea otters. Bacular form and diversity reflect multiple functions, and hence likely have multiple adaptive explanations within and across species.

In Carnivora, bacula grow throughout life in thickness and mass (particularly at the proximal or basal end), but not in length (Fig. 4). Bacular growth is most rapid around puberty. Differential growth occurs in different parts of the baculum (e.g., bacular apex, shaft, and base, in Steller's sea lion, *Eumetopias jubatus*; Miller *et al.*, 2000).

The baculum is anatomically complex and species-specific in many groups, so has been used extensively in mammalian systematics. In addition, bacular growth has been investigated in furbearers and game animals, because it can be informative about age and time of puberty. More recently, the baculum has been studied in the context of mate-choice and sexual-selection theories. In Alaska, the

Photo: Feng Li/Gettyimages.

U.S. Fish & Wildlife Service requires that hunters leave the baculum attached to the hide of sea otters and polar bears, to confirm sex. The seal baculum forms most of the mass of the male genitals that are taken illegally and legally [e.g., in commercial hunts of African fur seals (*Arctocephalus p. pusillus*) in Namibia, and harp seals in Canada], and are usually dried, then sold (mainly in Asia) whole or ground, for use as supposed aphrodisiacs or in traditional medicine (Fig. 5); they are also exported frozen, and served as putatively aphrodisiac-containing food (Fig. 6). Sexual maturation and reproduction may be affected by pollutants, so bacular size and form also may be informative in studies on pollution biology.

Baiji

Lipotes vexillifer

KAIYA ZHOU

I. Characteristics and Taxonomy

The baiji or Yangtze river dolphin is endemic to the middle and lower reaches of the Yangtze River in China. It is a relict species and the only living representative of a whole family of mammals. It was described early in the ancient dictionary, *Erh Ya*, published as long ago as 200 BC.

The baiji is a graceful animal with a very long, narrow and slightly upturned beak. It can be easily identified by the rounded melon, longitudinally oval blow hole, very small eyes, low triangular dorsal fin, and broad rounded flippers (Fig. 1). The color is generally bluish gray or gray above and white or ashy white below. Females are larger than males. Maximum recorded length for females is 253 cm and for males is 229 cm (Zhou, 1989). Significant differences between the sexes in external proportions were demonstrated in nine characters, and the skull size is also sexually dimorphic (Gao and Zhou, 1992a, b). The mouth is lined with 31–36 teeth in each tooth row. The crown of the tooth is conspicuously inclined labially and is slightly compressed antero-posteriorly. Its upper half recurves interiorly. The lower half of the lingual side of the crown is a broad, rounded cingulum. The enamel of the entire crown is ornamented with irregular vertical striae and ridges which present a reticular appearance. The lower end of the root widens to form slight anterior and posterior projections (Zhou *et al.*, 1979a). The structure of the stomach is unique in cetaceans. The forestomach is lacking, and the main stomach is divided into three compartments. The connecting channel between the main stomach and the pyloric stomach is absent (Zhou *et al.*, 1979b). The skull is characterized in having an extremely long slender rostrum and mandible (Fig. 2). The rostrum length exceeds two thirds of the condylobasal length. The rostrum bows slightly upward, bends left at the anterior end and is constricted transversely posterior to the end of the tooth row. The total number of vertebrae ranges from 41 to 45. The seven cervical vertebrae are unfused. The costal facets of the second to fifth thoracic vertebrae are located on the posterior edge of the centrum. The facet on the posterior edge of the sixth thoracic disappears or is vestigial, and that of the seventh thoracic sits on the anterior edge of the vertebral body (Fig. 3). The position of the costal facet on the thoracic vertebrae in baiji is unique and is opposite to that in the boto, *Inia geoffrensis*. This feature is one of the morphological bases for favoring rejection of close relationship between the two taxa.

The largest brain weighed was 590 g (Chen, 1979). The largest cranial capacity measured was 590 cm (Zhou *et al.*, 1979a). Comparing brain weight with that in delphinids of similar body size, the former is only about half of the latter. The cerebral hemispheres are short, wide, and highly convoluted. No trace of olfactory bulbs, tracts, or olfactory nerves has been found. The Yangtze River is turbid. The visibility from the surface downward is about 25–35 cm in April and 12 cm in August. A corresponding regression has taken

Figure 3 Seventh cervical vertebra and thoracic vertebrae of *Lipotes vexillifer*. From Zhou (1989).

place in the eye of the baiji. The eyes are much smaller and placed much higher than those of marine dolphins. The retinal ganglion cell and optic fiber numbers in baiji are 23,800 and 21,000, respectively (Gao and Zhou, 1987; Gao and Zhou, 1992a, b). Both counts are much lower than those in marine odontocetes. However, the eye of the baiji is functional and objects on the surface or near the surface directly in front of the eye can be distinguished (Zhou, 1989).

Since the baiji was nominated as a member of the Iniidae in 1918 (Miller, 1918), its systematic status and phylogenetic position among the four genera of classical river dolphins and other odontocetes has remained controversial for almost a century (Yan *et al.*, 2005). The species was previously classified as either in the family Platanistidae or in the family Iniidae (Brownell and Herald, 1972). Zhou *et al.* (1978) established the new monotypic family Lipotidae based on osteological studies and anatomy of the stomach. Barnes (1985) recognized a fossil, *Parapontoporia*, as morphologically intermediate between *Pontoporia* and *Lipotes* and placed *Lipotes* and the fossil taxon in a subfamily of Pontoporiidae. Conversely, Muizon (1988) placed the fossil taxon with *Lipotes* in Lipotidae, and Rice (1998) following Muizon to rank Lipotidae as a family. Molecular phylogenetic studies based on mitochondrial and nuclear genes, short interspersed elements (SINEs), and the complete mitochondrial genome since 2000 have strongly supported the referral of *Lipotes* to a separate family Lipotidae (Cassens *et al.*, 2000; Hamilton *et al.*, 2001; Nikaido *et al.*, 2001; Yang *et al.*, 2002; Yan *et al.*, 2005).

The only fossil placed close to *L. vexillifer* is *Prolipotes yujianensis* (Zhou *et al.*, 1984). The fossil is a fragment of mandible with teeth, including the posterior part of the symphyseal portion and initial part of the free portion of the mandibular rami. It was collected from the bank of the Yujiang River in China and considered roughly as Miocene in age. This indicates that the baiji is a relict species.

Parts of eastern and southern China are low-lying deltaic regions formed of sediments deposited by the area's river systems, such as the Yangtze and the Yujiang. Significant sea-level rise would transform these regions into shallow waterways of mixed fluvial and marine origin. This scenario is consistent with the geographical occurrence of the mandibular fragment in southern China (Hamilton *et al.*, 2001).

II. Distribution and Abundance

Baiji were in recent decades mainly in the mainstream of the middle and lower reaches of the Yangtze River (Zhou *et al.*, 1977). They did occur historically in Dongting and Poyang Lakes; both were appended water bodies of the Yangtze during intense flooding (Zhang *et al.*, 2003). About the turn of the twentieth century, Hoy and Pope collected specimens separately from Dongting Lake and near its mouth, where the lake joins the Yangtze. Dongting Lake was thus incorrectly reported to be the only habitat. The presence of this dolphin in the Yangtze River is noted in documents going back about 2000

years, when it was known only by the ancient name “Ji.” In the 1940s, the uppermost records in the Yangtze River were at Huanglingmiao and Liantuo in the Three Gorges area, approximately 50 km upstream of the Gezhouba Dam near Yichang (Zhou *et al.*, 1977). It could be found up to Yichang in the 1960s, which is about 1700 km up from the mouth of the river. However, the range was no farther upstream than Zhicheng in the 1970s and then Jingzhou (formerly called Shashi) in the 1990s (~170 km downstream of the dam site). In the lower part of the river, specimens were obtained in the Yangtze estuary, off the eastern end of Chongming Island, Shanghai, in the 1950s and 1960s (Fig. 4). The range has been no farther downstream than Liuhe since the 1970s. No dolphins were found downstream of Jiangyin, located 256 km upstream of the mouth during surveys in 1997–1999 (Zhang *et al.*, 2003). Some individuals were seen in Fuchun River, immediately south of the Yangtze, during the great flood of 1955, but they disappeared after the construction of the Xinanjiang Hydropower Station in 1957 (Zhou *et al.*, 1977).

The first rough estimate of abundance based on quantitative survey data (1979–1981) was only about 400 animals (Zhou, 1982). On the basis of surveys conducted in 1985–1986, Chen and Hua (1989) made an educated guess that the total population was around 300. Surveys between 1982 and 1986 suggested that there were 100 baiji in a 770-km segment of the lower Yangtze from Hukou to the river mouth (Zhou and Li, 1989). An estimate made by another research group based on surveys in the same segment in 1985–1986 was 78–79 dolphins (Chen and Hua, 1989). Repeated surveys of a 500-km segment of the lower Yangtze (Nanjing-Hukou) in 1989–1991 produced a maximal count of 12 individuals, leading Zhou *et al.* (1998) to infer a total abundance of about 30 baiji in that river segment. The authors reasoned that if the species still inhabited its historical range of about 1700 linear km of river, with a density similar to that found in their study area, the total population in the early 1990s would have been only about 100. Attempted comprehensive surveys of the entire species' range in 1997–1999 resulted in a maximal count (November 1997) of 13 dolphins (including one calf), leading to the generally accepted view that abundance had continued to decline and that the total population was by that time very small. The sighting rate in the 3 years of surveys declined at an annual rate of about 10% (Zhang *et al.*, 2003). Informed guesses in the early 2000s were that there could be only “a few dozen” and “very likely ... less than a hundred” (Reeves *et al.*, 2003) baiji left. An intensive 6-week multi-vessel visual and acoustic survey carried out in November–December 2006, covering the entire historical range of the baiji in the main Yangtze channel, failed to find any evidence that the species survives. Although a few undocumented sightings have been reported since 2004, the last authenticated records were that of a stranded pregnant female found in 2001 and a live animal photographed in 2002. The baiji is now thought to be probably extinct (Turvey *et al.*, 2007). In other words, there is no chance for survival of the species.

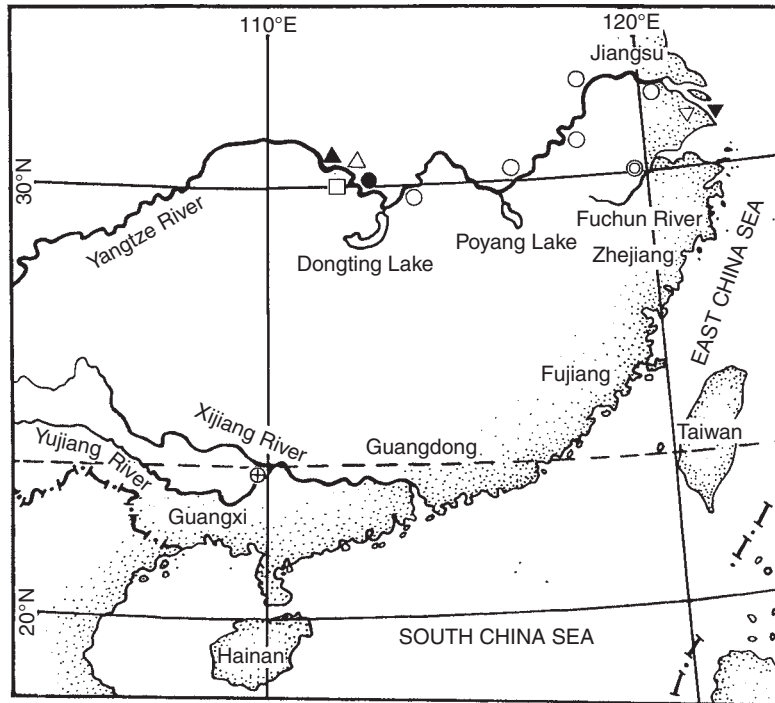

Figure 4 Map of China showing distribution of baiji, *Lipotes vexillifer*, and collection locality for the fossil, *Prolipotes yujiangensis*. (▲) Huanglingmiao and Liantuo, the uppermost records in the 1940s; (△) Yichang, the uppermost records in the 1960s; (□) Zicheng, the uppermost records in the 1970s; (●) Jingzhou, the upstream limit of distribution in the 1990s; (○) Distribution in the 1990s; (▼) Yangtze estuary, the lowest records in the 1950s and 1960s; (▽) Liuhe, the downstream limit of distribution in the 1970s; (⊙) Tonglu and Fuyang, records in the 1950s in the Fuchun River; (⊕) Guiping, locality where the fossil *Prolipotes yujiangensis*, was found.

III. Ecology

The river sections inhabited by the baiji were characterized by having one to several sandbars. Baiji were usually sighted immediately upstream or downstream of a sandbar, where a tributary enters the river. They were generally found in eddy countercurrents below meanders and channel convergences. These areas of former baiji occurrence are also prime fishing areas, set with nets, traps, and hooks (Zhou and Li, 1989).

The baiji appears to have taken any available species of freshwater fish, the only selection criterion being size. The fish could not be so large that it could go down the throat. Sometimes, dead fish were seen floating on the Yangtze with patches of scales torn off. They are believed to have been prey of baiji. At times, a baiji tried a number of times to swallow a larger fish, but in vain and finally let go (Zhou and Zhang, 1991). Occasionally, baiji and Yangtze finless porpoises (*Neophocaena phocaenoides asiaeorientalis*) groups appeared to feed together for short periods (Zhou *et al.*, 1998).

IV. Behavior and Physiology

Baiji lived in small groups. In the 1980s, the most common group size was 3–4 animals; the largest group observed was about 16 individuals in the middle reaches of the Yangtze River. These larger groups were probably temporary aggregations of several groups. The baiji usually surfaced without causing white water and breathed in a smooth manner (Fig. 5). It had a sequence of several short breathing

Figure 5 Baiji in the Yangtze River near Tongling. From Zhou and Zhang (1991).

intervals (10–30sec) alternating with a longer one, the longest one up to 200sec (Zhou *et al.*, 1994). Photographic identifications and sighting records showed that baiji groups made both local and long-range movements. The largest recorded range of a recognizable baiji was more than 200 km from the initial sighting location (Zhou *et al.*, 1998).

Three kinds of behavior, individual behavior, social behavior, and rhythmic behavior, were observed. Clockwise swimming occurred in night, and counterclockwise swimming took place mostly in the daytime. The total duration of either type of swimming in the course of 24h was nearly equal. Typical resting behavior occurred at night, with peaks in January and May–August (Liu and Wang, 1989). The baiji likely had two main kinds of signals, communication signals and

Figure 6 Baiji taken from the Yangtze River near Nanjing in 1982, with 103 hook scars and 5 ulcers in the skin.

echolocation signals. The former fell into several categories: call signals, bellows of short duration, and squeaks (whistles). Echolocation signals were composed of one pulse train. The bandwidth of these signals was wide and the energy mainly in ultrasonic frequencies (Wang *et al.*, 1989).

V. Life History

The baiji probably bred and gave birth in the first half of the year. The peak calving season appeared to be February–April. Body length at birth was estimated to be 91.5 cm for both males and females. Calves were closely accompanied by adults and remained alongside and slightly behind the dorsal fin of their presumed mother (Zhou and Li, 1989). They had about the same growth rate until they were about 4 years old based on estimates of dentinal growth layer groups (GLGs), which was the age at sexual maturation for males. After sexual maturation, males grew more slowly than females. The females attained sexual maturation at about 6 years. They continued to grow until about age 8. The smallest mature male and female described were 180 cm and 200 cm long, respectively. The oldest animal that was age-determined was a 242-cm-long female of 24 years of age, and a 21-year-old male was estimated to be about 214 cm in body length (Gao and Zhou, 1992a, b).

VI. Interactions with Humans

Unlike the case for most historical-era extinctions of large-bodied animals, the baiji was the victim not of active persecution but of incidental mortality resulting from massive-scale human environmental impacts (Turvey *et al.*, 2007). The range contraction and the decline in abundance were caused by a combination of factors: possibly some level of direct exploitation historically; incidental mortality from interactions with fisheries (Fig. 6); vessel traffic; management of navigation channels, and harbor construction; and loss or degradation of habitat by water development, land use practices, and pollution (Chen and Hua, 1989; Zhou *et al.*, 1998).

The Yangtze River is one of the chief river systems of the world, next only to the Nile and the Amazon in length. Nearly one-third of the population of China or almost 10% of the entire world population lives along the Yangtze Valley. It is suffering massive degradation. The banks of the Yangtze have been extensively modified to prevent destructive flooding of agricultural areas, thus reducing the floodplain area. Construction of dams and other barriers along the river and its tributaries has led to changes in fish abundance and distribution. Waste water volume discharged into the Yangtze is about 15.6 billion cubic meters per year. Approximately 80% of the waste waters are discharged

directly into the environment without treatment. Up to 1949, approximately 500 domestic commercial vessels operated on the river (Zhou *et al.*, 1998). River traffic increased drastically when China launched the free-market reforms in the 1980s. During the whole-range survey in 2006, a minimum of 19,830 large shipping vessels (>1 vessel per 100 m of river surveyed) and 1175 fishing vessels were seen between Yichang and Shanghai (Turvey *et al.*, 2007).

The baiji is classified in the World Conservation Union (IUCN) Red List as Critically Endangered—Possibly Extinct. It is designated in the Chinese national First Category of National Key Protected Wildlife Species and has full legal protection throughout its range. Unfortunately, the major threats are continuing, and conservation efforts were unable to save the baiji from extinction. The baiji is the first cetacean species known to have been driven to extinction by human activity.

Balance

FRED SPOOR

I. Introduction

The sense organ of balance for the perception of movement and spatial orientation is part of the inner ear, together with the organ of hearing. The mammalian inner ear is housed inside the petrous part of the temporal bone, in a complex-shaped space known as the bony labyrinth. The organ of balance, or vestibular system, consists of two types of motion sensors. The first one, two otolith organs in the membranous utricle and saccule, informs the

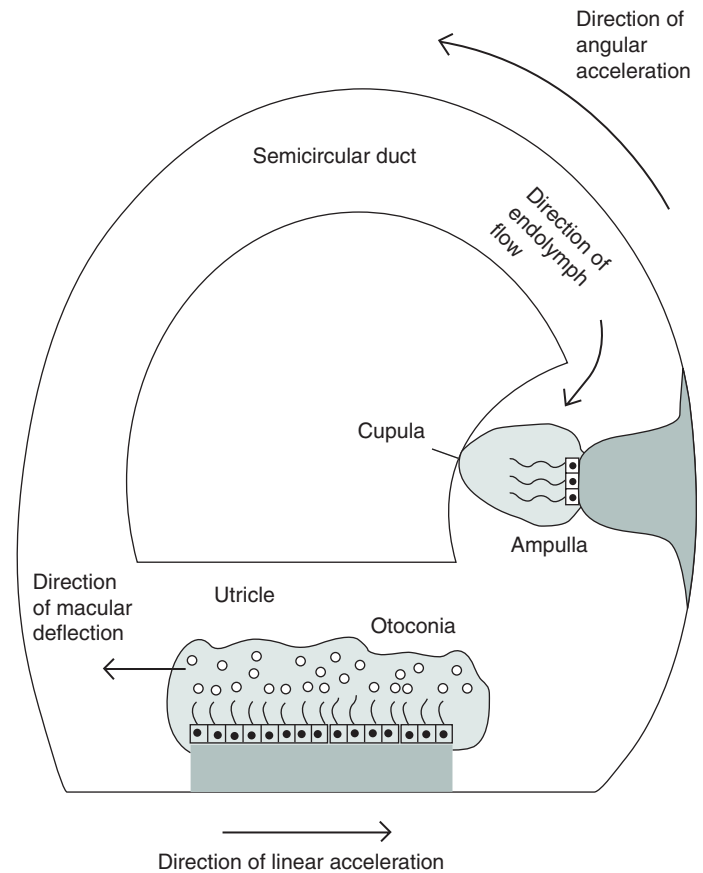

Figure 1 Schematic representation of the semicircular canal and otolith systems, only showing the utricle and one membranous duct. The respective inputs, rotational and linear acceleration, and inertia-based responses of the endolymph and macula are indicated.

brain about changes in gravitational direction and other forms of linear acceleration of the head. In each organ resides a matrix of gel with embedded dense crystals (a macula with otoliths or otoconia), which deforms by inertia in response to such head movements, and this is detected by an associated bed of hair cells (Fig. 1). Little is known of the mammalian otolith system in a comparative context in general, and in relation to life in marine environments in particular. Hence, this part of the organ of balance will not be considered further here (see Spoor and Thewissen, 2008, for details).

The second type of motion sensor concerns the semicircular canal system, which perceives rotational (angular) head movements. It comprises of three membranous ducts, anterior, posterior and lateral, that run inside the semicircular canals of the bony labyrinth. Each duct is connected with the membranous utricle inside the vestibule of the bony labyrinth, and thus forms a fluid circuit filled with endolymph (Fig. 1). The ampulla, a swollen section at one end of each duct, contains a cupula, a gelatinous structure which seals the duct. Changes in head rotation, acceleration or deceleration, will cause the endolymph to lag behind by inertia, slightly deforming the cupula. This is detected by haircells with cilia embedded in the cupula, and provides the neural output, which encodes the head rotation (NB: instant mechanical integration by the system makes that the neural output is directly proportional to rotational velocity, rather than acceleration). The three semicircular ducts of each ear are oriented in approximately orthogonal planes, and any head rotation will thus be sensed by at least one

duct. Moreover, the output from both ears is integrated to provide comprehensive representation of self-rotation. This information, combined with otolithic, visual and proprioceptive input, helps coordinate posture and body movements during locomotion, including the reflex stabilization of the head and eyes.

Empirically a relationship has been found among mammals between the length of the semicircular ducts of a species and its specific locomotor repertoire (Spoor *et al.*, 2007). Species that are agile and have fast, jerky locomotion have significantly larger-arc, and thus longer ducts relative to body mass than those that move more cautiously. Presumably this is because longer ducts render the canal system more sensitive, and adjusting length is a way of fine-tuning the sensitivity to match the requirements of particular locomotor behaviors. Relatively long, more sensitive ducts that characterize agile animals can instantly resolve small changes in head rotations and this is thought to be important for precise body coordination during fast and highly maneuverable locomotion. Other functionally important aspects, such as the lumen size (cross-section) of the ducts, the viscosity of the endolymph, or the structure of the cupula, have not been studied comprehensively in a comparative context.

II. Comparative morphology

Differences between aquatic and terrestrial mammals are largely known from studies using computed tomography (CT) to assess the bony semicircular canals rather than the enclosed membranous ducts. Valid functional information can nevertheless be obtained because the length of the duct along its arc is reliably reflected by that of the canal.

All cetacean species examined thus far have fully developed semicircular canals. However, taking into account the species' overall size they are remarkably small compared with other mammals and in particular with terrestrial species showing rapid and agile locomotion (Fig. 2). This can be demonstrated by measuring the average arc size of the canals, expressed by their radius of curvature (Fig. 1), and plotting it against body mass (as a measure of overall size). Among cetaceans the canal arc size varies with body size in the same way as other mammals (Fig. 3: regression lines are parallel). However, all cetacean species fall way below other mammals, as their canals are on average three times smaller for their body mass. In broad terms these differences mean that the canals of the blue whale (*Balaenoptera musculus*) are just smaller than those of humans, and those of the bottlenose dolphin (*Tursiops truncatus*) are smaller than those of a brown rat (*Rattus norvegicus*).

The semicircular canal arc size in fossil cetaceans that document the transition from land to water reach the small, modern proportions

Figure 2 Infero-lateral view of the bony labyrinth of (A) a typically agile primate *Galago senegalensis*, (B) the artiodactyl *Hippopotamus amphibius*, a sister taxon of extant cetaceans, and (C) the dolphin *Tursiops truncatus*. Images rendered from CT scans and corrected for body mass.

in the middle Eocene (Spoor *et al.*, 2002). Only the earliest cetaceans (pakicetids) have canals with the proportions of land mammals.

Sirenian semicircular canals have been studied in the dugong and the manatee (*Dugong dugon*, *Trichechus inunguis*). They are small in arc size, at the lower end of the range of non-cetacean mammals (Fig. 3).

Pinnipeds of which the canal arc sizes have been examined include three phocids, four otariids, and *Odobenus rosmarus*. The latter is not significantly different in arc size from terrestrial carnivores (27 species). On the other hand, all three canals are larger in the phocids, whereas the otariids have smaller anterior and posterior canals. See Spoor and Thewissen (2008) for details.

III. Functional Interpretation

The semicircular canal system of cetaceans is distinctly different from that of all other mammals, by having strongly reduced arc and lumen sizes. The regular pattern of this reduction suggests a functional adjustment of the system, rather than a vestigial condition marked by degeneration and redundancy. The hypothesis explaining this phenomenon, while being fully consistent with the pattern of canal variation seen in other mammals, is based on two key characteristics of cetaceans. The first one is that extant cetaceans, freed from the restrictions of gravitational pull and the need for substrate contact, are particularly agile and acrobatic when compared with terrestrial animals of similar body size (e.g., compare the killer whale *Orcinus* with the African elephant *Loxodonta*, or the dolphin *Tursiops* with the larger bovid species). The second characteristic is that cetaceans have integrated their head and trunk to streamline the body, and in most species the strongly shortened and frequently fused cervical vertebrae allow little neck motility. This has important implications because a motile neck isolates the head from body movements during locomotion. Head rotations are reduced, both passively by inertia, and actively via compensatory neck movements generated by the vestibulo-colic reflex. The canals supply this reflex, and by stabilizing the head thus keep their own input signal within limits. This feedback loop allows the semicircular canals of agile species to be sensitive (i.e., large-arc),

Figure 3 Average arc size of the three semicircular canals (radius of curvature, indicating duct length) plotted against body mass. Reduced major axis regressions are given for the non-cetacean mammal sample (174 species, \bullet) and for the cetaceans (16 odontocetes, \circ , and 8 mysticetes, m). The dugong (*Dugong dugon*, d) and manatee (*Trichechus inunguis*, t) are labeled individually.

without the risk of overstimulation. In cetaceans, on the other hand, little neck motility and ineffective head stabilization combined with acrobatic locomotion implies that the semicircular canal system is likely to experience substantially stronger rotatory input (resulting from movements of the entire body) than in terrestrial mammals of similar body size. The small arc size of cetacean canals may therefore reduce the sensitivity to match the high levels of uncompensated rotations, and avoid overstimulation of the canal system. The loss of canal sensitivity, in response to streamlining of the body, is arguably less critical in an aquatic environment than in, for example, an arboreal setting where less accurate sensory clues easily impair locomotor control. Moreover, less effective stabilization of the eyes is not critical in cetacean navigation which is driven by sonar rather than visual clues. Kinematic analyses of cetacean head motion in comparison with terrestrial mammals of similar size will be essential to test the hypothesis that the cetacean canal system experiences stronger rotatory input.

Sirenians do show reduced neck motility, but not the extreme semicircular canal reduction of cetaceans. However, they are slow and cautious in their swimming, so that fast and effective head stabilization is not a factor of importance. Their canal size is at the lower end of the non-cetacean mammalian variation, as are terrestrial species that are slow and cautious in their locomotion.

Among pinnipeds the semicircular canals of phocids and otariids are different in arc size from terrestrial carnivores, but none show the dramatic size reduction seen in cetaceans. This is expected because they all have motile necks enabling effective head stabilization. Likewise, that phocids have larger canals than terrestrial carnivores is expected, as they are particularly agile in their swimming, and thus follow the normal pattern seen among non-cetacean mammals. However, the smaller anterior and posterior canals of otariids are more difficult to understand. Otariids use a different mode of propulsion than phocids, a bird-like forelimb flight stroke, as opposed to bilateral hind limb undulation, and with a longer neck their center of gravity is located further forward. However, it is not clear how the otariid's smaller canals with reduced mechanical sensitivity relates to either their locomotor pattern or their body plan.

Baleen

DALE W. RICE

The term baleen (also called whalebone) is a mass noun that refers collectively to the series of thin keratinous plates ("baleen plates," Fig. 1) that make up the filtering apparatus in the mouth

of a baleen whale. The word derives from the Classical Latin *Balaena* and ultimately from the Greek Φάλλαμα [phallaina], "whale."

Baleen plates are suspended from the whale's palate and are arranged in a row down each side of the mouth, extending from the tip of the rostrum back to the esophageal orifice. The left and right sides are separated by a prominent longitudinal ridge along the midline of the palate. In the rorquals, the two sides are continuous around the tip of the palate, but in the other species the two rows are not confluent. Depending on the species, each "side" of baleen may contain anywhere between 140 and 430 plates. The plates are transversely oriented, and are spaced 1 or 2 cm apart, leaving a narrow gap or slot between adjacent plates. The plates are roughly triangular, with their horizontal basal edges embedded in the palate, their near-vertical labial edges facing outward, and their oblique, fringed lingual edges facing the inside of the mouth. Each plate is slightly curved, with its convex side facing forward, so that its labial edge is directed slightly backward; when the whale is swimming forward,

Figure 1 Parasagittal section through the palate of a sei whale (*Balaenoptera borealis*), at about midlength of the rostrum, showing the bases of several baleen plates. Anterior is to the right. See Fig. 2 for details.

Figure 2 Magnified section of the specimen in Fig. 1, showing the structure of the roots of the baleen plates.

this arrangement helps to direct the flow of water through the inter-plate gaps from the mouth cavity to the exterior side of the baleen row. The sizes of the plates are smoothly graded, with the longest ones half to two-thirds of the way back from the tip of the rostrum, and only rudimentary ones at the anterior and posterior ends of the row (Williamson, 1973; Pivorunas 1976, 1979).

Each baleen plate is made up of a middle layer, the medulla, which is sandwiched between the thin, smooth outer layers, or cortex (Fig. 2). The medulla consists of a mass of fine, hollow, hairlike keratinous tubules which run parallel to the labial side of the plate, and terminate along the lingual side; the tubules are embedded in and cemented together by a horny matrix.

Evolutionarily, plates presumably originated by modification of the transverse ridges present on the palates of many terrestrial mammals. In whale fetuses the baleen first appears as a series of crosswise ridges along each side of the palate. The palatal tissue of baleen whales is arranged in three layers. The basal layer, several centimeters thick, is the corium. This is overlain by a thin epithelial layer only a few millimeters thick. The outermost epidermal layer, several centimeters thick, is simply called the gum tissue. The corium gives rise to, and is continuous with, the medulla of each baleen plate, whereas the adjacent epithelial layer is deflected downward to produce the cortical layers of each plate. The dense, rubbery gum tissue does not contribute to the formation of the plates, but simply fills the spaces between their bases, where it provides them a firm support. As each plate grows downward, its cortical layers become cornified sooner than the medulla does. This leaves the first few centimeters of the base of the plate with a layer of soft, highly vascular, corial tissue sandwiched between the keratinous outer layers; this soft layer is often called the pulp, by analogy with the pulp in mammalian teeth (Utrecht, 1965). In life, baleen plates are extremely tough and flexible, but once removed they soon become brittle and are easily fractured.

Throughout the life of the whale its baleen plates grow continuously at their base, and wear away along their lingual margin. The cortex and the matrix of the medulla erode away first, freeing the ends of the fibrous tubules for a distance of about 10–20 cm. The freed tubules form a hairy fringe along the entire lingual side of the plate. The fringes of each plate lie back across the lingual edges of the plates

immediately behind them, the whole forming a dense hairy mat that covers the internal apertures to the gaps between the plates. This mat effectively filters out the food organisms while allowing the water to flow out of the whale's mouth through the gaps.

Like human fingernails, the thickness of the baleen plates varies with the nutritional state of the whale. Alternating periods of summer gorging and winter fasting leave a regular series of visible growth zones on the surfaces of the plates. These zones have been used to infer the ages of whales, but because of the constant wear, it is rare for more than five or six zones to remain in a plate (Ruud, 1945). A claim that evidence of individual ovulations could be detected in the growth patterns of baleen plates was never confirmed (Utrecht-Cock, 1965).

The number of baleen plates per side, and their maximum size, shape, color, and other physical attributes are diagnostic for each species of whale. The right whales (family Balaenidae) with their narrow, highly arched rostrum have 250–390 narrow and extremely long plates, about 0.15–0.25 m. wide and up to 2.50 m. long in the black right whales (*Eubalaena* spp.) and 4.00 m. in the bowhead whale (*B. mysticetus*); they are black with a fine whitish fringe. The pygmy right whale (*Caperea marginata*; family Neobalaenidae) has about 230 narrow, short plates up 0.70-m long and 0.12-m wide; they are white with a black labial margin. The gray whale (*Eschrichtius robustus*; family Eschrichtiidae) has 140 thick but narrow and short plates, up to 0.10-m wide and 0.50-m long; they are white or ivory in color, with a coarse white fringe that resembles excelsior. The rorquals (family Balaenopteridae) with their wide, flat rostrum, have 270–430 plates with a basal width 50–95% of their length, which varies from about 0.20 m in the small minke whales to 1.00 m in the huge blue whale. Each species of rorqual has a different color-pattern on its baleen plates: humpback (*Megaptera novaeangliae*)—black with dirty-gray fringe; northern minke (*Balaenoptera acutorostrata*)—white, sometimes with a narrow black stripe along labial margin; Antarctic minke (*B. bonaerensis*) and Omura's (*B. omurai*)—white with a wide black stripe along labial margin; Bryde's (*B. edeni*)—black with light gray fringe; sei (*B. borealis*)—black with fine, silky, white fringe; fin (*B. physalus*)—gray and white longitudinal bands, with fringe the same colors; blue (*B. musculus*)—solid black with black fringe. All of the species of *Balaenoptera* except the blue whale usually have at least a few all-white baleen plates at the tip of the rostrum, mostly on the right side; this asymmetry is most prominent in the fin whale and Omura's whale.

In the nineteenth century, the long baleen plates of the bowhead and right whales were much in demand for uses where a tough but limber material was needed, so they were the most valuable product of the whale fishery. Landings of whalebone at United States ports reached their highest in 1853, with 5,652,300 pounds worth \$1,950,000. The last year that any baleen reached the commercial market was 1930. Much of it was made into umbrella ribs, corset busks, and hoops for skirts. The fibrous fringes were used for brooms and brushes (Stevenson, 1907).

Baleen Whales (Mysticetes)

JOHN L. BANNISTER

I. Characteristics and Taxonomy

The baleen or whalebone whales (Mysticeti) comprise one of the two recent (non-fossil) cetacean suborders. Modern baleen whales differ from the other suborder (toothed whales, Odontoceti), particularly in their lack of functional teeth. Instead they feed, on relatively very small marine organisms, by means of a highly specialized filter-feeding apparatus made up of baleen plates (“whale-bone”) attached to the gum of the upper jaw. Other differences from toothed whales include the baleen whales’ paired blowhole, symmetrical skull, and absence of ribs articulating with the sternum.

Baleen whales are generally huge (Fig. 1). In the blue whale, the largest known animal grows to more than 30-m long and weighing more than 170 tons. Like all other cetaceans, baleen whales are totally aquatic, and like most of the toothed whales, they are all marine. Many undertake very long migrations, and some are fast swimming. A few species come close to the coast at some part of their life cycle and may be seen from shore; however, much of their lives is spent far from land in the deep oceans. Baleen whale females grow slightly larger than the males. Animals of the same species tend to be larger in the Southern than in the Northern Hemisphere.

Within the mysticetes are four families: (1) right whales (Balaenidae, balaenids); (2) pygmy right whales (Neobalenidae, neobalaenids); (3) gray whales (Eschrichtiidae-eschrichtiids); and (4) “rorquals” (Balaenopteridae, balaenopterids). Within the suborder, 14 species are now generally recognized. Their relationships, including their relationship to terrestrial ungulates, are indicated in Fig. 2.

Right whales (Balaenidae) are distinguished from the other three families by their long and narrow baleen plates and arched upper jaw. Other balaenid features include, externally, a disproportionately large head (approximately one-third of the body length), long thin rostrum, and huge bowed lower lips; they lack multiple ventral grooves. Internally, there is no coronoid process on the lower jaw and cervical vertebrae are fused together. Within the family are two distinct groups—the bowhead (*Balaena mysticetus*) of northern polar waters (formerly known as the “Greenland” right whale), and the three “black” right whales, *Eubalaena* spp. of more temperate seas, so called to distinguish them from the “Greenland” right whale. All balaenids are robust.

Pygmy right whales (*Caperea marginata*) have some features of both right whales and balaenopterids. The head is short (approximately one quarter of the body length), although with an arched upper jaw and bowed lower lips, and there is a dorsal fin. The relatively long and narrow baleen plates are yellowish white, with a dark outer border, quite different from the all-black balaenid baleen plates. Internally, pygmy right whales have numerous broadened and flattened ribs.

Gray whales (*Eschrichtius robustus*) are also somewhat intermediate in appearance between right whales and balaenopterids. They have short narrow heads, a slightly arched rostrum, and between two and five deep creases on the throat instead of the balaenopterid ventral grooves. The body is robust. There is no dorsal fin, but a series of 6–12 small “knuckles” along the tail stock. The yellowish-white baleen plates are relatively small.

Balaenopterids comprise the seven whales of the genus *Balaenoptera* (blue, *B. musculus*; fin, *B. physalus*; sei, *B. borealis*; Bryde’s, *B. edeni*; Omura’s, *B. omurai*; common minke, *B. acutorostrata*, Antarctic minke, *B. bonaerensis*), and the humpback whale (*Megaptera novaeangliae*). All have relatively short heads, less than a quarter of the body length. In comparison with right whales, the baleen plates are short and wide. Numerous ventral grooves are present, and there is a dorsal fin, sometimes rather small. Internally, the upper jaw is relatively long and unarched, the mandibles are bowed outwards and a coronoid process is present; cervical vertebrae are generally free. All eight balaenopterids are often known as “rorquals” (from the Norse “*rørkval*, whale with pleats in its throat”). Strictly speaking, the term should probably be applied to the seven *Balaenoptera* species, recognizing the rather different humpback in its separate genus, but many authors now use it for all eight balaenopterids.

Baleen whales are sometimes called “great whales.” Despite their generally huge size, some of the species are relatively small, and it seems preferable to restrict the term to the larger mysticetes (blue, fin, sei, Bryde’s, Omura’s, humpback) together with the largest odontocete (the sperm whale, *Physeter macrocephalus*).

Reviewing the systematics and distribution of the world’s marine mammals, Rice (1998) drew attention to the derivation of the Latin word Mysticeti, and clarified the status of a variant, Mystacoceti. He described the former as coming from Aristotle’s original Greek *mustoketos*, meaning “the mouse, the whale so-called” or “the mouse-whale” (said to be an ironic reference to the animals’ generally vast size). Mystacoceti means “moustache-whales,” and although used occasionally in the past (and more obviously appropriate for whales with baleen in their mouths) has been superseded by Mysticeti.

Within the suborder, 14 species are now generally recognized. Although Rice believed that all right whales belong with the bowhead in the genus *Balaena*, recent genetic analyses have recognized three separate right whale species, in the genus *Eubalaena*: in the North Atlantic (*E. glacialis*); in the North Pacific (*E. japonica*); and in the Southern Hemisphere (*E. australis*). Indeed, *Eubalaena* is the only mysticete genus where separate species are recognized in each hemisphere.

The taxonomic status of Bryde’s whales is confused. Currently one species is recognized (*B. edeni*) but it has several forms, at least one of which may be a separate species. The “ordinary” form has two distinct sub-forms—offshore and inshore. Another animal, *B. brydei*, was described from specimens taken off South Africa, but subsequently accepted as the same species as *B. edeni*. The situation has not been helped because the location of the type specimen of *edeni* was uncertain until recently and its genetic make-up has yet to be determined. A further similar but smaller species, Omura’s whale, *B. omurai*, was described in 2003, and recently accepted (Sasaki *et al.*, 2006 following genetic analysis, but it is not closely related to Bryde’s whales, lying outside the clade formed by blue, sei and Bryde’s whales (see Fig. 2). Subspecies have been described for several mysticete taxa, but only three are at present commonly in use. They are all blue whales, *B. musculus*: the Antarctic, sometimes known as the “true,” blue whale, *B. m. intermedia*; the North Atlantic and North Pacific blue whales (*B. m. musculus*); and the Southern Hemisphere, mainly

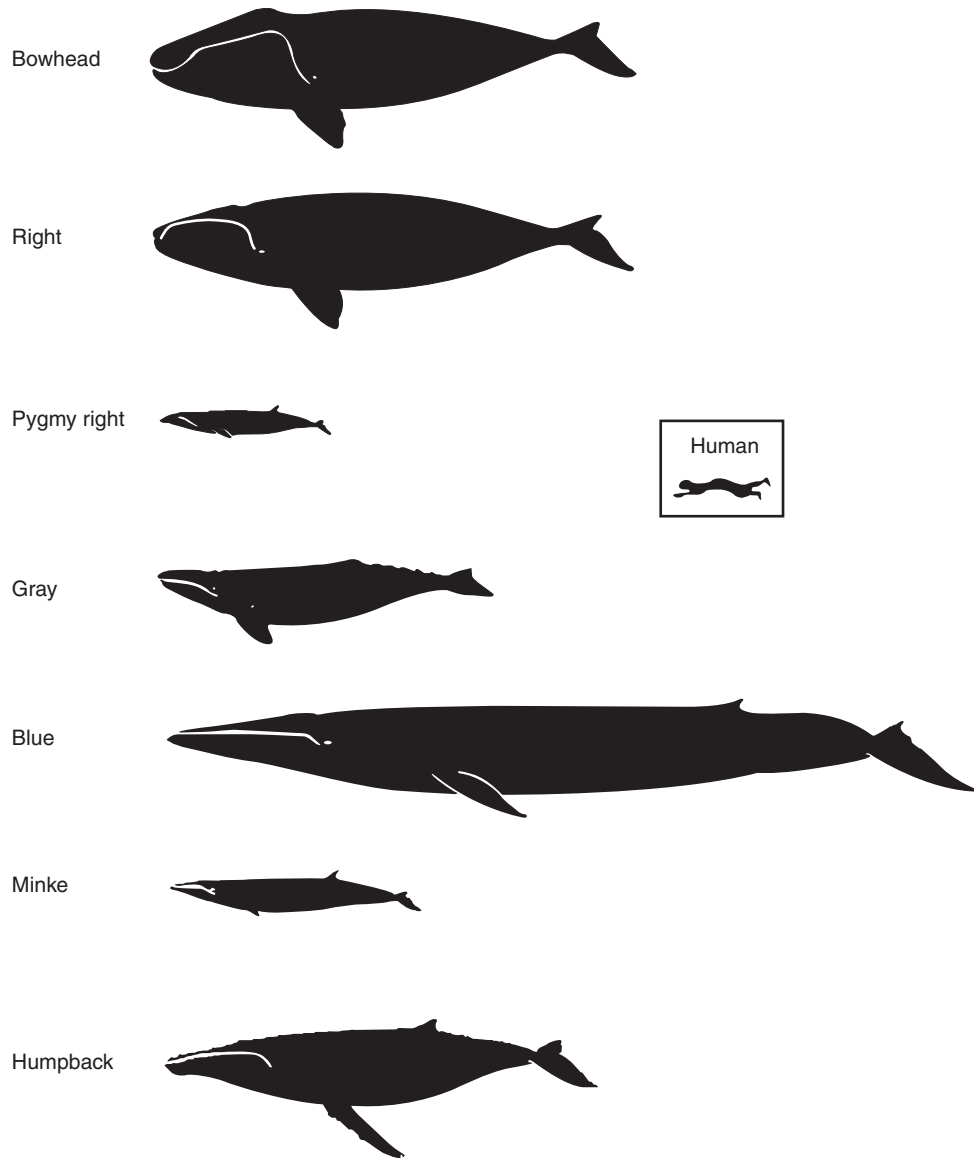

Figure 1 Lateral profiles of representative baleen whales, with a human figure, to scale.

Indian Ocean, pygmy blue whale, *B. m. brevicauda*. A “dwarf” form of the common minke (*B. acutorostrata*) occurs generally in lower latitudes of the Southern Hemisphere; it has yet to be formally described.

II. Distribution and Abundance

In addition to the subspecies mentioned in Section I, many stocks or populations have been recognized, some mainly for management purposes, based on more or less valid biological grounds. Some significant examples include:

1. *Bowhead whales*. As well as the currently most abundant population (the Bering-Chukchi-Beaufort Seas stock), four others are recognized—Hudson Bay-Foxe Basin; Davis Strait-Baffin Bay; Svalbard-Barents Sea; Okhotsk Sea.
2. *Right whales*. In the North Atlantic, two populations are currently recognized, western and eastern, with calving grounds off the southeast United States and northwest Africa. The latter may now represent only a relict population. In the North Pacific, there well may once have been two or more stocks, based on feeding ground

information; at least one is now centered in summer on the Sea of Okhotsk and another, though currently in very small numbers, summers in the Gulf of Alaska and Bering Sea.

In the southern right whale, there are several populations, defined by currently occupied calving grounds, but these cover only a proportion of the many areas known from historical whaling records to have once been occupied by right whales. Up-to-date information is available on presumed discrete populations wintering off eastern South America, South Africa, southern Australia and subantarctic New Zealand.

3. *Gray whales*. A western North Atlantic population may have persisted until the seventeenth or eighteenth centuries but is now extinct. The species now survives only in the North Pacific, where, in addition to a flourishing “eastern” stock, wintering on the coast of Baja California and summering in the Bering Sea, a very much smaller western sub-population (the “western” gray whale) summers in the Okhotsk Sea.
4. *Humpback whales*. In the North Atlantic, two major populations have been recognized, one based on animals wintering in

Figure 2 Phylogenetic tree of baleen whales (adapted from Rychel et al., 2004). *B. omurai*, not included here, lies between the clades for blue, Bryde's and sei whales and for fin and humpback whales (Sasaki et al., 2006). Also, three species of right whale (North Atlantic, North Pacific and southern) are now generally recognized.

the West Indies, the other, now possibly only a relict population, wintering around the Cape Verde Islands. In the North Pacific, three discrete wintering grounds have been recorded: around the Bonin Islands, Ryuku Islands, and Philippines in the west; around the Hawaiian Islands in the centre; and off Mexico in the east.

In the Southern Hemisphere, seven populations are currently recognized. Six are well-defined, based on calving (wintering) grounds either side of each continent (one off eastern Australia is closely related to animals wintering off New Caledonia and Fiji), and a seventh in the central Pacific. In the northwest Indian Ocean, there is a separate resident population which seems not to migrate.

Baleen whales thus occupy a wide variety of habitats, from open oceans to continental shelves and coastal waters, from the coldest waters of the Arctic and Antarctic, through waters of both hemispheres and into the tropics.

Most specialized is the bowhead, *Balaena*, restricted to the harsh cold and shallow seas of the Arctic and subarctic. The “black” right whales (*Eubalaena*) are more oceanic and prefer generally temperate waters, but come very close to coasts in winter to give birth, particularly in the Southern Hemisphere. Once believed not to penetrate much further south than the Polar Front (Antarctic Convergence, ~50–55°S) there have been recent records in the Antarctic proper, south of 60°S. Whether this is a new phenomenon is unclear: a

report by Sir James Clark Ross of many “common black” (i.e., right) whales in the Ross Sea (eastern Antarctic) at 63°S in December 1840 was discounted when their presence there later that century could not be confirmed. It has been suggested that the currently greatly reduced population of the western North Atlantic right whale, now wintering off the south eastern United States and summering in coastal waters north to the Bay of Fundy (~45°N), may represent the peripheral remnant of a more widely distributed stock, formerly summering north to Labrador and southern Greenland, i.e., to at least 60°N.

The pygmy right whale (*Caperea*) is restricted to Southern Hemisphere temperate waters, mainly between 30°S and 55°S; it can be found coastally in winter in some areas, and year-round in others.

Gray whales (*Eschrichtius*) are the most obviously coastal baleen whales. The long coastal migration of the eastern gray, from Mexico to Alaska, supports a major whale watching industry from November to March. In spring, the animals migrate through the Bering Strait into the more open waters of the Bering Sea, but still favoring more shallow waters.

Among the balaenopterids, fin and sei whales are probably the most oceanic, the former penetrating into colder waters than the latter in summer. Blue whales can be found closer inshore, but often associated with deep coastal canyons, e.g., off central and southern

California and western Australia. The Southern Hemisphere pygmy blue whale (subspecies *B. m. brevicauda*) is restricted to more temperate waters than the Antarctic blue whale (*B. m. intermedia*), not often being found much beyond 55°S. The coastal balaenopterid is the humpback (*Megaptera*), with long migrations between temperate/tropical breeding grounds and cold water feeding grounds. In the Southern Hemisphere, much of its journeys occur along the east and west coasts of the three continents. In the Northern Hemisphere, humpbacks are rather more oceanic, but still coastal at some stage in their migration: in the North Pacific they can be found wintering off the Hawaiian Islands and summering off Alaska; in the western North Atlantic they winter in the Caribbean and summer between New England, the west coast of Greenland, Iceland, and North Norway.

Minke whales are wide ranging, from polar to tropical waters in both hemispheres. In the Southern Hemisphere they can, with blue whales, be found closest to the ice edge in summer. Elsewhere minke whales can often occur near shore, in bays and inlets. Their migrations are less well-defined and predictable than the other migratory balaenopterids; in some regions they may be present year-round.

The most localized balaenopterids are Bryde's whale and its close relatives. They are the only balaenopterids restricted entirely to tropical/warm temperate waters, and probably do not undertake long migrations. The two "ordinary" forms of *B. edeni*—inshore and offshore, in several areas—can differ in their movements. Off South Africa, for example, the inshore form is thought to be present throughout the year, whereas the offshore form appears and disappears seasonally, presumably in association with movements of its food, shoaling fish.

III. Ecology

Although they include the largest living animals, baleen whales feed mainly on very small organisms, and while strictly carnivorous, on zooplankton or small fish. In "filter-feeding"—sieving the sea—baleen whales are quite different from toothed whales, where the prey is captured individually.

Filter-feeding has been described as requiring, in addition to a supply of food in the water, three basic features (1) a flow of water to bring prey near the mouth, (2) a filter to collect the food but allow water to pass through, (3) and a means of removing the filtered food and conveying it to the stomach for digestion. Baleen whales meet those requirements by (a) seeking out areas where their food concentrates, (b) either swimming open-mouthed through food or gulping it in, (c) possessing a highly efficient filter formed by the baleen plates, and (d) forcing the water containing the food out through the gullet and hence to the stomach. In (d) the tongue is presumed to be involved; in balaenopterids the process is aided by the distensible throat and the ability to open the lower jaw to almost 90°.

Although all baleen whales have a filter based on baleen plates, two rather different systems—essentially "skimming" and "gulping"—have evolved to filter a large volume of water containing food. Each relies on the series of triangular baleen plates, borne transversely on each upper jaw. The inner, longer border (hypotenuse) of each plate bears a fringe of fine hairs, forming a kind of filtering "doormat." Quite unrelated to teeth (which appear as early rudiments in the gums of fetal baleen whales), baleen consists of keratin and is close in composition to hair and fingernails. In right whales, filtration is achieved with very long and narrow plates in the very large mouth, in the very large head. The plates, up to 4-m long in bowheads and 2.7 m in other right whales, are accommodated in the mouth by an arched upper jaw, and

Figure 3 Head of a right whale, showing the arrangement of the filter-feeding apparatus. The anterior section of the baleen plates on the left side of this whale were removed to show fringes of right baleen plates and tongue. From Bonner (1980).

enclosed in massively enlarged and upwardly bowed lower lips (see Fig. 3). There is a gap between the rows at the front of the mouth, and the whole arrangement allows the whale to scoop up a great quantity of water while swimming slowly forwards. In balaenopterids, with their much smaller heads, the baleen plates are shorter and broader and the rows are continuous at the front. Taking in a large volume of water and food is usually achieved by swimming through a food swarm and gulping, while simultaneously greatly enlarging the capacity of the mouth by extending the ventral grooves, depressing the tongue and widely opening the lower jaw, almost to 90° from the body axis. The two systems allow, on the one hand, the relatively slow-swimming balaenids to concentrate their rather sparse food over a period, and on the other, the faster-swimming balaenopterids to take in large amounts of their highly concentrated prey over a shorter time.

Typically, baleen whales feed on zooplankton, mainly euphausiids or copepods, swarming in polar or subpolar regions in summer. That is particularly so in the Southern Hemisphere, where the summer distributions of several balaenopterids depend on the presence of *Euphausia superba* (known to whalers by the Norwegian word "krill") in huge concentrations in the Antarctic. In the Northern Hemisphere, with a more variable availability of food, balaenopterids are more catholic in their feeding. Humpbacks and fin whales, for example, feeding almost exclusively on krill in the south, often commonly take various species of schooling fish in the north.

The variety of organisms taken by the various baleen whale species in different regions is listed in Table I. Although most feeding occurs in colder waters, baleen whales may feed opportunistically elsewhere. All baleen whales but the one, the gray whale, feed in surface waters, generally within 100 m of the surface, and consequently, unlike many toothed whales, do not dive very deep or for long periods. Gray whales feed primarily on bottom-living organisms, almost exclusively amphipods, in shallow waters.

The baleen plate structure, particularly the inner fringing hairs, to some extent mirrors the food organisms taken, or (in the case of *E. superba*) different size classes. Thus there is some correlation between decreasing size of prey and fineness of baleen by species, viz. gray, blue, fin, humpback, minke, sei, and right whales. Where food stocks are very dense, e.g. around subantarctic South Georgia, fin, blue, and sei whales may all overlap in their feeding on *E. superba*.

Baleen whale food consumption per day has been calculated as some 1.5–2.0% of body weight, averaged over the year. Given that

TABLE I
Baleen Whale Food Items

Species	Sub-species	Common name	Food items	
			North hemisphere	South hemisphere
<i>B. mysticetus</i>		Bowhead whale	Mainly calanoid copepods; euphausiids; occasional mysids, amphipods, isopods, small fish	
<i>E. glacialis</i>		Northern right whale	Calanoid copepods; euphausiids	
<i>E. australis</i>		Southern right whale		Copepods; post-larval <i>Munida gregaria</i> ; <i>Euphausia superba</i>
<i>Caperea marginata</i>		Pygmy right whale		Calanoid copepods
<i>E. robustus</i>		Gray whale	Gammarid amphipods; occasional polychaetes, small fish	
<i>M. novaeangliae</i>		Humpback whale	Schooling fish; euphausiids	<i>Euphausia superba</i> (Antarctic); euphausiids, post-larval <i>Munida gregaria</i> , occasional fish (ex-Antarctic)
<i>B. acutorostrata</i>		Common minke (North Atlantic)	Schooling fish; euphausiids	
		Common minke (North Pacific)	Euphausiids; copepods; schooling fish	
	<i>B. a. ?spp.</i>	Dwarf minke		?Euphausiids, schooling fish
<i>B. bonaerensis</i>		Antarctic minke		<i>Euphausia superba</i> , <i>E. crystallorophias</i>
<i>B. edeni</i>		Bryde's whale	Pelagic crustaceans including euphausiids	Schooling fish; euphausiids
<i>B. omurai</i>		Omura's whale	?Euphausiids	?Euphausiids
<i>B. borealis</i>		Sei whale	Schooling fish	Copepods incl. <i>Calanus</i> ; <i>Euphausia superba</i>
<i>B. physalus</i>		Fin whale	Schooling fish; squid; euphausiids; copepods	<i>Euphausia superba</i> (Antarctic); other euphausiids (ex Antarctic)
<i>B. musculus</i>	<i>B. m. musculus</i>	Blue whale	Euphausiids; calanoid copepods; occasional amphipods, squid	
	<i>B. m. intermedia</i>	Antarctic blue		<i>Euphausia superba</i> (Antarctic); other euphausiids (ex Antarctic)
	<i>B. m. brevicauda</i>	Pygmy blue		Euphausiids, incl. <i>E. vallentini</i> , <i>E. recurve</i> , <i>Nyctiphanes australis</i>

feeding occurs mainly over about 4 months in the summer in the larger species, the food intake during the feeding season has been calculated at some 4% of body weight per day, approximately 4000 kg per day for a large blue whale. To survive the enormous drain of pregnancy and lactation, it has been calculated that a pregnant female baleen whale needs to increase its body weight by up to 65%. The ability to achieve such increase in only a few months' feeding indicates the great efficiency of the baleen whales' feeding system, as well as the considerable nutritive value of the food.

Apart from humans, the most notable baleen whale predator is the killer whale (*Orcinus orca*). Minke whales have been identified as a major diet item of killer whales in the Antarctic, and off British Columbia, Canada. Killer whale attacks have been reported on blue, sei, bowhead, and gray whales, although their frequency and success are unknown. Humpbacks often have killer whale tooth marks

on their bodies and tail flukes. Humpback and right whale calves in warm coastal waters are susceptible to attack by sharks. There are anecdotal reports of calving ground attacks on humpbacks by false killer whales (*Pseudorca*).

A form of harassment occurs on right whales on calving grounds off Peninsula Valdes, Argentina. Kelp gulls have developed the habit of feeding on skin and blubber gouged from adult southern right whales' backs as they lie at the surface. Large white lesions can result. The whales react adversely to such gull-induced disturbance; calf development may be affected and the whales may be driven elsewhere.

External parasites, particularly "whale lice" (cyamid crustaceans) and barnacles (both sessile and stalked) are common on the slower-swimming more coastal baleen whales such as gray, humpback, and right whales. In the latter, aggregations of light-colored cyamids on warty head callosities have facilitated research using callosity-pattern

photographs for individual identification. External parasites are much less common on the faster swimming species, although whale lice have been reported on minke whales (in and around the ventral grooves and umbilicus). The highly modified copepod *Pennella* occurs particularly on fin and sei whales in warmer waters; its presence on those species in colder waters, e.g., at South Georgia in the South Atlantic, has been taken to indicate migration from the north. A commensal copepod *Balaenophilus unisetus* often infests baleen plates in warm waters, especially on sei and pygmy blue whales.

A variety of internal parasites has been recorded, although some baleen whales seem less prone to infection than others. They appear, for example, to be less common in blue whales, but prevalent in sei whales. Records include stomach worms (*Anisakis* sp.), cestodes, kidney nematodes, liver flukes, and acanthocephalans (“thorny-headed” worms) of the small intestine.

The cold water diatom *Cocconeis ceticola* often forms a brownish-yellow film on the skin of blue and other baleen whales in the Antarctic. Since the film takes about a month to develop, its extent can be used to judge the length of time an animal has been there. Its presence led to an early common name for the blue whale—“sulfur bottom.”

For many years, the origin of small scoop-shaped bites on baleen whale bodies in warmer waters remained a mystery, until they were found to be caused by the small “cookie-cutter” shark, *Isistius brasiliensis*. Some species are highly prone to such attacks. In Southern Hemisphere sei whales the overlapping healing scars can impart a galvanised-iron sheen to the body.

IV. Behavior and Physiology

1. Sound production. Unlike toothed whales, baleen whales are not generally believed to use sound for echolocation, although bowheads, for example, are thought to use sound reflected from the undersides of ice floes to navigate through ice fields. However, sound production for communication, for display, establishment of territory or other behavior, is well developed in the suborder. Blue whales produce the loudest sustained sounds of any living animal. At up to nearly 190 decibels, their long (half minute or more), very low frequency (<20 Hz) moans may carry for hundreds of kilometers or more in special conditions. Fin whales produce similarly low-pulsed sounds (20 Hz). Minke whales also produce a variety of loud sounds. Right whales produce long low moans; bowhead sounds, recorded on migration past hydrophone arrays in nearshore leads, have been used in conjunction with sightings to estimate population size off northern Alaska. Southern right whales, at least, seem to use sound to communicate with their calves.

Humpbacks produce the longest, most complex sound sequences in “songs,” described as an array of moans, groans, roars and sighs to high-pitched squeaks and chirps, lasting ten or more minutes before repetition, sometimes over hours. It seems that only the adult males sing, generally only in or close to the breeding season. In any one breeding season, all the males sing the same song, changing slightly over successive seasons. Different populations have different songs; so much so, for example, that those off western Australia have a distinctly different song—less complex, less “chirpy”—than that heard on breeding grounds separated by the Australian continent, off the east coast. But an example of “cultural evolution” involving humpback songs has recently been reported where typical Australian east coast humpback song switched to a new, west coast version over a very short period, only 3 years, between 1995 and 1998, it seems as a result of the influence of a few male singers from the west coast (Noad *et al.*, 2000). “Songs” may also be heard in migrating humpbacks, but less so on the

cold water feeding grounds, where, if songs occur at all, they appear generally only as “snatches” or isolated segments.

2. Swimming and migration. With their streamlined bodies, rorquals include the fastest swimming baleen whales. Sei whales have been recorded at around 35 knots (>60 km/h) in short bursts; minke and fin whales are also known as fast swimmers, the latter up to 20 knots (37 km/h). Blue whales are among the most powerful swimmers, able to sustain speeds of over 15 knots (28 km/h) for several hours. On migration, humpbacks and gray whales average about 3–4 knots (5–7 km/hr), and bowheads only about 2.7 knots (5 km/hr). Migration speeds for southern right whales are not known, but medium range coastal movements off southern Australia indicate 1.5–2.3 knots (2.7–4.2 km/h) over 24 h for cow/calf pairs.

Baleen whales undertake some of the longest migrations known. Gray whales may cover some 5000 nautical miles (~9000 km) on the round trip between the Baja California breeding grounds and Alaskan feeding grounds. Southern hemisphere humpbacks may cover as much as 50° of latitude either way between breeding and feeding grounds, a round trip of some 6000 nautical miles (~11,000 km); recent records of humpbacks migrating between the Antarctic Peninsula and Costa Rica involved a single trip of ca 8400 km (4500 nautical miles), the longest recorded migration of any mammal. Not all baleen whale migrations are so well marked. The bi-annual movements of Bering Sea bowheads are governed by the seasonal advance and retreat of sea ice, which vary from year to year. Although Southern Hemisphere blue and fin whales all feed extensively in the Antarctic in summer, the locations of their calving grounds are not known. Sei whale migrations are relatively diffuse, and can vary from year to year in response to changing environmental conditions. By comparison, Bryde’s whales hardly migrate at all, presumably being able to satisfy both reproductive and nutritional needs in tropical/warm temperate waters. Even among such migratory animals as humpbacks, it may be that not all animals migrate every year: recent studies off eastern Australia have indicated that a proportion of adult females may not return to the calving grounds each year, and individuals have been reported in summer further north. However, Southern Hemisphere migrating humpbacks show segregation in the migrating stream: immatures and females accompanied by yearling calves are in the van of the northward migration, followed by adult males and non-pregnant mature females; pregnant females bring up the rear. A similar pattern occurs on the southward journey, with cow/calf pairs traveling last. Very similar segregation is recorded among migrating gray whales. However, not only is there segregation within some (possibly all) species, the species themselves may arrive on and leave the feeding grounds at different times. At South Georgia, where they were once common, fin whales tended to leave the feeding grounds after blue whales but before sei whales, the latter having arrived there last.

Baleen whale migrations have generally been regarded as taking place in response to the need to feed in colder waters and reproduce in warmer waters. Explanations for such long-range movements have included direct benefits to the calf (better able to survive in calm, warm waters), evolutionary “tradition” (a leftover from times when continents were closer together), and the possible ability of some species to supplement their food supply from plankton encountered on migration or on the calving grounds. Others have rejected these explanations, suggesting there may be a major advantage to migrating pregnant female baleen whales in reducing the risk of killer whale predation on newborn calves in low latitudes. More recently Rasmussen *et al.* (2007) have suggested that calf development in warm water may lead to larger adult size and greater reproductive success.

3. *Social activity.* Large aggregations of baleen whales are generally uncommon. Even on migration, in those species where well-defined migration paths are followed (e.g., gray whales and humpbacks), individual migrating groups are generally small, numbering only a few individuals. It has been stated that predation is a main factor in the formation of large groups of cetaceans, for example of open ocean dolphins. Given the large size of most adult baleen whales, predation pressure is low, and group size can be correspondingly small.

Blue whales are usually solitary or in small groups of two to three. Fin whales can be single or in pairs; on the feeding grounds they may form larger groupings, up to 100 or more. Similarly, sei whales can be found in large feeding concentrations, but in groups of up to only about six elsewhere. The same is true for minke whales, found in concentrations on the feeding grounds, but singly or in groups of two or three elsewhere. Social behavior has been studied intensively in coastal humpbacks, e.g., on the calving grounds. Male humpbacks compete for access to females by singing and fighting. The songs seem to act as a kind of courtship display. Males congregate near a single adult female, fighting for position. Such aggression can involve lunging at each other with ventral grooves extended, hitting with the tail flukes, raising the head while swimming, fluke and flipper slapping, and releasing streams of bubbles from the blowhole. As a result of such encounters, individuals can be left with raw and bleeding wounds caused by the sharp barnacles. Among southern right whales, surface active groups (known as SAGs) are often observed on the coastal calving grounds in winter, involving a tight group with a number of males pursuing an adult female, but with less aggression. As for humpbacks, it is not yet certain whether such behavior results in successful mating, although intromission in right whale SAGs is often observed.

Feeding balaenopterids have often been reported as circling on their sides through swarms of plankton or fish. It has been suggested that gray whales feed on their right sides, those baleen plates being more worn down, presumably through contact with the seabed. The most remarkable behavior, however, is reported from humpbacks. In the Southern Hemisphere, on swarms of krill, they may feed in the same “gulping” way as other balaenopterids. In the Northern Hemisphere, two methods are commonly reported—“lunging” and

“bubble netting.” In the former, individuals emerge almost vertically at the surface with their mouths partly open, closing them to force the enclosed water out through the baleen. In the latter, an animal circles below the food swarm; as it swims upwards, it exhales a series of bubbles forming a “net” encircling the prey. It then swims upwards through the prey with its mouth open, as in lunging.

V. Life History

Young baleen whales, particularly the fetus and the calf, grow at an extraordinary rate. In the largest species, the blue whale, fetal weight increases at a rate of some 100kg/day towards the end of pregnancy. The calf's weight increases at a rate of about 80kg/day during suckling. During that 7-month period of dependence on the cow's milk, the blue whale calf will have increased its weight by some 17 tonnes, and increased in length from around 7 to 17m. Blue whales attain sexual maturity at between 5 and 10 years, at a length of around 22m, and live for about 80–90 years. Adult female blue whales give birth every 2–3 years, pregnancy lasting some 10–11 months.

Other balaenopterids follow the same general pattern (Fig. 4). Mating takes place in warm waters in winter, birth following some 11 months later. A 7–11 month lactation period may be followed by a year “resting,” or almost immediately by another pregnancy. Most adults are able to reproduce from between 5 and 10 years of age, and reach maximum growth after 15 or more years. The smallest balaenopterid, the minke whale, is born after a pregnancy of some 10 months, at a length of just under 3m. Weaning occurs at just under 6m, after 3–6 months. The adult female can become pregnant again immediately following birth, but the resulting short calving interval is generally uncommon in baleen whales: 2–3 years is the norm, although humpbacks can achieve a similar birth rate, enabling their stocks to recover rapidly after depletion.

Right whales follow a similar general pattern, but there are some differences. In northern and southern right whales, gestation lasts about 11 months, weaning for about another year. Females are able to reproduce successfully from about 8 years (there are records of successful first pregnancies from 6 years), but the calving interval is usually a relatively regular 3 years. For bowheads, while growth is

Figure 4 “Typical” life cycle of a southern baleen whale. As modified by Bonner (1980), from Mackintosh (1965).

very rapid during the first year of life (from ~4.5 m), it may be followed by a period of several years with little or no growth. Sexual maturity occurs at 13–14 m: at the reduced growth rate that would not be reached until 17–20 years. Similarly, there is evidence of considerable longevity in this species: harpoon heads and an unexploded bomb-lance found in harvested whales and last known to be used off Alaska in the late nineteenth or early twentieth centuries indicate individual animals can be over 100-years old.

VI. Interactions with Humans

For centuries, baleen whales have borne the brunt of human greed, for products and profit. Only the sperm whale, largest of the toothed whales, has rivaled them as a whaling target. Black right whales (*Eubalaena*) were taken in the Bay of Biscay at least from the twelfth century, with the fishery extending across the North Atlantic by the sixteenth century. Attention then shifted to the Greenland whale (*Balaena*) near Spitzbergen (Svalbard), and later off southern and western Greenland. Both species' numbers were reduced to only small remnants, and in several areas (e.g., Spitzbergen and Greenland for *Balaena*, the north east Atlantic and the North Pacific for *Eubalaena*) the stocks were virtually exterminated. That destruction was undertaken using the "traditional" whaling method, with open boats and hand harpoons, on the "right" species—"right" because they were relatively easy to approach, floated when dead, and provided huge quantities of product (oil for lighting, lubrication and soap, and baleen ("whalebone") for articles combining flexibility with strength such as corset stays, umbrella spokes, and fishing rods.

Development of the harpoon gun and steam catcher, from 1864, greatly increased the rate of catching, but also allowed attention to turn to the largest baleen whales, the blue and fin whales, whose size and speed, and tendency to sink when dead, had prevented capture by the old methods. From its beginning in the North Atlantic, then, by the end of the century, in the North Pacific, "modern" whaling's next and most intensive phase moved south, first in 1904 at South Georgia, just within the Antarctic zone. Initially on humpbacks, (up to 12,000 were taken in 1 year, 1912, leading to very rapid stock decline) then on blue and fin whales, southern whaling based on such land stations—in the Antarctic in summer and the tropics in winter—was overtaken from the late 1920s by the great development of pelagic whaling, using floating factory ships. Huge annual Southern Hemisphere catches resulted—a maximum of over 40,000 in 1931—averaging around 30,000 animals per year in the later 1930s, and again after the World War II until 1965. Whereas blue whales had been the preferred target in the 1930s, their great reduction in numbers led to a shift in attention progressively over the years to fin whales, to sei whales in the 1960s, and finally to minke. With depletion of stocks and more stringent conservation measures, (killing of humpbacks, blue, and fin whales was banned from the mid-1960s, despite illegal catching until the early 1970s), catches fell to between 10,000 and 15,000 per year in the 1970s. The "old" whaling story had virtually repeated itself—enormous reductions through overfishing of one species or stock leading to exploitation of other species and stocks until, apart from minke whales, only remnants were left. From 1989, a moratorium on all commercial whaling eliminated that pressure, with the exception of limited whaling carried out under exemption for scientific research, and, since 1993, some commercial catching of minke whales in the eastern North Atlantic, and, since 2006, of fin whales off Iceland. Some "aboriginal" whaling has also continued in the Northern Hemisphere, on bowheads off

northern Alaska, gray whales in the Bering Sea, on fin and minke whales off Greenland, and on humpbacks in the Caribbean.

Despite the great scale of the kill in "old" and "modern" whaling, no whale species has become extinct through whaling, although a number of individual stocks have been reduced greatly; at least one, the North Atlantic gray whale, has disappeared within the past 200–300 years. In its most recent "Red List" of threatened animals, the World Conservation Union (IUCN, 1996 (Table II) includes no baleen whale species or stocks as either *Extinct*, or *Critically Threatened* (the latter within the *Threatened* category). Within the threatened category, seven taxa—three species, one subspecies, and three stocks—are listed as *Endangered* (*E*); four taxa—one species and three stocks—are listed as *Vulnerable* (*V*). Six taxa—two species, one subspecies, and three stocks—are listed as at *Lower Risk* (*LR*), and two taxa—one species and one subspecies—as *Data Deficient* (*DD*).

Those species under greatest threat (*E*), as determined in 1996, are the Northern Hemisphere right whales, sei, and fin whales, together with the Antarctic blue subspecies, two of the five bowhead stocks (Svalbard-Barents Sea, Okhotsk Sea), and the north west Pacific (western) gray. Next most threatened (*V*) are the humpback, two bowhead stocks (Hudson Bay-Foxe Basin, Davis Strait-Baffin Bay) and the North Atlantic blue. At lower risk (*LR*) are the southern right and Antarctic minke, one bowhead stock (Bering-Chukchi-Beaufort Seas), the North Atlantic (common) minke, north east Pacific (eastern) gray and North Pacific blue; all but one are further qualified as *conservation dependent* (*cd*, not *Vulnerable* because of specific conservation efforts). The exception is the North Atlantic (common) minke, listed as *near threatened* (*nt*, not *Conservation Dependent* but almost qualifying as *Vulnerable*). The two taxa for which insufficient information is currently available (*DD*) are Bryde's whale and the pygmy blue.

The International Whaling Commission's Scientific Committee, responsible for assessments of such stocks' current status, has reported encouraging recent reversals of stock decline for some stocks of some species. One, the eastern gray whale, has recovered under protection from commercial whaling (but with aboriginal catches up to some 150 per year) to at or near its "original" (pre-whaling) state, at about 26,000 animals. Similarly, the Northwest Atlantic humpback and several Southern Hemisphere humpback populations have been showing marked increase. The latest estimate of the North Atlantic stock, some 11,600 animals in 1992–1993, reflects substantial recovery since protection in the 1950s, while several Southern Hemisphere stocks (off southeastern Africa, eastern and western Australia) have been increasing, off Australia at around 10% per year since the early 1980s. Three southern right whale stocks (off eastern South America, South Africa, and southern Australia) have been increasing since the late 1970s at around 7% per year, although all are still well below their "original" stock size. Even the Antarctic blue whale, whose future has been of considerable concern, with estimates for the late 1980s at fewer than 500 animals for the whole Antarctic, has shown recent encouraging signs. Based on a series of Antarctic sightings cruises—mainly for minke whales but including other large whales—the most recent calculations give a population size of some 1700 in 1996, increasing at around 7% per year. At that rate, the population size might now be some four thousand, although still only a small fraction of its original population size, recently estimated at some 240,000.

One species or stock for which there is considerable concern is the western North Atlantic right whale. At very low absolute abundance (only some 300–350 animals), and while recently showing signs of increased reproduction, it is subject to considerable threat from human-induced mortality such as ship strikes and entanglement in fishing gear.

^eWestern gray whale.

^fEastern gray whale.

^gNorth Atlantic blue whale.

^hNorth Pacific blue whale.

It has been calculated (Laws, 1977) that the great reduction of baleen whales by whaling, for the Antarctic to around one-third of original numbers and one-sixth in biomass, must have left a large surplus of food—some 150 million tonnes per year—available for other consumers such as seals, penguins, and fish. (In a different way, earlier whaling in the North Atlantic, particularly on right whales, is believed to have influenced the spread of one sea bird—the fulmar—by providing food in the form of discarded whale carcasses.) In response to an increase in available food, there may well have been increases in growth rates, earlier ages at maturity and higher rates of pregnancy in some baleen whale species. However, the evidence is equivocal, as it is for competition between individual whale species. For some, for example right whales and sei, it has been suggested that an increase in one (right whales) could be inhibited by competition with another (sei whales). In the North Pacific, both sei and right whales can feed on the same prey—copepods—and sei whales can at times be “skimming” feeders, like right whales. However, evidence that they actually compete, on the same prey, in the same area, at the same time, and even on the same prey patch, is lacking. Similarly, there has been much debate and speculation on whether the recovery of the Antarctic blue whale has been inhibited by an apparent increase in minke whales. In that case, there may in fact be very little direct competition for food where the common prey is not limited in abundance (as in the Antarctic) and is available

in large patches. The recent increases at substantial annual rates for several stocks of Southern Hemisphere humpbacks and right whales, as well as the recent increase in numbers for the Antarctic blue whale (and possibly even for the fin whale), suggest that such competition is unlikely, at least where, as in the Antarctic, food supplies are abundant.

There is, however, increasing concern over the possible effects of climate change, with reductions in sea ice and rise in sea surface temperature. The former has been considered a factor in reducing the amount of krill available, and the latter has been shown to affect reproductive capacity—elevated sea surface temperature off South Georgia has recently been found (Leaper *et al.*, 2006) to affect conception and subsequent calving rates in the South American population of southern right whales.

Barnacles

DAGMAR FERTL AND WILLIAM A. NEWMAN

“Barnacle” is the common name for over 1000 marine species of the subclass Cirripedia. Barnacles are unique among crustaceans in being permanently attached as adults to a variety of inanimate and animate objects. They occur in polar, tropical, and temperate waters, being found from high on the shore to the depths of the ocean. The principal superorder is Thoracica, consisting of stalked (order Pedunculata) and sessile (order Sessilia) barnacles (Newman, 1996). Perhaps as many as 20 living barnacle species have some association with marine mammal species, primarily cetaceans (Newman and Ross, 1976). Barnacles attached to marine mammals are often referred to as ectoparasites; however, in actuality, they do not feed on their hosts, but use them as a moving substratum from which they can strain plankton from the passing water. As a result, “epizootic” is often considered a more appropriate term describing the barnacle’s lifestyle. This has been described as an example of symbiosis, usually commensalism, but barnacles create drag and can cause irritations. Therefore, they are perhaps best termed “semiparasitic,” since they survive and perpetuate themselves at the host’s expense. On the other hand, some marine mammals eat barnacles or their larvae.

I. Life History

Barnacles were described by Louis Agassiz and T. H. Huxley as nothing more than “a little shrimp-like animal, standing on its head in a limestone house and kicking food into its mouth” (Hoover, 2006). The barnacle’s life cycle usually includes six free-swimming planktonic naupliar stages that feed while progressing by molts to the cypris or cyprid stage, which searches for a place to settle. When settling, to anchor itself, the cyprid secretes cement from its antennules, from glands located in their base, and metamorphoses by molting into a juvenile, which begins to secrete adult cement and the calcareous plates that usually constitute its home. In the case of barnacles that attach directly to cetacean skin, a chemical cue from the host tissue likely induces larval settlement (Nogata and Matsumura, 2006).

Figure 1 The pseudo-stalked sessile barnacle *Xenobalanus* attached to the dorsal fin of a bottlenose dolphin. Courtesy of V. Thayer and K. Rittmaster, North Carolina Maritime Museum.

Through an opening between the plates, six pairs of feathery thoracic limbs (cirri) can emerge and spread out to sweep through the water like a net to entrap planktonic organisms. Most barnacles are hermaphrodites (i.e., individuals possess the reproductive structures of both sexes). The breeding season of barnacles that cling to whales is probably largely synchronous with that of the whales’ breeding season.

II. Sessile Barnacles

The Sessilia, or sessile barnacles, are stalkless, the usually well-articulated shell wall being attached directly to the substratum. Because of their superficial resemblance to acorns of oak trees, they are called acorn barnacles. Marine mammals host species of *Amphibalanus*, *Balanus*, *Cetopirus*, *Chelonibia*, *Coronula*, *Cryptolepas*, *Platylepas*, *Tubicinella*, and *Xenobalanus*. *Xenobalanus* superficially resembles a stalked barnacle since it has developed an aberrant pseudo-stalk, but it is nonetheless a sessile barnacle (Fig. 1).

III. Stalked Barnacles

The pedunculate, or stalked, barnacles are more primitive than the sessile barnacles. The terminal sac housing the appendages is called the capitulum. It is supported by a flexible, muscular stalk or peduncle attached to the substratum. The capitulum is usually protected by shell plates. *Conchoderma* spp., the goose barnacles (*Lepas* spp.), and rarely, the leaf barnacles (*Pollicipes* spp.), attach to marine mammals.

IV. Barnacles and Marine Mammals

Barnacles appear to settle in greatest numbers on large baleen whales, in contrast to toothed whales. Striped dolphins (*Stenella*

coeruleoalba) involved in a mass mortality event in the Mediterranean had an unusual abundance of barnacles likely due to the reduced movement and/or an impaired immune function of the skin of sick individuals (Aznar *et al.*, 2005). Orams and Schuetze (1998) demonstrated that *Xenobalanus* spp. were more prevalent on young than adult bottlenose dolphins (*Tursiops* spp.), presumably because they are less active and/or less resistant.

Cryptolepas rhachianecti, considered to be host-specific to the gray whale (*Eschrichtius robustus*), has been found on a killer whale (*Orcinus orca*) stranded in southern California and on belugas (*Delphinapterus leucas*) housed in San Diego Bay. *Xenobalanus globicipitus*, while world-wide in distribution, are almost always found on the trailing edges of the dorsal and pectoral fins and on the flukes of at least 27 cetacean species (Kane *et al.*, 2006; Fig. 1). What may remain of their wall in the skin of the host after death superficially resembles the

Figure 2 Humpback whale with the acorn barnacle *Coronula diadema* and a few stalked barnacles (arrows), *Conchoderma auritum* attached to them. Also visible are white-rim scars from acorn barnacles that have dropped or have been knocked off. Courtesy of Y. Ogino, off California, 1999.

wall of platylepas; this may account for a report (Mead and Potter, 1990) of platylepas on a bottlenose dolphin. *Tubicinella major*, which lives within a columnar shell opening at the surface of its host's skin, and usually found among callosities of southern right whale (*Eubalaena australis*), was once collected from the flank of a stranded northern bottlenose whale (*Hyperoodon ampullatus*). *Coronula* spp., the most generalized of the sessile whale barnacles, are large and generally attach to the skin of baleen whales (Scarff, 1986). *C. reginae* and *C. diadema* (Fig. 2) are commonly epizootics of humpback whales (*Megaptera novaeangliae*), attached to flukes, flippers, ventral grooves, genital slit, and the head (Clarke, 1966). *Cetopirus complanatus* closely resembles *C. reginae*, and both occur on the right whale (Scarff, 1986). Humpback males scrape each other with their barnacle-encrusted flippers (analogous to "brass knuckles") on the breeding grounds; one individual caught during whaling operations was reported to have as much as 450 kg of *Coronula* removed from it. On the other hand, various forms of grooming, including flipper-body grooming (Sakai *et al.* 2006), would likely remove freshly settled larvae and young juveniles; this may account for the lack of barnacles on the bodies of most small toothed whales.

Of the pelagic pedunculate barnacles, *Conchoderma auritum* and *C. virgatum* are commonly recorded from cetaceans, though *Pollicipes polymerus*, a rocky shore barnacle, was recorded on a humpback whale (Clarke, 1966). *Conchoderma* spp. require a hard surface for attachment. *Conchoderma auritum*, identified by its' rabbit ear-like appendages, may be found at a site where teeth are exposed and unprotected (Soto, 2001), such as on erupted teeth of adult male beaked and bottlenose (*Hyperoodon* spp.) whales (Fig. 3), or because of a malformation (including bone injury) in the jaw. *Conchoderma* spp. are less commonly found on baleen plates and were once collected from the penis of a stranded sperm whale (*Physeter macrocephalus*). *C. auritum* is often found attached to *Coronula* spp. (most commonly to *C. diadema*). *C. virgatum*, although sometimes attaching directly to a cetacean, is usually epizootic on other barnacles, and then most often on *C. auritum*. *C. virgatum* has been found on the parasitic copepods *Pennella* spp. and on the cyamid amphipod, *Neocyamus physeteris*, which crawls about on cetaceans and their barnacles (Clarke, 1966; Oliver and Trilles, 2000). *Lepas* spp. usually occur on floating objects, yet *L. pectinata* and *L. hillii* have been found between the teeth of some Mediterranean striped dolphins.

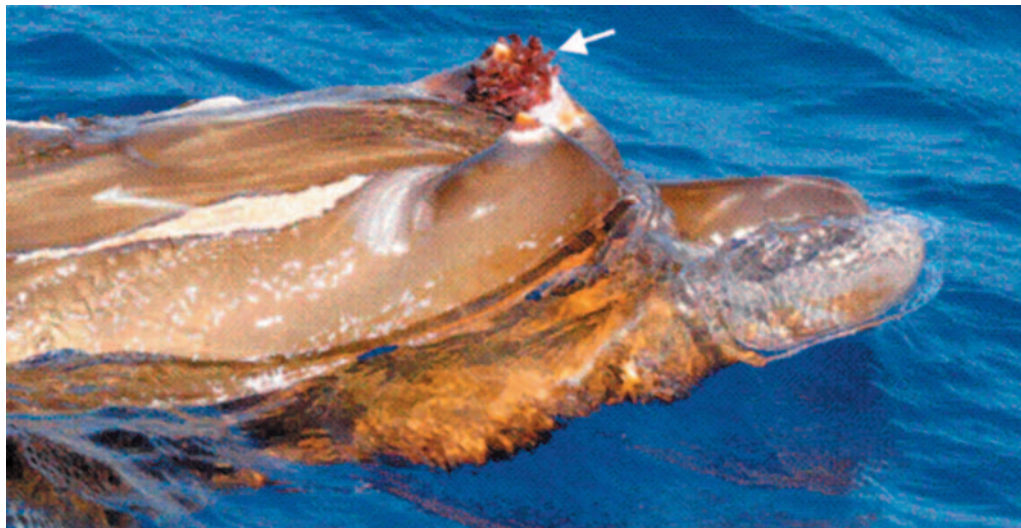

Figure 3 *Conchoderma auritum* (arrow) attached to the teeth of a Blainville's beaked whale (*Mesoplodon densirostris*) off Hawaii. Photo by Alice Mackay, courtesy Cascadia Research.

There are comparatively few published records of barnacles on pinnipeds, yet *Lepas pacifica*, *L. australis*, and *L. hillii*, as well as *Conchoderma auritum* and *C. virgatum*, are recorded from their dorsal body surface, attached to hair or even directly to the skin of various species, including both species of elephant seals (*Mirounga* spp.) (Best, 1971; Setsaas and Bester, 2006; Fig. 4).

Manatees (*Trichechus* spp.) may acquire acorn barnacles when in brackish or seawater, but when they enter fresh water the barnacles die and drop off, leaving temporary scars. The common barnacle found embedded in the skin of West Indian (*Trichechus manatus*) and West African (*T. senegalensis*) manatees is *Chelonibia manati* (Cintrón De Jesús, 2001), a close relative of its congeners on turtles. Moreover, turtle barnacles *Platylepas hexastylus* and *P. decorata* have been found on the dugong (*Dugong dugon*) and West Indian manatee. The brackish water species, *Amphibalanus amphitrite*, *A. eburneus*, *A. reticulatus*, and *A. improvisus*, and the marine species, *Balanus trigonus*, attach to the *Chelonibia* spp. on the manatees, rather than to their skin.

It is not surprising that some baleen whales eat barnacle larvae (Mayo and Marx, 1990) since the experimentally estimated filtering efficiency of 95% for plankton larger than 333 µm for the right whale (Mayo *et al.*, 2001) would include the larvae of pelagic and some coastal barnacles.

Sea otters (*Enhydra lutris*) in California and Alaska will eat the large acorn barnacles *Balanus nubilis* and *Semibalanus cariosus*. Fautot *et al.* (1986) reported otters feeding on *Pollicipes polymerus*, suggesting that they may be intentionally ingesting it if not simply being incidental to their take of mussels.

Basilosaurids

MARK D. UHEN

Basilosaurids are a paraphyletic group of archaeocete cetaceans known from the late middle to early late Eocene of all continents except Antarctica. The family includes 11 species in 8 genera in 2 subfamilies, although some authors elevate the subfamilies

Figure 1 Skull and lower jaw of *Dorudon atrox*, lateral view. This drawing is a composite drawn from specimens of *D. atrox* at the University of Michigan Museum of Paleontology by Bonnie Miljour.

Figure 2 Skeleton of *Dorudon atrox*, lateral view. This drawing is a composite drawn from specimens of *D. atrox* at the University of Michigan Museum of Paleontology by Bonnie Miljour.

to familial rank. They range in size from around 4 m (*Saghacetus osiris*) to around 16 m (*Basilosaurus cetoides*). Basilosaurids are probably the earliest fully aquatic cetaceans (Uhen, 1998) and are thought to have given rise to modern cetaceans (Barnes *et al.*, 1985; Uhen, 1998).

I. Basilosaurid Characteristics

Like all archaeocetes, basilosaurids lack telescoping of the skull like that seen in modern mysticetes or like that seen in modern odontocetes (see Fig. 1; Miller, 1923). In addition, basilosaurids are diphyodont (have two tooth generations: milk and adult teeth), lack polydony (11 or fewer teeth per jaw half), and retain a heterodont dentition, in which incisors, canines, premolars, and molars are easy to distinguish based on their morphologies (Kellogg, 1936; Uhen, 1998).

Basilosaurids also share a number of characteristics that distinguish them from other archaeocetes. All basilosaurids lack upper third molars, and the upper molars lack protocones, trigon basins, and lingual third roots. In addition, the cheek teeth of basilosaurids have well-developed accessory denticles on the cheek teeth (Fig. 1). The hind limbs of basilosaurids are greatly reduced (see Fig. 2; Gingerich *et al.*, 1990; Uhen and Gingerich, 2001) and lack a bony connection to the vertebral column. Basilosaurids also lack sacral vertebrae, although vertebrae that are likely to be homologs of sacral vertebrae are identifiable (Kellogg, 1936; Uhen, 1998).

Other characteristics may be found only in basilosaurids (within archaeocetes) but are currently not known from other archaeocetes. For instance, basilosaurid forelimbs had broad, fan-shaped scapulae

with the distal humerus, radius, and ulna flattened into a single plane (Fig. 2). In addition, the elbow joint motion was restricted to the same plane, and pronation and supination of the forelimb was not possible based on the articular surfaces of the distal humerus, proximal radius, and proximal ulna. Since forelimbs are poorly known in more derived protocetids, it is unclear whether these features are found only in basilosaurids, or whether they are characteristic of a larger group.

Some of the characteristics of basilosaurids can be seen in some protocetid archaeocetes, like *Georgiacetus*. Although the innominate of *Georgiacetus* is large, it does not appear to have been connected to the vertebral column. None of the vertebrae is fused into a sacrum, yielding a condition similar to that seen in basilosaurids. In addition, the cheek teeth of *Georgiacetus* have small accessory denticles, somewhat different from those in basilosaurids, but certainly larger than any of the serrations seen in other non-basilosaurid archaeocetes.

II. Taxonomy

Taxonomy for the family Basilosauridae is after Uhen (1998). Basilosaurinae and Dorudontinae are included here in the single family Basilosauridae following Miller (1923) because a single character state (elongate trunk vertebrae) distinguishes basilosaurines from dorudontines (Uhen, 1998). The names “zeuglodonts” and “zeuglodons” are often colloquially used to refer to basilosaurids or archaeocetes in general. These common names are derived from the disused generic name *Zeuglodon* (discussed below), and their usage should be avoided.

A. Basilosauridae Cope 1868

1. *Basilosaurinae* Cope 1868 Basilosaurines are basilosaurids with elongate posterior thoracic, lumbar, and anterior caudal vertebrae. All known basilosaurines are also considerably larger than all known dorudontines, with the exception of *Cynthiacetus* (see below).

A. *BASILOSaurus* Harlan 1834 *Basilosaurus* was the first archaeocete whale named. The name was first coined in 1834 by Richard Harlan, who mistook the large vertebrae for those of a large marine reptile, thus the misnomer of “king lizard” for a cetacean. This mistake was pointed out by Richard Owen in 1842, when he attempted to rename the animal *Zeuglodon cetoides*. *Zeuglodon* is considered a junior subjective synonym of *Basilosaurus*, but it has been applied to so many archaeocete whales as to have become a common name for archaeocete or basilosaurid. *Basilosaurus* contains three species from the late middle and early late Eocene: *B. cetoides* is known from the southeastern United States, *B. isis* is known from Egypt and Jordan, and *B. hussaini* is known from Pakistan (Uhen, 1998).

B. *BASILOTERUS* Gingerich *et al.* 1997 *Basiloterus* can be distinguished from *Basilosaurus* based on its anteroposteriorly long neural arch and more anteriorly projecting metapophyses. *Basiloterus* contains a single species, *B. drazindai*, based on a single lumbar vertebra from the late middle Eocene of Pakistan.

2. *Dorudontinae* Miller 1923

A. *DORUDON* Gibbes 1845 The genus *Dorudon* was erected in 1845 by Gibbes for a specimen of a small archaeocete that he dubbed *D. serratus*. This specimen is of a juvenile individual with deciduous teeth, making it difficult to compare to other specimens of adult individuals. Nonetheless, the number of species in *Dorudon* grew when Kellogg (1936) removed a number of species from the genus *Zeuglodon* and placed them in *Dorudon*. Subsequently, many of these species were synonymized and/or placed in other genera. Only *D. serratus* from the late Eocene of the southeastern United States, and *D. atrox* (formerly *Prozeuglodon atrox*) from the late Eocene of Egypt remain (Uhen, 1998).

B. *ZYGORHIZA* True 1908 The genus *Zygorhiza* was erected in 1908 by True for specimens of a small archaeocete from North America that he felt were different from *Dorudon serratus*. Some of these specimens had been part of Koch's *Hydrarchos* and had been called by many different names (Kellogg, 1936). *Z. kochii* can be distinguished from all other dorudontines by the presence of well-developed cuspsules on the cingula of the upper premolars. *Zygorhiza* currently includes *Z. kochii* from the late Eocene of the southeastern United States and *Zygorhiza* sp. from New Zealand, as European specimens assigned to *Zygorhiza* are more appropriately identified as *Dorudontinae incertae sedis* (Uhen, 1998).

C. *CYNTHIACETUS* Uhen 2005 The genus *Cynthiacetus* was erected by Uhen in 2005 for a large dorudontine that had a skull similar in size and morphology to the skull of *Basilosaurus*, but which lacked the elongate trunk vertebrae of *Basilosaurus*. Previously, animals such as this had often been called *Pontogeneus*, which Uhen designated a nomen dubium. Some of the vertebrae of Koch's *Hydrarchos* were large in size, but not elongate like those of *Basilosaurus*, and were given the name *Zeuglodon brachyspondylus*. Kellogg (1936) suggested that *Zeuglodon brachyspondylus* and Leidy's *Pontogeneus priscus* were the same, and used Leidy's generic name and the specific epithet *brachyspondylus* for the new combination. Neither of these previously named taxa is based on diagnostic type specimens. *Cynthiacetus* is found in both the late Eocene of the southeastern United States and Egypt.

D. *SAGHACETUS* Gingerich 1992 The generic name *Saghacetus* was coined in 1992 to subsume the former species *Dorudon osiris*, *Dorudon zitteli*, *Dorudon sensitivius*, and *Dorudon elliotsmithii* within a single species, *Saghacetus osiris*. *S. osiris* can be distinguished from other dorudontines based on its small size, and its slightly elongate lumbar and anterior caudal vertebrae. *S. osiris* is known only from the late Eocene of Egypt.

E. *ANCALECETUS* Gingerich and Uhen 1996 *Ancalecetus* includes one species, *A. simonsi*, which is similar to *Dorudon atrox* but has greatly modified forelimbs that were highly restricted in their range of motion. *A. simonsi* is known from the late Eocene of Egypt (Uhen, 1998).

F. *CHRYSOCETUS* Uhen and Gingerich 2001 *Chrysocetus* includes one species, *C. healyorum*, which differs from all other dorudontines in the smoothness of the tooth enamel, height of the premolar crowns, and the eruption of its adult teeth in a skeletally juvenile state. *Chrysocetus* is also the only dorudontine for which the innominate is known. *Chrysocetus* is known from the late Eocene of South Carolina (Uhen and Gingerich, 2001).

B. Questionable Basilosaurids

Excluded from this list is the genus *Gaviacetus*, which was referred to the Basilosauridae by Bajpai and Thewissen (1998). The identification of *Gaviacetus* as a basilosaurid was based on the likely absence of upper third molars in both the type specimen of *Gaviacetus razai* and the type specimen of *Gaviacetus sahnii* (Bajpai and Thewissen, 1998). In addition, Bajpai and Thewissen (1998) referred some elongate vertebrae to *G. sahnii* further supporting their placement of *Gaviacetus* in the Basilosauridae. Since no specimen of *Gaviacetus* clearly shows that the upper third molar is absent, or that any of the cheek teeth have accessory denticles, and since reference of postcrania to unasociated cranial material has proven problematic in the past, I prefer to leave *Gaviacetus* in the Protocetidae as it was originally described until it can be clearly shown to have basilosaurid synapomorphies.

Species that may not be basilosaurids are *Basilosaurus hussaini* and *Basiloterus drazindai*. These species (as well as the genus *Basiloterus*) are based solely on one and two vertebrae respectively. These vertebrae are thought to represent basilosaurines because they are elongate, like the vertebrae of *Basilosaurus*. Although this feature is a distinguishing characteristic of Basilosaurinae within Basilosauridae, it is clear that vertebral elongation is not restricted to basilosaurids. *Eocetus*, a protocetid from Egypt and North America, also has elongate vertebrae, although they are not as elongate as those of *Basilosaurus*. It is possible that *B. hussaini* and *B. drazindai* are also protocetids. Once cranial or dental material associated with vertebrae is found, it will be obvious whether these taxa should be retained in Basilosauridae.

III. Phylogenetic Relationships

The phylogenetic relationships among basilosaurids, and their relationships to other archaeocetes, mysticetes, and odontocetes are shown in Fig. 3. Many of the character state transformations that occur between basilosaurids and protocetids are associated with the adoption of a fully aquatic existence; such as presence of pterygoid air sinuses, extreme reduction of the hind limb, loss of the sacrum, increase in the number of trunk vertebrae, and the presence of dorsoventrally flattened posterior caudal vertebrae (Uhen, 1998). Other, such as the loss of M³, loss of lingual roots on the upper molars, and the development of accessory denticles on the cheek teeth, have to do with changes in feeding that are not as easy to interpret.

Figure 3 Cladogram of basilosaurids, selected non-basilosaurid archaeocetes, mysticetes, and odontocetes. Mysticetes and odontocetes not included in Dorudontinae.

Within Basilosauridae, basilosaurines are united by the presence of elongate trunk vertebrae, which dorudontines lack. *Pontogeneus* may be the sister taxon to Basilosaurinae based on its large size. Each genus of dorudontine is distinguishable from the other genera based on the presence of autapomorphies, but it is difficult to confidently link any of the genera based on any clear synapomorphies. The result is a polytomous relationship among the genera or an imbalanced tree with Mysticeti + Odontoceti nested well within Dorudontinae. *Chrysoctetus* is preferred as the sister taxon to Mysticeti + Odontoceti based on the interpretation of it and early mysticetes and odontocetes as monophyodont. Hopefully, some of the relationships among basilosaurids will become more secure as more of the anatomy of more of the species becomes known.

Beaked Whales, Overview

Ziphiidae

JAMES G. MEAD

Beaked whales belong to the odontocete family Ziphiidae. They are medium-sized cetaceans, adults ranging from 3 to 13m. They are characterized by a reduced dentition, elongate rostrum, accentuated cranial vertex and enlarged pterygoid sinuses. There are currently 21 recognized species in 5 genera. They are all pelagic, living in the open oceans and feeding on deep-water squid and fish.

I. Classification and Nomenclature

Family Ziphiidae

Subfamily Ziphyiinae

- | | |
|------------------------------|-------------------------|
| <i>Berardius aruxii</i> | Amoux's beaked whale |
| <i>Berardius bairdii</i> | Baird's beaked whale |
| <i>Tasmacetus shepherdii</i> | Shepherd's beaked whale |
| <i>Ziphius cavirostris</i> | Cuvier's beaked whale |

Subfamily Hyperoodontinae

- | | |
|--------------------------------|----------------------------|
| <i>Hyperoodon ampullatus</i> | Northern bottlenose whale |
| <i>Hyperoodon planifrons</i> | Southern bottlenose whale |
| <i>Indopacetus pacificus</i> | Longman's beaked whale |
| <i>Mesoplodon bidens</i> | Sowerby's beaked whale |
| <i>Mesoplodon bowdoini</i> | Andrews' beaked whale |
| <i>Mesoplodon carlhubbsi</i> | Hubbs' beaked whale |
| <i>Mesoplodon densirostris</i> | Blainville's beaked whale |
| <i>Mesoplodon europaeus</i> | Gervais' beaked whale |
| <i>Mesoplodon ginkgodens</i> | Ginkgotoothed beaked whale |
| <i>Mesoplodon grayi</i> | Gray's beaked whale |
| <i>Mesoplodon hectori</i> | Hector's beaked whale |
| <i>Mesoplodon layardii</i> | Straptoothed whale |
| <i>Mesoplodon mirus</i> | True's beaked whale |
| <i>Mesoplodon perrini</i> | Perrin's beaked whale |
| <i>Mesoplodon peruvianus</i> | Peruvian beaked whale |
| <i>Mesoplodon stejnegeri</i> | Stejneger's beaked whale |
| <i>Mesoplodon traversii</i> | Spade-toothed whale |

Figure 1 Details of the external morphology of an adult male *Mesoplodon mirus* (USNM 504612). (A) Lateral view of the whole animal; (B) lateral view of head; (C) lateral view of flipper; (D) lateral view of dorsal fin; (E) oblique ventral view of flukes.

The concept of the beaked whales as a separate group of cetaceans became common in the 1860s and 1870s as Gray uses the family Ziphiidae in his *Catalogue of Seals and Whales in the British Museum* (1866) as do Van Beneden and Gervais, in their epic *Ostéographie des Cétacés* (1868–1879). True (1910) studied ziphiid systematics.

The common name of the family, beaked whales refers to their pronounced rostrum or beak. The rostrum of beaked whales is, admittedly, relatively shorter than in most dolphins but relatively longer than most “whales.” Most beaked whales are encountered rarely enough that they do not have “common names” but rather “vernacular names,” that were coined by scientists.

The only beaked whales that are seen on a regular basis by fishermen (and whalers) are the northern bottlenose whale (*Hyperoodon ampullatus*) and Baird’s beaked whale (*Berardius bairdii*). The English name “bottlenose whale” was actually in common use as were the Norwegian name *nebhval* or *naebhval* and the Danish and German name *dögling* or their derivatives in other northern European languages. The name *tsuchi-kujira* or just *tsuchi* is the Japanese common name for Baird’s beaked whale (*B. bairdii*).

II. Anatomy

Living beaked whales are characterized externally by a pronounced rostrum (beak) which blends into a high forehead (or melon) without a break (Fig. 1); a pair of throat grooves; relatively small flippers with short fingers and relative long arm bones; small triangular dorsal fin that is placed far back on the body; and lack of fluke notches. Internally they have a reduction in teeth; fusion of the bones of the rostrum and development of extremely dense rostral elements in males; expansion of the pterygoid air sinus and elimination of its lateral bony wall; and elevation of the bones associated with the nose into a bony protuberance called the vertex (Fig. 2).

Several similarities between beaked whales and sperm whales became evident early. Partly these were due to retention of ancestral characters and partly due to similarities in ecology. Both groups of whales feed at considerable depth and are specialized to feed on squid.

Ziphiids in general have reduced their teeth to the point that teeth in the upper jaw are vestigial or absent and teeth in the lower jaw are reduced to one or two pairs that usually erupt only in adult males. The only exception to this is Shepherd’s beaked whale

Figure 2 Skeleton of an adult male *Mesoplodon densirostris* in the Australian Museum, Sydney (after Van Beneden and Gervais, 1868-79:Pl. XXII, Figure 9), Forelimb and pelvic rudiment are from an adult male of the same species in the American Museum of Natural History (after Raven 1942).

(*Tasmacetus shepherdi*) which has a full dentition in both jaws (see account under *Tasmacetus* for illustration).

The pronounced rostrum results from an anterior extension of the rostral and palatal elements of the skull, the maxilla, premaxilla, and vomer, coupled with a lateral compression to form a beak. Normally these bones are moderately extended in cetaceans to form pincer-like beak, and, in fact, the relative length of the rostra of some of the toothed whales, like the river dolphins, exceeds that of beaked whales.

Beaked whales have a high forehead, which sets off the long rostrum. This forehead is composed of the soft tissue, which forms the facial apparatus and the elevated cranium on which it rests. This soft tissue is responsible for sealing the nasal passages against water and modifying the emitted sound. The blowhole is crescent-shaped with the horns of the crescent pointing anteriorly, except in the genus *Berardius* where they point posteriorly. The forehead merges with the rostrum without a break or groove that is characteristic of other toothed whales, except the rough toothed dolphin (*Steno bredanensis*) which is similar to ziphiids (Fig. 1B).

Beaked whales have a pair of throat grooves which are in the shape of a “v” with its apex pointing forward. The anterior end of the throat grooves lies posterior to the symphysis of the lower jaws and anterior to the jaw joint (i.e., in the throat region). Throat grooves are present in gray whales and sperm whales but absent in all other species. They are not to be confused with the ventral grooves or pleats, which are much longer, stretching from the tip of the jaw back to the umbilicus in orquals.

Beaked whales have relatively small, unspecialized flippers. They consist of a relatively large forearm (radius and ulna) portion followed by a short phalangeal (finger) portion (Fig. 1C). This also occurs in porpoises (Phocoenidae) and orquals and appears to be a primitive cetacean character. The dorsal fin of beaked whales is small and triangular, not falcate. The dorsal fin is located on the posterior third of the body, usually over the anus at the junction of the abdomen and tail. The position of the dorsal fin in beaked whales correlates with a relatively long thorax and abdomen and short tail (Fig. 1D).

Beaked whales normally do not have fluke notches and the trailing edge of the flukes is unbroken. Embryologically the fluke notch is formed when the trailing edge of the flukes moves back beyond the end of the caudal vertebrae. The caudal vertebrae anchor the midline of the trailing edge resulting in a notch (Fig. 1E).

The reduction in teeth has proceeded to the point where all function teeth are lost in females and immature males and the dentition is only represented by a single pair of teeth in the lower jaw of males. Females and immature males have a pair of vestigial teeth. The dentition is apparently only used in male, intraspecific, aggression. The two exceptions to this are the genus *Berardius*, which has two pairs of mandibular teeth and *Tasmacetus*, which has a normal odontocete

dentition in both the upper and lower jaws. In *Tasmacetus*, the apical pair of mandibular teeth is enlarged, which suggests that the single pair of teeth in all other ziphiids represents the apical pair. A row of vestigial teeth is sometimes present in the gums of both the upper and lower jaws of some beaked whales, particularly *Mesoplodon grayi* and *Ziphius*.

Fusion of the bones of the rostrum in some males takes place with increasing age. As part of the fusion, the mesorostral canal is filled in by dorsal expansion of the vomer and the individual rostral elements fuse together. This is accompanied by an increase in density of the rostrum. The density of the core of the rostrum has been measured at 2.4 gm/cc in a male of *Mesoplodon carlhubbsi* and 2.6 gm/cc in a male *M. densirostris*.

The pterygoid air sinus is enlarged in the ziphiids, but remains confined to the pterygoid bone and lost its lateral wall. The anterior sinus is not developed in ziphiids. The vertex of the skull has been expanded both laterally and vertically beyond what occurs in all other odontocetes. The vertex is composed of the posterodorsal ends of the maxilla and premaxilla, the nasals and the medial ends of the frontals. The dorsal tip of the vertex has expanded laterally and anteriorly like a mushroom. This region is deeply involved with sound production and modification.

III. Fossil Record

Ziphiids first appeared in the fossil record in the early Miocene (Muizon, 1991). These early ziphiids had long rostra, full dentitions with the first mandibular tooth often hypertrophied, an elevated synvertex with a premaxillary crest, strong development of the pterygoid sinus with reduction of the lateral wall of the pterygoid and increase in the hamular process, and an auditory region of the skull that has minimal fenestration.

By the middle Miocene fossil ziphiids were abundant. This is a period of maximum diversity of the entire order Cetacea and certainly was for the ziphiids. It is unclear how the Miocene genera relate to the modern genera. There are about 14 genera of fossils currently recognized as ziphiids. Of these 14 genera there are at least 28 species that are based solely on rostral fragments. Critical work has demonstrated that two genera are based upon non-diagnostic fragments and have been regarded as nomina dubia. With further study, particularly of the genera that are based on rostral fragments, there is bound to be a lot of demonstrated synonymy.

Muizon (1991) classified modern and fossil Ziphiidae into three subfamilies (1) the Hyperoodontinae, which contains *Hyperoodon* and *Mesoplodon*; (2) the Ziphiinae, which contains *Ziphius*, *Berardius*, *Tasmacetus* and the fossil genera *Choneziphius*, *Ziphirostrum*, *Cetorhynchus*, and *Ninoziphius*; and (3) the Squaloziphiinae, which currently contains only *Squaloziphius* (Fig. 3).

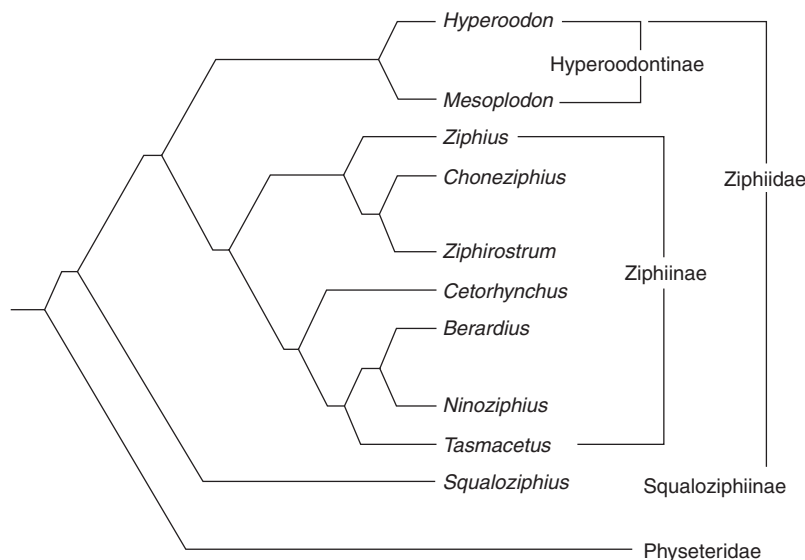

Figure 3 Cladogram of the Ziphiidae (after Muizon 1991). *Indopacetus* is included in *Mesoplodon*.

IV. Interactions with Humans

Because of their pelagic habits and general lack of concentrated populations, ziphiids have not had much contact with humans. The only fisheries that had ziphiids as a target species were the bottlenose whale fishery in the North Atlantic and the *Berardius* fishery in the North Pacific.

The bottlenose whale was hunted from the middle of the nineteenth century by Norwegian and British whalers. The catches of the bottlenose whale were part of a multi-species small whale fishery, where catches of one species may serve to subsidize catches of another when the population of the second species has fallen to such a point that fishing of it would not be economical. As a result the population was over-exploited and protected by the International Whaling Commission in the late 1970s.

Berardius was hunted primarily by the Japanese who fished it out of shore stations on the northeast coast of Japan since at least the seventeenth century. It was taken incidentally by other nations in the process of whaling for other species. The Japanese market was local to the whaling stations and would sometimes take *Ziphius cavirostris* and the occasional *Mesoplodon*. In the Southern Hemisphere, whalers rarely took the southern forms of *Berardius* (*B. arnuxii*) and *Hyperoodon* (*H. planifrons*). There were no fisheries based on them as the target species.

Ziphiids were moderately large, difficult to find and catch and had habits (deep diving) that did not suit them to captivity. The occasional live stranded animals were sometimes maintained in captivity in hopes of rehabilitating them and learning something of their behavior. The rehabilitation attempts were never successful and the animals always died quickly. One *Mesoplodon* calf that stranded in California in 1989 lived for 25 days in an aquarium.

Bearded Seal

Erignathus barbatus

KIT M. KOVACS

I. Characteristics and Taxonomy

Bearded seals are the largest of the northern phocid seals (Fig. 1). Adults are 2–2.5 m long and are gray-brown in color; some individuals have irregular light-colored patches. The weight of bearded seals varies dramatically on an annual cycle, but an average weight for adults is 250–300 kg. Females are somewhat larger than males in this species and can weigh in excess of 425 kg in the spring. The sexes are not easily distinguished. Pups are approximately 1.3-m

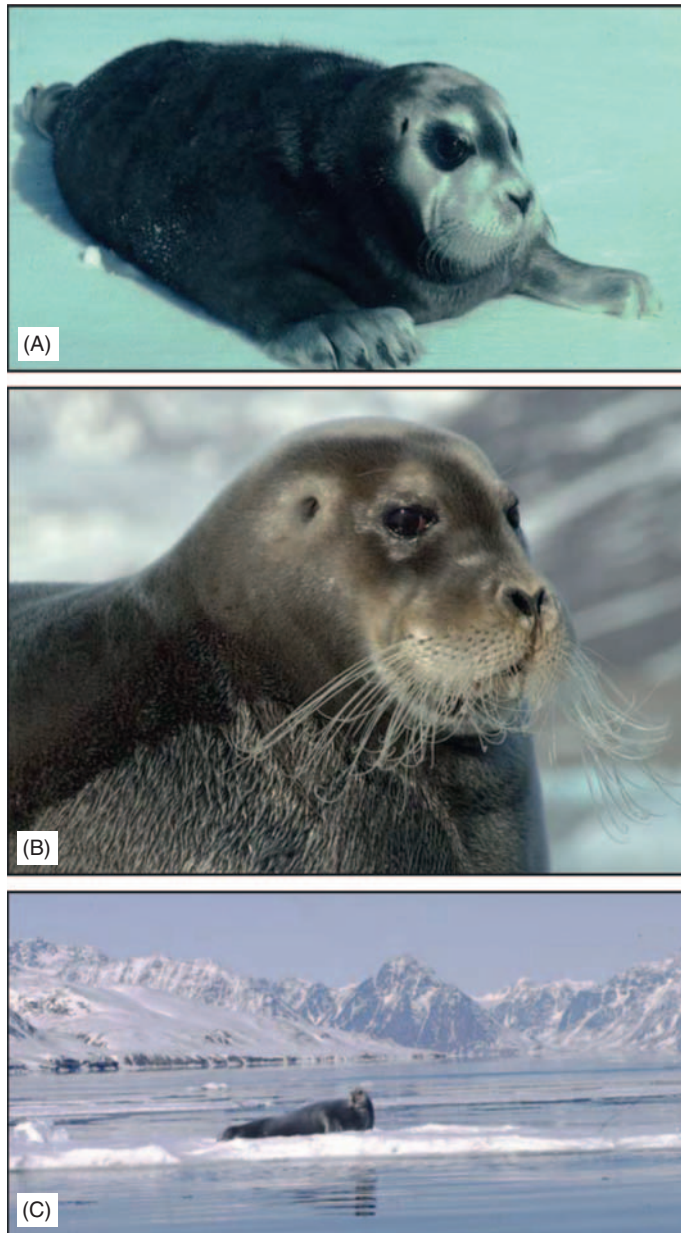

Figure 1 (A) Bearded seal pup, 2-days old. (B) Adult male bearded seal close-up showing the elaborate vibrissae. (C) An adult bearded seal in typical habitat.

long at birth and weigh an average of 33 kg. They are born with a partial coat of fuzzy gray-blue fur but have already commenced molting into a smooth dark-gray coat, with a light belly, that is their pelt by the time they are a few weeks old (Kovacs *et al.*, 1996). Their shed fetal hair is formed into disks (similar to hooded seals) that are passed with the placenta. Similar to adults, young animals often have irregular light patches here and there. Pups' faces have white cheek patches and white eyebrow spots that give them a “bandit” or “teddy-bear” appearance. Yearlings look very similar to pups, but the facial patterns are somewhat less distinct and they often have dark spots on their bellies.

Bearded seals have several distinctive physical features. Their body shape is very rectangular. Their heads appear to be small compared to their body size, similar to monk seals. They have very square-shaped fore flippers (with the longest toe being the middle one) which bear

very strong claws. Inuit people in the Canadian Arctic refer to this seal as “square-flippers” because of the shape of their front flippers. They also have extremely elaborate, smooth, facial whiskers that tend to curl when dry; this trait gives them their other common name—bearded seal. Females have four mammary glands (another characteristic shared with the monk seal lineage), unlike the other northern phocids, which have only two. Genetically and morphologically, the bearded seal is an intermediate form, sharing characteristics of the two Phocidae subfamilies (Phocinae and Monachinae). Bearded seals are the only species within the genus *Erignathus*.

The dentition of bearded seals is typical for phocid seals: I 3/2 C 1/1 PC 5/5 though anomalies in number are common and it is also not uncommon for the teeth of older animals to be worn to the gum-line.

II. Distribution and Abundance

Bearded seals have a patchy distribution throughout much of the Arctic and subarctic (Fig. 2; Burns, 1981). Their preferred habitat is drifting pack ice in areas over shallow water shelves. They are often found in coastal areas. Some populations are thought to be resident throughout the year, whereas others follow the retraction of the pack ice northward during the summer and southward once again in the late fall and winter (Kelly, 1988). They can maintain holes in relatively thin ice, but avoid heavy ice areas. During winter they concentrate in areas that contain polynyas or in areas where leads in the ice tend to be a regular feature, or along the outside of pack-ice areas. Juvenile animals wander quite broadly and can be found far south of the normal adult range. A neonate equipped with a satellite tag in Svalbard traveled south to Jan Mayen and then almost to the Greenland coast within the month following weaning, when the tag ceased to transmit. Based on the fact that bearded seals can be locally extirpated quite easily via hunting, it is thought that significant subpopulation structure exists across the Arctic; this is currently the subject of a genetics investigation.

It is not possible to provide accurate abundance estimates for bearded seals because they occur at low density, are spread over a very wide range, are difficult to survey logistically, and receive relatively little research attention. But, this species probably numbers in the hundreds of thousands globally.

III. Ecology

Bearded seals are a pack ice species. Generally, they are found in ice-filled waters throughout the year. But, levels of primary productivity and benthic biomass as well as sea ice have positive influence on abundance in a given area (Bengtson *et al.*, 2005). Bearded seals are known to come ashore in a few locales to rest, particularly at the time of peak molting in midsummer. Bearded seals are not deep divers; they feed in shallow, often coastal, areas and hence normally are not required to dive to depths more than 100 m. Pups dive to much greater depths during their first year (>450 m), but older, experienced animals remain in shallow water where most of their benthic prey resides (Gjertz *et al.*, 2000). Most dives are less than 10 min in duration, although they can dive for up to 20–25 min.

Bearded seals eat a wide variety of different types of prey, but they are predominantly benthic feeders, eating clams, shrimps, crabs, squid, fishes, and a variety of other small prey that they find near, on, or in the ocean floor. They can search soft-bottom sediments using their whiskers to find hidden prey that they get at using a combination of water jetting and suction (Marshall *et al.*, 2008). Some bearded seals in Svalbard have rust-colored faces and fore flippers. This coloration

Figure 2 Map showing the circumpolar, Arctic distribution of bearded seals (pink—the white area over the Arctic Ocean depicts the area that is usually quite consolidated sea ice).

is the result of iron-compounds from soft-bottom substrates sticking to the hairs while the animals feed and then chemically reacting with oxygen when brought to the surface. The rust material is actually stuck onto the hairs rather than in them.

Polar bears are the main predator of bearded seals, but walrus, killer whales, and Greenland sharks may also take bearded seals, particularly pups and juveniles. They are important as traditional food for humans in parts of their range.

IV. Behavior and Physiology

Bearded seals are largely solitary, although it is not usual to see them hauled out together in small groups along leads or at holes in the spring or early summer. It is quite unusual to see a bearded seal on land; they prefer to haul out on moving ice. They are rarely more than a body length from the water, and usually face toward the water. However, they are not wary in a general sense—in some areas such as Svalbard, Norway, they are very tame and can be approached by humans to within meters by boat without reaction.

The time of breeding appears to vary somewhat geographically, with peaks occurring sometime between late March and mid-May depending on the locality. Females give birth in a solitary fashion, on small drifting floes in areas of shallow water. Pups are born with a

thin layer of subcutaneous blubber, which is thought to be an adaptation to entering the water shortly after birth. Bearded seal pups swim with their mothers when they are only hours old. This precocial entry into the sea is likely a mechanism to avoid polar bear predation. Neonatal swimming skills develop quickly in this species, and pups can dive to depths more than 90 m and remain submerged for periods in excess of 5 min when they are only a few weeks old. They spend approximately half of their time in the water during the nursing period, which lasts a total of 18–24 days and commence foraging on solid food while still accompanied by their mother. Female bearded seals spend little time on the surface with their pups, beyond that which is necessary for nursing. Most of the time, they attend the pups from the water next to the floe on which the pup is resting at a given time. Females do leave their pups unattended for periods to forage during the lactation period (Krafft *et al.*, 2000). Mother-pup pairs tend to remain in an area for some days at a time, but can also move tens of kilometers from one day to the next. Pups grow quickly during the nursing period, gaining about 3.3 kg per day while drinking more than 7.5 l of milk per day. The fat content of the milk is quite stable through lactation, at about 50%. Bearded seal pups have leaner bodies at the time of weaning than less active phocid pups, but they still have significant blubber stores and a body composition that is about one-third fat (Lydersen and Kovacs, 1999).

Pups are about 110 kg when they are weaned. Weaning does not appear to be as abrupt as it is in most phocid species.

Mating takes place around the time that females leave their offspring. Male bearded seals perform vocal displays underwater to attract females and they also fight with other males during the breeding season. Their beautiful, but slightly melancholy, underwater songs are composed of a downward spiraling trill that can be heard for many kilometers in calm conditions (Cleator *et al.*, 1989). This behavioral trait of bearded seals is the most studied aspect of their biology. The onset of vocal displays (at least in captivity) is coincident with the onset of sexual maturity (Davies *et al.*, 2006). In the wild, males defend small patches of ocean with elaborate bubble displays, where they sing their songs intensively and repeatedly over a period of some weeks. Bearded seal calls exhibit marked geographic variation in call dialects, whereas repertoires of calls seem to be quite stable regionally (Risch *et al.*, 2007). Relatively little is known regarding the specifics of mating behavior of this species because pairing takes place in the water, but individual territorial males are known to occupy the same areas from 1 year to the next for at least several years (Van Parijs *et al.*, 2003), whereas transient males behave somewhat like “floaters” in the system (Van Parijs *et al.*, 2001).

Bearded seals shed their hair much more diffusely than other phocid seals, losing hair most of the year. But, they do have a concentrated period of molting in June when they prefer not to go into the water. At this time of year there is not a lot of ice available in coastal areas, so bearded seals can be seen in small groups on the available ice. Modestly dense aggregations can occur at this time of year, particularly in poor ice years.

The most notable sensory adaptation of bearded seals beyond their highly developed acoustic system is the extreme development of their facial vibrissae. They have approximately 244 highly sensitive, active-touch receptors within their facial whisker pads, which are among the most sensitive in the animal world with 1300 myelinated axons (“nerve-endings”) associated with each whisker (Marshall *et al.*, 2006). The extreme development of the sensitivity of the whiskers of bearded seals is presumably an adaptation to their benthic feeding habit.

V. Life History

Neonatal growth is fast, similar to all phocid seals, but growth over the rest of the first year of life is minimal by comparison. Female bearded seals reach sexual maturity when they are about 5 years old, whereas males are a bit older, usually 6 or 7 years when they reach maturity. Females give birth annually, similar to other phocid seals. Bearded seals normally live to an age of 20–25 years.

Some populations appear to follow an annual pattern of movement that follows the sea ice retreat in spring and expansion in the fall, whereas in other areas bearded seals seem to be quite stationary. This is likely primarily dependent on the availability of ice to haul out on during the summer season; calving glaciers for example often create ideal areas for bearded seals during summer in some coastal areas.

VI. Interactions with Humans

Bearded seals are an important subsistence resource for coastal people throughout much of the Arctic. Animals are harvested for use as human food, dog food, and for their thick leather, which is important for various traditional articles of clothing and for making skin

boats in Alaska, the Canadian Arctic, and in Greenland. Russia is the only country that has had a commercial-scale harvest of bearded seals. Soviet ships took catches that exceeded 10,000 animals in some years during the 1950s and 1960s. Quotas were introduced to limit the harvests of the declining populations in the Okhotsk and Bering seas, and the catch dropped to a few thousand bearded seals annually through the 1970s and 1980s. This hunt provided food for people and dogs and also fur-farm animal feed. Sinking losses are a serious problem when hunting bearded seals. During much of the year they sink when shot in open water or too close to edges; sinking loss is estimated to be as high as 50%.

Bearded seals fed on a wide variety of food types, many of them low in the food chain, so they tend to have low toxic chemical loads. The most obvious threat to this species, beyond overexploitation at a very local level, is climate change (Kovacs and Lydersen, 2008). Sea ice predictions suggest that the breeding habitat of bearded seals will decline dramatically in the decades to come.

This species has been kept in captivity in only one public aquarium, Polaria, in Tromsø, Norway.

Behavior, Overview

PETER L. TYACK

Marine mammalogists often divide behavioral research into categories defined by mode of study: “acoustics” is studied by recording underwater sounds with a hydrophone, “behavior” is often informally defined as that which can be seen by an observer watching animals, and “diving” is often studied by attaching tags to animals. This method-oriented view of behavior may be convenient for sorting different research traditions, but it obscures the integrated whole of behavior as it has been shaped by evolution. Each method yields its own view of behavior, but no one views alone can provide a complete picture.

Most behavioral ecologists divide behavior along functional lines, i.e., what is the problem the behavior has evolved to solve (Alcock, 1998)? The following is a short list of such problems:

- Foraging behavior: how to find, select, and process prey
- Predator avoidance or defense: the flip side of foraging from the prey’s point of view
- Dispersal and migration
- Competition and agonistic behavior
- Sexual behavior: how to find, court, and choose mates
- Parental behavior
- Social behavior and social relationships

This functional taxonomy of behavior is mirrored by Bradbury and Vehrencamp’s (1998) functional analysis of animal communication. A receiver can often be viewed as paying attention to a signal to answer a question related to one of these behavioral problems. When the receiver detects one signal out of a larger signal set, the signal can potentially help the receiver to reduce uncertainty about the correct answer. Bradbury and Vehrencamp (1998) suggest that a receiver’s questions can be divided into three categories (1) sender identity, (2) sender location, and (3) behavioral context. Depending on the problem, the receiver may be interested in different levels of recognition of the signaler: species, group, sex, age, or individual. Receivers usually need to know something about the location of the signaler: how far away is it? Is it within the receiver’s territory? Is it approaching or moving away? The behavioral contexts of animal communication bear a striking resemblance to the functional behavioral problems listed previously: conflict resolution, territory defense, sexual interactions, parent–offspring interactions, social integration, and environmental contexts such as those related to prey and predators. This article discusses marine mammal examples for each of these basic problems in the behavioral ecology of all animal species, with special emphasis on how the marine environment may affect adaptations of marine mammals.

I. Foraging Behavior: How to Find, Select, and Process Prey

The earliest studies of foraging in marine mammals focused on the stomach contents of dead animals in order to define what kinds of organisms were in the DIET of marine mammals. The best that observers could do in early field studies of living marine mammals was to identify behavior associated with feeding, where feeding was linked to observation of prey at the surface or chases, and so on. However, these observations do not do justice to the complex process by which animals find, select, and handle their prey. Increased efforts in foraging theory to identify the kinds of decisions faced by a foraging individual have focused attention on a more detailed view of the stages of foraging, and new techniques such as tags that can record behavior (Davis *et al.*, 1999; Johnson and Tyack, 2003) have improved our ability to collect the required data. This section discusses the various phases of foraging.

Marine mammals use every sensory modality available to find and select their prey. The optimal senses for solving a particular foraging problem depend on the setting. For example, vision is an excellent distance sense in air but has a limited range underwater. Even though polar bears (*Ursus maritimus*) are classed as marine mammals, they often hunt their prey in air and may use vision in air to search for their pinniped prey. Many seals and dolphins chase fish prey close enough to the surface to be able to use down-welling light to see their prey during daytime. Davis *et al.* (1999) have used video recorders attached to seals to capture images of prey as seals hunt. In many coastal areas, seals can see fish at ranges of 10 m or so. Deep-diving seals such as elephant seals (*Mirounga* spp.) have eyes specially adapted to the wavelengths and low light levels of the deep sea. Many deep-sea organisms have light-producing organs, and researchers have speculated that marine mammals may use vision to find bioluminescent organisms in the dark.

As terrestrial mammals, we humans are accustomed to thinking of vision as the best distance sense, but sound carries much better underwater than light. Some marine mammals have developed sophisticated adaptations to use sound for finding prey. Perhaps the best-known example is the sonar of dolphins. Dolphins and most toothed whales have an auditory system that is specialized for high frequencies, and they can produce a directional beam of intense high-frequency pulses of sound. Most toothed whales echolocate by producing a click and then listening for echoes from surrounding targets. When they are in a search mode, they may produce a slow series of clicks, listening for echoes. Madsen *et al.* (2005) used a tag to record echolocation clicks of foraging Blainville’s beaked whales (*Mesoplodon densirostris*) and echoes from prey. These whales typically detect several echoes from each click at varying time delays and ranges. When searching for prey, the beaked whale inter-click intervals are typically 0.4 sec, a two-way travel time corresponding to a range of about 300 m. Sometimes echoes from the seafloor are detected at ranges up to this maximum range. The prey whose echoes are recorded on the tag, however, are typically less than 15 m away from the clicking whale. The foraging whale will pass many of these targets by until it selects one. As the whale approaches to within a few meters of the prey, it changes from slow clicks to a rapid series of pulses with inter-click intervals of about 10 msec. Beaked whales, sperm whales (*Physeter macrocephalus*), and narwhals (*Monodon monoceros*) all show a pattern similar to that of foraging bats, where they search for prey with regular slow clicks and then accelerate clicks into a buzz as they capture prey. Sperm and beaked whales have an increase in angular acceleration at the end of the buzz as they maneuver to

capture the prey. Together, these results suggest that deep-diving odontocetes use slow series of clicks to monitor several targets at different ranges at the same time. When the whale has selected a prey item, it accelerates the clicks to get more rapid updates on the location of the prey as it maneuvers to capture it.

Although deep-diving toothed whales use echolocation to find prey in the dark depths, there is evidence that dolphins feeding in shallow waters use a combination of senses and cues to detect and select prey. When wild bottlenose dolphins (*Tursiops truncatus*) from inshore waters near Sarasota, Florida, are feeding, they produce echolocation clicks at very low rates (Nowacek, 1999). Dolphins in Sarasota had an overall average click rate of 0.39 click trains/min while foraging and a rate of 0.10 click trains/min while not foraging. Dolphins had the highest click rates and appeared to rely more upon echolocation when they were feeding on fish hiding in seagrass. In contrast, when dolphins were feeding in clear water over sand, they seldom clicked and appeared to rely primarily on vision. Gannon *et al.* (2005) showed that bottlenose dolphins turned toward playback of sounds from fish that are favored dolphin prey, indicating that dolphins may listen for the vocalizations of fish to detect select prey. The dolphins then appeared to use echolocation to pursue and capture the prey.

Dolphins and toothed whales are hunters who chase down individual prey items. Many species feed on highly mobile prey such as schooling fish. When a dolphin charges into a fish school, the fish usually disperse, and this can make it less efficient to find and chase down the remaining fish. Dolphins (Fig. 1) and killer whales (*Orcinus orca*) have been reported to coordinate their feeding so that some individuals keep the fish in a tight school as other individuals feed (Similä and Ugarte, 1993; Benoit-Bird and Au, 2003; Vaughn *et al.*, 2007).

Baleen whales have evolved to capture entire patches of prey in one mouthful. Balaenid whales, such as right (*Eubalaena* spp.) and bowhead whales (*Balaena mysticetus*), are specialized to feed on calanoid crustaceans. When balaenid whales feed, they swim through the prey patch with an open mouth. Because their baleen is very long

Figure 1 Dusky dolphins (*Lagenorhynchus obscurus*) exhibit coordinated feeding in Admiralty Bay, New Zealand. “Clean” headfirst re-entry leaps, shown here, are common during coordinated feeding; these leaps facilitate diving while allowing a dolphin to quickly catch a breath. The splash in the background is from an Australasian gannet (*Sula serrator*), which has just taken a plunge dive; gannets and other seabirds often feed in conjunction with dusky dolphins. Photo by Heidi Pearson.

and their head has a large cross-sectional area, they catch their prey by engulfing them in the water that flows into the mouth and out through the baleen. The basic problem faced by a feeding balaenid whale is to find a dense enough patch of prey to pay for the time and additional expense of swimming in the open-mouth foraging mode. Their prey move slowly enough that the feeding of balaenid whales is more like grazing than hunting. At times, balaenids coordinate their feeding by swimming in a staggered or “v shape” of up to 13 whales side by side. It is believed that such coordinated feeding keeps prey from escaping to the side, and may therefore more effectively “herd” prey towards each whale mouth (Würsig *et al.*, 1985).

Balaenopterid whales also feed on crustaceans along with fish, but their euphausiid prey are faster and more evasive than calanoid crustaceans. Balaenopterids also may capture schools of baitfish such as capelin, anchovy, sand lance, or even herring. These prey are more mobile than crustaceans, and balaenopterids have evolved a feeding mode that allows them to trap mobile prey. Balaenopterids have accordion-like pleats in the lower jaw, which can expand rapidly. When a balaenopterid feeds, it lunges while opening its mouth, forcing hundreds of gallons of prey and water into the mouth as the pleats expand. The whale then quickly closes its mouth, trapping the prey. The pleats then slowly contract, forcing the water through the baleen and leaving the prey behind. As with toothed whales, when balaenopterids such as humpback whales (*Megaptera novaeangliae*) feed on the most mobile schooling prey, such as herring, they may feed in coordinated groups. Perhaps the most striking reports concern a group of half a dozen or more female humpback whales who associated together each summer for several years in Southeast Alaska. Each individual played a specific role in prey capture, and their movements appeared to be coordinated with a regular series of vocalizations (D’Vincent *et al.*, 1985).

Marine mammals have evolved several different ways to feed on benthic prey that hide submerged in the sediment on the seafloor. Some bottlenose dolphins have been observed to echolocate on small sand dabs buried in the sand. The mustache of the walrus (*Odobenus rosmarus*) is exquisitely sensitive to touch, and walruses use the vibrissae in their mustache to detect prey in the sediment. Trained walruses have demonstrated remarkable abilities to use this mustache to determine the shape of objects, and presumably wild walruses use this ability to identify their favored prey within the sediment. Gray whales (*Eschrichtius robustus*) feed on benthic organisms by rolling more than 45° (usually to the right side), sucking mud and prey into the right side of their mouth and then straining out the prey with their baleen. Gray whales make distinctive pits, measuring about 1-m wide by up to 3-m long and about 1.5-m deep, in the seafloor when they feed in this way and these pits are big enough to be detected by sonar on surface ships.

Most marine mammals just swallow their prey whole, but some species face problems in handling their prey. Dolphins feeding on prey such as catfish with sharp spines may need to learn how to snap off the head and spines before they eat the rest of the fish. False killer whales (*Pseudorca crassidens*) measuring perhaps 3 m in length can capture a large mahi-mahi nearly half their size. It has been reported that one false killer whale may hold the fish while others rip off flesh. The most impressive prey handling among marine mammals involves the sea otter (*Enhydra lutris*), which feeds on shellfish such as abalone (*Haliotis* spp.) and sea urchins. Because these prey are too large or too strong for the otter to break the shell by biting it, most otters use a stone as a tool to open the shells. The sea otter will dive to get a shell, often carrying its stone tool in the axilla. When the otter surfaces, it lies with its stomach up with the stone on its stomach.

It then uses the stone either as a hammer or as an anvil, smashing the shell opens on the stone and then eating the flesh. It must be awkward to carry this stone while diving to feed, and some otters have simplified this by using a bottle for the same task. When the otter dives, it can leave the bottle floating on the surface and can then use it when it surfaces with shellfish.

II. Avoiding Predators and Defense from Predators

Many marine mammals are top predators and historically may not have faced heavy predation pressure. The primary predators for pelagic marine mammals over evolutionary time are the killer whale and sharks. However, in the last few centuries, humans have been extremely effective predators of marine mammals, driving some species such as the Steller's sea cow (*Hydrodamalis gigas*) to extinction. Seals on ice face the risk of predation from polar bears, and seals hauled out on beaches, especially pups, are at risk from other pinnipeds and terrestrial predators such as foxes. Seals on land are less mobile than at sea and appear to be at a higher risk of predation, for they will usually respond to the approach of a terrestrial predator by entering the water.

The great whales such as baleen and sperm whales are so large that their main predator is the killer whale. Killer whales live in stable groups. They attack large whales in groups and appear to coordinate their attacks in much the same way as a pride of lions (*Panthera leo*) or African wild dogs (*Lycaon pictus*) will attack a herd of ungulates, isolate an individual, and then hold it down to kill it. Baleen and sperm whales use their flukes as a weapon during such an attack, lashing them sideways through the water. Many cetaceans fall silent when a killer whale is detected nearby. After they have been detected, most small odontocetes appear to rely on speed to escape killer whales, whereas some pinnipeds may hide from them, either on the land or on the seafloor.

Early whalers had a predator's view of their marine mammal prey, and their observations make up an unusual body of data on predator defense in some species. While baleen whales often travel in groups, there is little sign of social defense from predators. The young calves of baleen whales may be more vulnerable to predation than adults, but a female with her young calf will tend to be sighted alone rather than with other whales in a group, suggesting that females with young may disperse to reduce the chance a predator will detect them. Sperm whales, however, appear to have a well-developed social defense from dangerous predators such as killer whales and human whalers. Sperm whale calves are born into groups of about 10 adult females with young. Because newborn calves cannot dive deep enough to follow their mothers for their 40- to 50-min foraging dives, they remain nearer the surface when the adults feed. The adults desynchronize their dives, however, so that there is less time that young calves are unattended by an adult. If a predator attacks the group, calves or wounded animals in the group will be surrounded by the rest of the adults. Most adults will face in toward the animal needing protection and will lash their tails facing outwards. This must have been a formidable defense against killer whales but was less successful with human whalers. Whalers knew how predictable this behavior was and would often intentionally injure one animal and leave it. They then could slowly kill each adult attending the injured animal, knowing that adults would be unlikely to abandon an injured group member.

The first step in lowering the risk of predation is to avoid detection. Some seals alter their foraging behavior apparently to avoid visual detection by predators. Female Galapagos fur seals

(*Arctocephalus galapagoensis*) are less likely to make their normal foraging trips when the moon is full. It has been suggested that this avoids the risk that a predator will see them in the moonlight. Because most small cetaceans have little chance to defend themselves from killer whales, they must emphasize strategies to avoid detection by these predators. Dusky dolphins (*Lagenorhynchus obscurus*) mill in the surf zone as killer whales pass by offshore. They will even hide in tidal lagoons and, at times, become stranded in these lagoons until the next tide. Baleen whales also have strategies to avoid detection by killer whales. For example, gray whales that were exposed to experimental playback of the sounds of killer whales fled into shallow water. The surf zone and kelp beds may be particularly good places to hide from an echolocating predator because they absorb and reflect sound, making echolocation more difficult. There is some evidence that killer whales may even have evolved countermeasures to these predator-avoidance strategies. There are two sympatric populations of killer whales in the inshore waters of the Pacific Northwest. One population, called residents, feeds primarily on fish; the other population, called transients, feeds primarily on marine mammals. When residents feed on salmon, a fish with poor hearing, the killer whales make regular series of loud clicks. When transients feed on acoustically sensitive marine mammals such as porpoises, dolphins, or seals have a much stealthier pattern of echolocation (Barrett-Lennard *et al.*, 1996). They produce fewer clicks, and those clicks that are produced are fainter and are produced with an erratic timing. These features appear to be designed to make marine mammal prey less likely to detect and avoid the killer whale.

Cetaceans are also subject to parasitism from animals that bite tissue without causing serious injury. In the tropics, many dolphins are subject to attack from the cookie cutter shark (*Isistius brasiliensis*), which takes bites of skin and blubber about 3 to 5 cm in diameter. Right whales (*E. australis*) in coastal bays in Argentina are subject to attack from seagulls, which peck chunks of skin and blubber from the back of a whale floating at the surface. Although this can evoke a strong behavioral reaction from the whale, right whales do not seem to have an effective defense from this attack, which may be made worse by the growth of seagull populations in areas with human settlements.

Evidence in several cetacean species shows that when an animal has been injured, other members of the group may support them for hours or days. Because marine mammals must breathe air, if they cannot surface on their own, they are at great risk of drowning. This caregiving behavior may cost the caregivers but at potential benefit to the incapacitated member of the group.

III. Migration and Orientation

Most marine mammals are excellent swimmers, and many species make annual migrations of thousands of kilometers. Most baleen whales have an annual migratory cycle that affects many aspects of their life. These whales are adapted to take advantage of a burst of productivity in polar waters during the summer. Baleen whales store enough energy reserves during their intensive summer feeding season to last for most of the year, and this annual feast/fast cycle helps to select for large size. A humpback whale that is born in the winter in a tropical breeding ground near 20° of latitude will typically migrate in the spring to summer feeding grounds in polar waters near 40–60° of latitude. Humpbacks have traditional feeding grounds and an individual will often visit specific banks or inshore feeding areas of scales of tens of kilometers. Dolphins on both coasts of the United States also show annual migrations of 1000 km

or more. Off the east coast of the United States, harbor porpoises (*Phocoena phocoena*) and bottlenose dolphins tend to move north in summer and south in winter. It is not known whether the colder temperatures in the north during winter are more important for this seasonal migration than are seasonal changes in prey distribution. Some pinnipeds also have annual migrations of thousands of kilometers. For example, northern elephant seals (*M. angustirostris*) that breed and calve near San Francisco may migrate as far as the Aleutian Islands to feed. Both males and females swim north after the breeding season, following the California Current. Some male elephant seals feed along oceanfronts on the boundary of the Alaska Stream. Very little is known about how marine mammals orient and navigate during migration, and even less is known about how they find oceanographic features such as fronts, which can be important cues for good places to forage.

Other species have more limited annual home ranges. The home ranges of sea otters may be limited to 1–17 km of coastline. Sea otters show strong fidelity to their home range. When 139 sea otters were flown 200 km to an offshore island as part of a reintroduction program, most of the otters left and at least 31 managed to return to the area where they had been captured. Bottlenose dolphins in the inshore waters of Sarasota, Florida, tend to be sighted within a home range of 125 km². “Resident” killer whales in the inshore waters of Puget Sound have seasonal ranges limited to an area several tens of kilometers by about 100 km. Even non-migratory species can be highly mobile. For example, resident killer whales will often swim 100 km or more in a day. Bottlenose dolphins and sea otters may suddenly leave their home ranges and swim 100 km away from the normal range.

IV. Competition and Agonistic Behavior

When animals are competing for the same resource, they may fight for access. Among animals that exploit a specific substrate, this competition may be for territory. This kind of territorial defense has been well described for many pinnipeds during the breeding season. Female pinnipeds haul out onto beaches or ice to give birth, and many species mate on land as well. This concentration of females creates a valuable resource for males. Males in many species will defend an area of beach from other males and may attempt to monopolize opportunities to mate with females there. For animals that live in the open ocean, resources are not likely to be as tied to a particular location, but rather will move. Animals in this setting are more likely to defend a particular resource at one time than to defend a patch of real estate. For example, a male humpback whale will not defend a specific location during the breeding time, but a male escorting a female will fight other males to limit their access to the female.

This pattern of males competing for access to females, either by defending a group of females or a territory (Fig. 2), is common among mammals and leads to behavioral and morphological adaptations. Males in these species are often larger than females. Some of the most extreme sexual dimorphism among mammals occurs in marine mammals where a successful male may mate with many females in one breeding season. For example, male elephant seals may be 10 times heavier than females (McCann *et al.*, 1989), and mature male sperm whales may be up to 3 times heavier than females (Connor *et al.*, 1998). Some behaviors appear to function to increase the apparent size of a male and may function as visual displays. For example, male humpback whales competing for access to females may lunge with their jaws open, expanding the pleated area under the lower jaw with water. Several observers have suggested this may function to increase the apparent size of a competitor. Males may have larger

Figure 2 A male sea otter (*Enhydra lutris*) patrols his territory in Prince William Sound, Alaska. The function of patrolling is to search for estrous (receptive) females and intruding males. Females (which are 35% smaller than males) may be attracted to resources contained within the territory such as prey, protection from wind and waves, and resting areas. Photo by Heidi Pearson.

weapons such as teeth or tusks than females. This is particularly striking in beaked whales. In most beaked whale species, the teeth may not erupt at all in females, whereas one or two pairs of teeth erupt in the lower jaw of males at about the time of sexual maturity. Males have scarring patterns, suggesting that these “battle teeth” are used in fights. Males may also have protection such as areas of toughened skin. Male elephant seals, for example, often strike one another on the chest, and this area has thickened and hardened skin.

Fighting often involves a gradually escalating series of threats and responses. Overstrom (1983) presented data suggesting this kind of escalated display for bottlenose dolphins in captivity. The earliest stages of a threat may involve one dolphin directing pulsed sounds toward another. The threat may escalate if the dolphin produces an open-mouth threat display while emitting distinctive bursts of pulses. The longer in duration or louder in sound intensity the pulses are, the stronger the threat may be. As another step in escalation, the animal may accentuate this display with abrupt vertical head movements. One of the most intense threat displays in dolphins is called the jaw clap. A dolphin starts the jaw clap display with an open mouth. The jaw clap consists of an abrupt closure of the gaping jaw, accompanied by an intense pulsed sound. Many of the agonistic visual displays used by bottlenose dolphins are related to movements used to inflict injury. For example, the open-mouth display looks like the first step in preparing to bite.

Some animals live in situations where they interact repeatedly with the same individuals repeatedly. In this setting, animals may develop a predictable hierarchy of who wins and loses in agonistic interactions. Male elephant seals establish a dominance hierarchy on the breeding beaches. The pace of competition is highest before the females appear on the beach. When males are competing using territory or dominance for access to females, they often sort out their competitive relations before the peak of the mating season. Dominance relations have also been studied in captive bottlenose dolphins. The most obvious competitive behaviors are violent fights in which each opponent responds to aggression with an aggressive response. This is not as useful for determining winners or losers as observation of more subtle submissive behaviors. A fight in which each opponent produces aggressive behaviors with no submission does not have an obvious winner or loser, but an animal can be identified as a loser of an interaction if it responds to a neutral or aggressive behavior with a submissive

one. Systematic observations of winners and losers in dyadic agonistic interactions reveal that adult males are dominant over adult females. The rate of agonistic interactions is higher in males than in females. The low rate of female agonism means that dominance is rarely contested among females, and female dominance can be stable over years. Two male dolphins in a pool reversed dominance status several times over the years of study. Male dominance relations were characterized by periods of relatively low agonism interspersed with periods of high rates of agonism when one male challenged the other. Little is known about dominance relations among wild cetaceans, but because individuals in many species interact repeatedly with the same conspecifics and can recognize different individuals, dominance relations are likely to be important.

V. Courtship and Sexual Behavior

Charles Darwin made a distinction between features selected to improve chances of mating and features selected for survival. He called selection for mating sexual selection to discriminate it from natural selection. Darwin defined two kinds of sexual selection: intersexual and intrasexual. Intersexual selection can increase the likelihood that an animal will be chosen by a potential mate; intrasexual selection can increase the likelihood that an animal will outcompete a conspecific of the sex for fertilization of a member of the opposite sex. Reviews that are more recent have included a third mode of sexual selection where a male may attempt to limit the choice of a female by coercing her to mate with him and not to mate with other males.

Differences between male and female mammals alter the costs and benefits of different elements of reproduction. Female mammals all gestate the young internally and are specialized to provide nutrition to the young after birth. In many species, and most marine mammal species, the female provides most of the parental care. Reproduction in most female mammals is limited by the amount of energy and nutrition they can acquire for pregnancy and lactation. Male mammals usually provide much less parental care to their young. This means that reproduction in most male mammals is limited by the number of females with which they can mate. This situation often leads to a polygynous mating system in which there is high variability in the mating success of different males, with some males mating with many different females and other males mating with none. Males in polygynous species often fight other males for access to females. This often leads them to have weapons and to be larger than females; the intensity of polygyny is sometimes estimated by assessing the difference in size of males vs females. As discussed earlier, some of the most extreme cases of sexual dimorphism in mammals occur in marine mammals.

Most traditional discussions of mating systems emphasize male strategies. For example, polygyny occurs where one male mates with more than one female; the number of males with which a female mates is not included in the definition. While the variance of reproductive success is higher in males than in females for most marine mammal species, female reproductive strategies can influence male strategies and impacts other areas of social behavior. Areas in which female reproductive strategies vary include the following:

- How seasonal and synchronized is estrus?
- Do females have one (monoestrous) or more (polyestrous) estrous cycles per year?
- Do females ovulate spontaneously or do they require the presence of a male to ovulate?
- How many males are available during estrus?
- Can the female select a mate?

If a female mates with more than one male, can she influence which male fertilizes the egg?

There are different patterns for the reproductive strategies of males and females in different polygynous mating systems. This article describes five different categories of male strategy that are used in the literature. The *resource defense strategy* is adopted by males who defend a resource used by females around the time of mating. In this case females do not select a mate but rather select an area for breeding and mate with the male defending this area. The *female defense strategy* is used by males who stay with a female and prevent other males from mating with her while she is receptive. The *sequential defense strategy* differs from the female defense strategy in that a male will defend a female through mating, but then leave in search of other mating opportunities. The distinction between these two male strategies depends in part on whether the female is mono- or polyestrous and on the degree of synchronization of different females. The strategy called by the name “scramble competition” occurs when a male searches for a receptive female, mates with her, and then moves on to search for another female without preventing access for other males. The last three models lie on a continuum of male strategies between pure guarding and pure roving. Whitehead (1990) used modeling to suggest that males should rove between groups of females if the duration of estrus is greater than the time it takes males to swim from group to group. At any one time, a male’s decision to leave or stay with a group probably includes other factors, such as his assessment of what other males are doing. A *lekking strategy* occurs when males aggregate in an area with no resources needed by the female and produce displays to attract the female. In leks, males provide no parental care and females select a male for mating.

Some of these male strategies preempt the ability of a female to select a male for mating. In the resource defense model, the female does not select a particular male, but rather will select a particular place with the resource she needs. She will then be most likely to mate with the male who happens to be defending this location. When a female can and does choose a male for mating, she may select a mate based on several different criteria. A female may select a male for inherent qualities based on indicators such as size, age, or an advertisement display. She may assess competition between males and select one based on this performance. In some species, males may compete for access to a particular location, and a female can select a good competitor by mating with a male in such a preferred spot. In some species, a female may mate with several males and allow competition between their sperm to determine which male fertilizes the egg. The males in this system would be likely to devote more resources to sperm production, sperm swimming speed, and so on than species that compete by fighting. Evidence shows that sperm competition may play a role in some cetaceans. Odontocete cetaceans have larger ratios of testis to body weight than most mammals. This contrast is also seen among mysticetes. Balaenid whales form mating groups with multiple males, but there is little sign of fighting between the males. Male right whales have testes weighing more than 900 kg; their testes weigh more than six times what would be predicted for a typical mammal of their body size (Brownell and Ralls, 1986). In contrast, humpback whale males, which fight for access to females, have testes weighing less than 2 kg.

Marine mammals are highly mobile, and in the open ocean it seems unlikely that males could defend a resource in a way that would preempt the ability of a female to use the resource yet mate with another male. Resource defense is much easier to envisage on land. While pinnipeds spend much of their life at sea, they haul out on a

solid substrate (land or ice) to give birth. Some of these species, such as elephant seals, also mate on land. Females have specific requirements for a place to give birth, and they often return to traditional areas. The selection by females of specific sites for mating and giving birth creates an opportunity for males to defend these sites in order to increase their chances of mating with the females who are selecting the site. In most otariid seals, males appear to employ resource defense strategies for mating. In many of these species, males will arrive before the females and will fight to establish territories that they defend from other males. In some phocid species that mate at sea, males may establish and defend territories just off the beach where females give birth. Genetic analyses of paternity, however, show that the fathers of some pups are not among the territorial males. This suggests that some males have alternate mating strategies.

There are marine mammal species in which males may adopt a strategy of attempting to preempt female choice by guarding a receptive female and preventing her from mating with other males. Northern elephant seal males arrive at breeding beaches before females and compete for dominance status and for position on the breeding beach. A dominant male can guard a group of females and prevent access for other males. If an alpha male can maintain his status, he can prevent access to a group of females for the entire breeding season. This pattern of guarding a group of females is less likely for cetaceans, which are highly mobile. Most male cetaceans would take a shorter time to swim between groups than the duration of female estrus, thus favoring a roving strategy. There is some evidence for sequential female defense in bottlenose dolphins. In field studies of Indian Ocean bottlenose dolphins (*T. aduncus*) in Shark Bay Western Australia and common bottlenose dolphins in Sarasota, Florida, groups of two or three adult male bottlenose dolphins may form consortships with an adult female (Connor *et al.*, 2000). A coalition of males may start such a consortship by chasing and herding a female away from the group in which they initially find her. Some of these consortships appear to be attempts by the males to limit choice of mate by the female, who may try to escape from the males. Males in these alliances may form consortships with several different females during a breeding season.

Many pinnipeds and some baleen whales produce reproductive advertisement displays that may play a role in mediating male–male competitive interactions and may also be used for female choice of a mate. Male humpback whales sing long complex songs during the winter breeding season. Singing males are usually alone and they usually stop singing when joined by another whale (Tyack, 1981). Aggressive behavior is often seen when a male joins a singer; when a female joins, apparent sexual behavior has been observed. Male humpbacks do not seem to be able to defend any resource needed by females on the breeding grounds, so this mating system has been described as a kind of floating lek. Vocal reproductive advertisement displays have also been reported for bowhead whales and many species of seal, including polar ice-breeding seals and harbor seals (*Phoca vitulina*). Most of the phocid seals known to produce songs mate at sea. These seals breed in conditions that foster the development of leks. Females gather to breed on isolated sites, but they mate after they have weaned their pups, so there are few resources males could defend. Females are so mobile that it would be difficult for males to prevent them from gaining access to other males. The females are already concentrated in hot spots around the places where they give birth. This creates an ideal setting for males to cluster near the females, producing advertisement displays to attract females for mating. Some of the songs of whales, of ice-loving seals and the bell-like sounds of the walrus stand as testimony to the

power of sexual selection to fashion complex and fascinating advertisement signals.

VI. Parental Behavior

All mammals have some parental care when the female lactates and suckles the young. The mothering role of the female is critical to mammalian life, and female parental care impacts many aspects of social behavior. There is enormous variability in parental care among marine mammals. Some phocid seals give birth to their young on unstable ice floes, where they cannot count on a stable refuge for the young. The hooded seal (*Cystophora cristata*) has responded to this situation by an intense 4-day period of lactation when the young pup doubles in weight. While female phocid seals generally stay with their young pup and fast while suckling, otariid females will leave their young in order to feed at sea and then they return to suckle the pup. This pattern leads to a large difference in duration of lactation, from 4 days to 2 months in phocids and from 4 months to 2 years in otariids. Most pinnipeds have yearly breeding seasons, so the longest periods of lactation are limited to about 12 months. However, tropical Galapagos sea lions (*Zalophus wollebaeki*) at times nurse their young for more than 12 months and produce young at intervals greater than a year. Phocoenid porpoises and some baleen whale species also have a strong annual breeding cycle. Some baleen whales, such as the blue whale (*Balaenoptera musculus*), wean their young after about 7 months so that the young can start taking solid food during the summer feeding season. All porpoises and baleen whales wean the young within a year. Toothed whales other than the porpoises stand at the other extreme of having very prolonged periods of parental care when the young are dependent. Bottlenose dolphins only 3 m or so in length often suckle the young for 3–5 years, which is remarkably long considering that the 30-m blue whale can wean the young in 7 months.

The longest periods of parental care known among marine mammals involve sperm whales and short-finned pilot whales (*Globicephala macrorhynchus*). In both species, mothers appear to suckle some calves for up to 13–15 years. The young may start to take some solid food by the first few years of life, but this suckling indicates a remarkably long period of dependency for the young. Adult female pilot whales typically start having young by 8–10 years, but by the time they are near 30–40, many cease to reproduce (Marsh and Kasuya, 1984). The ovaries become nonfunctional in these nonreproductive females, showing changes similar to those of human females after menopause. Female pilot whales may live into their 50s, suggesting that they may have a life expectancy 15–20 years after becoming nonreproductive. Most students of life history believe that the life history evolves to maximize lifetime reproductive success. If this has influenced the life history of pilot whales, it suggests that females switch their reproductive effort from having new offspring to parental care of their existing young. The 15- to 20-year duration of this period suggests that 15–20 years of parental care are required for the young to succeed or that these older females are caring for other kin, perhaps in a grandparental role.

VII. Social Behavior and Social Relationships

Not only do marine mammals show a broad range in the duration of the maternal bond, but also there is great diversity in the duration of social bonds in general, and especially in the importance of individual-specific social relationships. Resident killer whales have the most stable social groups known among mammals: no dispersal of either sex has been described. The only way group composition

changes among the resident killer whales of the Pacific Northwest is for an animal to die or for a new animal to be born. The best-known vocalizations from killer whales are group-distinctive repertoires of stereotyped pulsed calls. In contrast, bottlenose dolphins have very fluid social groups. In their fission–fusion society, group composition changes on a minute-by-minute and hour-by-hour basis. However, some individuals may have strong social bonds and be sighted together for years at a time. As was just discussed in the section on parental care, bottlenose dolphin calves suckle for 3–5 years. Adult male bottlenose dolphins may also form coalitions with one to two other unrelated males. Members of a coalition tend to be sighted together 70–100% of the time, and alliances may last for over a decade. It is thought that males form alliances to improve their chances of mating with females, but lone males are also successful breeders. Males within a coalition often have highly coordinated displays, both when feeding and when escorting a female. Each bottlenose dolphin produces an individually distinctive whistle vocalization called a signature whistle, which is probably used for individual recognition (Watwood *et al.*, 2004).

In sperm whales, males have different life history patterns than females. Calves are born into matrilineal groups of females and young. Each matrilineal unit numbers about 10 animals, but often two units associate for days at a time. Males may leave their natal groups when 5–10 years of age, and they then will join bachelor groups. As males grow, they move to higher latitudes and associate in smaller groups of males. As the males approach social and sexual maturity at 20–25 years of age, they are increasingly likely to associate temporarily with female groups during the breeding season, when they may mate with females. The social relationships of males thus change over their lifetime, and adult males appear to have only temporary associations. Young females may stay with their natal groups or may leave, but once they reach sexual maturity at 8–10 years of age, they will tend to associate with the same adult females for decades at a time. Because the matrilineal groups often join with other groups but segregate into the original groups, the females must recognize group members over periods of decades. Sperm whales make rhythmic patterns of sounds called codas. Early reports reported individually distinctive codas, but there are also shared codas that vary with the geographic region. Most of the variation in codas involves differences between groups, and it has been suggested that codas may reaffirm social bonds when a group joins after dispersing to forage. Female sperm whales must have stable social relationships with specific other individuals. These family groups appear to be the basic social unit of sperm whales, with a primary function of vigilance against predators and social defense of calves (Whitehead, 2003).

Baleen whales may feed in groups as do sperm whales, but female baleen whales appear to differ from sperm whales in the importance of group care of young. On the feeding grounds, baleen whales of all sexes are often seen in groups of varying sizes. For humpback whales, the size of the feeding group correlates with the horizontal extent of the prey patch. However, during the breeding season, when a female humpback has a calf, she is extremely unlikely to associate with another adult female. When one or more adults escort a female during the breeding season, the escorts are usually males. In baleen whales there is much less evidence for long-term social bonds than among most toothed whales. Odontocetes with little evidence for stable bonds are species such as the harbor porpoise and delphinids of the genus *Cephalorhynchus*, which also appear to have fluid groupings with few social bonds more stable than the mother-calf bond, which lasts less than 1 year in the porpoise. However, future research may find social bonds that have not yet been described.

There appears to be a correlation between the social relations of marine mammals and their communication patterns (Tyack, 1986). Baleen whales and pinnipeds with large apparently anonymous breeding aggregations use reproductive advertisement displays to mediate male–male and male–female interactions on the breeding grounds. Killer whales with highly stable groups produce group-specific repertoires of stereotyped calls. Seals and dolphins with strong individual-specific bonds use a variety of different vocalizations for individual recognition, but no such recognition signals are known for porpoises or *Cephalorhynchus*. Sperm whales appear to use deceptively simple clicks to produce a diverse set of signals consistent with their diverse social groupings.

VIII. Conclusions

Marine mammals face the same basic problems that have been identified by behavioral ecologists for all animals. However, marine mammals live in an environment that differs in many important ways from the terrestrial environment. Studies since the 1980s have provided ever-growing opportunities for fascinating comparisons between marine mammals and their terrestrial relatives and between the diverse taxa that live in the sea.

Beluga Whale

Delphinapterus leucas

GREGORY M. O’CORRY-CROWE

I. Characteristics and Taxonomy

The beluga whale is a member of the Monodontidae, the taxonomic family it shares with the narwhal, *Monodon monoceros*. Its name, a derivation of the Russian “beloye,” meaning “white,” appropriately enough captures its most distinctive feature, the pure white color of adults (Fig. 1). The Irrawaddy dolphin, *Orcaella brevirostris*, was considered by some to also be a member of this family. Although superficially similar to the beluga, recent

Figure 1 Beluga whale, *Delphinapterus leucas*. Flip Nicklin/Minden Pictures.

genetic evidence strongly supports its position as a member of the family Delphinidae (Lint *et al.*, 1990; LeDuc *et al.*, 1999). The earliest fossil record of the monodontids is of an extinct beluga *Denebola brachycephala* from late Miocene deposits in Baja California, Mexico, indicating that this family once occupied temperate ecozones (Barnes, 1984). Fossils of *D. leucas* found in Pleistocene clays in northeastern North America reflect successive range expansions and contractions of this species associated with glacial maxima and minima.

The beluga whale is a medium-sized toothed whale, 3.5–5.5 m in length and weighing up to 1500 kg. Males are up to 25% longer than females and have a more robust build. As their genus name (“..apterus”—without a fin) implies, they lack a dorsal fin and are unusual among cetaceans in having unfused cervical vertebrae allowing lateral flexibility of the head and neck. They possess a maximum of 40 homodont teeth, which become worn with age. Recent studies have found that beluga whales live much longer than previously thought. Levels of the radioisotope ^{14}C rose sharply in the marine environment in the late 1950s because of nuclear bomb testing, and researchers were able to detect this increase in growth layers in beluga teeth. Using this increase as a reference point they determined that beluga whales most likely lay down only one growth layer group a year, rather than two (Stewart *et al.*, 2006). As well as doubling the maximum-recorded age from around 40 to 80 years, this discovery has increased the age of first reproduction and necessitated a revision of other life history parameters. Neonates are about 1.6 m in length and are born a gray-cream color that quickly turns to a dark brown or blue-gray. They become progressively lighter as they grow,

Figure 2 The worldwide distribution of the beluga whale. The northernmost extent of its known range is off Alaska and northwest Canada and off Ellesmere Island, West Greenland, and Svalbard ($>80^{\circ}\text{N}$). The southern limit of distribution is in the St. Lawrence River in eastern Canada ($47\text{--}49^{\circ}\text{N}$).

changing to gray, light gray, and finally becoming the distinctive pure white by about age 14 in females and 18 in males (Fig. 3).

Belugas are supremely adapted to life in cold waters. They possess a thick insulating layer of blubber up to 15-cm thick beneath their skin, and their head, tail, and flippers are relatively small. The absence of a dorsal fin is believed by some to be an adaptation to life in the ice or perhaps as a means to reduce heat loss. In its place, belugas possess a prominent dorsal ridge that is used to break through thin sea ice.

II. Distribution and Abundance

The beluga or white whale inhabits the cold waters of the Arctic and subarctic (Fig. 2). Variation in body size across the species range has been taken as evidence of separate populations. The nonuniform pattern of distribution and predictable return of belugas to specific coastal areas further suggests population structure and has led to the treatment of these summering groups as separate management stocks. Re-sightings of marked or tagged individuals as well as differences in contaminant signatures and limited evidence of geographic variation in vocal repertoire add support to the independent identification of a number of these stocks. Although all are valid to varying degrees, many of these methods used for stock identification have limitations due to incomplete knowledge on year-round distribution, movement patterns, breeding strategies, and social organization. They provide little or no information on rates of individual or genetic

exchange, and although phenotypic differences are highly suggestive, they may not provide evidence of evolutionary uniqueness.

A number of molecular genetic studies confirmed that whales tend to return to their natal areas year after year and that dispersal among many separate summering concentrations is limited, even in cases where there are few geographic barriers (Brown Gladden *et al.*, 1997; O'Corry-Crowe *et al.*, 1997). These molecular findings reveal that knowledge of migration routes and destinations appears to be passed from mother to offspring, generation after generation. Such cultural inheritance of information leads to the evolution of discrete sub-populations, among which there is little dispersal. It is possible that many of these sub-populations may overwinter in a common area and that a certain amount of interbreeding may occur at this time. (deMarch *et al.*, 2002) Regardless of such potential gene flow, in situations where management is concerned with the degree of demographic connectivity among areas, demonstrating that few animals disperse among sub-populations is sufficient evidence to designate them as separate management stocks.

III. Ecology

The evolutionary history and ecology of belugas are inextricably linked to the extreme seasonal contrasts of the north and the dynamic nature of the sea ice. As well as adaptation to the cold, life in this region has necessitated the evolution of discrete calving and possibly mating seasons, annual migrations, and a unique feature distinguishing it from most other cetaceans, an annual molt.

Figure 3 Beluga whales concentrating near the coast during the brief summer. Note the dark to light gray color of younger animals compared to the white of adults. Flip Nicklin/Minden Pictures.

Figure 4 Aggregations of beluga whales interacting and rubbing on the substrate of a shallow estuary during the summer molt. Flip Nicklin/Minden Pictures.

As the sea ice recedes in spring, belugas enter their summering grounds, often forming dense concentrations at discrete coastal locations, including river estuaries, shallow inlets, and bays (Fig. 3). Several explanations have been proposed as to why belugas return to these traditional summering areas. In some regions, sheltered coastal waters are warmer, which may aid in the care of neonates. The occupation of estuarine waters also coincides with the period of seasonal molt. Belugas have been observed to actively rub their body surface on nearshore substrates (Smith *et al.*, 1992; Fig. 4), and the relatively warm, low-salinity coastal waters may provide conditions that facilitate molting of dead skin and epidermal regrowth (St. Aubin *et al.*, 1990; Smith and Martin, 1994). Belugas feed on a wide variety of both invertebrate and vertebrate benthic and pelagic prey. In some parts of their range it is clear that belugas are feeding in nearshore waters on seasonally abundant anadromous and coastal fish such as salmon, *Oncorhynchus* spp.; herring, *Clupea harengus*; capelin, *Mallotus villosus*; smelt, *Osmerus mordax*; and saffron cod, *Eleginus gracilis* (Kleinenberg *et al.*, 1964; Seaman *et al.*, 1982). The relative importance of the above factors in determining coastal distribution patterns may vary among regions depending on environmental and biological characteristics (Frost and Lowry, 1990). It is clear, however, that belugas exhibit some degree of dependence on specific coastal areas.

In many areas of the Arctic, belugas soon leave these coastal areas to range widely off shore. Satellite tracking has recorded

belugas moving up to 1100 km from shore and penetrating 700 km into the dense polar cap where ice coverage exceeds 90% (Suydam *et al.*, 2001). How these animals find breathing holes in this environment is still a mystery. Analysis of dive profiles suggests that beluga whales may combine the use of sound at depth to find cracks in the ice ceiling overhead. Diving data also indicate that belugas are probably feeding on deepwater benthic prey as well as ice-associated species, including polar cod, *Boreogadus saida*, closer to the surface (Martin *et al.*, 1998; Richard *et al.*, 2001).

Little is known about the distribution, ecology, or behavior of beluga whales in winter. In most regions belugas are believed to migrate in the direction of the advancing polar ice front. However, in some areas belugas may remain behind this front and overwinter in polynyas and ice leads. In the eastern Canadian Arctic some belugas overwinter in the North Water, a large area of open water in northern Baffin Bay (Finley and Renaud, 1980), while in the White, Barents, Kara and Laptev Seas belugas may occur year-round, remaining in polynyas in the deeper water during winter (Kleinenberg *et al.*, 1964; Boltunov and Belikov, 2002).

Killer whales (*Orcinus orca*), polar bears (*Ursus maritimus*) and humans prey on beluga whales. Belugas sometimes become entrapped in the ice where large numbers may perish or be hunted intensively by human.

IV. Behavior and Physiology

In contrast to the frozen smile of the oceanic dolphins, the ability of belugas to alter the shape of their mouth and melon enables them to make an impressive array of facial expressions. The lateral flexibility of the head and neck further enhances visual signaling and enable beluga whales to maneuver in very shallow waters (1–3 m deep) in pursuit of prey, to evade predators, and generally exploit a habitat rarely used by other cetaceans.

Belugas typically swim in a slow rolling pattern and are rarely given to aerial displays. In nearshore concentration areas, however, such as Cunningham Inlet on Somerset Island in the Canadian High Arctic, belugas may engage in more demonstrative behaviors including spy hopping, tail waving, and tail slapping (Fig. 4).

Studies using satellite-linked transmitters attached to free-swimming whales have confirmed that beluga are capable of covering thousands of kilometers in just a few months, in open water and heavy pack ice alike, while swimming at a steady rate of 2.5–6 km/hr (Lydersen *et al.*, 2001; Suydam *et al.*, 2001). Sensors on these transmitters have also recorded belugas regularly diving to depths of 300–600 m to the sea floor and utilizing different oceanographic regimes (Lydersen *et al.*, 2002). In the deep waters beyond the continental shelf belugas may dive in excess of 1000 m, where the pressure is 100 times that at the surface, and remain submerged for up to 25 min (Martin *et al.*, 1998; Richard *et al.*, 2001)!

Belugas are sometimes seen singly but more commonly occur in groups of 2–10 that may aggregate at times to form herds of several hundred to more than a thousand animals. Single animals are always large adults, while in mixed herds adult males may form separate pods of 6–20 individuals. Adult females form tight associations with newborns and sometimes a larger juvenile, presumably an older calf. These “triads” may join similar groupings to form large nursery groups. At certain times of the year, age, and sex segregation may be more dramatic than at others with males migrating ahead of, or feeding apart from females, young, and immatures. In general, group structure appears to be fluid, with individuals readily forming and breaking brief associations with other whales. Apart from cow–calf pairs there appear

to be few stable associations. However, considering the diverse vocal repertoire of beluga whales including individual signature calls, their wide array of facial expressions, and the variety of interactive behaviors observed, as well as the numerous accounts of cooperative behavior, this species appears capable of forming complex societies where group members may not always be in close physical proximity to each other.

In areas of open water beluga whales may divide their days into regular feeding and resting bouts. Belugas appear to predominantly hunt individually, even when within a group, but have also been observed to hunt cooperatively. A typical hunting sequence begins with slow directed movement combined with passive acoustic localization (search mode) followed by short bursts of speed and rapid changes of direction using echolocation for orientation and capture of prey (hunt mode) (Bel'kovitch and Sh'ekotov, 1990).

The beluga possesses one of the most diverse vocal repertoires of any marine mammal and has long been called the “sea canary” by mariners awed by its myriad sounds reverberating through the hulls of ships. Communicative and emotive calls are broadly divided into whistles and pulsed calls and are typically made at frequencies from 0.1 to 12 kHz. As many as 50 call types have been recognized; *groans*, *whistles*, *buzzes*, *trills*, and *roars* to name but a few. Although some geographic variation is apparent, efforts to determine whether there are substantial regional differences or dialects have been hampered by differences among bioacousticians in the categorization of vocalizations. Belugas are capable of producing individually distinctive calls to maintain contact between close kin and can conduct individual exchanges of acoustic signals, or dialogues, over some distance (Bel'kovitch and Sh'ekotov, 1990).

The echolocation system of the beluga whale is well adapted to the icy waters of the Arctic. Its ability to project and receive signals off the surface and to detect targets in high levels of ambient noise and backscatter enables it to navigate through heavy pack ice, locate areas of ice-free water, and possibly even find air pockets under the ice (Turl, 1990).

V. Life History

Females become sexually mature at age 9–12, males some time later. Gestation is 14–14.5 months with a single calf born in late spring-early summer prior to, or coincident upon entry into warm coastal waters. Mothers produce milk of high caloric content and nurse their young for up to 2 years, the entire reproductive interval averaging 3 years. Little is known about the mating behavior or mating season of beluga whales. Mating is believed to primarily occur in late winter-early spring, a period when most belugas are still on their wintering grounds or on spring migration. Mating behavior, however, has been observed at other times of the year and the question of whether they have delayed implantation is unresolved.

VI. Interactions with Humans

Because of their predictable migration routes and return to coastal areas, beluga whales have long been an important and reliable resource for many coastal peoples throughout the Arctic and subarctic. However, because past commercial harvesting drove a number of populations to the point of economic extinction, current levels of subsistence take from these populations may not be sustainable. Increasing human activity in the beluga's environment brings with it the threat of habitat destruction, disturbance, and pollution. In areas where there are large commercial fishing operations, belugas, particularly neonates, may be incidentally caught in gill nets. In a number of regions of the Arctic beluga whales exhibit strong avoidance reactions to ship traffic,

whereas in some coastal locations they appear to have developed a certain tolerance to boat traffic. The potential impacts of an emerging whale watching industry in more populated areas are as yet unquantified. In some areas belugas may also be victims of industrial pollution. A high incidence of various pathologies have been found in beluga whales in the St. Lawrence River in Canada and has been linked to high levels of heavy metals and organohalogenes found in these whales. Some of these toxins may act by suppressing normal immune response and there is concern that contaminants are adversely affecting population growth (Béland, 1996). Finally, there is concern over the possible downstream effects of hydroelectric dams on estuarine habitats and the environmental and health risks associated with oil and gas development and mining in the Arctic. Beluga whales were one of the first cetaceans to be held in captivity when in 1861 a whale caught in the St. Lawrence River went on display at Barnum's Museum in New York. Today, beluga whales are one of the more common and popular marine mammals in oceanaria across North America, Europe, and Japan. The majority of these animals were wild-caught, but successful breeding programs at a number of facilities are increasing the number of belugas born in captivity. Although the majority of beluga whales in captivity educate and entertain the public, a number of whales have been put to work by the navies of the United States and former Soviet Union.

The large sizes of some Arctic populations and flexible habitat requirements of beluga whales indicate that this species may not be as sensitive to the environmental consequences of current and future climate change as other arctic marine mammals (Laidre *et al.*, 2008). Nevertheless, a number of small, isolated populations at the southern margins of the species range may be vulnerable to continued climate warming, where habitat loss in concert with the genetic and demographic effects of small population sizes may compromise individual fitness and population viability (O'Corry-Crowe, 2008). Furthermore, it is difficult to predict the consequences for beluga whales of increased human activities across the Arctic associated with climate amelioration.

Biogeography

RICK LEDUC

I. Introduction

Biogeography is the study of the patterns of geographic distribution of organisms and the factors that determine those patterns. This discipline plays a critical role in our understanding of marine mammal evolution and adaptation (Berta *et al.*, 2006). Although marine mammals are very mobile, and there is an apparent lack of physical barriers in the world ocean, only *Orcinus orca*, *Physeter macrocephalus*, and perhaps some of the balaeopterids could arguably be considered to have cosmopolitan distributions. Other species have restricted distributions (e.g., coastal South America, Indo-West Pacific), reflecting their ecological requirements and their geographic centers of origin. Because related species tend to have similar ecological requirements and dispersal abilities, the distribution of higher taxa can also show distinct tendencies and restrictions, which reflect the cumulative distributions of their included species. For example, while delphinids, river dolphins, and sirenians have their highest diversity in tropical latitudes, most pinniped, ziphiid, and phocoenid species occur in temperate and polar regions. From a geographic perspective, specific regions can thus be characterized as centers of diversity for these higher taxa, and past global changes in the environment will have influenced their evolutionary history. For example, cooling of the world climates during the Tertiary may have contributed to the radiation of the cold-water adapted pinnipeds and mysticetes.

II. Types of Distributions

There has been considerable effort in recent years to better document what is known about marine mammal distributions (Rice, 1998; Read *et al.*, 2007). At the species level, distribution patterns can be described at different spatial scales. Broadly speaking, individual species are usually limited to certain latitudinal zones such as tropical, temperate, or polar regions. These descriptions can be further refined into subtropical, cold temperate, and so on, and correlated with patterns of ocean basin or hemisphere endemism. For example, *Stenella clymene* occurs only in the tropical Atlantic, *Eumetopias jubatus* in the cold temperate North Pacific, and *Dugong dugon* in the tropical Indo-West Pacific. On even smaller scales, species may be associated with specific physical features, such as the near-shore coastal areas (e.g., *Sousa* spp.) or the continental slope (e.g., *Berardius bairdii*), or with oceanographic features, such as specific water masses or even bodies of freshwater (e.g., *Lipotes vexillifer* and *Pusa sibirica*).

A few species, notably some of the baleen whales, are highly migratory, summering at high latitudes and spending the winter breeding season at lower latitudes. Some of the migrating rorqual species occupy (at least seasonally) a wide range of latitudes in both

hemispheres, although the movements of the Northern and Southern Hemisphere populations are seasonally offset such that they do not normally co-occur in the tropics. At the other end of the spectrum, there are some species (e.g., *Phocoena sinus* and *Monachus schauinslandi*) that have highly restricted ranges. If a formerly wide-ranging species is now limited to a small area, its distribution is considered relict.

There are distributions that are described as pan-tropical (or pan-tropical/temperate), exhibited by many delphinids, ziphiids (e.g., *M. densirostris*), kogiids (e.g., *Kogia breviceps*), and balaenopterids (e.g., *Balaenoptera edeni*). There are a few species and species pairs that occur at higher latitudes in both hemispheres but are absent from tropical waters, the so-called antitropical species and species pairs. These are seen in the families Delphinidae (e.g., *Lissodelphis* spp.), Ziphiidae (e.g., *Hyperoodon* spp.), Phocoenidae (e.g., *Phocoena sinus*/*P. spinipinnis*), Phocidae (e.g., *Mirounga* spp.), and Otariidae (e.g., *Arctocephalus townsendi*/*A. philippii*).

III. Ecology and History Determine Distribution

Beyond these descriptive aspects of biogeography are the factors that determine a given species' distribution. Generally, distributions are determined by the ecology and the history of the species. In some cases, distribution is limited because a species may not be adapted for living in certain environments. For example, tropical delphinids may not range into higher latitudes due to limitations on their abilities to thermoregulate in colder water or find food in different habitats. Tied into this is competition, either from closely related species or from ecologically similar species, which may exclude a species from a particular region in which it could otherwise survive. In the case of South American manatees, it is reasonable to surmise that competition places at least one boundary on the species' ranges. Throughout most of its range, *Trichechus manatus* occurs in both coastal and riverine habitats. However, it does not range into the Amazon River, where the exclusively freshwater *T. inunguis* occurs, although it occupies the coastal areas on either side of the river mouth. Here, the two species are parapatric, and competitive exclusion is likely at work.

The role that history plays in biogeographical patterns should not be overlooked, but it is not always evident from contemporary distributions. The dispersal abilities of organisms may partly explain why species occur in some areas and not in others. For example, the lack of otariids in the North Atlantic is probably not due to the lack of suitable habitat but rather lies in the inability of any North Pacific or South Atlantic species to get there. Of course, one could also tie this into their ecological requirements, in that dispersal to the North Atlantic would be more likely if North Pacific species ranged far enough north for animals to disperse via the Arctic Ocean across northern North America or Eurasia. For some species that have widely separated allopatric populations (e.g., *Cephalorhynchus commersonii*), dispersal from one region to the other is a likely explanation for their distribution. In other cases, vicariance events can explain allopatric distributions. For example, the two subspecies of *Platanista gangetica* occur in different river systems, the Indus and Ganges–Brahmaputra River systems. Although the two forms are not presently in contact, these rivers were all part of a single river until the late Pliocene and probably had sporadic connections through stream capture even until historical times. Therefore, the geographic separation of the populations is from a rather recent vicariance event.

Large-scale changes in the environment can have dramatic influences on species' distributions. For example, in times of global cooling, cold boundary currents in the ocean basins may have extended

farther toward the equator. This, in turn, could have enabled temperate species to disperse across the equator to similar habitats in a different hemisphere, giving rise to the antitropical species. Among the antitropical species and species pairs, some tendencies in their distributions are apparent. For example, the northern counterpart occurs in both the North Atlantic and North Pacific in only one species. Although the long-finned pilot whale, *Globicephala melas*, has only been recorded live from the North Atlantic and the Southern Hemisphere, more than 1000-year-old skulls of this species have been unearthed in Japan. For the rest of the seven or so recognized antitropical species and species pairs, all except *Hyperoodon* (which occurs in the North Atlantic) have their northern members limited to the North Pacific. Perhaps the oceanographic and climatic conditions that allow trans-equatorial dispersal for temperate species occur more frequently or become more developed in the Pacific basin than in the Atlantic. The right whales (*Balaena* spp.) present a slightly different scenario, but one that is consistent with this pattern. Now recognized as three distinct species, molecular analyses indicate that the species in the North Pacific (*B. japonica*) and southern ocean (*B. australis*) are more closely related to each other than either is to the North Atlantic species (*B. glacialis*), suggesting a more recent trans-equatorial dispersal in the Pacific basin. The above comparisons do not include the latitudinal migrant species, such as many of the species of balaenopterids. For these, their seasonal occurrence at low latitudes greatly facilitates trans-equatorial dispersal and would not likely require any significant change in oceanographic or climatic conditions.

Latitudinal migrants do, however, present questions regarding the selective advantage to conducting such extensive movements—sometimes covering thousands of miles (e.g., gray whales *Eschrichtius robustus* and humpback whales *Megaptera novaeangliae*). Their occurrence at high latitudes can be explained by the greater abundance of food, but the selective advantage to their seasonal movements to less productive wintering areas is not as apparent. The fact that they occur in high latitudes in the winter season with some regularity means that escape from winter cold may not be a major factor for adults. Calving in warmer climes does make sense, and mating during the same season could lead to wholesale movements of a population. An alternative explanation is that they leave high latitudes in the winter to escape from killer whales, which occur in much higher densities in these areas.

Beyond consideration of the underlying mechanisms of a single species' distribution, it is possible to make inferences about the origins of entire ecological communities. One approach is known as vicariance biogeography (Nelson and Rosen, 1981; Wiley, 1988). Vicariance biogeographers look for congruence between the phylogenetic relationships among species and their geographical distributions. Species distributions can be superimposed on phylogenetic trees to create what are called area cladograms (Fig. 1). If the area cladograms of several unrelated but geographically similar higher taxa are congruent, it is good evidence that a specific sequence of vicariance events operated on all of those taxa as speciation mechanisms. Furthermore, it may allow the researcher to make inferences about the centers of origin for the higher taxa being considered.

If possible, one should try to incorporate the fossil and geologic record when inferring historical mechanisms in biogeography, especially among distantly related taxa. A case in point can be seen in the river dolphins. Among the river dolphins, *Inia* and *Pontoporia* appear to be closest (albeit very distant) relatives among the extant species, the former occupying several South American rivers that flow into the Atlantic, and the latter occurring along the Atlantic coast of South America. However, the closest (albeit even more distant) living

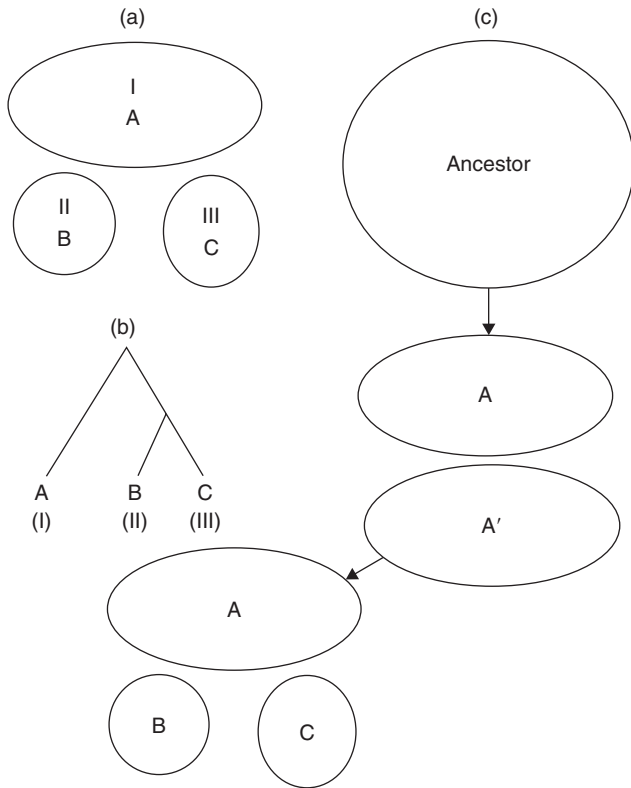

Figure 1 In vicariance biogeography, the speciation patterns are determined by vicariance events. The analysis attempts to reconstruct the sequence of vicariance events using the pattern of evolutionary relationships within a group of related species with allopatric distributions. (a) Species “A,” “B,” and “C” occupy ranges I, II, and III, respectively. (b) If a phylogenetic analysis determines that “B” and “C” are sister species to the exclusion of “A,” this pattern of relationships is applied to their respective geographic ranges in an area cladogram. (c) Under this scenario, the range of the ancestral species is first divided by a vicariance event into a northern and a southern half. Populations in these two areas speciate into species “A” and “A’.” Species “A” is the inferred immediate common ancestor to “B” and “C.” A later vicariance event divides the range of “A’” into eastern and western halves, giving rise to species “B” and “C.” If unrelated species groups occupying these areas show congruent area cladograms, the support for this sequence of vicariance events is strengthened.

relative of this pair is probably *Lipotes*, which is only found in the Yangtze River in China. Considering their freshwater and nearshore habits, it is not obvious from their contemporary distributions how they came to occupy areas a world apart. However, the fossil record has yielded intermediate species from various localities across the North Pacific. Furthermore, the geologic record shows that in the late Pliocene, the major river system in northern South America flowed westward, into what is now the Gulf of Guayaquil in Ecuador. It is thought that the ancestors of *Inia* entered this system from the Pacific. With the uplift of the Andes, much of the river reversed direction and flowed eastward, eventually becoming rivers such as the Amazon and Orinoco. With the North Pacific intermediate forms dying off, and the *Inia* lineage splitting to give rise to the ancestors of *Pontoporia* along the coast, one can see how the present-day species distributions came to be. It should be kept in mind, however, that determining the distributions of fossil taxa is notoriously difficult,

especially for offshore species that are poorly represented in accessible deposits.

In a more recent context, human activities have played and are playing a role in altering species distributions, most often in the form of range reduction. For example, hunting may have played some role in the extirpation of gray whales (*Eschrichtius robustus*) from the North Atlantic and was certainly the primary cause of the complete extinction of the baiji (*Lipotes vexillifer*). More indirect, but just as dramatic, will be the shifts or reductions in species’ distributions due to climate change, especially in high latitudes.

IV. Taxonomic Patterns

As mentioned in the introduction, species within higher taxa share characteristics of their distributions to some degree. It is therefore possible to characterize the distributions of the different groups of marine mammals. The sirenians are primarily a tropical group, with mostly allopatric species occurring in warm coastal waters and some rivers of the Indo-West Pacific and both sides of the Atlantic. The trichechids are represented by two species in the new world (*Trichechus manatus* and *T. inunguis*), and a single congener (*T. senegalensis*) in western Africa, indicating the occurrence of a past trans-Atlantic dispersal event within that lineage. The family Dugongidae, formerly more diverse and widespread, now has only one extant species (*Dugong dugon*) that occurs in the Indian and west Pacific Oceans. One recently extinct species of dugongid (*Hydrodamalis gigas*) had a restricted range in the Commander Islands of the North Pacific, an anomalously cool habitat for a sirenian.

The majority of phocid species inhabit cold temperate and polar regions. Although no species occurs in both the northern and Southern Hemispheres, there are numerous species that are circumpolar either in the Arctic (e.g., *Erignathus barbatus*) or in the Antarctic (e.g., *Lobodon carcinophagus*). In fact, all of the southern phocid species have very broad distributions, their range expansions probably assisted by the oceanic currents that traverse all longitudes in the southern ocean. In the Northern Hemisphere, however, the habitats and ocean currents are much more fragmented by the continental landmasses. In addition to the circumpolar species, there are northern species that have more restricted ranges, either endemic to a single ocean basin (e.g., *Halichoerus grypus*) or limited to landlocked bodies of water (e.g., *Pusa caspica*). In contrast to the rest of the family, the three recent (two extant) species of monk seals (*Monachus* spp.) inhabit(ed) warmer waters of the Mediterranean and eastern Atlantic, Caribbean, and Hawaii. The spread of monk seals to Hawaii must have occurred prior to the rising of the Isthmus of Panama, which has separated the Caribbean and Pacific basins for the past 3 million years.

As a group, the otariids are similar to the phocids in their distribution, although they are less well represented at very high latitudes (near the pack ice) and do not occur in the North Atlantic at all. In addition, individual species tend to have more restricted ranges that are widely allopatric from their congeners. For example, the fur seal genus *Arctocephalus* is very widespread in the Southern Hemisphere, represented by six species (with an additional species endemic to the Galapagos Islands and another to the eastern North Pacific). However, there are only a handful of localities where more than one species occurs together; for the most part the species are allopatric. It appears then that the dispersal abilities of fur seals have allowed them to colonize many areas in the Southern Hemisphere but have not prevented the resulting disjunct populations from speciating. The odobenids are represented by a single circumpolar Arctic species, the walrus (*Odobenus rosmarus*).

Cetacean species exhibit a wide range of distribution patterns. The family Balaenidae includes one antitropical species group (*Balaena* spp.) and one circumpolar Arctic species (*B. mysticetus*). The gray whale and the various species of balaenopterids are mostly latitudinal migrants in both hemispheres, although the Bryde's-like whales (*Balaenoptera brydei*, *B. omurai*, and *B. edeni*) are restricted to tropical and warm temperate waters, and some primarily migratory species include isolated populations that may be non-migratory (e.g., *Megaptera novaeangliae* in the northern Indian Ocean). In addition to the widespread common minke whale (*Balaenoptera acutorostrata*), the Southern Hemisphere also contains an endemic species of minke whale (*B. bonaerensis*). Similarly, the Southern Hemisphere is also home to two distinct forms (considered subspecies at present) of blue whale (*B. musculus*). In both of these cases, it is not known if the two southern forms represent divergent lineages that arose within the southern ocean or if they were the result of independent dispersal events across the equator.

Sperm whales (*Physeter macrocephalus*) are virtually cosmopolitan, and the kogiids (*Kogia sima* and *K. breviceps*) are worldwide in tropical and warm temperate waters. Beaked whales show a variety of distribution patterns, including pan-tropical species (e.g., *M. densirostris*), antitropical species pairs (*Berardius* spp.), and ocean basin endemics (e.g., *M. bidens*). Some (e.g., *M. peruvianus*) are only known from a few strandings within limited geographic areas. For most species of sperm whales and beaked whales, so little is known about their habits and ecological needs that it is difficult to hypothesize about the mechanisms that have led to their present distributions.

Three of the four species of river dolphins (*Inia geoffrensis*, *Lipotes vexillifer*, and *Platanista gangetica*) occur only in freshwater in specific tropical river systems, with the fourth species (*Pontoporia blainvillei*) having a restricted marine coastal range. The two species of monodontids (*Monodon monoceros* and *Delphinapterus leucas*) are circumpolar in the north, and are among the few resident polar cetaceans, although fossil species of this family occurred as far south as San Diego, California.

Apart from a single Indo-West Pacific coastal species that also ranges into freshwater (*Neophocaena phocaenoides*), the phocoenids are strictly marine and cold temperate to warm temperate in distribution, some with very restricted ranges (e.g., *Phocoena sinus*). Only one phocoenid, *P. phocaena*, has invaded the North Atlantic, becoming very widespread in both oceans of the Northern Hemisphere and even establishing isolated populations in the Black Sea and off West Africa.

The most speciose family of marine mammals, the delphinids, shows a wide variety of distributions, from pan-tropical species (e.g., *Stenella attenuata*) to ocean basin endemics (e.g., *Lagenorhynchus albirostris*) to species with wide-ranging but disjunct populations (e.g., *Delphinus capensis*). Many delphinids are pelagic, although some inhabit coastal waters (e.g., *Cephalorhynchus* spp.) and some even invade freshwater (e.g., *Sotalia fluviatilis*). Only one, *Orcinus orca*, seems to regularly range to the pack ice in the far north and south. For the many pan-tropical/warm temperate species, the continental landmasses effectively separate the populations inhabiting the Indian and Pacific Oceans from those inhabiting the Atlantic Ocean, raising the question of how they came to inhabit all the ocean basins. It has been hypothesized that during warm climatic periods, warm water extended far enough south to allow interchange and range expansion around the Cape of Good Hope. This would enable some species to become pantropical in their distribution, and the subsequent retreat of the warm water and isolation of populations could provide a speciation mechanism for the establishment of the tropical species endemic to the Atlantic Ocean (*S. frontalis* and *S. clymene*).

V. Conclusion

Why do species live where they do? Answering such a simple question requires the examination of clues from the past as well as the present. Biogeography involves such diverse disciplines as geology, paleontology, ecology, physiology, behavior, and systematics. For marine mammals, studying biogeographical patterns presents real challenges. There is a paucity of information about past distributions and habitats, gaps in our knowledge of contemporary and recent distributions, uncertainties about evolutionary relationships, and a tremendous amount to learn about the basic ecology and physiology of many marine mammals.

Blubber

SARA J. IVERSON

Blubber, a dense vascularized layer of fat beneath the skin, is one of the most well-known and universal characteristics of marine mammals. Although it is not strictly present in polar bears (*Ursus maritimus*) or sea otters (*Enhydra lutris*), all cetaceans, sirenians and pinnipeds have blubber and it may comprise up to 50% of the body mass of some species at certain life stages. Blubber has long been recognized as the primary and most important site of fat, and thus also energy, storage in marine mammals. However, blubber also has a number of other important functions. The blubber layer serves as an insulator in mammals living in often cold marine environments and is thus central to their entire process of thermoregulation.

Blubber also affects buoyancy and functions as a body streamliner and elastic spring for efficient hydrodynamic locomotion. Although blubber is a dynamic tissue, which can reflect both nutritional state and life history stage of individuals, the tissue itself has likely evolved to best suit the lifestyles, stresses and constraints of specific groups and even individual species of marine mammals. Hence, the study of blubber can provide unique insights not only into phylogenetic relationships and environmental adaptations, but also into aspects of individual feeding habits, foraging ecology, species distribution, and demography that are otherwise difficult to study.

I. The Structure of Blubber

A. Tissue Characteristics

Blubber is a specialized subcutaneous layer of fat found only in marine mammals and is different from other types of adipose tissue in that it is anatomically and biochemically adapted to serve as an efficient and adjustable thermal insulator. The blubber layer is almost continuous across the body of marine mammals, lying over but not tightly fixed to the underlying musculature but absent on appendages. Although nearly continuous, the thickness, structure, and biochemical composition of the blubber can vary greatly over the body of an individual in some species and these differences are likely associated with localized differences in function. Consistent with its role as an insulator, there also usually exists a thermal, as well as biochemical, gradient through the depth of the blubber layer. The outer layer (nearest the skin) is usually cooler than the inner layer (nearest the muscle or body core) and activities of individual enzymes in each of these locations may be adapted to function at the different respective temperatures. The polar bear also deposits huge quantities of fat subcutaneously, which likely provides some degree of insulation. However, this superficial adipose tissue does not appear to be a specific anatomical adaptation for that purpose as it does not differ in structure from the superficial fat depots of other large terrestrial carnivores (Pond *et al.*, 1992).

Blubber, like other adipose tissue, is composed of numerous fat cells called adipocytes. Adipocytes develop prior to filling with fat and are composed, like other cells, of mostly protein and water. Once developed, adipocytes can alternately fill and empty with lipid and thus can change greatly in size. Mature adipocytes are generally large and spherical and packed densely into adipose tissue. The cells are surrounded and held in place by a mesh of structural collagen fibers. Although most other types of adipose tissue contain small to moderate amounts of collagen, blubber is distinct in being greatly enriched in collagen and elastic fibers. This gives blubber a firm, tough, and fibrous character from which it derives much of its mechanical and functional properties. The histological structure of the blubber in pinnipeds is relatively uniform throughout its depth. However, in some cetaceans, there is a distinct stratification of the tissue into an inner, middle, and outer layer based on the size, shape, and metabolic characteristics of adipocytes, as well as on the lipid and collagen content of the tissue. Blubber also contains numerous blood vessels and specialized shunts called arterio-venous anastomoses (AVAs), which allow larger and swifter blood flow than would be possible through capillaries alone and are important to the thermoregulation process. The blubber of manatees has been considered unusual in that a layer of muscle is imbedded in the middle of the ventral blubber layer, however, a similar arrangement has also been found at certain body sites in some otariids. A possible functional significance for this arrangement is not known.

B. Variation in Thickness and Proximate Composition

The thickness of the blubber layer varies among species. In general, because body volume increases more rapidly than body surface area, larger species tend to have greater maximum blubber thickness. Thus, the depth of the blubber layer can be commonly 7–10 cm in adult pinnipeds, 20–30 cm in fin whales (*Balaenoptera physalus*) and up to 50 cm in the bowhead whale (*Balaena mysticetus*). In contrast, in one of the smallest odontocetes, the harbor porpoise (*Phocoena phocoena*), blubber depth generally reaches only 2.5–3.0 cm.

Beyond general species characteristics, the amount, depth, and chemical composition of the blubber also vary with age, nutrition, and reproductive status. The adipose tissue of many newborn mammals is empty of lipid, filling quickly after birth during the lactation period. Proliferation of fat depots in immature mammals is due to an increase in both adipocyte numbers and size. However, in adults, changes in the size of fat depots are primarily due to filling or emptying of adipocytes. The same appears largely true in the case of blubber. Although neonates of large baleen whales are born with a blubber layer that is several centimeters thick, most pinniped neonates are born with very little blubber, at less than 3 mm in depth in some otariids and accounting for less than 5–6% of body mass in most phocids. Most newborn pinnipeds rely instead primarily on fur (otariids) or lanugo (downy hair grown by fetuses, which remains for short periods after birth in many phocids) and delayed entry into the water. For instance, in newborn harp seals (*Phoca groenlandica*), blubber represents less than 6% of body mass and contains only 20% lipid (Worthy and Lavigne, 1983). This rapidly changes during the 12-day lactation period, such that the blubber of a newly weaned harp seal can comprise up to 50% of body mass and contains greater than 90% lipid, representing abundant and replete fat cells. In contrast, during reduced food intake or fasting, lipid is mobilized rapidly from adipocytes and hence undernourished marine mammals are characterized by greatly reduced blubber thickness and lipid content. Likewise, during annual events associated with fasting, such as lactation or molting in some species, blubber is also reduced in depth and lipid content with fat mobilization. For instance, the sternal blubber of female harbor seals (*Phoca vitulina*) changes during the 24-day lactation period from 3.8 to 1.4 cm in depth and from 92.3% lipid, 2.2% protein, and 5.5% water to 76.9% lipid, 5.9% protein, and 17.2% water (Bowen *et al.*, 1992); i.e., the increases in protein and water content reflect the larger proportion of “emptier” fat cells. In a similar manner, lipid content of adipose tissue in polar bears has been shown to reflect reproductive status and likely changes in prey availability (Thiemann *et al.*, 2006).

C. The Lipids in Blubber

Depot lipid in animals is stored predominantly as triacylglycerols, which consist of three fatty acids esterified, i.e., linked by an ester bond to a glycerol molecule (three-carbon alcohol). The synthesis, storage, and catabolism of fatty acids are the components of lipid energy metabolism. Fatty acids in the marine food web are exceptionally complex and are characterized by high levels of long-chain polyunsaturated fatty acids (PUFA). During digestion of triacylglycerols by monogastric mammals, fatty acids are released from the glycerol backbone but not degraded and they are carried in the bloodstream and taken up by tissues the same way. These fatty acids are then either used for energy or stored as triacylglycerols in adipose tissue. Thus, fatty acids travel up the food chain intact, and

because the kinds of fatty acids that can be biosynthesized or modified in mammals are quite limited, most fatty acids found in marine mammal blubber arise from the dietary intake of fish and other prey lipids. Hence, marine mammal blubber lipid is usually characterized by high levels of long-chain PUFA as well as unique fatty acids produced at lower trophic levels of the marine ecosystem.

Marine mammals, like other mammals, can also synthesize some of their own fatty acids from sources such as dietary amino acids consumed in excess of body needs (glucose would be another source but is scarce in diets of marine mammals). These synthesized fatty acids are usually restricted to those with 16 or 18 carbon atoms and usually, at most, one double bond (i.e., 16:0, 16:1 n -7, 18:0, and 18:1 n -9). Although these fatty acids are also common in all prey items of marine mammals, some are undoubtedly deposited in marine mammal blubber from biosynthesis.

There are several exceptions to the general characteristics of marine mammal blubber lipids described earlier. In addition to the usual fatty acids that are synthesized by all mammals, one very unusual fatty acid, isovaleric acid, is also found in the blubber of some species of toothed whales (odontocetes) which can arise only from localized biosynthesis. Isovaleric acid is unusual in that it is both very short (five carbons) and branched. When present, it is found in highest concentrations in the outermost layer (nearest the skin) of blubber (Koopman *et al.*, 2003). Additionally, besides the most common form of storage lipid, triacylglycerols, some marine mammals (primarily some odontocetes) store some or all of their fatty acids in blubber as wax esters (Koopman, 2007). A wax ester is a single fatty acid esterified to a long-chain (22–34 carbon) alcohol. In general, wax esters are firm, stable, and resistant to degradation. This is why sperm whale (*Physeter macrocephalus*) oil was popular as an illuminant in the last century.

II. Role of Blubber in Temperature Regulation: Heat Conservation and Dissipation

As a whole-body envelope of insulation, blubber is central to thermoregulation in marine mammals. Marine mammals, like all mammals, are homeothermic endotherms and hence need to maintain a stable body core temperature of about 37°C in cooler (usually <25°C) and often much colder (–1 to 5°C) fluid environments. Additionally, heat is always lost far more rapidly to water than to air because the thermal conductivity of water is 25 times that of air. There are several ways marine mammals have dealt with this problem. One is to increase body size, which decreases the surface-to-volume ratio and thus provides less surface area per unit volume over which to lose heat. Even the smallest marine mammals are considered large mammals, being one to two orders of magnitude larger than small terrestrial mammals such as rodents and insectivores. Additionally, and perhaps more importantly, large body size generally allows for thicker insulation (be it fur or blubber), which further decreases heat conductance.

Although fur is a far more effective insulator than blubber in air and is used as the sole means of insulation by sea otters, fur acts by trapping pockets of air (a poor thermal conductor) among hairs, which then forms the effective insulative layer. Thus, potentially when fur is wetted, but more significantly when diving under pressure (as most marine mammals do), fur is compressed, expelling the air layer and thus losing its insulative properties. In contrast, blubber does not compress with depth and it is a good insulator because, like air, it has a lower thermal conductivity than water.

Adipose tissue is also less metabolically active than other tissues and thus requires less perfusion by blood, which would otherwise tend to cause heat loss at the body surface. Nevertheless, because blubber is vascularized, circulatory adjustments allow both heat conservation and dissipation as necessary. An important means of regulating heat transfer in marine mammals is by restricting and diverting blood flow through the blood vessels and AVAs in blubber. Restricting blood flow to the blubber's surface (i.e., skin) conserves body heat and allows blubber to act as an effective insulator against cold. Conversely, increasing blood flow into the blubber allows sometimes massive redistribution and dumping of body heat in cases of either very warm water or air or during intense activity (Heath and Ridgeway, 1999).

The effectiveness of blubber as an insulative layer depends on its thickness, lipid content, and lipid composition. As an insulation layer increases in thickness, the lower critical temperature of an animal decreases and thus the animal can accommodate a broader ambient temperature range without having to increase its metabolism for heat production (i.e., to remain thermoneutral). As mentioned earlier, many marine mammals, especially those of larger body size, possess a thick blubber layer, allowing them to remain thermoneutral at most of the temperatures of the world's oceans and, for some pinnipeds, even at air temperatures of –10 to –20°C on polar ice. However, smaller species are limited in the depth of blubber they can carry and also have relatively more surface area over which to lose heat. Hence, most of the smallest cetaceans do not occur at high latitudes. Less insulation increases the lower critical temperature of an animal and requires increased metabolism for heat production. The harbor porpoise is the smallest cetacean species to inhabit temperate waters of the Northern Hemisphere. Although its blubber depth is only several centimeters thick, it is generally twice the thickness and contains more lipid than does a similarly sized dolphin inhabiting tropical waters. These properties appear to confer up to four times greater insulative capacity (Koopman, 2007).

Depletion of lipid from blubber stores will decrease the insulative capacity of the tissue and may seriously compromise an individual, especially if nutritionally stressed. Thus, small species such as the harbor porpoise must feed nearly continually to maintain metabolism and to preserve their blubber's thickness and insulative capacities. In contrast, large whales can fast and mobilize blubber reserves for weeks or months, yet can remain thermoneutral due to a low surface-to-volume ratio as well as the maintenance of a still relatively thick blubber layer. Especially in cetaceans, the thickness, structure, and insulative properties of the blubber may vary across different regions of the body and thus the function of the blubber as an insulator may also vary regionally.

Variation in the lipid composition of blubber may also confer differing insulative capacities. As stated previously, the blubber of marine mammals is composed of large amounts of unsaturated fatty acids. Unsaturated fatty acids have lower melting points than do saturated fatty acids. Thus even when the temperature of the outermost layer of the blubber and skin are near that of cold ambient temperatures, blubber tissue can remain fluid and an effective insulator if the melting point of its fatty acids is low. Saturated and monounsaturated fatty acids abundant in marine mammal blubber (e.g., 16:0, 16:1, 18:0, and 18:1) have melting points of 13–70°C. However, nutritionally important polyunsaturated fatty acids are usually plentiful in marine mammal diets and thus in blubber, conferring an overall melting point in blubber lipid of less than –15°C. Additionally, in some small cold-water cetaceans such as the harbor porpoise, Dall's porpoise (*Phocoenoides dalli*), the bottlenose dolphin (*Tursiops*

truncatus), and the beluga (*Delphinapterus leucas*), high concentrations of the very unusual branched short-chain isovaleric acid are biosynthesized and deposited in blubber (see earlier discussion). Isovaleric acid has an extremely low melting point of -37.6°C , which clearly provides fluidity to especially the outer blubber layer of these animals. Although the exact physiological function of isovaleric acid is not understood, its presence may contribute to the superior insulative properties observed previously in harbor porpoise blubber. In contrast to most other marine mammals, while manatees (*Trichechus* sp.) can also store large amounts of blubber, they generally do not tolerate temperatures below 20°C . As plant eaters, manatees must synthesize the majority of their blubber fatty acids, which would thus be restricted in their degree of unsaturation. However, little is known about the effectiveness of manatee blubber as an insulator in cold temperatures or the role that lipid composition might play in this ability.

III. Role of Blubber in Energy Storage and Water Balance

Blubber, as a rich energy store, is important in the lives of marine mammals because of the critical role that stored lipid plays in their ecology, reproduction, and survival. Perhaps surprisingly, even though marine mammals obviously live in the environment within which they also forage, reproduction and especially lactation are often spatially and temporally separated from their feeding grounds. For instance, the greatest areas of feeding activity for the large baleen whales are in polar regions during the high primary productivity of summers. However, they migrate in winter to warm tropical waters of low food availability to give birth and nurse their young. In phocid and otariid pinnipeds, parturition and lactation occur on land or ice and thus these activities are also separated from the feeding environment of the lactating female. Female polar bears spend the first 3–4 months of lactation in winter dens, without eating or drinking.

In all female mammals, lactation represents the greatest energetic cost of reproduction, requiring large amounts of nutrient transfer and elevated maternal maintenance costs. Hence, lactation is usually associated with increased maternal food consumption. However, because large energy reserves can be stored in blubber in the form of lipid, baleen whales and large phocid seals are the only mammals (besides holarctic bears) that can complete much or all of lactation without feeding. Again, because a smaller body size constrains the size of blubber stores, the smaller phocids and otariids are able to fast for only portions of lactation. All species of marine mammals produce high fat milks (usually 30–60% fat) to maximize the efficiency of fat transfer from maternal blubber into milk and the subsequent efficiency of neonatal fattening and growth. In species that fast throughout lactation, females switch almost completely to a fat-based metabolism. For instance, during a 16-day lactation period, a gray seal (*Halichoerus grypus*) female draws 97% of the energy required for her own metabolic needs and 90% of the milk energy supplied to her pup solely from her blubber stores. Furthermore, the extent to which she can both maintain lactation and produce a fat pup depends on the size of the blubber layer she starts out with (Mellish *et al.*, 1999). Fasting female polar bears use their extensive subcutaneous adipose tissue in a similar manner during the first months of lactation in winter dens.

Blubber deposition is equally critical to the suckling neonate, both for thermoregulation and to act as an energy reservoir. For

example, most newly weaned phocid pups rely on blubber deposited during the suckling period to survive their own subsequent fast of several weeks or months after their mothers have departed the breeding grounds. The energy supplied from blubber is critical to survival of the young while they learn how to forage on their own.

Adult males of many marine mammal species also fast or greatly reduce food intake during the breeding season and during their annual molting period. During these times they rely on stored lipid in blubber as their energy source. Sirenians also use blubber during fasting. For instance in the Amazon, manatees (*Trichechus inunguis*) face dry seasons of up to 6 months at a time, where low waters restrict them to the deep water areas of larger lakes where the aquatic plants they feed upon are unavailable. Hence, food intake during these periods is nil.

Finally, besides being an important fat and energy source for marine mammals, blubber is a critical source of water that is essential to maintaining water balance during fasting. Each kilogram of lipid that is mobilized from blubber and oxidized for energy use by an animal generates a net production of 1.07 kg of metabolic water. In fact, oxidation of blubber yields enough water such that individuals usually do not require an additional external source. This is true even of lactating females that are exporting large quantities of water in milk daily. For instance, a gray seal female exports about 23 kg of water in milk over a 16-day lactation period while fasting and has no external access to water during this time (Iverson *et al.*, 1993). Thus, in most species, blubber functions to maintain both water balance and energy metabolism during periods of fasting.

IV. Role of Blubber in Locomotion

Several forces act on animals swimming in fluids, and blubber plays a significant role in the way marine mammals deal with these forces. The predominant restrictive force is drag, but the vertical forces of gravity and buoyancy also exist. Drag is the force that resists the movement of a body through a medium and is much greater in seawater than in air due to seawater's higher density and greater viscosity. The single most effective way to reduce both drag and the power required for forward motion through a fluid is to have a smooth streamlined shape. Although all marine mammals tend to be somewhat streamlined in body shape as defined by their musculoskeletal system, blubber provides their form with a smooth sculpted contour. Blubber thickness is often distributed across an animal in a nonuniform manner that ensures this. For instance, the blubber over the hind end of a seal may be thicker than would be necessary for insulative purposes. The blubber layer here instead serves to taper the animal more gradually than would be dictated by the musculoskeleton. In fact, another very important means by which to reduce drag on a body is to be spindle-shaped, i.e., to have a gradually tapering tail end. This acts to reduce the wake left by the animal moving through the water and hence further reduces the forces of drag. Again, blubber creates this effect in cetaceans by a thickening and sculpting of the tailstock (Pabst *et al.*, 1999). This locomotor function may actually constrain the way in which animals utilize their blubber as energy reserves. In large baleen whales as well as the smallest harbor porpoise, blubber may be greatest in depth and fat content, even during nutritional stress, in the posterior dorsal and tail areas of the body (Lockyer, 1987; Koopman, 1998), as blubber in these areas serves important locomotory functions by both streamlining and possibly acting as a biomechanical spring, capable of temporarily storing and releasing elastic strain energy (Pabst, 1996).

Finally, blubber also plays a role in the buoyancy of marine mammals. Buoyancy is the force that acts on a body submerged in water where, if the mass of the body is greater or less than the volume of water it displaces, it will experience either a net downward or net upward force, respectively. In most marine mammals (except the sea otter), buoyancy will be determined primarily by the ratio of its adipose tissue to lean body tissue and body mass. Fat-filled adipose tissue is less dense than seawater, whereas lean tissue is more dense. Thus, the degree to which marine mammals store blubber will affect their buoyancy and thus the energy expended in moving or maintaining position in water. Although some newly weaned phocid pups may be positively buoyant at greater than 43% adipose tissue, most adult marine mammals will not be positively buoyant and thus are not likely to require any counteracting of this force when at the bottom of dives or when feeding at the benthos. However, changes in blubber stores will clearly affect the degree to which they are negatively buoyant. Studies have demonstrated that seals descend faster during diving when they are more negatively buoyant than when they are less negatively buoyant, providing evidence that seals adjust their diving behavior in relation to seasonal changes in buoyancy (Webb *et al.*, 1998; Beck *et al.*, 2000).

V. Insights from the Study of Blubber

Marine mammals are widely distributed in tropical, temperate, and cold oceans of the world and show a diversity of distributional patterns and apparent physiological adaptations. However, our understanding of these patterns, as well as of the foraging ecology of most marine mammals, is hindered by the difficulties in observing free-ranging animals that spend most or all of their lives at sea. Blubber is clearly of central importance to the structure and function of marine mammals. Due to the fact that blubber has evolved to serve complex functions, and yet the composition and amount of blubber carried by an individual can change rapidly, its study can provide unique insights into the lives of marine mammals as well as the ecosystems in which they live.

The ultrastructure, thickness, and proximate composition of blubber can provide insights into the feeding status of individuals as well as the functional significance of the blubber itself. As stated previously, the proximate composition, especially lipid content, of blubber changes radically in response to feeding and fasting behavior and thus, along with other nutritional indices, may be used to indicate nutritionally stressed vs robust individuals. Because many marine mammals go through predictable annual periods of fasting and fattening, the proximate composition of blubber can also be used to indicate the life cycle stage of an individual. In some cetaceans, the characteristics of blubber differ greatly across sites of the body and thus study of these properties can provide insight into the functions of blubber. For instance, the structure and composition of blubber at specific sites suggest that in some areas on the body (e.g., the thoracic-abdominal area), blubber may play a more important role in insulation and energy storage, whereas at other sites (e.g., the thick ridge posterior to the dorsal fin or at the caudal peduncle) blubber may serve more important roles in maintaining hydrodynamic shape and other locomotory functions (Koopman, 1998; Pabst *et al.*, 1999). Thus, the study of how blubber at these various sites is utilized during times of fat mobilization may provide further insight into adaptations of blubber structure. For example, the finding that blubber in the area of the caudal peduncle is rarely used and always thicker than needed for insulation, even during severe nutritional stress, lends support to the hypothesis that it may be more important in

that region for structural support and locomotory functions than as an insulator or energy provider.

Blubber can also provide insight into adaptation and phylogenetic relationships. For instance, the characteristic of storing blubber lipid primarily as wax esters appears to be confined to a group of the odontocetes (i.e., beaked whales and the sperm whale, *Physeter catodon*). The species in which blubber consists primarily of wax esters, although all closely related, are also all pelagic deep divers. Hence the study of their blubber may provide insight into phylogenetic patterns as well as roles that wax esters may play in deep diving animals (Koopman, 2007). The presence of isovaleric acid is likewise confined to a fairly restricted group of animals, which also may be under special thermal constraints (see earlier discussion). Thus the study of isovaleric acid in blubber may provide clues to its function and potential value in insulation. Additionally, in several species the presence of isovaleric in the outer layer of blubber increases in direct proportion with age, suggesting the possibility of using its level in blubber to estimate ages of unknown individuals in the same population (Koopman *et al.*, 2003).

Finally, the fatty acids in blubber can provide powerful insights into the foraging ecology and diets of both individuals and populations of marine mammals. As stated previously, fatty acids in the marine ecosystem are complex and diverse, fatty acids often travel up the food chain intact, and there are narrow limitations on their biosynthesis in marine mammals. Hence the fatty acids of marine mammal blubber arise in large part from dietary intake and therefore can be used to study aspects of diet and foraging ecology (Iverson, 1993). Given the dynamic nature of lipid mobilization and deposition in marine mammal blubber, fatty acids can provide insight into diets over both time and space. Studies on wild and captive animals demonstrate that there is direct deposition of dietary fatty acids in both marine mammals and their prey and that the influence of dietary fatty acid intake on blubber composition is both substantial and predictable, whether or not rapidly fattening (Iverson *et al.*, 1995; Kirsch *et al.*, 2000). Considered alone, fatty acids stored in a predator can provide powerful qualitative insight into spatial and temporal differences in foraging and diets of individuals and populations. However, recent advances have developed methods that use fatty acids in predators, along with their prey, to quantitatively estimate species composition of predator diets (Iverson *et al.*, 2004). Quantitative fatty acid signature analysis (QFASA) accounts for effects of predator metabolism on fatty acid deposition, and then determines the weighted mixture of prey species fatty signatures that most closely resembles that of the predator's fatty acid stores to thereby infer its diet. QFASA has been validated and used to estimate diets of free-ranging individuals in a number of pinniped species and the polar bear (Iverson *et al.*, 2004, 2006). A blubber biopsy (100–500 mg), or adipose tissue sample, from a free-ranging animal provides relatively non-invasive information about diet that is not dependent on prey with hard parts, nor limited to only the last meal, as are analyses of fecal or stomach contents. This is accomplished most easily in pinnipeds where, using a medical biopsy punch, one can safely obtain a complete sample through the full depth of 5–10 cm. However, in cetaceans, blubber is generally much thicker and layering of fatty acids in the blubber is more pronounced, with dietary fatty acids being most reflected in the inner and middle layers nearest the deep body core. Thus, less work has been done on live animals in these species. Nevertheless, QFASA is now being used to address broad ecosystem-scale processes and is providing new insight into foraging patterns and ecology of free-ranging marine mammals that would otherwise not be possible.

VI. Other Specialized Fats

In addition to blubber, several other unusual and specialized fat bodies exist that are unique to a single group of cetaceans, the odontocetes or toothed whales. These fat bodies occur in the forehead tissue (melon) and in and around the mandibles of the lower jaw (mandibular fats) and play important roles in hearing and echolocation. They are composed of a unique array of lipid classes and fatty acids that are likely synthesized with these head tissues (Koopman *et al.*, 2003, 2006). These unusual fats are believed to facilitate sound reception by acting in the melon to focus high frequency sound produced in the nasal passages, while in the mandibular fats, they are organized to form a channel to transmit received sounds to the ear. In all odontocetes examined, short- and branched-chain fatty acids appear to be concentrated in the center of the inner mandibular fat body and immediately adjacent to the earbones. Because sound travels more slowly through these types of fatty acids, this should cause sound entering an odontocete head to bend inwards and be directed to the ears (Koopman *et al.*, 2006). The unique arrangement of lipids within these fat bodies and their direct effect on sound transmission is an important area of current research.

In conclusion, blubber and other fats play a number of major roles in the lives of marine mammals. These fats can also be a powerful tool in trying to understand adaptive solutions of species living in marine environments as well as insights into their ecology and behavior.

Blue Whale

Balaenoptera musculus

RICHARD SEARS AND WILLIAM F. PERRIN

The blue whale is a baleen whale belonging to the family Balaenopteridae, which includes the group of cetaceans known as rorquals (Fig. 1). Common names are blue whale, sulfur-bottom, Sibbald's rorqual, great blue whale, and great northern rorqual. The largest animal known to have existed on Earth, it is found worldwide, ranging into all oceans (Yochem and Leatherwood, 1985).

I. Characteristics and Taxonomy

On average, Southern Hemisphere blue whales are larger than those in the Northern Hemisphere. The largest recorded were caught off the South Shetlands and South Georgia and were 31.7–32.6 m (104–107 ft) long. The largest recorded for the Northern Hemisphere was a 28.1-m (92-foot) female reported in whaling statistics from catches in Davis Strait. In the North Pacific females of 26.8 m (88 ft) and 27.1 m (89 ft) have been recorded. A 190-ton female was reported taken off South Georgia in 1947; however, body weights of adults generally range from 50 to 150 tons. For maximum size descriptions, female measurements are used because female baleen whales are larger than males.

Figure 1 Blue whale showing the characteristic mottled pigmentation of the species. Drawing by Daniel Grenier.

Blue whales project a tall (up to 10–12 m) spout, denser and broader than that of the fin whale, *B. physalus*, which in calm conditions can help distinguish between the two species. When surfacing, the blue whale raises its massive shoulder and blowhole region out of the water more than other rorquals. The prominent fleshy ridge just forward of the blowhole, known as the “splash guard,” is strikingly large in this species.

When seen from above, blue whales have a tapered elongated shape, with a huge broad, relatively flat, U-shaped head, adorned by a prominent ridge from the splash guard to the tip of the upper jaw or rostrum and massive mandibles. The baleen is black, half as broad as its maximum 1-m length, and 270–395 plates can be found on each side of the upper jaw. There are 60–88 throat grooves or ventral pleats running longitudinally parallel from the tip of the lower jaw to the navel, which enable the throat or ventral pouch to distend when feeding.

The dorsal fin is proportionally smaller than in other balaenopterids and varied in shape, ranging from a small nubbin to triangular and falcate and is positioned far back on the body. The flippers are long and bluntly pointed, slate gray, with a thin white border dorsally and white ventrally; they reach up to 15% of the body length.

In the field, particularly on bright days, blue whales generally appear much paler in coloration than all species of large whale except for the gray whale, *Eschrichtius robustus*, with which it should not be confused due to a great difference in size. Above water, the characteristic mottled pigmentation is a blend of light and dark shades of gray displayed in patches of varying sizes and densities. The underwater color is slate blue on overcast days to silvery or turquoise blue on bright sunny days depending on the clarity of the water. The mottling is found along the body dorsoventrally, occasionally on the flippers, but not on the head and tail flukes. Two prominent pigmentation configurations are found in blue whales, one where a darker, dominant background is mottled with sparser pale patches of pigmentation, while in the other there is a predominantly pale background mottled with sparser dark patches. Blue whale pigmentation can vary, however, from very sparse mottling, where the individual appears uniformly pale or dark, to densely mottled individuals, where the pigmentation is a highly contrasted variegation of spots unique to each whale, which is used in studies involving individual identification. Distinct chevrons curving down and angled back from the apex on both sides of the back behind the blowholes and either pale or dark in tone can be found on some individuals. The tail flukes, sometimes striated ventrally, are predominantly gray above and below; however, some individuals do have white patches of pigmentation on the ventral surface that are used for individual identification (Calambokidis *et al.*, 1990; Sears *et al.*, 1990). The trailing margin of the tail is either straight or curves very slightly from each tip to the median notch. A yellow-green to brown cast, caused by the presence of a diatom (*Cocconeis ceticola*) film, can be seen covering all or part of the body of blue whales found in cold

waters. The yellowish, diatom-induced tint is the reason the “sulfur-bottom” moniker was once used for blue whales.

Three subspecies have been designated: what has been considered the largest, *B. musculus intermedia*, found in Antarctic waters; *B. musculus musculus* in the Northern Hemisphere; and *B. musculus brevicauda*, from the subantarctic zone of the southern Indian Ocean and south western Pacific Ocean, also colloquially known as the “pygmy” blue whale. Although the latter designation is now generally accepted, its validity remains in question.

Our knowledge of the phylogeny of the baleen whales is still in flux. In recent molecular studies, the blue whale has been variously suggested to be the sister taxon of a clade including the Bryde’s (*B. edeni*) and sei (*B. borealis*) whales, in combination with them a sister clade of the fin and humpback (*Megaptera novaeangliae*) whales, with gray whales (*Eschrichtius robustus*) the next up the tree (Rychel *et al.*, 2004); in the same arrangement, but with the minke whales (*B. acutorostrata* and *B. bonaerensis*) coming in before the gray whale (Nikaido *et al.*, 2005; Sasaki *et al.*, 2005); again in the same arrangement but with the gray whale not included in the analysis, the balaenids being a sister clade to all the balaenopterids (Nishida *et al.*, 2007); and sister taxon to a clade containing all the other baleen whales except the balaenids (Hatch *et al.*, 2006). In a morphological cladistic analyses, it grouped with the common minke whale in a clade sister to the humpback (Steeman, 2007). Further work is obviously needed.

II. Distribution and Abundance

Despite having been reduced greatly due to whaling, the blue whale remains a cosmopolitan species separated into populations from the North Atlantic, North Pacific, and Southern Hemisphere (Fig. 2). In the North Atlantic, eastern and western subdivisions are recognized. Photo-identification work from eastern Canadian waters indicates that blue whales from the St. Lawrence, Newfoundland, Nova Scotia, New England, and Greenland all belong to the same population, whereas blue whales photo-identified off Iceland and the Azores appear to be part of a separate population. The best known population in the North Atlantic is that found in the St. Lawrence from April to January, where 435 individuals have been catalogued photographically (Sears *et al.*, 1990). Apart from the Icelandic and Azores sightings, few blue whales have been reported from eastern North Atlantic waters recently. North Atlantic blue whale abundance probably ranges from 600 to 1500 at this time, although more extensive photo-identification and shipboard surveys are needed for more reliable estimates.

In the North Atlantic, blue whales reach as far north as Davis Strait and Baffin Bay in the west, whereas to the east they travel as far north as Jan Mayen Island and Spitzbergen during summer months. Whales sighted recently in winter and spring off the Azores and Canary Islands could be migrating north along the mid-Atlantic ridge to Iceland, where they are seen from May to September.

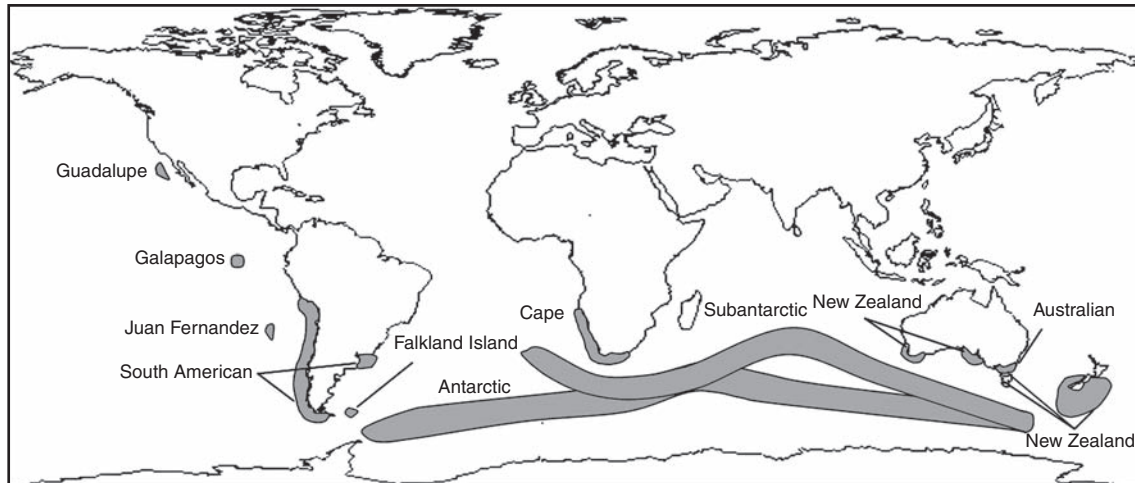

Figure 2 Global distribution of blue whales. Darker gray indicates higher densities.

Others probably migrate along the European coast, far offshore and out around Ireland north to either Iceland or Norway. It is not clear where the whales winter in the North Atlantic. Some have been observed in the St. Lawrence as late as February; however, acoustic studies have revealed that they are spread out across the North Atlantic basin, south as far as Bermuda and Florida, with concentrations south of Iceland, off Newfoundland and Nova Scotia. The southernmost observations on the eastern side of the North Atlantic are in the waters between the coast of Africa and the Cape Verde Islands.

In the North Pacific, where as many as five subpopulations were thought to exist, acoustic analysis of blue whale vocalizations now indicates there are no more than two. The best known is that from the eastern North Pacific where blue whales can be found as far north as Alaska but are regularly observed from California in summer, south to Mexican and the Costa Rica Dome waters in winter. Abundance estimates of approximately 3000 animals ($CV = 0.14$) by line-transect methods and 2000 by capture-recapture (photo-identification) have been determined for this population, which has been studied extensively over a good portion of its range (Calambokidis and Barlow, 2004). From late fall to spring, blue whales can be found in the Gulf of California, Mexico, and south to offshore waters of Central America. By April and May they migrate north along the West coast of North America, where a large proportion is found in California waters. From there some reach Canadian waters, and other groups may disperse north to the Gulf of Alaska or west toward the Aleutian Islands.

Few blue whales have been reported recently from the western North Pacific, including the Aleutian Islands, Kamchatka, Kurils, and Japan. They are thought to migrate to Kamchatka or the Kuril Islands and probably farther northeast.

Blue whales are also found in the northern Indian Ocean; however, it is not clear whether these form a distinct population.

In the Southern Ocean, where the blue whale was historically most abundant, it is very rare today, with the abundance estimate at 1700 (95% confidence interval 860–2900) (Branch *et al.*, 2007). A population of 424 ($CV = 0.42$) has been estimated to frequent the Madagascar Plateau in the austral summer (Best *et al.*, 2003). Although the general population structure in the Southern Ocean is not well understood, evidence shows discrete feeding stocks. A feeding and nursing ground was recently discovered in southern Chile (Hucke-Gaete *et al.*, 2004). Consistent with these feeding

areas, the International Whaling Commission has assigned six stock areas for blue whales in the Southern Hemisphere.

III. Ecology

Food availability probably dictates blue whale distribution for most of the year. Although they can be found in coastal waters of the St. Lawrence, Gulf of California, Mexico, and California, they are found predominantly offshore. They appear to feed almost exclusively on euphausiids (krill) worldwide in areas of cold current upwellings (e.g., in the Southern Hemisphere—Branch *et al.*, 2007). When they locate suitably high concentrations of euphausiids, they feed by lunging with mouth wide open and gulping large mouthfuls of prey and water. The mouth is then almost completely closed and the water is expelled by muscular action of the distended ventral pouch and tongue through the still exposed baleen plates. Once the water is expelled, the prey is swallowed. When they feed just a few meters below the surface, they often surface slowly, belly first, exposing the throat grooves of the ventral pouch, roll to breathe, and evacuate the water before diving to take their next mouthful. If the prey is close to the surface, blue whales lunge vigorously on their sides or lunge up vertically by projecting their cavernous lower jaws 4–6 m up through the surface. Although surface feeding has often been observed during the day, it is more usual for blue whales to dive to at least 100 m into layers of euphausiid concentrations during daylight hours and rise to feed near the surface in the evening, following the ascent of their prey in the water column. In the North Atlantic, blue whales feed on the krill species *Meganyctiphanes norvegica*, *Thysanoessa raschii*, *T. inermis*, and *T. longicaudata*; in the North Pacific, *Euphausia pacifica*, *T. inermis*, *T. longipes*, *T. spinifera*, and *Nyctiphanes simplex*. In Antarctic waters they prey on *E. superba*, *E. crystallorophias*, and *E. valleritini*.

Documentation of natural mortality is rare. The principal predator is the killer whale, *Orcinus orca*, but there is little evidence of attacks on blue whales in the North Atlantic or Southern Hemisphere. However, in the Gulf of California, Mexico, 25% of the blue whales photo-identified carry rake-like killer whale teeth scars on their tails, indicating that attacks occur with some regularity but are probably rarely successful. In the St. Lawrence, ice entrapment, where animals have been crushed, stranded, or suffocated by current and wind-driven ice floes in the late winter-early spring, has been reported.

IV. Behavior and Physiology

Blue whales are observed most commonly alone or in pairs; however, concentrations of 50 or more can be found spread out in areas of high productivity.

Although not noted for raising their flukes when diving, approximately 18% of blue whales observed in the western North Atlantic and Northeast Pacific do so. This is an individual characteristic, and if the individual is relaxed it will generally raise its flukes high up in the air on each sounding dive. When disturbed, blue whales that raise their flukes when diving will often not raise their tails as high out of the water or not at all and dive more quickly from the surface.

When foraging or feeding at depth, blue whales will generally dive for 8–15 min; 20-min dives are not uncommon. The longest dive recorded was of 36 min; however, dives of more than 30 min are rare. They generally swim at 3–6 km/h when feeding. When traveling, they can attain speeds of 5–30 km/h and when chased by boats, predators, or interacting with other blue whales, they can reach upward of 35 km/h.

Blue whales vocalize regularly throughout the year with peaks from midsummer into winter months. The majority of vocalizations are low frequency or infrasonic sounds of 17–20 Hz, lower than humans can detect. Their sounds, at 188 decibels (re: 1 μ Pa at 1 m) are one of the loudest and lowest made by any animal. The calls can be heard easily for hundreds of kilometers, thousands of kilometers under optimal oceanographic conditions, and may cover whole ocean basins. The low frequencies are ideal for communication between individuals of a widely dispersed and nomadic species through water without much loss of information. Geographic variation, seasonality, and diel variation in the sounds have been studied intensively in recent years (Stafford, 2003; Širović *et al.*, 2004; Stafford *et al.*, 2004, 2005; Wiggins *et al.*, 2005); the sounds may prove to be useful in delineating populations (McDonald *et al.*, 2006).

Little is known of mating behavior in the species. However, female–male pairings have been noted with regularity in the St. Lawrence from summer into fall, some lasting for as long as 5 weeks. When a female–male pair is approached by a third blue whale, or even a fin whale, vigorous surface displays ensue, where all three animals can be seen racing high out of the water, porpoising forward, causing an explosive bow wave splash, and even at times breaching. Such interactions usually last for 7–25 min.

V. Life History

Blue whales reach sexual maturity at 5–15 years of age; however, 8–10 years appear to be more usual for both sexes. Length at sexual maturation in females from the Northern Hemisphere is 21–23 m and is 23–24 m in the Southern Hemisphere. Males reach sexual maturity at 20–21 m in the Northern Hemisphere and at 22 m in the Southern Hemisphere. Mating takes place starting in late fall and continues throughout the winter. Females give birth every 2–3 years in winter after a 10- to 12-month gestation period. The calves, which weigh 2–3 tons and measure 6–7 m at birth, are weaned when approximately 16 m long at 6–8 months. No specific breeding ground has been discovered for blue whales in any ocean, although mothers and calves are sighted regularly in the Gulf of California, Mexico, in late winter and spring. A portion of the Northeast Pacific Ocean blue whale population could be using this region as a breeding ground.

Longevity is thought to be at least 80–90 years and probably longer. What is certain, however, after extensive photo-identification fieldwork on known individuals in the St. Lawrence and northeast Pacific, is that they live for at least 40 years.

VI. Interactions with Humans

Because of its great size and the commercial value of the products it yielded, the blue whale was hunted relentlessly beginning in the late 1800s. The greatest number of blue whales was taken from the early 1900s until the late 1930s, with the peak being in the 1930–1931 season when nearly 30,000 were killed. The height of blue whale whaling coincided with the advent of explosive harpoons, steam power vessels, and the construction of factory ships, which could process whale carcasses at sea. The blue whale was severely depleted by whaling, particularly in the Southern Hemisphere, where during the first half of the twentieth century 325,000–360,000 were killed in Antarctic waters alone. A further 11,000 were taken in the North Atlantic, primarily in Icelandic waters, and 9500 in the North Pacific. This unbridled hunt for blue whales, which lasted until its worldwide protection in 1966, brought the blue whale to the brink of extinction and it is still an endangered species today. However, there is evidence for population increase in the Antarctic (Branch, 2004).

Although reports of blue whales approaching vessels are rare, at least 25% of the blue whales photo-identified in the St. Lawrence carry scars that can be attributed to collisions with ships, including whale-watching vessels. This type of scarring has been reported for a few Northeast Pacific blue whales as well. Ship strikes in heavy shipping areas, such as the St. Lawrence and California coast, may have an impact at populations, but data are not available at this point.

Though 12% of blue whales found in eastern Canadian waters carry marks related to contacts with fishing gear, few lethal entanglements have been reported. The size and power of this whale probably enables it to tear through fishing gear relatively unscathed.

Persistent contaminants accumulated over time, such as PCBs commonly found in blue whales from eastern Canadian waters, may have an impact on reproduction and limit the recovery of certain populations.

It has been shown that blue whales react strongly to approaching vessels. The degree of reaction depends on the whale's behavior, as well as the distance, speed, and direction of the vessel at the time of approach. The increasing anthropogenic noise may have an impact on blue whales and their habitat and could also limit recovery of this species.

features of marine mammal teeth and bones are typical for mammals, and vertebrates, in general, but others are unique or unusual. Some of these may have evolved in conjunction with their shifts to marine habitats.

I. Bone

A. Bone Structure and Composition

Bone consists of highly calcified, intercellular bone matrix, and three types of cells—osteocytes, osteoblasts, and osteoclasts. The outer surface of bone is covered by periosteum, which is bound to bone by bundles of collagen fibers known as Sharpey’s fibers, and the inner bone surface is lined with endosteum (Fig. 1). Periosteum is thicker than endosteum, but both consist of fibrous connective tissue lined with osteoprogenitor cells, from which osteoblasts are derived. Osteoblasts are the cells that synthesize bone matrix proteins and are active in bone matrix mineralization. Bone matrix (also known as osteoid) consists of about 33% organic matter (mostly Type I collagen) and 67% inorganic matter (calcium phosphate, mostly hydroxyapatite crystals). The osteoblasts occur as simple, epithelial-like layer at the developing bone surface. As the bone matrix mineralizes, some osteoblasts become trapped in small spaces within the matrix (lacunae). These trapped osteoblasts become osteocytes, the cells responsible for maintenance of the bony matrix. Each lacuna holds only a single osteocyte but is connected with adjacent lacunae by microscopic canaliculi, which house cytoplasmic processes of the osteocytes. Osteoclasts are large, multi-nucleated cells that occur in shallow erosional depressions (Howship’s lacunae) on the resorbing bone surface and secrete enzymes that promote local digestion of collagen and dissolution of mineral crystals.

Bone is commonly classified according to its gross appearance as cancellous bone (bone with numerous, macroscopic interconnecting cavities, or trabeculae, also known as spongy or trabecular bone) or compact bone (dense lamellar bone without trabeculae), but both types have the same basic histological structure. In a typical mammalian long bone the diaphysis (shaft) is composed predominantly of compact bone, with cancellous bone confined to the inner surface around a central, medullary cavity (Fig. 1A), while the epiphyses (articular ends) consist mostly of cancellous bone overlain by a thin, smooth layer of compact bone. In short bones a core of cancellous bone is completely surrounded by compact bone, and in the flat bones of the skull, inner and outer plates of compact bone are separated by the diploë, a layer of cancellous bone.

Bone also can be classified histologically, as woven (primary) bone and lamellar (secondary) bone. Woven bone, or primary bone has an irregular structure and is usually replaced in adults by the more highly mineralized lamellar bone. Lamellar bone is organized into thin layers (lamellae), usually 3–7 μ m thick, which contain parallel collagen fiber bundles. Lacunae containing osteocytes are located between lamellae. There are three types of lamellae: concentric, interstitial, and circumferential (Fig. 1B). Concentric lamellae are arranged in circular layers around a long axis, the haversian canal, which is a vascular channel containing blood vessels, nerves, and connective tissue. Adjacent vertical channels are connected by more horizontally oriented vascular channels (Volkmann’s canals). The entire complex consisting of several layers of concentric lamellae around a vascular channel is known as an osteon or haversian system. Interstitial lamellae, which appear as irregularly shaped areas between adjacent osteons, consist of lamellae that are remnants of osteons destroyed during bone remodeling. Circumferential lamellae are arranged parallel to each other and comprise the outer circumferential lamellae laid down next to the periosteum and the inner circumferential lamellae laid down next to the endosteum.

Bones and Teeth, Histology of

MARY C. MAAS

The bones and teeth of marine mammals, like those of other vertebrates, consist of both organic and mineral components. Because the mineral component (mostly calcium phosphate) predominates, the constituents of bones (bone and calcified cartilage) and teeth (cementum, dentine, and enamel) are referred as “hard tissues.” Each of these hard tissues is distinguished both by its composition and by its microscopic structure. Many of the histological

Figure 1 (A) Schematic model of the wall of a mammalian long-bone diaphysis, consisting of an outer layer of compact bone and an inner layer of cancellous bone, surrounding a central medullary cavity. Periosteum covers the outer bone surface, and endosteum covers the inner bone surface. B. Bone Formation, Growth, and Remodeling

Osteogenesis (bone formation) of membrane bone (intramembranous bone and dermal bone) occurs directly, by mineralization of matrix formed by osteoblasts within condensations of mesenchyme. Osteogenesis of endochondral bone (cartilage bone) occurs indirectly, by deposition and mineralization of bone matrix on a pre-existing cartilage matrix (endochondral or cartilage bone). Bone continues to grow through remodeling, as old bone is resorbed through activities stimulated by osteoclasts, and new bone is laid down through the activities of osteoblasts. Influences on bone remodeling include strain and stress imposed by movement and muscle action, hormones, and growth factors. For example, parathyroid hormone is linked to osteoclast proliferation and activity, and calcitonin, a hormone synthesized within the thyroid, has an inhibitory effect on osteoclast activity (Marks and Popoff, 1988). Modifications of hormonal controls on bone growth and remodeling, in specific parts of the skeleton, are probably responsible for specializations in bone density patterns in some marine mammals (see below). In addition to this typical osteoblastic bone formation, osteogenesis can occur through direct transformation of cartilage or fibrous tissue into bone (metaplastic bone). Metaplastic transformation of chondrocytes into osteoblasts may account for the formation of osseous globules found in the endosteal endochondral bone of some archaeocetes (Buffr n il *et al.*, 1990). Osseous globules are pseudolamellar bone deposited in empty lacunae that once housed chondrocytes, but their mode of origin is controversial.

Because bone growth occurs throughout life, periodic growth marks in skeletal tissue, in particular, periodical deposition of periosteal bone layers, are potentially useful in mammalian age determination. Techniques of skeletal tissue age determination involve the counting of growth layer groups. Growth layer groups are sets of incremental growth lines defined by at least one change in mineral

density, such as between more stained and less stained layers or dark and light layers. However, the dynamic nature of bone growth and remodeling limits the accuracy of bone growth layer group counts.

C. Marine Mammal Bone

Marine mammals show two very different trends in bone architecture and histology, reduced bone density and increased bone density, both of which are associated with their aquatic habits (Wall, 1983). Deep-diving marine mammals, especially Recent cetaceans, have bones that are less dense than homologous elements in terrestrial mammals. They efficiently overcome buoyancy at depth by the active mechanism of lung collapse, while at surface their lighter bones enhance buoyancy, allowing them to float with relatively little expenditure of energy. A pattern of reduced bone density has been thoroughly documented in small to medium-sized odontocetes, some of the large-bodied cetaceans, and some phocids (notably the elephant seal, *Mirounga*) and is characterized by replacement of cortical bone (the compact bone surrounding medullary cavities) with cancellous bone, which also fills the medullary cavities. This condition is apparently caused by imbalance between bone resorption and redeposition beginning early in ontogeny, and is probably under hormonal control. Increase in cancellous bone in these mammals does not appear to be pathological—the microscopic architecture of cancellous bone in cetacean limbs is significantly more organized than that of typical osteoporotic bone.

In contrast, shallow-diving marine mammals, such as sirenians, overcome buoyancy while diving in large part by the static mechanism of *increased* bone density. Their bones are much denser than typical mammals' bones. This is achieved in different ways; that is, either by osteosclerosis, by pachyostosis, or by a combination of both conditions (pachyosteosclerosis) (Domning and Buffr n il, 1991). Sirenians show pronounced pachyosteosclerosis, especially in the

thoracic and occipital regions. Similarly, walruses and some seals have unusually dense limb bones.

Ongoing research in bone histology of extinct marine mammals indicates that both increased bone density and reduced bone density have evolved independently several times in different groups of marine mammals. The earliest sirenians show pronounced pachyosteosclerosis. Likewise, in contrast to Recent cetaceans, some bones of extinct Eocene archaeocetes are osteosclerotic. The earliest cetacean, *Pakicetus* (Pakicetidae), shows a pattern of osteosclerosis similar to that seen in extant semiaquatic mammals, achieved through osteoclast inhibition (Gray *et al.*, 2007). Later, more fully aquatic archaeocetes, including *Ambulocetus* (Ambulocetidae), *Kutchicetus* (Remingtonocetidae), and *Gaviacetus* (Protocetidae) show histological features associated with pachyostosis as well as osteosclerosis. These features are even more pronounced in *Georgiacetus* (Protocetidae) where osteoclast activity is further reduced (Gray *et al.*, 2007) and in the protocetid *Eocetus* where hyperostosis of the periosteal cortex and infilling of the medullary cavity with cancellous bone occurs in ribs and vertebrae (Uhen, 1999). In *Basilosaurus* (Basilosauridae) osteosclerosis of ribs is very pronounced, with total replacement of medullary trabecular bone by compact bone (Buffr n il *et al.*, 1990). In contrast, long bones of some durodontine archaeocetes show reduced thickness of periosteal compact bone, as in modern cetaceans (Madar, 1998). This, along with greater degree of bone remodeling in ribs of *Zyghoriza* (Durodontinae) than in other archaeocetes suggests that a regional pattern of histological change preceded the systemic osteoporosis of later cetaceans, in conjunction with the functional requirements of the shift from terrestrial to semiaquatic to fully aquatic locomotion (Gray *et al.*, 2007).

The ear region of cetaceans also is characterized by histological specializations of the bone. Both periotic and tympanic bones are noteworthy for their density, compactness, and high mineral content, in comparison with other mammals. This pachyosteosclerosis is due to the hypermineralized state of embryonic woven bone, which is maintained throughout life, rather than later remodeling; its occurrence early in development (in the common dolphin, it begins during the fetal stage and is complete by the first year) probably reflects its role in sound transmission (Buffr n il *et al.*, 2004).

Bone of one marine mammal, the toothed whale *Mesoplodon densirostris*, exhibits unique histological features. The rostral bone of this odontocete, which is among the densest bone known among tetrapods, is characterized by hypermineralized secondary osteons. These osteons have unusually well-aligned parallel and platy hydroxyapatite crystals and a tubular network of unusually thin collagen fibrils, and thus differ markedly from the structure of haversian systems of typical mammalian lamellar bone (Zylberberg *et al.*, 1998).

Periodic deposition of periosteal bone layers has been used in studies of age determination in mammals, though limited in use by the fact that mammalian bone undergoes remodeling throughout life (Klevezal, 1996). Bone growth layer groups have been studied in a variety of marine mammals including sirenians, pinnipeds, and odontocetes.

II. Cementum

A. Cementum Structure and Composition

Teeth of marine mammals, like all mammals, consist of a crown, which extends above the gums, and one or more roots, which extend below the gum line and hold the teeth in bony sockets (alveoli). The roots are covered by cementum (also known as cement), which sometimes extends to cover part of the crown, overlapping the cervical enamel. Cementum, along with the periodontal ligament, comprises

the periodontium, the attachment apparatus of teeth. Cementum is similar in composition to bone. Its mineral component (65% by wet weight) consists of crystals of an impure form of hydroxyapatite similar in shape and size to those of bone. Its organic component (up to 20% of the total tissue) includes cementocytes (cementum cells), ground substance containing proteoglycans, intrinsic collagen fibers, and extrinsic collagen fibers (Sharpey's fibers). The intrinsic fibers and ground substance are the primary constituents of cementum. Intrinsic fibers, like collagen fibers of lamellar bone, are small, on the order of 1–2 μm in diameter. The extrinsic Sharpey's fibers are much larger, typically 3–12 μm in diameter. The intrinsic fibers, ground substance, and cementocytes are derived from cementoblasts, but the extrinsic fibers are derived from fibroblasts of the periodontal ligament.

Cementum is classified according to the relative proportions of the different components, although the different types are gradational. Thus, cementum can be classified as cellular or acellular depending on the relative proportions of cementocytes and ground substance, or it can be classified according to its fiber composition (Fig. 2). Extrinsic fiber cement occurs close to the alveolar bone and is dominated by well-mineralized Sharpey's fibers contained within highly mineralized acellular ground substance. Mixed fiber cement contains intrinsic collagen fibers as well as Sharpey's fibers and ground substance, and may or may not contain cementocytes. Intrinsic fiber cement, which contains only intrinsic collagen fibers, ground substance, and cementocytes, occurs close to roots. In cellular mixed fiber cement and intrinsic fiber cement, cementocytes are contained in lacunae of variable shape that form within the mineralizing ground substance.

Incremental growth layers known as cementing lines or resting lines are sometimes a prominent histological feature of both cellular and acellular cementum. Cementing lines, like the incremental growth layers found in bone, dentine, and enamel, are distinct layers that parallel the developing surface. Due to periodic variation in mineralization during development, they contrast with adjacent layers. Cementum growth layer groups, like those of bone and dentine, can be empirically defined by at least one change in mineral density, such as between translucent and opaque layers, dark and light layers, ridge and groove, or more stained and less stained layers. Empirical studies have shown that cementum growth layer groups record the periodicity of tissue formation, and thus are useful in age determination.

B. Marine Mammal Cementum

Cementum in marine mammals is for the most part structurally similar to that of other mammals. Cementum growth layer groups are used in conjunction with dentine and bone growth layer groups to estimate age in marine mammals, though their relative clarity varies among species. In some species, cementum formation continues beyond that of dentine, which is an advantage in age determination. In ziphiid whales, where the cementum typically extends over most of the crown and may comprise the bulk of the tooth, cementum growth layer groups are distinguishable without magnification. Ziphiids also have been reported to have an unusual, possibly vascular cementum (Boyde, 1980).

III. Dentine

A. Dentine Structure and Composition

Dentine comprises the bulk of the volume of teeth of most mammals. In the crown, dentine is covered by enamel and in the root it is covered by cementum. Circumpulpal dentine surrounds the pulp

Figure 2 Scanning electron micrographs of an isolated tooth of an unidentified delphinoid cetacean (Yorktown Formation, Pliocene, from the Lee Creek Mines, North Carolina, USA). The specimen has been sectioned longitudinally, polished, and etched with dilute HCl. (A) High magnification view of cementum, which grades from extrinsic fiber cement on the outer periphery (top) to mixed fiber cement closer to the cementum-dentine junction (bottom). Classification of cementum depends on the proportion of Sharpey's fibers contained within the matrix. (B) Thin layers of enamel and cementum lie peripheral to dentine of the crown and root. Dentine growth layer groups appear as pairs of dark/light bands. (C) High magnification view of dentine. The walls of cross-sectioned dentine tubules contain hyper-mineralized peritubular dentine (ptd). Less mineralized intertubular dentine (itd) occurs between tubules.

cavity, which contains connective tissue, nerves, and blood vessels. Circumpulpal dentine is distinguishable histologically from a thin outer layer known as mantle dentine (in the tooth crown) or hyaline dentine (in the root). Dentine tubules, which radiate out from the pulp to the outer dentine surface, are distinctive features of dentine. They are narrow (1–4 μm diameter) tubular structures that form during dentine development around odontoblast (dentine-forming cells) cell processes. In adult teeth tubules contain mostly fluid and amorphous cell debris.

The organic component of dentine consists mainly of very small (on the order of 50 nm in diameter) collagen fibrils. The collagen fibrils in circumpulpal dentine are laid down parallel to the developing dentine surface and perpendicular to the dentine tubules but the mantle dentine contains some large (>1 μm in diameter) collagen fiber bundles known as von Korff fibers. Von Korff fibers are oriented parallel to tubules.

Dentine has 75% mineral (hydroxyapatite). Most of the small (2–3 nm in thickness and probably 20–100 nm in length) hydroxyapatite crystals are aligned parallel to each other and to the small collagen fibrils, but others are radially oriented and form spherical or semi-spherical structures known as calcospherites. Calcospherites are difficult to distinguish histologically because they typically fuse together. Areas where mineralization is incomplete and calcospherites have not fused are called interglobular dentine. Most mineralization of dentine takes place along the developing dentine front, but dentine deposited in tubule walls (peritubular dentine) undergoes further mineralization (Fig. 2C). In some cases, tubules become occluded by mineralization, forming sclerotic dentine. Denticles (smooth-surfaced, spherical mineralized bodies with a laminar structure) sometimes form by mineralization of collagen fibers within the pulp cavity. These denticles may become attached to the inner surface of the dentine, or embedded in it during continued dentine formation.

B. Marine Mammal Dentine

The dentine of most marine mammals is structurally similar to that of other mammals, but there are some exceptions. In some, notably the narwhal and sperm whale, the large von Korff fibers are not restricted to the mantle dentine but extend throughout the thickness of dentine, where they are located in the walls of dentine tubules. Denticles have been reported in some odontocetes and sclerotic dentine is found in some marine mammals, especially in seals.

Marine mammal dentine is characterized by prominent incremental growth layers (Fig. 2B) that lie at angles to dentine tubules, and vary in their intensity, both within and among individuals. The finest scale layers are the incremental von Ebner lines, which probably reflect diurnal variation in matrix fiber arrangement. Von Ebner lines appear as alternating dark and light lines in ground sections under polarized light. Other, larger-scale incremental growth layers reflect changes in density due to differences in mineralization. These include the neonatal line, a very prominent growth layer that marks physiological disturbance associated with birth, and other less distinct and consistent growth layers whose physiological bases are uncertain. In some seals, the growth layer groups are accentuated by layers of interglobular dentine. Whatever their origins, there is a regular repetition to growth layer groups that seems to reflect annual or semiannual growth cycles, and counting of dentinal growth layer groups is a primary basis of age determination in pinnipeds, sirenians, and odontocetes.

IV. Enamel

A. Enamel Structure and Composition

Enamel covers the tooth crown in most mammals. It is the most highly mineralized tissue in the body, consisting almost entirely (95% by weight) of highly structured arrangements of hydroxyapatite crystallites. The remaining fraction consists of water and two classes of proteins unique to enamel—enamelin, which predominate in mature (fully mineralized) enamel, and amelogenin, which predominate in developing enamel. The histological structure of enamel reflects the organization of crystallites into units of increasing scale,

two of which are enamel prisms and enamel types. This structural organization is determined during enamel development. Unlike bone, cement, and dentine, enamel does not remodel after its initial deposition.

Enamel matrix is secreted by ameloblasts. The activity of these enamel-secreting cells commences at the enamel-dentine junction (EDJ) and continues as ameloblasts retreat outwards, away from the EDJ. Mineral crystals precipitate and grow within the enamel matrix left by the retreating ameloblasts. The orientation and arrangement of the crystallites, and thus the structure of the mature enamel, depends on the shape of the secretory end of the ameloblast. The simplest enamel structure is formed by ameloblasts with flat secretory surfaces. In most mammal teeth, however, the bulk of the enamel is laid down by ameloblasts whose secretory ends form protrusions, called Tomes processes, surrounded by flattened areas called ameloblast shoulders. Because enamel crystallites grow perpendicular to the differently oriented secretory surfaces of the Tomes process and the ameloblast shoulder, there is a regular pattern of discontinuities in crystallite orientations. These discontinuities define the boundaries of enamel prisms and interprismatic enamel.

Enamel prisms are cylindrical bundles of largely parallel hydroxyapatite crystals extending outward from the EDJ towards the outer tooth surface. The prism boundaries are defined by differences in orientations prismatic crystallites and those of the adjacent enamel that fills the spaces between prisms. This enamel is called interprismatic enamel. It is compositionally identical to enamel prisms, but differs in crystallite orientation. The submicroscopic gap produced by the change in crystallite orientations at the prism-interprismatic boundary is known as the prism sheath (Fig. 3). Prism sheaths contain slightly greater concentrations of water and protein than the surrounding enamel, and thus are less dense. This allows prism patterns (the cross-sectional shapes and packing arrangement of prisms and interprismatic enamel) to be distinguished in ground sections or in acid-etched scanning electron microscope preparations. Prisms may have closed, circular cross-sections or open, arc-shaped cross-sections. Prism patterns have been used to distinguish among some mammalian groups, but there is considerable variation within individuals and considerable parallelism among different groups.

Enamel types describe the organization of enamel at a scale greater than individual crystallites or prisms. Common enamel types include parallel crystallite enamel, radial enamel, and decussating enamel. Parallel crystallite enamel, a type of nonprismatic enamel, is a volume of enamel in which hydroxyapatite crystallites are parallel to each other with no discontinuities in orientation and lacking larger-scale structural features, other than incremental lines. Radial enamel refers to a volume of prismatic enamel where prism long axes are parallel to one another and directed radially outward from the EDJ. Decussating enamel is a volume of enamel characterized by layers of parallel prisms, one or more prisms in thickness, whose long axes alternate in orientation with prisms in adjacent layers. Decussating enamel, also known as Hunter-Schreger bands (HSB), includes undulating HSB, where layers of similarly oriented prisms have a gently undulating course from the EDJ to the surface, and zigzag HSB, where the layers undulate with a pronounced vertical amplitude. Differences in enamel types have a phylogenetic component, but also have different mechanical properties that can be important functionally—parallel crystallite enamel may be harder than prismatic enamel, but prismatic enamel, especially decussating enamel, is more resistant to cracks induced by chewing stress. Zigzag enamel is thought to be especially resistant to cracking. Most mammal teeth are composed of more than one enamel type.

Figure 3 (A) Scanning electron micrograph of fractured enamel near tip of tooth (unidentified Pliocene odontocete, Lee Creek Mine, North Carolina, USA). The naturally fractured surface (at top) shows that the prisms take a straight course from the enamel-dentine junction (EDJ) to the outer surface, as is typical in radial enamel. (B) High magnification view showing enamel prisms (P) sectioned oblique to their long axes. Prism crystallites are parallel to each other, but not to crystallites in adjacent interprismatic enamel (IP). Arrows indicate the position of the prism sheath, which has been artificially enlarged in this acid-etched specimen.

Cross-striations, a record of the daily incremental deposition of enamel, are sometimes evident in both prismatic and nonprismatic enamel. In the scanning electron microscope cross-striations appear as alternating constrictions and varicosities along the length of the prism, suggesting that they reflect variations in rate of enamel secretory activity. More prominent incremental lines, known as brown striae of Retzius, also transect prisms or crystallites. They are oriented parallel to the developing enamel surface, and probably reflect regular interruptions in growth, although their causes and periodicity are not clear.

B. Marine Mammal Enamel

Although the crowns of most marine mammal teeth are covered with enamel, there is considerable variation in its structural complexity among and within orders. Likewise, prism patterns vary among and within orders, though there is no compelling evidence that prism patterns are diagnostic of particular marine mammal groups.

Most extant cetaceans have thin, structurally simple enamel. In some the enamel consists of a thin layer of radial prismatic enamel with or without an outer layer of nonprismatic parallel crystallite enamel, and in many species the tooth enamel consists entirely of nonprismatic parallel crystallite enamel. In contrast, the most primitive cetacean, the fossil *Pakicetus*, had relatively thick enamel with a more complex structure consisting of parallel crystallite enamel, radial enamel and a thick inner layer of undulating Hunter-Schreger bands. Later archaeocetes show the same arrangement of enamel types, but almost all more derived odontocetes have much less complex enamel. This has led some workers to conclude that the enamel of most extant cetaceans is evolutionary degenerate. Only two extant odontocetes, the Indus dolphin *Platanista* and Amazon dolphin *Inia* have well-developed, undulating HSB. It is unclear whether these were independently acquired in response to functional demands of their diet or a primitive retention from archaeocete ancestors.

Extant sirenians (*Dugong* and *Trichechus*) are reported to have radial enamel with variably circular and arc-shaped prism cross-sections. Similar enamel has been reported for some fossil sirenians, and it is likely that this is primitive for the group. Pinniped enamel has not been described in detail, but enamel of some species appears to be more complex than that of sirenians. *Phoca* has undulating HSB, and walrus enamel shows a transition from undulating HSB to zigzag HSB near cusp tips.

Enamel incremental lines generally are not used in age determination of marine mammals. The thin enamel of many species makes resolution of these lines difficult, and, more importantly enamel only records the period of tooth development during which enamel is laid down, which, in most cases, is before birth.

Bottlenose Whales

Hyperoodon ampullatus and *H. planifrons*

SHANNON GOWANS

I. Characteristics and Taxonomy

Bottlenose or bottle-nosed whales are large, robust beaked whales (6–9 m) distinguished by their large bulbous forehead and short dolphin-like beak (Fig. 1). They are chocolate brown to yellow in color, being lighter on the flanks and belly. This coloration is believed to be caused by a thin diatom layer. Newborns are gray with dark eye patches and a light-colored forehead. The maxillary crests of males become larger and heavier with age, leading to a change in the shape of the forehead, with mature males having a flat, squared-off forehead whereas females/immature males have a smooth-rounded forehead. The dense bone in the male's forehead may be used for male–male competition, as males head-butt one another (Gowans and Rendell, 1999). Males possess a single pair of conical teeth at the tip of the lower jaw (in females, they remain unerupted); however, these teeth are rarely visible in live animals.

Northern (*H. ampullatus*) and southern (*H. planifrons*) bottlenose whales are the only recognized species within the genus *Hyperoodon* in the family Ziphiidae (Mead, 1989). Recent molecular work on southern bottlenose whales indicates that there may be more than one species (Dalebout *et al.*, 1998). Sightings of a large beaked whale in the tropical Pacific has been identified in the past as a bottlenose whale (either *H. planifrons* or a third, undescribed *Hyperoodon* sp.), however recent evidence suggests these whales are Longman's beaked whale (*Indopacetus pacificus*) (Dalebout *et al.*, 2003).

Figure 1 A northern bottlenose whale underwater.

II. Distribution and Abundance

Northern bottlenose whales are found in subpolar and cold temperate waters of the North Atlantic, from the ice edge to the Azores, almost always in waters deeper than 500 m (Wimmer and Whitehead, 2004). They concentrate in submarine canyons, continental shelf edges, and other areas of high relief. A resident year-round population is found in the Gully, a large submarine canyon 200 km off the coast of Nova Scotia, Canada. Gully residents also use nearby canyons but do not appear to make long-distance migrations to other centers of distribution (such as off Labrador, Iceland, Norway, the Faroes, or the Azores). Whales found in different areas of the Atlantic have different length distributions, indicating that there may be geographic isolation between the different whaling grounds. Analysis of both nuclear and mitochondrial DNA indicates reproductive isolation between bottlenose whales in the Gully and Labrador, however there is likely mixing between bottlenose whales from Labrador and Iceland (Dalebout *et al.*, 2006).

Southern bottlenose whales are found throughout the Southern Hemisphere, from the ice edge to 30°S. There are no known areas of concentration, although relatively little effort has been made to identify or census these animals.

III. Ecology

Bottlenose whales are deep divers feeding predominantly on squid of the genus *Gonatus*, although other species of squid are eaten (Hooker *et al.*, 2001). Adult *Gonatus* are primarily benthic, although juveniles may inhabit the water column. Fish (including herring and redfish) and benthic invertebrates such as starfish and sea cucumbers are occasionally consumed. Time-depth recorders on two northern bottlenose whales in the Gully indicated that these whales were routinely diving to or near the sea floor over 1400 m below the surface (Hooker and Baird, 1999).

Evidence from whaling suggests that northern bottlenose whales migrate north in spring and south in the fall; however, evidence for this is weak and this migration may actually represent a migration of whaling vessels. Stomach contents of stranded animals indicate that both northern and southern bottlenose whales can travel over long distances (~1000 km), although it is not known if these movements are routine. Most individuals in the Gully appear to be year-round residents, although they do routinely spend time outside the canyon, often in nearby canyons. Gully animals do not appear to make long-range migrations.

IV. Behavior and Physiology

Both northern and southern bottlenose whales are typically found in small groups (one to four individuals), although groups of up to 20

have been observed. Nothing is known about the social organization of southern bottlenose whales, and only the Gully population of northern bottlenose whales has been studied (Gowans *et al.*, 2001). In the Gully, individuals live in fission–fusion groups and most associations are brief (on the order of minutes to a few days). Females form a loose network of associates with most members of the community. However, mature males form long-term companionships with other mature males and these associations last for years. The function of these associations is unknown, but they may be linked to mating and may be similar to male coalitions in bottlenose dolphins.

Northern bottlenose whales are often described as curious, as they will often approach boats. Whalers exploited this behavior to find groups of bottlenose whales, and as healthy whales would often remain near wounded individuals, the entire group was often captured.

V. Life History

Analysis of whaled carcasses off Labrador indicates sexual maturation at 7–11 years for males and 11 years for females (Benjaminsen and Christensen, 1979). A single calf is born after a gestation of at least 12 months. The oldest individual caught during whaling was 37.

VI. Interactions with Humans

The commercial hunt for northern bottlenose whales began in the 1850s and extended until the 1970s. Over 80,000 whales were captured during this period, and many more were harpooned but not recovered (Benjaminsen and Christensen, 1979). Pre-exploitation numbers are estimated at 40–50,000 whales, although this number is at best a rough guess. There is no current estimate for the size of the North Atlantic population, but it is unlikely that it has fully recovered from whaling (COSEWIC, 2002). Approximately 160 individuals reside in the Gully currently, and this population is likely still recovering from the whaling catch of approximately 60 animals taken from the area in the 1960s. The Scotian Shelf population (including the Gully) is considered to be Endangered under Canadian law.

The study in the Gully represents the first long-term study of live beaked whales. Crews from several documentary films and magazines have visited the Gully, as it is one of the few places where beaked whales can be observed routinely.

Bowhead Whale

Balaena mysticetus

DAVID J. RUGH AND KIM E. W. SHELDEN

I. Characteristics and Taxonomy

Bowhead whales, sometimes called Arctic right whales, Greenland right whales, great polar whales, or *ahvik*, are members of the family Balaenidae (Mysticeti, Cetacea) that live most of the year associated with sea ice in northern latitudes (Braham *et al.*, 1980; Burns *et al.*, 1993). Bowheads have never occurred in the Southern Hemisphere.

Bowheads are readily identifiable by their large size, rotund shape, lack of a dorsal fin, dark color, white chins, triangular head (in profile), and neck (an indentation between the head and back). They are predominantly black, but most have characteristic white patterns on their chins, undersides, around their tail stocks, and on their flukes (Fig. 1). These patterns distinguish them from the similar-appearing right whales (*Eubalaena* spp.) and are unique to each individual. The white portions of the pattern around the tail and on the flukes increase in extent with age. Most bowheads accumulate distinctive, permanent marks on their backs, perhaps resulting from contact with sea ice or the sea floor when feeding. The bowed appearance of the mouth gives them their name.

These huge marine mammals are among the largest animals on earth, weighing up to 75–100 tons (Reeves and Weatherwood, 1985). Males grow to 14–17 m in length and females 16–18 m, perhaps as long as 20 m. Their flukes are 2–6 m across. The head constitute over a third of the bulk of the body, and the baleen may reach lengths of 4 m (no other whale has baleen longer than 2.8 m) with 230–360 plates on each side of the mouth, making the capacious mouth quite possibly the largest of any animal ever. To insulate them from the icy water, bowheads are wrapped in blubber 5.5–28 cm thick covered by an epidermis up to 2.5 cm thick. This combination of blubber and skin is the thickest of any whale species.

II. Distribution and Abundance

Currently there are four or five recognized stocks of bowheads defined by geographically distinct segments of the species' total population: the Western Arctic (or Bering–Chukchi–Beaufort stock) found around Alaska, Okhotsk Sea in eastern Russia, Davis Strait and Hudson Bay in northeastern Canada (sometimes considered separate stocks), and Spitsbergen in the North Atlantic (Rugh *et al.*, 2003; Heide-Jørgensen *et al.*, 2006). According to fossil records, bowhead whales may have emerged in the Northern Hemisphere during the Pliocene (roughly 8 million years ago). Genetic mixing among the current stocks was possible during the relatively warm interglacial periods (e.g., AD 1000–1200) when reduction in sea ice meant whales could move between the Atlantic and Pacific Basins. Movement between the Beaufort Sea and Hudson Bay was stopped by icier seas during the "Little Ice Age" (AD 1400–1850). Until recently, temperatures have been cool enough to keep ice across most of the east–west passages of the Arctic, isolating the Western Arctic and Davis Strait–Hudson Bay stocks.

The largest remnant stock, the Western Arctic stock, consists of over 10,000 whales (George *et al.*, 2004) that migrate from the Bering Sea in the winter through the Chukchi Sea to the Beaufort Sea in the summer. This stock is growing at an annual rate of 3%. Prior to commercial whaling, there may have been 10,000–23,000 whales in this stock.

The Davis Strait–Hudson Bay stock is now thought to number at least 7000 bowheads (Cosens *et al.*, 2006), though there may have been over 11,000 prior to commercial whaling. In the Okhotsk Sea, there are now only about 300–400 bowheads where there originally were more than 3000. The Spitsbergen stock, originally at 24,000 bowheads, supported a huge European fishery, but today there are only tens of whales left (Shelden and Rugh, 1995).

III. Ecology

The only predators of bowhead whales, other than humans, are killer whales (*Orcinus orca*). Scars from killer whale teeth were found on approximately 4–8% of the whales taken in the subsistence hunt by Alaskan Eskimos (George *et al.*, 1994). In part, the bowheads'

close association with sea ice may be a way of seeking refuge from killer whales.

As many as 60 species have been found in bowhead stomachs, but the preferred prey are copepods (11 species) and euphausiids (2 species), plus mysids and gammarid amphipods (Lowry, 1993).

IV. Behavior and Physiology

Bowheads feed throughout the water column, sometimes on the surface (called “skimming”) and sometimes at or near the seafloor (as evidenced by mud smeared across their heads and backs, Würsig and Clark, 1993). A bowhead’s huge mouth can engulf large volumes of water, including prey, and, as the tongue rises, the water is pushed out, trapping prey on the inside fringed surfaces of the baleen, which acts as a filter all the way around the mouth. The massive tongue (up to 5 m long and 3 m wide) then sweeps the food off the baleen into a very narrow digestive tract. Sometimes a dozen bowheads will feed together in an echelon formation, similar to a line of migrating geese. Perhaps this coordinated effort helps the whales entrap their prey.

Bowheads are well adapted to the risky occupation of being air-breathing mammals in seas often covered with thick ice: they can withstand breaking through ice up to 60 cm thick, and their diving abilities are exceptional—possibly exceeding an hour. These abilities are critical to finding breathing holes when swimming under sea ice. The very low-frequency and very loud calls bowheads produce may help them find mates or assist in following each other when navigating through sea ice. The only other whales commonly found in ice as far north as bowheads are belugas (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*), toothed whales with some of the same characteristics seen in bowheads: smooth backs and relatively thick blubber.

V. Life History

Bowheads probably mate in late winter or early spring, but sexual activity may occur in any season (Nerini *et al.*, 1984). Acoustics probably play a vital role in reproduction because bowheads are vocally active during the mating season and can hear each other 5–10 km away. Breaching (leaping completely out of the water) and fluke slapping (when the tail smashes down on the water surface) may also play a role in attracting a mate or asserting dominance, but the role of these behaviors is not well understood. Bowhead whales have been observed mating in pairs as well as in larger mating groups. There is a great deal of physical contact and turning in these groups, perhaps as several males attempt to copulate with one female.

More than a year after mating (13–14 months), calves are born, usually during the spring migration between April and June. Calves are about 4 m long at birth. Females have calves 3–4 years apart. The following spring, the young whales, now 6–8 m long, are weaned. After this, juvenile growth is slow compared to other baleen whales. At roughly 15 years of age, when 12–14 m long, females become sexually mature, and males become sexually active when 12–13 m long (Nerini *et al.*, 1984). Bowhead whales may live longer than any other mammals; ancient harpoon points recently discovered in hunted whales and eye lens analysis indicate some bowheads live for more than a century (George *et al.*, 1999).

VI. Interactions with Humans

Commercial whaling had a profound effect. The bowhead’s large size, long baleen, and thick blubber have made them such a valuable commodity that whalers went to great lengths to kill them (Braham *et al.*, 1980; Bockstoce, 1986). Commercial whalers from 17th to

19th centuries were so efficient that they depleted stock after stock of these whales. In fact, even a century after commercial whaling ceased, all bowhead stocks are still considered endangered.

In modern times, Native Alaskans kill about 40 whales per year through quotas set by the International Whaling Commission (IWC). The Chukotka Natives of Siberia have been allotted five bowheads per year from the Alaska quota. Independent of the IWC quota, the Canadian government has allowed a limited hunt of bowheads from the Western Arctic stock (in the eastern Beaufort Sea) and from Davis Strait and Hudson Bay.

Bow-Riding

BERND WÜRSIG

One of the most fascinating behaviors of dolphins is when they ride the bow pressure waves of boats. Dolphins probably have been bow-riding ever since swift vessels plied the seas, propelled by oar, sail, or very recently in the history of seafaring, motor. The Greeks wrote of bow-riding in the eastern Mediterranean and Aegean Seas by what were most likely bottlenose (*Tursiops truncatus*), common (*Delphinus delphis*), and striped dolphins (*Stenella coeruleoalba*).

Bow-riding consists of dolphins, porpoises, and other smaller toothed whales (and occasionally sea lions and fur seals) positioning themselves in such a manner as to be lifted up and pushed forward by the circulating water generated to form a bow pressure wave of an advancing vessel (Lang, 1966; Hertel, 1969). Dolphins are exquisitely good at bow-riding, able to fine-tune their body posture and position so as to be propelled along entirely by the pressure wave, often with no tail (or fluke) beats needed. Bow-riders at the periphery of the pressure wave do need to beat their flukes, and so do bow-riders of a slowly moving vessel or one with a very sharp cutting instead of pushing bow.

There is often quite a bit of jostling for position at the bow, as dominant animals of a group edge others to a less favorable position, or as one is displaced from the bow by another one approaching (Fig. 1). It is great fun for a person to lean over the bow of a vessel and watch these inter-animal antics, as well as the fine-tuning of positioning, effected by slight body turns and almost imperceptible movements of the flippers. Bow-riding dolphins also tend to emit what sounds to the human listener like a cacophony of underwater whistles and “screams,” sounds implicated in high levels of social activity (Brownlee and Norris, 1994). Bow-riding is probably the dolphin behavior most noted, and most enjoyed, by seafaring people the world over.

Of course, riding the bow also makes these animals susceptible to being lanced or harpooned in areas where they are taken by humans. Where this occurs near shore and in apparent smaller populations, dolphins become shy of the bow (Norris, 1974), but on the high seas or in deeper water, probably in larger populations, dolphins often still ride the bow after tens to hundreds of years of (generally small scale) human hunting.

While many species of dolphins, porpoises, and small toothed whale ride the bow, some do not; and in some species, certain populations do not. Bottlenose dolphins are well-known bow-riders the world over, but even they do not ride in some areas (even where they are not hunted) or on some types of vessels. For example, off the shores of Texas in the Gulf of Mexico, they generally do not approach any vessel

Figure 1 Common dolphins (*Delphinus delphis*) on the bow of a sailing vessel off Panama. Photo by Bernd Würsig.

Figure 2 Two bottlenose dolphins (*Tursiops truncatus*) leap for a breath between rides on the bow of a shrimp vessel near shore in the Gulf of Mexico. Photo by Bernd Würsig.

smaller than 15m long to bow-ride, apparently finding the smaller bows not worth their while. Instead, they “hitch a ride” on the oil tankers and freighters, sometimes larger shrimping vessels while enroute to and from the shrimping grounds, at times bow-riding for 20 or more kilometers at a stretch. Dolphins ride underwater, and must leave their position to breathe, leaping forward and at an angle to the surface before falling back toward the advancing bow in a welter of foam (Fig. 2). Dolphins also ride the stern waves (or wakes) of boats, which present a different hydrodynamic challenge than bow-riding; and in some areas, dolphins that do not approach the bow will nevertheless ride in the influence of a large (or fast small) vessel’s wake.

Most oceanic dolphins ride bow waves, with notable exceptions in areas of intensive hunting, such as by tuna vessels of the eastern Tropical Pacific, where vessels chase dolphins in order to net the tuna often affiliated with a dolphin school (Perrin, 1968). However, riding the bow is also “mood dependent”; dusky dolphins (*Lagenorhynchus obscurus*), for example, will not approach vessels when they have not fed for two or more days. These same dolphins will race toward a boat from several kilometers during and after social/sexual activities that take place immediately after bouts of feeding on schooling anchovy (Würsig and Würsig, 1980).

Why do dolphins bow-ride? It has been proposed that it is a mechanism to efficiently travel from one place to another. However, this is unlikely, for one often sees bow-riding dolphins after some time heading back to whence they picked up the vessel. Instead, it is more likely that riding the bow is done for enjoyment, for the sport of it; in other word, play. This is of great interest to behaviorists, for there are not too many non-domesticated adult mammals that habitually engage in activities just for the fun of them, although the list is growing with detailed observations in nature.

Bow-riding was certainly not “invented” by dolphins as a sport when human-made vessels first came on the scene. Instead, it appears to have been adapted from other wave-riding forms. Dolphins ride on the lee slopes of large oceanic waves and on the curling waves (or surf) that are formed as oceanic waves touch near-shore bottom (these two “rides” are hydrodynamically quite different; Hertel, 1969). Dolphins “body surf” much as do humans, but dolphins are generally much better surfers than humans. Dolphins also ride the bow waves of surging whales such as baleen whales and sperm whales (*Physeter macrocephalus*). Dolphins even “entice” whales to surge ahead by rapidly crossing back and forth a whale’s eyes and snout. The whale surges forward in response (and apparent annoyance), often blowing forcefully during the surge. An abrupt bow wave is formed, and the previously heckling dolphins are all lined up in that wave, apparently enjoying its momentary pressure effect. This activity can go on with one whale for 20 min or more, until the whale tires, the bow wave becomes less distinct, and the dolphins abandon it to try with another whale or to go about other activities. They have had their fun, and we are left to wonder what is going on in that large brain during these bouts of quite obvious play.

organs and brain intimate the selective pressures, which may have led to exclusively aquatic life. There are some obstacles, however, in understanding brain evolution in these animals. First, we are only marginally familiar with the brain morphology of very few species, and here we are familiar with mainly the bottlenose dolphin (*Tursiops truncatus*; discussed later). Second, the brain itself does not fossilize; only the outer shape can be studied in natural endocasts, and these are biased covering blood vessels, meninges, and by geological artifacts. Thus, the tracing of brain evolution in fossils is difficult and should be supplemented by phylogenetic reconstruction on the basis of extant relatives. Third, although the comparative consideration of analogous developmental trends (primates) may be useful for the understanding of brain evolution in highly encephalized aquatic mammals, the paucity of data often leads to an overestimation of these analogies.

Among the most fascinating characteristics of toothed whales are the exceptionally large size of their brains, both in absolute and in relative terms, and the extremely dense folding of the neocortex. Whereas dolphins usually have a brain mass of about 200–2000 g, the maximal size is attained in killer whales (*Orcinus orca*) and (giant) sperm whales (*Physeter macrocephalus*) approximating 10,000 g. Basically, odontocete brains show the typical mammalian bauplan and are as complicated morphologically as those of other mammalian groups. To some extent, they parallel the simian and the human brains. In this respect, however, it has to be kept in mind that cetaceans have been subject to profound modifications in brain morphology and physiology during 50 million years of separate evolution in the aquatic environment. Moreover, it is still very difficult to correlate the results of behavioral and physiological research on dolphins with existing neuroanatomical data. Because invasive experimentation is not possible in cetaceans, the functional significance of such data can only be elucidated via comparison with other aquatic or terrestrial mammals.

Most studies during the last decades have focused on the morphology and the potential physiology of the adult toothed whale brain and its functional systems (Jelgersma, 1934; Jansen and Jansen, 1969; Glezer *et al.*, 1988; Ridgway, 1990). Concerning the development of the odontocete brain, the very few recent papers were dedicated to the striped dolphin (*Stenella coeruleoalba*), harbor porpoise (*Phocoena phocoena*; Buhl and Oelschläger, 1986), spotted dolphin (*Stenella attenuata*), narwhal (*Monodon monoceros*), and sperm whale (Oelschläger and Kemp, 1998). Reviews of information on the mammalian brain, including that of marine mammals can be found in Nieuwenhuys *et al.* (1998).

I. Morphology of the Cetacean Brain

A. General Appearance

Whereas its development in the embryonal and early fetal period is similar to that of other mammals, the brain of adult whales and dolphins is rather spherical in comparison with that of generalized land mammals (Oelschläger and Oelschläger, 2002) and somehow reminiscent of a boxing glove (Fig. 1). In correlation with the so-called “telescoping” of the skull along the beak-fluke axis, both the cranial vault and the brain are short but wide and even more so in toothed whales (odontocetes) than in baleen whales (mysticetes). In the bottlenose dolphin (Fig. 1), the hemispheres are rounded and high, and the anterior profile is rather steep. In ventral aspect (Fig. 2), the contour of the odontocete forebrain is more trapezoidal, whereas in mysticetes it is more trilobate, with the area of the insula (Fig. 3) being visible externally as an indentation between the orbital and the temporal lobes only (Figs 1 and 2). In comparison with hoofed animals, the telencephalic hemisphere seems to be rotated rostralward and ventralward

Brain

HELMUT H.A. OELSCHLÄGER AND
JUTTA S. OELSCHLÄGER

Adaptation to aquatic environments is a multiconvergent phenomenon seen in a number of mammalian groups and species (Oelschläger and Oelschläger, 2002). In toothed whales (odontocetes), both the body shape and the morphology of the sensory

leading to a subvertical position of the corpus callosum (Fig. 1). In some odontocetes (bottlenose dolphin, sperm whale), the posterior myelencephalon and the anterior spinal cord curve around the cerebellum. Via an S-shaped transition, the spinal cord then continues straight along the body axis, thus accounting for the shortening of the cetacean neck region.

The ventricular system reflects the foreshortening of the brain in the tight coiling of the lateral ventricles, the shortness of the fronto-orbital region (anterior horn), the lack of an occipital pole of the hemisphere (no posterior horn), and the large size of the midbrain (cerebral aqueduct).

B. Telencephalon

1. Cortex In comparison with generalized tetrapod mammals (Oelschläger and Oelschläger, 2002), the surface of the telencephalic hemispheres is extremely convoluted, particularly in toothed whales (Figs 1–3). Gyrification in baleen whales is presumably less extreme because of the greater width of their cortical layers. It is the neocortex that accounts for the large size of the telencephalon and thus the large size of the brain (percentage of the neocortex: 63% in the generalized Franciscana, *Pontoporia blainvillei*; 87% in the sperm whale).

As in higher primates, most of the cortex of the cetacean olfactory and limbic systems (allocortex) is either restricted to the rostral base of the hemisphere (paleocortex; olfactory system) or located at the inferior horn of the lateral ventricle in the temporal lobe

(archicortex: hippocampus). The archicortex in cetaceans, and particularly in toothed whales (Fig. 3), is much smaller than in terrestrial mammals. This correlates well with the small size of other limbic components, e.g., the fornix as the fiber tract of the hippocampus and the mammillary body as a relay structure, whereas the cortical fields above the corpus callosum (“limbic lobe,” Fig. 1) and the entorhinal cortex on the temporal lobe are well developed. As in primates, the cortex of the cetacean limbic lobe presumably does not have an immediate relationship to olfaction. With respect to other large mammals, olfactory components seem to be much reduced or even lacking in adult toothed whales. In contrast to the situation in baleen whales where the nose is small but obviously functional, odontocetes do not exhibit an olfactory part of the nose, olfactory bulb or tract, and the central parts of the olfactory system are moderately developed. In these animals, the mechanical impact of pneumatic sonar signal generation may have led to the elimination of the nasal chemoreceptor systems during evolution (Oelschläger, 2008).

A. SURFACE CONFIGURATIONS The fissural or gyral pattern of the cetacean cortex, which has been discussed in many papers in the past, bears general resemblance to that of carnivores and ungulates (Figs 1–3). On the convex lateral surface and the vertex of the hemisphere, the main fissures (ectosylvian, suprasylvian, lateral sulcus) run around the Sylvian cleft more or less concentrically. Thus, for example, the ectosylvian gyrus is bordered by the ectosylvian and suprasylvian sulci, the suprasylvian gyrus by the suprasylvian and lateral sulci, and the lateral gyrus by the lateral and entolateral

(paralimbic) sulci. As in other high-encephalized mammals, the insular area (Fig. 3) is covered by so-called “opercula” of the neighboring neocortex, which meet at the lateral hemispherical fossa (Sylvian cleft) and are combined in the term perisylvian cortex (Fig. 1). The medial cortex of the hemisphere is subdivided by the suprasplenic sulcus or limbic cleft and the entolateral or paralimbic cleft. Far rostrally and ventrally, the cruciate sulcus (Fig. 1) separates an anterior motor cortical field from a posterior somatosensory field and is therefore a candidate for homologization with the ansate sulcus in hoofed animals as well as the central sulcus in primates. It is unclear whether the “calcarine sulcus,” which originates from the paralimbic cleft and encircles the oval lobule (Fig. 1B), is the homolog of the primate calcarine fissure that houses the primary visual field. Electrophysiological mapping experiments in dolphins have detected visually responding cortical fields in a more anterior and lateral position on the vertex of the hemisphere.

In one of the most plesiomorphic whales (*Susu* or Indus river dolphin; *Platanista gangetica*), gyrification is still relatively simple. In the dorsal aspect, the main fissures are straight, smooth, and remind of the situation in the mesonychid *Synoplotherium*, a fossil terrestrial relative of the cetaceans. Brain length in the latter still exceeded brain width, the formation of a temporal lobe had only just begun, and the olfactory system was well developed. Archaic fossil cetacean (archaeocete) brains are difficult to interpret morphologically because they apparently had large retia mirabilia on the surface of the brain as is seen in living baleen whales, where they largely conceal the posterior (cerebellar) part. Their telencephalic hemispheres were obviously small and showed no signs of gyrification.

B. LOCALIZATION OF CORTICAL AREAS Electrophysiological cortical mapping experiments in the bottlenose dolphin located the motor neocortical field in the frontal (orbital) lobe rostral to the paralimbic lobe (Fig. 7). The motor cortex is characterized by the presence of giant pyramidal neurons and gives rise to the pyramidal tract. Laterally and caudally, the motor field is separated from the somatosensory field by the so-called “cruciate” sulcus. The somatosensory field is situated rostral to the visual and auditory fields. The position of the visual fields is somewhat more complicated. Although different in many aspects from other mammalian visual cortices, those of the dolphin are apparently well developed and highly differentiated. All authors place visual cortex in the lateral gyrus, whereas some distinguish a primary visual field near the medial border of the suprasylvian gyrus from a secondary field in the lateral gyrus. Other authors find an additional visual area in the medially adjacent part of the paralimbic lobe (Fig. 7). On the basis of histological analysis, a visual field has also been reported for the borders of the supposed “calcarine” sulcus that separates the oval and lingual sublobules of the paralimbic lobe (Fig. 1). The large primary auditory field lies on the vertex of the hemisphere in the suprasylvian gyrus and lateral to the visual field(s), the secondary auditory field lies more laterally in the medial part of the ectosylvian gyrus (Fig. 7).

Viewed as a whole, the topography of the motor and sensory projection fields of dolphins differ from that in other mammals. However, these primary cortical fields in cetaceans have retained the sequence found in plesiomorphic terrestrial mammals. Therefore, it seems as if the hemisphere would have been expanded to such a degree in a caudal and a ventral direction (huge temporal lobe) that the auditory cortex now extends as a belt along the vertex of the hemisphere and reaches further caudally in the dolphin than the visual field, which is located more in the center of the hemisphere. The lateral surface of the whale hemisphere may be interpreted as a large “association cortex” connecting the auditory fields with other sensory and motor areas.

2. Commissures The size of the individual commissural systems is specific for cetaceans and shows correlations with cortical and nuclear structures throughout the forebrain (Figs 1B, 3, and 4).

The anterior commissure, which links neocortical and paleocortical areas of both temporal lobes, is obviously weak due to the considerable reduction of the olfactory system. The corpus callosum is the main link between the neocortical fields of both hemispheres and is rather thin in dolphins relative to total brain mass and in comparison with the situation in other mammals. The cross-sectional area of the cetacean corpus callosum (defined by its area in the midsagittal plane) related to brain mass generally decreases in larger-brained toothed whales, thereby suggesting that increases in brain weight are not necessarily accompanied by increases in callosal linkage between the telencephalic hemispheres. Thus, the corpora callosa of a killer whale

and a human brain show the same cross-sectional area, with the killer whale brain being some five times heavier than that of the human. Furthermore, this regression of the corpus callosum in larger species obviously has not been compensated by an enlargement of other commissural tracts. In conclusion, the interhemispheric connectivity seems to correlate inversely with brain weight insofar as larger brains possess a lower neocortical neuronal density with the possible result that relatively fewer fibers constitute the corpus callosum. An additional explanation for the regression of the corpus callosum in larger brains could be a smaller percentage of cortical neurons establishing interhemispheric connections and thus a certain independence on the part of both hemispheres. In electroencephalographic experiments, sleeping bottlenose dolphins have been reported to show signs of wakefulness

(low voltage, fast activity waveforms) in one hemisphere and sleep (high voltage, slow wave) in the opposite hemisphere. The posterior commissure (Figs 1, 4, and 8) is very well developed. Provided that its connections to other brain structures are similar to those in terrestrial mammals, the considerable size of the posterior commissure in cetaceans may suggest massive projections from somatosensory relay nuclei of the brain stem and the cerebellum to the contralateral pretectum and thalamus.

3. Basal Ganglia All components of the basal ganglia as known from other mammals are present in cetaceans (corpus striatum, globus pallidus, claustrum, amygdaloid complex) and for the most part show the usual topographic relationships to each other and to neighboring

structures (Jansen and Jansen, 1969, Morgane and Jacobs, 1972). Moreover, their histological organization corresponds well with that in other mammals. The caudate nucleus as the main part of the large corpus striatum, which bulges distinctly in the area of the “olfactory tubercle” (olfactory lobe) together with the putamen, is largely separated from the latter by a well-developed internal capsule.

Reports regarding the size of the basal ganglia in cetaceans are contradictory in the literature. Quantitative analysis (Schwerdtfeger *et al.*, 1984) has shown that in the generalized Franciscana the corpus striatum, one of the most important centers for locomotion, is large and attains a size index between that of prosimian and simian monkeys. Moreover, as in primates, a size correlation between the striatum and the neocortex seems to be valid for dolphins as well.

The structure of the amygdaloid complex very closely resembles that of other mammals. The size of the amygdala as a whole seems to have been only slightly affected by the reduction of the paleocortex in odontocetes, giving the impression that this nucleus (as in primates) is largely independent of the olfactory system. Its relative size in the Franciscana seems to be larger than in primates presumably on account of its interconnections with the hypertrophied auditory system and the temporal lobe. Particularly the lateral amygdaloid nucleus may bear some relation to auditory function since this nucleus is extremely well developed both in whales and in bats. However, the corticomедial group of the amygdaloid nuclei, which largely depends on the olfactory system functionally, nevertheless occupies the same proportion of the entire amygdaloid complex in the harbor porpoise as in the macrosmatic sheep.

C. Diencephalon

The relative size of the diencephalon in plesiomorphic dolphins (Franciscana; Susu) is approximately the same as that in monkeys (Figs 1B and 3). There are no reliable data for advanced, delphinid dolphins. The predominant structure is the thalamus. The shape of the diencephalon in mediosagittal aspect is often rather wedge-like in adult cetaceans, with the hypothalamus bending slightly caudalward and tapering in the direction of the hypophysis, particularly in larger toothed whales. In late embryos and early fetuses the floor of the hypothalamus is rather long, whereas it is rapidly foreshortened in later stages during the telescoping process and especially in larger toothed whales. Thus, the transverse interpeduncular fossa between the optic chiasm and pons appears slit-like in adult toothed whales (Figs 1B, 2, and 8).

1. Epithalamus The habenular complex is large and the habenular commissure well developed. The pineal organ is reduced or even lacking in cetaceans. A pineal rudiment is present between the habenular and the posterior commissures in embryos and early fetuses of dolphins and the sperm whale, but not in the early fetal narwhal (Oelschläger and Kemp, 1998). In adult whales and dolphins, many observers found the pineal organ to be lacking; it seems plausible that in this case the two fiber tracts unite into a commissural complex (common dolphin; Oelschläger *et al.*, 2008). Rudiments of the pineal organ have also been found in the humpback whale (*Megaptera novaeangliae*) and fin whale (*Balaenoptera physalus*).

2. Thalamus Basically, the organization of the large thalamus in cetaceans corresponds well with that in a variety of terrestrial mammals, among them ungulates and primates. There are four groups of nuclei in the dorsal thalamus that constitute about 92% of the thalamus in the bottlenose dolphin: the anterior, medial, ventral, and lateral nuclei. (1) The anterior group of nuclei, which is related to the cortex of the large cetacean limbic lobe, is well developed but constitutes only

a small part of the total dorsal thalamus. The anteroventral nucleus, which projects to the anterior limbic cortex, dominates this group. In contrast, the mammillary body and the interconnecting mammillothalamic tract are comparatively small and thin. (2) In the medial group of the thalamus, the mediodorsal nucleus is remarkably large and merits special interest because of various connections with olfactory and limbic structures as well as a presumed phylogenetic size correlation with the frontal (orbital) lobe of the mammalian telencephalic hemisphere. (3) The ventral group consists mainly of somatosensory nuclei and constitutes a large part of the dorsal thalamus. In mammals, generally, its ventral posterior nucleus (VPN) receives afferents via the medial lemniscus and the spinothalamic and trigeminothalamic tracts and dispatches a main projection to the somatosensory cortex. In the bottlenose dolphin, the ventral posterior nucleus is relatively small and projects to the neocortex anterior to the suprasylvian auditory area (Fig. 7). Compared to its lateral subnucleus, where the body region is represented, the medial subnucleus of the VPN with the head representation is relatively large. In dolphins, the limited somatosensory representation of the body is also reflected in the spinal cord (Oelschläger and Oelschläger, 2002). (4) As in higher primates, the lateral group of thalamic nuclei in cetaceans is dominated by the massive pulvinar, the largest single complex in the thalamus of the bottlenose dolphin. The pulvinar more or less merges in both the strongly protruding medial geniculate nucleus (MG; auditory) and the large lateral geniculate nucleus (LG; visual). The main projection of the inferior pulvinar targets the suprasylvian gyrus, and that of the medial pulvinar targets the ectosylvian gyrus, whereas the lateral pulvinar projects to the border of the lateral and suprasylvian gyri. The MG is impressively large in cetaceans (Fig. 4) and reflects the outstanding development of the auditory system in these animals. Ventral portions of the MG project to the primary auditory area of the suprasylvian gyrus (Fig. 7), dorsal portions to the “secondary” auditory area in the ectosylvian gyrus as well as to the temporal operculum (perisylvian cortex; Fig. 1). In the bottlenose dolphin, the LG is surprisingly well developed, though less so than the MG. The LG projects to the visually excitable part of the lateral gyrus (Figs 4 and 7), but does not show the laminar organization usually associated with biretinal projection. This may be related to the fact that in cetaceans the fibers in the optic nerve show a complete or almost complete decussation.

3. Hypothalamus The basal part of the diencephalon exhibits an organization similar to that encountered in other mammals. The anterior, tuberal, and posterior hypothalamic nuclei are evident but not particularly prominent. The paraventricular and supraoptic nuclei are obvious because of their large hyperchromatic cells, the latter nucleus being especially well formed. As in other mammals, the supraoptic commissure is well developed and well organized. The small size of the mammillary bodies, which in the postnatal animal do not protrude at the brain surface, correlates with the weak development of the hippocampus, postcommissural fornix, and mammillothalamic tract.

D. Brain Stem and Cerebellum

The percentage of the dolphin midbrain in the total brain volume is relatively low and ranges between that of prosimian and simian primates. Nevertheless, the size index, which is related to the body size and the regression line of basal insectivores (shrews, hedgehogs, tenrecs), shows a remarkable increase of this structure even in plesiomorphic “river dolphins” (*Pontoporia blainvillei*, Schwerdtfeger *et al.*, 1984). This may be attributable to the growth of auditory system components (Figs 2–5 and 7–8). The cerebellum and pons

are well developed and the myelencephalon (medulla oblongata) is very large in comparison with that of other mammals. This may be due to the considerable growth of cranial nerve nuclei and their connectivity, particularly those of the trigeminal, auditory, and motor systems.

A. SELECTED NUCLEI The cetacean brain stem comprises the nuclei known from other mammals; this could be confirmed in our work on the fetal narwhal.

The oculomotor nucleus is the largest eye muscle nucleus, a fact that correlates well with the diameter of the oculomotor nerve. In comparison, the trochlear and abducent nuclei and nerves are rather small and thin in most cetaceans. The sensory trigeminal nuclei (motor, principal, and spinal nucleus) are very well developed, reflecting the large relative size of the cetacean head and the diameter of the trigeminal nerve, which is maximal or submaximal among the cranial nerves. Within cetaceans, the motor nucleus was also the trigeminal is reported to be larger in mysticetes but subdivided more clearly in odontocetes. The sensory principal nucleus was also reported to be larger in baleen than in toothed whales, and its dorsal part giving rise to the well-developed trigeminothalamic tract (Wallenberg). The facial nucleus is very large in cetaceans and often bulges at the ventral surface of the medulla (tuberculum faciale). The nucleus was also divided into a number of cell groups, which can be differentiated from each other cytologically. Each of these cell groups is believed to be responsible for specific muscles or muscular systems, e.g., the dorsal group for muscles of the upper respiratory tract around the blowhole (epicranial complex; Cranford *et al.*, 1996), which are involved in the generation and emission of sonar signals in toothed whales. In comparison with other mammals, the ambiguous nucleus is large in cetaceans, which is similar to some bats (mouse-eared bat; *Myotis myotis*). This nucleus, which is larger in mysticetes than in odontocetes, innervates the muscles of the pharynx, larynx, and the striated muscles of the esophagus via the glossopharyngeus–vagus–accessorius nerve complex. When as in other mammals, it should be involved in cetacean respiration, food processing, and sound production in the larynx. The nucleus of the accessory nerve, which extends into the spinal cord, is moderately developed. This may be related to the extreme foreshortening of the cervical region, restrictions in head and shoulder girdle movability, and the transformation of the forelimb into a steering device (flipper). The hypoglossal nucleus, a derivative of the motor column in the first (occipital) embryonal spinal segments, is well developed, although the flexibility of the tongue is reported to be restricted in most cetaceans. In large baleen whales, the tongue may attain the body mass of a full-size elephant.

Nuclei related or belonging to the extrapyramidal motor system are located in the rostral mesencephalon and in the formatio reticularis throughout the rhombencephalon. The elliptic nucleus (Figs 1 and 8: e, E), which is situated within the central gray rostral or dorsal to the oculomotor nuclear complex, is very conspicuous; in the past it was thought to be unique for the Cetacea until a similar nucleus was found in the elephant. For some time, it was unclear whether the nucleus of Darkschewitsch is integrated into the elliptic nucleus or is even equivalent to this nucleus. Today, the latter opinion is the generally accepted one. In cetaceans, the elliptic nucleus projects via the medial tegmental tract (Fig. 8: mtt) to the rostral medial accessory inferior olive (IO) and correlates with a hypertrophy in cerebellar structures (Cb; discussed later). The red nucleus in cetaceans is little known. In contrast to ungulates, which possess a large rubrospinal tract and lack a spinal pyramidal tract, cetaceans have both weak rubrospinal and corticospinal tracts. The pontine nuclei (Fig. 8: P)

are exceptionally well developed in cetaceans; they receive strong cortical projections and give rise bilaterally to the large brachia pontis (middle cerebellar peduncles, pcm). Thus, the size and the caudal extension of the pons are directly related to the size of the neocortex and the neocerebellum.

The cetacean inferior olive (Figs 1–2, 4–5, and 8: IO) is characterized by an extraordinary development of its medial accessory subnucleus, particularly its rostral portion; in comparison, the principal olive and the dorsal accessory olive appear small. In the two cetacean suborders, there are only minor differences in the relative development of the subnuclei, and both inferior olives join each other in the midline. The rostral part of the medial accessory olive receives massive input from the elliptic nucleus via the medial tegmental tract, and its pronounced development in cetaceans seems to be related to the immense size of the cerebellar posterior interposed nucleus (PIN) and the paraflocculus (Oelschläger *et al.*, 2008). In terrestrial mammals, the medial accessory inferior olive is part of a fiber system involved in directional hearing.

B. CEREBELLUM The cetacean cerebellum is very large (Figs 1–2, 5–6, and 8), its size obviously being linked phylogenetically with that of the neocortex. In older studies, the relative mass of the cerebellum in baleen whales with respect to total brain mass (average: 20%) was reported to represent a maximal development within the mammalia as a whole. Recently, however, comparative analysis has shown that in relation to body mass the cerebellum of baleen whales is not as voluminous as in larger delphinids such as the killer whale. Concomitantly, it became obvious that the large proportion of the cerebellum in the total brain volume of baleen whales is attributable to the relatively small size of the forebrain. Indeed, in double-logarithmic regressions, baleen whales rank a little higher than sperm whales, beaked whales, and “river” dolphins but distinctly below the delphinid cetaceans. With respect to the regression line in the “basal insectivores,” the cerebellum of the plesiomorphic La Plata dolphin ranks higher than the averages of prosimian and simian monkeys but lower than that of the human. In a group of delphinid species, indices of the total brain mass and cerebellum mass relative to body mass exceeded other groups (sperm whales, river dolphins, baleen whales) by up to three times.

Within cetaceans, the cerebellum of the baleen whales is much better understood owing to ontogenetic histological studies. Only minor external differences, however, seem to exist between the cerebella of toothed and baleen whales. Thus, the mysticete cerebellum is more rounded and slightly hourglass-shaped in the dorsal aspect, whereas the odontocete cerebellum is somewhat more flattened dorsoventrally as a consequence of the stronger telescoping of the brain and resultant overlapping of the cerebellum by the cerebral hemispheres.

The cerebellum consists of two large hemispheres and a comparatively narrow vermis (Figs 1–2, 6, and 8). Two transverse fissures separate three cerebellar lobes: the primary fissure separates the smaller anterior (rostral third) from the large posterior lobe (caudal two-thirds), and the posterolateral fissure separates the posterior lobe from the small flocculonodular lobe. These size relations between the lobes are characteristic for cetaceans. In midsagittal section (Fig. 6), the conventional subdivision of the vermis into nine lobules of the mammalian cerebellum is obvious. In cetacean cerebellar hemispheres, the small size of the anterior lobe may be explained by electrophysiological findings in other mammals indicating that the hemispherical parts of this lobe comprise the cortical representation of the fore and hind limbs that are highly modified or

even have vanished in these animals. The caudally adjacent ansiform lobule, which also receives input from the limbs, is similarly small. However, the representation of the head in the simple lobule of the posterior lobe is rather large, and the considerable size of the paramedian lobule (body representation) has been related to the enormous significance of the tail in cetaceans. The paraflocculus, situated between the parafloccular and the posterolateral fissures (Fig. 6), is exceptionally large, particularly the ventral parafloccular lobule. The latter comprises about half of the surface of the cerebellar hemisphere. In mammals, the paraflocculus usually receives climbing fibers from the rostral part of the medial accessory inferior olive (Fig. 8). In cetaceans, both structures are exceptionally large, which strongly indicates a functional relationship between the paraflocculus on the one side and trunk and tail on the other side. The flocculonodular lobe as the principal terminus of primary and secondary vestibulocerebellar fibers (“vestibulocerebellum”) is very small in cetaceans, particularly the floccular component. In mammals, generally, the latter is responsible for the regulation of vestibulo-ocular and optokinetic movements as well as compensatory activities of the neck muscles in so-called smooth pursuit movements of the eyes, particularly in carnivorous animals. Dolphins, however, which have limited neck mobility and can use their visual system only during daylight, may have to rely on their auditory system instead to follow their prey effectively.

In the ontogeny of the cetacean cerebellar cortex, which is three-layered, the fundamental mammalian pattern of transverse and longitudinal zones is discernible. These longitudinal zones are obviously related topographically to the development of the cerebellar nuclei (anterior, medial and posterior interposed nuclei, lateral cerebellar nucleus). In cetaceans, the lateral intermediate cortical zone (C2 zone) is enormously developed, occupying about three-fourths of the cerebellar surface (paraflocculus) and correlating with the huge posterior interposed nucleus.

C. MAIN FIBER SYSTEMS: MEDIAL LEMNISCUS In cetaceans, the afferent spinal system (proprioceptive sensitivity) is moderately developed in accordance with the reduction of the hind limbs and pelvic girdle. In these animals, the dorsal funiculi (gracile and cuneate fascicles) are strikingly small; they are thought to convey input predominantly from the flippers and the tail (sense of position). Nevertheless, cutaneous sensitivity in the trunk was reported to be high. The medial lemniscus is weak in the caudal medulla oblongata, but becomes considerably stronger at more rostral medullary levels, presumably owing to the addition of afferent systems of the head (auditory, trigeminal systems).

1. Trigeminothalamic Tract (Wallenberg) The dorsal part of the principal sensory trigeminal nucleus gives rise to the trigeminothalamic tract. The latter terminates in the medial part of the ventral posterior thalamic nucleus as the main somatosensory thalamic nucleus. As in ungulates and the elephant, where it is extremely well developed, the tract is thought to be responsible for intra- and perioral sensitivity in cetaceans innervating, e.g., tactile bodies on the lips of fin whales and sei whales (*Balaenoptera borealis*) and the epicranial complex (Cranford *et al.*, 1996) in toothed whales.

2. Medial Tegmental Tract The elliptic nucleus (Figs 1B and 8: e), which almost “replaces” the red nucleus in Cetacea, is extraordinarily developed in whales and elephants, and gives rise to the strong medial tegmental tract (mtt) that proceeds to the rostral part of the huge medial accessory inferior olive (IO). The latter nucleus also receives afferents from the spinal cord (spino-olivary tract) and

projects to the lateral intermediate (C2) zone in the huge paraflocculus. The paraflocculus, which was shown in the rat to be the main target of auditory pontocerebellar projections and was estimated in the blue whale (*Balaenoptera musculus*) to receive three-fifths of the pontocerebellar fibers, has a massive projection to the posterior interposed nucleus (PIN) of the cerebellum (Cb). From the latter nucleus, ascending fibers run to the elliptic nucleus and other nuclei at the diencephalic/mesencephalic border which, in turn, project to the inferior olive via the medial tegmental tract (Fig. 8). Similar to the medial accessory olive, the paraflocculus also has been associated with mass movements of the posterior trunk and tail, the only region where the axial skeleton possesses a reasonable range of motion. The medial tegmental tract thus seems to be part of a recurrent circuit (elliptic nucleus, inferior olive, paraflocculus, posterior interposed nucleus, elliptic nucleus), which combines auditory input with locomotor activity and illustrates the dominant position of hearing among sensory systems in whales (acousticomotor navigation; Oelschläger, 2008; Oelschläger *et al.*, 2008).

3. Pyramidal Tract The tract originates in the neocortical motor area rostral to the “cruciate” sulcus (Figs 1A and 7) and runs through the internal capsule. At mesencephalic levels, the localization of the pyramidal tract is difficult, and it is very small at high medullary levels. Typical macroscopical “pyramids” as seen in terrestrial mammals are not present in cetaceans. Here, the pyramidal tracts are weak and situated lateral to the inferior olivary complex, both inferior olives joining each other midsagittally (Figs 2, 4, and 5). Obviously, the extremely well-developed rostral medial accessory olive, which occupies the ventromedial area in the medulla, has pushed the pyramids lateralward. Caudal to the inferior olives, the pyramidal tract disappears in baleen whales. In toothed whales, the pyramidal tracts merge, their crossing (decussation) being described by most authors as indistinct and the pyramidal tract as small and hardly visible (Oelschläger, 2008). Thus, it is likely that pyramidal (corticospinal) fibers do not descend more than a few (cervical) segments in the spinal cord. This pattern resembles much that is seen in hoofed animals and the elephant. In terrestrial mammals, there is an inverse relationship between the development of the pyramidal tract and that of the rubrospinal tract. Perissodactyls and artiodactyls have small pyramidal tracts, whereas their rubrospinal tracts are large. The opposite is seen in primates whose small rubrospinal tract is coexistent with a large spinal pyramid. Such an inverse relationship is not encountered in Cetacea: here, both the rubrospinal and corticospinal tracts are small, which is a speciality in cetaceans.

II. The Cetacean Spinal Cord

Within the nervous system, the spinal cord (Figs 4A and 8) is responsible for the innervation of the trunk and tail as well as the pectoral and pelvic girdles together with their appendages. Thus, the spinal cord mediates between the locomotory apparatus of the body and the brain by transmitting sensory vs motor information.

All cetaceans are characterized by (1) the subtotal reduction of the pelvic girdle and hind limb and the transformation of the pectoral girdle and fore limb into a steering device (hydrofoil) and (2) the extraordinary development of the axial musculature, thus contributing to the spindle shape of the body required for efficient locomotion by the trunk-and-tail complex. Many of the adaptations in the locomotory apparatus are reflected in the morphology and histology of the spinal cord (for further information *cf.* Oelschläger and Oelschläger, 2002).

III. Functional Systems

A. Chemoreceptor Systems

Adult baleen whales still have a small but functional nose probably equipped with an olfactory mucosa and an olfactory nerve, and they possess an olfactory bulb, slender olfactory peduncle, and an olfactory tubercle, a situation resembling that of the human. As a consequence of the adaptation to sonar orientation and communication (high-energy sonar clicks and drastic pressure changes in the upper respiratory system), toothed whales have reorganized their nasal system to such a degree that a short olfactory peduncle is found in the adult animal only very rarely (sperm whale; bottlenosed whale, *Hyperoodon ampullatus*). In general, toothed whale embryos display the anlage of an olfactory bulb, but the latter is reduced in early fetal stages (Oelschläger and Kemp, 1998). Interestingly, however, a remnant of the bulb persists as the large ganglion of the terminal nerve (Buhl and Oelschläger, 1986) that is responsible for the establishment of the hypothalamo-hypophyseal-gonadal axis in prenatal mammals and thus for sexual behavior and reproduction in the adults. In adult dolphins, the terminal ganglia contain the highest number of neurons found within the mammalia (Ridgway *et al.*, 1987). These facts argue both for the non-olfactory nature of the terminal nerve and its possible implications in the control of blood flow in the nose and basal forebrain, in maintenance of the epithelial lining of the upper respiratory tract, and in the sensory control of sonar signal emission as well. A vomeronasal organ (Jacobson's organ) and nerve are absent in cetaceans.

In spite of the strong general reduction of the olfactory system in toothed whales, the olfactory tubercle seems to be well developed even in comparison with that in baleen whales, which possess a small but presumably functional olfactory system. In many cases, the tubercle may not be clearly separated from the neighboring diagonal band and prepiriform cortex, a configuration often called "olfactory lobe" (Fig. 1). In reality, it is the large corpus striatum (basal ganglia) that protrudes here at the basal surface of the brain as an "olfactory" tubercle and is covered by an incomplete layer of thin paleocortex, a situation analogous to that in humans. The remaining paleocortex (diagonal band, piriform cortex, cortical part of amygdala) is moderately developed. The amygdala as a whole, however, is rather large in cetaceans for other reasons (see Section III.E).

Dolphins are clearly sensitive to chemical stimuli (both natural and artificial compounds), and some cetaceans were reported to have functional taste buds. With the olfactory part of the nose disappearing during prenatal development, dolphins still may resort to their taste buds and the trigeminal innervation of the oral cavity for chemoreception.

B. Visual System

In most cetaceans, the visual system is reported to be fairly well developed (Figs 1–2, 4, 7, and 8). In the adult harbor porpoise, the optic nerve contains 81,700 axons, in the bottlenose dolphin 147,000–390,000 axons compared to 193,000–250,000 axons in the domestic cat and 1,200,000 in the human. The Amazon River dolphin (*Inia geoffrensis*) shows a rather low axon count (15,500), and the optic nerve of the Susu, whose eye lacks a lens and may be capable of serving as a light receptor only, contains a few hundred axons. Large whales have moderate numbers of axons. In baleen whales, the optic nerve may contain approximately the same number of axons (252,000–347,000) as in the bottlenose dolphin, whereas in the sperm whale, with roughly the same body weight and relatively smaller eyes, only 172,000 axons

were counted (Morgane and Jacobs, 1972; *cf.* Oelschläger and Kemp, 1998).

Bottlenose dolphins have a thick retina comprised of rods and cones. The fovea centralis is band-shaped and the neurons in the ganglionic layer very large (up to 150 μm in diameter) with thick dendrites and myelinated axons of up to 9 μm . Cetaceans have laterally placed eyes and, if at all, one small binocular visual field rostrally and ventrally as well as another one dorsally and slightly caudally. The optic fibers show a complete or almost complete decussation, and the lateral geniculate body is not laminated. The superior colliculus is large in most cetaceans, as is the case in many land mammals, including ungulates, carnivores and primates. Dolphins show a definite stratification of the superior colliculi, where layers typical of terrestrial mammals are recognizable. In some baleen whale species, the superior and inferior colliculi are approximately of the same size (length and width), but in others (Southern right whale, *Eubalaena australis*; blue whale, *Balaenoptera musculus*) the inferior colliculi have double the surface of the superior colliculi. In toothed whales, this relation may range from 2:1 to 7:1 (in the Susu).

Electrophysiological mapping studies in dolphins have located the visual cortex not in the dorsocaudal or occipital part of the hemisphere but in a more central position near the midline (Figs 7 and 8). Although well developed, the physiological importance of the cetacean visual system should be by far inferior to that of the auditory system because of functional restrictions in murky water and in darkness.

C. Auditory System

The auditory system in whales and dolphins basically corresponds to that in terrestrial mammals; however, the various components have been adapted morphologically and physiologically to the specific conditions of hearing under water (Figs 1–5, 7, and 8).

In general, auditory structures are smaller in baleen whales than in toothed whales. According to the impressive diameter of the vestibulocochlear nerve and the number of axons in the cochlear nerve, the cetacean ventral cochlear (VC) nucleus and other auditory centers are very large. The secondary auditory fiber tracts (trapezoid body, acoustic striae) are well developed. In the La Plata dolphin as well as in the harbor porpoise and the common dolphin (*Delphinus delphis*), the absolute volume of the cochlear nuclei is 6–10 times larger than in the cat and the human, in the beluga (*Delphinapterus leucas*) it is 32 times larger, and in the fin whale 20 times larger. Numbers of cochlear neurons range between 583,000 and 1,650,000; i.e., 6–17 times that of the human. The ratio of primary cochlear nerve fibers to secondary cochlear neurons is between 1:5 and 1:8 (in human 1:4). The volume of other auditory nuclei is either very large in comparison or very low, even if we take into account the different body mass of the animals. In the La Plata dolphin, multiples 17 times the volume of the cat's nuclei are found in the nucleus of the trapezoid body and 39 times the intermediate nucleus of the lateral lemniscus. A comparison between volumes of auditory nuclei in the common dolphin and the human is even more impressive. There are multiples for the dolphin VC (16x), lateral superior olive (150x), single nuclei of the lateral lemniscus (up to 200x), and for superior auditory centers such as the inferior colliculus (12x) and laminated medial geniculate nucleus (7x). The cetacean VC is composed of five subunits consisting of specific neuron populations that are also found in terrestrial mammals. This has been proved by cytological investigations in the Franciscana involving the morphology of the axon terminations. The nucleus of the trapezoid body is well developed: a

great mass of fibers passes from the VC into the trapezoid body, to the ipsilateral and contralateral nuclei of the lateral lemniscus, and to the inferior colliculus. Interestingly, the dorsal cochlear nucleus (DC) could not be found in many toothed and baleen whales, perhaps because of its reduction to the point of insignificance. Obviously, this nucleus is engaged in the assessment and/or elimination of “auditory artifacts” caused by positional changes of the head and pinnae toward a sound source. In terrestrial mammals (including bats) with “normal” external ears and good movability of the head and pinnae, the DC is well developed and even laminated.

The existence of a medial subnucleus (MSO) apart from the lateral subnucleus (LSO) in the superior olive is discussed in the literature on toothed whales. In some species, the two subnuclei of the superior olive cannot be distinguished, and whether the medial nucleus is very small or even lacking in other species, as has been reported for bats, is not clear at present. In mammals, roughly speaking, the MSO is believed to be engaged in the processing of lower frequencies, the LSO in the processing of higher frequencies including ultrasound. Therefore, it has to be expected that the LSO is larger in toothed whales and the MSO in baleen whales, reflecting the actual neurophysiological adaptation (audiogram) of these animals.

The components of the midbrain tectum differ in size in baleen whales and toothed whales. In most mysticetes the superior colliculi (vision) are larger or at least as large as the inferior colliculi (audition), whereas odontocetes have very large inferior colliculi (Figs 1B, 3, 4, 6, and 8).

The striking dominance of the sense of hearing in adult toothed whales has been emphasized by a number of investigators. Indeed, the auditory system has stamped the morphology, size, and connectivity of the whole odontocete brain (Fig. 8) owing to the necessity of processing vast amounts of acoustic information and on account of the high propagation velocity of sound in water (Ridgway, 1990) and the need of background noise suppression. In the adult sperm whale and other toothed whales, the auditory system seems to be the major source of information. Even when the animals dive to considerable depths and the visual system progressively loses its importance for orientation and the detection of prey, the auditory system might still be functional (navigation by auditory input). Toothed whales scan their surroundings with a sonar system (clicks) and are probably able to integrate the acoustic input together with visual information into two- or even three-dimensional ephemeral images (echolocation imagery) within their extended neocortical auditory projection fields. In addition, communication between individuals by means of acoustic signals clearly is very important for whales and dolphins, especially during hunting activity and/or when vision is reduced. Pelagic dolphins, in particular, tend to live in larger groups. In the open sea, their natural environment is largely represented by the distributional pattern of their kin, which changes more or less continually.

D. Vestibular System

The four major vestibular nuclei usually found in mammals are also present in cetaceans. The lateral vestibular nucleus of Deiters (magnocellular part) is most conspicuous here and its dimensions are fairly impressive. Most of the other nuclei are rather small. Via the vestibular nerve, the lateral vestibular nucleus receives projections mainly from the maculae in the labyrinth; apart from this, its connections are very similar to those of cerebellar nuclei. In mammals, generally, the other vestibular nuclei receive input from the semicircular canals, but the latter are minute in toothed whales. In these animals Deiters' nucleus, which receives massive input from

the cerebellum, mainly projects to lumbosacral spinal segments via the lateral vestibulospinal tract and seems to be involved in the coordination and modulation of acousticomotor navigation.

E. Limbic System

In odontocetes, the various cortical and subcortical components of the limbic system show different degrees of development (Figs 1B, 2, 3, and 8). In adult toothed whales, the hippocampus and the mammillary body are unusually small and interconnected by a relatively thin fornix, whereas the anterior thalamic nuclei and the habenulae are better developed than in other mammals. The amygdaloid complex is large in toothed whales (Schwerdtfeger *et al.*, 1984). In contrast to the nucleus of the olfactory tract, which is totally dependent on olfactory input, the amygdala (taken as a whole) is well developed in microsmatic species (baleen whales, human) and even in anosmatic species (toothed whales). This indicates that, apart from olfactory stimuli, input to the amygdala arises from other sources, among them the auditory system. Furthermore, the remarkable development of the cortical limbic lobe (periarchicortex) in the dolphin again points to the largely non-olfactory character of this system.

F. Cranial Nerves

The eye muscle nerves are thin in smaller cetaceans, particularly in river dolphins with their reduced eyes where the nerves may even be completely lacking. In marine dolphins, the oculomotor nerve comprises the highest number of axons (about one-third that in the human), followed by either the trochlear or the abducent nerves. In large whales (especially baleen whales), the numbers of axons in the eye muscle nerves are distinctly higher and correspond to the situation in the human.

The trigeminal nerve is the thickest cranial nerve in baleen whales and sometimes in the sperm whale as well, whereas in all of the other toothed whales the vestibulocochlear nerve has the maximal diameter (Figs 1A, 2–6, and 8). The diameters of the axons tend to be thin in the trigeminal nerve, whereas cochlear axons rank among the thickest mammalian axons known. In the smaller toothed whales so far investigated, the trigeminal nerve contains 82,000–156,000 axons (human: 140,000). The fact that the trigeminal nerves in the sperm whale and the baleen whales have about the same number of axons (490,000 vs 370,000–500,000) may be explained by the extreme size of the forehead region innervated in these animals.

The vestibulocochlear complex is the largest cranial nerve in most toothed whales, and it is the second largest in baleen whales (Figs 1A, 2, 4, 5A, and 8). In the sperm whale, it contains 215,000 axons, whereas in baleen whales the axon numbers vary from 154,000 to 179,000. Smaller toothed whales have 84,000 (harbor porpoise) to 171,000 axons (beluga), the latter thus ranking near the much larger baleen whales (human: 50,000). The ratio of auditory and vestibular axons within the eighth nerve is disputed in the literature. Some earlier authors found that in the bottlenose dolphin (total: 116,500 fibers) the cochlear fibers comprise about 60% of all the vestibulocochlear fibers (a percentage known from the human). Modern studies report a similar total axon number (113,000), but a much higher fraction of cochlear axons (97%) as opposed to a very low number of vestibular axons. In comparison with the human (19,000 vestibular axons), dolphins possess only one-fifth in vestibular axons, a fact which correlates well with their small semicircular canals, the low number of vestibular ganglion cells, and with the observation that the diameter of the vestibular nerve is barely one-tenth that of the cochlear nerve.

The variation in thickness of the facial nerve and in the number of its axons throughout the cetaceans again sheds some light on biological correlations. Thus, the facial nerve in the sperm whale is nearly as thick as the vestibulocochlear nerve (Fig. 5), containing about 3 times as many axons as in the large baleen whales, 3–8 times more axons than in smaller toothed whales, and 25 times more than the human. Large baleen whales rival sperm whales in body size, and in these giants the head may attain one-third of the total length and mass of the body. In contrast, the absolute and the relative size of the head in other toothed whales is much smaller. Accordingly, it may be speculated that the prominent thickness of the facial nerve and large number of its motor axons in the sperm whale are attributable to the extreme size of the forehead which has to be regarded an oversized “sound machine.” Here, the forehead is characterized by the unique amount of acoustic fat tissues and massive blowhole musculature (innervated by the facial nerve) that helps to stabilize the giant fat bodies and to adjust their shape (acoustic lenses) during the emission of sonar signals.

IV. Neocortex

A. Layering and Cell Morphology

For a biological interpretation of the cetacean brain, we have to review some existing data about the neocortex, e.g., brain/body mass relationship, absolute and relative cortex mass, and the structure of the neocortex, i.e., the layering, neuron density, synapse number and density, as well as the density of gliocytes. The latter cells nourish, isolate, protect, stimulate/modulate and regenerate the neurons and therefore are as essential for neocortical activity as the neurons themselves.

No other brain surpasses the cetacean brain in richness and complexity of neocortex gyrification. Moreover, toothed whales exhibit encephalization indices which are second to that in the human. Their neocortex shows an extremely tight folding and has a maximal surface area within mammalia. At the same time, dolphins have cortical widths known from ungulates, and even large whales do not seem to attain the average cortical thickness of higher primates (human).

In principle, the cetacean neocortex is six-layered and similar to that in other mammals (Fig. 3). Regional differentiation, however, is indistinct, and cortex lamination is not well expressed, particularly due to the widespread absence of a distinct layer IV in adult toothed whales and the moderate granularization of the cortex, in general. In whales, layer one (molecular layer) can comprise about one-third of the total cortical width, whereas layer II is thin but rich in small pyramidal neurons, the perikarya of which stain intensively with cresyl violet (Nissl stain). This second layer corresponds to the outer granular layer in the human. Its pyramidal cells that border on the molecular layer are mostly “extraverted” in whales, i.e., they show a clear predominance of apical (subpial) dendrites over basal dendrites. Layer III is thick and characterized by a variety of pyramidal cells with comparatively smaller neurons populating the outer half of the layer, whereas larger cells occupy the inner half. In view of the special role played by layer IV (corresponding to the inner granular layer in the human) as a major input layer for thalamocortical specific afferents in advanced land mammals, the precise cytoarchitectonic definition of this layer in cetaceans and its neuronal composition is crucial. It was postulated that, in eutherian mammals, layer IV appears and develops in proportion to the progressive displacement of specific thalamic afferents from the first (molecular) layer to midlevels of the cortex. In evolutionary advanced primates and ungulates, layer IV of the sensory neocortex is relatively wide and

consists mainly of small granular, i.e., non-pyramidal cells mostly of the spiny stellate type. The fact that a lower degree of granularization also exists in insectivores and insectivorous bats and that layer IV is often not discernible here, led to the assumption that the structure of the cetacean neocortex is “primitive” and allegedly shows a considerable number of other plesiomorphic features. These are the lack of definite boundaries, gradual morphological transitions between functionally separate neocortical areas, a poor lamination pattern, a thick layer I, extraverted pyramidal neurons in layer II, a dense band of large pyramidal neurons referred to as layer III/V, overall weak granularization with a predominance among non-pyramidal neurons on the part of large isodendritic stellate cells, a well-developed layer VI, and a lack of giant pyramidal cells. In some cortical areas of the fin whale brain, however, a narrow zone where nerve cells are sparse or lacking seems to mark the site of layer IV, and also the corresponding external stria of Baillarger was found in a dolphin. Very young postnatal bottlenose dolphins also show a remnant of this layer. The innermost part of the cetacean cortex, presumably corresponding to layers V and VI in terrestrial mammals, usually displays no clear stratification and fades out into the white matter.

According to Deacon (1990), the common ancestor of all cetaceans very likely possessed layer IV granule cells as do the hyraxes or conies (mammals with precursors of genuine hooves), plesiomorphic members of the paenungulate (subungulate) order which also includes the sea cows (sirenians) and elephants. In the highly encephalized elephants, layer IV was found to be lacking in all cortical areas, and their neocortex architecture is strikingly similar to that of the fin whale. The loss of the granule cells in layer IV in cetaceans was therefore regarded a rare derived trait that may be correlated with the shift of the orphaned terminations of the specific thalamic afferents (originally terminating in layer IV) back to layers I and II, thus allowing more neurons in layer II to persist.

However, based on Golgi studies, there is little reason for thinking that the neocortex in the dolphin exhibits less variety than in other mammals, and a fair proportion of true stellate and other non-pyramidal cells exist in the dolphin cortex scattered throughout the layers III and V, which may combine functions of afferent, efferent, and associative layers. Moreover, the distribution of neuronal size classes is rather similar to that occurring in other mammals.

Comparative immunocytochemistry (GABA, calcium-binding proteins) in the primary visual and auditory cortex of dolphins has revealed that the overall quantitative characteristics of the neurons are similar to those in other mammalian orders, being closer to insectivores and rodents in some features and to bats and primates in some other characteristics. Interestingly, in dolphins the laminar distribution of neurons containing neurofilament protein SMI 32 differs from that in primates (monkey), where this protein is mostly found in neurons of layer III which furnish specific corticocortical connections between visual areas and high order association systems. In dolphins, SMI 32 is found exclusively in very large pyramidal neurons situated in layers III/V. The latter neurons are believed to play a complex role, combining functions of the afferent, efferent, and associative layers of the dolphin neocortex.

B. Neuron Density

The density of nerve cells is subject to considerable variation throughout the cetacean neocortex not only from area to area but also within the individual layers, although the relatively small and densely packed neurons in layer II account for at least 50% of all the

neurons in a given cortical block. Other variations in relevant papers result from different methods of quantitative analysis that have been used (discussed later).

The neuronal density in unspecified cortical areas of two fin whales is around 6800 cells/mm³, similar to an elephant brain (6900/mm³) of about the same size. In comparison with approximately 18,000/mm³ in the human and more than 100,000/mm³ in rat and mouse. This may suggest that there is a direct relationship between cortical neuronal density and brain mass. Other cell counts, however, reported an average of 57,000 neurons/mm³ for the adult human. Neuron counts in a series of toothed whales again revealed some decrease in density with increasing body size and absolute brain mass (harbor porpoise 13,200; bottlenose dolphin 13,000–44,200; beluga 12,300; humpback whale 8300/mm³). Total counts of neurons beneath 1 mm² of cortical surface (cortical unit) do not take into consideration the different width of the neocortical plate in various mammals and result in 28,500 cells for the adult bottlenose dolphin and 46,400 in an animal of 18 days. Other authors gave a figure of 147,000 was given for all neocortical areas studied in a series of mammals ranging from mouse to human except for the primate visual cortex which harbors about twice as many neurons. A recent investigation within a series of five delphinid species shows that neuron number per cortical unit in three sensory areas (150 μm width, 25 μm thickness, extending from the pial surface to the gray/white transition) is inversely related to brain mass (Poth *et al.*, 2005). Thus, although the larger brains have larger neocortex volumes, the cortical gray matter decreases in favor of the white matter and the decrease in neuron number per cortical unit does not seem to be compensated by an increase in cortical thickness.

The mean size of neuronal perikarya has no definitive relation to brain size. Whereas primates tend to have a similar mean neuronal size and size distribution, other mammals, including cetaceans, show a tendency to increase neuronal size with increasing brain weight. Dolphins have moderate neuron sizes more or less similar to those found in ungulates (sheep, cow, and horse) and in the elephant. Volume measurements reported a maximal neuronal volume of over 20,000 μm³ in the harbor porpoise, which is about double the maximal volume found in ungulates and small- to medium-sized for the human.

C. Synapses

The synaptic parameters of the visual neocortex in dolphins show many of the qualitative and quantitative features of the generalized mammalian bauplan: For example, the quantitative relationship between the number of synapses contacting different components of cortical neurons such as perikaryon, dendritic shafts, and dendritic spines does not differ significantly from these parameters in most other mammals. The same holds true for the distribution of other synaptic parameters throughout the cortical layers such as the area and form factor of individual synaptic boutons, the length of active zones (densities) of synaptic membranes, and several parameters relating to synaptic vesicles.

In their neocortex, dolphins show a mixture of potential conservative and advanced features at the cortical architectonic level as well as at neuronal and synaptic levels. When looking at the cortex as a whole, the aforementioned so-called conservative features occur mostly in the superficial layers I and II, whereas the deeper layers III–VI are characterized as more or less equivalent to those in advanced terrestrial mammals with the exception of layer IV. To date, adequate comparative data on ungulate groups or other aquatic mammals are not available. Interestingly, cetaceans have a much

lower neuronal density but, at the same time, a much higher synaptic density per volume unit and per neuron than terrestrial mammals. The majority of all synapses (70%) is found in cortical layers I and II. The latter seem to receive the brunt of cortical input as opposed to layer IV in many terrestrial mammals. Thus, in cetaceans, layer II seems to be the main relay element conveying information from the subcortical and intracortical afferents via layer I to the other cortical layers. All of these data, however, are difficult to interpret as to their significance both for function and for the evolution of the cetacean neocortex.

With respect to the total number of synapses in their cortices (0.87 vs 1.3×10^{14}), the dolphin and the human resemble each other much more closely than other mammalian species. This appears to reflect primarily the generally large volume of the neocortices in both dolphin and human brains as well as the maximal number of synapses per neuron compensating for minimal neuronal density in the dolphin.

D. Glia

There are only a few data available on gliocytes in the cetacean neocortex. In the bottlenose dolphin, glial density was found to vary in different cortical areas from 28,000 to 93,200 cells/mm³, values rather similar to those in the human (average: 40,000–100,000 cells/mm³). The number of gliocytes per number of neurons (glia/neuron ratio) is species-specific, i.e., varies among the mammalian groups and during ontogenesis owing to changes in neuron density. This basically implies that larger brains have higher glia/neuron ratios. Thus, the ratio rises from small rodents (mouse, rabbit: 0.35) via ungulate species (pig, cow, and horse: 1.1), the human (1.68–1.78) and the bottlenose dolphin (2–3.1), to large whales (fin whale: 4.54–5.85). Also, the glia/neuron ratio within each species increases from birth to maturity, thereby signaling the importance of glia for growing neurons and, thus, for neocortical function. And this implies the necessity of comparing only mature specimens. Accordingly, in species with similar neocortex volumes, the glia/neuron ratio may be interpreted both ways, i.e., in favor of neurons and of glia, respectively, as both are of equal importance.

In summary, the morphology of the dolphin neocortex seems to be equivalent to that of advanced terrestrial mammals, but its specific features are not yet understood. With respect to both ontogenesis and evolution, the allometric process of thinning out the number of neuroblasts and/or neurons via the generation of increasing amounts of glia and neuropil for their connectivity seems to proceed faster in cetaceans than in other mammals. At the same time, the cortical plate seems to spread out more widely than in other mammals, leading to an extremely extended and convoluted neocortex with a minimal neuron density but maximal synaptic density per neuron.

V. Morphological Trends in Toothed Whales

In the Franciscana (*Pontoporia blainvillei*), one of the least specialized living toothed whales (average brain mass of the adult: 220 g; body mass: 35 kg), the encephalization index (EI: 5.7) ranges above the level of prosimians (lemurs, *Tarsius*) and in the lower echelon of simians (monkeys, apes, and human), whereas the EI level of marine dolphins (13.5) is above that of simian primates but clearly below that of the human. From what we know today, already the Franciscana brain shows all the features typical of toothed whales and of whales, in general, although in a comparatively moderate developmental condition. In progressive pelagic dolphins, these features have reached a maximum as to brain size and structural

differentiation: (1) a large telencephalon and, at the same time, the total loss of the rostral olfactory and the whole accessory olfactory system, and the reduction of the remaining paleocortex. The archicortex and some other components of the limbic system are very small, but the limbic lobe cortex seems to be well developed. The neocortex is very much extended and convoluted. As in primates, the neocortex is by far the largest brain structure in river dolphins and other cetaceans. Its size index is higher in river dolphins than the average of prosimians but clearly lower than that of simians. Even higher values for the neocortex can be expected for marine dolphins. Giant cetaceans are difficult to interpret because their brains, although approaching 10 kg in total mass, are dwarfed by their huge bodies. Besides the neocortex, the striatum is one of the most progressive telencephalic structures and indicates a high functional capacity of the motor systems. The amygdala, another component of the basal ganglia and belonging to the limbic system, is considerable in size, although its corticomedial part largely consists of paleocortex. (2) The diencephalon (thalamus) is large owing to the exceptional volume of different nuclei (medial, dorsal, ventral, medial geniculate, and pulvinar). (3) The large volume of the midbrain is significant due to the extreme size of some components of the auditory system. Thus, for example, the inferior colliculus is much larger than the superior colliculus and the nuclei of the lateral lemniscus are extremely well developed. (4) Another major character is the large size of the cerebellum and particularly of the paraflocculus and posterior interposed nucleus as well as associated structures (elliptic nucleus, pons, inferior olive, and accessory fiber tracts). Interestingly, the central vestibular complex of whales is extremely reduced as are the semicircular canals (Oelschläger, 2008). Deiters' nucleus (lateral vestibular nucleus), however, is very large in toothed whales, presumably in correlation with its functional role as an interface between the cerebellum and the motoneurons of the spinal cord in acousticomotor navigation. (5) Finally, the medulla oblongata is, comparatively speaking, very large due to the outstanding development of the relevant auditory and trigeminal nuclei.

VI. Cetacean Strategies in Aquatic Adaptation

As in other mammals, the cetacean brain can be regarded as the true center of the body responsible for maintenance of physiological conditions (homeostasis) and survival. By means of the cranial and spinal nerves, the brain and the spinal cord collect all of the sensory information available, evaluating, synthesizing, and transforming it into optimal behavioral responses in manifold aspects: orientation, feeding, defense, communication, and reproduction. Thus, the brain not only represents all parts of the body but also mirrors the eco-physiological situation of the animal within its niche. On account of these tight correlations, evolutionary changes in the environment and in the biology of the species must show in the morphology of the nerves and brain. Rapid transgressions of mammalian groups into totally different habitats have obviously been related to strong selection pressure, i.e., such adaptational processes (in geological terms) unfold rather quickly and may lead to profound changes in brain morphology and function, reflecting changes in the body's periphery.

Whale ancestors had to overcome severe problems with respect to their new environment: As carnivorous plesiomorphic ungulates, they faced high water resistance because of an unfortunate body shape needing hydrodynamic styling. Ancient whales may have been luring amphibious animals comparable with crocodiles. Three-dimensional active hunting and communication underwater in darkness, turbid waters or at greater depths, however, not only

required a spindle-shaped body with reduced or modified limbs but also changes in the phonation and hearing processes. In this respect, the use of high-frequency sounds proved advantageous but necessitated the complete remodeling of the upper respiratory tract as a sound generator and transmitter, the modulation of the ear region as well as the incorporation of the mandible as a secondary sound receiver. Concomitantly, this new life-style on the basis of sonar orientation and communication facilitated the improvement of the central auditory system (as to capacity, versatility, and precision) which can be regarded as the dominant sensory system of toothed whales. The benefits and the success of acousticomotor navigation and the need of adequate brain centers for the analysis of multifaceted and complicated incoming sounds may have spurred the hypertrophy of nuclei along the ascending auditory pathway and expanded neocortical areas (maps) for acoustic detection and memory. A large number of modules in the dolphin neocortex may facilitate the quick scanning and subsequent synthesis of two- or three-dimensional images of their environment and allow intense and diversified social interactions with the members of their group.

Brain Size Evolution

LORI MARINO

I. Introduction

The study of brain size among three major living groups of marine mammals, cetaceans, pinnipeds, and sirenians, is a study in contrasts. Phylogenetic and ecological factors have shaped the course of brain evolution in each group in distinct ways. The resulting diversity of brains provides an illustration of the different successful paths that were taken in the evolution of marine mammals.

II. The Meaning of Encephalization

Brain size evolution is embodied in the concept of encephalization, which was originally put forth as an Encephalization Quotient (EQ) by anthropologist Harry Jerison. Jerison widely applied this measure to comparisons across different species. EQ is a measure of observed brain size relative to expected brain size derived from a regression of brain weight on body weight for a sample of species. EQ values of one, less than one, and greater than one indicate a relative brain size that is average, below average, and above average, respectively. For example, a species with an EQ of 2.0 possesses a brain twice as large as expected for an animal of its body size. The EQ values reported here are based on a large sample of living mammalian species from Jerison (1973, 1978).

Besides the whole brain, changes in the size of various brain components have also occurred throughout marine mammal evolution and contribute to changes in the overall brain size. Some of these changes are measurable but undoubtedly many changes in the relative size of structures occurred in all marine mammals that are not apparent from the fossil record.

III. Accessing the Fossil Record

Studies of brain size evolution in fossil marine mammals have depended upon measuring the volume of the endocranial cavity in fossil specimens. Because the specific gravity of brain tissue is nearly the value of water volumetric data have been typically converted to

units of weight. In addition to the general problem of finding intact fossil crania, early studies were hampered by difficulties accessing the sediment-filled endocranium. Researchers have taken advantage of the fortuitous occurrence of intact natural endocasts but these are rare. Also, the earlier studies often resulted in overestimates of brain mass from endocranial volume because they did not take into account that total endocranial volume is partly comprised of non-neural, e.g., vascular, components. Cetaceans, for instance, possess a massive endocranial system of blood vessels, called the rete mirabile, which surrounds the brain and can sometimes account for nearly 20% of total endocranial volume. Most recent studies take these vascular structures into account when estimating brain size from endocranial volume. Recently, Computed Tomography (CT) has proven to be an important tool in the study of fossil endocranial features because it is nondestructive and enables more accurate, precise, and reliable measurement of endocranial features than traditional methods.

IV. Brain Sizes in Fossils and Modern Species

A. Brain Size Evolution in Archaeocetes

The fossil record of early cetacean brain evolution includes the transition from the immediate land ancestor of cetaceans to the extinct aquatic forms known as archaeocetes. The range of EQs estimated for early, middle, and late archaeocetes is from 0.25 to 0.49 (Table I and Fig. 1) and archaeocetes appear to have experienced no increase in encephalization above their land precursors.

B. Brain Size Evolution in Odontocetes

The suborder Odontoceti appeared during the early Oligocene and radiated rather dramatically in that epoch and into the Miocene. Data suggest that by the early-mid Miocene odontocetes possessed their present encephalization levels (Table I and Fig. 1) and that there was a significant increase in odontocete encephalization levels with their emergence at the Eocene-Oligocene boundary. Those data that do exist suggest that by the early-mid Miocene at least several odontocete species possessed encephalization levels substantially above that of archaeocetes and within the mid-range of living species (Table I and Fig. 1). These data imply that some important changes in brain size occurred during the Oligocene after the turnover from archaeocetes to early odontocetes. Unfortunately, there are no brain size data on odontocetes during the Oligocene. Data on brain size in odontocetes during the Pliocene and Pleistocene are likewise lacking.

The EQs of living odontocetes are generally on a par with nonhuman primates. But some species have achieved a level of encephalization second only to modern humans (EQ ~ 7.0) and equal to or above that of the recent hominid ancestor *Homo habilis* (EQ ~ 4.4). Therefore, a number of odontocete species are significantly more encephalized than other mammals, including nonhuman primates. There is, however, a range of encephalization levels within the odontocetes. The sperm whale (*Physeter macrocephalus*), with an EQ of 0.58, is an example of an odontocete species subject to disproportionate body enlargement for which the measure of EQ is not particularly meaningful. The Delphinidae, however, are the family that contains several species with exceptionally high EQs above 4.0. These include the bottlenose dolphin (*Tursiops truncatus*), the Tucuxi dolphin (*Sotalia fluviatilis*), the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), and the common dolphin (*Delphinus delphis*).

Odontocete brain evolution was also characterized by increased foreshortening and widening of the brain which coincided with telescoping of the skull. There was a trend towards increased relative size of auditory processing regions such as the acoustic cranial

TABLE I
Estimates of Brain and Body Weight, and EQ for Some Fossil and Living Marine Mammal Species

<i>Species</i>	<i>Estimated brain weight (g)</i>	<i>Estimated body weight (g)</i>	<i>EQ^a</i>
Order Cetacea			
Suborder Odontoceti ^b			
Family Ziphiidae			
<i>Mesoplodon mirus</i>	2355	929,500	1.97
<i>Mesoplodon europaeus</i>	2149	732,500	2.11
<i>Mesoplodon densirostris</i>	1463	767,000	1.39
<i>Ziphius cavirostris</i>	2004	2,273,000	0.92
Family Kogiidae

^aEQ is based on a reference group of modern mammals from Jerison (1973).

^bFor living species, estimated brain and body weights are averaged across several specimens in most cases.

^cBody weight estimates for fossil specimens are often general estimates of adult species-specific values and are not necessarily from the same specimen(s) for which brain weight estimates are obtained.

Figure 1 Pattern of change in encephalization over geological time in archaeocetes and extinct odontocetes, compared with living odontocetes and mysticetes. Encephalization is plotted as EQ where the reference group is a large sample of living mammals.

nerve and inferior colliculus. In living odontocetes this is evident in the larger relative size of the inferior colliculus to the analogous midbrain visual processing area, the superior colliculus. In addition, structures associated with the processing of olfactory information regressed. Furthermore, the cerebral cortex of odontocetes (and cetaceans in general) has achieved an extremely high level of gyrification. Although surface morphology is not always discernible from fossil endocasts, it is generally thought that this was not a feature of archaeocete brains.

C. Brain Size Evolution in Mysticetes

The suborder Mysticeti appeared and diversified in the Oligocene and consisted of primitive toothed taxa in addition to the earliest baleen-bearing whales. Extant groups appeared in the mid-late Miocene. There are two problems associated with examining brain size evolution in mysticetes. First, the data on fossil and living

mysticete brain size are scarce. This is partly due to the difficulties associated with extracting and measuring such large brains. Second, mysticete brains tend to be smaller than expected relative to body size despite their large absolute size. This is partly due to the enormous body masses achieved by mysticetes.

As in the sperm whale, mysticete bodies are greatly enlarged in ways that do not necessarily require a concomitant increase in neural tissue. EQs of living mysticetes are therefore unrepresentative of actual brain enlargement, with all values falling substantially below 1.0 (Table I and Fig. 1). For this reason, although encephalization has probably occurred throughout mysticete evolution EQ is not an appropriate measure of it in this group, particularly in comparison with terrestrial mammals. In fact, to the extent that disproportionate increases in body size have played a role in body enlargement in any fully aquatic species, EQ will be underestimated relative to terrestrial mammals.

Many of the changes in morphology and size of brain components that occurred in odontocetes also characterize mysticete brain evolution, but to a lesser extent. For instance, unlike in odontocetes, olfactory tracts have remained in some mysticete species and the hypertrophy of the auditory processing regions is not as extreme as in odontocetes.

D. Brain Size Evolution in Sirenia

Sirenian brain evolution has been markedly conservative with regards to relative brain size. Fossil endocasts of early Eocene sirenians (among the earliest) were small in relation to the skull and already very similar to modern forms. Sirenian encephalization levels are among the lowest of modern mammals. According to the same formula used to derive cetacean encephalization quotients in cetaceans, the Florida manatee (*Trichechus manatus*) possesses an EQ of about 0.35 and the dugong (*Dugong dugon*) about 0.5. The EQ of Steller's seacow (*Hydrodamalis gigas*) was approximately 0.25 (Table I). Body size enlargement explains some of the reason for these low EQs but, given that cetaceans of the same body size possess higher EQs, not all.

Unlike odontocetes, sirenians do possess olfactory bulbs. Perhaps the most striking contrast, however, is the fact that cetacean and sirenian brains anchor the two ends of the spectrum of cortical

gyrification. Whereas the cetacean cerebral cortex is thin and highly convoluted, the sirenian cortex is unusually thick and almost lissencephalic (smooth). Interestingly, despite these differences, the relative volume of the cerebral cortex in both sirenians and cetaceans is on a par with nonhuman primates.

E. Brain Size Evolution in Pinnipedia

Pinnipeds diverged from terrestrial carnivores during the early Miocene. This is a relatively more recent date than cetaceans and sirenians diverged from their land ancestors. The pinniped brain, therefore, still bears a number of resemblances to that of terrestrial carnivores. Living pinnipeds possess EQs which hover around the average for terrestrial mammals. For instance, the ringed seal (*Phoca hispida*) possesses an EQ of 1.75, the harbor seal (*Phoca vitulina*) 2.08, and the Weddell seal (*Leptonychotes weddellii*) 0.76 (Table I). These values are fairly representative of pinniped EQ in general. Pinniped olfactory structures are reduced, but not to the same degree as in cetaceans. The cerebral cortex is highly convoluted (and more so than most terrestrial carnivores) but lies somewhere in between the extreme degrees of gyrification and thickness found in cetaceans and sirenians. The pinniped brain is somewhat more spherical in shape than in terrestrial carnivores but did not undergo the dramatic change in overall morphology exhibited in cetaceans.

V. Discussion

Much more information is needed before we can obtain a complete picture of patterns of brain size evolution in marine mammals. However, what does seem clear is that the different marine mammal groups evolved along distinct paths that led to a great variety of levels of encephalization in modern species. For instance, among odontocetes there was a substantial increase in encephalization in the Oligocene lineages which has led to the existence of a number of dolphin and porpoise species with relative brain sizes challenging only the hominid mammalian line. The relationship between mass and organization must be explored further, as well as the phylogenetic and ecological factors that led to the differential development of brain size among the various marine mammal groups.

Breathing

DOUGLAS WARTZOK

Oxygen is the final electron receptor in the metabolism of marine mammals as it is in all other mammals. Marine mammals obtain oxygen from the air and they breathe at the surface. In contrast, most feeding, mating, and other activities essential to survival occur beneath the surface. Thus most marine mammals minimize the time and they are at the surface and have evolved to load oxygen quickly and use it efficiently. For marine mammals, the breath-holding portion of the breathing cycle is significantly extended compared to the oxygen intake portion.

Because a distinguishing feature of marine mammals is their breath-holding ability, this characteristic has received much more attention than their breathing. However, a number of aspects of marine mammal breathing have necessarily been modified from terrestrial mammals in order to accommodate their submerged lifestyles. As with many modifications from terrestrial mammals, those related to breathing show the greatest difference in those species that dive the deepest and the longest.

In general, cetaceans, otariids, and manatees take only one breath per surfacing. Manatees return to a normal, shallow dive after a single breath. The deeper-diving cetaceans take a series of breaths, each in a subsequent surfacing event, before another dive. Phocid seals remain at the surface for a series of breaths after a dive.

I. Lung Oxygen Stores

Every inspiration that fills the lungs with air brings in four times as much nitrogen as oxygen. Because nitrogen is neither bound to a carrier in the blood nor metabolized in the tissues, the partial pressure of nitrogen in the blood will equilibrate with that in the lungs. If gas exchange is allowed to take place during a dive, the resulting higher partial pressure of nitrogen in the blood and tissues will result in the formation of nitrogen gas bubbles when the external pressure is reduced as the animal comes to the surface. Thus deep-diving marine mammals limit the exchange of gas from lungs to blood during dives.

Most phocids have been observed to exhale before diving. Weddell seal (*Leptonychotes weddellii*) pups, which are observed to dive after an inspiration, are an occasional exception. At this developmental stage they are shallow divers. California sea lions (*Zalophus californianus*) may dive after a partial inspiration, but then vent air during descent. Dolphins and porpoises making shallow dives routinely dive on inspiration. These breathing behaviors correlate well both with the proportion of total oxygen stores in the lung at the start of a dive and with lung size in proportion to the body size of various marine mammals. Phocids dive with 7% of total oxygen stores in the lung, fur seals with 13%, and delphinids with 22% (Fig. 1; Kooyman, 1973, 1989). The proportionate size of the lung in phocids and manatees is about the same as in terrestrial mammals such as the horse and the human (Fig. 2; Slijper, 1976), whereas the lung size is greater than expected in delphinids and smaller than expected in whales. An outlier in these considerations is the sea otter (*Enhydra lutris*) whose lung is close to three times the expected size for its body mass and accounts for 75% of oxygen stores. The sea otter is not a deep-diving marine mammal, and the relatively large lung in the sea otter may be primarily used for buoyancy when the animal is resting at the surface.

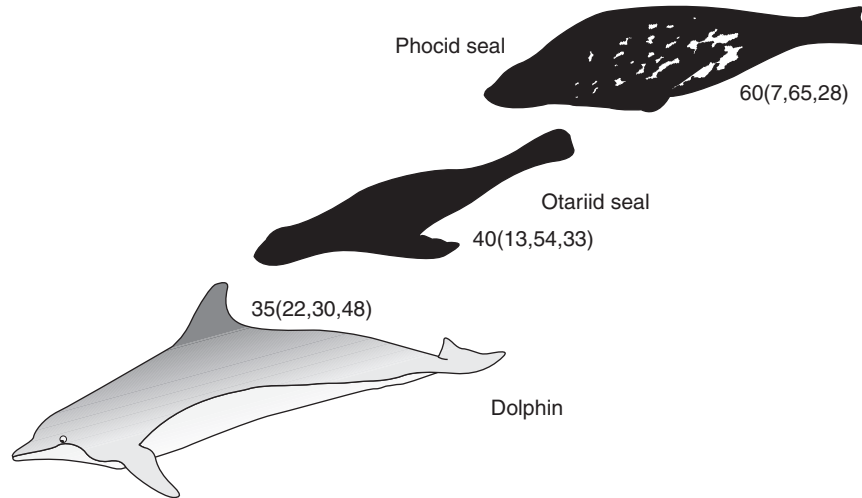

Figure 1 Generalized total oxygen storage of major taxa of marine mammals expressed in $O_2 kg^{-1}$. Numbers in parentheses are the percentage of total oxygen store found in the lungs, blood, and muscle, respectively. Modified, with permission, from G. L. Kooyman, 1989 © *Diverse Divers: Physiology and Behavior*, Springer Verlag.

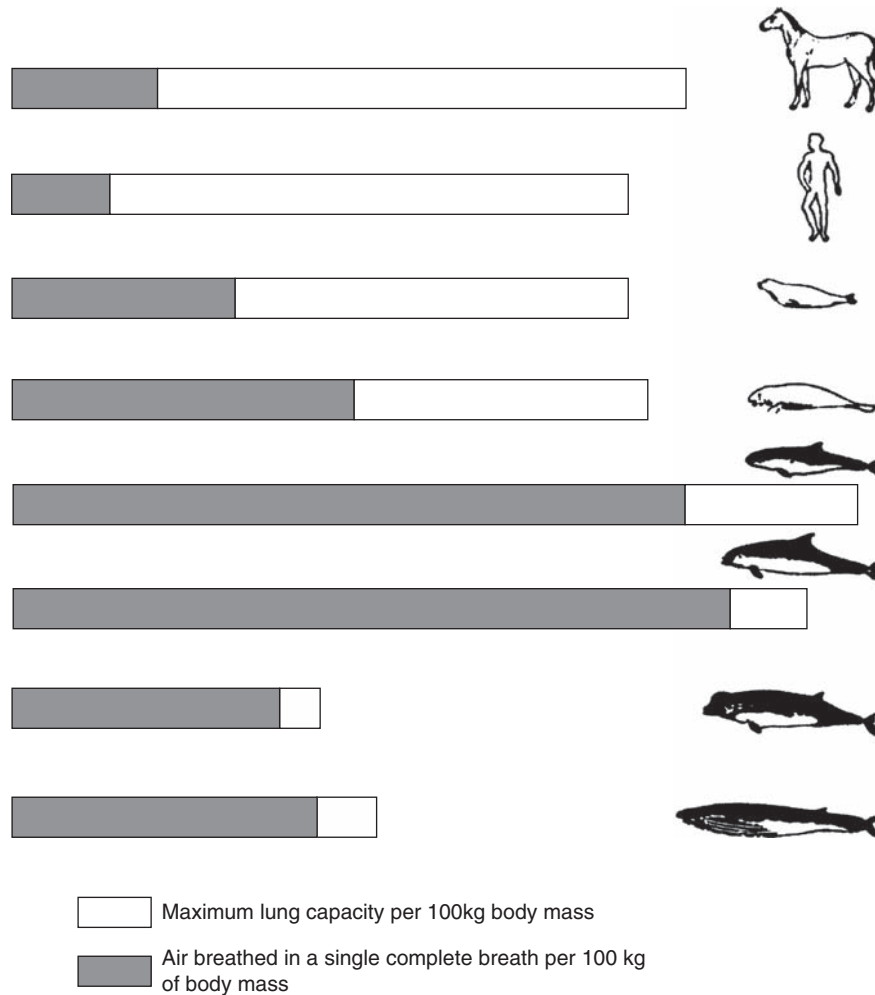

Figure 2 The maximum amount of air that the lungs can hold, and the amount of air breathed in and out with each breath, calculated per 100kg of body mass for a horse, a manatee, a harbor porpoise, a bottlenose dolphin, a bottlenose whale, and a fin whale. Modified, with permission, from E. J. Slijper, 1976 ©, *Whales and Dolphins*, University of Michigan.

II. Tidal Volume

The tidal volume (the amount of air breathed in or out during normal respiration) is a larger proportion of the total lung capacity (TLC) in marine mammals than it is of terrestrial mammals. In a typical terrestrial mammal the volume of air inhaled and exhaled in one breath is in the range of 10–15% of TLC. In marine mammals, tidal volume is typically greater than 75% of TLC. The maximum tidal volume or vital capacity (VC) in terrestrial mammals is not more than 75% of TLC, whereas in marine mammals the VC can exceed 90% of TLC. Several factors contribute to the large tidal volume in marine mammals. Marine mammal lungs contain more elastic tissue than those of terrestrial mammals (Kooyman and Sinnett, 1979). The ribs contain more cartilage and are thus more compliant than those of terrestrial mammals. The lung is also more compliant. Marine mammal lungs can collapse and reinflate repeatedly, whereas in terrestrial mammals, lung collapse is a serious situation that requires intervention to reinflate. Although both terrestrial mammals and marine mammals inspire actively and expire passively, the features noted earlier allow a much greater elastic recoil of the lungs, chest cavity, and diaphragm, and thus a greater tidal volume in proportion to TLC.

The terminal portions of the airways in all marine mammals are supported and reinforced by cartilage or muscle. One purpose of this reinforcement is to provide a less collapsible region into which alveolar gases can be forced during a dive to prevent gas exchange with blood at high pressures. This prevents increased nitrogen tensions in the blood and tissues as noted previously. A second purpose of the reinforcement is to keep the terminal airways open even at high-flow rates of gases in and out of the lung during a breath and to allow high expiratory flow rates even as the lung volume decreases. Fig. 3 shows the flow volume profile comparison during exhalation between a harbor porpoise (*Phocoena phocoena*) and a human. There are two striking differences. First, the flow rates are much higher in terms of VC/sec. Second, the flow rates remain very high; even down to a small fraction of the VC. These two factors together allow very rapid exhalation of the full VC. Inspiration takes somewhat longer.

The bottlenose dolphin (*Tursiops truncatus*) completes an exhalation and inhalation cycle in approximately a third of a second. With a tidal volume of 10 l, flow rates through the air passages can be as high as 70 l/sec. In gray whale (*Eschrichtius robustus*) calves the duration of expiration and inhalation is closer to half a second, but the tidal volume can be as great of 62 l, and the maximum flow rate as great as 202 l/sec. Gas flows through the external nares at speeds up to 44 m/sec during inspiration and 200 m/sec during expiration. Cetaceans usually initiate expiration prior to the blowholes breaking the surface. The explosive nature of the expiration creates the small droplets that make the blow visible and clears the upper respiratory passages and the area around the blowholes of any residual water. The time that the blowholes are above the surface is mostly used for inspiration.

The large tidal volume allows for more oxygen loading and greater carbon dioxide unloading during a single breath at the surface. Even in a resting state, the carbon dioxide content of expired air in seals is twice as great as it is in humans. After extended breath holds, alveolar oxygen levels can be as low as 1.5%. The oxygen and carbon dioxide content of expired air after surfacing can provide indirect evidence of physiological adjustments to diving. In bottlenose dolphins, the oxygen content in the first breath after a dive to 200 m is greater than it is in the first breath after an equivalent amount of swimming at 20 m (Ridgway, 1972). The interpretation is that the collapse of lungs in the deeper dive prevented the exchange of oxygen with the exchange of oxygen with the blood during the dive. For the same reason, the content

Figure 3 Comparison of the flow-volume curves of a human (dashed line) and a harbor porpoise (solid line). Note that in the human, after the volume falls below about 80% of vital capacity, the flow rate declines steadily, but this is not the case in the porpoise. Modified, with permission, from G. L. Kooyman and E. E. Sinnett, 1979 ©, *Mechanical properties of the harbor porpoise lung*, *Phocoena. Res. Physiol.* **36**, 287–300, Elsevier Science.

of carbon dioxide in the first breath is always less after a dive to depth than after a dive near the surface. In gray seals (*Halichoerus grypus*), the end tidal partial pressure of oxygen in the first exhalation after surfacing is similar to that in the last breath before submergence, again indicating that the lungs were collapsed at depth and there was no gas exchange.

III. Hyperventilation

Marine mammals often hyperventilate both before and after a dive. Hyperventilation before a dive leads to increased oxygen tensions and reduced carbon dioxide tensions. Hyperventilation arises through an increase in the frequency of breathing and the tidal volume. Although both can initially increase during hyperventilation, lung dynamics requires an eventual reciprocal relationship between tidal volume and frequency of breathing. In Weddell seals, hyperventilation of five to six times resting is accomplished by increasing the tidal volume 1.5–2 times and the respiratory frequency 3 times. If the respiratory frequency rises above 25 breaths/min, the tidal volume, as a proportion of the TLC, is close to that of terrestrial mammals. Harp seals (*Pagophilus groenlandicus*) with respiratory rates of 27 breaths/min and harbor seals (*Phoca vitulina*) with rates of 35 breaths/min have tidal volumes between 20% and 30% of TLC. Because marine mammals normally have such large tidal volumes, they have much less ability to increase total ventilation in response to exercise than terrestrial animals. A human can increase respiration by 4 times and can increase tidal volume by greater than 4 times for an overall increase in ventilation of more than 16 times resting compared to the 5–6 times resting maximum for a Weddell seal.

Marine mammals often exhibit an increase in heart rate on approach to the surface. It has been suggested that this anticipatory tachycardia coincides with the restored perfusion of peripheral tissues so the oxygen levels in the blood drop even lower as the carbon dioxide levels rise. These changes in blood gases increase the gradient between partial pressures in the blood and the lungs and lead to more rapid oxygen uptake and carbon dioxide exhausting during the first breaths at the surface. When gray seals show no anticipatory tachycardia, they do not achieve the maximum rate of oxygen uptake during the first few breaths.

The increased heart rate and breathing on surfacing lead to a rapid restoration of oxygen tensions. In fact, in Weddell seals the blood oxygen partial pressures in the postdive recovery period routinely end up exceeding the resting values. It appears that the purging of carbon dioxide is more critical for determining readiness to dive again than is the replenishing of oxygen. In Weddell seals the partial pressure of carbon dioxide falls to resting levels within a couple minutes after aerobic dives, but may take up to 10 min to reach resting levels after long dives, which rely on anaerobic metabolism. The fact that hyperventilation can continue for an hour after the partial pressures of oxygen and carbon dioxide return to resting levels indicates that prolonged hyperventilation is driven more by lactate-induced changes in the acid–base balance in the blood.

IV. Ventilation Control

Seals show a more fully developed mammalian reflexive response of increased ventilation to decreases in inspired oxygen concentration or increases in inspired carbon dioxide concentration at an earlier age than terrestrial mammals. However, adult seals show little ventilatory response to decreased oxygen concentration. Instead the adult seals respond by increasing the proportion of time they are at the surface relative to the total time between dives. Apparently the adult seals are able to substitute behavioral control of diving patterns for reflexive control of ventilation.

Breathing hyperoxic gas increases the dive time of Weddell seals, has no effect on the dive time of manatees, and shortens the dive time of hooded seals. A suggested explanation for the latter surprising finding is that the seal breathing a hyperoxic gas mixture dove before it had exchanged all the carbon dioxide and the increased carbon dioxide resulted in the shortened dive time.

Both the nostrils of pinnipeds and the blowhole of cetaceans are normally closed when the controlling muscles are relaxed. The closure in pinnipeds is maintained by muscle tone and pressure of the moustacial pad. Contraction of the nasal and moustacial pad muscles results in a movement of the pad and an opening of the nostrils. In cetaceans, muscles must contract to open the blowhole and to move the nasal so that it is not blocking the airway.

Pinnipeds on land often show a breathing pattern similar to that during diving with breathing periods (eupnea) being shorter than breath hold periods (apnea). The ratio between apnea and eupnea while on land is greatest in those species that normally dive for the longest periods. The periods of apnea also tend to be longer when the animals are asleep than when they are awake. Even the longest bouts of sleep apnea appear to be aerobic: plasma lactate and glucose remain stable even though oxygen tensions drop to very low levels, carbon dioxide tensions increase, and respiratory acidosis occurs. In elephant seal (*Mirounga* spp.) pups, awake apnea does not exceed about 5 min whereas sleep apnea can be as long as 14 min. The pups show a parallel increase in mean sleep apnea and mean dive duration during their first year of life.

Pups of several species have been observed to have a higher breathing rate than adults. Weddell seal pups take breaths/min

compared to the 8 breaths/min rate of adults. Pups of Australian (*Neophoca cinerea*) and New Zealand (*Phocartos hookeri*) sea lions take 13 breaths/min whereas adults of these species typically breathe 3–5 times per minute.

On land and in the water different stages of sleep in pinnipeds are associated with different breathing patterns in different species. During rapid eye movement sleep, breathing is regular and at rates up to 16/min in gray seals, irregular in harp seal pups, and absent in elephant seal pups. Elephant seal pups sleeping in shallow water rise to the surface to breathe without showing brain wave patterns associated with wakefulness. In contrast, Caspian seals (*Pusa caspica*) sleeping below the surface awake prior to surfacing and breathing.

Some species of delphinids show unihemispheric brain waves associated with sleep. Thus there is one cerebral hemisphere that is always awake to control surfacing and breathing. Northern fur seals (*Callorhinus ursinus*) sleeping in the water also sometimes show unihemispheric sleep patterns with one cerebral hemisphere awake to control surfacing and breathing. In contrast to delphinids, no pinniped has shown exclusively unihemispheric sleep brain waves.

V. Oxygen Loading and Dive Time

Several authors have modeled the diving behavior of marine mammals based on oxygen loading curves at the surface compared with energy expenditure while below the surface. There have been various models based on what the animal may be attempting to maximize, be it time in a deep prey patch, gross energy intake during a dive, net energy intake, energetic efficiency, and so on. All the models conclude that there should be some relationship between the duration of a dive and the time breathing at the surface, either pre-dive or post-dive. Although some species do show such relationships over certain dive time intervals, not all species show the expected patterns. The time Weddell seals spend at the surface is independent of preceding dive duration up to the aerobic dive limit. Beyond that time, the surface time increases exponentially with the preceding dive time. However, gray seals (*H. grypus*) show a direct proportionality between dive time and surface time up to dive times of 7 min. Surface time is independent of dive time for dive times greater than 7 min. Surface time of sperm whales (*Physeter macrocephalus*) shows a slight trend to decrease with increasing dive time, but is basically independent of dive time. Elephant seals can maintain, over periods greater than 24 hr, a pattern of long, deep dives followed by surface intervals of 3 min or less. Some of these differences are attributable to species variation among groups with different diving strategies and oxygen loading needs. Additional explanations of the breakdown of models relating surface oxygen uptake to underwater duration and activity include lowered metabolic rates underwater, passive gliding descents, and animals not maximizing any of the foraging related parameters. For example, ringed seals (*Pusa hispida*) appear to be constrained by a risk averse strategy. Diving under shore fast ice, ringed seals gain access to air only at a few breathing holes. If a seal finds a breathing hole occupied by another seal or detects a polar bear above the hole, it will need oxygen reserves to locate an alternate breathing site.

VI. Water Conservation during Breathing

Because marine mammals obtain most of their water requirements from their prey and through metabolic production of water, conservation of water is an important adaptation in marine mammals. Renal adaptations for water conservation are discussed elsewhere, but water can also be lost through ventilation. Both pinnipeds and

cetaceans exhale air that is not saturated with water vapor. In bottlenose dolphins, the respiratory water loss is reduced by 70% over what it would be compared to a terrestrial mammal breathing dry air. Countercurrent heat exchange and induced turbulence in the nares and nasal sac system allow for the extraction of a majority of the water vapor in the air coming from the lungs. In seals, the bones in the anterior part of the nasal cavity (turbinates) create a very dense mesh through which the expired air must pass. Moist air flowing over this large surface area gives up much of this water before being exhaled.

VII. Breathing Patterns in Response to Disturbance

Changes in breathing patterns have been used extensively as indicators of disturbance of marine mammals in response to human activity. In many cases, a statistically significant change has been observed in the interbreath interval, total number of breaths during a surfacing, or proportion of time spent at the surface. Although these changes may be statistically significant, it is questionable whether they are biologically significant for an individual animal or indicative of any long-term consequences for the population.

Breeding Sites

MARK A. HINDELL

Giving birth to young and the subsequent nursing of those young present unique problems to marine mammals. The strategies that marine mammals employ to deal with these problems can be divided into two broad groups (1) those animals that need to leave the water to breed [seals and polar bears (*Ursus maritimus*)] and (2) those animals that remain at sea to breed (cetaceans, sirenians, and otters). Whichever strategy is used, a crucial component of the reproductive process is the site used for breeding (here, the term breeding is restricted to parturition and suckling and does not include mating). The breeding sites used by marine mammals are quite diverse, both in terms of geography and physical characteristics, ranging from polar to equatorial regions and from sandy beaches to deep ocean basins. Which sites are used for breeding by a

particular species is determined by a complicated mixture of factors including evolutionary history, requirements of the young, requirements of the adults, biological characteristics (such as the proximity of prey), and physical characteristics (such as water temperature or beach substrate). Riedman (1990) and Reynolds and Rommel (1999) provide excellent reviews.

I. Species that Leave the Sea to Breed

All species of seal and polar bears leave the sea to give birth and most also need to be ashore to suckle their young. Some species (predominantly the phocids) remain ashore for most, if not all, of the lactation period, whereas in others (the otariids) the females regularly return to sea to forage during lactation. Only harbor seals (*Phoca vitulina*) and walrus (*Odobenus rosmarus*) have been reported to suckle young at sea. The sites used by these animals for breeding can be divided into two groups: those that breed on land and those that breed on ice.

A. Marine Mammals that Breed on Land

Pregnant polar bears leave the arctic pack ice with the onset of spring to breed on land. The deteriorating summer pack ice is too unstable for the bears, which have a relatively long period of cub dependence. Females excavate caves in the side of riverbanks or hillsides, thereby by getting close to the permafrost and providing an environment with a stable temperature. As summer progresses and snowfall increases these caves get snowed in and the females need to maintain a cavity with sufficient wall thickness to provide insulation, but also thin enough to allow the passage of air.

Twenty species of seals breed on land. This includes all species of Otariids (fur seals and sea lions) and six of the Phocids (true seals) (Table I). None of these species uses any kind of shelter and all give birth and suckle on the beach exposed to wind, rain (or snow), and waves. Land breeding seals often occur in very large aggregations during the breeding season, which may offer some protection from the weather, but this also puts them at risk of being damaged in fights between adult seals. Land-based breeding sites occur at all but the most extreme polar latitudes.

Some species utilize both land and ice breeding sites. Gray seals (*Halichoerus grypus*) breed on beaches in northern Europe and America, but on pack ice in Northern Canada. Although primarily a land breeding species, harbor seals also breed in pack ice in northern Canada.

Most land breeding seals use islands as their principal breeding sites, with only a few species utilizing mainland beaches. This is likely to be an attempt to avoid large mainland predators, including humans. Generally, species have quite specific requirements of their island breeding sites, and so suitable island breeding sites are often limited. Consequently, those sites that are suitable tend to hold very large numbers of seals, which provides an ideal condition for the evolution of polygyny.

Different species have different substrate requirements. Most species use gradually sloping sandy beaches, such as those used by northern elephant seals (*Mirounga angustirostris*). Fur seals, which are generally more agile than phocids, can also breed on rocky substrates, but again this is quite species-specific. For example, at Macquarie Island where both Antarctic (*Arctocephalus gazella*) and subantarctic (*A. tropicalis*) fur seals breed, *A. gazella* use the open beaches, whereas *A. tropicalis* breeds on nearby rocky headlands.

TABLE I

Monk seal—Mediterranean, <i>M. monachus</i>	Island/mainland
Elephant seal—Northern, <i>Mirounga angustirostris</i>	Island/mainland
Elephant Seal—Southern, <i>M. leonina</i>	Island/mainland
Harbor seal, <i>Phoca vitulina</i>	Island/mainland/ice
Gray seal, <i>Halichoerus grypus</i>	Island/mainland/ice

^aFrom Riedman (1990).

The reasons for these different preferences are unknown but may arise from resource partitioning.

Proximity to a food source may be another factor that determines the location of breeding sites for some land breeding seals. For example, female otariids need to return to sea to replenish their energy reserves regularly during the lactation period. As their pups are fasting during these trips to sea, faster growth and heavier weaning masses can be achieved if the foraging trips are kept as short as possible. Breeding sites are often located close to the continental shelf break or other oceanographic features that tend to have enhanced primary productivity. In cases where this is not possible, such as the subantarctic fur seal breeding site on Amsterdam Island, female foraging trips are much longer than in other species (or populations) and the pups have correspondingly lower growth rates.

Land breeding phocid seals generally have no requirement for feeding during lactation, and therefore the breeding sites can be located considerable distances from the foraging sites. Southern elephant seals (*Mirounga leonina*), for example, tend to feed in high latitude waters, but breed thousands of kilometers away on subantarctic islands. In this case, the primary requirement of a breeding site is suitable beach structure and perhaps a moderate climate to help the pup in its early life.

B. Marine Mammals that Breed on Ice

Thirteen species of pinnipeds breed on ice, either floating pack ice or fast ice attached to the land (Table II). Ice breeding seals tend to be monogamous, and this is likely to be a consequence of

TABLE II

^aFrom Riedman (1990).

the breeding habitat. Ice, unlike suitable beaches for land breeding seals, is not a limited resource, and females can haulout anywhere to breed, so large aggregations of females tend not to occur. This limits the opportunities that males have to monopolize access to several females, and the best strategy for them is to find a female and remain with her until estrus. Weddell seals (*Leptonychotes weddellii*) are an exception to this rule, as they breed on fast ice, with limited access to open water. Female Weddell seals therefore tend to aggregate around tide-cracks and other sources of permanent open water.

Most ice breeding seals give birth and suckle their young on the ice. The exceptions to this rule are ringed seals (*Pusa hispida*) and Baikal seals (*P. sibirica*) which can use snow lairs under ice ridges. These lairs afford some protection from the elements and predators, although polar bears and foxes are adept at locating and breaking into these lairs.

Although pack ice is the breeding substrate, many species have preferred geographic regions to which they move for the breeding season. Harp seals (*Phoca groenlandicus*), for example, migrate to the southerly edge of the pack ice, and occupy only a small part of their overall range during the breeding season. The biggest areas are around Newfoundland and off western Greenland. Hooded seals (*Cystophora cristata*) show a similar pattern of migration, moving from widespread northerly feeding areas to more proscribed breeding areas which appear to be associated with the Continental shelf at the southern extent of the summer pack ice. This may provide the adults with access to the shelf for feeding immediately after weaning their pups.

II. Species that Stay at Sea to Breed

Three groups of marine mammals are sufficiently adapted to a marine existence to give birth or suckle their young in water. These are the cetaceans, the sirenians, and the otters. By giving birth at sea, these animals are no longer constrained to use what is essentially a limiting resource—land. Nonetheless, many species still have quite specific requirements of their breeding sites, and migrate thousands of kilometers to reach their breeding grounds. Such profound

separation of feeding and breeding sites incurs large energetic costs, so the specific characteristics of these areas must be of considerable importance.

Dugongs (*Dugong dugon*) and manatees (*Trichechus* spp.) have no specialized breeding site requirements. Young are born and remain with their mother while she forages on sea grass beds. Likewise, sea otters (*Enhydra lutris*) give birth at sea and the cubs remain with their mothers. Neither group appears to migrate to specific regions for breeding and remain within their foraging areas.

Cetaceans are the only group of ocean breeding marine mammals in which some species have clear separation of feeding areas and breeding areas. Within the cetaceans, breeding sites can be loosely categorized as (i) coastal, (ii) open ocean, or (iii) non-specific. Species with non-specific breeding sites are those that show no evidence of requiring different environments for breeding. This group contains most of the odontocetes and several of the mysticetes. Many of the smaller odontocete species do make seasonal migrations, but these are not clearly linked to breeding, and seem more related to changes in prey distribution.

Several species of beaked whales appear to have year round high latitude distributions, and do not migrate for breeding, giving birth and suckling their young in polar waters. This behavior is also seen in two mysticete species, the minke (*Balaenoptera acutorostrata*) and the bowhead (*Balaena mysticetus*) whales. Although bowhead whales do seem to move southwards before breeding, they never leave the pack ice zone.

A. Cetaceans with Coastal Breeding Sites

Humpback whales (*Megaptera novaeangliae*) have several recognized breeding grounds and all are associated with coastal regions. The Southern Hemisphere populations use either the coast of the major southern continents (South Africa, Australia, or South America) or smaller oceanic islands such as Tonga and Fiji, with the preferred sites generally north of 30°. The Northern Hemisphere humpbacks move to the Caribbean, Hawaii, or Cape Verde Islands.

Eastern gray whales (*Eschrichtius robustus*) move south from arctic feeding grounds to breed in Baja California and, as with humpbacks, the breeding sites are close inshore. In fact, they are so inshore that they are close enough to be seen from land and form the basis of a tourist industry.

Of the inshore breeding cetaceans, the right whales (*Eubalaena* spp.) are least migratory. Neither the southern (*E. australis*) or the northern (*E. glacialis* and *E. japonica*) right whale species make long migrations to their breeding sites, but both species favor coastal sites and sheltered bays for giving birth. Individual southern right whales show high levels of breeding site fidelity and use the same bays on several consecutive breeding events.

Only one odontocete species, the beluga (*Delphinapterus leucas*), seems to have an inshore migration so that it can breed in shallow inshore waters.

Why these species seek out inshore waters is not really known. Aside from the thermal advantages common to all migrating whales (Section II.B), the specific advantages associated with inshore breeding are likely to be related to environmental conditions and predator avoidance.

B. Cetaceans with Oceanic Breeding Sites

Less is known about the characteristics of the breeding sites for these species due to their lack of coastal aggregations, and so much of what is known comes from early tagging studies and whaling records.

Fin whale (*Balaenoptera physalus*) breeding sites are widely spread over oceanic waters in temperate and subtropical waters. There is evidence that some fin whales move toward land and even form loose aggregations, but they do not cross the continental shelf, remaining in deep water. The little information available for blue whales suggests that they use similar breeding sites to fin whales. This may also be the case for sei (*B. borealis*) whales, although they may not penetrate tropical waters. Bryde's (*B. edeni*) whales do not seem to migrate to breed; presumably this is a reflection of this species' largely tropical habitat all year round.

There is on-going debate regarding the reasons for the use of temperate or equatorial breeding sites by mysticete whales. Thermal and energetic advantages to new-born calves are possibilities, but if so, why do some species such as the minke and the bowhead whales, as well as many smaller odontocetes, remain in high latitude waters to breed? An alternative view is that the abundant and predictable food supply of food at high latitudes declines over the dark winter months, but only the species with large body size (and lower mass specific metabolic rates) are able to make the long migrations which allow them to take advantage of warmer waters.

Bryde's Whales

Balaenoptera edeni/brydei

HIDEHIRO KATO AND WILLIAM F. PERRIN

I. Characteristics and Taxonomy

Bryde's whales are the least known of the large baleen whales. We are not even sure how many species are represented in this complex of temperate and tropical whales. They were long confused with sei whales (*Balaenoptera borealis*) because of morphological similarities; this confusion lasted into the 1970s. Bryde's whales were first described by Anderson (1878) based on examination of a stranded balaenopterid on Thaybyoo Creek beach, Gulf of Marataban, Burma. He gave it the scientific name *Balaenoptera edeni* in honor of the British high commissioner in Burma, Sir Ashley Eden. Olsen (1913) found an unrecognized species among "sei whales" caught in Durban, South Africa, and gave it the scientific name *B. brydei* in honor of his sponsor Johan Bryde, a pioneer in South African whaling from the traditional whaling port of Sandefjord. Junge (1950) concluded that the two names were synonymous based on examination of a skeleton collected in Pulu Sugi, Singapore. Further studies by Omura (1959) and Best (1960) supported Junge's view, and their conclusion had been generally

accepted until recently, with *B. edeni* having priority as the scientific name. (The common name remained “Bryde’s whale” probably due to its wide popularity). However, today it is not clear how many species of Bryde’s-whale-like baleen whales are there or what their scientific names should be (Rice, 1998). Wada and Numachi (1991) found that a small form occurring off the Solomon Islands and Java did not accord with other Bryde’s whales in allozymes. These results suggesting the existence of at least two species were supported by mtDNA analyses reported by Yoshida and Kato (1999); the Solomon Islands and Java whales were more closely related genetically to sei whales than to “ordinary” Bryde’s whales. The potential nomenclature at that point became some permutation of the names *B. brydei*, *B. edeni*, and perhaps a needed third new name. Rice (1998) had proposed provisional recognition of the existence of two species, with the nomenclature unsettled. Subsequently, a specimen of the same apparently undescribed species reported by Wada and Numachi (1991) washed ashore in southern Japan, and based on as well as and the earlier molecular data, Wada *et al.* (2003) described the new species *Balaenoptera omurai* (see chapter Omura’s Whale). Sasaki *et al.* (2006) confirmed the genetic distinctness of the new species and its occurrence in the Philippines based on analysis of a bone sample from a whale taken in an artisanal whale fishery (LeDuc and Dizon, 2002). They further suggested that large and small forms of the “ordinary” Bryde’s whale should be considered full species, *B. brydei* and *B. edeni*, respectively. However, the degree of differentiation between the two forms is of a level that could be considered consonant with subspecific separation. Moreover, small- and large-form Bryde’s whales from various regions around the world have not yet been compared on a global basis. We here straddle the fence and follow Rice’s (1998) lead of suggesting that there may be either one or two species of Bryde’s whales (aside from Omura’s whale). One needs to be aware that the names *B. edeni* and *B. brydei* are used variously by the present workers in the field; e.g., one recent reference listed below (Kanda *et al.*, 2007) refers to “ordinary” large Bryde’s whales which is known globally as *B. brydei* (following Sasaki *et al.*, 2006), whereas two others (Heimlich *et al.*, 2005; Murase *et al.*, 2007) refer to the same whales in the western and eastern Pacific as *B. edeni*, the name presently used by the International Whaling Commission (IWC).

A nomenclatural problem remains with Omura’s whale. The genetic identity of the holotype specimen of *B. edeni* (in a museum in Calcutta) is unknown. It was at the upper end of the size range for Omura’s whale and the small form of the Bryde’s whale (the “*edeni*” type) but still physically immature, and it comes from an area of potential overlap of the two forms of Bryde’s whale and the new species. If genetic analysis determines that it belongs to the new species (Omura’s whale), then that species will bear the name *B. edeni*. If it proves to be a Bryde’s whale, then the Bryde’s whale (if there is only one species) will bear the name *B. edeni*, *B. brydei* will fall into synonymy, and the name *B. omurai* will stand for Omura’s whale. Hopefully a genetic analysis will be carried out on the holotype specimen of *B. edeni* to resolve the situation.

Bryde’s whales are medium-sized balaenopterids. Females are larger than males throughout life, by about 2 ft (0.5–0.6 m) at full maturity. It is believed they reach 15.5 m, but most are much smaller. As demonstrated by Best (1977) for South African Bryde’s whales, animals from coastal stocks or stocks inhabiting rather areas are generally smaller than those from migratory pelagic stocks (the small-form and large-forms described earlier). Southern Hemisphere animals are also larger than Northern Hemisphere animals. In the South Africa and western North Pacific stocks, body length increases

rapidly until 4–5 years, reaches about 90% of asymptotic length for both sexes at about 10 years, and ceases to increase at about 20–25 years. The length–weight relationship is given by the equation (Ohsumi, 1980):

$$W = 0.0126 L^{2.76}$$

where *W* is body weight in metric tons and *L* is body length in meters.

If mean lengths at physical maturity in the western North Pacific stock are substituted into the equation, weight estimates are 15.0 (at 13.0 m) and 16.6 (at 13.5 m) tons for males and females, respectively.

Bryde’s whales closely resemble sei whales but have a number of distinctive characteristics (Fig. 1). Body color is principally dark smoky gray above and white below, but the dark area extends down to include the throat grooves and the flippers. The boundary between dark and light areas is diffuse. The rostrum is V shaped as in other balaenopterids (Fig. 1). The head occupies about 24–26% of the body.

Figure 1 (A) Bryde’s whale in western North Pacific in summer 1993 (photograph by Tomio Miyashita); (B) head region has a lateral ridge on the rostrum of an animal off South Africa. Photograph by Keiko Sekiguchi, 1997.

The dorsal fin is extremely falcate with a tapering tip and is located at 25.2–26.6% of body length anterior to the flukes. The flukes are broad (23.5–24.4% of body length), with rather straight posterior margins.

Pelagic Bryde's whales, such as those in the western North Pacific stock or the offshore form off South Africa, bear large numbers of oval pit-like scars from bites by the tropical cookie cutter shark (*Isistius* sp.), which serve as the evidence of migration to tropical waters. This scarring is usually most extensive on the lateral side of the peduncle, leading to an appearance like that of galvanized iron. Such scarring is rare on animals of the coastal form off South Africa; this may also be true for coastal animals in neritic waters off Kochi, southwestern Japan, indicating that the whales do not migrate to tropical waters. Best (1977) further noted that the coastal form has thin scratches on the undersurface of the tail and ventral keel and suggested that these scratches are due to accidental touching of the sea bottom in shallow waters.

The throat grooves extend to or beyond the navel, whereas those of the sei whale do not reach the navel. The number of grooves between the flippers is 54–56.

The most distinctive external character allowing the discrimination of Bryde's whales from other baleen whales is the presence of

three prominent ridges on the rostrum (Fig. 1). The ridges run from just behind the tip of the snout to anterior of the blowholes. They are composed of one central ridge and two lateral sub-ridges.

Bryde's whales have 285–350 dark slate-gray baleen plates on each side of the mouth. They are much broader and have coarser bristles than those of sei whales. The longest plate may reach 40 cm in length above the gum. Best (1960, 1977) reported a clear difference in the proportion of length to breadth of the plates in South Africa, with those of the inshore form being more slender than those of the offshore form. Kawamura (1978) found animals in the South Pacific to have finer bristles than those in the western North Pacific stock, probably reflecting a difference in their feeding habits.

The skull occupies about 24.1–25.8% of the total body length. It is relatively broad, short, and flat for a balaenopterid skull (Fig. 2). The rostrum is also relatively short and pointed. Its sides are nearly parallel posteriorly but slightly convexly curved anteriorly. The curved and robust mandible is also conspicuous among balaenopterids. The vertebrae formula is C 7 + D 13 + L 13 + Ca 21–22 = 54–55, for a total slightly lower total count than in sei whales (56–57). Cervical vertebrae are unfused, and thoracic (dorsal) vertebrae have short neural processes. The ribs are relatively thin and broad and are usually numbered

Figure 2 Dorsal and ventral views of a skull of Bryde's whale caught in the western North Pacific and landed at Bonin Island in July 1983. Photograph by Hidehiro Kato.

13–14. The first rib has a double head, a characteristic shared with the sei whale. The phalangeal formula is I (6), II (5), IV (5), V (3).

II. Distribution and Abundance

Although there is a general pattern of migration toward the equator in winter and to higher latitudes in summer, Bryde's whales are seen throughout tropical and warm temperate waters of 16.3°C or warmer year round. Their occurrence has been reported from all tropical and temperate waters in the North and South Pacific, Indian Ocean, and South and North Atlantic between 40°N and 40°S (Fig. 3).

In the western North Pacific, Bryde's whales occur in temperate and tropical waters off the Pacific coasts of Japan, Taiwan, and Philippines to 150°W, with the northern limit corresponding approximately to the southern margin of the subarctic boundary at about 40°N and the southern limit at about 2°S. This is the western North Pacific stock, with abundance estimated at about 24,000 (CV = 0.20; IWC, 1997). Bryde's whales inhabit the east China Sea; this stock extends to the coastal waters of the Pacific side of southwest Japan but is restricted to the west of the Kuroshio warm current (Kato *et al.*, 1996). Bryde's whales also occur in eastern tropical Pacific waters, mainly west of 150°W between 20°N and 10°S; abundance is estimated at 13,000 (CV = 0.20). Bryde's whales also inhabit the Gulf of California throughout the year; these are assumed to constitute an independent stock. They are also widely seen in the Southern Hemisphere, occurring continuously from the east coast of Australia to 120°W in a zone between the equator and about 30°S, including northern New Zealand. In the eastern South Pacific, the species is distributed in coastal waters off South America from the equator to 37°S. Occurrence seems to be related somewhat to seasonal upwelling events. Little is known about stock structure in these

areas, but it is expected that the coastal stock(s) is genetically different from those of the western South Pacific.

Bryde's whales are common throughout the Indian Ocean, from waters north of 40°S such as the Bay of Bengal and the Arabian Sea. Geographical concentrations occur south of Java to the west coast of Australia (east of 90°E), in the central Indian Ocean (65–90°E), off Madagascar (35–65°E), and off South Africa (east of 35°E). Stock structure in these areas has not been fully examined other than to confirm the existence of inshore and offshore forms off South Africa (discussed later). However, it would not be realistic to assume that one homogeneous stock is distributed over the Indian Ocean.

Two allopatric forms of Bryde's whale known as the inshore and offshore forms are found off the west coast of South Africa (Best, 1977). The inshore form is restricted to within 20 miles from the coast and is seen there throughout the year. The offshore form occurs in waters over 50 miles from the coast and migrates north to the equator in winter. Accurate estimates of population abundance are not available for either stock. Little is known about distribution and stock structure in the rest of the Atlantic, especially in the Northern Hemisphere. However, Bryde's whales have been sighted or stranded from Morocco south to the Cape of Good Hope in the east and from Virginia south to Brazil in the west, including the Gulf of Mexico, the Caribbean, and off Venezuela. Most recently, Best (2001) suggested that there may be three populations off southern Africa, a pelagic population of large whales off the west coast and separate populations of small whales on the east and west coasts.

Genetic analysis of large-form (offshore) Bryde's whales (nominally *B. brydei*) from populations in different ocean basins and hemispheres suggests that there is a little gene flow between the populations and that they should be treated as separate entities for purposes of management (Kanda *et al.*, 2007).

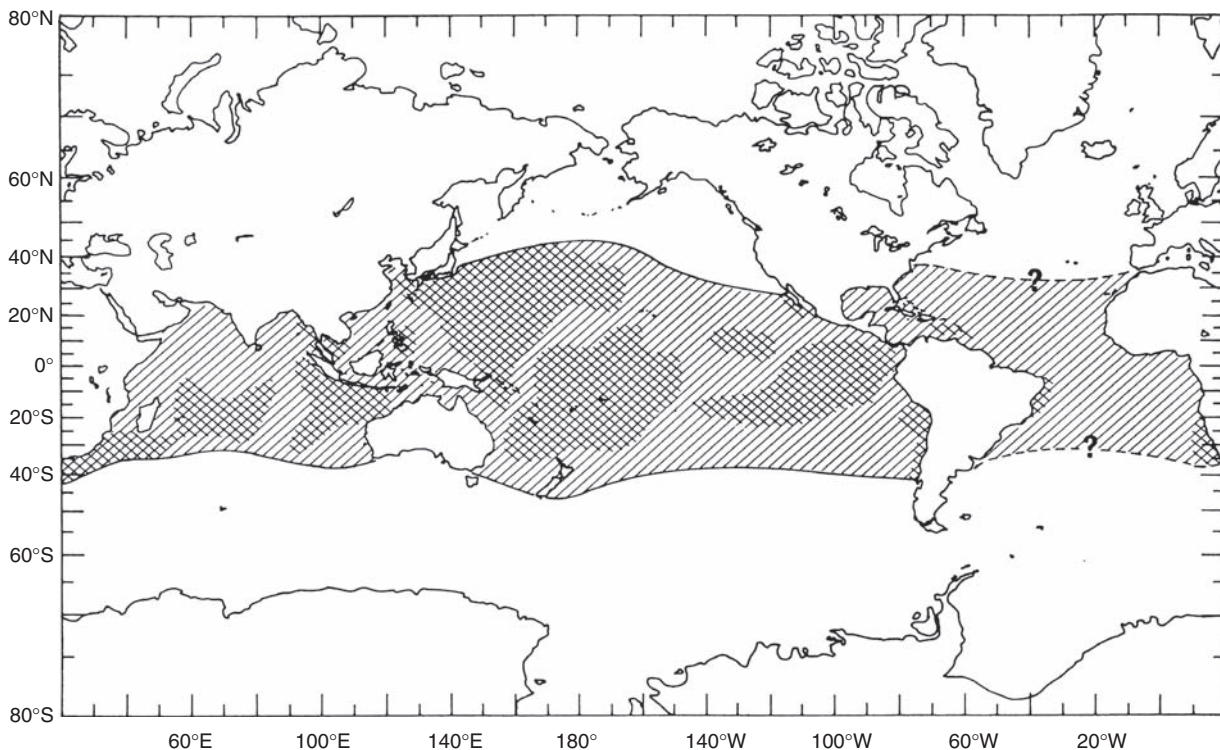

Figure 3 Worldwide distribution of Bryde's whales based on published or available information. Dense hatch represents areas in which higher densities are expected.

III. Ecology

Bryde's whales feed mainly on pelagic schooling fishes such as pilchard, anchovy, sardine, mackerel, herring, and others. They were observed feeding on sardines off Brazil (Siciliano *et al.*, 2004). However, they also feed on small crustaceans such as euphausiids and copepods as well as on cephalopods and pelagic red crabs (*Pleuroncodes*) (Best, 1960, 1977; Nemoto and Kawamura, 1977; Ohsumi, 1977a; Kawamura, 1980). They are considered opportunistic feeders, unlike sei whales, which concentrated on copepods. Off South Africa, they tend to be dependent on euphausiids in pelagic waters and feed on schooling fishes in coastal waters; thus feeding habits may be characteristic of stocks (Best, 1977). However, in the pelagic North Pacific, prey selection was shown for Japanese anchovy in 1 year and krill in the next (Murase *et al.*, 2007). Balaenopterids consume about 4% of body weight daily at the peak of the feeding season; this corresponds to approximately 600–660 kg per day for a Bryde's whale.

Bryde's whales are sometimes seen within high-density patches of bonito (*Sarda*) in pelagic waters in the North Pacific. This may be a result of two predators chasing the same prey. Similarly, off the coasts of Kochi and Kasasa, southwestern Japan, it is very common to see Bryde's whales feeding in patches of sardines or juvenile tuna, especially in summer. They have also been observed to utilize bubble net foraging with slow circle swimming under the surface.

IV. Behavior and Physiology

Bryde's whales do not gather into large groups. They are usually seen singly or in groups of 2–3 in the North Pacific, with a maximum group size of 12. They usually surface steeply like other balaenopterids. The blow is 3–4 m high. The dorsal fin is seen after the blow and then sometimes the dorsal keel is seen. They seldom fluke up before diving. It is generally believed that they usually move at 2–7 km/h but can swim as fast as 20–25 km/h and dive up to 300 m. Bryde's whales breach more often than other balaenopterids. They produce powerful low-frequency tonal and swept calls similar to the calls of other balaenopterid whales (Cummings, 1985). Spatial-temporal variation in frequency and call types may be related to sex, seasonal activity, or population differences (Heimlich *et al.*, 2005; Oleson *et al.*, 2003).

V. Life History

Although Bryde's whales have a life history similar to that of other balaenopterids, there are species-specific aspects due to the fact that they remain in tropical and temperate waters throughout the year. As for many other migratory large cetaceans, little is known about the breeding grounds, even for inshore or coastal stocks, although it is generally believed that they must be somewhere in lower latitudes for the migratory stocks. In waters off the inshore waters of the Pacific coast of Japan and the East China Sea, females accompanied by small calves sometimes appear in early spring, but there is no direct evidence that they give birth there. In pelagic stocks, peaks of both conception and calving are in winter; although these are much more diffuse than in other migratory balaenopterids. Best (1977) reported that breeding is not seasonally restricted for inshore animals off South Africa; this may be true for other local stocks.

Gestation lasts for about 11 months. Length at birth is about 4 m. The sex ratio at birth is not different from parity (Best, 1977). Lactation lasts about 6 months and calves wean at about 7 m in body

length. Males attain sexual maturity at 11–11.4 m and females at 11.6–11.8 m in the western North Pacific stock. Taking into account bias due to operations and regulation of whaling, Best (1977) found length at sexual maturity for the inshore form to be less than for the offshore form off South Africa, by 1 ft in females and 3 ft in males. The mean age at sexual maturity is slightly less than 7 years. Based on the annual ovulation rate (0.42–0.46) for pelagic Bryde's whale stocks (Best, 1977; Ohsumi, 1977b), the calving interval is about 2 years. Inshore waters off South Africa are very frequent ovulators (1.88 per year), but this does indicate a higher pregnancy rate but rather probably results from the extended breeding season. In summary, Bryde's whales have a 2-year reproductive cycle composed of 11–12 months gestation, 6 months of lactation, and 6 months resting.

VI. Human Interactions

Bryde's whales were not harvested commercially or substantially until recent times; their value became relatively important in the late 1970s with the shift of whaling to the smaller species. However, commercial harvest of this species has been prohibited by a moratorium imposed by the IWC in 1987.

Because Bryde's whales had been mainly exploited after substantial improvement of IWC stock management procedures adopted in 1975 (the new management procedure or MNP), stocks have been kept relatively stable. A reliable estimate of the population trend for North Pacific Bryde's whales has been available for the western North Pacific stock from a comprehensive assessment conducted by the IWC in 1995 and 1996. According to the assessment (IWC, 1997), the population has been increasing since 1987, and the current population level (mature females in 1996 relative to 1911) ranges from 56.7% to 81.4%.

Burmeister's Porpoise

Phocoena spinipinnis

JULIO C. REYES

I. Characteristics and Taxonomy

P*hocoena spinipinnis* was described from a specimen captured by fishermen at the mouth of La Plata River, Argentina (Burmeister, 1865; Brownell and Praderi, 1984; Brownell and Clapham, 1999). It belongs to the family Phocoenidae, whose members share the presence of premaxillary eminences in the skull, a reduced posterior extension of the premaxillae not reaching the nasal and, at least in the living species, small spatulated teeth. The Spanish name for this porpoise is "marsopa espinosa" (spiny porpoise) which refers to the series of dermal tubercles present in the dorsal fin. Some vernacular names include "chanchito marino," "tonino" (in Peru), and "antonino" (in southern Chile).

The body is stocky with a small, blunt head lacking a beak and proportionally large flippers (Goodall et al., 1995; Figs 1 and 2). The dorsal fin is a diagnostic feature in this species. It is placed far back,

Figure 1 Lateral (A) and ventral (B) views of a female Burmeister's porpoise from Peru.

Figure 2 Detail of the head of a Burmeister's porpoise.

triangular in shape, and canted backward, its leading edge bears a series of 2–4 rows of tubercles ending near the tip of the fin (Fig. 3). The tubercles become larger and sharper in older animals. The flukes are medium sized, with rounded tips and an almost straight trailing edge.

Maximum length reported is 200 cm for specimens from Uruguay. On the Pacific coast of South America, the largest male and female were 182 and 183 cm long, respectively. Maximum known body mass for specimens from the Pacific is 72 kg for a male of 170 cm long ($n = 70$) and 79 kg for a female of 173 cm long ($n = 60$). In the Atlantic, a 191-cm female weighed 105 kg, whereas male of 178 cm length weighed 78 kg.

The coloration of Burmeister's porpoise observed in fresh carcasses and live animals is dark gray, sometimes lead gray, on the back and sides with a light gray to white around the abdominal field. A few animals may present a brownish hue. There is a well-defined

Figure 3 Dorsal fin of a Burmeister's porpoise, showing the dermal tubercles characteristic of the species.

eye patch surrounded by a light gray to white halo. An anterior extension of this eye patch may reach the dark gray lip patch. A wide, dark gray blowhole-to-apex stripe joins the lip patch. The flipper stripe is dark gray, being wide and reaching the lip patch on the right side, and thinner and joining the chin patch on the left side of the head; the flipper stripe may be flanked by thin, light gray stripes. In the abdominal field a pair of stripes extends toward the genital area, splitting into accessory stripes that end in the mammary slits in females and run parallel to the perineal groove in males.

The skull of *P. spinipinnis* (Fig. 4) resembles in several aspects to those of the harbor porpoise, *Phocoena phocoena*, and the vaquita, *Phocoena sinus*, although it has a less antero-posterior compression of the braincase and the dorsal aspect of the supraoccipital is in line with the plane of the rostrum, whereas in *P. sinus* and *P. phocoena*, this portion of the supraoccipital forms an angle with the long axis of the rostrum. Further characteristics differentiating *P. spinipinnis* from *P. sinus* include a longer rostrum, a larger vertex, fewer alveolar teeth, and hamular processes of pterygoids longer than wide and with mesial borders widely separated.

Little information is available on the axial skeleton. Vertebral counts for two specimens were C7, D14, L15, Ca31–35 = 67–68. The first three cervical vertebrae are fused. The first eight pairs of ribs have both capitular and tubercular articulation to the vertebrae. The phalangeal formula is I2, II8, III7, IV4, and V2.

Fossil phocoenids have been found in Peru (de Muizon, 1986; Yáñez *et al.*, 1994), including *Piscolithax longirostris* and *Lomacetus ginsburgi* from the Late Miocene and Early Pliocene in the Pisco Formation. A single incomplete fossil calvarium of *P. spinipinnis* is known from Chile, although locality and date are not known for the specimen. Analysis of the mitochondrial DNA control region and cytochrome *b* gene indicates that *P. spinipinnis* is closely related to

Figure 4 Skull of an adult Burmeister's porpoise (ACOREMA-219, male): (A) dorsal, (B) ventral, and (C) lateral views, and (D) mandible.

P. sinus and both are related to the spectacled porpoise (*Phocoena dioptrica*) (Rosel *et al.*, 1995).

II. Distribution and Abundance

On the west coast of South America, the northernmost record of Burmeister's porpoise is from Paita, northern Peru (5°01'S), at the latitude where the Humboldt Current veers to the west as it is integrated into the South Equatorial Current. From here, the distribution extends south along the Peruvian and Chilean coasts to Valdivia, Chile (39°50'S) (Grimwood, 1969; Clarke, 1962; Goodall *et al.*, 1995; Guerra *et al.*, 1987). There are no confirmed records from the fjords in southern Chile, but the species has been observed in the Magellan Strait, the Beagle Channel, and near Cape Horn. On the east side of the continent, this porpoise is reported from Argentina, Uruguay, and up to Santa Catarina State in Brazil (~28°S) (Pinedo, 1989; Simões-Lopes and Ximenez, 1989). Based on the data derived from specimen records and analysis of oceanographic variables, it has been proposed that the range of this species is continuous from Paita, Peru, to the La Plata River Basin, Argentina, with records in Uruguay and Brazil related to the intrusion of cold waters associated with the Subtropical Convergence (Sarmiento and Tantaleán, 1991; Molina-Schiller *et al.*, 2005).

Differences in body size between Pacific and Atlantic Burmeister's porpoises led to the proposal of two different stocks of the species (Rosa *et al.*, 2005). Analysis of both mitochondrial and nuclear DNA reinforce the existence of a "Peruvian stock" and a "Chilean-Argentinean stock." Further research is needed based on both morphological and molecular analysis for a better determination of the geographic boundaries of these stocks. There are no abundance estimates for this species.

III. Ecology

Throughout its range, Burmeister's porpoise is found mainly in coastal waters, 100–1000 m from shore and 5–25 m deep. Off Argentina, however, some animals have been captured in waters 30–60 m deep and 50 km from shore. Water temperatures during sightings ranged from 4°C to 19.5°C. Sightings and captures are reported in all seasons, although in some areas such as southern Chile there seem to be seasonal movements following prey. Seasonal occurrence has also been reported in San Jose Gulf in Argentina. Movements of porpoises following seasonal intrusions of cold waters associated with the Subtropical Convergence may account for the records of this species in Uruguay and Brazil.

Burmeister's porpoise feeds mainly on fishes, the species varying with region. In both Peru and Chile, Peruvian anchovy (*Engraulis ringens*) and hake (*Merluccius gayi*) are by far the main preys consumed, together with other small fish and squids. Off Argentina, sardines, tailed hake, shrimps, and squids are preferred. A few specimens examined in Uruguay and Brazil had mostly fish and squids. There is no information on foraging strategies.

The nematode *Stenurus australis* (Sarmiento and Tantaleán, 1991) is found tightly packed in the cranial sinuses and the inner ear of Burmeister's porpoises over 125 cm in length, suggesting that infestation may be timed with the beginning of ingestion of solid food. The campulid trematode *Nasitrema globicephalae* has been also found in the same location, although in low numbers and only in adult porpoises. In Argentina, *Stenurus minor* has been reported in the cranial sinuses and around the tympanic bulla of animals incidentally taken in nets (Corcuera *et al.*, 1995). The lungs may

be infected with the nematodes *Pseudalius inflexus* and *Halocercus* sp. Gastrointestinal parasites include the trematodes *Synthesium tursionis*, *Pholeter gastrophylus*, and *Braunina cordiformis*; the nematodes *Anisakis typica*, *Anisakis simplex*, and *Pseudoterranova* sp.; and the acantocephalan *Polymorphus (Polymorphus) cetaceum* (Torres *et al.*, 1992). The latter is present in porpoises from southern Chile and Argentina but absent in Peruvian specimens despite the large sample examined. Parasitic crustaceans of the genus *Isocyamus* have been reported in porpoises from Peru, although prevalence is low (6%). These whale lice are located in fresh wounds, the angle of the mouth, the genital slit, the axillae, and the angle at the base of the dorsal fin. The ectocomensal barnacle *Xenobalanus globicipitis* is found on the tips of flippers, the dorsal fin, and on the flukes of Burmeister's porpoises in Peru, with a maximum of 40 barnacles reported for a single animal. Neither cyamids nor ectocomensal barnacles have been reported from other locations outside Peru.

IV. Behavior and Physiology

Swimming behavior is described as unobtrusive (Würsig *et al.*, 1977). This porpoise surfaces causing little disturbance in the surface and with little of the body surface exposed and dives with gentle rolls, which combined with the low dorsal fin may account for the difficulty of spotting this species at sea. On occasion it can swim very fast when approached by a boat. There are no reports of "porpoising" or bowriding, although a few animals have been observed riding waves and leaping out of the water. Underwater speed is estimated at 4 km/h, while time under the water surface ranges from 1 to 3 min.

Group size has been usually reported as between two and eight. Based on confirmed sightings, both modal and median group size in this species is 2. From 27 confirmed sightings, mean group size has been estimated at 7.38, with 78% of the sighted groups containing 1–4 animals. Large aggregations of 50–70 animals are sometimes encountered (Van Waerebeek *et al.*, 2002). One of the largest aggregations, comprising nearly 150 porpoises, was sighted off north-central Peru in water 27–31 m deep. The animals were scattered over a large area in small groups of 1–5 individuals (including several mother–calf pairs) forming a loose association. The cause and frequency of these events are unknown, but they may account for sporadic large catches of this species in coastal fisheries.

V. Life History

In Peru, average length at sexual maturity in females is around 154.8 cm (Goodall *et al.*, 1995a, b; Reyes and Van Waerebeek, 1995). Pregnancy rate has been estimated at 60%, although considering that some fetuses are too small to be noted, this is thought to be an underestimate. Records of pregnant females simultaneously lactating suggest that annual reproduction may take place. The average length at sexual maturation in males has been estimated as 159.9 cm. There is no evidence of seasonality in the male reproductive cycle.

The size at birth is around 86 cm. The sex ratio in 31 fetuses did not deviate from 1:1. Mating may take place during the austral summer (December through March), with some successful mating occurring outside this season. Gestation may last 11–12 months.

Age data are scarce for this species. Maximum estimated age is more than or equal to 12 growth layer groups (GLGs) for a

196-cm female and more than or equal to 5 GLGs for a 179-cm male. Animals from Argentina may reach physical maturity at a length of 200 cm.

VI. Interactions with Humans

The largest capture of Burmeister's porpoise occurs off Peru (Read *et al.*, 1988; Van Waerebeek and Reyes, 1990; Reyes and Oporto, 1994; International Whaling Commission, 1994). Published data indicate that 200 to more than 400 porpoises are taken annually in Peruvian gillnet fisheries (targeted for a variety of demersal fishes including sharks and rays) and used for human consumption. Although most takes of this species in Peru are incidental, there is evidence that direct gillnetting in large porpoise aggregations does occur, and it may account for occasional high landings of the species in central Peru. Small numbers of porpoises are incidentally captured in fisheries off northern Chile. A gillnet fishery for rat fish and sciaenids operating in southern Chile takes a few hundred animals each year, which are used as bait in other fisheries (Lescrauwaet and Gibbons, 1994). The number of small cetaceans including Burmeister's porpoises reportedly taken directly for crab bait in southern Chile has shown some decline since 1990, due to several factors modifying the fishery's operations. A few animals may be taken in gillnets in Tierra del Fuego, Argentina; evidence of the use of porpoises as human food in the Beagle Channel area dates back some 6500 years. Off the northern coast of Argentina, an estimated 21–25 Burmeister's porpoises are captured every year in gillnet fisheries (Corcuera *et al.*, 1994). A shark fishery operating off Uruguay took only 8 porpoises in a 16-year period (Praderi, 1990), supporting the idea that the presence of the species off Uruguay and Brazil is related to temporary changes in oceanographic conditions.

Organochlorine compounds have been studied in Burmeister's porpoises from northern Argentina. The levels of pollutants (including DDT metabolites and PCBs) in the blubber are considered very low compared with other marine mammals. Pollutant levels have not been studied in other areas within the species' range.

Bycatch

SIMON NORTHRIDGE

Marine mammals sometimes get caught up and killed in fishing operations. In many cases these deaths are entirely unintended by the fishermen concerned and are incidental to the main fishing operation. They are therefore often referred to as incidental catches. More often they are referred to as “bycatches,” although this term is also used to described the capture of some species that, while not the main target of a fishery, still have some value and may therefore be landed. Incidental catches are generally unwanted and discarded. The term bycatch is now commonly used to describe any sort of unintended capture.

Bycatches of marine mammals have probably occurred for as long as people have been putting nets and lines into the water. Most species of marine mammal that occur in places that are heavily fished have been recorded caught in at least one type of fishing gear. Most types of fishing gear have been reported to ensnare marine mammals at one time or another. Some captures seem to defy reason. Large whales, for example, may become caught in a single lobster pot line, and porpoises can get caught in simple fish traps that they are able to find their way into, but not out of. One estimate of global bycatch levels suggests that over 300,000 marine mammals per year are killed in fishing operations globally (Read *et al.*, 2006).

In the past, and indeed in many parts of the world today, bycatch of marine mammals might be treated as a useful bonus and landed for consumption. During the latter half of the twentieth century, however, fishing technology has changed faster and more completely than ever before, which has led to a reappraisal of the issues surrounding bycatch and incidental catch. Nets have become larger and stronger, numerous new fishing techniques have been devised, and fishing intensity throughout the world has increased dramatically, nearly trebling marine fishery landings over a period of just 40 years. Such developments have had unintended negative impacts on non-target species, including marine mammals, so that bycatches have now become a critical issue for some marine mammal populations.

Marine mammals generally reproduce slowly, and their populations are not able to withstand much additional non-natural mortality. The removal of just 1% of the population per year may be more than a marine mammal population can sustain in the longer term. Bycatch is recognized as one of the most important sources of anthropogenic mortality among many species of marine mammals (Reeves *et al.*, 2003; Lewison *et al.*, 2004). For this reason, many nations now legislate to protect marine mammal populations from deliberate or accidental exploitation, and there are several international agreements with the same aim.

Legislation to protect marine mammals from excessive mortality has resulted from a variety of case studies that have uncovered unsustainable levels of incidental capture. Several of these cases have become widely publicized and have generated considerable public attention and debate.

I. Examples

A. Eastern Tropical Pacific Tuna Purse Seine Fishery

The first interaction to be recognized as a serious concern for the conservation of marine mammals was the large-scale capture of pelagic delphinids, mainly *Stenella* and *Delphinus* species in the United States tuna purse seine fishery of the eastern tropical Pacific Ocean (ETP). Tuna boat skippers learned in the 1950s that they could catch large tuna by herding dolphin schools with speedboats and then surrounding them with long, deep, purse seine nets. Fishermen were exploiting the curious fact that in the ETP and some other places, large yellowfin tuna *Thunnus albacares* will school under and follow dolphin schools. Once the dolphins and associated tuna are surrounded, the nets can be “purse,” whereby the bottom end of the net is closed off, thereby catching the tuna. At this point the dolphins can still surface to breathe within the encircled net and could escape by jumping over the floats. Pelagic delphinids, however, seem to find it difficult to escape from such an enclosed situation, and many became trapped and died under folds of the surrounding purse seine.

This fishing technique was begun in the 1950s, but was not recognized as a potential conservation problem until the early 1970s, when a monitoring program was established. During much of the 1960s and up to 1972, annual mortalities are thought to have ranged between 200,000 and 500,000. Thereafter a variety of efforts were made to reduce the kill, but tens of thousands of dolphins were still being killed annually throughout most of the 1980s. Pantropical spotted dolphins, *Stenella attenuata*, were the most frequently killed species, and numbers of this species in the ETP were more than halved over the 1960s and 1970s. Populations of other species were also severely impacted.

Largely as a result of public pressure, and the introduction of “dolphin safe” tuna retailing, this practice has now been greatly reduced. New techniques have been devised by the skippers to ensure that a very high proportion of the dolphins used in this way to catch tuna are encouraged to escape from the nets before the fish are removed. Under a training and monitoring scheme run by the Inter-American Tropical Tuna Commission, dolphin mortality had been reduced to less than 1500 animals per year by 2004 (Anon, 2004). Efforts continue to reduce these figures further still. However, despite the great reduction in the kills, the populations have not shown strong signs of recovery; effects of continued large-scale chase and capture may contribute to this failure to rebound (Gerrodette and Forcada, 2005; Wade *et al.*, 2007).

Throughout the world, since the discovery of the effect of the ETP tuna fishery on dolphin populations, it has become clear that there are numerous other fisheries in which marine mammals are being killed in large numbers. In some cases, populations or species have been threatened with extinction. Two of the most severe cases are those concerning the baiji *Lipotes vexillifer*, which has recently been declared extinct, and the vaquita *Phocoena sinus*.

B. The Baiji

The baiji (*L. vexillifer*), otherwise known as the Chinese river dolphin, used to inhabit the middle and lower parts of the Yangtze River system in China. The total population size was thought to have numbered a few hundred in the 1980s, and numerous publications warned of its imminent demise throughout the 1990s and into the present millennium. The major source of mortality for this species was snagging in “rolling hook” fishing lines. These are lines equipped with many closely set, sharp, unbaited hooks designed to snag fish foraging on the river bed in the same areas as the Baiji. In one study, 45% of all known Baiji deaths were attributed to snagging in rolling hooks. A recent intensive survey found no remaining baiji and concluded that the species was extinct, probably due to unsustainable bycatch in local fisheries (Turvey *et al.*, 2007).

C. The Vaquita

The vaquita (*P. sinus*) is a species of porpoise restricted to the upper part of the Gulf of California in Mexico. Population studies suggest that less than 600 animals remained by 1997, that numbers are declining, and that the species is in critical danger of extinction. Again, the major source of mortality is incidental catches in fishing operations, in this case gill nets for fish and shrimps. Gill nets are simple long panels of netting that are set to stand vertically in the water with floats along their top and a weighted rope on their bottom. Depending on the amount of weight added, they either sit on the seabed floating upward or they float at the surface hanging down. They are left to ensnare fish that happen to swim into them, but also catch marine mammals by entangling them. Annual vaquita mortality in gill net fisheries is estimated at around 40–80 per year, which is clearly an unsustainable level of mortality given the size of the population. Progress towards reducing entanglement has been slow in spite of efforts to phase out gill nets in the vaquita’s core range, and the development of schemes involving compensation for fishermen (Rojas-Bracho *et al.*, 2006).

II. Causes for Concern

Although these examples are perhaps the most extreme cases, there are numerous others around the world where significant numbers of marine mammals are killed incidentally in fishing operations. It is usually the smaller species and those that occur in continental shelf waters where most fishing occurs that are impacted most heavily.

Incidental catches do not always impact on entire species. In many instances, marine mammal species may be widespread and in little danger of overall extinction. Nevertheless, incidental catches may be frequent enough to reduce or eliminate a local population (Fig. 1). This is the case for the harbor porpoise, *Phocoena phocoena*. Although they are in no imminent danger of extinction as a species, in several areas including the Gulf of Maine off the US northeast coast, incidental catch rates are or have been high enough to push local populations into decline. In other parts of its range, including

Figure 1 A harbor porpoise entangled in a cod gillnet in the North Sea, one of many hundreds dying this way every year in European gillnet fisheries. Photo by Nigel Godden/Sea Mammal Research Unit.

the Baltic Sea, harbor porpoises have all but disappeared. Although the cause of this disappearance is not known for sure, the use of gillnets in the Baltic has been intense in recent decades, and it is widely believed that bycatch has played a significant role.

Throughout the world, small inshore species such as the harbor porpoise are known to be victims of bycatch in fishing operations, but the level of such bycatches and the likely impacts remain unknown. Monitoring bycatch rates and estimating population sizes are both very expensive. A significant issue in this regard is that there does not need to be a very large number of bycatch kills for the total effect to be significant. When a marine mammal population numbers in the hundreds or even the tens of thousands, a few individuals to a few hundred individuals taken per year may be enough to generate a population decline. Furthermore, even when the marine mammal population is much larger, if the fishery is also large, significant bycatches can occur while still remaining unknown. Generally, bycatches are rare events. Typically in European and North American coastal gillnet fisheries, a capture event only occurs in one or two out of every hundred fishing operations. Such low levels may remain unnoticed, although the aggregate effect over a large number of vessels and operations may be significant. Such low levels of capture also make monitoring more difficult.

Although most attention worldwide has focused on the potential conservation issues that incidental catches of marine mammals raise, animal welfare considerations are also a concern. Whereas some bycatch of marine mammals in fishing operations is an inevitable consequence of fishing, in some nations any large-scale fatalities of marine mammals are publicly unacceptable regardless of whether they are sustainable at a population level.

III. Attempts to Resolve the Problem

Most of the numerically significant bycatches of marine mammals tend to be in static fishing gear, mainly gill nets. Despite the attention focused on this subject in recent years, it is still not known how or why marine mammals actually become caught in such nets. It is not known, for example, whether mammals are attracted to nets by the curiosity or by the presence of trapped fish, whether they do not notice the netting, or whether they simply do not understand the

potential consequence of swimming into it. Despite our ignorance, some progress has been made toward resolving the problem.

One potential solution to the problem of marine mammal capture in gill nets has been developed in North America. Pingers, or acoustic beacons, exploit the sensitive hearing of marine mammals by emitting an intermittent, short, high-pitched noise that most fish cannot hear but that appears to repel or warn off marine mammals. Attached at regular intervals along the length of a gill net, these pocket-sized devices have been shown to reduce the numbers of bycaught marine mammals, mainly harbor porpoises, but also dolphins and sea lions, by up to 90%. Pingers were first developed in Canada, and their use is now mandatory in several US and EU fisheries.

Pingers certainly appear to be useful, but there are still some concerns about their use. If, as seems to be the case, pingers displace animals from an area adjacent to the fishing gear, and if they are used to the very large numbers that would seem to be necessary in some areas, then it is also possible that marine mammals may become excluded from parts of their foraging habitats. Pingers rely on having their batteries replaced or on being recharged, and they rely on people performing this task to ensure that they continue to work. This can be an expensive and time consuming operation that many people might eventually prefer to forget about. Finally, the pingers themselves are expensive, so that the cost of equipping a net with pingers may exceed the cost of the net. In many less-developed countries, it is unlikely that they will ever become widely used for this reason alone.

Issues with mobile fishing gear are somewhat different. There are or have been several initiatives worldwide that aim to keep marine mammals out of towed fishing gear. In the ETP tuna fishery referred to earlier, special techniques, and nets have been developed to help dolphins to escape from the purse seine net once the net has fully encircled the school of tuna. During the “backdown procedure” the skipper reverses the vessel and is able to sink a part of the net float line under the water, enabling the dolphins to escape. This part of the net is also made up with a smaller meshed panel, the Medina panel, reducing the chances of dolphins becoming entangled as they escape. Similarly, in New Zealand, special marine mammal escape devices have been designed and used in squid trawls. A large grid is placed near the rear of the net, set at a 45° angle to the vertical plane. Fish can pass through the grid, but larger animals such as sea lions are forced upward and out the net through an escape hatch. Similar devices have been designed and tested for dolphins in the United Kingdom and France.

In general, the incidental capture of marine mammals is caused by a combination of fishing technique or gear design and the behavior of the marine mammal. Resolving problematic interactions therefore involves some combination of change to fishing gear use or design and the manipulation of marine mammal behavior. Very little is known about the behavior of marine mammals in relation to fishing gear, especially in the context of incidental capture. In part this is because of the difficulties of studying marine mammals underwater and the rarity of such events in most cases, which makes observing their occurrence very difficult. Finding solutions to the problem is therefore a slow and arduous process.

Most fishing practices and gear designs have been adopted by fishing communities because they are effective in catching fish, and

making changes may therefore reduce the profitability of a fishery. Effective mitigation measures therefore need to be devised in collaboration with the fishing community to minimize the adverse impacts on fish catches and ensure that bycatch rates once lowered remain low, but they may also require a legislative approach to ensure compliance. In this respect, managing the incidental capture of marine mammals may be seen as part of a much more wide-ranging and ongoing problem of managing a global industry that, in the last 50 years, has outgrown its resource base.

C

California, Galapagos, and Japanese Sea Lions

Zalophus californianus,
Z. wollebaeki, and *Z. japonicus*

CAROLYN B. HEATH AND WILLIAM F. PERRIN

I. Characteristics and Taxonomy

The California, Galapagos, and Japanese sea lions are closely related species that together comprise the genus *Zalophus*. They occupy (or occupied, in the case of the extinct Japanese sea lion) widely separated regions of the Pacific, including the

temperate western and eastern North Pacific and the tropical Galapagos Archipelago (Fig. 1).

The three sea lions are now regarded as separate species: *Zalophus californianus* (Lesson, 1828), *Z. wollebaeki* (Sivertsen, 1953), and *Z. japonicus* (Peters, 1866), respectively. Previously they were typically considered to be geographically isolated subspecies (*Z. californianus californianus*, *Z. c. wollebaeki*, and *Z. c. japonicus*), but recent discoveries of substantial morphological and behavioral differences among them led to their reclassification. Most recently (Sakahira and Nimi, 2007) analysis of ancient DNA extracted from skeletal remains of the Japanese sea lion has determined that it is most closely related to the California sea lion, with a 7.02% divergence in nucleotides, a level suggesting that the two forms diverged 2.2 million years ago in the late Pliocene.

California sea lions are highly sexually dimorphic: the weight and length for adult males is about 350 kg and 2.4 m compared to about 100 kg and 1.8 m for adult females. Males in the Gulf of California appear to be smaller than their Pacific counterparts. Newborn California sea lion pups weigh 6–9 kg for females and males, respectively. They are dark brown to black until they molt to a tawny brown color at 4–6 months (Fig. 2). Females remain this color throughout adulthood, whereas male coats typically darken as they age. Adult males usually are a dark brown, but can range from light brown to black. All individuals appear darker when wet. It is difficult to distinguish females from young males until the latter begin developing the chest, dark color, and sagittal crest of adult males (Fig. 3). The sagittal crest, which is unique to *Zalophus*, is usually topped by white fur and is quite conspicuous. Galapagos sea lions are smaller than California sea lions and appear to be much less sexually dimorphic. Females weigh

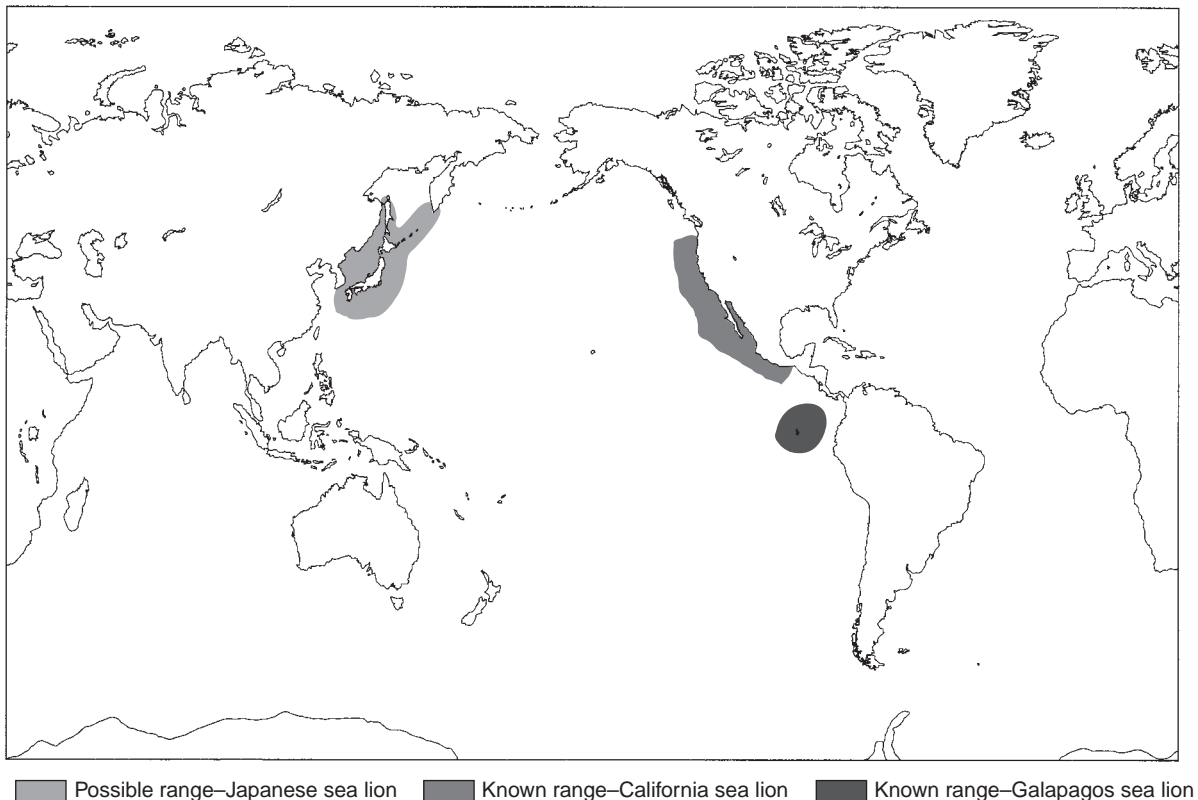

Figure 1 Ranges of California, Galapagos, and Japanese sea lions. The Japanese sea lion is extinct.

Figure 2 An adult female California sea lion suckling her pup after returning from a feeding trip at sea (Photo by C. B. Heath).

Figure 3 An adult male California sea lion on his territory, with pups playing in protected shallows. The broad neck and chest are indicative of an adult male; the fat deposits they contain will sustain him while fasting for the duration of his tenure. Galapagos and Japanese sea lions are similar in appearance to California sea lions. Photo by C. B. Heath.

about 80 kg. No weights are available for males. Young California and Galapagos sea lions are especially playful, spending much time chasing and mock fighting with each other, playing with objects such as kelp and feathers, and bodysurfing. All age classes are fairly vocal; territorial males are exceedingly so. Little is known about the physical characteristics of the Japanese sea lion.

II. Distribution and Abundance

The main breeding areas of California sea lions include the Channel Islands in southern California and Mexican islands off the

Pacific coast of Baja and in the Gulf of California. Rarely, births may occur as far north as the Farallon Islands off central California. Outside the breeding season, animals (mostly males) are common as far north as Vancouver Island. Vagrants occur as far north as Prince William Sound, Alaska, and as far south as Chiapas, Mexico. Females and immatures may disperse from the breeding islands to forage but apparently do not migrate as extensively as males.

Differences in mitochondrial DNA indicate that the Pacific and Gulf of California populations of California sea lions have long been genetically isolated. MHC genetic differences are consistent with either ecologically distinct patterns of selection pressures and/or geographical isolation (Bowen *et al.*, 2006). However, no differences have been found in the cranial morphology of the two populations, and subadult males appear to migrate between colonies in the southern Gulf of California and those along the Pacific Coast of Mexico. The degree of interchange between Mexican and US populations is not known.

Galapagos sea lions breed on all the islands of the archipelago. In 1986, a small rookery was established outside of the Galapagos on Isla de La Plata off the coast of Ecuador. Vagrants have been reported along the mainland coast of Ecuador and on Islas del Coco (Costa Rica) and Gorgona (Columbia).

Although historical and archeological records are incomplete, Japanese sea lions appear to have lived in coastal areas from Kyushu to southern Kamchatka. Their range was likely centered along the west and east coasts of Honshu, off Shikoku and Kyushu, in the Seto Inland Sea, and on islands in the Sea of Japan and the Izu region. Known rookeries include Takeshima and Ullung-do in the southern Sea of Japan, the northwest and also central-eastern coasts of Honshu, and four islands in the Izu region. Vagrants have been noted to southwestern Sakhalin, the Kuril Islands, southern Kamchatka, and the east coast of South Korea.

The US population of California sea lions is currently estimated to be at least 141,842 (Carretta *et al.*, 2007); an additional unknown number were at sea or hauled out at unsampled locations during the census. Annual pup production is currently 40,000–50,000. Maximum population growth rate is estimated at 6.52%; however, massive pup mortality during El Niño years greatly reduces growth. The most recent counts indicates continued growth of the population. A 2000 census of the Mexican Pacific coast resulted in an estimate of about 75,000–87,000 California sea lions (Lowry and Maravilla-Chavez, 2005). Annual growth estimated by two methods was 0.4% and 3.2%. A 1992 census of the Gulf of California population recorded about 23,000 animals; correction factors yielded a population estimate of about 31,000 (Aurioles and Zavala, 1994). Thus, the total California sea lion population is about 248,000.

The Galapagos sea lion has been largely spared the commercial exploitation that depleted the California sea lion population. However, the number of Galapagos sea lions apparently does fluctuate frequently due to El Niño events and epidemics of seal pox. The population was estimated at 20,000–50,000 in 1963. Following the 1997–1998 El Niño, which was accompanied by up to 90% pup mortality and 45% overall mortality, the population was estimated at only about 14,000 individuals (Salazar, 1999).

Between 30,000 and 50,000 Japanese sea lions may have existed in the mid-1800s. Heavy, unregulated hunting depleted the population such that by the 1950s 50 to 60 animals on Takeshima were the only ones reported. The IUCN lists the species as extinct; some scientists believe this status needs to be confirmed by surveys in remote regions.

III. Ecology

California and Galapagos sea lions breed on sandy beaches and rocky areas on remote islands. Because females must forage at sea during lactation, breeding areas are restricted to regions of high marine productivity. California sea lion rookeries along the Pacific coast are in a very productive upwelling zone, and productivity in the Gulf of California is also very high due to tide- and, wind-generated upwelling. The waters of the continental margin adjacent to areas once used by breeding Japanese sea lions are quite productive. Although low productivity generally excludes otariids from breeding in the tropics, the islands in the Galapagos Archipelago are bathed in nutrient-rich upwelling currents. This creates an isolated pocket of high productivity, which supports the Galapagos sea lions. The importance of high productivity can be seen in the devastation that occurs during El Niño events, when a plume of warm, nutrient-poor water emanating from the equatorial Pacific decreases the availability of the sea lions' prey. These frequent, but unpredictable events are most severe in the eastern tropical Pacific where the Galapagos sea lion lives, with lesser impacts at the higher latitudes occupied by California and Japanese sea lions. Sea lions living in the Gulf of California, Mexico, may be largely protected from the effects of El Niños; strong tidal mixing there should be able to resupply nutrients to surface waters during an El Niño event.

The breeding habitat occupied by *Zalophus* ranges from temperate to tropical regions. As a result, breeding animals are often subjected to high temperatures while on land. The effects of these high temperatures and of El Niño events are described in detail below and in section IV.

California sea lions eat a wide variety of prey, which is determined to some degree by its relative availability. The most common prey items in southern California are market squid (*Loligo opalescens*), northern anchovy (*Engraulis mordax*), Pacific whiting (*Merluccius productus*), rockfish (*Sebastes* spp.), jack mackerel (*Trachurus symmetricus*), Pacific mackerel (*Scomber japonicus*), and blacksmith (*Chromis punctipinnis*) (Lowry *et al.*, 1986; Lowry and Carretta, 1999). Anchovy, whiting and rockfish are also important in the Mexican Pacific and Gulf populations, as are midshipmen (*Porichthys* spp.). Myctophids, sardines, cutlassfish, alopis, tusk eels, anchoveta, grunts, squids, and bass are frequently prey in various areas of the Gulf (Sanchez, 1992; García-Rodríguez and Aurióles-Gamboa, 2003; Mellink and Romera-Saavedra, 2005). Diet in the Gulf varies greatly among years, seasons, locations; and probably individuals, including with variation in the availability of the Pacific sardine (*Sardinops sagax*). El Niño events cause shifts in the DIET, and species otherwise rarely consumed, such as the pelagic red crab, may become more common in the diet. Feeding can occur at any hour of the day. Dives typically last for about 2 min, but can be as long as 10 min. Dive depth averages 26–98 m but can be well over 200 m (Feldkamp *et al.*, 1991). Sea lions in California may follow dolphins to take advantage of their better food-finding abilities (Bearzi, 2006).

The staple of the Galapagos sea lion diet is sardines. During El Niño events, however, partial shifts to green eyes (1982–1983) and myctophids (1997–1998) have occurred (Trillmich and Dellinger, 1991; Salazar, 1999). Galapagos sea lions forage within a few kilometers of the coast, feeding during the daytime on a near-daily basis. Dive depth averages 37 m but can reach 186 m. There is no information on what the Japanese sea lions ate.

The environmental changes that occur during El Niño events also elicit behavioral responses by *Zalophus*. However, unlike the fairly constant heat stress experienced on rookeries, the environmental

stresses associated with El Niño are unpredictable and only occur every few years. In addition, because the degree of stress varies among events and locations, the sea lions' responses must be somewhat flexible. El Niños cause a reduction in prey availability for *Zalophus* throughout much of its range (Keiper *et al.*, 2005). The potential consequences of this reduction are mitigated somewhat by adaptations that have evolved over the sea lions' long history of coexistence with El Niños. However, the severe impacts of some El Niño events demonstrate the limits of these adaptations. The 1982–1983 El Niño was a particularly strong one, and much is known about its effects on the California sea lions that breed in southern California. Some non-breeding sea lions in this region responded to local prey depletion by migrating north to more productive areas. Many immatures and some adult females left their normal winter foraging areas and migrated to central California (Huber, 1991). Emigration was thus apparently an option for some individuals to reduce the effects of El Niño. Territorial males in southern California showed no measurable effects from this event, most likely due to their pre-season foraging farther north. Adult females, however, appeared to be more tied to the general vicinity of the BREEDING SITES, where prey reduction was more pronounced. The increase in spontaneous abortions during the 1982–1983 winter indicates that some of these females were unable to find adequate prey (Francis and Heath, 1991). Females that did manage to produce full-term pups then faced the greater challenge of nourishing them. Feeding during lactation makes females quite vulnerable to localized decreases in food availability. In southern California they attempted to compensate for decreased prey by increasing their foraging effort while at sea, partially shifting their prey, and by slightly prolonging their feeding trips (Lowry *et al.*, 1986; Ono *et al.*, 1987). These efforts, however, were inadequate to compensate for the strength of the 1982–1983 El Niño. Females apparently made less milk: pups suckled less, grew more slowly, and weighed less at age 2 months (Ono *et al.*, 1987). Pup mortality increased, and pup production decreased by 30–71% at various islands. Fewer of the male pups were weaned by age 1 year, and more of them stayed on their birth island and suckled into their second year. Fewer females mated during the El Niño summer, presumably a sign that they were undernourished. As a result, pup production was still low in the following year. Because pup production took several years to return to pre-El Niño levels, it is possible that there may have been some mortality of breeding females and juveniles associated with this event. In Mexico, pup production on at least one Pacific island decreased by 50% during the 1982–1983 El Niño, while effects appeared to be very weak in the Gulf (Aurióles and Le Boeuf, 1991). An even stronger El Niño occurred in 1997–1998. While not as widely monitored for its effects on California sea lions, they appear to have been even greater.

The reduction of prey during El Niño events is particularly strong in the eastern tropical Pacific. Because Galapagos sea lions are isolated from alternative feeding areas by vast expanses of unproductive tropical waters, emigration to better feeding areas is not an option for them. Mortality has thus been very high for this species during El Niño events. Between 80% and 95% of the pups born in 1982 did not survive their first year of life. Pup production at various rookeries in 1983 was between 3% and 65% of normal years. Adult female mortality was estimated at 20%, and territorial male mortality was particularly severe (Trillmich and Dellinger, 1991). During the 1997–1998 El Niño, pup mortality was close to 90%, and mortality for the overall population was about 45% (Salazar, 1999).

Oceanic conditions also change in Japan during El Niño events, but what effects this may have had on the Japanese sea lions is not known. The oceanographic counterpart to El Niños are Las Niñas, periods of

generally cooler ocean temperatures and greater productivity. Little is known of their effects on pinnipeds or any role they might play in the recovery from El Niño events.

The toxin domoic acid produced by blooms of the diatom *Pseudo-nitzschia australis* has emerged as a cause of massive episodic mortality of California sea lions (Lefebvre *et al.*, 2000; Scholin *et al.*, 2000; Gulland *et al.*, 2002). The majority of rescued affected animals die in captivity or strand again when “cured” and released (Gulland *et al.*, 2002). Domoic acid has also been shown to cause reproductive failure (Brodie *et al.*, 2006).

The growing arsenal of toxic chemicals and waste that makes its way into marine mammals’ habitats and prey has generated much concern. This is particularly relevant for the Channel Islands population of California sea lions; their proximity to the major metropolitan areas of southern California exposes them to a great deal of urban and industrial runoff, waste, and debris (Connolly and Glaser, 2002; Kannan *et al.*, 2004; Stapleton *et al.*, 2006). Levels of contaminants are lower in Gulf of California sea lions (Del Toro *et al.*, 2006). Because they are high-level predators, sea lions are vulnerable to compounds such as organochlorines (e.g., DDT and PCBs) that become increasingly concentrated as they move up the food chain. Laboratory studies of such compounds have revealed that they can suppress pinniped immune systems, rendering them more vulnerable to disease. However, establishing such clear cause-and-effect relationships in wild populations exposed to organochlorines is more difficult due to confounding factors. California sea lions were found to have elevated levels of organochlorines associated with increased stillbirths and premature pupping, but the level of contribution of disease to this problem could not be determined. One link that has been shown is between levels of PCBs and mortality from carcinoma (Ylitalo *et al.*, 2005). Although the specific links among chemicals, immune system responses, and disease or mortality are incompletely understood, enough indications of problems exist to warrant caution and further research.

IV. Behavior and Physiology

In southern California, where California sea lions have been studied extensively, animals can be found on the breeding islands year-round. The number ashore increases rapidly in May with the onset of the breeding season. At this time adult males begin fighting for territories along the shorelines of the rookeries. Most are unsuccessful and retreat to sea or to “bachelor” beaches nearby. Those that establish territories maintain their boundaries with ritualized displays and frequent barking. Territorial males fast throughout their tenure, surviving on fat accumulated during the off-season. Tenure lasts from 1 to 45 days and may end when residents are displaced by another male or when their fat reserves are depleted. Some males maintain territories for multiple breeding seasons. Throughout May and June females give birth to a single pup a few days after coming ashore. Vocal and olfactory imprinting follows birth and is used by mothers and pups to reunite after separations (Fig 4). Mothers spend the first week postpartum with their pup and then begin alternating feeding trips at sea with suckling bouts on land. The feeding trip length is largely determined by the distance to the foraging grounds and the availability of prey. It averages 2–3 days, but varies with location and year. Stays on land average 1–2 days. This pattern continues until the pup is weaned. Females mate about 27 days after giving birth, an unusually long interval for otariids. Not all females breed every year. At many rookeries, females form “milling” groups as a prelude to mating (Fig 5). In these groups of 2–20 females, the females often mount each other and the territorial male. Eventually 1–2 of the females mate and the milling activity ends (Heath, 1989).

Figure 4 An adult female California sea lion vocalizes to her newborn pup. Mothers and pups imprint on each others’ calls and smell at birth, which helps them recognize each other and reunite after separations. Note remnants of the amniotic sac on the pup.

Figure 5 A “milling” group of California sea lions consisting of several females and one male (large individual on right). These groups form in some areas as a prelude to mating. Females often mount each other or the territorial male while in these groups. Note the male’s sagittal crest, which is unique to *Zalophus*.

While ashore, both males and females make regular movements to the water to cool off (Peterson and Bartholomew, 1967).

After the breeding season ends in August, most adult and subadult males leave the southern California rookeries and migrate north, where they feed throughout the fall and winter. Females and juveniles appear to disperse to feed in the general vicinity of the breeding islands.

California sea lions living in the Gulf of California, Mexico, experience a similar annual cycle with some notable differences. The pupping season lasts 1–2 weeks longer for at least some rookeries in the northern half of the Gulf (Morales, 1990), and the interval between birth and mating appears more variable than in the US population (Heath, 1989). About 40% of the adult males in this region remain around the breeding islands year-round, and the age of weaning appears to be both older and more variable than in southern California (Heath *et al.*, 1996). The breeding season is very protracted in the Galapagos sea lion, and territorial males are observed most of the year. Births occur from June to March, but the peak pupping period varies among rookeries and years. The interval between birth and mating has been estimated at about 3 weeks. Females with new pups interfere aggressively in sibling conflicts, defending the younger pup (Trillmich and Wolf, 2008). Territorial males sometimes go to sea to feed, thus often losing their territory to another male, but sometimes reclaiming it upon their return. Migration within the archipelago is minimal (Wolf and Trillmich, 2007).

California sea lions are highly intelligent and adaptable animals, capable of learning a simple sign language in captivity (Schusterman and Krieger, 1986). Both California and Galapagos sea lions can recognize individuals in the wild through scent, sound, and probably sight. They are also gregarious animals, with much opportunity for social interaction during the breeding season, at least. These traits would seem to dispose them to sustained relationship with other individuals; however, the only obvious social bond is between mothers and their offspring. Perhaps longer term studies of permanently marked individuals will reveal other types of relationships.

Life is a compromise, and pinnipeds have evolved many adaptations in response to the sometimes conflicting pressures of breeding on land and feeding at sea. Certain environmental conditions can increase the costs or benefits of some of these adaptations and bring about compensatory changes in behavior. Two such conditions—high air temperatures on ROOKERIES and decreased prey availability during El Niño events—play particularly important roles in shaping the breeding and foraging behavior of California and Galapagos sea lions. For example, male California sea lions engaged in foraging trips extending over more than twice the distance and lasting 3 times as long during anomalous oceanographic conditions in 2005 as compared to 2004 (Weise *et al.*, 2006).

California sea lion females are very particular about male behavior. Boisterous, overly attentive, or aggressive males are typically abandoned and left to sit alone on their territories. Any interference with female movements is simply not tolerated. Should a male attempt to block a female's path, she needs only to extend her neck out and up, and sway it side to side as she walks. This long-neck display signals males that she requires free passage; the rare male that does not respond to this will likely be subjected to a display of jerky hopping and flipper slapping, which will dissuade him from interfering further. Males seem to have little option but to acquiesce if they are to be successful at breeding.

Why might this situation exist, especially in such apparent contrast to some otariid species where females may be herded, threatened, and even injured by territorial males? The explanation appears to partly lie in the animals' thermoregulatory needs. The particularly warm climate in which *Zalophus* breed increases the cost of moving between marine and terrestrial habitats. The blubber, fur, and large size that insulate against cold ocean waters can lead to overheating while ashore, thus making necessary regular access to wet substrate or water for cooling. The breeding fat of adult males intensifies their thermal stress, thereby limiting the distribution and number of territories. Successful males have territories containing access to water; others must abandon

their territories (and any hopes of mating) during the heat of the day. Breeding females must also have access to cooler shoreline areas on a near-daily basis, and they regularly travel through several males' territories while moving from resting to cooling areas. Furthering this pattern of female movements is the unusually long interval (about 21–27 days) between birth and MATING. During that interval females must also make regular feeding trips to sea to replenish their milk supplies. A male that prevented these premating thermoregulatory and feeding excursions by herding the females would be left with, at best, only severely stressed females, which are not likely to mate. Thus the combination of warm breeding areas and delayed mating together foster a system in which males may control each other, but not the females. Rather, when it is time to mate, many females leave the male's territory in which they have given birth and mate with another male that they may have encountered in their movements about the rookery. Females show a surprising degree of unity in their selection of mates. As a result, many males holding territories during the breeding season never or rarely mate, while a few males mate with many females (Heath, 1989). This dramatically increases the degree of polygyny in California sea lions: males make the first cut by excluding many of their gender from the rookeries, and females make another cut via their selection of mates.

The influence of temperature on behavior can also be seen in the high percentage of copulations that occur in contact with the water. This percentage increases in hotter regions, as does the amount of time females spend cooling off at the shoreline. In the Gulf of California, where air temperatures are very high, nearly all territorial defense and breeding activities are restricted to the water (Heath, 1989; Garcia, 1992).

Galapagos sea lions show a similar response to high air temperatures with their great reliance on shoreline areas for cooling. Females with pups segregate in areas offering the most options for cooling (tidepools, rock surfaces close to the water, shade), whereas males congregate in areas where only shade is available (Wolf *et al.*, 2005).

Environmental conditions in at least part of the former range of the Japanese sea lion are similar to those of its congeners. However, barring the discovery of historical records, we will never know if their behavioral responses were the same as those of the California and Galapagos sea lions.

Standard metabolic rate at the surface in captive California sea lions has been estimated at 1.9 to 3 times that for terrestrial mammals of similar size and decreased by about half during submersion (Hurley and Costa, 2001). Full aerobic diving capacity is not reached until a weight of about 125 kg at 4–6 years of age (Weise and Costa, 2007). However, benthic-feeding pinnipeds in nature may often exceed their aerobic dive limit (Costa *et al.*, 2001).

V. Life History

Most California sea lion pups are weaned by 10–12 months of age. The number that continue to suckle as yearlings or even 2-year-olds varies among years (Francis and Heath, 1991). Pup mortality is roughly 15–20% for the first 6 months of life. In the Gulf of California, normal pup mortality to age 6 months is about 5%. In the southern Gulf of California, at least, it then increases to about 40% for the next 6 months as pups venture into the water (Aurioles and Sinsel, 1988). Sexual maturity occurs at about 4–5 years of age, although males are not large enough to hold breeding territories for several more years. Longevity is estimated at 15–24 years. Sources of mortality include starvation, infection, sharks, killer whales (*Orcinus orca*), toxic phytoplankton blooms, entanglement, shooting, and disease.

As with all other parameters, we have virtually no information regarding the life history of Japanese sea lions.

VI. Interactions with Humans

The annual return of pinnipeds to predictable breeding areas makes them particularly vulnerable to exploitation. Subsistence hunting of California sea lions probably occurred for several thousand years without much of an effect on the population. However, commercial harvesting during the 1800s and early 1900s in southern California and Mexico reduced the population to only about 1500 animals by the 1920s (Zavala-González and Mellink, 2000). The harvest, which at various times was for hides, blubber, meat, predator control, or the whiskers and BACULA sold as aphrodisiacs, probably focused on adult males. A floundering market coupled with protective legislation allowed the population to start increasing by the 1940s, although some killing and live collecting continued until the 1970s. The 1972 US Marine Mammal Protection Act and similar legislation in Canada and Mexico greatly facilitated the population's recovery. Like all marine mammals, California and Galapagos sea lions spend a good portion of their lives in remote areas or underwater, hidden from our view. However, the California sea lion is one of the most familiar marine mammals. This is due in part to their being the most commonly used "seal" performer in animal park shows and also to their habituation to human presence in some areas, especially where there is a comfortable dock or buoy to be acquired by this tolerance. These activities are indicative of their intelligence and flexible nature, which itself can sometimes lead to less positive interactions with humans.

Is the sea lion an enviable hunter or lowly thief? The answer to this question is largely a matter of perspective. Certainly, California sea lions are highly skilled at catching their prey of fish and squid, and their growing population consumes many tons of them yearly [e.g., depredation on salmon (Weise and Harvey, 2004) and competition with artisanal fisheries in Mexico (Aurioles-Gamboa *et al.*, 2003)]. As with many predators, they are also flexible and opportunistic in their search for food, as their diet and thus foraging patterns vary with age, location, and environmental changes caused by things such as El Niño and commercial fishing. While this flexibility is partly responsible for the recovery of this species, it at times also brings them into direct COMPETITION WITH HUMAN FISHERIES. Healthy populations of fish, sea lions, and humans have coexisted throughout much of our history; however, the demand for marine resources generated by a rapidly increasing human population, coupled with its increasingly efficient exploitation of those resources, has heightened concerns about competition between humans and other marine predators. This, combined with the highly visible actions of individual sea lions that have learned to exploit the easy take from fishing lines and nets, has led some to view California sea lions as marine pests rather than an integral part of a healthy ecosystem.

Close interactions with fisheries causes entanglement in gear leading often to death for the sea lion. This occurs most often in set and drift gillnet fisheries (Carretta *et al.*, 2007). However, it is estimated that a safe level of incidental take in US waters would be about 8500, an order of magnitude greater than the present estimated or likely take. Mitigation measures that show promise to reduce incidental mortality and depredation are the use of acoustic pingers (Barlow and Cameron, 2003) and use of nets only during the day and when sea lions are not around (Maravilla-Chavez *et al.*, 2006).

Another form of competition occurs when sea lions make themselves at home on docks and other man-made resting areas. Although this can be quite inconvenient, in areas such as Pier 39 in

San Francisco, the situation has been converted into a popular tourist attraction.

Entanglement with marine debris is a problem found in all populations of California and Galapagos sea lions. Materials such as packing bands and discarded fishing line or nets can become caught on the animals' necks or flippers, leading to injury, infection, reduced feeding efficiency, or death. Sea lions are also killed incidentally in some fisheries.

The southern California population of California sea lions is currently thriving and is thus apparently quite able to recover from its interactions with humans. The extinction of the Japanese sea lion, however, reminds us that there can be limits to this recovery. This is especially true for smaller populations, such as those of the Galapagos sea lions or the Mexican population of California sea lions. If harmful human activities were to increase substantially or happened to coincide with natural stresses such as epidemics or El Niño event, recovery might not be so rapid or complete.

Callosities

MASON T. WEINRICH

Perhaps no external feature on any baleen whale is as distinctive as the hardened, raised patches of skin, called callosities (pronounced cal-OS-it-ies), found on the head of all extant right whale species (North Atlantic right whale, *Eubalaena glacialis*, North Pacific right whale, *E. japonica*, and Southern right whales,

Figure 1 The top of the head of a northern right whale (*Eubalaena glacialis*) showing the most prominent callosity, usually called the bonnet, on its summit. The tip of the snout of the whale is toward the right, and the spray on the left indicates the blowhole. A second callosity is visible near the waterline, on the lower jaw.

E. australis; Fig. 1). These features are unique characteristic of the genus *Eubalaena*, and are immediately notable and visible upon sighting the whale. Old whalers called the most visible callosity, on the tip of the rostrum, the “bonnet”; that name has stuck to the present day.

The term callosity gained acceptance in the first part of the twentieth century. The word extends from the term “callus,” which refers to a variety of thickened tissues in many species. Speculation of their origin included the possibility that the callosity was an “excrecence” (a commonly used term in the late nineteenth century) from barnacles found on the head, abrasions from rubbing the head, or that they were irritations from whale lice. A number of whalers and scientists have noted the coincident occurrence between hair clusters on the whale and callosities, and Payne *et al.* (1983) note that callosities also occur in the same locations as facial hair in humans, e.g., above the eyes, behind the nostrils (blowholes) and along the lip (lower and along the ridge above the upper jaw), and on the “chin.” Although there are some locations where callosities are found and hairs are not present, large callosities have at least a scattering of hairs over their surface, and smaller ones often have at least a single hair near the center of the callosity.

Callosities are a naturally occurring physical feature of the whale. In late term fetuses and immediately after birth, the areas where callosity tissue will erupt can be seen as lighter gray patches as opposed to darker gray/black surrounding skin, although the skin is still smooth. Shortly after birth, the callosity tissue erupts and acquires a pitted, jagged texture which stays with each animal throughout its life.

Although the callosities maintain their gray color throughout life, they often appear white, yellow, or orange because of the coloration of the whale lice living there. Whale lice (*Cyamid* spp.) are a small amphipod that in right whales have developed a unique relationship. Cyamids are found primarily in the crevices and crannies formed by callosity tissue. Because of reduced laminar flow, they can more easily adhere to the whale in these callosity patches. It appears that the cyamids feed on the dead, sloughing skin of the whale but do not hurt the host on which they live. Herein, they reproduce and form dense colonies, which create the whitish coloration seen highlighting the callosities (and allowing for individual photo-identification of right whales). Three different cyamid species can be found

on right whales—*Cyamus ovalis*, *C. gracilis*, and *C. erraticus*—each with a unique coloration. Young southern right whale calves predominantly have an orange coloration to their head from an infestation of *C. erraticus*, which is typically replaced by *C. ovalis* when the calf reaches 2 months of age and their initial rapid growth slows (Rowntree, 1996). One scientist has even proposed that eruption of callosities in young whales may be facilitated by cyamids which, through eating a portion of the skin which comprises the callosity, create an area of lowered laminar flow in which they could more easily adhere to the whale, although this remains to be confirmed.

The function of callosities remains unknown. Male southern and northern right whales have, on average, a greater portion of the surface area of their head covered by callosity tissue than do females. These may be used by males in mating competition, and observers have reported seeing males in mating groups “deliberately” running the dorsal side of their heads along the backs of other males, with the recipient of the scrape reacting by “twisting and writhing” (Payne and Dorsey, 1983). Given the sensitivity of cetacean skin, it would be likely that contact from the callosity of another animal would be painful. While use in competition may account for the greater amount of callosity tissue in males, it does not explain why callosities are also present in females. Rowntree (1996) hypothesized that callosities may also function to raise sensory hairs from the laminar flow close to the skin, to detect dense swarms of plankton (also suggested for the tubercles and sensory hairs found on the rostrum of humpback whales, *Megaptera novaeangliae*). She further suggested that the ability of the whale to sense the behavior of cyamids in response to the presence of plankton (such as standing in a feeding position) around the sensory hairs may facilitate the whale’s detection of its prey.

In the past 30 years callosities have received increased attention from cetologists photo-identifying individual right whales, as the pattern of the callosities varies between individuals. In the southern right whale, individual identification is facilitated by a configuration where the bonnet callosity covers only the front portion of the rostrum, and there are several additional “rostral islands” between the bonnet and the blowholes. This is referred to as a “broken” callosity. Researchers can then use the shape of the bonnet in addition to the number, location, and shape of the rostral islands to identify individuals. In the North Atlantic right whale, however, the callosity can cover the entire

Captive Breeding

TODD R. ROBECK, JUSTINE K. O'BRIEN AND
DANIEL K. ODELL

I. Marine Mammals in Captivity

Animals have been held in captivity in one form or another for hundreds, if not thousands, of years. Private collections turned into “public” collections. A private animal collection at Schloss Schönbrunn, Vienna, Austria, was opened to the public in 1765 and is considered to be one of the first modern zoos. The first marine mammals to be held in captivity may have been polar bears (*Ursus maritimus*) and various pinnipeds. Reeves and Mead (1999) provide an excellent overview of marine mammals in captivity. Harbor porpoises (*Phocoena phocoena*) may have been held as early as the 1400s, polar bears since about 1060, and walrus (*Odobenus rosmarus*) since 1608. As with terrestrial animals, marine mammals were held in private collections.

However, most pinnipeds and some sirenians were not held in captivity until the late 1800s and early 1900s. Being considerably more difficult to capture, transport, and maintain, cetaceans, with few exceptions, have only been held in captivity since the mid-1900s. According to Reeves and Mead (1999), 4 species of sirenians, 33 pinnipeds, 51 cetaceans, the polar bear, and the sea otter (*Enhydra lutris*) have been held in captivity. Of these, 2 species of sirenians, 22 pinnipeds, 15 cetaceans, the polar bear, and the sea otter have reproduced in captivity. Among these, however, only a few species, such as the polar bear, California sea lion (*Zalophus californianus*), harbor seal (*Phoca vitulina*), bottlenose dolphin (*Tursiops truncatus*), and killer whale (*Orcinus orca*), have enough numbers and have been reproductively managed with enough production to be considered part of a successful captive breeding program.

Successful captive breeding of any marine mammal requires a combination of an appropriate habitat, adequate nutrition and a social structure that is conducive toward successful reproduction. It becomes obvious when analyzing the history of successful births and survivorship of these species in captivity that early animal managers had little thought or, in some cases, knowledge of the requirements necessary for the development of successful breeding programs. In contrast, past records of breeding and survivorship with recent trends beginning in the mid-1980s where captive breeding successes have equaled or, in some cases, surpassed the best scientific estimates of wild population breeding and survivorship, and one can see just how far the captive marine mammal community has evolved. Detailed censuses of captive marine mammals in North America (Asper *et al.*, 1990; Andrews *et al.*, 1997) have shown the increasing numbers of captive-bred marine mammals, particularly California sea lions, harbor seals, and bottlenose dolphins. In 1995, 70% of the California sea lions, 56% of the harbor seals, and 43% of the bottlenose dolphins on display in North American facilities were captive-born. This compares with 3%, 4%, and 6%, respectively, in 1975.

II. Why Breed Marine Mammals in Captivity?

A. Legal Necessity

In the “early days,” when animals were just being displayed as “curiosities,” it was easier to collect replacements when animals died. In most countries today this is simply not possible. Despite only a

area between the tip of the rostrum and the blowholes, referred to as a “continuous” callosity (found only rarely in southern right whales). Identification can be confounded since the whale lice on and around the callosities are mobile, sometimes masking the true edge of the callosity. However, by using additional distinctive features, including the three-dimensional configuration of the callosities, additional scars or marks, and crenulations on the lower lip, North Atlantic researchers have still been able to reliably identify each individual. Photographic catalogs of identified right whales, primarily of their callosity patterns, are maintained for the North Atlantic Ocean (by the New England Aquarium, Boston, MA), the North Pacific Ocean (the US National Marine Fisheries Service), and in the numerous places in the Southern Hemisphere, including off of South America near Peninsula Valdez, Argentina and off the coast of Brazil, off the coast of South Africa, and off of New Zealand’s sub-Antarctic Auckland Islands (Best *et al.*, 2001). Additional collections of photographs of individual right whales based on callosities and other natural markings exist in various institutions around the world.

few species of marine mammals being threatened or endangered, they and their habitats are protected by a myriad of national and international laws and regulations. Although a number of countries are considering regulation of the minimum conditions (e.g., pool size and volume, water quality, food quality and handling, medical care) under which marine mammals may be held in zoos, marine parks, or research facilities, apparently only the USA has such regulations in place. Even though the natural habitat of most marine mammals cannot be duplicated in captivity, the trend is toward larger, more complex, habitat-oriented displays and exhibits. Together, the various laws and regulations have reduced the collection of wild marine mammals and have eliminated smaller facilities that did not have the financial resources to adequately provide for their animals as required by law.

The just-mentioned laws and regulations favor captive breeding programs. A successful captive breeding program eliminates costly field expeditions and animal transports.

B. Maintaining/Enlarging a Captive Population

A successful captive breeding program can provide animals for other institutions with adequate holding facilities but without the financial resources to maintain a breeding colony or (if even possible) to collect wild animals. Captive-born animals have a known medical history and, to some extent, are imprinted on their keepers. Captive breeding programs have, out of necessity, reduced the impact on wild populations of marine mammals. Professional organizations such as the Association of Zoos and Aquariums (AZA) have established studbooks and other programs to assist with the management of captive animal breeding colonies. For example, studbooks track individual animals from birth to death and their reproductive histories. Computer programs are used to pair animals to optimize genetic diversity. In the USA, formal studbooks exist for the beluga whale (*Delphinapterus leucas*), common bottlenose dolphin, Florida manatee (*Trichechus manatus latirostris*), gray seal (*Halichoerus grypus*), harbor seal, northern fur seal (*Callorhinus ursinus*), and polar bear and several others are under development. Similar studbooks are in place on other continents. The AZA also hosts a Marine Mammal Taxon Advisory Group whose function is to promote managed captive breeding of marine mammals.

C. A Breeding Program as a Scientific Resource

A successful captive breeding program is a unique scientific resource in that it allows one to document, in great detail, various aspects of reproductive behavior, reproductive physiology, and the subsequent birth, growth, and development of the offspring. This is particularly valuable for cetaceans, which are typically difficult to study in great detail in their natural habitat due to various environmental factors and the fact that they spend most of their lives underwater. It is, however, most important to recognize that studies on captive marine mammals, even in the best breeding colonies, do not and cannot replace field studies. Both types of studies (i.e., laboratory and field) are necessary to fully describe the biology of a species.

Routine components of a proper animal husbandry program include regular physical exams, collection of blood, urine, and fecal samples, body measurements, and body weights. These samples and data are virtually impossible to collect from wild marine mammals. Consider, e.g., what it would take to get a daily urine sample from a wild bottlenose dolphin or killer whale! Captive animals are easily conditioned to provide urine samples and to station for blood sampling, body measurements, and so on. Figures 1, 2, and 3 illustrate the kinds of observations that can be made and the kinds of data that can be gathered.

Figure 1 Birth of a killer whale (*Orcinus orca*) at SeaWorld Florida. Photo credit: SeaWorld Florida.

D. A Breeding Program as a Conservation Resource

A successful captive breeding program may provide the physical and human resources necessary to save some species of marine mammals in imminent danger of extinction (Ralls and Meadows, 2000). These resources may allow us to maintain a viable gene pool until the habitat can be restored or other reasons for endangerment are eliminated. While such an undertaking is certainly honorable and the right thing to do, the magnitude of the job should not be underestimated and there are, at the present time, obvious limits based in good measure on the sheer size of the animals. For example, the population of right whales (*Eubalaena glacialis*) in the western North Atlantic Ocean is about 350 animals and may be decreasing due to human activities. These animals may reach lengths of 18 m and weights on the order of 20 tons. No facility in existence today (or likely to be in the foreseeable future) could hold a breeding group of right whales. However, threatened or endangered marine mammals such as the Hawaiian and Mediterranean monk seals (*Monachus schauinslandi* and *M. monachus*, respectively) and the river dolphins (families Platanistidae, Iniidae, and Pontoporiidae) could be maintained in viable captive breeding colonies. The importance of taking immediate action on behalf of these species is demonstrated by the recent extinction of a small cetacean, the baiji (*Lipotes vexillifer*). If a captive breeding colony had been established, this species would still be present today and this colony may have provided potential animals for reintroduction to the wild.

III. Assisted Reproductive Technologies (ART)

The domestic animal industry [cattle (*Bos* spp.), pigs (*Sus* spp.), horses (*Equus caballus*)] long ago realized that it is much more efficient to move genetic material (e.g., semen) to different facilities than it is to move the animal. Methodologies for semen collection, preservation, and transportation, along with methods for artificial insemination (AI), induction of superovulation, and embryo collection and transfer, were developed and are in widespread use worldwide today. Some of these techniques have been applied successfully to endangered animals. And recently, AI has been successfully developed in three species of marine mammals; killer whales, bottlenose dolphins, and Pacific white-sided dolphins (*Lagenorhynchus obliquidens*) (Robeck *et al.*, 2003, 2004, 2005).

What then are the needs for the development and application of ART to marine mammals? The most obvious ART that should be

Figure 2 Serum progesterone of killer whale (*Orcinus orca*) from birth through sexual maturity and calving and showing estrus cycling and pregnancies. Progesterone levels were “zero” until after 1900 days of age.

Figure 3 Killer whale (*Orcinus orca*) growth (length) curve as an example of data that can be gathered from captive-bred animals.

developed and the one that is most likely to have an immediate impact on the genetic management of captive marine mammals is AI. Once developed in all captive species, AI can provide an immediate mechanism for marine mammal managers to increase the genetic fitness of their respective populations without having to rely on the transportation of animals between facilities. Wild animal population studies have shown that dolphins develop strong social ties to other animals and that these bonds can be maintained throughout the life of the animals (Connor *et al.*, 2000). To what extent these bonds are important for

the health of these animals can only be speculated, but it seems prudent for managers who have groups of compatible animals to carefully consider the impact of removing or introducing individuals on the population social dynamics. Further, bringing animals from other locations may expose the new population of animals to bacterial or viral organisms, which they have no natural resistance against.

The development of AI, the most common assisted reproductive technology, for commercial use began in the 1950s. The successful application of AI and other ART to domestic species and humans was

in part because of their accessibility for research into their reproductive mechanism or reproductive physiology. Critical importance for the successful application of ART in any species is the determination of how reproductive hormones, particularly luteinizing hormone (LH), relate to ovulation (Sorensen, 1979).

Once ARTs were developed in domestic species, it was naively believed that they could easily be transferred to exotic species. However, relatively little success was realized with exotic animals until the late 1970s when an endocrinological breakthrough occurred. This breakthrough was the ability to analyze reproductive hormones in urine. This technology was successfully used to characterize the endocrinological events in a wide range of exotic species, including for the first time in marine mammals; the killer whale (Walker *et al.*, 1988). Other smaller cetacean species proved more difficult to train for urine collection, and detailed endocrinological evaluations would have to wait until a technique was developed for training urine collection in bottlenose dolphins (Lenzi, 2000). This simple technique has since revolutionized urine collection and the subsequent endocrine evaluation of cetaceans (whereas Pinnipeds are yet to undergo such extensive evaluation). As a result, nearly 15 years after the first published report of urinary hormones in killer whales, endocrine characteristics have now been reported in four additional cetacean species.

Although the capability to characterize the endocrine cycle is critical, for it to be useful to predict the timing of the actual insemination, it must first be related to ovulation. For deduction of the temporal relationship between urinary hormones and ovulation in cetaceans, two important techniques had to be developed. This first was an assay system that could rapidly detect the LH surge—a brief and dramatic hormonal surge that in most mammalian species precedes ovulation at a regular interval. The second was to develop a method to allow for consistent observation of ovarian activity using transabdominal ultrasonography. Brook (2001) was the first to develop a technique to accomplish this in the bottlenose dolphin. This simple technique which relies on understanding the anatomical location of the ovaries in relationship to the abdominal musculature has since been successfully utilized to consistently locate ovaries in many other captive marine mammals, including the killer whale, beluga, the Pacific white-sided dolphin (Fig. 4), and the false killer whale (*Pseudorca crassidens*). Finally, by combining this ultrasound technique with rapid LH assay systems, landmark research was completed that allowed characterization of the timing between the LH surge and ovulation (Robeck *et al.*, 2004, 2005). This information then opened the door for the development and application of AI in cetaceans.

Once ovulation timing could be predicted, the optimum timing of insemination had to be systematically determined for each species. However, before any AI attempts could be made the collection of semen had to be developed. Currently, collection of semen on a routine basis has been achieved only in a few marine mammal species, and as one would expect, this list correlates with the species where AI has now been accomplished. The first species where semen collection was successfully trained was the bottlenose dolphin (Keller, 1986). Bottlenose dolphins seem to have consistently elevated libidos and thus were relatively easily trained to provide semen via manual stimulation. Since the success with bottlenose dolphins, four killer whales and three Pacific white-sided dolphins and one beluga have been trained to provide semen on a regular basis. Obviously, to reach the full potential of AI, all genetically valuable males should be trained to provide semen.

Once the semen has been collected, it must be stored temporarily for immediate use or permanently by cryopreservation. Semen cryopreservation has been successfully accomplished by different methods (straws, pellets, or cryovials) in all of the species for which

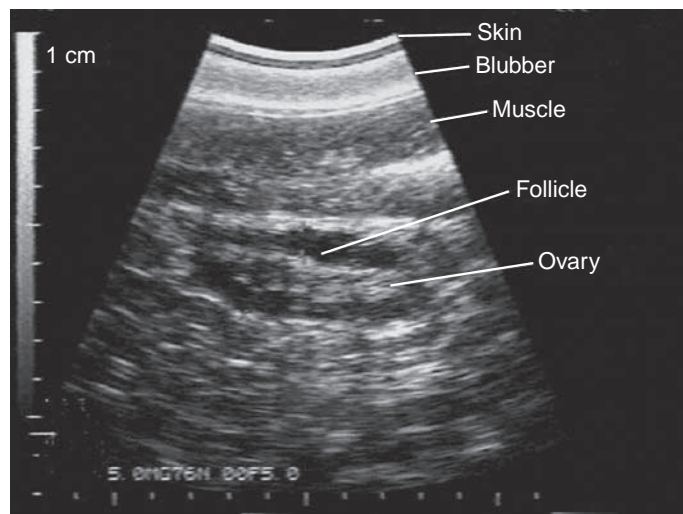

Figure 4 Sonographic image of an ovary of a Pacific white-sided dolphin (*Lagenorhynchus obliquidens*) showing a follicle.

semen has been obtained (Schroeder and Keller, 1990; Robeck and O'Brien, 2004; Robeck *et al.*, 2004; O'Brien and Robeck, 2007). Although cryopreserved semen provides a long-term supply of genetic material from a particular animal and is the only method currently available to store semen for long (greater than a few days) periods of time, when used with AI it has approximately half the fertilizing life span of fresh semen. As a general rule, frozen-thawed semen must be deposited in the uterus and at close proximity to ovulation. Fresh, cooled semen, having a longer fertilizing life span than frozen-thawed semen, can be placed with less accuracy, generally in the true cervix or distal uterine body, and with a greater time interval prior to ovulation. Thus, when attempting to develop AI, first attempts are generally made using fresh cooled semen.

All of the successful AIs in marine mammals have been performed using an endoscope to deposit either fresh or frozen-thawed semen into the uterus (uterine body or the horn). Before this could be accomplished, a thorough understanding of female reproductive tract anatomy was essential. Despite the close phylogenetic relationship between captive delphinids, significant variation exists in their reproductive tract morphology. For example, bottlenose dolphins have a pseudocervical vaginal fold or flap that must be traversed before encountering the true cervix. Knowledge of the anatomy of the bottlenose dolphin would do little to help placement of semen into the uterine body of a closely related member of the delphinid family, the Pacific white-sided dolphin. This species has a cervix which is composed of a series of three annular folds that present anatomical barriers to the placement of semen. The killer whale, another member of the delphinid family, has a completely different arrangement consisting of two longitudinally ridged cervixes aligned in series.

Once the semen has been deposited and ovulation has occurred, how do you determine if you have had success? With the application of ultrasound for pregnancy detection (Williamson *et al.*, 1990), more and more marine mammal practitioners have become aware of the fact that all species of captive delphinids can exhibit variable periods of false pregnancies. These periods of elevated progesterone are currently endocrinologically indistinguishable from pregnancy. Thus, pregnancy can only be confirmed with the use of ultrasound.

In the bottlenose dolphin, the conception rate after AI using frozen-thawed semen is 65–70%. AI in this species has been taken a step further by the development of sperm-sorting technology, a

Figure 5 The world's first female bottlenose dolphin (*Tursiops truncatus*) born at SeaWorld San Diego (California) after using AI with X-selected spermatozoa. Photo credit: Mike Aguilera, SeaWorld San Diego.

sex predetermination method (Johnson *et al.*, 1989). The ability to skew the sex ratio through insemination of females with X chromosome-bearing (female) spermatozoa helps to alleviate space and social problems that often occur with multiple adult breeding males. AI of sex-sorted, cryopreserved sperm could also contribute to improved genetic management of captive populations in the same way as conventionally frozen sperm. Further, small populations can be replenished at a faster rate with higher numbers of females than males. Development of this technology for application to bottlenose dolphin population management has led to the world's first cetacean pregnancy using AI with sex selected then cryopreserved sperm (O'Brien and Robeck, 2006). The technology has been integrated into SeaWorld's multi-site reproductive and genetic management program for this species, with five sex-selected (female) calves being born to date (O'Brien and Robeck, unpublished data; Fig. 5). Sex sorting of previously frozen spermatozoa, derived from ejaculates or post-mortem epididymal samples can also be accomplished providing species-specific modifications are developed in controlled studies (O'Brien *et al.*, 2004, 2005). The diverse applications of sperm sorting in conjunction with AI have great implications for the genetic and social management of captive cetaceans, particularly those which are endangered with extinction.

IV. Challenges for the Future

If self-sustaining populations are to be developed, then all reproductively capable animals must contribute to the gene pool. Producing viable offspring is the primary goal of any captive breeding program, but it must be managed to avoid overpopulation of the facility and to prevent or minimize inbreeding. This may require separate facilities for adult males, preparturient females, and females with new offspring. Breeding may be regulated simply by separating the sexes or by neutering (physically or chemically) both males and females.

Currently, many populations of marine mammals are kept in small groups or same-sex groups. Therefore, a large portion of reproductively mature animals within these groups are not reproducing. These animals are functionally excluded from contributing to the collective captive gene pool. Therefore, valuable financial resources and pool space are being used for a minority of the available genetic lines. This inefficient use of animal resources must be corrected before long-term population stability can be achieved. Judicious use of contraception and continued development of AI in all captive

marine mammal species would help managers optimize utilization of the population's genetic pool. However, if the maximum utilization of genetic resources does not result in a predictable stable population, then genetic infusions from wild stocks will be necessary. ART may provide another answer to this future dilemma if semen (and possibly oocytes) can be collected from wild animals that are incidentally or purposely killed in fisheries or subsistence hunting activities. Alternatively, temporary capture of wild males, followed by semen collection using electro-ejaculation, then release back into the wild after appropriate monitoring, could also represent a means of obtaining valuable genetic material for potential infusion into the captive population using ART. As an alternative to the ART solution or until ARTs such as AI and IVF were perfected, managers could "borrow" adult males from wild populations for 1–2 years for breeding purposes and then return them. This, of course, involves considerable expense and there is no guarantee that any given animal would breed successfully.

Captivity

PETER CORKERON

I. The Debate

The debate over the ethics of marine mammals in captivity is essentially about cetaceans (whales, dolphins, and porpoises) because other marine mammals such as seals and sea lions do not inspire the same passion as whales and dolphins do. The ongoing debate over whether cetaceans should be kept in captivity is relatively recent in contrast to the history of human/marine mammal interactions. Human interest in marine mammals was initially based on the commercial value of killing seals and whales for oil, meat, and hides. The larger animals represented a greater profit, so small marine mammals such as dolphins were mostly considered to be pests to fishermen. Occasional reports of marine mammals being kept in captivity as curiosities are scattered throughout history: polar bears (*Ursus maritimus*) were kept by Scandinavian rulers prior to the Middle Ages; a killer whale (*Orcinus orca*) that had been live stranded was kept and used for sport by Roman guards during the first century ad; and seals were kept in menageries by the eighteenth century. In the mid-1800s, P. T. Barnum displayed belugas (*Delphinapterus leucas*) and common bottlenose dolphins (*Tursiops truncatus*) in his New York museum for a short time, and in the late 1800s, the Brighton Aquarium in England displayed harbor porpoises (*Phocoena phocoena*) for several months. A new era of modern marine mammal exhibits began in the late 1930s

when the Marine Studios at Marineland opened in Florida, USA (Reeves and Mead, 1999).

At first, marine mammal facilities were quite popular. During the 1950s, 1960s, and 1970s, the number of aquaria and zoological parks displaying marine mammals increased rapidly to meet public demand, especially in Europe, North America, and Australasia. Simultaneously, technology and methods for the capture, transport, and maintenance of marine mammals improved with increasing knowledge and experience. Scientists took advantage of the ability of the animals at these facilities to conduct groundbreaking research on dolphin acoustics, human/dolphin communication, dolphin brain function, hearing and echolocation, and behavior. Soon the public became more familiar with dolphins through shows at aquaria and from "Flipper," a popular TV show, in which a dolphin was portrayed as a free-ranging family friend. With this heightened awareness, the public began to understand that dolphins were not large fish, but intelligent and friendly marine mammals. However, the image transformation inspired—at least in part by animals at marine mammal facilities—would soon become a public relations nightmare for the industry that helped to make these animals popular.

II. The Impact

In developed nations, the boom in aquaria and oceanaria experienced through the 1970s came to a near halt during the mid-1980s due to the growing debate over keeping cetaceans in captivity. Pressure from non-government organizations (NGOs) and changes in public opinion forced the closure of some existing facilities and prevented some new facilities from being opened. While the 1990s saw a decline in the number of facilities for keeping cetaceans in Australia and some parts of Europe, but the number of captive facilities increased in other parts of the world, notably in Asia, Latin America, and the Caribbean, where there was little or no domestic agitation against oceanaria.

Compared with most terrestrial mammals, marine mammals are expensive and difficult to maintain in captivity. They require a good deal of logistical support, such as high-quality food sources, specialized veterinary care, large enclosures, and expensive water-quality maintenance systems. Cetaceans and sirenians (manatees, *Trichechus* spp., and dugongs, *Dugong dugon*), being wholly aquatic, present greater logistic difficulties than any other marine mammals. A few species predominate at these facilities because they have shown greater success in captivity, and because they are relatively easy to capture. Of these animals, those most often used in public performances include common or Indo-Pacific (*Tursiops aduncus*) bottlenose dolphins, belugas or killer whales, and California sea lions (*Zalophus californianus*), whereas phocids such as harbor seals (*Phoca vitulina*), sea otters (*Enhydra lutris*), and sirenians are more typically maintained in non-performing exhibits.

Most modern facilities in developed nations maintain high standards of operation and animal care. However, many facilities, particularly those in less developed nations, fall well short of such standards and internationally, new captive facilities are opening mostly in less developed nations. There is concern that capture and holding facilities that are effectively unregulated exist, particularly in southeast Asia and parts of Latin America and the Caribbean, supplying animals to support the growth of the aquarium industry in these regions.

Even if only for short periods of time, almost every species of marine mammal other than most of the great whales have been maintained in captivity. As an anomaly, two young gray whales (*Eschrichtius robustus*) were kept in captivity for about 1 year each, and a wealth of

behavioral and physiological data was collected. However, most others are dolphins and porpoises, pinnipeds, and several members of the carnivores. Animals are kept captive for different reasons: display in zoos and aquaria, military work, scientific (including military) research, and rehabilitation for injured or sick animals prior to release, although these categories are not mutually exclusive. Recent years have seen the growth of “swim-with” programs, where visitors pay to enter the water with captive cetaceans, and “Dolphin Assisted Therapy,” where people with illnesses spend time with captive dolphins. Size and temperament are generally the limiting factors in keeping some marine mammal species for long periods of time. Most are kept in zoos and aquaria, some live in open ocean enclosures. However, many commercial facilities with cetaceans are not traditional zoological gardens but marine parks where there tends to be more emphasis on performances by animals. (Temporary restraint for a few minutes to hours for research purposes is not considered as captivity here.)

III. Regulations for Collection, Care, and Maintenance

A. International Regulations

In general, regulations dealing with marine mammals in captivity cover collection, care, and maintenance of animals, and movements of animals between countries. The extent to which existing laws are administered and enforced varies internationally. The International Whaling Commission (IWC) is the central international instrument for the protection of whales; however its effectiveness is debated. National attitudes to whaling, and to hunting small cetaceans, do not necessarily transpose to captivity. Norway, for example, a staunch whaling nation, has a national ban on keeping cetaceans in captivity, although seals are kept for display and scientific research.

The major instrument regulating the international trade in captive cetaceans is the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). Most cetaceans are listed in CITES Appendix II, which provides a means of regulating and monitoring trade for species not threatened with extinction but which are vulnerable to overuse. This listing allows for international trade with properly issued permits. Some cetaceans that are kept in captivity (or due to their size could be kept in captivity) are listed in Appendix I of CITES, indicating that they are either currently threatened with extinction or may be affected by trade. These include the recently deemed to be extinct baiji or Chinese river dolphin (*Lipotes vexillifer*), Ganges river dolphin (*Platanista gangetica gangetica*), Indus River dolphin (*P. g. minor*), tucuxi (*Sotalia fluviatilis*), Indo-Pacific humpback dolphin (*Sousa chinensis*), Atlantic humpback dolphin (*Sousa teuszii*), finless porpoise (*Neophocaena phocaenoides*), and the vaquita (*Phocoena sinus*). With regard to marine animals, the CITES convention includes the requirement that suitable housing and care is available, and for Appendix I listed animals, that they are not to be used for “primarily commercial purposes.”

Most nations keeping marine mammals in captivity are signatories to CITES, although this does not guarantee problems cannot occur, as the export of bottlenose dolphins from the Solomon Islands to Mexico in 2003, in dubious circumstances, demonstrated. International agreements can regulate capture, but most trade in wild-caught animals now comes from nations with few or no regulations on capture, or with regulations that are ignored. International pressure on some nations (e.g., Iceland in 1989) has resulted in the closure of their capture industry.

In the USA, Congress passed unprecedented regulatory legislation in 1972 to bring under its protection all marine mammals within

the borders of its jurisdiction: The Marine Mammal Protection Act (MMPA)’s intent was to protect marine mammals from human actions (predominantly fishing) that led to extinction. However, the MMPA specifically authorized the collection of free-ranging animals for scientific research and public display and education. Depending on the species involved, the collection of marine mammals is governed by a permit process administered either by National Oceanic and Atmospheric Administration (NOAA) Fisheries or the Fish and Wildlife Service. The standards for the maintenance of marine mammals in research or public display facilities are established and monitored by the Animal and Plant Health Inspection service under the US Animal Welfare Act, and all marine mammal-related activities are monitored by the presidentially appointed Marine Mammal Commission. Although collection is still permitted in the USA, there have not been many bottlenose dolphins collected for US facilities since 1989 due to a self-imposed moratorium observed by members of the Alliance of Marine Mammal Parks and Aquariums on capturing bottlenose dolphins from the Gulf of Mexico. In addition, there is a changing trend regarding holding and breeding bottlenose dolphins in North America. In 1976, 94% of captive bottlenose dolphins held were originally free-ranging, 6% were captive born. By 1996, 44% of bottlenose dolphins were captive born.

Several countries have legislated regulations or guidelines to govern collection and maintenance of marine mammals since 1972. New Zealand passed an MMPA in 1978; and in 1980, Australia passed the Whale Protection Act. In Australia, the state of Victoria put a ban on issuing permits for keeping cetaceans for display or for collecting them for export. Here, legislation does not absolutely preclude issuing a permit to capture free-ranging animals, but general government policy, the legal requirement for public comment on an application for capture, and the need for signed Ministerial approval for capture permits, all mean that it is highly unlikely that permits would be issued. Canada developed guidelines that forbid the capture of killer whales and gives priority to Canadian institutions when considering permits to capture belugas. However, in the past 10 years for which data are available (1997–2006), 28 belugas have been imported into Canada from the Russian Federation (data downloaded from the UNEP-WCMC CITES trade database, <http://www.unep-wcmc.org/citestrade/>).

Legislation can interact with government policy and public opinion to affect the capture industry. For example, guidelines established in some countries such as the UK do not specifically prohibit the collection and display of marine mammals. However, following a scientific review of appropriate standards for dolphinarium (Klinowska and Brown, 1986), all displays of cetaceans in the UK were closed, as existing facilities could not meet the new standards. The last dolphinarium in the UK closed in the early 1990s. Movements of cetaceans into and within the European Union (EU) are regulated under EU wildlife trade regulation, established to fulfill EU member nations responsibilities under CITES. Trade in animals listed under Annex A of this Regulation (including all cetaceans) is permitted for “research or education aimed at the preservation or conservation of the species,” breeding for conservation, and biomedical research (the latter is not relevant for cetaceans), but not simply for commercial use.

In Japan, multi-species drive fisheries combine capturing cetaceans alive for aquaria and dead for food. US legislation requires that captures be conducted humanely, effectively denying animals from the Japanese fishery to institutions in the USA. The World Association of Zoos and Aquariums (WAZA) and the American Zoo and Aquarium Association have issued statements describing drive fisheries as inhumane and calling for their cessation. The WAZA

resolved in 2004 (Anonymous, 2004) that taking animals from drive fisheries into captivity was against their code of ethics, to which all members of the Association (including those in Japan) must adhere.

Regional conservation agreements have also been developed. Several nations that are signatory to the Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas (ASCOBANS) are mandated to take part in conservation and research measures. Such measures include preventing the release of potentially harmful substances into the environment, developing fishing gear to reduce bycatch, and reducing the impact of other potentially harmful human activities. They are obliged to prohibit intentional killing of small cetaceans and to release immediately any healthy small cetaceans caught incidentally (Anonymous, 1992).

B. Care and Maintenance

The first published accounts of the behavior of captive cetaceans were provided by Charles Townsend in the early 1900s when he was the director of the New York Aquarium. His observations of a group of bottlenose dolphins described their social behavior and some sensory capabilities. Townsend understood the importance of developing health care and water treatment regimes to promote long-term survival. Requirements for the care and maintenance of marine mammals can vary dramatically between countries and can vary between jurisdictions within a country. These requirements include regulations regarding pool dimensions and construction materials, food quality and feeding schedules, water quality, air quality, veterinary care, and educational message. There are countries (e.g., the USA) where the agency responsible for overseeing capture and international transport is different from that responsible for care and maintenance.

A core aspect of the argument against maintaining captive cetaceans is that it is impossible to provide an adequate environment for cetaceans in captivity. The basic reasons put forward for this are: that pools can never be of adequate size; that regardless of size, pool construction is inappropriate; and that it is impossible to keep animals in suitable social groups. Even the larger commercial facilities, e.g., one that includes a complex of four linked (sand-bottomed, rock-lined) pools of 30,000,000l, with a maximum depth of 7.5m, holding 12 bottlenose dolphins, will be considered inadequate to some, because they see them as an inadequate substitute for the home ranges of free-ranging dolphins. Facilities differ greatly in their resources, and so the quality of their environment.

IV. Issues

A. Experiencing Captive Marine Mammals

Zoos and aquaria in North America alone are visited by over a hundred million people each year. There is an assumption by the supporters of such facilities that people, having experienced living marine mammals in close proximity, will be more likely to develop (or enhance) their marine conservation ethic. It is clear that public support for marine mammal conservation increased substantially in the latter half of the twentieth century. It is also clear that marine environmental degradation, particularly through overfishing, also increased substantially at the same time. Putting aside this disconnect, the extent to which commercial oceanaria have contributed to peoples' enhanced affection for marine mammals has yet to be measured and reported in a compelling manner and, not surprisingly, is questioned by some of those calling for closures. Also debated is the extent to which this was historical, and whether peoples' attitudes

today are also influenced. The public view of killer whales seemingly changed radically at the same time as they appeared in captivity, supporting the "captive animals as ambassadors" argument. However, other factors were also in play, including TV programs that presented such animals to a wider public and in a new light.

Unfortunately, as noted, there is little current research (by either side) on the extent to which visiting aquaria affects peoples' conservation ethic. Around four-fifths of respondents to a survey carried out in 1998 (Kellert 1999) believed that facilities should not be permitted to display marine mammals unless there was scientific or educational benefit. Over 90% of respondents felt that facilities should not be allowed to keep marine mammals in captivity unless the animals were well maintained, both physically and mentally.

Some opponents of keeping cetaceans captive suggest that it would be better if people were to view cetaceans through commercial whale watching, and that viewing captive cetaceans enhances an inappropriate world view (e.g., demonstrating human dominance over nature). Nearly 80% of respondents to the survey cited earlier had been to a zoo or an aquarium in the previous 5 years, but less than 20% had been whale watching over the same period (Kellert, 1999). Whether most people who visit aquaria would go whale watching if the aquaria did not exist is unknown, but if they did, it could result in an extra several million people a year going whale watching in US waters. The environmental impact of this has not been estimated, but could be substantial. Another argument that conservation benefit could be achieved through multimedia presentations featuring whales and dolphins in the wild is being developed but remains untested.

Most of this discourse is set in a Western context. The greatest growth in facilities keeping captive marine mammals is occurring in the developing world, and so this discourse may be inappropriate. Public awareness of marine mammals in most other nations is less developed than it is in the West. It may be that zoos and aquaria can make a significant contribution in these countries. However, improving conservation outcomes from experiencing captive cetaceans presupposes that the quality of educational material provided in structured programs at zoos and aquaria is acceptable. One institution in Bangkok maintaining captive cetaceans also advertises an "Orangutan boxing show" (see <http://safariworld.com/>), suggesting that this presupposition can be misplaced.

B. Scientific Value of Captive Marine Mammals

The value of studies conducted with captive marine mammals has also come under scrutiny. However, before field studies of living cetaceans burgeoned (after the late 1970s), captive animals were the major means by which scientists collected data on biology and behavior. Some phenomena such as echolocation may remain unproved were it not for studies on captive animals. Even today, the echolocation capabilities of most dolphin species remain unknown, and controlled experiments with captive animals are the main way by which this information is obtained.

Because there are many other questions that are intractable using free-ranging animals, captive marine mammals remain the primary source of data for several fields, including comparative psychology, cognition, and immunology, and captive studies contribute substantially to aspects of acoustics and physiology. However, recent technological improvements have allowed playback experiments to ask acoustic questions of free-ranging animals, although problems of experimental design still plague this field (Deeke, 2006). The remarkable sensory and cognitive abilities of dolphins are, paradoxically but

understandably, two of the arguments used against their maintenance in captivity.

Most of the opposition to the scientific value of captive marine mammals appears to be based on two considerations: the extent to which inference can be drawn from captive studies to the biology of free-ranging animals, and whether the results of such research provide ethical justification for keeping animals captive. Interplay continues between work on captive and free-ranging animals. For example, attempts to understand the factors leading to the decline of Steller's sea lions (*Eumetopias jubatus*) have been informed by captive studies of diet and physiology (Rea *et al.*, 2007; Tollit *et al.*, 2007), studies of free-ranging animals (Trites *et al.*, 2006; Ban and Trites, 2007), and synthesis by modeling (Gu enette *et al.*, 2006).

Regulations controlling the manner in which marine mammals are maintained for scientific research, and ethical limitations on research, vary between countries. These limitations are not necessarily related to other legal controls over keeping marine mammals. For example, in one experiment, thermocouples were surgically implanted (under anesthesia) into the brains of a juvenile harp (*Phoca groenlandica*) and a juvenile hooded (*Cystophora cristata*) seal. The conscious animals were then force-dived to assess the manner in which seals' brains cooled while diving (Odden *et al.*, 1999). Such an experimental protocol would be unlikely to obtain ethics approval in many countries, yet was permitted in Norway, where maintaining cetaceans in captivity is banned completely.

C. Captive Breeding for Conservation

Breeding animals in zoological gardens has a role in the conservation of some endangered species. It has been suggested that such *ex-situ* conservation provides a justification for maintaining aquaria. However, developing such programs should not be an excuse to ignore our responsibility to implement conservation strategies to protect *in-situ* populations and their habitat. Furthermore, captive breeding claims for cetaceans need to be carefully evaluated. There was a project to maintain baiji in captivity in "semi-natural reserves" as part of the attempt to conserve this species. This project, supported in principle by the World Conservation Union's Cetacean Specialist Group, was unsuccessful. Despite international recognition that *ex-situ* conservation was the strategy with the best chance to conserve baiji, it failed to achieve this important goal. Debate within the scientific community as to how to manage this program continued up to the year prior to the declaration of the baiji's likely extinction (Reeves and Gales, 2006; Wang *et al.*, 2006; Yang *et al.*, 2006).

The baiji example helps illuminate the difficulties confronting those wishing to develop *ex-situ* breeding programs for marine mammals. Captive breeding programs require significant numbers of captive animals to reduce the probability of inbreeding. This appears logistically improbable at present, as animals, money and space seem unlikely to become available. The species most commonly maintained in captivity are not at conservation risk, so expertise is lacking for species that may require conservation measures in the foreseeable future. Artificial insemination is a useful tool to reduce inbreeding among animals held in countries where free-ranging animals are no longer captured, but its value in *ex-situ* conservation seems limited at present. The animals most likely to benefit from *ex-situ* conservation programs are those listed on CITES Appendix I, but the vaquita, the cetacean most likely to go extinct next, is also not likely

to be saved through captive breeding. The Chinese experience keeping finless porpoises in "semi-natural reserves," developed during the baiji project, offer possibilities, but these reserves are yet to demonstrate that they can be self-sustaining. Permits for the capture or importation of individuals from species at risk are unlikely to be issued in countries where the probability of successful captive breeding is highest. Although it seems unlikely that zoos and aquaria will contribute to species conservation through captive breeding, rehabilitating sick or injured animals can have conservation value.

D. Rehabilitation

At times, free-ranging marine mammals that are ill, injured, or have suffered some misadventure require rehabilitation. In most cases, these are from species that are not at risk of extinction, and so the issue is one of animal welfare rather than conservation. An exception to this is the efforts made to rehabilitate Florida manatees (*Trichechus manatus latirostris*) where rehabilitation and subsequent release of each individual manatee has clear conservation value. By contrast, an attempt to rehabilitate a dugong hand-raised after stranding as a young calf, into the waters of southeast Queensland proved unsuccessful, and the animal, emaciated and injured, was recaptured 6 months after release. The dugong is now held in a purpose-designed facility with educational displays, in an attempt to use it as an "ambassador" for its species.

The contrasting examples of manatees and dugongs suggest that with each rescue comes the possibility of acquiring new knowledge that can benefit all marine mammals, endangered or not. Opposition to the role of commercial captive facilities in rehabilitation tends to be strongest in countries with effective networks to deal with marine mammal strandings and disentanglements, separate from commercial zoos and aquaria. In other places, zoos and aquaria are the organizations with the resources, funding and expertise to handle injured or sick animals effectively, and their role in rehabilitation can be significant.

E. Release

Perhaps in response to the decrease in collecting free-ranging animals, attention in some countries through the 1990s and early part of this century focused more on releasing those already held captive. Attempts have been made to release captive dolphins back to the waters from which they came. Following the closure of "Atlantis," in Perth, Western Australia, nine bottlenose dolphins were released in 1992. Animals were radiotracked after a gradual release back to the waters from which some had been caught 11 years previously (three were captive born). After a few weeks, three animals in very poor condition were returned to a sea pen, but the fate of most was unknown, due to the failure of the radio tags (Gales and Waples, 1993). The animals that were recovered all died of poisoning in late 1999.

The release program for Keiko, the killer whale that starred in the movie "Free Willy," encapsulates some of the issues regarding captivity and release. Caught as a calf by the Icelandic capture industry, imported to Canada then to Mexico, where he was held in an inadequate pool with no other members of his own species, the public was alerted to his plight by his movie role. NGOs organized his importation to another captive facility in the USA, where his condition improved before he was moved to Iceland, where he was held in a sea pen and trained to catch prey prior to his release, in the summer of 2002. In just under 2 months, he swam to Norway, resumed contact with people, and inadvertently became a tourist attraction.

In concert with Norwegian authorities, those responsible for his release moved him to a more secluded area, intending to re-release him. He died of pneumonia in late 2003, ending the 9-year project, and demonstrating that life does not always imitate the movies.

However, not all release projects have failed. In 1990, two young male bottlenose dolphins, held captive for 2 years, were released into the waters from which they were taken. Both animals were successfully re-integrated into their social group and showed no aberrant interactions with humans (Wells *et al.*, 1998). However, this was a well-designed and relatively brief period of captivity, and the animals were released precisely with the group from which they had been captured.

Just as the conservation value of zoos and aquaria should be questioned, so too should the value of release projects. Do the perceived benefits of the ambassadorial value of the release outweigh the costs (e.g., funding for conservation projects foregone) and risks associated with such projects? Likewise, release programs raise their own ethical issues (Waples and Staggoll, 1997). The legacy of Keiko's project—his ambassadorial value appears to be in demonstrating that high-profile, well-designed, expensive release attempts can fail—on future releases remains to be seen.

F. Funding

Just as some zoos and aquaria contribute significant funds and resources to rescue and rehabilitation programs, some agencies keeping captive marine mammals also support research programs. For example, most of the research into cetaceans' acoustic faculties has been funded through the US Office of Naval Research (ONR). There have been suggestions that the significant contribution made by the ONR to funding cetacean research affects the capacity of scientists to comment openly on issues related to the US Navy, although this is disputed (Gannon *et al.*, 2004; Weilgart *et al.*, 2005). Some captive facilities and groups opposed to captivity either employ full-time research staff or provide funding for research projects. The relative funding provided by the two groups varies dramatically between countries, and there are places where one or both of the two groups contribute significantly to research effort.

G. Military Use of Marine Mammals

Humans have a long history of using animals for military purposes. The sensory abilities of some animals are appreciably better than those of humans and our tools, so animals are used to detect enemies or weaponry. Tracker dogs (*Canis lupus* spp.) are one example. The information in the public domain regarding military use of marine mammals suggests that this is the major use of marine mammals by the military. The ability of dolphins, small whales, and sea lions to detect and retrieve objects or people, and their ability to make repeated deep dives without suffering from the bends, make them valuable for military operations. For example, in this century dolphins have been used for mine detection in wars (http://www.spawar.navy.mil/sandiego/technology/mammals/mine_hunting.html).

The major argument against this is that it is inherently unethical to train animals for involvement in warfare. Most military uses involve marine mammals working in the open sea, rather than being maintained in enclosures. This can involve animals spending time in waters to which animals may not be physiologically adapted, which is another area of concern. As marine mammals are relatively expensive to train and keep, very few nations use them for military purposes. After

the collapse of the Soviet Union, lack of funding to maintain marine mammals used by the Soviet Navy has led to ex-military animals being sold internationally.

V. Conclusion

The debate continues over whether marine mammals, especially whales and dolphins, should be kept in captivity. In general, less concern is expressed over keeping other marine mammals. Basically, the debate between pro- and anti-captivity groups is simple: does any benefit achieved by holding animals in captivity outweigh any costs involved—both to the individual animal and to the population from which the animal came—assuming that all parties view “benefit” as contributing to the conservation of free-ranging marine mammals. Both sides believe their position to be valid and rational.

The growth of oceanaria in countries with relatively weak rule of law and increasing captures of free-ranging animals to fill the needs of these facilities has created new challenges for those opposing captivity. There are situations where the concern that taking free-ranging animals will threaten populations seems justified. Indo-Pacific humpback dolphins and Irrawaddy (*Orcaella brevirostris*) dolphins in some parts of southeast Asia have been identified as at risk from the burgeoning, and effectively unregulated, aquarium industry. To prevent this, no captures should be permitted unless stock structure is well understood and takes are demonstrably sustainable, but realities on the water suggest that such regulation is unlikely to be introduced or enforced. However, when compared with other anthropogenic threats to the viability of marine mammal populations, takes for captivity appear to generally represent a localized problem.

There will probably always be differences in peoples' ethical stance regarding whether it is appropriate to keep animals, especially cetaceans, in captivity. But perhaps through comparison with other anthropogenic influences, some common ground in the debate can be found. A dichotomy is generally made between captivity and “the wild.” “The wild” implies pristine, or at least healthy, environments, unsullied by human intervention. But the influence of human activities, particularly resulting from fisheries and global warming, on marine environments is so pervasive and profound that “the wild” is becoming a misnomer. The dichotomy is between animals held in captivity, in conditions that vary dramatically between institutions, and animals living in oceans that are also affected by peoples' activities, also to differing degrees. On many issues—marine pollution, overfishing, whaling, marine mammal rescue—some (but by no means all) oceanaria and zoos hold positions that are indistinguishable from organizations that oppose captivity. The WAZA position against drive fisheries is an example.

Attempts to rehabilitate marine mammals that have spent most of their lives in captivity have not met with resounding success, yet breeding programs for some species, particularly bottlenose dolphins, have. So marine mammals in captivity appear a fact of life for the foreseeable future. At the same time, substandard facilities are still opening around the world, and capturing free-ranging animals to stock their tanks. In the USA at least, far more people go to zoos and aquaria than go whale watching, and whale watching can have deleterious impacts (Lusseau, 2004; Bejder *et al.*, 2006). Perhaps common ground could be found between the more responsible members of both sides of the debate, in working to improve conditions at substandard facilities, ensuring that live captures are (at the very least) managed humanely and are sustainable, and improving the educational content of all displays.

Caspian and Baikal Seals

Pusa caspica and *Pusa sibirica*

NOBUYUKI MIYAZAKI

I. Characteristics and Taxonomy

Baikal seals (*Pusa sibirica*) and Caspian seals (*P. caspica*) have common features such as small size, delicate skull, and affinity for ice. Based on mtDNA haplotypes, Caspian seals were derived from the common ancient type of *Pusa* 60 million years ago and were subsequently isolated in the Caspian Sea. Baikal seals were derived from a ringed-seal-like ancestor in the Arctic Ocean and isolated in Lake Baikal 40 million years ago (Sasaki et al., 2003).

Baikal seals, which do not have distinct spots, are uniform dark silver gray dorsally and light yellowish gray ventrally (Fig. 1). Caspian seals are irregularly spotted with brown or black against a light grayish yellow background (Fig. 2).

The Baikal seal possesses enlarged eyes that enable it to find prey in water as deep and clear as that in Lake Baikal (Endo et al., 1998a, b, 1999). The skull of the Caspian seal possesses the same thin frontal bone and dorsoventrally developed zygomatic arch found in the Baikal seal that are required to accommodate the enlarged eyeball in the orbit (Endo et al., 2002). A large zygomatic width, greater length of jugal, and smaller orbital width are correlated with the large orbit in these species. There is a slightly closer morphological affinity between Baikal and ringed seals than between Baikal and Caspian seals. This relationship coincides well with the genetic relationship among these indicated by analysis of mtDNA (Sasaki et al., 2003).

II. Distribution and Abundance

The population of Baikal seals from 1971 to 1978 was estimated to be between 68,000 and 70,000 animals (Pastukhov, 1978a). In 1987–1988, an outbreak of morbillivirus infection resulted in a large mass mortality of Baikal seals (Grachev et al., 1989). A mass death also occurred in 1998.

The Caspian seal population declined from about 1 million animals early in the twentieth century to 360,000–400,000 by the end of the 1980s (Krylov, 1990). In the spring of 1997, a mass death of several thousand seals occurred.

III. Ecology

Baikal seals feed mainly on four fish species: the greater golomyanka (*Comephorus baicalensis*), the lesser golomyanka (*C. dybowskii*), the Baikal yellowfin sculpin (*Cottocomephorus grewingki*), and the longfin sculpin (*C. comephoroides*), all of which are not of commercial value. In captivity, an adult Baikal seal consumed up to 5.6 kg of fish per day (Pastukhov, 1969).

Caspian seals in the northern Caspian Sea feed on *Clupeonella engrauliformis*, *C. grimmi*, *C. delicata caspia*, Gobiidae, *Rutilus rutilus caspicus*, *Atherina mochon pontica*, *Lucioperca lucioperca*, other fish species, and crustaceans (Khuraskin and Pochtovaya, 1997). It is estimated that an adult Caspian seal takes 2–3 kg fish per day, or approximately 1 metric ton of fish per year.

Hazardous chemicals (heavy metals, organochlorine compounds, organotin compounds, radionuclides, etc.) are present in high concentrations in Baikal and Caspian seals, which are long-lived

Figure 1 Baikal seal. Photo courtesy of Dr. Yuuki Watanabe.

Figure 2 Caspian seal on Pearl Island, northwestern North Caspian Sea.

(>40 year) top predators in the enclosed ecosystems (Dietz *et al.*, 1990; Frank *et al.*, 1992; Nakata *et al.*, 1995; Watanabe *et al.*, 1998, 1999; Kajiwara *et al.*, 2002 Yoshitome *et al.*, 2003; Ikemoto *et al.*, 2004).

IV. Behavior and Physiology

Movements and dive patterns of Baikal seals appear to be associated primarily with seasonal diet movements of their primary prey, golomyanka and sculpins, and are correlated secondarily with patterns of ice formation and thaw. Based on data obtained by Argos satellite-linked transmitters, most dives of Baikal seals are to depths of 10–50 m, although a few dives exceed 300 m (Stewart *et al.*, 1996). Dives may last between 2 and 6 min, but a few dives exceed 40 min. According to Watanabe *et al.* (2004), who used an advanced Japanese data logger, Baikal seals dived almost continuously, to an average of 68.9 m, with dives deeper than 150 m being concentrated around dusk and dawn. Maximum depth was 245 m. Mean and maximum duration was 6.0 min and 13.5 min, respectively. In the daytime, dives were characterized by higher swimming speeds (mean: 1.2 m/sec) and upward-directed acceleration events. At night, dives were shallower around midnight and characterized by lower speeds (0.9 m/sec) and non-directional deceleration events. Baikal seals actively chased pelagic fishes such as golomyanka during the day and swam upward at around 2 m/sec. at a body angle of 40°, suggesting that the

seals use vision to search and chase for silhouetted prey against the brighter water overhead. Experimental research on stroke-and-glide swimming pattern using lead weights indicated that body density of the seal is 1027–1046 kg/m³, corresponding to 32–41% lipid content, for the weighted condition, and 1014–1022 kg/m³, 43–47% lipid content, for the unweighted condition (Watanabe *et al.*, 2006).

For two adult male Caspian seals using Argos satellite-linked transmitters, most dives were less than 50 m in depth whereas a few exceeded 200 m. Dives were mostly less than 50 sec long but some exceeded 200 sec.

Mass die-off of thousands of Baikal seals in Lake Baikal occurred in 1987–1988, and the virus isolated from the dead Baikal seals was identified as canine distemper virus, which genetically and antigenetically was close to the canine distemper virus isolated from a dog and a ferret (Grachev *et al.*, 1989; Osterhaus *et al.*, 1989; Mamaev *et al.*, 1995, 1996). According to Ohashi *et al.* (2001), a virus neutralizing test and ELISA (enzyme-linked immunosorbent assay) clearly suggested that a distemper virus epidemic occurred in Caspian seals in early 1997 and that the canine distemper virus infection has continued to occur in Lake Baikal in recent years. The genome of canine distemper virus found in one of the dead Caspian seals and the sequence of the *P* gene in that animal were distinct from those of the Baikal seal virus, laboratory strains, and field isolates from terrestrial animals in other area (Forsyth *et al.*, 1998). According to Kennedy *et al.* (2000), the mass die-off of Caspian seals was caused by a canine distemper virus.

V. Life History

The maximum known age in both sexes in Baikal seals is 56 years for females and 52 for males (Pastukhov, 1993). According to Amano *et al.* (2000), the oldest age of Baikal seals in samples ($n = 73$) collected in 1992 was 24.5 years for females and 35.5 years for males. In Caspian seals collected from Pearl Island in the western North Caspian Sea ($n = 118$), the oldest age was 43.5 years for females and 33.5 years for males.

Growth in length of Baikal seals appears to cease around the age of 15 years (Amano *et al.*, 2000). The seals may continue to grow for 8–9 years after the age of sexual maturation (6 years for females and 7 years for males). Asymptotic body length is 140 cm in males and 130 cm in females. In Caspian seals, growth appears to cease around the age of 10 years, which is the age of sexual maturation in both

sexes. Asymptotic body length is 118 cm in males and 111 cm in females.

Most Baikal seals breed by 6 years for females and 7 years for males (Thomas, 1982). Newborn pups are 65 cm in body length and 4.1 kg in body weight on average. A rather high rate of twinning (4% of annual births) is exhibited compared to other seals (Pastukhov, 1968). Mating may occur underwater in March at about the time mothers wean their pups. Mothers nurse the pups in a birthing lair. The lactation period is estimated at 2–3 months. The mating system is assumed to be polygamous with little or no pair bonding. In winter, when Lake Baikal is covered with ice averaging 80–90 cm in thickness with a maximum of 1.5 m, seals are sighted throughout the lake and adjacent to breathing holes in the ice. In Baikal seals of 7 years or more, 84% of females give birth to a pup yearly (Pastukhov, 1993).

Caspian seal pups are born on the ice from the middle of January to the end of February and are about 60 cm in length. Mating takes place between the end of February and the middle of March. Sexual maturity is attained at 4–6 years in females and 6 years in males (Ognev, 1935; Fedoseev, 1975). The pregnancy rate of Caspian seals over 9 years was 31.3% ($n = 30$) in 1997 and 1998.

VI. Interactions with Humans

The number of Baikal seals taken annually has varied. Before 1917 about 2000 to 9000 were taken; in 1930 about 6000; and currently between 5000 and 6000 (Pastukhov, 1978b). According to Khuraskin and Pochtoyeva (1997), 115,000–174,000 Caspian seals have been hunted annually since the early nineteenth century. A total of 86,000 animals were killed in 1966. From 1970, seal hunting on the northern ice was limited to a catch of 20,000–25,000 pups.

Cephalorhynchus Dolphins

C. heavisidii, *C. eutropia*, *C. hectori*, and *C. commersonii*

STEPHEN M. DAWSON

I. Characteristics and Taxonomy

The four dolphins of the genus *Cephalorhynchus* are small, coastal species. They are blunt-headed (hence the frequent mistake of calling them porpoises), chunky dolphins with rounded, almost paddle-shaped flippers. The most characteristic feature of the genus is the dorsal fin, which is proportionately large, either with a shallowly sloping leading edge and a rounded, convex trailing edge [like a Mickey Mouse ear: Hector's (*C. hectori*), Commerson's (*C. commersonii*), and Chilean dolphin (*C. eutropia*)] or upright and roughly triangular (Heaviside's dolphin, *C. heavisidii*). In color pattern, Chilean dolphins and Hector's dolphins are most similar.

The *Cephalorhynchus* dolphins are among the smallest dolphins. Indeed, in length, Hector's dolphins from New Zealand's South Island (maximum 145cm; ca. 50kg) and South American Commerson's dolphins (maximum 146cm; ca. 45kg) are the smallest of all dolphins. Both Hector's and Commerson's dolphins have isolated populations in which individuals grow larger. Commerson's dolphins at the Kerguelen Islands grow to 174cm (86kg) and Maui's dolphins (North Island Hector's dolphins) reach at least 152cm (65kg). In both Hector's and Commerson's dolphins females are 5–10% larger than males. Far fewer Heaviside's and Chilean dolphins have been measured, so it is not clear whether females are larger in these species also. Heaviside's dolphins reach about 174cm (ca. 75kg), and Chilean dolphins reach at least 167cm (ca. 63kg).

Studies of mtDNA suggest that the *Cephalorhynchus* dolphins originated from a common Lissodelphinine ancestor in South Africa. Following the west-wind drift, the genus colonized New Zealand, then South America. Commerson's dolphin and Chilean dolphin are proposed to have speciated along the two coasts of South America during the glaciation of Tierra del Fuego (Pichler *et al.*, 2001).

Two of the *Cephalorhynchus* species have genetically isolated populations. One isolate, a subspecies of Commerson's dolphin (*C. commersonii kerguelenensis*; Robineau *et al.*, 2007) is found at

the Kerguelen Islands (see later) and probably arose via a founder event, perhaps ten thousand years ago. The other, a subspecies of Hector's dolphin, (*C. hectori maui*; Baker *et al.*, 2002) probably arose via this species' extreme site fidelity and a population bottleneck. South Island Hector's dolphins (*C. hectori hectori*) are fragmented into three genetically distinctive populations (east coast, west coast, south coast), which could only be maintained if there were very low levels of interchange among them (Pichler *et al.*, 2001). Interestingly, a recent study of mtDNA sequences in Heaviside's dolphin from almost 1000 nmi of South African/Nambian coast showed no evidence of population subdivision (van Vuuren *et al.*, 2002).

The *Cephalorhynchus* dolphins are all shallow-water species, but their radiation shows that they have made exceptional movements establishing new populations in similar habitats—a process perhaps triggered by low water temperatures and extensive glaciation during ice ages.

II. Distribution and Abundance

Cephalorhynchus dolphins are found only in Southern Hemisphere waters (Fig. 1). Heaviside's dolphin occurs off the west coast of South Africa and Namibia. Hector's dolphin is found solely off New Zealand. The Chilean dolphin is found in the coastal waterways of Chile and along the exposed west coast. The remaining species, Commerson's dolphin, has the strangest distribution. Its principal stronghold is in the inshore waters of Argentina and in the Strait of Magellan, but it also occurs at the Falkland Islands, and has an isolated population 8500km away at the Kerguelen Islands, in the Indian Ocean. The Kerguelen Commerson's dolphins are larger, retain the darker juvenile coloration into adulthood, and show skeletal and genetic differences. All *Cephalorhynchus* species favor waters less than 100m deep and are often seen in the surf zone, especially in summer.

Of the four species, only Hector's dolphin has had its abundance assessed quantitatively throughout its range. The South Island subspecies is most common along the east and west coasts of the South Island between 41°30'S and 44°30'S, with regions of high abundance at Banks Peninsula and between Greymouth and Westport. Total abundance is estimated at 7270 (CV = 16.2%; Dawson *et al.*, 2004; Slooten *et al.*, 2004). The North Island subspecies is found on the west coast between 36°25'S and 39°S but is regularly seen only between the entrance of Manukau harbor and Port Waikato. Its abundance is estimated at 111 (CV = 44%; Slooten *et al.*, 2006b).

South American Commerson's dolphins are found off the east coast between Rio Negro (40°S) and Cape Horn (55°15'S) down into the Drake Passage (61°50') and also at the Falkland Islands. They are common between Peninsula Valdez and Tierra del Fuego (42°S to 54°S) and very common in the eastern Straits of Magellan, where an aerial survey in summer 1984 indicated a population of around 3200. A more recent survey (June 1996) suggested a much smaller population size (1206; CV = 27%; Lescrauwaet *et al.*, 2000) but it is not clear whether this difference is due to a decline in abundance, differences in survey methods, or seasonal redistribution of the population. Recent aerial surveys suggest a total population of about 21,000. At Kerguelen, Commerson's dolphins are restricted to the immediate vicinity of the islands, where they are most frequently seen on the eastern side in the Golfe du Morbihan.

Heaviside's dolphins are found on the west coast of Southern Africa from 17°09'S on the Namibian coast to around Cape Town (34°13'S). Sightings are frequent between Walvis Bay and Cape Town. Abundance in the southern part of its range, along a 390-km stretch of the west coast north of Cape Town is estimated at 6345

Figure 1 Distribution of the four *Cephalorhynchus* dolphins.

(CV = 26%; Elwen, 2007). High mtDNA diversity also implies a relatively large population size.

Chilean dolphins have been seen over a very wide latitudinal range, from Valparaíso (33°S) to near Cape Horn (55°15'S), on both open and sheltered coasts. They are seen regularly in only a few places, however, including Valdivia, Golfo de Arauco and at Isla Chiloé. These local populations are likely to be very small. For example, at southern Isla Chiloé, among the places where this species is most commonly seen, a recent detailed study estimated a local population of 59 (CV = 4%; Heinrich, 2006). Sightings in the Chilean channels are very rare. A boat survey covering 1600 nmi in March/April 2006 made only five sightings of Chilean dolphins between Ushuaia and the southern tip of Isla Chiloé. The total population appears to be very small (low thousands at most). Suggestions that the species is becoming very rare are impossible to refute without further dedicated survey work.

As part of work to assess the likely effectiveness of marine protected areas for conserving Hector's dolphin (and Maui's dolphin), the dolphins' offshore distribution has been studied via intensive aerial surveys off the South Island west coast, at Banks Peninsula on the east coast, and the North Island west coast. At Banks Peninsula, where large rivers to the north and south have resulted in broad shallowly shelving underwater plains, Hector's dolphins range much farther offshore than elsewhere (maximum 16.3 nmi in summer; 18.2 nmi in winter; maximum depth = 90 m). In similar surveys off the west coasts of the North and South Islands we have not seen the species beyond 5.3 nmi offshore, nor in water deeper than 60 m

(Rayment *et al.*, unpublished data). In all areas they are very seldom seen in water deeper than 50 m in summer.

III. Ecology

A. Diet

All four species feed on a wide variety of coastal prey, focusing on benthic and small pelagic schooling fish and squid. The South American species supplement their fish/squid diet with crustaceans (mysids, euphausiids, and *Munida* spp.) and, strangely, algae (Goodall, 1994a, b). Juvenile hake are the dominant prey item in the diet of Heaviside's dolphins, which, unusually in this genus, also includes a significant component of octopus. The diet of Hector's dolphins is more varied on the South Island east coast, where eight species of fish and squid make up 80% of the diet by mass, than it is on the corresponding west coast (where four species make up 80%; Dawson and Slooten, 1996).

Individual dolphins in this genus appear to be at least seasonally resident in a local area. Long-running, year-round studies on Hector's dolphins have shown that individuals usually range over about 30 km of coastline (Bräger *et al.*, 2002). Chilean dolphins at Isla Chiloé appear to have similar, or even smaller home ranges (Heinrich, 2006). In all species at least some individuals remain in local areas year-round, though inshore abundance is generally reported to be lower in winter. Individual Hector's dolphins have been resighted in the same general area year-round, for over 20 years. In general Hector's dolphins tend to spread out, form smaller groups and range further from shore in winter. This seasonal difference in distribution

appears to be greatest at Banks Peninsula, where, on intensive aerial surveys out to 15 nmi offshore, 81% of dolphins seen were within 4 nmi from shore in summer, but only 44% in winter (Slooten *et al.*, 2006a). Similar surveys on the South Island west coast show that fewer dolphins are found within the first mile offshore in winter, but that the limit of offshore extent is very similar in summer (5.3 nmi) and winter (5.2 nmi; Rayment *et al.*, unpublished data).

There is no evidence for large-scale migration in any of the *Cephalorhynchus* species. The largest documented movements are of about 250 km, in Commerson's dolphins (Coscarella, 2005). Despite wide-ranging surveys over more than 20 years, no two sightings of the same individual Hector's dolphin are more than 106 km apart. Small home ranges have been confirmed by satellite tagging in Heaviside's dolphin and Hector's dolphins. The data from Heaviside's dolphins suggest inshore-offshore diurnal movement, most probably driven by movements of their principal prey, juvenile hake (Elwen *et al.*, 2006).

IV. Behavior and Physiology

Small group sizes are characteristic of this genus. Though occasionally sightings of more than 50 have been made, most sightings are of between 2 and 10 individuals. In high-density areas, there may be several such groups nearby. In Hector's dolphin, these often coalesce to form a large, temporary group of 25 or so. Large groups

often show boisterous behavior such as chases, leaps, and lobtailing. Sexual displays and copulation are also more common after groups have joined (Slooten, 1994). Such large groups are usually short-lived; often splitting after 10–30 min. Frequently groups lose, gain or swap members in this process. Associations among adult Hector's dolphins are weak. It is likely that the other species are similar.

Hector's, Commerson's, and Heaviside's dolphins are strongly attracted to boats, and readily bow-ride. Chilean dolphins are commonly reported to be shy and elusive, and this is confirmed by a recent hilltop study of reactions to boats in Yaldad Bay, on Isla Chiloé (Ribiero *et al.*, 2005). Some groups, however, are boat positive, repeatedly bow-riding or wake-surfing (see Fig. 2). Chilean dolphins have been heavily hunted in parts of their range and their usual wariness of boats has probably been acquired.

All *Cephalorhynchus* species are thoroughly at home in turbulent water close to shore and are frequently seen surfing.

The sounds of Hector's dolphin and Commerson's dolphin have been studied in detail. Almost all the sounds are short (*ca.* 140 μ sec, roughly 1/7000 sec), high-frequency (*ca.* 125 kHz) narrow-band, ultrasonic clicks (Fig. 3) which are used in "trains" of a few dozen to several thousand (Kamminga and Wiersma, 1982; Dawson and Thorpe, 1990). Clicks may contain one, two or three main pulses and appear to have a role in communication and well as sonar. Hector's dolphins use complex clicks disproportionately in social contexts and a particular

Figure 2 The four *Cephalorhynchus* dolphins (clockwise from upper left): Hector's dolphin (photo by author), Commerson's dolphin (photo by Marine Mammal Lab, CENPAT, Puerto Madryn), Heaviside's dolphin (photo by Simon Elwen, University of Pretoria), and Chilean dolphin (photo by author).

type of click is used preferentially in feeding (Dawson, 1991). Click rates can be exceptionally high (maximum 1149 clicks/sec). Such high click rates generate an audible tone of the same frequency as the click rate. These signals, which sound like a “cry” or “squeal,” are strongly linked to aerial behaviors in Hector’s dolphins, and apparently indicate excitement. They have been recorded from all four *Cephalorhynchus* species. It seems that the *Cephalorhynchus* dolphins do not whistle, as other delphinids do.

Preliminary analysis of Maui’s dolphin sounds show no obvious differences to those made by South Island Hector’s dolphins. Given this, and the close similarity of the sounds of Hector’s and Commerson’s dolphins, it is likely that the sounds of Heaviside’s and Chilean dolphins will be similar also.

V. Life History

Reproduction has been studied only in Commerson’s dolphins and Hector’s dolphins, but the limited information available for Heaviside’s and Chilean dolphins suggest they are similar. Females bear their first calf between 6 and 9 years, in spring to late summer. Males reach sexual maturity at 5–9 years. Mating and calving occur in spring to late summer, and the gestation period is around 10–11 months. Maximum ages so far found via ageing teeth from dissected dolphins are 20 (Hector’s dolphin; Slooten, 1991) and 18 (Commerson’s dolphin; Lockyer *et al.*, 1988). At Banks Peninsula, six photographically identified Hector’s dolphins were first seen in 1985 and known to be alive in 2006, hence are at least 22 years old.

Studies of photographically identified Hector’s dolphins suggest that mature females calve every 2–4 years. Late maturity, relatively short life, and long intervals between calves inevitably result in a low population growth rate. Modeling studies have shown that Hector’s

dolphin populations, in the absence of human impact, would be expected to grow by about 2% per year (Slooten and Lad, 1991).

VI. Interactions with Humans

All four species have, at some stage, been hunted for food or bait. The South American species have fared worst: they have been extensively hunted for bait for crab pots. In Chile, estimates of numbers taken range from 1250 to 4120 dolphins/year (comprising mostly Peale’s, Chilean, and Commerson’s dolphins; Lescrauwaet and Gibbons, 1994) in the late 1970s and probably reached a maximum between 1980 and 1986. As many as 1300–1500 Chilean dolphins may have been harpooned each year near the Western Strait of Magellan in the late 1970s and early 1980s (Goodall, 1990b). Chilean dolphins are now virtually absent from this area. Direct take for bait seems to have ceased; legislation is now more restrictive and the crab fishery has declined. However, there is no monitoring of cetacean catches (deliberate or incidental), and enforcement of existing legislation in such a remote and convoluted area is practically impossible.

All four *Cephalorhynchus* species suffer some degree of incidental catch in fishing gear. In South America, bycaught animals have been used as bait and for human consumption, but it is suspected that this is now uncommon. Numbers taken currently are unknown for any of the four species. While a wide range of fishing methods are known to have resulted in *Cephalorhynchus* mortality (including gillnetting, purse seining, trawling, lobster potting), gillnets pose a larger problem than any other fishing method.

In the mid-1980s an average of 57 Hector’s dolphins were caught each year in gillnets in the Canterbury region of the east coast of New Zealand’s South Island. Given the low reproductive rate of this species, it was clear that this level of catch was unsustainable.

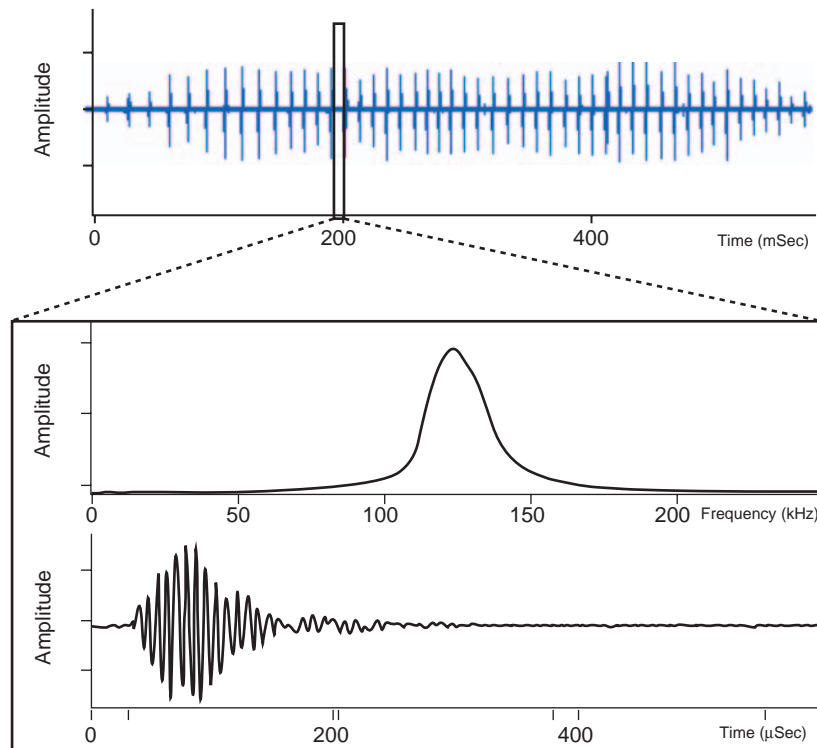

Figure 3 A “train” of high-frequency Hector’s dolphin clicks, with a “zoomed” section showing the waveform and spectrum shown for an example click.

An 1170-km² sanctuary, in which commercial gillnetting is effectively illegal and amateur gillnetting restricted to particular times and places was established in 1989. This has reduced, but not solved the bycatch problem in Canterbury (Dawson and Slooten, 2005). Analysis of observed catches in the Canterbury region in 1997/1998 suggest that 18 Hector's dolphins were caught in commercial gillnets to the north, south, and offshore of the current sanctuary. Observer coverage since has confirmed a continuing bycatch problem but has been insufficient to estimate how many are taken.

On the shores of Argentina it is very common to see intertidal gillnets set from the shore. This is an artisanal fishery targeting inshore fish species and king crabs. The nets are normally fixed to the bottom at low tide and take advantage of large tidal ranges to be completely submerged at high tide. Bycatch of Commerson's dolphin on the La Angeleno coast and in the Ria Gallegos estuary in the Santa Cruz province has been estimated at 179 for the 1999/2000 fishing season (Iñíguez *et al.*, 2003). Given that this style of gillnetting is widely used in Argentina, and that members of the *Cephalorhynchus* genus have low reproductive rates and very low potential for population growth, bycatch of Commerson's dolphins, at least in this area, is almost certainly unsustainable. Bycatch of Commerson's dolphins is also associated with the rapidly expanding mid-water trawl fisheries along the Atlantic Patagonian coast.

Salmon and mussel farming is becoming widespread in the sheltered inlets of Chile, especially north of 44°S. This development is most intensive in Isla Chiloé, where it overlaps with resident groups of Chilean dolphins. In Yaldad Bay, these dolphins have been shown to avoid mussel farms (Ribiero *et al.*, 2007). In addition to direct competition for space, increased aquaculture-related boat traffic has caused changes in dolphin behavior (Ribiero *et al.*, 2005), and is likely to exacerbate overall impact. There is significant potential for burgeoning aquaculture to displace dolphins from some of these areas.

There appear to be fewer threats to Heaviside's dolphin than to the others (Best and Abernathy, 1994). Its abundance, along with high levels of genetic diversity and apparent lack of genetic population structure are all good signs. It seems that this species, and Commerson's dolphin, despite the high level of impacts on the latter, are the most numerous members of this genus.

The Chilean dolphin needs urgent consideration. Impacts over the last three decades have been severe and the population is substantially reduced. Recent detailed studies at Isla Chiloé confirm high site fidelity (Heinrich, 2006), which appears to be a characteristic of this genus. In these small local populations, even an apparently low level of mortality, such as that caused by increasing use of intertidal gillnets to catch escaped salmon at Chiloé, could be enough to ensure continuing decline. High site fidelity also increases susceptibility to habitat modification and decreases potential for declining local populations to be replenished from elsewhere. Hence there is real risk of population fragmentation, as has happened in Hector's dolphin. Wide-ranging population surveys are urgently needed before we can say with confidence whether the species numbers hundreds (as the most dire warnings imply) or thousands.

South Island Hector's dolphins have received some direct conservation action, via the Banks Peninsula Marine Mammal Sanctuary. Recent surveys and modeling suggest that the Banks Peninsula population is still declining. In part this is because they range far further offshore at Banks Peninsula than elsewhere, and hence the Sanctuary's 4 nmi offshore boundary provides less protection than was assumed (Slooten *et al.*, 2006a).

Maui's dolphins (North Island Hector's dolphins) are now protected from gillnetting along a 210 nmi stretch of open coast (most of

the dolphins' current range), out to 4 nmi offshore. Both commercial and amateur gillnetting is allowed within the harbors in this zone, and trawling is permitted on the open coast beyond one nautical mile from shore. This protection was brought about by evidence of (a) apparent contraction in alongshore range over the last 20 years, (b) decline in the number of mtDNA lineages present in current samples, (c) analyses of the level of bycatch in fishing operations, (d) continuing discovery of gillnet-marked Maui's dolphin carcasses, and (e) bycatch in gillnets and trawl nets reported during interviews with fishers (Dawson *et al.*, 2001). Maui's dolphins currently number about 111 individuals (CV = 44%; Slooten *et al.*, 2006b) and are probably the most seriously endangered marine mammal.

- encompassing empirical and theoretical research in fields as diverse as mathematics, conservation, physiology, geography, and behavior. Cetacean ecology describes the relationships between cetaceans and their physical and biological environment, including their interactions with prey, predators, competitors, and commensals.
- Studying whales or dolphins in their natural environment is a formidable challenge. This is not only due to the logistical constraints of attempting to study highly mobile, oceanic animals that spend nearly all of their lives underwater, but also because of the political and legal constraints of working on protected species, which include most cetaceans. Early insights into cetacean ecology came largely from anecdotes and observations handed down by early whalers (Herman Melville's *Moby Dick* is a classic example). Although much remains unknown, technological developments over the past decade have greatly facilitated our understanding of cetacean ecology. Insights gained from individuals fitted with devices that transmit data on location and depth of dive through a satellite and to a researcher's desk, from linking movements and distribution with remotely sensed data on surface water properties of the ocean, or from sophisticated shipboard equipment designed to quantify density of prey in the water column are just three examples of technological advancements that have greatly contributed to clarifying cetacean ecology.
- Cetaceans include approximately 84 species; new species continue to be described. They are a diverse group (Perrin, 1991). They range in size from less than 1 m long for a newborn vaquita (*Phocoena sinus*), to 33 m in an adult blue whale (*Balaenoptera musculus*); they occupy water ranging in temperature from -2°C to over 30°C ; they exhibit a diverse array of life history strategies. Consider the sperm whale (*Physeter macrocephalus*) which can remain beneath the water for over an hour and dive to depths of several thousand meters, the Ganges river dolphin (*Platanista gangetica*) which inhabits fresh water so turbid it is functionally blind, beaked whales of the genus *Mesoplodon* which are so pelagic and so elusive that some have never been seen alive in the wild, the gray whale (*Eschrichtius robustus*) which annually migrates some 15,000 to 20,000 km between breeding and feeding areas, and the bowhead whale (*Balaena mysticetus*) which uses its rostrum to break ice in the Arctic.
- One of the challenges of ecology is to search for pattern within diversity. Despite their diversity of form, behavior, and habitat, all cetaceans have some key features in common that underscore the fact that they are secondary marine forms, derived from terrestrial ancestors. That they are all air-breathing, live-bearing homeotherms provides a unifying theme. This chapter provides an overview of cetacean ecology with the ultimate goal being to identify some unifying principles in the ways that cetaceans interact with each other and with their environment.

I. Habitat

A. Habitat in the Ocean

Marine habitat is largely about oceanography. Terrestrial habitat is typically defined by the interaction between physical structure (as defined by physiography, and characteristics of primary producers) and meteorological factors, whereas marine habitat is almost entirely defined by hydrographic, physical, and chemical properties of water (e.g., water masses, surface currents, fronts, eddies, island wakes). Marine habitat types can be geographically fixed, when referring to the benthos or coastal ecosystems, e.g., but in most cases, marine habitat is not static in space or time. Instead, habitat types move with the water masses and surface currents that define them. Physical structure can define marine habitat, in the case of kelp forests or

Cetacean Ecology

LISA T. BALLANCE

Ecology is the study of the natural environment and of the relationships of organisms to each other and to their surroundings. From its natural history beginnings in the late 1800s, the field of ecology has blossomed into a diverse discipline,

coral reefs, e.g., but in most cases, this type of physical structure is completely absent from marine habitats. Light attenuates more quickly and sound travels faster and farther in water as compared to air; thus marine organisms, including cetaceans, rely less on vision and more on the auditory sense than terrestrial mammals. The base of the trophic web in marine systems is formed by planktonic organisms. There is no analogous counterpart in terrestrial systems and marine animals have therefore evolved unique and specialized morphological and behavioral adaptations for taking advantage of this prey base.

On a global scale, cetaceans have invaded a large proportion of the ocean's habitats. They inhabit coastal waters up to and including the surf zone (gray whale, some populations of bottlenose dolphins *Tursiops truncatus*, harbor porpoise *Phocoena phocoena*, Commerson's dolphin *Cephalorhynchus commersonii*), neritic waters over continental shelves (long-beaked common dolphin *Delphinus capensis*, *Lagenorhynchus* spp., *Cephalorhynchus* spp., *Phocoena* spp.), and the most oceanic of systems (sperm whale, Fraser's dolphin *Lagenodelphis hosei*, beaked whales). They are found in tropical waters (pan-tropical spotted dolphin *Stenella attenuata*), temperate seas (Risso's dolphin *Grampus griseus*), and polar oceans, up to and within pack ice (beluga *Delphinapterus leucas*, bowhead whale). They utilize much of the water column, some being confined to relatively shallow depths (most dolphins and baleen whales), and others diving to thousands of meters (sperm whale, many beaked whales). And they have invaded the world's major river systems (Ganges, Indus, Amazon/Orinoco).

Cetaceans in different habitats might be expected to show differential development of adaptations which reflect selective pressures of the environments in which they function. For example, species in polar seas must conserve heat and so, bowhead whales have relatively large bodies, thick blubber layers, and short appendages. Deep-diving species (sperm and beaked whales) must conserve oxygen and might be expected to have large blood volumes, high hematocrit, and a well-developed diving response. Species that forage in low light conditions (night feeders, deep divers, species living in turbid rivers) should have well-developed echolocation abilities relative to those that function in habitats with greater light levels and better visibility.

The geographic range that a single species occupies runs from cosmopolitan to extremely local. For example, the killer whale (*Orcinus orca*) can be found throughout the world's oceans and, with the exception of humans, is the most wide-ranging mammal on earth. At the other extreme is the vaquita, a tiny porpoise that occupies a few hundred square km in the northern Gulf of California. And some species migrate between widely separate breeding and feeding areas; this pattern is characteristic of most (if not all) of the baleen whales.

B. Species–Habitat Relationships

The relationship between a species and its habitat is a defining feature of its ecology. Species–habitat relationships form the basis for defining a species' ecological niche, in turn, a driving factor in determining competitive relationships, and a species' role in communities. Species–habitat relationships identify core requirements, critical knowledge for effective management and conservation. And a solid understanding of species–habitat relationships allows for prediction of distribution and abundance (Ferguson *et al.*, 2006), prediction that can facilitate mitigation of anthropogenic impacts such as ocean noise and climate change.

Because quantification of species–habitat relationships by definition involves integration of two very different types of data: species and habitat, and because marine habitat is so often defined by

oceanographic features, the study of species–habitat relationships is not straight forward. Simple correlations between a species and one or two directly measured oceanographic variables form the basis for early understanding of these relationships. More recently, two types of analytical tools have been used (Redfern *et al.*, 2006). Descriptive methods include overlays of species data on maps of oceanographic measures, correlation analysis, goodness of fit metrics, analysis of variance, and ordination. Modeling techniques are more sophisticated analytically, requiring parameter estimation, model selection, uncertainty estimation, and model evaluation. Many of these methods are still being developed.

In many geographic regions and for many species, we are beginning to identify those features that correlate with centers of distribution, thereby possibly identifying what may be called critical habitat. For example, some species associate with ice edges (beluga), some with continental shelf edges or seamounts (beaked whales), and some with shorelines (gray whale, bottlenose dolphin, harbor porpoise). For oceanic species habitat preferences are often defined by less obvious features: physical and chemical characteristics of the water itself, which define water masses and current boundaries. For example, some species associate with cold-water currents (Heaviside's *Cephalorhynchus heavisidii*, Commerson's, Peale's *Lagenorhynchus australis* dolphins). Blue whales in the eastern Pacific are found in relatively cool, upwelling-modified waters with high primary and secondary productivity. And in the eastern tropical Pacific, pantropical spotted dolphins and spinner (*Stenella longirostris*) dolphins segregate from common dolphins (*Delphinus* spp.) according to thermocline depth and strength, sigma-t (a measure of seawater density computed from surface temperature and salinity), and surface water chlorophyll content. These differences are statistically significant and these species-specific distribution patterns track oceanographic variation on a seasonal and interannual basis (reviewed in Ballance *et al.*, 2006).

Prey are likely the drivers of these species–habitat relationships, not the physical variables typically used in these types of analyses. In fact, there are a number of studies which have linked general distribution and movement patterns of cetacean species (humpback *Megaptera novaeangliae*, fin *Balaenoptera physalus*, long-finned pilot whales *Globicephala melaena*, Atlantic white-sided *Lagenorhynchus acutus*, bottlenose, common dolphins) with those of their prey.

II. Food, Feeding, and Foraging

A. Cetacean Prey

Most of what is known about the food of cetaceans comes from data collected from dead animals, through directed fisheries, incidental mortality, or strandings. Prey of cetaceans fall into four general categories.

The first prey type consists of small individuals which school at relatively shallow depths (surface to several hundred meters). These are primarily planktonic crustaceans (euphausiids, copepods, amphipods), and small fish [e.g., herring (*Clupea* spp.), sardine (*Sardinops* spp.), anchovy (Engraulidae), sandlance (Ammodytidae)]. They tend to occur in temperate or polar seas or in those tropical latitudes that are associated with high productivity. They generally occur at low trophic levels, have small body sizes, and occur in dense aggregations. Accordingly, the cetaceans feeding upon them capture multiple individuals simultaneously, have large body sizes, and have evolved filtering mechanisms (baleen) to strain prey items from the water. All mysticetes feed on this prey type.

The second prey type is comprised of larger organisms that also school at relatively shallow depths (surface to several hundred meters),

or migrate up to shallow depths during the night. This includes many pelagic fishes [e.g., hake (*Merluccius* spp.), pollock (*Pollachius* spp., *Theragra* spp.), myctophids (Myctophidae)] and schooling squids (*Loligo* spp., *Dosidicus* spp.) that occur throughout the world's oceans. Because these prey are larger, they generally occupy higher trophic levels and are captured individually. Their cetacean predators typically have smaller body sizes. They include all of the large-schooling dolphins (e.g., dusky *Lagenorhynchus obscurus*, common, striped *Stenella coeruleoalba*, spotted dolphins) and some small-schooling or solitary species (e.g., bottlenose, Commerson's, river dolphins *Platanista* spp.). These cetaceans tend to have a high tooth count, pointed teeth, and pointed snouts, all adaptations for pursuing fast, individual prey.

The third prey type is comprised of large, solitary squid (e.g., *Gonatus* spp.). These are most often found in deep waters throughout the world's oceans. Because of their size and solitary habits, they are captured individually. Cetacean predators of these prey include the sperm whale, dwarf, and pygmy sperm whales (*Kogia* spp.), all of the beaked whales (Ziphiidae), and pilot whales (*Globicephala* spp.). They are deep divers and tend to have reduced dentition, rounded heads, and well-developed melons, the latter perhaps indicative of the importance of echolocation for prey detection in the dark depths.

The final prey type includes species at high trophic levels that are themselves top predators. These include predatory fishes [e.g., tunas (Scombridae), sharks, salmonids], marine birds, pinnipeds, and cetaceans, including the largest of whales [rorquals (*Balaenoptera* spp.) and sperm whales]. Few cetaceans are able to take these prey items. They include the killer whale and, possibly, false killer whale (*Pseudorca crassidens*), and pilot whales. Two distinct forms of killer whales occur in waters off the west coast of North America: those that take fish and those that take mammals and birds. There is some indication that multiple ecotypes are found in Antarctic waters, and perhaps throughout the world's oceans (Pitman *et al.*, 2007).

B. Capturing Prey

Cetaceans have two main types of feeding apparatus: baleen and teeth. Baleen is used for straining prey items from the water or, in the case of the benthic-feeding gray whale, from the sediment. Teeth are used for catching individual prey items. Species with a high tooth count use them to grasp individual prey; those with a low tooth count tend to be suction feeders.

Most of what is known about prey capture strategies is relevant to cetaceans which feed on small prey that school at relatively shallow depths (the mysticetes). This is because it is relatively easy to observe these animals feeding in the wild. Mysticetes have baleen plates suspended from the roof of their mouths that they use to strain prey items from the water. The number of baleen plates, their length, and the density of baleen fibers per plate vary between species and are correlated with prey size. The Balaenidae (right whales *Eubalaena* spp., bowhead whales) and sei whales (*Balaenoptera borealis*) have the greatest number of plates with the finest filtering strands and feed mainly on tiny copepods. Blue whales and most other rorquals have an intermediate number of plates with coarser filtering strands and feed on larger prey items such as euphausiids and small fishes. Gray whales have the fewest number of plates with the coarsest strands and are largely bottom feeders, sifting benthic infauna from muddy substrate.

In addition to specializing on different prey sizes, baleen whales have specialized feeding methods that also correlate with the morphology of their baleen. "Skimmers," the right whales, swim slowly with their mouths open through dense clouds of slow-swimming

copepods. "Gulpers," including most rorquals, lunge into dense schools of euphausiids or fishes with their mouths open, closing them rapidly to trap their prey. All rorquals have throat grooves that run along the ventral surface of the mouth and throat, which allow the buccal cavity to expand during a lunge, taking in huge quantities of water, and with this, prey. A variation on this type of feeding is used by humpback whales when they form "bubble nets": streams of bubbles emitted from the blowhole as the whale swims in a circular pattern toward the surface. The bubbles form an ascending curtain, which concentrates prey inside. Most of these cetaceans are solitary feeders but they regularly aggregate in areas of high prey density and, when prey are extremely dense, will feed co-operatively at times, through bubble-net feeding or in staggered echelon formations.

Cetaceans that feed on larger fish and squid that school at relatively shallow depths capture individual prey items and swallow them whole. High speed is important, as is vision. Typically these predators forage co-operatively, herding prey into tight aggregations and capturing them in turn. Acoustic signaling is presumably important for the co-ordination of schooling activities. Some cetaceans in this group feed as individuals, particularly those found in coastal areas. They show a wide range of prey capture behaviors, including slapping fish with their flukes and deliberately stranding themselves on the beach in pursuit of fishes.

Cetaceans taking large, solitary squid feed at depth, in partial to full darkness. For this reason, not much is known about how they capture prey. They probably do not feed co-operatively because their prey do not school, and because most of these cetaceans occur in small schools and are slow swimming. Most have reduced dentition, and evidence indicates that they are suction feeders, using the gular muscles and tongue in a piston-like action to suck prey into their mouths. How they are able to get close enough to their prey to suck them in remains a mystery. One intriguing idea is that they are able to partially stun prey with echolocation bursts (Norris and Møhl, 1983).

Cetaceans that prey upon top predators show a wide range of prey capture methods and hunt as individuals as well as co-operatively in groups, depending upon prey size and characteristics. For example, killer whales may take pinnipeds by beaching themselves intentionally to grab adults and pups from rookeries but hunt co-operatively to take dolphins and large whales. Co-operative behaviors include prey encirclement and capture, division of labor during an attack, and sharing of prey (Pitman *et al.*, 2001).

C. Locating Prey

Most cetaceans are visual predators, at least in part. For odontocetes, echolocation is equally important in locating and targeting prey, more so than vision in some species. Although only confirmed for a handful of captive species, all odontocetes are assumed to be able to echolocate and to use this sense extensively when foraging. At present, there is no evidence that mysticetes have the ability to echolocate, although they do produce low frequency sounds that travel long distances (hundreds of km). The long wavelengths of these pulses cannot resolve features finer than the wavelengths themselves (tens of m), and so, it is doubtful that they could be used to locate and target prey patches. The effective range of vision and echolocation is a function of water clarity and the specific echolocation abilities of a species, but both are probably limited to distances on the order of hundreds of meters to a few km.

On a larger spatial scale, patchiness and variability in space and time are characteristic of most marine ecosystems and little is known

about how cetaceans locate prey in such environments. Presumably, many species simply travel large distances in a continuous search. This is particularly likely to be the case in regions of low productivity, where prey patches are few and far between, such as the oceanic tropics. Here, schooling may increase the chances of encountering a patch (the more eyes and ears, the better), and dolphin schools have been observed moving through the water in wide line-abreast formations, apparently searching for prey.

There are circumstances under which prey occur predictably in space and time, and it is likely that cetaceans search for and exploit these opportunities. For example, oceanographic features (e.g., boundaries between currents, eddies, and water masses) increase prey abundance or availability by enhancing primary production, by passively carrying planktonic organisms, and by maintaining property gradients (e.g., fronts) to which prey actively respond. Topographic features also (e.g., islands, seamounts) are sites of prey aggregation. Therefore, a good foraging strategy is simply to locate these physical features and many species of cetaceans (right, blue, fin, humpback, sperm, killer whales, spinner, Risso's, common, Atlantic spotted *Stenella frontalis* dolphins) have been found to associate with them.

Many species of cetaceans locate and associate with predictable point sources of prey. For example, killer whales aggregate around pinniped rookeries when young seals and sea lions are weaning. Rough-toothed dolphins (*Steno bredanensis*) associate with flotsam in the oceanic tropics, which serves to aggregate communities of animals at a wide range of trophic levels (Pitman and Stinchcomb, 2002). A wide variety of cetaceans associate with fishing operations to take their discards or their target species.

And there are times when prey are more accessible than others. The pelagic community of fishes and invertebrates, which live at depth during the day but migrate to the surface at night, provides an opportunity for cetaceans to predictably locate prey near the surface, and some dolphins (spotted, spinner, dusky, common) are known to feed on organisms in this community at night.

III. Cetacean Predators

By far the most important non-human predator of cetaceans is the killer whale. Their pack-hunting behavior allows them to take everything from the fastest dolphins and porpoises to the largest whales, including blue and sperm whales. Other predators known to occasionally prey on smaller or weakened individuals include large sharks, and possibly false killer and pilot whales. Polar bears (*Ursus maritimus*) take cetaceans along the ice edge.

The ecological significance of this predation pressure in the lives of whales and dolphins is difficult to assess, but it may be significant (Corkeron and Connor, 1999; Pitman *et al.*, 2001). Individual large whales often show signs of killer whale tooth rake marks on their flippers, fins, and flukes, and up to one-third of the bottlenose dolphins off eastern Australia bear shark bite scars, suggesting that they regularly encounter predators. It has been hypothesized that large whales may undergo their annual migrations to reach calving grounds in areas of lower killer whale densities (i.e., the tropics). Aggregative behavior is a common defensive strategy among prey species and it is possible that schooling evolved in dolphins primarily as a defense mechanism against predators. These kinds of behavioral adaptations have cascading effects influencing not only distribution and abundance, but also social structure, timing and mode of reproduction, foraging strategies, and speciation patterns. Although its significance has been downplayed, the degree to which predation (top-down forcing) has structured cetacean ecology may have been under-estimated.

Sharks are the other main predator of cetaceans. Large-bodied sharks can maim or kill individual cetaceans but are likely significant predators only for smaller bodied dolphins or perhaps tiny calves of larger bodied cetaceans. The tiny cookie-cutter shark (*Isistius brasiliensis*) can also be considered a cetacean predator. These tropical sharks regularly take scoops of skin and muscle from many species of cetaceans and while these wounds are not fatal, they leave scars for the remainder of an individual's life.

IV. Schooling

Like many animals, cetaceans form aggregations for two main reasons: feeding and protection. Feeding can bring animals together in passive aggregations in areas of high resource abundance. Alternatively, animals may actively seek others to take advantage of benefits provided by other school members. Schools also serve to protect members from predation, by providing cover for individual members, by confusing predators with synchronized movements of many individuals, by reducing the probability of predation on any one individual, by increasing the chance of detection of a predator, and by providing for co-ordinated defense. Occurring in large groups also increases the potential for social interactions, including reproduction; this may only be a secondary benefit of schooling.

The majority of cetaceans occur in schools, although there are some species that regularly occur solitarily or in very small groups of pairs or trios (many mysticetes, large male sperm whales, most beaked whales, dwarf and pygmy sperm whales, and river dolphins). Most schooling species have characteristic school sizes (although they can vary somewhat area to area). For example, rough-toothed dolphins typically occur in groups of 10–20, pilot whales occur in schools of dozens, and some oceanic dolphins (*Stenella* spp., *Delphinus* spp.) regularly occur in groups of hundreds or thousands (Wade and Gerrodette, 1993).

School size correlates with feeding habits: species that form large schools are almost all shallow-diving species that feed mainly on schooling prey, whereas those which occur in school sizes of 25 or fewer tend to be (a) deep-diving species and feed mainly on larger squids or (b) coastal species feeding on dispersed prey. School size also correlates with predation pressure; large cetaceans, presumably subject to lower predation pressure than small species, occur only in small groups, whereas small cetaceans, subject to higher predation pressure, occur in schools whose size correlates with openness of habitat: the more open, the larger the school size. School size should correlate with resource availability and will affect reproductive strategies, although the nature of these relationships remains largely unexplored.

Although most schools are monospecific, several species regularly occur in mixed-species schools. Some of these associations appear to be opportunistic: bottlenose dolphins, e.g., have been recorded to occur with over 20 different species of whales and dolphins. Other associations appear to be more prescribed: spotted and spinner dolphins regularly occur together in mixed schools. Risso's, Pacific white-sided (*Lagenorhynchus obliquidens*), and northern right whale (*Lissodelphis borealis*) dolphins are commonly found in association. The nature of these interactions (e.g., why these species-specific associations occur, how these species avoid competition) is unknown.

V. Communities and Coexistence

Studies of communities typically focus on identifying member species and their interactions and then address mechanisms for their coexistence. These kinds of studies comprise a large part of the

ecological knowledge for many terrestrial species. In contrast, very little is known about this aspect of cetacean ecology.

There are regularly occurring species assemblages. For example, pantropical spotted and spinner dolphins are frequently found in mixed-species schools in association with yellowfin tuna (*Thunnus albacares*) and are accompanied by large and speciose flocks of seabirds; this association is particularly prevalent in the eastern tropical Pacific, as opposed to other tropical oceans. There are variations in typical co-occurrence patterns. In the Gulf of Mexico, e.g., five species of *Stenella* coexist in a relatively small area, more *Stenella* species than any other tropical ocean. The nature of the interactions between species in these assemblages, why they associate, and the reasons for variations in community membership patterns are almost completely unknown.

Coexisting species, particularly those that are closely related or have similar ecological roles, potentially compete for resources. An often cited example is the southern ocean, where the relative abundances of cetaceans, pinnipeds, and seabirds, all krill consumers, have been reported to have changed between pre- and post-whaling years. One plausible explanation is competitive release: the decrease in biomass of cetacean predators released a huge prey base of krill to pinnipeds and seabirds, both of which were able to increase in abundance (Laws, 1977).

Ecological theory states that stable communities of coexisting species must differ in resource utilization in some way: through prey species or size specialization, differential habitat use, or diet pattern. Such niche partitioning is fairly clear for cetaceans on a broad scale. For example, there are species that feed on fish and those that feed on squid. There are species feeding in shallow water and those that feed at depth. Some cetaceans feed at night and others during the day.

On a smaller scale, one of the best known examples of niche partitioning is for baleen whales. In this group, there is a fair degree of prey specialization that presumably allows for niche partitioning in areas of sympatry. Blue whales feed almost entirely on euphausiids; fin whales and humpbacks feed mainly on fishes but take euphausiids when they are abundant; and right whales and sei whales feed mainly on copepods. Odontocetes provide additional possible examples. Bottlenose, short-beaked common (*Delphinus delphis*), pantropical spotted dolphins, and harbor porpoise exhibit diet specialization among age, sex, and reproductive class, although this diet specialization could be due to differing energy requirements. Aside from these examples, very little is known about how, or if, cetaceans partition resources.

Ultimately, to understand community structure, the mechanisms by which species partition resources, not merely the presence of differences in resource use, are of principal interest. The question then becomes, given that there are differences, what mechanisms can explain them? Community ecologists have identified interference and exploitative competition, mutualism, morphological or physiological factors, and habitat structure as potential mechanisms for maintaining resource utilization differences. This is an area that remains almost completely unexplored for cetaceans and the communities in which they are found.

VI. The Role of Cetaceans in Marine Ecosystems

What role do cetaceans play in marine ecosystems and what is their significance? Most cetaceans are apex predators. As such, they take tons of prey from the ecosystem. In so doing, it seems likely that cetaceans affect the life history strategies and population biology of their prey, as well as organisms at other trophic levels that interact in various ways with these prey. Little is known about the details of

Figure 1 Australasian gannets (*Sula serrator*) feed on small-schooling fish (e.g., pilchard, *Sardinops neopilchardus*) which have been herded to the surface by dusky dolphins (*Lagenorhynchus obscurus*) in Admiralty Bay, New Zealand. Photo by Christopher Pearson.

these dynamics, although this may be the most significant way in which cetaceans impact marine ecosystems.

More specific effects have been documented. For example, benthic feeders such as gray whales alter habitat by regularly turning over substrate (between 9% and 27% of the benthos in the northern Bering Sea) and therefore, significantly affect the species composition of benthic communities. Feeding cetaceans provide feeding opportunities for seabirds by driving prey to the surface, sometimes injuring or disorienting it (Fig. 1). In one study up to 87% of all feeding individuals from four seabird species in the Bering Sea associated with gray whale mud plumes (Obst and Hunt, 1990). Large whales dying at sea may sink to the bottom and provide rare but superabundant food and habitat for deep-water species. There is evidence that mollusc communities may have specialized on these resources for the past 35 million years, and some speculate that whale carcasses may have been instrumental in the dispersal of hydrothermal-vent faunas. Feces of some cetaceans, particularly large whales in areas of low productivity, may play a significant role in nutrient cycling. Cetaceans are host to a variety of commensal or parasitic species; in some cases (Cyamid whale lice), these species are completely dependent on cetaceans through all life stages.

VII. Macroecology

Macroecology is a branch of ecology that attempts to characterize the relationships between organisms and their environment by increasing the spatial and temporal scale of investigation. Macroecologists ask questions about the relationships between abundance, distribution, and diversity of individuals, populations, or species and incorporate principles of biogeography, paleobiology, systematics, and the earth sciences in their search for pattern. Macroecology is a relatively recent field but has resulted in significant and novel insights. For example, the concept of species richness hotspots, the underlying mechanisms that produce them, and the ecological and conservation implications are all products of the macroecological perspective. These advances pertain largely to terrestrial systems but there are notable exceptions. Worldwide patterns of tuna and billfish diversity indicate that there are clear hotspots, areas of high species richness, that appear to hold in general for other taxa and trophic levels, and are functions of

oceanography (Worm *et al.*, 2005). The significance of these patterns and their relevance to cetaceans is unknown, but a promising field of investigation.

VIII. Concluding Remarks

The field of cetacean ecology is a dynamic discipline. Technological advances and heightened interest have resulted in a great deal of additional knowledge, a trend that will no doubt continue. However, any attempts to make ecological sense of cetaceans as marine organisms and to interpret their distribution patterns, foraging ecology, community structure, and role in ecosystems must take into account the fact that many cetaceans today exist as remnant populations that have been drastically reduced through anthropogenic effects: commercial exploitation, incidental mortality, and habitat destruction. Additionally, the study of cetacean ecology is no longer relevant without incorporating anthropogenic influences into the biological environment; these are pervasive and in many cases, permanent. The recent declaration of extinction of the baiji (*Lipotes vexillifer*) (Turvey *et al.*, 2007) and an almost certain similar fate for vaquita if drastic measures are not immediately taken (Jaramillo-Legorreta *et al.*, 2007) are tragic indications of the state of many marine ecosystems. This means that cetacean ecologists must also add human sociology, economics, and policy to the list of disciplines that will likely affect the search for ecological patterns.

Cetacean Evolution

R. EWAN FORDYCE

I. Patterns of Evolution

Fossils show that cetaceans arose from terrestrial ancestors more than 50 million years ago. They have evolved to become the dominant group of marine mammals in terms of taxonomic and ecological diversity and geographic range. Structural, genetical, and ecological patterns in living species are used widely to infer cetacean evolution. Fossils provide the only direct evidence of extinct species and past structures; they indicate extinct clades and ecologies, revealing patterns not seen today. Patterns from modern and fossil species have, since 2000, hugely expanded understanding of evolution, although high-level/deep-time phylogenies yet show limited agreement. Discussion of evolution depends on an agreed phylogenetic approach. Here, concepts of crown and stem group are fundamental, especially when comparing fossil vs molecular evidence for deep-time events. For any clade (monophyletic group), the crown group comprises all the living species plus all descendants of their most recent common ancestor. This monophyletic crown group may contain only one species; it may also contain extinct species. The stem group comprises those species, all extinct, that are closer to the crown group than to any other clade.

There is little conclusive evidence on evolutionary rates, modes, and mechanisms of ancestor-to-descendant transitions. Evolutionary processes at the species level have likely included natural selection, sexual selection, coevolution, founder effects, vicariance, and hybridization. At larger scales, changes in ocean structure/ocean ecosystems correlate with some changes in structural/ecological evolution in Cetacea, suggesting that the distribution and abundance of global food resources have played major roles in evolution.

II. Ancient Ecology

Ecology is the sum of interactions that species have with their environment, biological, physical, and chemical. Paleocology explores such relationships of the past. On geological timescales, evolution and paleocology are inextricably linked, for evolution occurs through natural selection and adaptation to the environment. An appreciation of paleocology thus helps understand the history of Cetacea. Several ecological factors have been considered repeatedly in accounts of cetacean evolution (Fig 1), including feeding and predator–prey interactions, migration, thermal adaptations, and habitat shifts.

For extinct species, lifestyle can be inferred in several ways. The traditional approach of “taxonomic uniformitarianism” assumes that a fossil had similar ecological strategies to its close living relatives: the present is applied to the past. Thus, e.g., fossil sperm whales

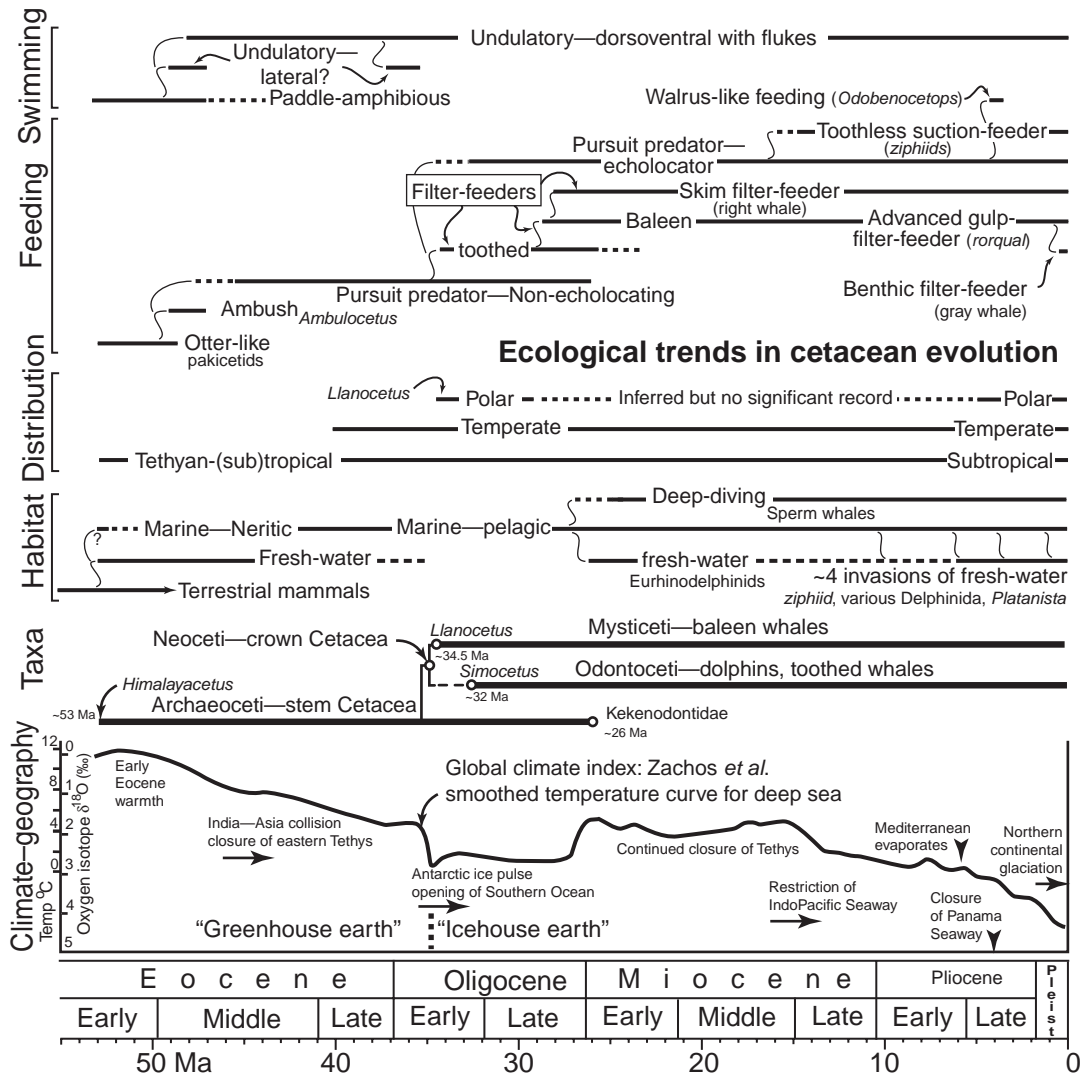

Figure 1 Summary of inferred ecological strategies important in cetacean evolutionary history plotted against geological time, inferred global climate, geographic/oceanic change, and taxon history. Selected taxa are given as examples. Slightly revised from Figure 1, in *Cetacean Evolution*, R. E. Fordyce, “*Encyclopedia of Marine Mammals*” (W. F. Perrin et al., eds), Copyright Elsevier 2002.

presumably were deep divers. However, fossils show that cetaceans have evolved through long-term change in structure, with natural selection providing the adaptive fine-tuning. Structural change, then, implies changes in ecology. Clearly, taxonomic uniformitarianism should be supported by other methods. The method of extant phylogenetic bracketing (Witmer, 1995) proposes that some attribute present in crown (living) species can be inferred to have occurred in an extinct species or extinct clade within the crown group. For example, extinct species within the crown Odontoceti can be inferred to have echolocated because phylogenetically adjacent living species echolocate.

For some fossils, ancient ecologies may be inferred by analogy. The bizarre extinct Peruvian *Odobenocetops* species, or walrus whales, have no structural equivalents among living Cetacea, but their jaw form was remarkably similar to that of the unrelated living walrus, *Odobenus rosmarus*. A comparable style of suction feeding on molluscs is inferred. This approach to paleoecology can

be expanded by studying functional morphology, which includes reconstructing soft tissues onto fossils using known modern correlations of muscle, nerve, and vessel to bone. Finally, geological evidence (e.g., from sediments and isotopes) can help identify the ancient environments in which cetaceans lived, sometimes indicating dramatic or novel ancient ecologies.

III. Major Radiations

Changes in structure and diversity of fossils reveal three major radiations—times of functional, ecological, and taxonomical diversification—in cetacean history. First, cetaceans diversified in near-tropical shallow waters of the Tethys seaway between India and Asia about 45–53 million years before the present (Ma), spreading into temperate waters by 40 Ma. This early phase of evolution was influenced by local marine productivity (Gingerich, 2005), although the initial shift to fresh waters may have been for protection rather than

feeding (Thewissen *et al.*, 2007). Up to 20 genera of Archaeoceti (stem or basal Cetacea) were present in the Lutetian (geological) stage, and over 40 species have been reported for the interval 34–53 Ma (Uhen and Pyenson, 2007; see also pdwb.org). This initial radiation of archaeocetes involved shifts from riverine and near-shore marine settings to fully oceanic habits, accompanied by changes in locomotory and hearing mechanisms (Gingerich, 2005). In terms of structural variation and, by inference, ecology, these early cetaceans were comparable with living mysticetes and did not show the wide disparity seen among living odontocetes. Archaeocete diversity dropped late in Eocene times, foreshadowing the rise of Neoceti.

The second major radiation, involving the Neoceti or crown group Cetacea, occurred early in the Oligocene (Fordyce, 2003; see also FOSSIL RECORD). Echolocating odontocetes and filter-feeding mysticetes appeared about 35 Ma and diversified rapidly in about 5 M years after originating from Eocene archaeocetes which neither echolocated nor filter-fed. Concurrent events included the final breakup of Gondwana, opening of the Southern Ocean, cooling and increased tropics-to-polar temperature gradients, and changes in ocean ecosystems and productivity. Probably, cetaceans radiated in direct response to new ecological opportunities in rapidly changing oceans (Lindberg and Pyenson, 2007; Berger, 2007). In the Late Oligocene, 23.5–29 Ma, there were 16 families or higher clades and probably approximately 50 species, with some species ranging into polar and fresh waters. A few relict Oligocene archaeocetes are known.

Third, the middle and the late Miocene 10–12 Ma, saw the start of a marked radiation of “modern” mysticetes and odontocetes and a decline of ancient groups. Crown balaenopterids and Delphinida radiated to become major components of fossil assemblages, with crown Delphinoidea well established in the Pliocene (see FOSSIL RECORD). Two extinct delphinoid families (Odobenocetopsidae, Albireonidae) appeared briefly. Some archaic cetacean groups, including the Eurhinodelphinidae, Squalodontidae, and other members of the Platanistoidea, declined to extinction. Many crown genera appeared by the start of the Pleistocene, 2 Ma, but evolutionary patterns during the following ice ages are not clear because of a patchy fossil record. It has been suggested that many north–south species pairs evolved in the later Pleistocene but molecular studies point to earlier north–south splits.

IV. Evolutionary Processes

Darwin’s original evolutionary mechanism, natural selection, is the process that leads to the adaptation or “fine-tuning” of organisms to the environment through beneficial structure or behavior. The result is differential reproductive success. Intra- or interspecific competition for limited resources, especially food, is a fundamental part of natural selection. Some cetologists have indicated that competition for food is important among species of baleen whales and between baleen whales and other plankton-eating vertebrates, with implications for the origins of the species involved. However, the structure of the feeding complexes of baleen whales, mode behavior of feeding, and geographic distribution indicate that, in spite of sympatry, niche overlap and thus competition are limited between species (Pastene *et al.*, 2007). Perhaps previous competition among ancestral species led to taxonomic and ecological divergence seen today. Among fossils, platanistoid dolphins declined in diversity as delphinoids diversified in the middle to late Miocene; this pattern of extinction in one group and radiation in another could indicate that delphinoids out-competed platanistoids (Fordyce and Muizon, 2001). However, differences in jaw and skull structure imply little ecological overlap between the two groups. Perhaps changing

oceanic circulation and climate at about this time caused the extinction of platanistoids and allowed the radiation of delphinoids.

Darwin identified sexual selection as a mechanism in evolution. Here, one sex chooses a specific member of the other sex as a mating partner. Sexual selection plausibly accounts for sexual dimorphism, particularly in structures involved in display, and has been linked with polygamous mating systems. Examples of possible sexually selected structures in male Cetacea include the large dorsal fin in *Orcinus orca*, conspicuous mandibular teeth in many ziphiids, prominent foreheads in species of *Hyperoodon* and *Globicephala*, and the prominent tusks in *Monodon monoceros* and the extinct *Odobenocetops leptodon*. Perhaps the size dimorphism in some species also results from sexual selection; examples include male *Physeter macrocephalus*—with its grossly enlarged forehead—and female *Balaenoptera* species.

Hybridization is potentially important in the origin of new species, and cetacean hybrids are known, e.g., in *Balaenoptera*, between *Phocoenoides* and *Phocoena*, and between several genera of Delphinidae. However, no convincing cases for speciation by hybridization have been identified in Cetacea.

Coevolution, especially involving mimicry, predator prey, and host–parasite interactions, is an important phenomenon. For cetaceans, mimicry is seen in pygmy and dwarf sperm whales, *Kogia* spp.; these have a remarkably shark-like form complete with underslung jaw and pigmented false gill slit. Presumably, to look like a predator will lessen the chance of being preyed upon. Predation may have other roles in evolution. The presence of predators, such as the killer whale, *Orcinus orca*, has been used to explain species-specific distribution patterns, including the distinctive and supposedly ancient migration patterns of mysticetes from poles to tropics (Corkeron and Connor, 1999).

Convergent evolution occurs when species show similarity not inherited from a common ancestor. Among Cetacea, the “river dolphins,” long discussed as if they form a real group, encompass species in four different families. *Platanista*, however, is convergent in its riverine habits, small body size, and long rostrum with the three delphinoid relatives *Inia*, *Pontoporia*, and *Lipotes*. The southern delphinid *Cephalorhynchus hectori* is similar in body form and some aspects of ecology and behavior to the unrelated porpoise *Phocoena phocoena* (Phocoenidae). Unrelated groups have convergently reduced and lost teeth, as seen in living *Mesoplodon* (Ziphiidae) and the Pliocene ziphiid-mimic delphinid *Australodelphis*.

There is a wide interest in the developmental mechanisms that allow rapid evolution of the structure. Consider heterochrony, which involves a change in timing or rate of development of structures relative to the equivalent processes in an ancestor. Some features might evolve when juvenile structures persist into adult stages (pedomorphosis), whereas others arise when structures develop “beyond” that of the ancestral adult stage (peramorphosis). Apparent pedomorphic features in Neoceti include the shortened intertemporal region and longer vomer and mesorostral groove, the rounded cranium and persistent interparietal bone on the skull of many Delphinidae and Phocoenidae, and the down-turned rostrum and relatively symmetrical skull in Phocoenidae. Possible peramorphic features include extra body parts, e.g., increase in number of vertebrae, as in Dalls porpoise, *Phocoenoides dalli*, or phalanges generated through a delayed halt in development.

V. Evolution and Geography

Darwin realized that speciation is often related to geography. The range of a species may either be split by a change in physical

habitat (namely, split by a vicariant event) or be expanded by dispersal beyond normal limits. Populations that become geographically isolated through such events can diverge and, via allopatric speciation, may become new species. Most discussion of such ideas focuses on terrestrial habitats, but there are clear marine parallels. During 50M years of cetacean history, geographic changes have included the closure or opening of some straits and ocean basins, dramatic swings in continental shelf habitat area through sea level fluctuations, and major shifts in current systems, upwellings, and latitudinal water masses. Oceanic temperature regimes changed in parallel. This physical evolution of the oceans probably influenced cetacean evolution at many levels.

The distributions of modern and fossil Cetacea indicate an important role for geography in evolution (Fig. 2). Some living species have obvious northern and southern populations or closely related north-south species pairs, but do not occur in the tropics. Such bipolar or antitropical distributions probably arose allopatrically when populations became isolated either side of the tropics through changing sea temperatures or current regimes, sometimes leading to speciation. Antitropical distributions are marked (Rice, 1998) in populations of porpoises *Balaenoptera*, species of right whales *Eubalaena*, some beaked whales (Ziphiidae species of *Berardius*, *Hyperoodon*, and *Mesoplodon*), and dolphins (Delphinidae, e.g., *Lissodelphis* spp.).

Among delphinids, molecular studies reveal that six antitropical species of *Lagenorhynchus* split at varying times, not just during the geologically recent (~2Ma) ice ages, and that these species represent two or more different lineages (LeDuc *et al.*, 1999). At least one genus appears to have speciated around an ocean: four species of the delphinid genus *Cephalorhynchus* occur around the circum-Antarctic Southern Ocean. There is some fossil evidence for allopatric species pairs: closely related species of the small dolphin *Kentriodon* that occur in Miocene strata in California and Maryland perhaps evolved from an ancestor that ranged through the central American seaway before the uplift of Panama.

For porpoises, the endangered vaquita *Phocoena sinus*, from the Gulf of Mexico, perhaps originated when a few of Burmeister's porpoise, *Phocoena spinipinnis*, crossed the equator only tens of thousands of years ago. The vaquita, with its limited distribution and low genetic variability, illustrates founder effects; a new population, e.g., in an isolated region beyond normal range limits, may be established by only a few original founders which are not genetically representative of the original population.

Sea level fluctuations have changed the extent of continental shelf habitat dramatically, especially during cycles of glaciation and cooling over the last 2M years. At peak glaciation, sea level was 100+ m lower than at present, leading to fragmentation or loss of shelf habitat for long intervals, along with colder conditions. Such habitat change could lead to extinctions. However, if species durations typically exceed 100,000 years, as is plausible, then most living cetaceans have survived several of these fluctuations. The record of Late Pliocene and Early Pleistocene Cetacea includes a few species from shallow-water habitats (e.g., the dolphin *Parapontoporia*) that might have later disappeared because of Pleistocene climate changes and/or habitat loss.

Some cetacean groups show significant change in range over time. The beluga and narwhal (Monodontidae) are now restricted to cold north polar waters, but during warmer Pliocene times (4Ma), monodontids occurred far south in subtropical waters. Further evidence for changing geographic ranges comes from archaeocetes, which, for about 10M years after their origin, were subtropical to tropical, later spreading to temperate regions. The peak modern diversity for Cetacea is in temperate waters.

Allopatric speciation results from lineage splitting or cladogenesis. New species could also evolve by anagenesis, involving transformation from an ancestral to descendant species without lineage splitting. Anagenetic change would produce a fossil record with two or more species in succession and might be expected in lineages containing geographically wide-ranged species. Species with limited ranges seem more likely to experience allopatric speciation. Among living Cetacea, the sperm whale *Physeter macrocephalus* represents a genus with a single abundant and widely distributed species with no immediate relatives (sister species), and anagenesis might be considered in explaining its history.

Freshwater settings were important in the early transition of cetaceans from land to sea in the Tethys. Early archaeocetes were amphibious, with well-developed hindlimbs, and they include species from freshwater strata. Freshwater habits for some archaeocetes are indicated by oxygen isotopes from teeth. Fossil Neoceti also show several reinvasions of freshwaters. For example, one unnamed Late Oligocene species of Eurhinodelphinidae occurs in lake sediments of central Australia. The dolphin shows no obvious structural adaptations to a lacustrine habitat, but the presence of several specimens of slightly differing geological age indicates long-term occupation of the habitat. A single large ziphiid fossil is known from Miocene freshwater sediments of Kenya. All the living "river dolphins" arose from marine ancestors, some well known from fossils, which invaded freshwaters in Asia and South America in up to four separate events. Mysticetes seem never to have occupied river systems.

VI. Life History Traits

In terms of life history traits, cetaceans appear to be K-strategists (Estes, 1979). That is, compared with many other mammals, cetaceans are large animals that have slow reproductive rates, produce a single offspring, show significant parental of young, have long reproductive lives, and have relatively low mortality rates. This reproductive strategy has been linked, in an evolutionary sense, to the nutritional requirements of both the young and the parents and thus to food availability. The fossil record of cetaceans, which shows major evolutionary change linked to oceanic change, supports the idea that food resources have been fundamental in cetacean history. The exact roles of physical vs biological effects, namely, bottom-up or top-down drivers, in cetacean evolution are contentious.

VII. Taxonomic Longevity

How long do species and genera persist? The fossil record shows that few, if any, species have ranges longer than one geological stage (a stage is a time unit commonly 4–5M years) (Uhen and Pyenson, 2007). Amongst extinct Cetacea, the close-spaced succession of Eocene archaeocetes points to species durations of 1–2M years. Living species can be traced back into the Pleistocene but not reliably longer, further implying durations of approximately 2M years. Molecular studies can estimate dates for separation of lineages of crown species, e.g., 1.9 to 3 and 3.8 to 9.6M years for species of *Lagenorhynchus* and greater than 5M years for *Balaenoptera musculus* and *B. physalus*. Dates for lineage separation, however, are not necessarily the same as dates for species durations. Beyond the species, some crown genera have reliable fossil records back to the Early Pliocene or Late Miocene, e.g., approximately 6Ma for *Balaenoptera*, and approximately 5Ma for *Delphinus*. The supposed origin for crown right whales, *Balaena* and *Eubalaena*, pre-dating *Morenocetus* at 20Ma, is surprisingly long and needs verifying. Similarly, some molecular predictions for

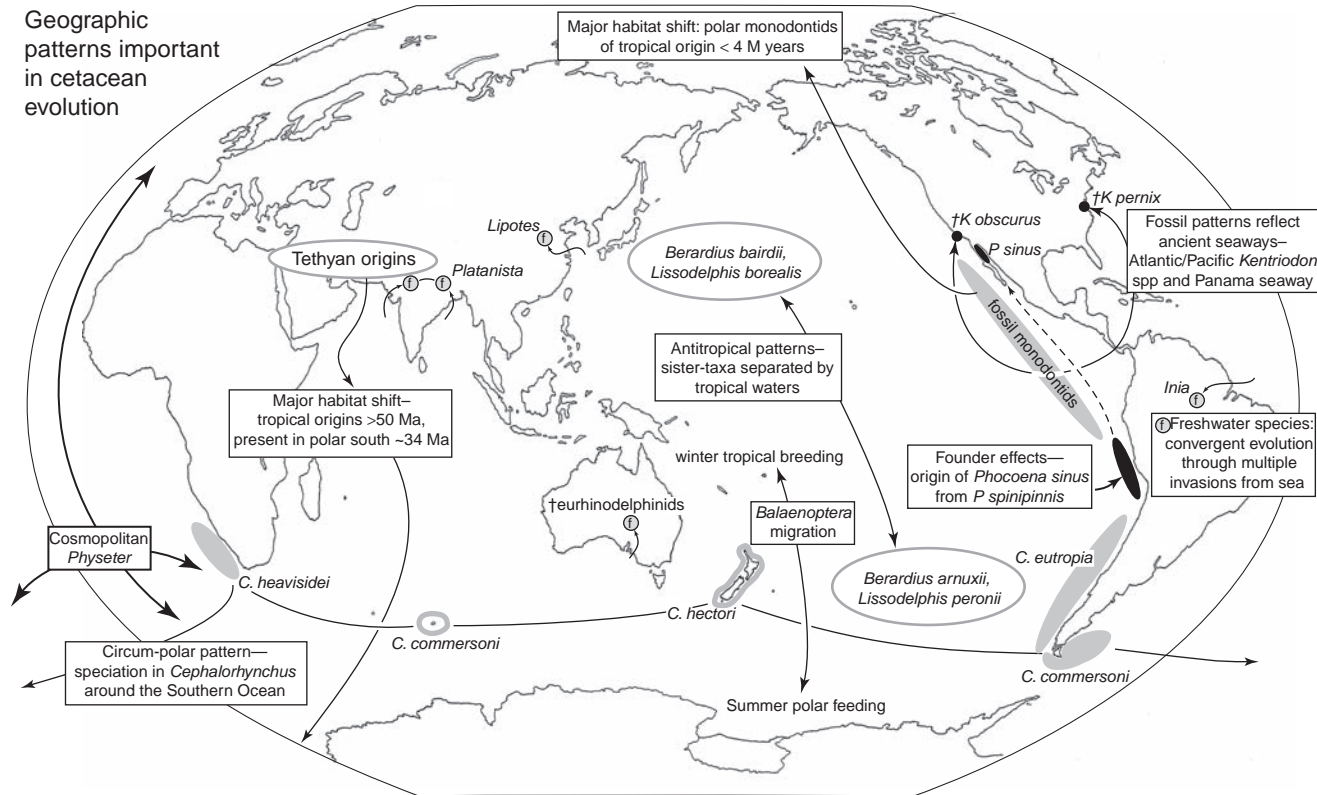

Figure 2 Distribution patterns illustrating the possible role of geography in cetacean evolution. Patterns indicated include antitropical and circum-Antarctic distributions, allopatric species pairs between oceans, founder effects, convergent origins for various freshwater dolphins, habitat expansion in general for Cetacea tropical origins, followed later by spread as far as the poles, and geologically recent changes in habitat. Selected taxa are given as examples. Fossils are marked with a dagger. Slightly revised from Figure 3, in *Cetacean Evolution*, R. E. Fordyce, “*Encyclopedia of Marine Mammals*” (W. F. Perrin et al., eds), Copyright Elsevier 2002.

origins of crown genera are markedly longer than indicated by the fossil record.

Little is known about rates of evolution in Cetacea. Family-level patterns in the fossil record, and some molecular studies, imply phases of rapid radiation, and presumably rapid evolution, for the Oligocene. Unlike the situation for some terrestrial mammals, the cetacean fossil record is too sparse to reveal quantifiable change in structure over time. For living species, no speciation event has been dated reliably enough to clearly reveal evolutionary rate, but there is some evidence that the vaquita, *Phocoena sinus*, evolved fast, over tens, rather than hundreds, of thousands of years.

VIII. Diversity and Disparity

Diversity is the number of species within a taxon (such as a genus or a family) and is effectively an index of taxonomic richness, whereas disparity indicates the variation in structure or basic design within a taxon. Diversity is easy to assess, particularly now that advances in the philosophy and practice of systematics have produced a generally accepted species level classification of living cetaceans, but the study of disparity is still developing. A comparison of the two living clades Odontoceti and Mysticeti reveals quite different patterns of diversity (Fig. 3). Mysticetes

Figure 3 Phylogenetic patterns of species diversity at the family level among living Cetacea, using currently understood higher-level relationships. Traditionally, families are clusters of species and genera with a similar body plan; thus, families usefully reveal disparity at high levels within the Cetacea. Mysticetes are less speciose and less disparate than odontocetes; delphinids and then ziphiids are the most speciose and most disparate of the odontocetes.

include 14 species in four families. The Balaenopteridae is most speciose, with 8 species in two genera (*Balaenoptera*, 7; *Megaptera*, 1). Broadly speaking, species of *Balaenoptera* vary in size, distribution, and behavior, but species boundaries may be blurred. Species are distinguished mainly on aspects of the feeding apparatus baleen size and spacing, size and shape of the upper jaw, and skeletal differences are rather minor. Thus, disparity appears low. The gray whale, *Eschrichtius robustus*, is structurally quite different (disparate) from other mysticetes and is generally placed in its own monotypic family, although some molecular studies place it within the Balaenopteridae. Fossils show the gray whale lineage to extend at least back to the Pliocene, approximately 4 Ma.

Odontocetes include at least 74 species in 10 families. With 38 species, Delphinidae is the most diverse family of cetaceans, and disparity seems much higher than, e.g., within Balaenopteridae. Among delphinids, there is a great variation in body size and proportion, skull form, proportions of the feeding apparatus and teeth, and distribution of air sinuses in the skull base. Among beaked whales (Ziphiidae; 21 species), the genus *Mesoplodon* has 14 rather similar species in which only adult males are separated easily. Disparity here appears low and awaits explanation in terms of evolutionary ecology within the genus. Among other odontocetes, 4 species of small long-beaked “river dolphins” each represent a single family: Iniidae, Pontoporiidae, Lipotidae, and Platanistidae. Although these “river dolphins” are superficially similar externally, they differ markedly in skull form—hence the common separation into 4 families. The most intriguing is *Platanista gangetica* (family Platanistidae), which appears to be the last of the ancient and once diverse superfamily Platanistoidea. For crown *Platanista*, Platanistidae, and Platanistoidea, diversity is low (one living species of *Platanista*), with no fossil record, but many stem platanistoid lineages include diverse species ranging back to 28–29 Ma.

As a group, odontocetes are structurally diverse. Huge variation is seen in the skull, involving the shape, size, and sometimes basic construction of the feeding apparatus and teeth, facial region, including bony origin for nasofacial muscles implicated in echolocation, nasal passages, acoustic system, and air sinuses in the skull base. Disparity might be viewed as caused by reduced constraints on body form, allowing specialization in many different directions. This explanation for disparity, however, does not explain the ultimate origin of structural diversity. Future study of odontocete structural diversity could involve constructional morphology, which offers an alternative to the strongly selectionist/adaptationist accounts of structure and evolution in modern literature.

XI. Extinction

Extinction, the disappearance of lineages, is the fundamental complement to evolution. Clearly, a species goes extinct when the number of individuals and geographic range drops to nil. The fossil record reveals that extinction is inevitable and, for lineages, usually terminal; few species go extinct by evolving into descendants. Among different styles of extinction, there is no evidence that cetaceans have been involved in mass extinction comparable to that affecting dinosaurs. Taxonomic extinction (the disappearance of a clade) has occurred, as shown by the fossil record of such well-defined clades as the odontocetes Eurhinodelphinidae and Squalodontidae, and the *Cetotherium* group of mysticetes. Environmental change might explain extinction through loss of habitat or food or through climate change. Most extinction has probably involved the piecemeal extinction of single species, but the cetacean fossil record is too patchy to

expect pattern or cause to be clear. Species susceptible to extinction are those in low-diversity clades, e.g., one or two species in a genus, with no close relatives, occurring in geographically limited physical settings that are unstable over geological time. For Cetacea, this means particularly the “river dolphins.” Conversely, widely distributed oceanic species would seem resistant to extinction.

Patterns of extinction beg a question that ecologists might consider unthinkable: Are there vacant modern niches that formerly were occupied by Cetacea? For example, stem Platanistidae lived in shallow marine settings until about 10 Ma, but *Platanista* now occurs only in freshwaters, and species of Squalodontidae and Eurhinodelphinidae were widely distributed before their demise in the later Miocene. Judging from the functional complexes seen in the latter fossils, there are no modern equivalents to these groups: some morphotypes and lifestyles have disappeared.

Cetacean Fossil Record

R. EWAN FORDYCE

I. Introduction

The fossil record of Cetacea—whales, dolphins extends back more than 50 million years (Fig. 1). Hundreds of species are known, based on fossils from near-shore to deep-ocean marine strata and, occasionally, freshwater sediments. Remains vary from less common near-complete skeletons through skulls and teeth to abundant single and usually undiagnostic bones (Fordyce and Muizon, 2001). The taxonomy at family level is adequate to review the diversity and spatio-temporal distribution of fossil Cetacea, although cladistic relationships of families and other taxa to one another, and clade names, are volatile, and cetologists should use cladistic results with caution. Standard zoological techniques are used in taxonomy, classification, and analysis of function. Routine geological techniques are used to date fossils, to interpret sedimentary environments, and to extract geochemical signals such as isotopes from fossils. The fossil record shows patterns of evolution and extinction that link strongly with biological and physical environmental change in the oceans. Fossils provide the only direct means of dating clade origins and thus calibrating molecular clocks.

II. Occurrence, Environment, and Age

Fossil cetaceans occur in sedimentary rocks. Originally, remains accumulated in mud, silt, sand, or gravel which, as flesh decayed, was buried and turned to rock through compaction and/or deposition of cementing minerals. Sedimentary rocks are recognized as discrete formations (genetically unified bodies of strata), and are named formally, e.g., the Calvert Formation, Maryland. Marine mammals come from strata including sandstone, mudstone, limestone, greensand, and phosphorite, most of which are marine rocks now exposed on land. Rare fossils have been recovered from the sea floor. Because broadly similar rock types may form at different times and places, sedimentary rocks must be dated to establish their time relationships.

Two correlated timescales, relative and absolute, are used for the fossil record. The relative timescale has named intervals (epochs; Fig. 1) in an agreed international sequence: Eocene, Oligocene, Miocene, Pliocene, and Pleistocene. These epochs are usually subdivided into early, middle, and late. Stages (e.g., Aquitanian of Fig. 1) may provide finer subdivision. Typically, distinct age-diagnostic fossils are used to recognize time intervals. The most reliable dates are based on oceanic microfossils with short-time ranges, such as foraminifera, which allow correlation between ocean basins. Because of compounded errors of long-distance correlation, ages are rarely accurate to within 1 million years, and many fossils can be placed only roughly within a stage. Beyond the relative timescale, absolute dates in millions of years are needed to understand rates of processes in phylogeny (involving, e.g., molecular clocks) and in geology (involving, e.g., rates of sediment accumulation or of climate change). Absolute dates are usually obtained from radiometric analysis of grains of volcanic rock interbedded with fossiliferous strata.

III. The Fossil Record

Fossil cetaceans are classified on the evidence of skeletons (Fig. 2). No other significant body parts preserve, and fossils have not yet produced biomolecules useful in molecular taxonomy. Skulls are by far the most versatile and thus important elements in classification,

Figure 1 Stratigraphic record and inferred relationships of family-level clades of Cetacea. Timescale shows absolute time, Epochs (e.g., Eocene) and their subdivisions (e.g., early, middle, and Stages (e.g., Priabonian). Bars show age ranges for family-level cetacean taxa: crown clades and wholly extinct clades (infilled bars), stem clades (heavy dash), and grades (open bars). Accuracy of ranges varies between different groups and different time intervals. Inferred relationships follow literature cited in text. Some, but not all, major regions of uncertainty are indicated.

but teeth and, rarely, other bones (vertebrae, limb elements) have been used at times (Fordyce and Muizon, 2001).

Methods of handling, recording and interpreting specimens are ever-changing; consider, e.g., the development of CT and laser

scanning, of computer-aided phylogenetics and shape analysis, and of geochemistry. Computer databases have become fundamental basic tools which allow rapid access to information worldwide (e.g., relevant here: <http://pbdb.org>). An important conceptual advance since

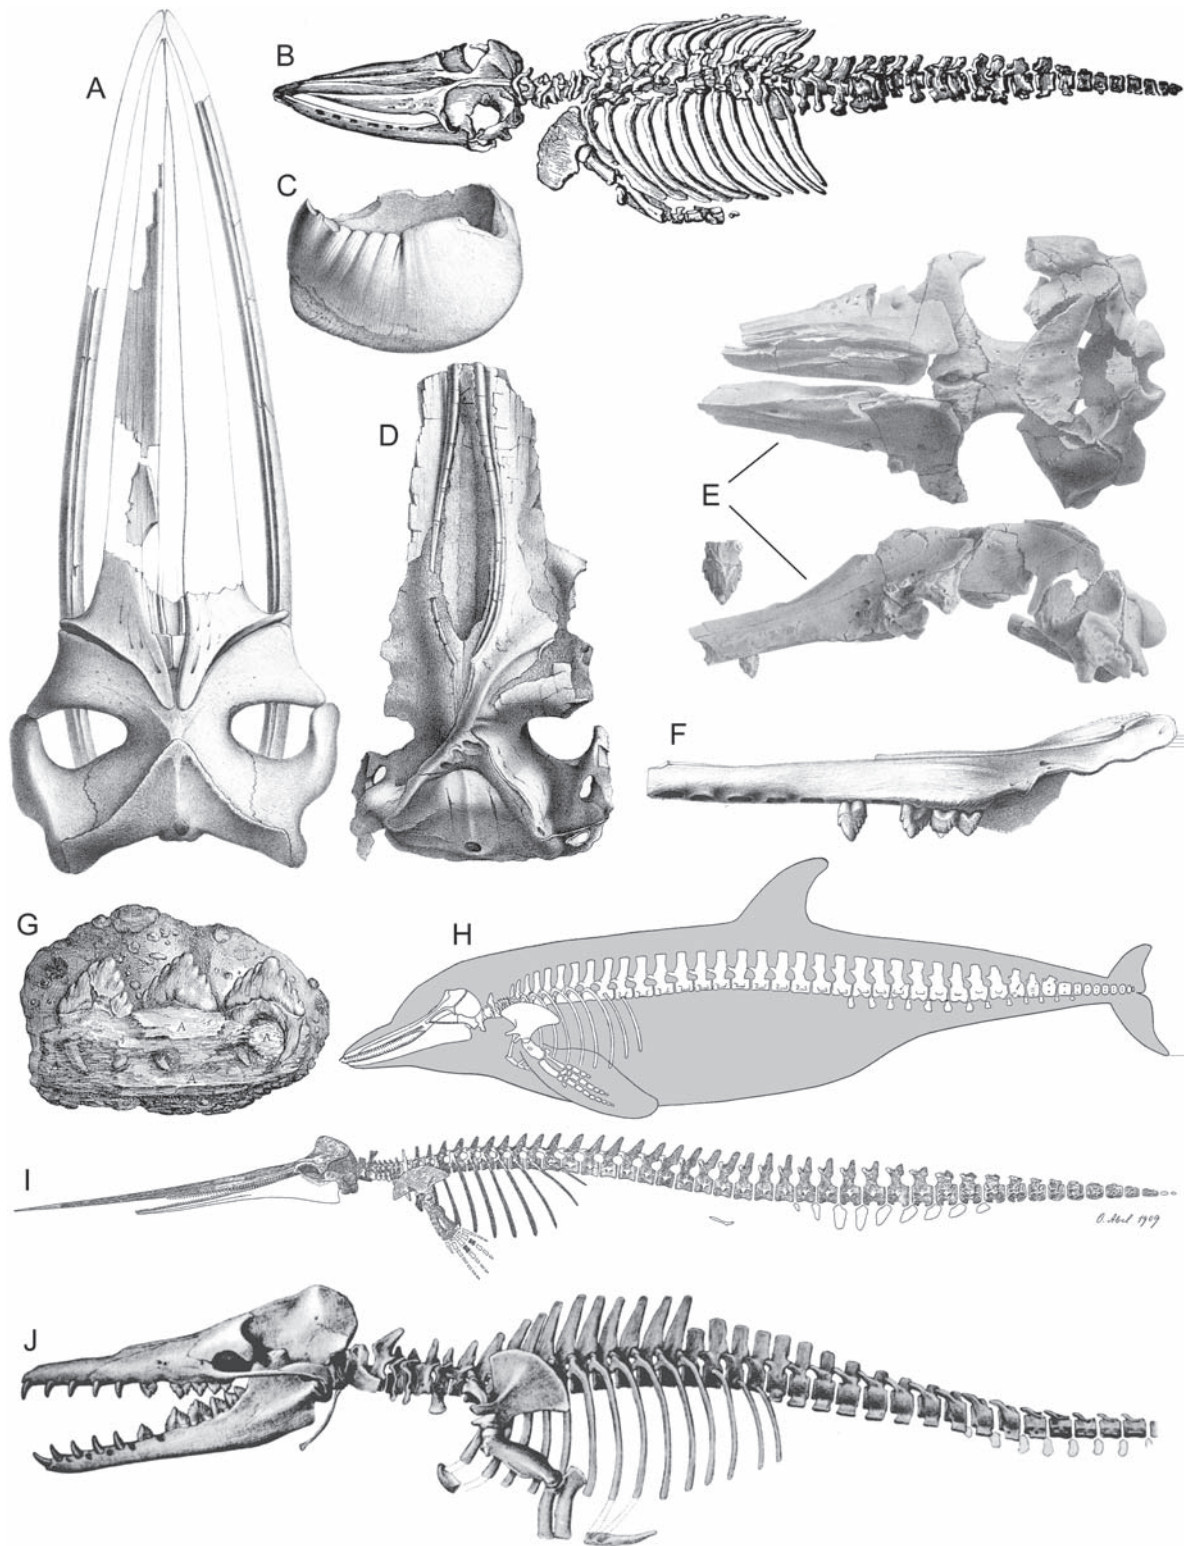

Figure 2 Historically important fossil cetaceans figured in early paleontological and systematic literature. (A) *Cetotherium rathkii* (Mysticeti), skull; from Van Beneden and Gervais 1868–1880. (B) *Protororqualus cuvieri* (Mysticeti), skeleton; from Zittel 1925. (C) *Balaena primigenia* (Mysticeti), tympanic bulla; from Van Beneden and Gervais 1868–1880. (D) *Metopocetus vandelli* (Mysticeti), skull; from Van Beneden and Gervais 1868–1880. (E) *Agorophius pygmaeus* (Odontoceti), skull and tooth; from True 1907. (F) *Squalodon gratelupi* (Odontoceti), part of upper jaw; from Van Beneden and Gervais 1868–1880. (G) *Squalodon melitensis* (Odontoceti), teeth; from Scilla 1670. (H) *Kentriodon pernix* (Odontoceti), skeleton; from Kellogg 1927. (I) *Schizodelphis longirostris* (Odontoceti), skeleton; from Abel 1931. (J) *Saghacetus osiris* (Archaeoceti), skeleton; from Stromer 1908.

2000 is the gradual introduction of stem- and crown-group terminology into cetacean taxonomy and phylogeny, although this approach is not yet used widely.

Cladistic analyses abound, particularly for the Neoceti, using variable combinations of modern anatomy, molecules, and fossils. Molecular phylogenies give a fairly consistent higher level pattern which is reflected in some but not all morphological cladograms. Contradictory cladograms are inevitable, because many clades are sampled poorly in terms of quality of specimens, number of species, and spectrum of crown-to-stem species. Few analyses of Neoceti agree on, e.g., the number of suprageneric clades and their content. There are implications for crown- and stem-group nomenclature, sister-group relationships, and the known vs predicted times of origins for genera and families. The use of new suprageneric clades for each new rearrangement of often long-known and sometimes fragmentary taxa, without adding major new data from revealing new specimens, is a dubious advance. Where possible, the summary below uses “traditional” family names to convey current understanding.

A. Archaeoceti

Knowledge of basal whales has expanded dramatically since 1980, giving new insights into phylogeny, ecology, and distribution (Gingerich, 2005). For many years, basal archaeocetes were known only from *Protocetus atavus* (Mokattam Formation, Middle Eocene, ~46.0 Ma; Egypt-Tethys) (Kellogg, 1936). Since the 1980s, new finds, especially in the eastern Tethys, have greatly increased the diversity of species, genera, and families (Thewissen, 1998; Gingerich, 2005). Basal archaeocetes are placed in the Pakicetidae, typified by the small *Pakicetus inachus*, from non-marine redbeds of the Kuldana Formation (49–49.5 Ma), Pakistan. Skull structure indicates limited underwater hearing capabilities, and the teeth are simpler than those of many later forms. *Pakicetus* has been cited as evidence that the earliest cetaceans radiated slowly in productive shallow waters of the Tethys seaway between Asia and India. The fragmentary jaw of *Himalayacetus subathuensis* from India has been used to push the pakicetid (and cetacean) record back to approximately 53.5 Ma. Isotopes from *Himalayacetus* indicate marine foraging habits, but other pakicetids were probably fresh water (Clementz *et al.*, 2006). Other pakicetids include *Ichthyolestes* and *Nalacetus*, also from the eastern Tethys. It was long thought that pakicetids arose from the terrestrial artiodactyl group Mesonychia, but molecular recognition of the hippopotamus as the sister taxon to Cetacea called mesonychid links into question. Later studies have supported links with hippopotamus, with small deer-like raoullids, and still with mesonychids (Geisler and Uhen, 2003; O’Leary and Gatesy, 2007; Thewissen *et al.*, 2007).

The family Protocetidae, now expanded beyond *Protocetus*, is an Early to Middle Eocene grade for species in which the skull has an enlarged supraorbital shield, the mandible has a large mandibular foramen, and hindlimbs are reduced. Protocetids lack the complex teeth and pterygoid sinuses of younger cetaceans. Many protocetids have been named since 1990, with 14 genera in three subfamilies forming a comb-like sequence of genera rather than a single clade. Some protocetids occur in the western Tethys to western central Atlantic, including the large *Eocetus* (Egypt, North Carolina), *Pappocetus* (Nigeria; North Carolina) *Natchitochia* (Louisiana), apparently *Protocetus* (Texas), and *Carolinacetus* (South Carolina). Protocetids have a high diversity in the eastern Tethys, judging from the range of teeth and skulls from Pakistan and India. *Babiacetus* (~43.5 Ma) is known from teeth and jaws, while partial skulls represent the slightly older (45.5–46-Ma) *Gaviacetus*, *Takracetus*, and

Indocetus. *Rodhocetus kasrani* (Domanda Formation, 46–46.5 Ma; Pakistan) has a skeleton strikingly intermediate between that of land mammals and later whales (Gingerich, 2005). Cetacean features include the short neck vertebrae and more-posterior vertebrae adapted for dorsoventral oscillation, but *Rodhocetus* retains a femur and sacrum. *Rodhocetus* is from deep- rather than shallow-water deposits, implying early colonization of offshore habitats. Another protocetid, *Georgiacetus vogtensis* (McBean Formation, 40–41 Ma; Georgia) shows derived features in the cheek-teeth, an incipient pterygoid sinus in the skull base, and a reduced link between sacrum and pelvis, all of which presage features seen in the more-crownward Basilosauridae.

Two other rather specialized archaeocete families are reported only from the Early and Middle Eocene of the eastern Tethys (Thewissen, 1998). Firstly, *Ambulocetus natans* (Kuldana Formation, 48–49 Ma; Ambulocetidae) includes a substantially complete skeleton with a long-snouted skull and well-developed fore- and hind limbs. *Ambulocetus* perhaps swam using pelvic paddling and dorsoventral undulations of the tail, comparable in style to some modern otters. A crocodile-like mode of predation in water is possible, but locomotion on land was probably clumsy. Secondly, the family Remingtonocetidae includes specialized long-snouted Middle Eocene species of *Remingtonocetus* and four other genera, known from at least partial skulls (43.5–~45 Ma). Despite previous suggestions, remingtonocetids are unrelated to odontocetes.

Basilosaurids, from the later Middle and Late Eocene, ranged well beyond the Tethys. Opinions differ as to whether there is one family (with two subfamilies, Basilosaurinae and Dorudontinae), or two families, based around *Basilosaurus* and *Dorudon*. These archaeocetes are typified by the 15 m long *Basilosaurus cetoides*, first described, and named as a fossil reptile, from Louisiana (Jackson Formation, Late Eocene, 36–~39 Ma; western North Atlantic; Kellogg, 1936). The large size of *Basilosaurus*, and its elongate vertebrae, are specialized features used to recognize a clade Basilosaurinae. Also included is *Basilosaurus isis* (~39 Ma; Egypt, central Tethys), which has small but functional hind limbs of ungulate-like character (Gingerich, 2005). Large later Eocene archaeocetes, presumably basilosaurines, have been reported from scattered localities worldwide (e.g., Northeastern Atlantic, proto-Southern Ocean, Southwest Pacific and eastern Tropical Pacific), indicating a wide range for Cetacea in Eocene time.

The second subfamily of basilosaurids, the Dorudontinae, is a grade which includes smaller, more generalized and somewhat dolphin-like species of *Dorudon*, *Saghacetus*, and others. The genera are rather similar to one another, and are diagnosed on size, tooth form, and limb form. The typical species *D. serratus* is fragmentary, but other dorudontines include some magnificent fossils (e.g., *Dorudon atrox*, Birket Qarun Formation, 39–40 Ma; Egypt; Uhen, 2004). The small *Saghacetus osiris* (Fig. 2j) ranges into the latest Eocene, Priabonian, or 33.7–37.0 Ma (Gingerich, 2005), and thus overlaps in age with the oldest of the Neoceti. The formally named dorudontines are from the Tethys and western Central Atlantic, but fragmentary late middle Eocene specimens from New Zealand indicate an early geographic spread.

Basilosaurids differ from more basal archaeocetes in having cheek-teeth with complex denticles, and expanded basicranial air sinuses. These features, which imply more sophisticated feeding and hearing capacities, link basilosaurids closely with early odontocetes and mysticetes. Some dorudontines have been identified as sister taxa to the Odontoceti + Mysticeti (Uhen, 2004; Gingerich, 2005), while basilosaurines seem too specialized, in terms of large size and elongate vertebral bodies, to be directly ancestral to living cetaceans.

Fragmentary Oligocene fossils with archaeocete-like features, e.g., *Kekenodon onamata* (New Zealand, Kokoamu Greensand, Late Oligocene, 27–~28 Ma; Kekenodontidae), have been known since the 1800s. For a while, such animals were thought to be basal toothed mysticetes. By 2004, it was apparent that the *Kekenodon*-like animals are indeed archaeocetes in Kellogg's classical sense; they fall cladistically between dorudontines and the Neoceti. *Kekenodon* and unnamed New Zealand specimens occur in the same late Oligocene strata as early crown Mysticeti and Odontoceti.

B. Mysticeti

Since the 1960s, the fossil record of mysticetes has expanded to reveal diverse toothed and toothless Oligocene species which effectively “bridge the gap” between archaeocetes and baleen-bearing crown Mysticeti. The latter is the clade containing extant rorquals (Balaenopteridae), right whales (Balaenidae) and the more enigmatic gray whale (Eschrichtiidae) and pygmy right whale (Neobalaenidae). The crown clade is conceptually different from group Chaeomysticeti, or toothless baleen whales (Mitchell, 1989). This summary reviews families: at crown level, the Balaenopteridae, Balaenidae, Eschrichtiidae, and Neobalaenidae, and for the fossil record, Aetiocetidae, Llanocetidae, Mammalodontidae, Janjucetidae, Cetotheriidae, Diorocetidae, Aglaocetidae, Pelocetidae, Eomyesticidae, and Cetotheriopsidae. Mysticetes, fossil and living, are generally considered filter feeders, although feeding mode is contentious for some toothed groups.

Pivotal in discussion of mysticete origins is *Aetiocetus cotylaleus* (Aetiocetidae; Yaquina Formation, Late Oligocene) from Oregon. Initially, this small cetacean was identified as an archaeocete because it has teeth, but other features, including the flattened triangular rostrum, indicate that it is an archaic mysticete. Aetiocetids are moderately diverse in their reported North Pacific range, and include species of *Chonecetus* and *Morawanocetus* from Japan (Barnes *et al.*, 1995) and perhaps the fragmentary early Oligocene (~32 Ma) *Willungacetus* of Australia. From Victoria, on the margins of the proto-Southern Ocean, are two other notable toothed species each in its own family: the short-snouted *Mammalodon coliveri* and *Janjucetus hunderi* (about Oligocene–Miocene boundary, 23–~24 Ma; Mammalodontidae and Janjucetidae; Fitzgerald, 2006). *Mammalodon* and *Janjucetus* show some specialized features that are highly disparate from other mysticetes, such as tiny skull size, rostrum remarkably shorter than the cranium, big orbits, and prominent robust occluding teeth. These animals are relicts that represent basal Mysticeti. It is debatable how their structure and inferred habits, including raptorial macrophagy, truly represent the early stages of mysticete history. Perhaps *Mammalodon* and *Janjucetus* were highly specialized, pedomorphic, geographically restricted forms that lived in extreme marginal settings in isolated seas not used by contemporaneous crown Mysticeti and Odontoceti, having abandoned the filter-feeding habits otherwise typical of mysticetes.

The oldest reported archaic toothed mysticete is *Llanocetus denticrenatus* (Llanocetidae), named from a fragmentary toothed jaw and a brain cast from the La Meseta Formation, latest Eocene (~35 Ma) of Seymour Island, Antarctica (Mitchell, 1989). A nearly complete large skull is now known; the skull was originally about 2 m long, and has a broad rostrum with widely spaced denticulate teeth that occluded with the lower teeth. The exact role of the teeth in feeding is uncertain, but it is possible that spaces between the teeth were filled with proto-baleen. The posterior of the *Llanocetus* skull is superficially quite like that of basilosaurid archaeocetes. A smaller

Llanocetus-like toothed mysticete is known from the basal Oligocene of New Zealand.

Remains of toothless baleen-bearing mysticetes, the Chaeomysticeti of Mitchell (1989), are common in Miocene and younger strata worldwide. Whitmore and Sanders (1977) reported few Oligocene baleen whales, but since 1977, the late Oligocene record back to 28–29 Ma has expanded significantly. Many fossils, particularly those older than late Miocene (~12 Ma) are more archaic than living baleen whales, and have long been placed in the family Cetotheriidae (Fordyce and Muizon, 2001). Cladistic analyses allow the traditional use of a paraphyletic/ polyphyletic grade Cetotheriidae to be abandoned (Bouetel and Muizon, 2006; Steeman, 2007). Cetotheres are typified by the small Middle Miocene (12–13 Ma) *Cetotherium rathkii* from Ukraine (Paratethys), which differs from living mysticetes in that the upper jaw (rostrum) thrusts back into bones of the braincase with a sharp narrow triangular apex, almost obscuring the nasal bones (Fig. 2a). The related early Pliocene *Herpetocetus sendaicus* (Yushima Formation, Japan) has a similar rostral structure and, further, shows the strange superficially reptilian jaw articulation that led Van Beneden to propose *Herpetocetus* in 1872. *Piscobalaena*, *Nannocetus*, and *Metopocetus* (Fig. 2d) are also in the extinct clade Cetotheriidae, which ranges from middle Miocene to early Pliocene (4–16 Ma) (Bouetel and Muizon, 2006; Steeman, 2007). It is not clear where other named archaic mysticetes—former “cetotheres”—belong, or whether the Cetotheriidae lies in the stem Mysticeti, or with gray whale (*Eschrichtius*, Eschrichtiidae) within the crown Mysticeti.

Two other families are reported only from the Oligocene, which was generally a time of great diversification of Mysticeti. The Eomyesticidae contains the long narrow-skulled species of *Eomyesticetus*. Eomyesticetids, including associated skulls and skeletons, are important members of late Oligocene cetacean assemblages from New Zealand; “*Mauicetus*” *lophocephalus* is a widely recognized example. Whether the Cetotheriopsidae, containing *Cetotheriopsis* and *Micromysticetus*, is distinct is debatable; the fossils are too fragmentary to elucidate overall structure and likely lifestyle. Eomyesticetids and cetotheriopsids reportedly form a clade basal to crown Mysticeti (Geisler and Sanders, 2003).

The family Balaenopteridae comprises the fast swimming, gulp feeding, rorquals (*Balaenoptera*) and humpback whale (*Megaptera*). Many fossils have been assigned to the family since the 1800s (Fig. 2b), although there has long been debate on how to distinguish archaic balaenopterids from cetotheres. Cladistic analysis allows crown and stem Balaenopteridae to be differentiated, with the crown group including fossil species in *Parabalaenoptera* and nominally *Megaptera*; living *Megaptera novaeangliae* is the most basal crown species (Deméré *et al.*, 2005). The oldest crown balaenopterid identified is the late Miocene (~10–11 Ma) “*Megaptera*” *miocaena*, which is notably younger than some of the crown divergence times predicted from molecular phylogenies (Sasaki *et al.*, 2005). There are many records of later Miocene, Pliocene and Pleistocene *Balaenoptera* fossils, but none has resolved the time of origin of any one living species. The middle Miocene *Eobalaenoptera* is of uncertain position, not clearly the oldest known balaenopterid. A unifying feature of the crown balaenopterids is the distinctive structure above the orbits on the skull, where the frontal bone above the eye is depressed to house the large muscles that close the lower jaw.

Cladistic studies disagree on which fossil genera are closer to crown Balaenopteridae than to other family clades of mysticetes. Perhaps some genera, including former “cetotheres,” belong in the Balaenopteroidea, as extinct clades: the Diorocetidae (*Diorocetus* and others), Aglaocetidae (*Aglaocetus* and others) and Pelocetidae

(*Pelocetus* and others) (Steehan, 2007). These are mostly animals with skulls 1 to 2 m long, representing species comparable in size to minke whale. Fossils come from Miocene and Pliocene localities mainly around Europe and the Americas. It is not clear that such fossils deserve separate family status, given the highly variable nature of type or reference material, and reliance on earbones to define clades. Also debatable is the position of the Late Oligocene (~24 Ma) *Mauicetus*, a minke whale-sized gulp-feeder: the most basal genus in the Balaenopteroidea (Steehan, 2007) or, alternatively, a stem balaenopterid? Other *Mauicetus*-like fossils from New Zealand are older, at approximately 26 Ma, emphasizing the antiquity of rorquals.

The living gray whale *Eschrichtius robustus* has a fossil record extending about 0.5 M years into the Pleistocene. Historic gray whale bones indicate that these animals occurred in the North Atlantic, where they were probably exterminated by hunting. Of older putative gray whales, a fragmentary, but convincing, Late Pliocene eschrichtiid is known from Teshio, Japan (Ichishima *et al.*, 2006). *Archaeschrichtius* (Italy, late Miocene) is based on a mandible. On the origin of eschrichtiids, morphological cladistic analyses variously place *Eschrichtius* close to balaenids, to balaenopterids and, unexpectedly, to cetotheres.

Right whales are known from many fragmentary fossils (Fig. 2c), but few that include informative material such as skulls (Bisconti, 2005). Modern right whales are large, slow moving, skim feeding mysticetes which are skeletally so conservative as to have long been placed in one genus, *Balaena*, although *Eubalaena* is now used for other than bowhead whale. The oldest named fossil right whale is the early Miocene *Morenocetus parvus* (~20 Ma) from Patagonia, but an older unnamed stem balaenid has been reported from New Zealand (Kokoamu Greensand, ~28 Ma). Perhaps *Morenocetus* is cladistically closer to *Balaena* than to *Eubalaena*, with the crown Balaenidae originating before approximately 20 Ma (Bisconti, 2005); an early divergence, approximately 17 Ma (Sasaki *et al.*, 2005), is predicted for the molecular split between *Balaena* and *Eubalaena*. Such divergence times imply extremely slow structural evolution in living right whales. Notable younger fossil balaenids include the small early Pliocene (4–5 Ma) *Balaenella brachyrhynchus* (Kattendijk Sand, Belgium), and the contemporaneous large *Balaena ricei* (early Pliocene, Yorktown Formation, Atlantic Coastal Plain).

There is no firm published fossil record of Neobalaenidae to indicate the origins of the enigmatic pygmy right whale, *Caperea marginata*. *Caperea* has long been presumed to belong close to the Balaenidae, a position supported by most anatomical cladistic studies (Steehan (2007)). However, molecular analyses generally place *Caperea* closer to *Eschrichtius* and balaenopterids. The skull of *Caperea* is quite disparate from balaenids, suggesting that the molecular relationships should be considered seriously. Useful fossils, however, are lacking.

C. Odontoceti

Odontocetes are much more diverse in terms of taxa (families, genera) and structure than are mysticetes. Living odontocetes all appear to be echolocating raptors, and a similar lifestyle is inferred for most extinct species. Late Eocene odontocetes have been reported from Washington State, but are not formally named. The oldest named odontocete is the small *Simocetus rayi* (Simocetidae; Alsea Formation, Oregon; Fordyce, 2002), of early Oligocene age (perhaps 32 Ma). The skull in *Simocetus* is generally archaic, but the animal has a highly specialized downward arched upper jaw (rostrum) with a toothless

tip; perhaps this was a sediment-grubbing slurry-feeder. Facial structures suggest that *Simocetus* could echolocate. Basicranial features hint at links with enigmatic species of *Squaloziphius* and *Argyrosetus* (both provisionally Eurhinodelphinidae, within crown Odontoceti). *Simocetus* clearly is not close to the late Oligocene *Agorophius pygmaeus* (Cooper Marl, Late Oligocene, >24 Ma, South Carolina; Whitmore and Sanders, 1977). *Agorophius* typifies the Agorophiidae, a family widely used until 1980 as a grade for archaic odontocetes. Where *Agorophius* belongs within the Odontoceti is uncertain for lack of information on the species, as the holotype skull is lost, and the one useful published figure is a lithograph from the 1860s (Fig. 2e). There is no compelling reason to regard the Agorophiidae as a basal clade of odontocetes.

The most basal named odontocete is *Archaeodelphis patrius*, based on a fragmentary skull of uncertain origin and possible Oligocene age. Uniquely, this enigmatic species barely shows evidence of the nasofacial muscles which, in other odontocetes, are implicated in echolocation. Despite its reputedly ancestral position, because its orbit (lacrima) and skull base are somewhat specialized, *Archaeodelphis* is not directly on a lineage leading to living species. Almost as archaic is *Xenorophus*, a bizarre Late Oligocene genus containing one or two species with specialized facial structures superimposed on an archaic skull (Whitmore and Sanders, 1977).

Sperm whales (*Physeter macrocephalus*, and *Kogia* spp.) appear to be the most basal living odontocetes. The oldest fossils of *P. macrocephalus*, marking the crown Physeteridae, are geologically young fragmentary specimens of uncertain Pleistocene to possibly latest Pliocene (~2 Ma). Skulls of stem physeterids are rare but informative; they are pivotal in cladistic studies (Bianucci and Landini, 2006), and help to recognize the subfamilies Physeterinae, Hoplocetinae, and Aulophyseterinae. Early Miocene sperm whales, such as *Diaphorocetus* and *Idiorophus* from the South Atlantic, show the characteristic basined facial bones of later sperm whales, while features of the brain case link them firmly with other odontocetes. Many named fossil sperm whales are based on isolated teeth which, however, reveal little about the actual animal or about relationships. The fragmentary *Ferecetotherium kelloggi* is reportedly late Oligocene (23 + Ma; Maikop Formation, Paratethys-Caucasus), providing the earliest record for stem physeterids. There is no reliable fossil evidence for the age of the crown *Kogia* (living dwarf and pygmy sperm whales, variously termed Kogiidae or Kogiinae), but molecular studies on *K. sima* imply crown origins well before 4 Ma (Chivers *et al.*, 2005). The oldest stem kogiids are later Miocene species from the eastern Pacific, including *Praekogia* from Isla Cedros (Almejas Formation, ~6 Ma), and the large narrow-skulled *Scaphokogia* from the Pisco Formation of Peru (Muizon, 1988a). The *Kogia* clade probably arose amongst stem physeterids/physeteroids.

Fossil beaked whales, Ziphiidae, are reported widely as isolated and worn rostra ("beaks" or upper jaws) and rarely as more complete skulls from unconformities, and from modern oceanic phosphate sediments (Bianucci *et al.*, 2007). Such fossils may be reworked from older sediments, and difficult to date. The oldest well-dated ziphiid is the middle Miocene (13–15 Ma) *Archaeoziphius microglenoides*, which is close to the crown genera *Berardius* and *Tasmacetus* (Lambert and Louwye, 2006). Like most modern species, crown-ziphiid fossils have high crania and robust rostra with reduced teeth. Anatomical cladistic studies recognize the subfamilies Hyperoodontinae, Ziphiinae and Berardiinae, all with both living and extinct species. There are no firm reports of stem Ziphiidae. The widely discussed *Squaloziphius emlongi* (Clallam Formation, Oligocene–Miocene, ~23 Ma, Washington; Muizon, 1991) is not clearly a beaked whale, and other ancient

supposed ziphiids (e.g., *Notocetus*) are platanistoids. Perhaps the most unusual occurrence of a fossil cetacean is that of a large ziphiid in fresh water Miocene strata of Kenya.

The content and relationships of the Platanistoidea are contentious. Is the crown clade monotypic (*Platanista* only), or polytypic (all living “river dolphins”), and do platanistoids lie between physeterids and ziphiids or nearer to delphinoids (Muizon, 1991; Nikaido *et al.*, 2001; Geisler and Sanders, 2003)? This summary views Platanistoidea as comprising Platanistidae and diverse extinct relatives: Squalodelphinidae, Waipatiidae, Squalodontidae, Allodelphinidae, and the less certainly recognized Proqualodontidae, Patriocetidae and Dalpiazinidae. Geisler and Sanders (2003), however, excluded most of the latter from Platanistoidea and also from crown Odontoceti.

Crown Platanistidae contains only the bizarrely disparate riverine *Platanista gangetica* from India and Pakistan, with no fossil record. Notable stem platanistids are known, all Miocene (6–~16 Ma) long-beaked shallow marine forms from the western North Atlantic and Paratethys (Barnes, 2006): *Prepomatodelphis*, *Zarhachis*, *Pomatodelphis*. These dolphins have facial crests which place them close to *Platanista*, but because of the dorsoventrally flattened jaws, Barnes classified them in the Pomatodelphininae. The record suggests that *Platanista* invaded fresh water late in its history.

Muizon (1991) recognized the extinct Squalodelphinidae as sister taxon to the Platanistidae. Squalodelphinids are typified by the long-beaked *Squalodelphis* (Early Miocene, Mediterranean); they have heterodont teeth and asymmetrical crania, but no facial crests. Southern squalodelphinids include several species of *Notocetus* from the latest Oligocene–early Miocene (18–~24 Ma; New Zealand, Patagonia) bordering the Southern Ocean. A small heterodont marine dolphin with a slightly asymmetrical skull, *Waipatia maereuhenua* (late Oligocene, ~25 Ma; New Zealand) typifies a late Oligocene–early Miocene family Waipatiidae, basal to the Platanistidae + Squalodelphinidae (Fordyce, 1994). As with other early odontocetes, *Waipatia* shows skull features which indicate an ability to echolocate. Other previously enigmatic odontocetes, such as *Sulakocetus* and *Microcetus* from the Tethys–North Atlantic, also may be waipatiids.

Probably the best recognized of the extinct platanistoids are the shark-toothed dolphins, Squalodontidae. These are geographically widespread medium to large odontocetes with long rostra and conspicuous, large, triangular heterodont teeth (Rothausen, 1968) (Fig. 2f, g); there are no comparable living long-jawed robust-toothed raptors. Squalodontids were long considered central in the phylogeny of living odontocetes, but recently they have been recognized as platanistoids (Muizon, 1991). Squalodontids are typified by *Squalodon gratehupi* (Early Miocene, ~20 Ma, eastern North Atlantic) (Fig. 2f). Other species with more-complete skulls, from both northern and Southern Hemisphere locations, are important in diagnosing the group. The squalodontids include at least *Squalodon* and *Phoberodon*, but exclude many taxa, originally based on teeth, now known to belong elsewhere including Mysticeti and Archaeoceti. Notable undescribed late Oligocene species are known from South Carolina and New Zealand, while the youngest squalodontids are late middle to early late Miocene (10–12 Ma, Rothausen, 1968). It is not clear whether the robust broad-beaked *Prosqualodon* (latest Oligocene–early Miocene (18–~24 Ma, marginal Southern Ocean) deserves its own family, Prosqualodontidae, or belongs in Squalodontidae. Likewise, the late Oligocene *Patriocetus*, with a wide, almost shelf-edged, rostrum, has been placed in a monotypic Patriocetidae but equally could be a disparate squalodontid. *Patriocetus* lived in isolated waters of the Austrian Paratethys.

The Allodelphinidae encompasses the extinct marine *Allodelphis* (Jewett Sand, Early Miocene, ~20 Ma; California) and a few other Northeast Pacific species as young as late Miocene. Allodelphinids are basal platanistoids with a unique premaxillary structure (Barnes, 2006). The most enigmatic of the reputed platanistoids is the extinct Dalpiazinidae of Muizon (1988b), established for the early Miocene fragmentary *Dalpiazina* [*Acrodelphis*] *ombonii*. Formerly, this and other Miocene species with dorsoventrally flattened rostra, reminiscent of *Pomatodelphis* (discussed earlier), were placed in the widely cited Acrodelphidae which, however, is no longer used because of questionable typology.

Species in the extinct Eurhinodelphinidae are small- to medium-sized dolphins with dramatically long rostra on which the long premaxillae are toothless (Fig. 2i). Species of *Schizodelphis*, *Xiphiacetus* and others were significant members of early, middle and perhaps late Miocene cetacean faunas in the Atlantic, and the family ranged into the Pacific (Lambert, 2005). There appear to be no modern ecological equivalents. The early record is patchy; Oligocene forms comprise the poorly known *Iniopsis* (a fragmentary skull, Paratethys–Caucasus) and an unnamed Late Oligocene species from lake strata of central Australia which marks an early invasion of fresh waters. Relationships are uncertain; eurhinodelphinids could lie with delphinoids, with platanistoids, with ziphiids, or between physeteroids and other crown Odontoceti (Muizon, 1991; Geisler and Sanders, 2003; Lambert, 2005). Another extinct group, the monotypic early Miocene Eoplatanistidae, is close to eurhinodelphinids.

The remaining odontocetes include the ocean dolphins (Delphinidae) and close relatives Phocoenidae and Monodontidae. The exact relationships of other dolphin groups are more contentious; Muizon (e.g., 1988c) placed all in the Delphinida, as followed here. Dolphins—(Delphinida) generally dominate odontocete fossil assemblages from the late Miocene on. Most early or archaic fossil dolphins have been placed in the Kentriodontidae, variously used as a grade or clade. Kentriodontids are geographically widespread small to medium-sized long-beaked animals with more or less symmetrical skulls and near-homodont teeth. *Kentriodon* includes *Sotalia*-sized dolphins (Fig. 2h) that were widespread in the early Miocene, as indicated by fossils from the northwest Atlantic, and around the Pacific. Many other genera (e.g., *Delphinodon*, *Tagicetus*, *Pithanodelphis*, *Atocetus*) have been reported from northern and a few southern localities. Rare *Kentriodon*-like fossils are known from the late Oligocene (>23 Ma). The oldest alleged Delphinidae are late Miocene (5–11 Ma), but it seems that no well-dated, well-preserved, named delphinid is older than Pliocene. Nevertheless, stem delphinids presumably evolved by 10–11 Ma, given the known record of their likely sister taxon Phocoenidae. Named delphinids are major components of, especially, Pliocene assemblages (2–5 Ma). For example, fossils from northern Italy (Bianucci, 1996) include skulls, teeth, earbones referred to *Stenella*, *Tursiops*, *Orcinus*, *Hemisyntrachelus*, and *Astadelphis*. Fossil delphinids include some unusual morphotypes, such as the Antarctic Pliocene *Australodelphis*, which is toothless and convergent in form with beaked whales.

Like delphinids, porpoises (Phocoenidae) and white whales (Monodontidae) range back to the late Miocene. Phocoenids have a better record than monodontids, with the oldest stem taxon, *Salumiphocaena stocktoni*, from the eastern North Pacific (Monterey Formation, 10–11, California; Barnes, 1985). *Salumiphocaena* shows characteristic phocoenid features, such as premaxillary eminences and a frontal boss. Rosel *et al.* (1995) predicted an origin for phocoenids at 12–16 Ma, and suggested a radiation for most crown species

2–3 Ma. There is no older record of well-dated firmly identified crown porpoises, and the diverse extinct genera, such as *Piscolithax*, *Lomacetus*, and *Haborophocoena*, are unrevealing about predicted crown origins. However, the Mio-Pliocene *Piscolithax* is a stem phocoenid, originating before the crown radiation (Fajardo-Mellor *et al.*, 2006). Judging from fossils, most of phocoenid history occurred in the north to eastern tropical Pacific.

A meager record of monodontids gives little clue about crown or stem origins. Fossils of the living species of *Delphinapterus* and *Monodon*, from mid-latitude North Atlantic shores, have not been reported firmly to be older than Pleistocene, 2 Ma, and most are likely late Pleistocene, less than 0.5 Ma. In the Atlantic, an early Pliocene *Delphinapterus* occurs in North Carolina (Yorktown Formation, ~4.5 Ma; Whitmore, 1994). The archaic (presumed stem) monodontid *Denebola brachycephala* is from Isla Cedros, equatorial eastern Pacific (Almejas Formation, late Miocene, >5 Ma), and other unnamed late Miocene and Pliocene monodontids have been reported from the Pacific coast of North America and Peru (Barnes, 1984).

Two extinct families of presumed delphinoids are reported from the late Miocene-early Pliocene of the eastern Pacific. Barnes (1984) based the Albireonidae on the porpoise-like *Albireo whistleri*, from Cedros Island. Two species of tusked “walrus whales” (*Odobenocetops*: *Odobenocetopsidae*) are from the Pisco Formation, Peru (Muizon and Domning, 2002). The latter are uncannily like the living walrus, *Odobenus*, in skull form. Some cetologists have doubted that *Odobenocetops* is a cetacean because of its highly disparate form. Neither genus, *Albireo* or *Odobenocetops*, has been subject of detailed published cladistic analysis; they have been linked with Phocoenidae and Monodontidae respectively.

Three families of “river-dolphin” are sister taxa to the Delphinoidea in both anatomical and molecular phylogenetic analyses: the Pontoporiidae + Iniidae, and more basally, the Lipotidae. Each family is represented by a single living species with no noteworthy fossil record, but each is known from stem representatives. Stem pontoporiids occur in freshwater strata in South America and Mio-Pliocene marine rocks bordering the eastern North Pacific and the North Atlantic. The small short-beaked *Brachydelphis mazaesi* (Pisco Formation, 12–~15 Ma) from Peru is so disparate that it has been put in its own subfamily (Pontoporiidae: Brachydelphininae; Muizon, 1988a) related to the long-beaked Peruvian marine fossil *Pliopontos littoralis* (4–~5 Ma), the large marine fossil *Pontistes rectifrons*, and the living paralic-neritic franciscana (*Pontoporia blainvillei*). Early Pliocene (~4.5 Ma) *Pontoporia*-like fossils are known from North Carolina (Yorktown Formation), and there are significant late Miocene pontoporiids from Europe (Pyenson and Hoch, 2007).

In the early 1900s, many fossils were placed in the family Iniidae, with the living *Inia geoffrensis*, but most of these belong elsewhere. Stem iniids (the Ischyrorhynchinae) include the South American freshwater *Ischyrorhynchus* and *Saurodelphis* (late Miocene, “Mesopotamiense” horizon, >5 Ma; Cozzuol, 1996), and the fragmentary marine *Goniodelphis hudsoni* (Early Pliocene, 4–5 Ma) from Florida. Stem iniids must have arisen with their sister taxon Pontoporiidae; iniids thus have a significant ghost lineage at least back to approximately 12–15 Ma.

The baiji, *Lipotes vexillifer*, apparently now extinct, was a riverine descendant of a marine lineage known from long-beaked species of *Parapontoporia* from Isla Cedros (Almejas Formation, ~5 Ma) and southern California (San Diego Formation, ~2–3 Ma) (Barnes, 1984; Pyenson and Hoch, 2007). According to Muizon (1988c), neither genus is close to *Pontoporia*. The problematic *Prolipotes*, based on a

fragment of possibly Miocene lower jaw from freshwater deposits in China, is too incomplete to confirm a relationship with *Lipotes*.

Cetacean Life History

SUSAN J. CHIVERS

A species' life-history strategy is defined by parameters that describe how individuals allocate resources to growth, reproduction, and survival. The allocation of resources presumably results from natural selection maximizing the reproductive fitness of individuals within a species. Biologists studying life-history strategies collect data to answer questions about how long individuals of a species live, the ages at which they become sexually mature and first reproduce, and where and when they travel to find sufficient food to survive (Fig. 1). In search of answers, these biologists may be found in a laboratory estimating an individual animal's age, at a computer modeling growth rates, or at sea observing animals in their natural habitat.

Among cetacean species, the life-history strategies are diverse and differ markedly between the two cetacean suborders: the baleen whales (suborder Mysticeti) and the toothed whales (suborder Odontoceti). This diversity demonstrates the range of successful strategies that have evolved and enable cetaceans to live in a completely aquatic environment as well as the influence of their phylogeny on adapting them to a particular niche. Reviewing the strategies of species within each suborder reveals that the baleen whales share more similar life-history characteristics. All species are large and long lived, and all of the baleen whales, except the bowhead whale (*Balaena mysticetus*) and Bryde's whale (*Balaenoptera edeni*), make long-range annual migrations between breeding grounds in tropical waters and feeding grounds in temperate or polar waters. However, the life-history patterns observed among odontocetes are more varied. These species range in size from the small, relatively short-lived (<24 years) harbor porpoise (*Phocoena phocoena*) to the large, relatively long-lived (>70 years) sperm whale (*Physeter macrocephalus*) and occupy diverse habitats, ranging from pelagic and coastal ocean waters to estuarine and fresh waters.

The life-history strategies for relatively few cetacean species are known in detail. Most of the biological data available for baleen whales were collected during whaling operations, whereas odontocetes have been studied from animals incidentally taken during fishery operations, taken in directed fisheries, found stranded on the

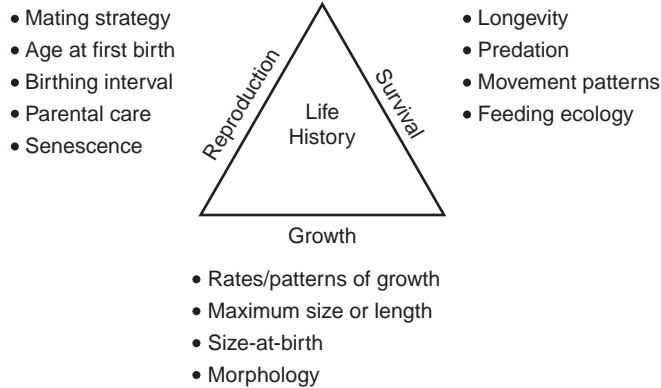

Figure 1 Studies of cetacean life-history integrate data describing an individual animal's allocation of resources to growth, reproduction, and survival. Compiling data from many individuals allows the parameters listed next to each category to be estimated, which in turn describes the growth, reproduction, and survival strategies of a species. Life-history data may be collected by observing individual animals in directed photo-identification, tagging, marking or telemetry studies, or by necropsying animals to collect teeth for aging, body length measurements for quantifying growth rates, gonads for determining reproductive condition, and skin for estimating individual relatedness or determining "local" adaptations using molecular genetic techniques.

beach, or observed in the wild or in captivity. Among the most well-known cetacean life histories are the humpback whale (*Megaptera novaeangliae*), fin whale (*B. physalus*), common bottlenose dolphin (*Tursiops truncatus*), and killer whale (*Orcinus orca*). Three of these species—the humpback whale, common bottlenose dolphin, and killer whale—have each been the subject of long-term studies, which have provided unique data about the natural variability of a species' life-history strategy based on the observed demographics of individual animals. Our knowledge about the life-history strategies of cetacean species is still incomplete, particularly for rarely encountered species, but our knowledge is expanding rapidly as more specimens are collected and new techniques are developed.

I. Characteristics of Cetacean Life Histories

Although diverse life-history strategies are exhibited by cetacean species, there are a few common characteristics that are likely necessary adaptations to live successfully in a completely aquatic environment. All species give birth to single, large, and precocial young. The presence of multiple fetuses or multiple births has been documented only rarely, and there are no known cases of successfully reared multiple offspring. Gestation times are approximately a year. Among the baleen whales, the estimates for gestation range from 10 to 12 months, and among the odontocetes, estimates range from 10 months for the harbor porpoise (Gaskin *et al.*, 1984) to 14 or 15 months for the sperm whale (Best *et al.*, 1984) and 17 months for the killer whale (Olesiuk *et al.*, 1990; Baird, 2000). Most of the small delphinids (e.g., *Stenella* spp.) have gestation periods of 11 to 12 months (Perrin and Reilly, 1984). The length of the gestation period in part balances the cost of producing a large neonate. Additionally, all cetaceans are relatively long lived. Among baleen whales, estimates of longevity range from 6 decades for the minke whale (*B. acutorostrata*) up to 10 decades for the fin whale and more than

10 decades for the bowhead whale, while among odontocetes, estimates of longevity range from approximately 2 decades for the harbor porpoise up to 7 decades for the sperm whale. Bowhead whales are the cetacean species known to live the longest, and a weapon fragment recovered from a whale in 2007 indicated that these whales may live between 115 and 130 years. Additional generalizations about life-history strategies are presented in Section III.

II. Methods of Studying Life History

Longitudinal and cross-sectional studies of cetacean species have provided data necessary for understanding their life-history strategies. Longitudinal studies are rare but valuable, because they provide unique data on the variability of individual demographics. Three species, the humpback whale (Clapham, 1996), the common bottlenose dolphin (Wells and Scott, 1990), and the killer whale (Olesiuk *et al.*, 1990), have been the subject of ongoing studies that originated during the 1970s. These studies are possible because individuals are relatively accessible and easily distinguishable in the field by natural markings. These studies have quantified individual variability in reproduction and survival through time and have provided unique insights into the species' life-history strategy by incorporating observations of the species' social behavior and ecology. However, most of our knowledge about cetacean life-history strategies is the result of cross-sectional studies. In these studies, data are collected from individual animals sampled primarily from directed or incidental takes. The primary advantage of these studies is that a complete suite of morphological and biological data can be collected, which allows explicit determination of reproductive and physical maturity as well as an estimate of age. Estimates of age for most cetaceans are made from the layering patterns evident in the ear plugs or ear bones of baleen whales (Lockyer, 1984; Christensen, 1995) and in the teeth of odontocetes (Perrin and Myrick, 1980). One exception is bowhead whales, which have been aged using an aspartic acid racemization technique and the recovery of weapon fragments from carcasses (George *et al.*, 1999). Accurate determination of reproductive maturity in both sexes requires examination of the gonads. In females, the presence of one corpus or more in the ovaries indicates sexual maturity, and in males, the presence of spermatazoa and large seminiferous tubules in histologically prepared testes tissue indicates sexual maturity (Perrin and Reilly, 1984). Physical maturity is determined in both sexes by examining the vertebral column for evidence of fusion. That is, when the vertebral epiphyses are fused with the centrum, an animal is considered physically mature.

Life-history studies are designed to collect data on body size, age, and reproductive and physical maturity from many individuals to estimate parameters that characterize a species' allocation of resources to growth, reproduction, and survival. Estimated parameters may include age-specific growth and pregnancy rates, the average age at attainment of sexual maturity, calving interval and longevity. Age is the primary independent variable for all studies, because age explicitly demonstrates the tradeoff in resource allocation to growth and reproduction during an individual animal's life. The expected pattern of resource allocation from birth through attainment of sexual maturity is primarily for growth and then for reproduction once sexual maturity is attained. Also the probability of an individual surviving to the next age class increases with increasing age after weaning until sexual maturity is attained and then remains high throughout the individual's reproductive years. Data on age-specific growth and reproductive rates, combined with estimates of age-specific survival rates, are essential to comparing and contrasting the life-history strategies of different species.

III. Cetacean Life-History Patterns

The neonates of all cetacean species are relatively large when compared to other mammal species. In fact, neonate size ranges from approximately 29% of the female's asymptotic total body length in most of the baleen whales to between 40% and 48% of the female's length in the odontocetes. The large size of neonates, combined with their ability to swim and grow rapidly immediately after birth, increases their probability of survival. The lactation period for the baleen whales lasts only about 6 months, and the young grow rapidly during that period because the fat content of the milk is high. However, the calves of odontocetes grow more slowly, and the lactation period lasts approximately a year or more. The difference in calf growth rates between the two suborders of cetaceans is probably due to the transfer of energy to the young through the milk. Oftedal (1997) has estimated that the energy output through milk ranges from 0.40 to 1.06 MJ/kg^{0.75} for mysticetes and from 0.09 to 0.17 MJ/kg^{0.75} for odontocetes. For species with a lactation period of more than a year, the additional investment likely further increases the calf's probability of survival by facilitating the learning of social behaviors (e.g., common bottlenose dolphin, short-finned pilot whale, *Globicephala macrorhynchus*).

Patterns of growth differ between the sexes of many cetacean species, resulting in some degree of sexual dimorphism. Both males and females have high growth rates while suckling, but growth slows after weaning and again after reaching sexual maturity. However, the sex that grows largest tends to grow for a longer period of time and may have higher growth rates after weaning. Among baleen whales, females attain lengths that are generally 5% larger than the males. Similarly, among odontocetes, the females are slightly larger than the males in the porpoises and river dolphins. However, for other odontocetes, males are larger than females. Sexual dimorphism is most marked in sperm whales, in which males are 60% larger than females. Among the smaller delphinids, such as the common bottlenose dolphin, pantropical spotted dolphin (*Stenella attenuata*), and common dolphins (*Delphinus* spp.), males are approximately 2–10% larger than females.

The breeding cycle for all cetacean species has three parts: a gestation period, a lactation period, and a resting, or anestrous, period. This cycle is 2 years or more for most cetacean species. The exceptions are the minke whale and harbor porpoise, which can breed annually. The breeding cycle of the blue (*B. musculus*), Bryde's, humpback, sei (*B. borealis*), and gray (*Eschrichtius robustus*) whales includes an 11-month gestation period, a 6- to 7-month lactation period and a 6- to 7-month resting, or anestrous, period for a minimum of a 2-year cycle, while the breeding cycle for the bowhead and right whales (*Balaena glacialis*) is 3 to 4 years starting with a 10- to 12-month gestation period. Furthermore, the breeding season of baleen whales is synchronized with their migration cycle. These species travel long distances to breed in tropical waters. The exceptions are the Bryde's whale and the pygmy Bryde's whale, which spend all year in tropical waters and do not breed synchronously (Lockyer, 1984). Several hypotheses have been proposed for the adaptive significance of the large-scale migrations of baleen whales. Although the phenomenon remains unexplained, hypotheses of increased survival rates for neonates in tropical waters by reducing thermoregulatory demands or the risk of predation by killer whales have been proposed (Corkeron and Connor, 1999).

Similar to other life-history characteristics, the breeding cycle for odontocetes is more variable than that of mysticetes. Porpoises have the shortest breeding cycle, which is approximately 1 year and includes a 10-month gestation. In fact, annual breeding among the porpoises has been well documented for the harbor porpoise. The

Figure 2 Mother and calf pantropical spotted dolphin (*Stenella attenuata*) in the eastern tropical Pacific. Photographed by R. L. Pitman.

smaller delphinid species seem to have 2- to 3-year calving intervals, which include an 11- to 12-month gestation and a 1- to 2-year lactation period. However, the larger odontocetes such as the killer whale, short- and long-finned (*G. melas*) pilot whales, and sperm whale have calving intervals of more than 3 years, which includes a 12- to 17-month gestation period and a 2- to 3-year, or longer, lactation period. Breeding synchrony also varies among odontocetes. Species inhabiting temperate waters like the harbor porpoise have been found to have more synchronous breeding seasons than species inhabiting tropical waters. For example, studies of the pantropical spotted dolphin (Fig. 2) and the striped dolphin (*S. coeruleoalba*), which inhabit tropical waters in the Pacific Ocean, found that young are born throughout the year, although most births occur during the spring and fall (Perrin and Reilly, 1984).

Age at attainment of sexual maturity is delayed in all cetacean species as would be expected for large, long-lived mammals. However, the range of ages is quite broad and reflects the unique set of adaptations that characterize the life-history strategy of each species. The range in age of sexual maturity among the baleen whales is from approximately 4 years for humpback whales to approximately 10 years for the fin, sei, and Bryde's whales (Lockyer, 1984) and to 25 years for bowhead whales (George *et al.*, 1999). Among odontocetes, the range in age at attainment of sexual maturity is about the same as that observed for the baleen whales and seems to be correlated to a degree with longevity and body size. The youngest age at attainment of sexual maturity is 3 years for harbor porpoise, which is the smallest odontocete and is estimated to live approximately two decades (<24 years). However, many of the larger odontocetes reach sexual maturity at ages of 10 years or more and live for four or more decades (Perrin and Reilly, 1984).

Reproductive success varies throughout the life of female cetaceans. Initially, reproductive success is relatively low, peaks several years after the age at attainment of sexual maturity and then declines as the female ages. This phenomenon is also characteristic of large terrestrial mammals and is probably due in part to a tradeoff in costs

between reproduction and growth that must occur because physical maturity is attained several years after sexual maturity and to learning to care for young. Evidence for low reproductive success among newly matured females has been documented in the common bottlenose dolphin and the fin whale. Lower reproductive rates for older females have also been documented in the common bottlenose dolphin as longer interbirth intervals for older females that include a 3- to 8-year lactation period. Postreproductive females with senescent ovaries have been identified in only a few odontocetes, including the short-finned pilot whale (Marsh and Kasuya, 1986) and the pantropical spotted dolphin (Myrick *et al.*, 1985), but senescence has not yet been identified in any of the baleen whales. The adaptive significance of senescence is not yet understood but likely contributes to increased reproductive success. For example, several species that exhibit senescence also have fairly complex social structures (e.g., sperm whale, short-finned pilot whale), and the role of postreproductive females in their societies may be associated with increased survival rates of the young by these females participating in the care of young that are not their own.

IV. Characteristics of Male Life Histories

The life-history characteristics of males are less well known than those of females, primarily because this knowledge is less critical to understanding a species' reproductive potential and population dynamics. In this sense, females are the limiting sex. However, knowledge about the life-history strategies of males provides a more complete picture of a species population dynamics and provides information about the species' breeding strategy and social structure.

One of the major differences between the life-history strategies of male and female cetaceans is the age at attainment of sexual maturity. In species with the greatest degree of sexual dimorphism, the difference in age at attainment of sexual maturity for males and females is greatest. This difference reflects the additional time required to grow to about 85% of their asymptotic length, which is the approximate size at which all mammals become sexually mature. For example, sperm whale males reach sexual maturity at a much later age than females. The estimated age at attainment of sexual maturity for the female sperm whale is from 7 to 13 years and for males, is approximately 20 years (Best *et al.*, 1984; Rice, 1989). The difference is similar in the killer whale and the short- and long-finned pilot whale (Lockyer, 1993; Baird, 2000). However, the smaller delphinid species that show less sexual dimorphism reach sexual maturity at more similar ages. In fact, the difference in age between the sexes is about 3 years for the common bottlenose dolphin, pantropical spotted dolphin and spinner dolphin (*S. longirostris*) with males reaching sexual maturity at the older age (Perrin and Reilly, 1984).

Sexual dimorphism has been used as a predictor of cetacean mating systems. For example among odontocetes, the degree of sexual dimorphism exhibited by the sperm whale, short-finned pilot whale, and killer whale has been hypothesized to indicate male–male competition in a polygynous mating system. The presence of scars inflicted by other males provides evidence of male–male competition in sperm whales. However, fairly recent data that the short-finned pilot whale and killer whale have limited male dispersal from natal pods and likely breed promiscuously suggests that sexual dimorphism may have evolved for reasons other than mating. One interpretation of these data is that the presence of large males in their

natal pod enhances their reproductive fitness by improving, e.g., the foraging efficiency of the pod (Wells *et al.*, 1999).

V. Life-History Parameters and Demography

Knowledge of a species' life-history strategy provides the foundation for understanding the species' demography because their life-history characteristics reflect the species' adaptations to a particular niche, which is bounded by constraints of the environment as well as their morphology and physiology. While life-history studies primarily focus on individual variability in traits that express these adaptations for a species, each study can usually only focus on a particular group of animals within the species. The comparison of studies made on different groups of animals within a species' range, however, reveals variability in the average expression of life-history traits among demographically isolated populations. For example, pantropical spotted dolphins north and south of the equator have different breeding seasons, and the estimates of asymptotic length for animals in the western Pacific are 4 to 7 cm longer than those from the eastern Pacific (Perrin and Reilly, 1984). Similar examples exist for other cetacean species. There are also examples in the literature of cetacean populations responding to changes in the availability of resources through time. This is called density dependence. For example, changes in the age at attainment of sexual maturity for fin, sei, and minke whales through time have been reported and are presumed to be a response to increased per capita resource availability following reductions in population abundance that resulted from commercial whaling (Lockyer, 1984). Similarly for the striped dolphin and the spinner dolphin, changes in the age of sexual maturity and pregnancy rates have been reported and explained as responses consistent with increased resource availability that resulted from decreased population abundance (Perrin and Reilly, 1984). Ultimately, these responses are reflected as changes in the population's growth rate. In addition to understanding a species' life-history strategy and its inherent variability, recognition of these types of population-level responses is important to consider when developing conservation and management plans.

Estimates of age-specific reproductive rates and survival rates are critical to quantifying a species' demography. However, for nearly all cetacean species, age-specific survival rates are unknown and are likely to remain so. Because demographic studies must include age-specific survival rates, unique solutions have been sought to allow the estimation of survival rates based on imperfect knowledge (Barlow and Boveng, 1991). Longitudinal studies like those of the common bottlenose dolphin and the humpback whale provide the only source of data to estimate survival rates, and these data are generally used as a guide for estimating survival rates for other species with similar, but less well known, life histories.

VI. Life-History Studies and the Future

Several new technologies are being actively applied to studies of cetacean species and are contributing to our knowledge about their life-history strategies. Specifically, the expansion of molecular genetic techniques, the development of satellite and VHF (Very High Frequency) tracking technology, and the collection of high-resolution vertical aerial photographs have allowed more detailed data collection on individual animals. For example, the application of molecular genetic markers as tags for individuals has been successfully demonstrated

Figure 3 A pantropical spotted dolphin (*Stenella attenuata*) wearing a radio tag and time-depth recorder to study diving behavior. Photographed by M. D. Scott.

with the humpback whale data set (Palsbøll, 1999). Application of this technique to cetacean species whose individuals cannot be readily recognized by natural marks may facilitate life-history studies for those species. Additionally, the results of molecular genetic studies on several cetaceans, including the beluga whale (*Delphinapterus leucas*) and Dall's porpoise (*Phocoenoides dalli*), have confirmed hypotheses of male-biased dispersal (O'Corry-Crowe *et al.*, 1997; Escorza-Treviño and Dizon, 2000). Although not a particularly surprising result, because male-biased dispersal is common among large terrestrial mammals, molecular genetics provided the tool to examine large data sets to address this question for cetacean species. Two other technologies are contributing to our understanding of cetacean breeding patterns. These are the development of molecular techniques to identify pregnant individuals by measuring hormone concentrations in the blubber, which will allow pregnancy rates to be estimated for populations of wild cetaceans, and the collection of high-resolution vertical aerial photographs to identify breeding seasons of cetacean populations using measurements of animal size (Perryman and Lynn, 1993). Similarly, the development of satellite and VHF tracking technology is continuing and providing new insights about how cetacean species live their lives. There have been notable successes documenting movement patterns of beluga whales in the Arctic (Martin *et al.*, 1998) and blue whales in the North Pacific (Mate *et al.*, 1999) using satellite tags, and documenting the diving behavior of a number of cetacean species using VHF tags (Hooker and Baird, 2001) (Fig. 3). As these and other new technologies continue to be developed and applied, new insights about the life-history strategies of all cetacean species will be provided that will complement and expand knowledge obtained from more traditional life-history study methods.

Cetacean Prenatal Development

JOY S. REIDENBERG AND
JEFFREY T. LAITMAN

Very little is known about the specifics of intrauterine growth and development in cetaceans. Indeed, the precise time intervals of such development, the basic genetic determiners, and any distinctive growth trajectories are basically unknown. What is known about cetacean prenatal development is that, as they are mammals, it is to be expected that the same basic stages of early cell division, pattern formation, organogenesis, and growth and differentiation will also be similar. For example, the “embryonic” period is usually defined as the time frame within which an animal’s body plan and its organs and organ systems (i.e., integument, skeletal, muscular, nervous, circulatory, respiratory, digestive, urinary, and reproductive) are established. Once all organs form, the “fetal” period of growth and distinctive development commences. Cetacean prenatal development will similarly follow this course. It is also to be expected that the absolute time of these periods will differ both from terrestrial species, between odontocetes and mysticetes, and among the different species therein.

Many studies that have noted aspects of cetacean prenatal development (most in passing rather than by detailed, systemic analysis) have used terms such as “embryo” or “fetus” in a seemingly imprecise manner. Adding to this complexity is the fact that the precise gestation periods for many cetacean species are not known. In light of the earlier discussion, our use of the terms embryo and fetus (or embryonic and fetal periods) should be taken as representing approximate guides to stages of development rather than as a precise descriptor of an absolute time frame.

It is important to remember in discussing cetacean prenatal development that most current knowledge derives from observations on embryonic or fetal specimens discovered in pregnant cetaceans either found stranded or taken aboard whaling ships. In many cases, only a length or weight is recorded (if at all) with an occasional description of external appearance. It is usually impossible to distinguish the age of the specimen, as the date of conception and the length of gestation cannot be known with any certainty. As most breeding and calving seasons are known, however, some approximations are available and have been provided. In this chapter, we focus on changes occurring in the late embryonic through fetal periods.

We refer to the review articles by Štěřba *et al.* (1994) and Thewissen and Heyning (2007) for a discussion of the embryonic period.

I. Integument and External Characteristics

The overall coloring of the embryo appears light pink, due to the transparency of the skin (integument) allowing the underlying tissues perfused with blood to be visible (Fig. 1). The skin consists of the epidermis (which has four layers), dermis, and hypodermis, which increase in thickness throughout the embryonic period (Meyer *et al.*, 1995). Skin coloration begins during the early fetal period. In mysticetes, dark coloration occurs initially along the rostrum bordering the opening of the oral cavity. As the fetus grows, dark patches appear along the dorsum of the thorax and the abdomen, and on the pectoral flippers, tail flukes, and dorsal fin (Fig. 2). The separate and irregularly shaped patches fuse and grow into a more uniform pattern. For many species, this is usually a countershaded pattern of dark dorsum and light ventrum that resembles the adult’s coloration (Fig. 3).

Hairs can be found along the surfaces of the upper jaw. In odontocetes, hairs appear on the lateral aspect near the tip of the rostrum, whereas in mysticetes, they are found both laterally and dorsally on the broad rostrum. In some cetacean species, these hairs can also be found on the margins of the lower jaw. These hairs appear to have some tactile properties and may derive from the vibrissae of terrestrial mammals. Although most odontocetes will lose these hairs shortly after birth (except perhaps platanistids), they are retained into adulthood in some species of mysticetes.

External ears (pinnae) do not develop, thus maintaining a streamlined surface contour in the ear region of cetaceans. Only a remnant of the external auditory canal is visible as a small hole present in the skin behind the eye.

Mammary glands (mammary) are epidermal organs derived from modified sweat glands. In terrestrial mammals, and presumably cetaceans, the mammary develop along a mammary ridge (the “milk line”), which extends bilaterally from the axilla (where the forelimb joins the thorax) to the inguinal region (where the hindlimb joins the pelvis). The position of the mammary that eventually develop varies in different species: thoracic (e.g., primates, sirenians), thoraco-abdominal (e.g., felids), thoraco-inguinal (e.g., canids, suids), and inguinal (e.g., ungulates). Cetacea, like their ungulate relatives, only develop inguinal mammary. In females, the teats (nipples) of the mammary are internalized, being withdrawn into the mammary slits (which are positioned with one on either side of the genital slit). This internal location helps streamline the body contour and thus reduce drag during locomotion.

It is difficult to sex the cetacean embryo or early fetus, as they only display a small genital tubercle (Fig. 1). As the genital tubercle develops, however, it is directed cranially in males and caudally in females (Amasaki *et al.*, 1989b). Although the penis/clitoris may be totally exposed in an earlier fetus, the external genitalia are usually not completely visible in the full-term fetus as they are withdrawn into the genitoanal slit. In a postmortem specimen, the penis usually protrudes through the slit due to relaxation of the retractor penis muscle (Fig. 2). The genitoanal slit opens into a common vestibule occupied caudally by the anus and rostrally by the urogenital openings. In males, the urethra is contained in the penis; in females, the urethra is independent of the clitoris, and there is a separate opening for the vagina. In males, the genitoanal slit is elongated, reaching almost to the navel. In comparison, the genitoanal slit of females is very short, appearing only between the two mammary slits. Both

Figure 1 Two early fetal long-finned pilot whales (*Globicephala melaena*) obtained postmortem from pregnant, beach-stranded whales on the shores of Cape Cod, Massachusetts, USA. (A) Lateral view of a fresh specimen of a very small, unpigmented fetus that appears pink. This is due to the transparency of the thin skin allowing the color of the blood-perfused tissues to show through. Based upon its external appearance, this appears to be a very early fetus, probably very close to the transition between the embryonic and the fetal periods of development. Note the prominent rostrum and the rudimentary development of a dorsal fin, tail flukes, and genital tubercle. The dark spot above the mouth and anterior to the eye appears to be the left nostril. (B) Ventral view of an early fetus preserved in alcohol. The unpigmented fetal skin (which was pink) is now discolored to a tan hue. The tail is folded laterally to the left side. Due to desiccation, the skin is shrunk against the skeleton revealing the shapes of the skull, ribs, individual segments of the flipper phalanges, and the caudal vertebrae. Note the large eyes, prominent rostrum, attached umbilical cord, and genital tubercle just caudal to the umbilicus. C, caudal fluke; D, dorsal fin; E, eye; F, flipper; G, genital tubercle; N, nostril; R, rostral tip; T, tympanic (ear/pinna) area; U, umbilicus/umbilical cord; V, vertebrae.

males and females have a streamlined external shape, as the penis/clitoris is withdrawn into the genitoanal slit and there are no scrotal (testes are intra-abdominal) or labial skin protrusions, thus further reducing drag during swimming.

II. Musculo-Skeletal System

The forelimb extremities of whales are called pectoral flippers. Although cetaceans are derived from a quadrupedal ancestor, adult whales do not possess hindlimbs. During the embryonic period, both forelimb and hindlimb buds are present as paddle-shaped projections, with the forelimb developing before the hindlimb

(Amasaki *et al.*, 1989c). The rudimentary hindlimb buds form skeletal element anlagen, vascular plexes, and nerves (Sedmera *et al.*, 1997a), but are completely absorbed by the fetal period (Thewissen *et al.*, 2006). By birth, the only remaining vestige of the hindlimb is a skeletal remnant of the femur embedded into the lateral body wall, and a rudimentary pelvis that is not attached to the vertebrae. The forelimbs, however, continue developing during the embryonic and the fetal periods. Early on, they assume the elongated shape of a typical mammalian arm and forearm, with grooves separating the digits apparent toward the distal edge. The skin overlying the flippers matures faster than the skin over the trunk (Meyer *et al.*, 1995). The stalk-like arm and the forearm foreshortens into one functional

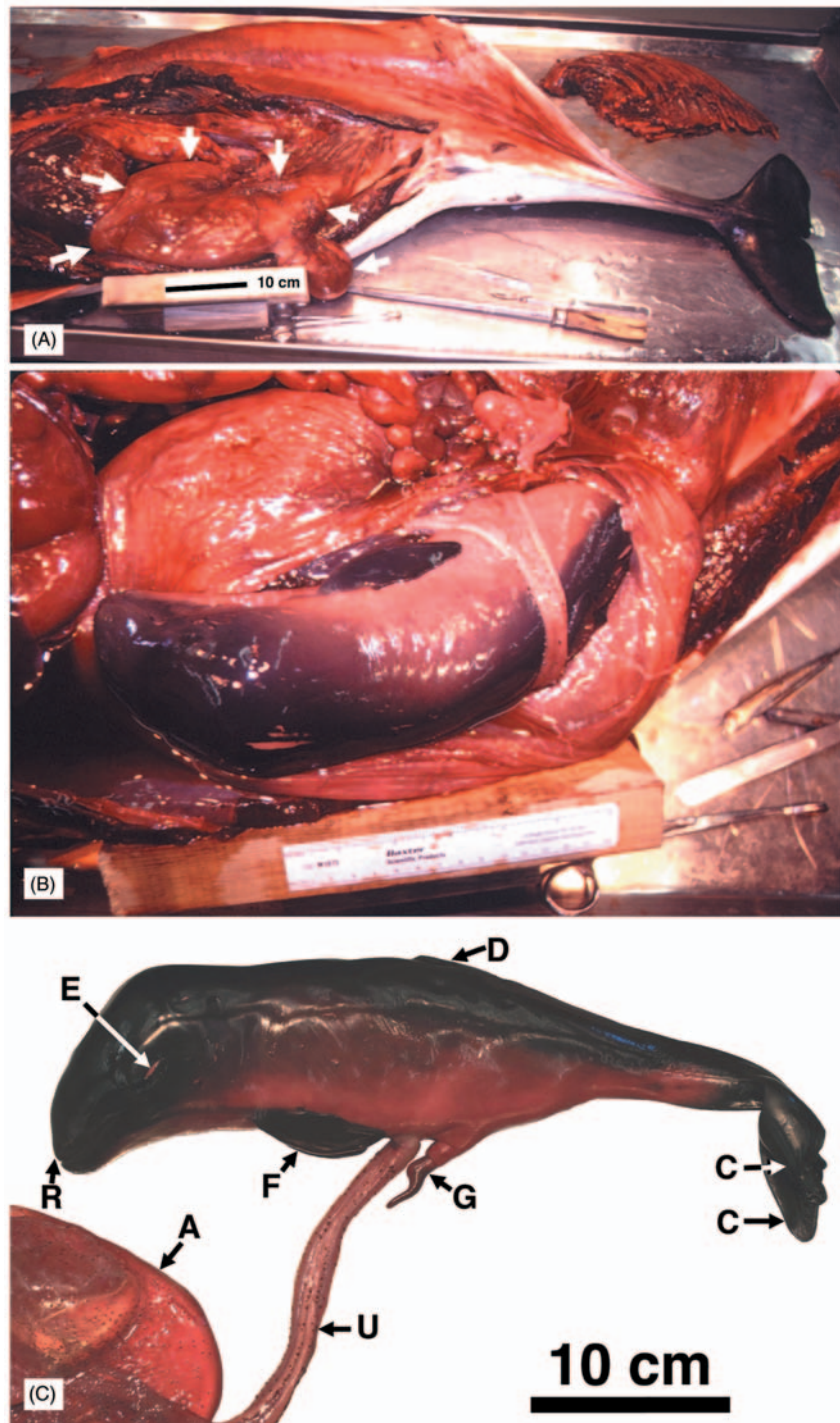

Figure 2 Pregnant harbor porpoise (*Phocoena phocoena*) and her fetus, obtained postmortem from a beach-stranding in Cape Cod, Massachusetts, USA. (A) Note the pregnant uterus in situ as revealed during a necropsy (outlined by white arrowheads). The fetus occupies only one horn of the bicornuate uterus. The other uterine horn and ovary are displaced out of the maternal abdominal cavity to the right of a wooden block with a scale-bar. (B) This is a close-up showing the uterus opened to reveal the fetus. Note the fetal head is directed toward the maternal abdomen, whereas the fetal tail is directed toward the maternal vagina. The umbilical cord can be seen wrapped around the abdominal region of the fetus. (C) The fetus after removal from the uterus. The umbilical cord is still attached and the amniotic sac has been removed and is visible in the lower left area of this image. Note the presence of amniotic "pearls" (i.e., black dots present on the umbilical cord and the amniotic sac). The penis is fully extruded due to postmortem muscle relaxation. The dorsal fin is still folded flat against the back. Black skin pigmentation is present. The fetus is not yet large enough to warrant curling, and thus no fetal folds are found. A, amniotic sac; C, caudal fluke; D, dorsal fin; E, eye; F, flipper; G, penis protruding from genital slit; R, rostral tip; U, umbilical cord.

unit. The skeletal elements (humerus, radius, ulna, and carpal bones) lose their mobility at the elbow and the wrist joints, maintaining flexibility only at the shoulder joint.

During the fetal period, the manus of the pectoral flipper fuses into a paddle-shape (the distal portion never separates into individual digits, and the interdigital grooves disappear). Odontocete flippers contain five digits—a pattern reminiscent of a terrestrial ancestry. The number of digits within the flipper varies in mysticetes; members of the Balaenidae and Eschrichtidae families retain all five digits, whereas the rorquals (members of the family Balaenopteridae) have reduced that number to four. The tip of the flipper elongates in the caudal direction as differentiation of the phalangeal cartilages progresses proximo-distally. The central digits exhibit hyperphalangia (or polyphalangia), i.e., the number of phalangeal elements expands beyond the maximum of three found in most terrestrial mammals (Calzada and Aguilar, 1996). The degree of hyperphalangia varies greatly between species. For example, the second and the third digits of *Globicephala melas* have 14–15 and 11 phalanges respectively, whereas there are seven elements in each of these two digits in *Stenella attenuata* and only five for each of these digits in *Physeter macrocephalus*. Expansion in the number of phalangeal elements, rather than in the lengths of the elements, probably helps support the elongated form of the flipper while retaining some small degree of flexibility that is reminiscent of fin function in fish. Hyperphalangy and elongated pectoral flipper form may also relate functionally to increasing/decreasing aspect ratio (i.e., relationship between length and width), hydrodynamic form (streamlining effects), or locomotor function (limited to steering, braking, and lift in most species, but can include increased maneuverability or propulsion, e.g., humpback whales) (Cooper *et al.*, 2007a, b).

The tail flukes do not appear until the fetal period, after the hindlimbs have regressed. The midline of the tail enlarges dorsally and ventrally in the vertical plane to form the slender and hydrodynamic tail-stock. The number of caudal vertebrae may increase above that typically seen in terrestrial mammals (perhaps up to 24 in mysticetes and perhaps up to 48 in odontocetes, compared with up to 21 in ungulates). Note that the actual number of caudal vertebrae is difficult to determine with accuracy, as there are no clear anatomical landmarks to separate the caudal region from the lumbar region. The caudal tip develops two horizontal plates of tissue that do not contain any skeletal elements. These plates form the tail flukes. As the fetus nears full term, the tail flukes curl ventrally at their caudal tips so that they are directed rostro-medially (Fig. 3). This curling of the flukes makes the tail tip more compact and easier to present through the vagina during birth (see later).

At about the same time that the tail flukes appear, a bulge develops along the midline of the back in the region where the dorsal fin will form (Fig. 1). The bulge-shape is then modified to a species-specific shape (e.g., falcate, triangular, rounded, ridge). When sexual dimorphism in fin height is seen (e.g., *Orcinus*), it does not occur prenatally. The vertebrae of the back unfold from the embryonic curvature (ventrally concave), to a horizontally aligned column in the early fetal period. In the late fetal period, however, the growing fetus folds again, only this time the body curves laterally. This flexibility may be possible, in part, due to the lack of a sacrum and lengthening of the vertebral column. There are additional lumbar vertebrae in most cetaceans (perhaps up to 15 in mysticetes and perhaps up to 29 in odontocetes), compared with the usual six of ungulates or five of humans. Again, this number is difficult to determine with accuracy, as there is no sacrum or pelvis, and rib articulations can vary. As the side of the fetal head approximates the tail, the dorsal fin folds

flat against the concave side of the body (Fig. 3). Dorsal fin folding facilitates vaginal delivery (see later).

The ribs of odontocetes are hinged along the lateral aspect, giving each rib two osseous elements joined by a synovial joint. Postnatally, this will facilitate thoracic cavity collapse during diving (as pressure increases with depth, the volume of air in the lungs will decrease).

III. Head and Neck

The large embryonic head lies in the typical mammalian pose with the face directed ventrally at 90° to the long axis of the body. The maxillary and the mandibular regions form a ventrally projecting, conical rostrum that curves slightly caudally. This projection resembles a parrot's beak, being rather thick at the base. In the early fetal period, the rostrum elongates, particularly in the long beaked species (e.g., *Stenella longirostris*, *Platanista gangetica*). In the mid-fetal period, the head and neck junction straightens into the adult position, aligned horizontally with the body. The neck region is shortened and stiffened and in many species (e.g., *Globicephala macrohynchus*) all the seven cervical vertebrae become cranio-caudally compressed and fuse together (Ogden *et al.*, 1981). This enables a smoother transition in form between the head and the thorax, and a midline head position relative to the body's longitudinal axis. The shortened neck enhances streamlining and fusion of the cervical vertebrae improves head stability during locomotion. Vertebral fusion limits lateral or rotational head motion, leaving only dorso-caudal head movements (which help begin the propulsive body wave) at the large joint between the first cervical vertebra and the skull's enlarged occipital condyles.

The hyoid apparatus is derived from the second and the third branchial arches. The single basihyal and paired thyrohyals form the large "U"-shaped plate to which the muscles of the tongue, larynx, and sternum attach, and the paired epihyals, ceratohyals, stylohyals, and tympanohyals form the osseous chains bilaterally connecting the basihyal with the skull (Reidenberg and Laitman, 1994).

The mandible (jaw) forms around a cartilaginous precursor (Meckel's cartilage) derived from the first branchial arch. The cetacean mandible is largely comprised of a horizontal body, with very little (if any) vertical projection forming the ascending ramus. The condylar process is short, and the condylar head may appear to rest directly superior to the caudal portion of the mandibular body. In many odontocetes, the condylar head migrates with fetal development to the caudal aspect of the mandible, whereas in some mysticetes, the condylar head occupies the dorso-caudal edge of the mandible. Although the ascending ramus develops most of its vertical height postnatally in many terrestrial mammals, the ascending ramus of cetaceans remains practically nonexistent through the adult stage.

The caudal portion of the first branchial arch contributes to the formation of the upper portions of the first two ear ossicles (malleus and incus). The caudal portion of the second branchial arch contributes to the lower portion of these same two ear ossicles as well as the body of the third ossicle (stapes, except for the footplate, which derives from the otic placode).

In terrestrial mammals, and presumably cetaceans, the skull is derived from two types of bones: chondrocranial (that which preforms in cartilage and then ossifies), and desmocranial (that which does not form a cartilaginous stage, but rather directly ossifies in mesenchyme). The portion preformed in cartilage (the skull base) tends to be less plastic in its shape than that which ossifies from

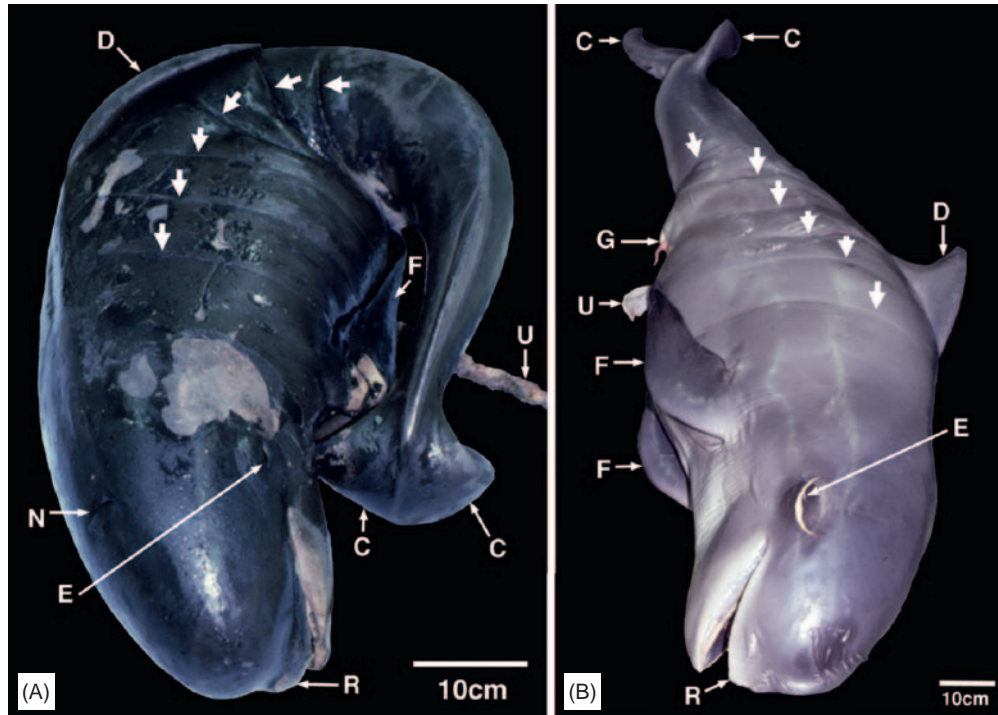

Figure 3 Full-term fetal long-finned pilot whales (*Globicephala melaena*) obtained postmortem from pregnant, beach-stranded whales on the shores of Cape Cod, Massachusetts, USA. Both whales were stored frozen and then thawed. Note the darker gray to black pigmentation of the skin, and the well-developed melon that now overrides the rostrum. The lighter patches are areas where the skin has sloughed off postmortem. (A) Near full-term fetus curled in the fetal position as it was found in utero, with the tail folded against the left side. The umbilical cord is evident under the distal tail-stock. The left lateral surface of the thorax and the abdomen shows a number of dorso-ventral fetal folds (white arrowheads; grooves between skin folds located mainly on the lateral abdominal wall of only one side). Note the prominent crimping along the pronounced concavity at the beginning of the tail-stock. The dorsal fin lies flat against the body and the tail flukes are curled ventrally. (B) The near full-term fetus has been uncurled from its fetal position, and the flukes and the dorsal fin have been extended. The fetal tail was originally curled to the right, as evidenced by the prominent fetal folds along the right lateral abdominal surface (white arrowheads). The tip of the penis can be seen protruding through the genital slit, just caudal to the stalk of the umbilical cord seen near the right flipper tip. The crescent-shaped tear in the fragile skin over the right eye and the wrinkles on the melon (forehead region) are freeze-thaw artifacts. C, caudal fluke; D, dorsal fin; E, eye; F, flipper; G, genital slit with protruding penis; N, single nasal opening (blowhole); R, rostral tip; U, umbilical cord.

membranes (the cranial vault). Cetaceans appear to be no exception to this rule. In fact, they are an excellent example of the plasticity of the cranial vault, as this region is grossly modified compared with terrestrial mammals.

In the fetal period, the elements of the cranial vault begin to shift their relative positions so that the maxilla approximates or meets the occipital dorsally. This process of bony overlapping (called “telescoping”) creates a layered appearance to the skull, where portions of bone are buried on the inner surface. In odontocetes, the parietals are depressed laterally and the premaxillary and the maxillary bones overlap the frontal bone dorsally, whereas in mysticetes, the premaxilla slides over the frontal and the base of the maxilla moves under the frontal bone. The cranial vault thus changes shape from dolichocephalic (longer than wide) to brachycephalic (wider than long). The ear ossicles begin to rotate into their adult position during the

early fetal period. No paranasal air sinuses (i.e., maxillary, ethmoid, sphenoid, or frontal) form within the skull either prenatally or postnatally (a diving adaptation that prevents injury from expanding/contracting the volume of an enclosed air space during depth/pressure changes). The bony nares migrate caudally to the near adult position on the dorsum of the head.

The structures of the nasal region are forming in the early fetal period, but asymmetry is not detected yet. Nasal conchae (bony plates that project from the nasal septum and walls in terrestrial mammals) never form. The nasal plugs (the tissues that close off the airway) are present, and may derive from the tissue that forms the upper lip in terrestrial mammals. The melon, which may also derive from this same tissue, has not yet formed the characteristic bulge in the forehead region. The nasal air sacs, diverticulae of the nasal tract, begin to bud off the soft tissues of the nasal passageways.

The nasal apertures, which appear initially on the dorsum of the rostrum (Fig. 1), begin to migrate caudally toward the adult position at the top of the head. They can be found near the junction of the rostrum and the swelling containing the forebrain. The nasal skull grossly transforms so that the nasal floor projects ahead of the nasal passageways into the rostrum, whereas the lateral parts (which form the walls of the nasal passages) shift from horizontal to vertical (Klima, 1999). There are two separate bony nasal passageways in all cetaceans. The soft tissues above the skull that surround the nasal passageways are maintained as two separate tubes in mysticetes. In odontocetes, however, the two soft tissue passageways fuse near their exit at the skin into one common blowhole opening. There are further differences within odontocetes in the development of the nasal skull. *Phocoena* has the most posteriorly positioned nares, whereas *Physeter* has the most anteriorly positioned nares. There are additional specializations in *Physeter* related to the unique forehead containing the spermaceti organ, including asymmetrically sized and positioned narial openings in the skull and soft tissue pathways through the head.

The larynx (voice-box) forms from cartilage elements of the fourth through sixth branchial arches. Its position in cetaceans is similar to that found in terrestrial mammals. The front part (epiglottis) overlaps its ventral surface with the dorsal surface of the soft palate, creating a bridge to channel air from the nasal region into the trachea and the lungs. In odontocetes, the larynx undergoes elongation of its rostral portion, forming a “goose beak” shape that inserts into the nasal region. The epiglottis elongates during the mid-fetal period. The posterior cartilages (corniculates) are still shorter than the epiglottis, and will not reach their full proportions (i.e., exceed the epiglottis in height) until the fetus reaches full term. The laryngeal “goose beak” of odontocetes inserts into a muscular sphincter derived from the palatopharyngeal arch of the soft palate. Postnatally, this interlock will keep the rostral opening of the larynx connected with the posterior nasal cavity. This connection imparts circumferential protection from the digestive tract, allowing air to flow between the nasal region and the lungs for sound production while prey is swallowed whole underwater. Internally, the odontocete larynx develops a midline fold (which is bifurcated in *Kogia breviceps*) that appears homologous to the vocal folds of terrestrial mammals (Reidenberg and Laitman, 1988). The mysticete larynx more closely resembles that of terrestrial mammals, except that there is a large and muscular sac attached ventrally in the midline (Reidenberg and Laitman, 2007). In *Caperea marginata*, this sac lies on the right side.

Late in the fetal period, both odontocetes and mysticetes form tooth buds. Odontocete teeth are single cusped and usually conical in shape with species-specific variations, e.g., narwhal (long spiral tusk), platanistids (needle-shaped), beaked whales (flattened and broad), and porpoises (flattened, spade-shaped). Postnatally, teeth are used primarily for grasping and aggression. As there are no incisors, canines, or molars (odontocetes are “homodonts”—all teeth have the same shape), the task of breaking up food is passed onto the stomach (see later). The tooth buds of fetal mysticetes are sometimes multicusped, resembling the teeth of related terrestrial mammals (Slijper, 1979). The mysticete tooth buds are more numerous in the upper jaw than in the lower jaw, but all are usually resorbed before birth. The formation of rudimentary baleen plates, which occurs concurrently with tooth bud degradation, may be induced by the process of tooth bud resorption (Ishikawa and Amasaki, 1995). As the mysticete fetus grows, longitudinal baleen ridges form in the gums of the upper jaw. These longitudinal ridges develop transverse divisions and rows of papillae comprised of epidermal folds that become cornified. The cornified papillae, which

are tubular in shape, elongate and coalesce with their neighbors to form baleen plates (Slijper, 1979).

Throat grooves are a series of parallel, longitudinal folds found on the external, ventral surface of the head in rorqual mysticetes that enable expansion of the oral cavity. In other mysticetes and some odontocetes, a single pair of throat grooves can be found at the base of the jaw, and may indicate expansion of this region during tongue and hyoid depression (see later). In rorqual mysticetes, throat grooves begin forming in the fetal period, appearing initially between the umbilicus and the pectoral flipper. A second set of ventral throat grooves appears next near the tip of the mandible. Toward the end of gestation, the two sets of throat grooves join to form one complete set running from the mandibular tip to the umbilicus. These throat grooves enable expansion of the floor of the mouth to engulf prey during feeding.

In both mysticetes and odontocetes, lingual papillae develop along the lateral border of the tongue during the fetal period. Since newborn cetaceans lack lips, these papillae probably play an important role postnatally during nursing in grasping the teat, creating a seal for suction, and forming a channel for milk to flow into the oral cavity. These papillae attain maximal size in the early postnatal period of odontocetes, but can sometimes be found persisting in adults.

The tongues of mysticetes and odontocetes differ greatly in their construction, and this difference is evident in the fetal stage. Odontocete tongues are more closely related to the tongue of terrestrial mammals, being very muscular. Their tongues have large insertions on the broad bones of the hyoid apparatus (Reidenberg and Laitman, 1994). This arrangement helps depress the tongue into the throat like a piston, thereby creating enough negative pressure to draw in prey—a mechanism referred to as “suction feeding.” The mysticete tongue (particularly in rorqual whales) is unusual in its structure because it can be flattened against the floor of the mouth and expanded laterally along with the throat pleats during prey engulfing. In addition, there is a fibrocartilage structure in the ventral throat region of rorqual whales that may be related to attachment of the mylohyoid muscle. This structure may aid jaw mechanics and support the tongue and floor of the mouth during expansion/contraction of the throat grooves.

IV. Internal Organs

The tracheal rings usually develop as “O”-shaped rings, unlike the “C”-shaped rings of most terrestrial mammals. A bronchus leading to the right lung develops above the carina (tracheal bifurcation). As this bronchus emerges directly from the trachea above the primary (main stem) bronchi, it is termed a “tracheal bronchus.” A right tracheal bronchus is a feature also found in the closely related artiodactyls.

The lungs mature from the embryonic glandular stage, to the fetal canalicular stage (see Drabek and Kooyman, 1983 for more information on stages of lung development). Next, muscular sphincters develop around the terminal bronchioles. Since this feature is not found in terrestrial mammals, it may be an adaptation for diving. The next phase of development is the alveolar stage. By the mid-fetal period, cartilaginous rings develop in the terminal bronchioles. This is another feature not found in terrestrial mammals that may also be an adaptation for diving, since the cartilage rings may keep the terminal airways patent under high pressures and during lung collapse at depth.

During the embryonic period, the heart is visible and has probably undergone a similar differentiation as in other mammals. The

heart begins as a straight tube, but during the late embryonic period, it folds and forms septa that eventually divide it into four chambers found in all mammalian hearts. The cetacean heart, however, shows differences in shape from terrestrial mammals. In both odontocetes and mysticetes, it is laterally (transversely) broad and cranio-caudally compressed, with the apex being formed by both ventricles. The cetacean heart has specializations which may be adaptive for diving, such as anastomoses between the dorsal and the ventral inter-ventricular arteries, and hypertrophy of the right ventricle (Tarpley *et al.*, 1997). Diving adaptations also occur in the great vessels, such as an expandable aortic arch.

The internal carotid artery, which is a major supplier of blood to the brain in terrestrial mammals, tapers dramatically in the neck and terminates under the skull base at the carotid canal before reaching the brain. This reduction of the internal carotid artery probably occurs in all cetaceans that exhibit cervical retia mirabilia (see later) as this is the only structure it appears to supply. Interestingly, the internal carotid artery is also reduced or absent in many artiodactyl species. The ductus arteriosus (a fetal vascular connection between the aorta and the pulmonary artery) was thought to remain patent postnatally, but a study in adult pilot whales showed that it does close (Johansen *et al.*, 1988). This is no different from terrestrial mammals, and is probably the condition in other cetaceans as well.

The fetus develops complex networks of anastomosing, coiled blood vessels called retia mirabilia. These vessel masses are found in regions surrounding the dorsal thoracic cage, the region near the foramen magnum, and the spinal cord. Although the functions of retia mirabilia are not known, it is thought that they are adaptations to diving and resurfacing. Their vessel structure may compensate for the rapid pressure changes of descent and ascent with a slow and a sustained response that moderates blood flow. By dampening oscillations in blood pressure, sensitive tissues, such as heart muscle or the brain and spinal cord, continue to receive steady perfusion, thus avoiding oxygen debt and lactic acid build up. As these vessels appear to store blood near vital tissue (e.g., brain, spinal cord, heart), they may thus function as a reservoir, distributing blood to these oxygen sensitive tissues when normal circulation is affected (e.g., as pressure increases during diving, or metabolism is slowed). A less widely held hypothesis for the retia mirabilia's function is in trapping the nitrogen bubbles (emboli), which may come out of solution in the bloodstream during ascent from a prolonged dive. These bubbles are potentially fatal, as they can block smaller blood vessels and therefore interrupt blood flow in the capillary beds of organs (a condition known in human divers as decompression sickness, or caisson disease).

The fetus also develops a complex network of vessels that supply and drain the testes and the uterus. These vessels are arranged in a plexus to enable thermoregulatory countercurrent exchange. This conserves heat where needed and allows extra heat to be drawn away from these organs. Thus, the male can keep the testes cool and the pregnant female can keep the fetus in the uterus from overheating, despite their internal location under the insulating blubber (Rommel *et al.*, 1993).

In mammals, gut development begins with a single, relatively straight gastrointestinal tube that is suspended in the midline of the coelom. As the embryo develops, the gut tube differentiates into the foregut and the hindgut, and as each section further develops its specific shapes, individual regions of the gut tube begin to rotate into different positions within the coelomic cavity. Toward the end of the embryonic period, the thoraco-abdominal wall is distended. This is probably because the stomach is developing its multiple chambers and intestinal rotation is occurring. Cetaceans develop

a multichambered stomach (see Tarpley *et al.*, 1987, on *Balaena mysticetus*; Mead, 2007, on beaked whales) much like that found in closely related ruminant artiodactyls, the closest group of living land mammals to the cetaceans. The divisions of the cetacean stomach include, from proximal to distal: forestomach, main stomach, and pyloric stomach. As it does in ruminants, the cetacean forestomach arises from the stomach bud rather than the esophagus (Amasaki *et al.*, 1989a), but is not divided into the three small chambers (rumen, reticulum, psalterium) found in, e.g., the cow. The size of the forestomach may be dependent upon the consistency of the prey. In odontocetes, a large and a muscular compartment may signify a function in breaking down whole fish or crustaceans, whereas a smaller compartment possibly relates to a diet of soft prey such as cephalopods. In mysticetes, the forestomach is smaller than the main stomach, perhaps relating to the relatively small size of their prey. The cetacean main stomach and pyloric stomach (which can have up to 12 chambers, e.g., beaked whales) is equivalent to the cow's single rennet stomach (Slijper, 1979).

The process of intestinal rotation probably resembles that of other mammals, involving temporary herniation (protrusion) into the umbilicus, rotation and folding, and then return of the contents back to the abdomen where they lie more compactly. Thus, by the early fetal period the abdomen is no longer distended from the process of intestinal rotation. The cecum and large intestines then further differentiate, developing circular folds that divide the intestines into multiple connected chambers resembling the haustra (sacculations) of terrestrial mammals (Amasaki *et al.*, 1989a).

In embryos of terrestrial mammals, and presumably cetaceans, the earliest kidney is the mesonephros, comprised of ducts and tubules. The embryonic metanephric duct, which buds off the mesonephric duct, becomes the ureter. As the mesonephros regresses, a second kidney structure, the metanephros, develops around the metanephric duct and is retained as the final kidney.

The fetal kidney develops as a cluster of many small and relatively independent kidney units called renicles, which will be retained in the adult. An adult kidney divided into renicles or lobes is not unusual in mammals (e.g., ox, otter), and may indicate persistence of the fetal condition. The apparent functional advantage of a kidney divided into renicles in large mammals appears to be related to a maximum size for the length of the tubules, which might otherwise be too long for proper function in a large single kidney.

The urogenital sinus (derived from the embryonic cloaca) becomes the urethra. The urinary bladder develops from the proximal portion of the allantois.

The remnants of the mesonephric duct become the efferent ductules, epididymis, and deferent duct for sperm transport in males. The gonads (ovaries and testes) develop from gonadal ridges, which are paired thickenings of the coelomic epithelium. In females, paramesonephric (Mullerian) ducts develop simultaneously with the mesonephric ducts. The paramesonephric ducts become the bicornuate uterus and oviducts in females, but degenerates in males except for the prostatic sinus.

In males, the testes are intra-abdominal, i.e., they do not descend as in most terrestrial mammals, and thus there is no scrotal sac. The internalization of these structures helps streamline the body shape, thus reducing drag during swimming. Interestingly, cetaceans develop a gubernaculum (which functions in testicular descent in terrestrial mammals), but do not develop the peritoneal out-pocketing that occurs with testicular descent (the vaginal process) during the fetal period (van der Schoot, 1995). A complex vascular plexus supplies the testes (see later), functioning as a countercurrent heat

exchanger to keep the testes cool despite their internal location under the insulating blubber.

The genital tubercle gives rise to the penis or clitoris (Amasaki *et al.*, 1989b). The external genitalia are not usually visible externally in the full-term fetus as they are withdrawn into the genital slit (see earlier discussion on genitoanal slit and contents).

V. Nervous System

Brain development in the embryonic period resembles that of other terrestrial mammals. The brain is comprised of three main sections: prosencephalon (forebrain), mesencephalon (middlebrain), and rhombencephalon (hindbrain). The corticospinal tract does not develop to the same degree as terrestrial mammals, probably owing to the loss of the hindlimbs and the reduced role of the forelimbs in propulsion. The cochlea is enlarging, whereas the vestibular system is rudimentary in size—a disparity that will remain in the adult. Olfactory bulbs and nerves are present in both odontocete and mysticete embryonic brains.

The rate of brain growth and degree of encephalization differs for different species (Pirlot and Kamiya, 1975). In the early fetal period, typical cetacean features begin to develop. For example, the olfactory bulbs and nerves disappear in odontocetes. In mysticetes, however, the olfactory bulbs and nerves are retained. Since adult mysticetes retain olfactory mucosa, it is presumed that they use a sense of smell to help locate plankton, particularly swarms of krill. There is some dispute, however, as to the existence of a vomeronasal organ (a chemoreceptive organ that functions mainly in detecting sexual pheromones in terrestrial mammals). Although it had been thought that adult whales had a vomeronasal organ, fetal studies of mysticetes and odontocetes show both the vomeronasal organ and the nerve to be absent (Oelschläger *et al.*, 1987). The function of a cetacean vomeronasal organ is purely speculative, but may include detecting the presence and mating status of other whales and perhaps even the odor of food in the mouth. The terminal nerve (a sensory, but not chemosensory, derivative of the olfactory placode sometimes called “cranial nerve 0”) persists and may function in autonomic innervation of intracranial arteries and mucous epithelium of the nasal air sacs.

In the mid-fetal period, the head and the neck regions align horizontally. During this process, the cervical section of the spinal cord, which was previously flexed ventrally, must now arch under and around the cerebellum to join the thoracic spinal cord (the dorsal aspect is thus concave). As the cervical vertebrae are compressed, much of the cervical spinal cord is contained within the skull.

VI. Gestational Length

Since whales are related to the terrestrial ungulates, it is not surprising that their gestation is of a similar length (Table I). Horses, for example, have a gestation of 11 months (compared with 9 months for a human’s pregnancy and 22 months for an elephant’s gestation). Gestation in mysticetes lasts for 10–14 months. The length of gestation in odontocetes, however, is more variable, ranging 9 to 17 months. The length of the gestation is not correlated with body size (e.g., although the sperm whale is the largest odontocete, its gestation period is nearly the same as the smaller pilot whale and less than the Baird’s beaked whale).

The length of gestation in cetaceans may be related to food supply and migration. Mysticetes mate in warm waters, migrate to cold waters to feed, and then migrate back to warm waters to calve. This

behavioral cycle, which takes 1 year, thus appears to be related to gestational length. Interestingly, since most feeding occurs in the colder waters, a pregnant mysticete whale may well be fasting while simultaneously spending energy in migratory locomotion and nourishing a growing embryo/fetus. In this regard, it is significant that the first half of the pregnancy (largely embryo development) takes place during the migration to the feeding areas, whereas the second half of the pregnancy (largely fetal growth) takes place during the migration back to the calving areas. A whale migrating to the feeding areas is not carrying a large load of stored energy, compared with a whale returning to the calving areas from the feeding areas. In some species, pregnant whales may increase food intake by 50–60% above normal during the last 6 months of gestation. Thus, the energy demands on a whale in the early pregnancy stages may be smaller than that of a whale in the later stages of pregnancy, when the fetus is growing at a rapid rate. In odontocetes, these energy constraints appear to have less of a temporal impact on gestational periods. This may be due, in part, to a more constant energy supply (year-round access to a food supply) for those species that migrate, or the lack of migration in other species.

Since the calf must be able to swim, see, hear, and vocalize immediately after birth, the nervous and the muscular systems of the calf must be well developed. This also translates to a fairly long gestation, with as much development as possible occurring prenatally (compared with the human baby, which completes much of its neuromuscular development postnatally). The long gestation also enables calves to grow to a large size before birth, reaching approximately 1/4 to 1/3 of the mother’s size. Once the fetus has attained a near adult form, the most dramatic changes appear to be mainly in the overall size of the fetus. As the fetal period progresses, the growth rate rapidly increases. For example, the blue whale (*Balaenoptera musculus*) gains approximately 100 kg/day in the last 2 months alone. Large newborns are also common among the whales’ closest land relatives, the ungulates, which also have well-developed neural and muscular systems at birth. An additional advantage of a large calf is a smaller surface-to-volume ratio (which helps the calf conserve heat). Thus, since whales have relatively large calves it is not surprising that multiple births are a rarity.

VII. Maternal Uterus, Placenta, and Umbilical Cord

Cetaceans have a bicornuate uterus (two horns joined in a Y-shape). The fetus usually develops in one horn (either horn for mysticetes, but most frequently the left horn for odontocetes), whereas the other horn is generally occupied by the allantois (one of the embryonic membranes) and placenta. The cetacean uterus has a complex vascular plexus that functions in countercurrent heat exchange (Rommel *et al.*, 1993). This keeps the fetus from overheating, despite its insulated location under the maternal blubber and adjacent to the locomotor musculature of the maternal abdomen.

The placenta is epithelio-chorial (or cotyledon), which means that the maternal and the fetal tissues do not fuse into one tissue, as in humans. Rather, their vascular systems remain separated by two epithelial layers with separate capillary beds. This arrangement ensures that the two layers separate relatively easily at birth, thus minimizing the inevitable loss of blood. Not surprisingly, this type of placenta is also found in the ungulates, the group of terrestrial mammals most closely related to cetaceans.

The umbilical cord is short and thick, with “amnion pearl” knobs on the outer surface that appear to regulate development

TABLE I
Cetacean Gestations and Newborn Calf vs Adult Measurements

	Gestation (in months)	Newborn calf length, weight	Mature adult length, weight
Mysticetes			
Right whale (<i>Balaena glacialis</i>)	12	4.5–6 m, 1,000 kg	10.09–17.7 m, 9,055–80,000 kg
Bowhead whale (<i>B. mysticetus</i>)	13–14	3.6–4.5 m, 1,000 kg	11.5–18 m
Pygmy right whale (<i>Caperea marginata</i>)	10	1.5–2 m	5.47–6.45 m, 3,100–3,500 kg
Gray whale (<i>Eschrichtius robustus</i>)	13–14	4.5–5 m, 500–800 kg	13–15.2 m, 14,000–35,000 kg
Humpback whale (<i>Megaptera novaeangliae</i>)	11–11.5	4–5 m, 900–1,500 kg	11.5–19 m, 25,000–48,000 kg
Minke whale (<i>Balaenoptera acutorostrata</i>)	10	2.4–3 m, 300–400 kg	6.9–10.7 m, 4,000–13,500 kg
Bryde's whale (<i>B. brydei</i> , <i>B. edeni</i>)	11–12	3.95–4.3 m, 900 kg	11.6–15.6 m, 16,000–25,000 kg
Sei whale (<i>B. borealis</i>)	11.5–12	4.5 m, 780 kg	13–18.3 m, 20,000–25,000 kg
Fin whale (<i>B. physalus</i>)	11	6.4–6.5 m, 1,750–1,800 kg	17.5–27 m, 30,000–90,000 kg
Blue whale (<i>B. musculus</i>)	11–12	7–8 m, 2,000–3,000 kg	19–31 m, 100,000–200,000 kg
Odontocetes			
Sperm whale (<i>Physeter macrocephalus</i>)	14–16	3.5–4.5 m, 1,000–1,016 kg	8.3–20.5 m, 16,000–57,000 kg
Pygmy sperm whale (<i>Kogia breviceps</i>)	11	1.2 m, 30 kg	2.42–3.7 m, 400 kg or less
Dwarf sperm whale (<i>K. sima</i>)	9–12	1–1.04 m, 14 kg	1.97–2.86 m, 210–303 kg
Cuvier's beaked whale (<i>Ziphius cavirostris</i>)	12	2.5–3 m	5.1–7.5 m, 3,000 kg
Baird's beaked whale (<i>Berardius bairdii</i>)	17	4.5–4.8 m	10–12.8 m, 11,000 kg
Northern bottlenosed whale (<i>Hyperoodon ampullatus</i>)	12	3–3.5 m	6–9.8 m
Southern bottlenosed whale (<i>H. planifrons</i>)	12?	2.5–2.9 m, 150–200 kg	5.7–7.8 m
Hector's beaked whale (<i>Mesoplodon hectori</i>)	?	1.8–2.1 m	4–4.5 m, 800 kg or less
True's beaked whale (<i>M. mirus</i>)	?	2.2–2.3 m, 136 kg	4.8–5.3 m, 1,394 kg
Gervais' beaked whale (<i>M. europaeus</i>)	?	1.6–2.1 m, 49 kg or more	3.7–5.2 m, 1,178 kg or more
Sowerby's beaked whale (<i>M. bidens</i>)	12	2.4–2.7 m, 185 kg	5.05–5.5 m
Gray's beaked whale (<i>M. grayi</i>)	?	2.1–2.42 m	4.74–5.64 m, 1,075–1,100 kg
Andrews'/deepercrest beaked whale (<i>M. bowdoini</i>)	10?	2.2 m	4.5 m or less
Hubb's beaked whale (<i>M. carlhubbsi</i>)	?	2.5 m	5.3 m, 1,432 kg
Strap-toothed whale (<i>M. layardii</i>)	9–12?	0.76–2.8 m	5–6.2 m
Blainville's beaked whale (<i>M. densirostris</i>)	?	1.9 m, 60 kg	4.5–5.8 m, 1,033 kg
Ganges river dolphin (<i>Platanista gangetica</i>)	10.5	0.67–0.9 m	1.7–2.5 m, 69–85 kg
Amazon river (boto) dolphin (<i>Inia geoffrensis</i>)	9–12	0.75–0.8 m, 7–8 kg	2–2.6 m, 100–160 kg
Chinese river dolphin (<i>Liptotes vexillifer</i>)	?	0.57–0.95 m, 10 kg or less	2.1–2.5 m, 125–160 kg
Franciscana (<i>Pontoporia blainvillei</i>)	10–11	0.7–0.8 m, 7.3–8.5 kg	1.4–1.74 m, 25 kg–53 kg
Beluga whale (<i>Delphinapterus leucas</i>)	14–14.5	1.5–1.6 m, 79–80 kg	3–5.5 m, 400–1,500 kg
Narwhal (<i>Monodon monoceros</i>)	14–15.3	1.5–1.6 m, 80 kg	3.4–4.7 m, 1,000 kg
Commerson's dolphin (<i>Cephalorhynchus commersonii</i>)	11–12	0.65–0.75 m	1.25–1.75 m, 35–86 kg
Hector's dolphin (<i>C. hectori</i>)	?	0.5–0.7 m	1.2–1.8 m, 50–60 kg
Rough-toothed dolphin (<i>Steno bredanensis</i>)	?	1 m	2.2–2.3 m, 122 kg
Humpback dolphin (<i>Sousa chinensis</i>)	?	0.9–1.08 m	2.1–3 m, 85–284 kg
Tucuxi/gray river dolphin (<i>Sotalia fluviatilis</i>)	10–10.2	0.7–0.92 m	1.3–1.9 m, 35–40 kg
Bottlenosed dolphin (<i>Tursiops truncatus</i>)	12	0.9–1.3 m, 32 kg	1.9–4 m, 90–650 kg
Indian Ocean/Red Sea bottlenose dolphin (<i>T. aduncus</i>)	12	1.03 m, 13.8 kg	1.8–2.43 m, 176–200 kg
Pan-tropical spotted dolphin (<i>Stenella attenuata</i>)	11.2–11.5	0.8–0.9 m	1.8–2.57 m, 100–119 kg
Atlantic spotted dolphin (<i>S. frontalis</i>)	12	0.76–1.20 m	1.9–2.3 m, 110–143 kg
Spinner dolphin (<i>S. longirostris</i>)	9–11	0.7–0.8 m	1.3–2.16 m, 26.5–75 kg
Striped dolphin (<i>S. coerulealba</i>)	12–13	0.8–1 m	2.16–2.4 m, 131–156 kg
Common dolphin (<i>Delphinus delphis</i>)	10–11.5	0.76–0.86 m	0.93–2.6 m, 70–163 kg

(continues)

TABLE 1 (Continued)

	Gestation (in months)	Newborn calf length, weight	Mature adult length, weight
Fraser's dolphin (<i>Lagenodelphis hosei</i>)	10–12?	0.95–1 m	2.25–2.65 m, 200 kg or more
White-beaked dolphin (<i>Lagenorhynchus albirostris</i>)	?	0.95–1.6 m, 40 kg or more	2–3 m
Atlantic white-sided dolphin (<i>L. acutus</i>)	10–12	1.08–1.22 m	2–2.8 m
Pacific white-sided dolphin (<i>L. obliquidens</i>)	10–12	0.8–1.24 m	1.7–2.5 m, 75–181 kg
Dusky dolphin (<i>L. obscurus</i>)	11	0.55–0.70 m, 3.7 kg	1.6–2.1 m, 40–80 kg or more
Northern right whale dolphin (<i>Lissodelphis borealis</i>)	?	0.8–1 m	2–3.1 m, 115 kg
Southern right whale dolphin (<i>L. peronii</i>)	?	0.86 m, 5 kg?	2.18–2.5 m
Risso's dolphin (<i>Grampus griseus</i>)	12–14	1.1–1.5 m, 59 kg	2.6–4.3 m, 500 kg
Melon-headed whale (<i>Peponocephala electra</i>)	?	1 m	2.2–2.75 m, 160–275 kg
Pygmy killer whale (<i>Feresa attenuata</i>)	?	0.8 m	2–2.6 m, 150–225 kg
False killer whale (<i>Pseudorca crassidens</i>)	15.1–15.6	1.2–1.93 m, 80 kg	3.5–6 m, 700–2,200 kg
Killer whale (<i>Orcinus orca</i>)	12–17	2.06–2.5 m, 180 kg	4.6–9.75 m, 2,600–10,500 kg
Long-finned pilot whale (<i>Globicephala melas</i>)	12–16	1.38 m, 55–85 kg	3.8–6.3 m, 280–1,750 kg
Short-finned pilot whale (<i>G. macrorhynchus</i>)	14.9–15	1.4–1.85 m, 55 kg	3.01–7.2 m, 600–3,950 kg
Irrawaddy dolphin (<i>Orcaella brevirostris</i>)	14	0.9–1 m, 12.3–12.5 kg	2.1–2.75 m, 85–150 kg
Finless porpoise (<i>Neophocaena phocaenoides</i>)	11–12	0.6–0.9 m	1.2–1.9 m, 35 kg
Harbor porpoise (<i>Phocoena phocoena</i>)	11	0.7–0.9 m, 5–9 kg	1.4–2 m, 40–90 kg
Burmeister's porpoise (<i>P. spinipinnis</i>)	11–12	?	?
Spectacled porpoise (<i>P. dioptrica</i>)	?	0.46–0.8 m?	1.8–2.4 m
Dall's porpoise (<i>Phocoenoides dalli</i>)	11–12	0.95–1 m, 25 kg	1.7–2.2 m, 123–200 kg

? = missing or estimated datum

(cornification) of fetal skin (Fig. 2). It contains two arteries and two veins, as well as an allantoic duct. When the calf is born, the umbilical cord breaks off at the fetal end, allowing the calf to swim unhindered to the surface. Since the mother does not appear to bite off the umbilical cord, it is presumed to break with little force at the moment of birth. The umbilical ring contains invaginations that probably weaken the connection between the fetal epithelium and the umbilical cord. The umbilical arteries and veins are also constricted and weak where they enter the fetal abdomen. The umbilical cord attaches midway along the length of the fetus (unlike the more caudal attachment found in fetuses of other mammals, in which the neck contributes more to fetal length than the tail). Thus, the umbilical cord will be stretched taut to the same degree regardless of whether the head or the tail is delivered first. The stretch from the delivered fetus pulling taut the umbilical cord, which is attached via the placenta to the mother's uterus, may cause its rupture at the umbilicus.

VIII. Fetal Position and Birth

Birth takes place underwater. In most observed captive births in odontocetes, the fetal tail emerged first through the vaginal opening. This tail-first presentation may appear unusual, particularly when compared with the usual head-first presentations of most terrestrial mammals. Interestingly, captive manatees have also been observed to deliver their young tail-first underwater. Although births in the wild have been less frequently documented, they appear to be more commonly tail-first presentations in odontocetes and may be equally

tail-first or head-first in mysticetes. As the pelvis in whales is rudimentary, it appears to have little, if any, effect on passage of the fetus during birth. In fact, the large size of the cetacean brain at birth may be possible, in part, because of the ease with which the large head of the fetus can be delivered through this rudimentary pelvis. Since there is no significant bony constriction at the pelvic outlet, there does not appear to be a physical need for a head-first delivery as in most large terrestrial mammals.

The higher frequency of tail-first presentations also may be explained by the shape and the intrauterine position of the fetus. The cetacean fetus has a fusiform shape, with the rostrum and the tail-stock both being relatively small in diameter. The tail flukes, dorsal fin, and pectoral flippers are very pliable, and are flattened against the body (fin and flippers) or curled back toward the midline to form a small knob (flukes). This folding and curling not only helps keep the fetal body within the smallest dimensions, but it also enables the fetus to maintain a relatively smooth exterior contour with no protrusions to inhibit delivery through the vagina. In addition, the whole fetus is laterally flexed into a U-shape, with the tail recurved toward the head so that the flukes are positioned adjacent to the rostrum. While this fetal folding reduces the intrauterine volume needed for carrying the fetus, it also leaves the fetus with both its rostrum and its tail flukes directed toward the maternal tail. However, since the uterine horn is also folded, only one end of the fetus can thus be directed toward the cervix. In odontocetes, it is most commonly the tail. Since the tail flukes are smaller than the cetacean head, they can therefore slip out the vagina more easily and thus are more likely to emerge first.

The head being directed away from the cervix before parturition may be a function of either fetal shape or fetal weight. Since both the center of gravity and the largest diameter is closer to the fetal head, its “rest” position may more likely be with the heavier fetal head nearer the center of gravity of the mother (Fig. 2). This places the fetal head in the more distensible part of the mother’s abdomen, and away from the more mobile tail-stock (which, due to locomotor constraints, may have less capability for expansion).

Once the fetus is settled into this birth position, continued growth appears to cause it to recurve caudally to fit within the mother’s abdomen. Unlike terrestrial mammals, the head is not flexed ventrally in the late-term cetacean fetus because there is practically no neck and the cervical vertebrae are largely fused. Rather, the fetus folds in half laterally to conserve space. The curved midsection of the fetus takes up more room in the maternal abdomen than the fetal head and tail. Thus, the fetal abdomen is placed cranially in the mother, where there is more room for expansion, whereas the fetal head and tail are directed caudally near the less expandable maternal tail-stock. Although the fetal head is directed caudally, it is positioned at the tip of the uterine horn (which is thus also folded to face caudally) and not adjacent to the cervix. In this folded position, it is unlikely that the fetus can reposition itself to completely switch from a tail-first to a head-first presentation. As the fetus is delivered, its body must unfold. Thus, midway through parturition, the fetal head will again face toward the maternal head as the fetal body straightens. The newborn calf bears light colored bands and shallow vertical grooves, called “fetal folds,” along the skin of the lateral abdomen (Fig. 3). These markings indicate the concave side of the fetus as it was folded *in utero*.

Circulatory System

PAUL J. PONGANIS

I. Introduction

Although the circulatory systems of marine mammals follow the general mammalian plan, they are most notable for features associated with the diving response, thermoregulation, and large body mass. This chapter will emphasize anatomical and functional aspects of the circulatory system in these animals.

The cardiovascular reflexes and adjustments which occur during diving are reviewed in Chapter Diving Physiology. Specific features of the circulatory system vary with orders, families, and species. These adaptations include large blood volumes, large capacitance structures (spleens and venous sinuses), venous sphincter muscles, vascular adaptations for thermoregulation, aortic windkessels, and vascular retia. The heart, arterial and venous systems, and blood volume will be discussed first. Then specific structural adaptations of the circulation in various groups will be considered.

II. General Anatomy

A. Heart

The basic structure and size of hearts in pinnipeds and cetaceans are typical of mammals. The four-chambered heart, with right ventricular outflow to the lungs, and left ventricular output to the systemic circulation, weighs 0.5% to 1% of body mass in most pinnipeds and small cetaceans (Slijper, 1962; King, 1983). In the great whales, relative heart mass is smaller, about 0.3% to 0.5% of body mass. Chamber size, stroke volume, and resting cardiac output and heart rate (where measured) are also in the general mammalian range, and in agreement with mammalian allometric equations. Both the foramen ovale and ductus arteriosus are closed in adult seals and cetaceans as in other mammals. Therefore, utilization of an intermittent fetal circulatory pathway does not appear to be a mechanism to bypass a potential increase in pulmonary vascular resistance during diving.

B. Arterial/Venous Systems

General aspects of the arterial and venous systems in marine mammals are remarkable for several features (Elsner and Gooden, 1983; Butler and Jones, 1997). First, dense sympathetic nerve innervation of proximal as well as distal arteries in seals may represent a mechanism by which the intense sympathetic vasoconstriction of the dive response can be maintained independent of local tissue metabolite induced vasodilatation in the periphery. Angiography during forced submersions of seals supports this model. Second, venous capacitance is highly developed, especially in phocid seals and whales. This includes a large hepatic sinus and posterior vena cava,

the latter of which in seals has been estimated to be capable of storing a fifth of the seal's blood volume. Presumably, this large venous capacitance is related to the large blood volume of seals.

In some species, the spleen appears to be a significant storage organ for red blood cells (Butler and Jones, 1997; Kooyman and Ponganis, 1998). Increased splenic volumes in several pinniped species, and extensive sympathetic nerve innervation and smooth muscle development in the splenic capsule, are consistent with this storage role. Fluctuations in hematocrit between resting and diving states, or anesthetized and stressed states also support such a role for the spleen in seals. It has been estimated that 30% of the blood volume can be stored in the spleen in Weddell seals.

Another feature of the venous system, again well developed in both seals and whales, is the extradural venous system (Harrison and Tomlinson, 1956). These veins, located within the vertebral canal and above the spinal cord, receive blood flow from the brain, back, and pelvic regions (Fig. 1). They are linked with both the posterior and anterior vena cava via paravertebral communicating veins. In seals and cetaceans, the extradural veins are the primary venous drainage of the brain; the internal jugular vein is poorly developed or absent. The function of such a prominent vertebral venous system in these animals is unclear. In humans, it has been noted that extradural vein flow may participate in brain temperature regulation, and that, in the upright posture, the vertebral veins, kept open by attachment to the bony walls of the vertebral canal, are the primary cerebral venous drainage since blood flow decreases in the jugular veins due to venous collapse in the upright posture (Gauer and Thron, 1965). The direction and magnitude of flow within the extradural vein vary with the respiratory cycle (Ronald *et al.*, 1977). During a breath hold (apnea), extradural vein flow is low and has been reported to vary in direction (i.e., rostrally or caudally; Fig. 2). However, during breathing (eupnea), extradural vein flow is increased and rostral in direction (Fig. 3). It has been estimated that the extradural vein may contribute as much as 20% of eupneic venous return to the heart via its intrathoracic connections to intercostal veins, the enlarged right azygous vein, and the anterior vena cava (Ponganis *et al.*, 2006). These intrathoracic connections allow transmission of negative inspiratory pressures within the chest to the extradural vein. This enhances rostral blood flow during the inspiration since the ligamentous attachments of this vein to the vertebral canal prevent

Figure 1 Venous anatomy of the phocid seal (modified from King, 1983). Notable features include the prominent extradural vein, large hepatic sinus, vena caval sphincter muscle, and numerous intrathoracic venous connections (pericardial venous plexus, intercostals veins, right azygous vein). Structures are not drawn to scale.

Figure 2 Routes of venous return of blood to the heart during a breath hold (modified from Ponganis et al., 2006; after King, 1983). Blood flow in the extradural vein is low in magnitude and variable in direction. Primary control of venous return is via the vena caval sphincter. Blood also returns to the heart via the anterior vena cava.

Figure 3 Routes of venous return of blood to the heart during breathing (modified from Ponganis et al., 2006; after King, 1983). Primary return is again via the posterior vena cava, and the anterior vena cava. It is postulated that extradural vein flow may also contribute as much as 20% of venous return during inspiration via connections to the intercostal veins, right azygous vein, and pericardial plexus. (Arrows do not indicate magnitude of flow at any site).

collapse of the vein. Therefore, at least one important function of the prominent extradural vein in seals may be its contribution to eupneic venous return to the heart.

C. Blood Volume

Blood volumes are elevated and contribute to increase blood oxygen stores in marine mammals (Butler and Jones, 1997; Kooyman and Ponganis, 1998). On a mass specific basis, most measurements indicate that blood volumes are 2–3 times the 70 ml/kg human value, and that blood volume is greater in more active, and in longer diving species. The largest blood volumes (200–260 ml/kg) have been found in some of the best divers, including elephant seals, Weddell seals, and sperm whales.

III. Structural Adaptations

A. Vascular Thermoregulatory Adaptations

The parallel pattern of counter-flowing arteries and veins, characteristic of counter current exchange units, is present in the flukes and flippers of cetaceans (Scholander and Schevill, 1955). Such arrangements, characteristic of blood vessel patterns in the limbs of many animals, are considered to conserve body heat by transferring heat from warm, out-going arterial blood to cool venous blood returning

from the limb. A superficial venous system, which does not return in conjunction with out-going arteries, also occurs in the skin. These veins, which have well-developed muscular walls, are considered to represent a route by which heat can be dissipated to the environment during periods of thermal stress.

Another structural adaptation observed in pinnipeds is the presence of numerous arterio-venous (a-v) anastomoses in the skin (Bryden and Molyneux, 1978). These structures represent a mechanism by which blood bypasses tissue capillary networks, and instead shunts directly from the arterial to venous system. The a-v anastomoses are distributed uniformly over the body surface of phocid seals, but, in otariids, are found in greater densities in the flippers. It is presumed that flow through these vessels allows heat exchange at the skin surface.

More recently, counter current anatomy has been observed in the reproductive organs of dolphins and pinnipeds (Rommell et al., 1995). It has been proposed that return of blood from the skin via vascular anastomoses allows relatively cool venous blood to prevent overheating of these organs. Temperature patterns along the length of the colon in the dolphin have been consistent with this hypothesis.

B. Aortic Bulbs/Windkessels

In pinnipeds, again particularly in phocid seals, the aortic root (ascending aorta) is dilated, forming the so-called aortic bulb. The

bulb can accommodate the stroke volume ejected by the heart, and it is more distensible than the distal aorta. It has been proposed that the aortic bulb acts as a windkessel: gradual contraction of the bulb due to elastic fibers within its wall contributes to maintenance of blood flow especially to the brain and heart during diastole (relaxation phase of the cardiac cycle).

The ascending aorta, aortic arch, and proximal carotid arteries of whales are also very compliant, and have also been hypothesized to act as a windkessel and preserve blood flow during diastole (Shadwick and Gosline, 1994). This is especially important in whales because long diastoles accompany slow heart rates. Low heart rates can occur in whales due to both their large body masses and the cardiovascular responses which occur during diving.

Maintenance of blood flow and pressure during a long diastole is of course critical to the brain, but also to the heart. This is because coronary perfusion occurs during diastole when the heart is relaxed. Myocardial flow is dependent on the diastolic blood pressure as the driving pressure. Thus, species which are either large or have more profound diving responses are likely to have some form of an aortic windkessel.

A compliant ascending aorta may also contribute to a reduction in the impedance that the left ventricle must pump against during the peripheral vasoconstriction of the diving response. This reduction in afterload will decrease the work and oxygen consumption of the heart, which is of course beneficial to a diver with a limited oxygen supply.

C. Vascular Retia

The *retia mirabilia* (wonderful nets) of cetaceans have long been noted by anatomists (Slijper, 1962; McFarland *et al.*, 1979). These plexuses of anastomosing arteries and veins occur along the vertebrae and base of skull, and are especially prominent in the thorax. The vascular retia are well developed in dolphins, in fact, more so than in large whales; they are also found in sirenians.

The thoracic rete is supplied by vessels from the aorta, which anastomose to form a complex, spongiform structure beneath the dorsal thoracic wall (Fig. 4). This vascular tissue extends around the vertebrae into the vertebral canal, and forms the primary arterial blood supply to the brain in cetaceans. The carotid arteries are vestigial or absent. The spinal meningeal artery in dolphins extends from the rete to the brain. Although mean blood pressure in the spinal meningeal artery of dolphins is equal to the aortic pressure, it is notable that the pressure is non-pulsatile; there is no systolic peak or diastolic trough. Thus, the cetacean brain appears to receive non-pulsatile blood flow. The significance of such a flow pattern as well as the function of the retia are unknown.

Slijper also reports the presence of large venous retia in the abdomens of whales. Hypotheses about the role of the retia have included windkessel functions, intrathoracic vascular engorgement to prevent “lung squeeze” during diving, thermoregulation, and modification of composition of the blood.

D. Inferior Vena Caval Sphincter

In most pinnipeds, the posterior vena cava is associated with a striated muscle sphincter at the level of the diaphragm (Fig. 5). Again, this is most well developed in phocid seals (Harrison and Tomlinson, 1956; King, 1983). The sphincter is innervated by the right phrenic

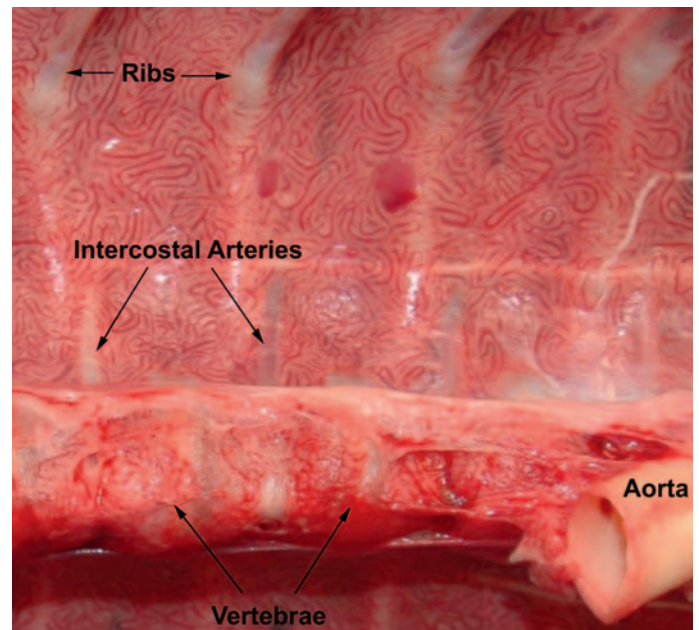

Figure 4 Ventrol view of thoracic rete mirabile (red swirls between ribs) in the right chest of a common dolphin, *Delphinus delphis*. Resection of the aorta reveals intercostal arteries at base of spinal column. These vessels extend into the rete. Dorsal is on bottom.

Figure 5 The posterior vena caval sphincter muscle of an elephant seal (modified from Harrison and Tomlinson, 1956). A: Transected muscle of the vena caval sphincter and B: openings of the pericardial venous plexus into the thoracic portion of the posterior vena cava.

nerve, and is located cranial to the large hepatic sinus and inferior vena cava. Relaxation/contraction of the sphincter has been observed angiographically during forced submersions, and it is assumed that this is a mechanism to regulate venous return to the heart during diving bradycardias (Harrison and Tomlinson, 1956; Ronald *et al.*, 1977; Elsner and Gooden, 1983). Vena caval sphincters are also described in whales (Slijper, 1962); they presumably regulate blood return from the large venous capacitance vessels in the abdomen (posterior vena cava and venous rete).

Another venous structure, especially developed in phocid seals, is the pericardial venous plexus (Harrison and Tomlinson, 1956). This extensive venous network is connected to intercostal veins, internal thoracic veins, and a sub-diaphragmatic venous plexus; empties into the posterior vena cava just cranial to the vena caval sphincter (Figs 1 and 5). It is especially developed in the better diving seals such as elephant seals. Its significance is unknown, although it has been reported to be associated with brown fat and has been hypothesized to function in thermoregulation (Blix *et al.*, 1975). It may also be part of the pathway for eupneic venous return.

Classification (Overall)

DALE W. RICE

Four clades of placental mammals (class Mammalia: cohort Placentalia) independently evolved adaptations for life in the oceans. These are the still-living pinnipeds (sea lions, walruses, and seals), cetaceans (whales, dolphins, and porpoises), and sirenians (manatees and dugongs), and the extinct desmostylians. The pinnipeds are amphibious animals capable of terrestrial locomotion, and must haul out on shore to give birth. The cetaceans and sirenians (except for a few primitive Eocene species) are totally aquatic, having lost their hind limbs and evolved huge muscular tails with terminal flukes for swimming. The extinct desmostylians were quadrupedal amphibious creatures. The pinnipeds and cetaceans are carnivorous, the sirenians and desmostylians are herbivorous. Although primarily oceanic, several members of each of the three living groups have secondarily invaded freshwater habitats. The systematics of all of these sea mammals, living and fossil, is a flourishing field of research; many details are currently contested, and several paraphyletic groupings await resolution, so changes in the prevailing classification (Table I) may be anticipated.

I. Pinnipeds

The pinnipeds were long classified as order Pinnipedia, separate from but closely related to the terrestrial carnivores of the order Carnivora. In recent years cladistic analyses of both morphological and molecular data have clearly shown them to be members of the suborder Caniformia of the order Carnivora.

Two strongly differentiated groups of living pinnipeds were long recognized: the eared seals, or sea lions and fur seals (family Otariidae), and the earless, or true, seals (family Phocidae); the walruses (family Odobenidae) were usually associated with the former group. Some taxonomists maintained that pinnipeds are a diphyletic assemblage, and that the eared seals shared a common ancestry with the bears (family Ursidae), while the true seals were most closely related to the weasel group (family Mustelidae), or more specifically the otters (subfamily Lutrinae). Those authorities allocated the pinnipeds to two superfamilies: Phocoidea for the family Phocidae, and Otarioidea, which included the extinct families Enaliarctidae and Desmatophocidae, and the extant Otariidae and Odobenidae. The Enaliarctidae included several late Oligocene and early Miocene genera that were postulated to have given rise to the other three families of otariids in the Miocene (Repenning and Tedford, 1977).

With the advent of cladistic methods, a different picture emerged. All of the molecular analyses and most of the morphological analyses have supported the hypothesis that all pinnipeds shared a common ancestry. However, the position of the pinnipeds within the suborder Caniformia is still disputed. Although some investigators favor a sister-group relationship to the Ursidae, other studies (Bininda-Emonds and Russell, 1996; Dragoo and Honeycutt, 1997) do support a closer affinity to the Mustelidae. One analysis placed the genus *Kolponomos* as the sister taxon of the pinnipeds. *Kolponomos*, an amphibious bear-like creature that lived along the coasts of Washington and Oregon during the Miocene, is currently listed in the family Amphicyonodontidae, a paraphyletic group from which the Ursidae descended (Tedford *et al.*, 1994). With the present preponderance of evidence, the most appropriate classification is that of McKenna and Bell (1997), who rank the

Extinct taxa are marked with a dagger (†), and taxa that appear to be paraphyletic are marked with an asterisk (*). Abbreviations: E = early; M = middle; L = late; Eoc. = Eocene; Olig. = Oligocene; Mioc. = Miocene; Plioc. = Pliocene; Pleist. = Pleistocene; Rec. = Recent

¹Sources: McKenna and Bell 1997 (pinnipeds); Gingerich 2005 (archeocetes); Fitzgerald 2006 and Steeman 2007 (mysticetes); Fordyce and Muizon (1991) with updates (odontocetes); Domning 1994 and Gheerbrant *et al.*, 2005 (Sirenians); Inuzuka 2000 (desmostylians).

pinnipeds as the superfamily Phocoidea, and the bear-like terrestrial carnivores as the superfamily Ursoidea, both under the parvorder Ursida, and place the mustelids in parvorder Mustelida; those authors also included all the genera of amphicyonodonts as unallocated stem groups of the Phocoidea.

The cladistic studies have also reopened the question of interfamilial relationships of pinnipeds. A total-evidence analysis indicated the following "phyletic sequence": Desmatophocidae—Phocidae—Odobenidae—Otariidae (Dragoo and Honeycutt, 1997). The traditional pairing of the Odobenidae with the Otariidae was likewise

supported by molecular and morphological analyses of the living taxa. However, a comprehensive morphological analysis (Berta and Wyss, 1994) affirmed the paraphyletic nature of the Enaliarctidae, and arranged the other families of pinnipeds in the following phyletic sequence: Otariidae—Odobenidae—Desmatophocidae (paraphyletic).

Mention must be made of three other fossil genera of "otter-like seals" or "seal-like otters." These are *Potamotherium* with two species from freshwater Oligocene and Miocene deposits in Europe and North America, *Semantor macrurus* from freshwater Miocene or Pliocene deposits of Kazakhstan, and *Necromites nestoris* from

a marine Pliocene stratum of Azerbaijan. The latter two are known only by the hinder halves of their skeletons. All three have been proposed as primitive pinnipeds or phocids, but their phylogenetic placement remains totally problematic.

II. Cetaceans

Whales differ so much from other placental mammals that their evolutionary relationships long remained conjectural. Gregory (1910) ranked Cetacea as a superorder—one of seven into which he divided all placental mammals. Simpson (1945) ranked Cetacea as an order, but made it the sole member of “cohort” Mutica, one of his four cohorts of placental mammals. Both of these classifications implied that the Cetacea had no close affinity with any of the other orders of mammals.

The marked anatomical dissimilarities between the baleen whales and the toothed whales led a few earlier cetologists to question the monophyly of the Cetacea, but none of them ever proposed an explicit hypothesis of diphily. However, all recent studies, both morphological and molecular, overwhelmingly confirm the monophyletic origin of cetaceans.

During the past several decades a remarkable series of Eocene fossil cetaceans has been unearthed, mostly near the shores of the ancient Tethys Sea in Pakistan, India, and Egypt (Thewissen, 1998). These finds document the rapid evolutionary transition of the cetaceans from amphibious quadrupeds to fully aquatic forms during the interval from 34 to 54 million years ago (Ypresian through Priabonian). The phylogenetic relationships among these primitive Eocene cetaceans have yet to be fully resolved. For the interim they are allocated to five families, some of which are paraphyletic (Uhen, 2004). The entire assemblage has traditionally been included in the paraphyletic suborder Archaeoceti.

Early cladistic analyses of morphological data from fossil and living taxa showed the cetaceans (order Cetacea) and the extinct mesonychids (order Acreodi or Mesonychia) as monophyletic sister groups, which together constituted the sister group to the monophyletic Artiodactyla (O’Leary and Geisler, 1999). The mesonychids were cursorial, wolf-like creatures whose feet had five toes that bore hoof-like claws; they lived throughout the Holarctic from the early Paleocene to the early Oligocene. This apparent close relationship between the mesonychids and cetaceans became the generally accepted hypothesis (Luo and Gingerich, 1999), and led McKenna and Bell (1997) to classify both in order Cete, and to reduce Acreodi and Cetacea to subordinal rank. They further divided the Cetacea into two infraorders, Archaeoceti and Autoceta [*sic*], with the latter including the Mysticeti (baleen whales) and Odontoceti (toothed whales) as parvorders.

However, a contradictory classification resulted when cladistic analyses were based solely on the molecular data. In those studies the Cetacea consistently appeared within the Artiodactyla (even-toed hoofed mammals), and now a sister–taxon relationship between the cetaceans and hippos (family Hippopotamidae) is strongly supported (Nikaido *et al.*, 1999; Shimamura *et al.*, 1999). Especially strong support for this hypothesis comes from the presence of SINEs (short interspersed elements) in the genomes, SINEs are unique nucleotide sequences of 70 to 500 base pairs, more than 1000 copies of which are inserted throughout the genome. Because of these features, convergence of SINE sequences between any two lineages, or complete loss of the complement of SINEs, is virtually impossible. Thus they are near-perfect characters for phylogenetic analyses. Many authors then classified the living orders Artiodactyla and Cetacea under a supraordinal taxon Cetartiodactyla. Subsequent molecular studies are converging toward a consensus classification of the living Cetartiodactyla:

CETARTIODACTYLA	Montgelard, Catzeflis, and Douzery (1999)
TYLOPODA	Illiger (1811) Camels
ARTIOFABULA	Waddell, Okada, and Hasegawa (1999)
SUINA	Gray (1868) Pigs
CETRUMINANTIA	Waddell, Okada, and Hasegawa (1999)
CETANCODONTA	Arnason <i>et al.</i> (2000) ¹
ANCODONTA	Matthew (1929) Hippopotamuses
CETACEA	Scopoli (1777)
MYSTICETI	Cope (1869) Baleen whales
ODONTOCETI	Flower (1867) Toothed whales
RUMINANTIA	Scopoli (1777)
TRAGULINA	Flower (1883) Chevrotains
PECORA	Linnaeus (1758) Pecorans

At first paleontologists were skeptical of these molecular results. Despite the rich fossil record of the artiodactyls, there appeared to be no evidence that would support the derivation of cetaceans from hippos or any other subclade within the Artiodactyla. There was a gap in the fossil record between the early Eocene, when cetaceans arose, and the late Miocene, when the hippos first appeared. However the latter objection would be weakened if Boisserie *et al.* (2005) are correct in claiming that hippos are simply late-surviving anthracotheres. The anthracotheres were mostly amphibious pig-like creatures that lived from the middle Eocene to the Miocene.

Are cetaceans the sister group to the Mesonychia, or did they arise from within the Artiodactyla? This controversy was finally resolved with the recovery of the heel bones (astragali) of three species of ancestral cetaceans which had functional hind legs: *Pakicetus attocki* and *Icthyolestes pinfoldi* of the Pakicetidae and *Rodhocetus balochistanensis* of the Protocetidae (Gingerich *et al.*, 2001; Thewissen *et al.*, 2001). These three cetaceans were found to have had “double-pulley” heel bones, a character diagnostic of the Artiodactyla. On this type of astragalus the articular facets on both the proximal (tibial) end and the distal (navicular) end are trochleated, or shaped like the wheel of a pulley. Subsequent studies revealed other morphological similarities between whales and hippos (Geisler and Uhen, 2003).

Price *et al.* (2005) calculated a fully resolved “supertree” for all living species of Cetartiodactyla, based on all available published morphological characters. Their results were congruent with the classification based on molecular data, noted above. The most recent and comprehensive phylogenetic analysis of both living and fossil taxa, based on morphological characters, again was largely congruent with the molecular results as far as the living taxa are concerned (Geisler *et al.* 2007). In this tree the Cetacea, Hippopotamidae, and the extinct Raoellidae appear as an unresolved trichotomy; the anthracotheres appear as the sister group to this clade. Thewissen *et al.* (2007) made a detailed comparison between the earliest cetaceans and the Raoellidae, both of which lived in the same area during the Eocene, and concluded that the two taxa are sister groups.

¹Arnason *et al.* (2000) proposed the name CETANCODONTA as a replacement for WHIPPOMORPHA Waddell, Okada, and Hasegawa (1999). This change was made to avoid confusion with the name HIPPO MORPHA Wood (1937), which is currently in use as a suborder of the order Perissodactyla.

The raoellids were raccoon-sized amphibious creatures—Thewissen *et al.* (2007) likened their habitus to that of the living water chevrotains (*Hyemoschus aquaticus*) of central Africa.

The more advanced post-Eocene cetaceans are postulated to have descended from an archeocete, most plausibly a member of the family Basilosauridae, subfamily Dorudontidae. The monophyly of each of the two modern suborders, Mysticeti and Odontoceti, is strongly corroborated by a suite of complex morphological synapomorphies. The oldest fossil cetacean allocated to the suborder Mysticeti is *Llanocetus denticrenatus* (family Llanocetidae) from the end of the Eocene of the Antarctic Peninsula. This and several Oligocene genera of the families Aetiocetidae, Janjucetidae, Kekenodontidae, and Mammalodontidae all possessed teeth rather than baleen. In the late Oligocene appeared the first toothless, baleen-bearing cetaceans; they were long assigned to the family Cetotheriidae, a paraphyletic assemblage from which the four living families descended. In a recent cladistic analysis, Steeman (2007) resolved the old Cetotheriidae into five monophyletic families: Cetotheriidae (*sensu stricto*), Cetotheriopsidae, Pelocetidae, Aglaocetidae, and Diorocetidae.

The earliest members of the suborder Odontoceti appeared in the late Oligocene. During that epoch there lived a number of peculiar genera whose phylogenetic relationships remain unresolved. One distinctive superfamily, the Eurhinodelphinoidea, or long-snouted dolphins, diversified and then died out during the Miocene. All of the living odontocetes other than the peculiar river-dolphins clearly fall into three superfamilies, Physeteroidea (sperm whales), Ziphiioidea (beaked whales), and Delphinoidea (dolphins, porpoises, etc.), all of which first appeared in the late Oligocene (Muizon, 1988, 1991). Beaked whales were long thought to be closely related to sperm whales, but a majority of recent cladistic analyses suggest that they are closer to the delphinoids. Studies of the river-dolphins have resulted in an emerging consensus that the Platanistidae are only distantly related to the others, and are closer to the family Squalodontidae, or shark-toothed porpoises, that lived during the Miocene. The Iniidae, Lipotidae, and Pontoporiidae appear to constitute one or more branches from the ancestral lineage of the Delphinoidea.

III. Sirenians

Because of their superficially whale-like physique, many nineteenth century naturalists classified the sirenians as the “herbivorous cetacea.” Modern studies have revealed that the Sirenia, along with the extinct Desmostylia, are marine members of a supraordinal group called the Tethytheria, which also embraces the elephants (order Proboscidea) and several other extinct groups (Ray *et al.*, 1986). The earliest sirenians had four limbs and were capable of terrestrial locomotion (Domning, 2001). The early to middle Eocene *Prorastomus* (family Prorastomidae) probably swam with only its hind limbs, but the middle Eocene *Protosiren* (family Protosirenidae) probably used its well-developed tail as well. The latter genus thus foreshadowed the still-living Dugongidae and Trichechidae, fully aquatic forms which have lost their hind limbs and swim by means of caudal flukes (Domning, 1994).

IV. Desmostylians

The affinities of the Oligocene and Miocene desmostylians long remained problematic because they were known only from skulls recovered from the North Pacific rim, but many early authors classified them as a suborder of the Sirenia. Discovery of complete skeletons finally showed them to be quadrupedal hippopotamus-like animals, sufficiently different from sirenians to be ranked as a separate order. The most recent cladistic analysis places the Desmostylia

closer to the Proboscidea than to the Sirenia (Ray *et al.*, 1994). McKenna and Bell (1997) demoted the Tethytheria to a suborder of their new order Uranotheria, under which they ranked Sirenia as one infraorder, and also included the Desmostylia and Proboscidea as parvorders under the infraorder Behemota, but almost all recent authors still refer to Desmostylia as an order. Two families are recognized, Paleoparadoxiidae and Desmostylidae (Inuzuka, 2000).

V. Other Marine Species

Several species of mammals that belong to otherwise terrestrial groups have become facultative or obligate members of the marine ecosystem (Rice, 1998). The polar bear (*Ursus maritimus*; family Ursidae) and the arctic fox (*Vulpes lagopus*; family Canidae) range widely over the north polar pack-ice. Among the 10 or so species of otters (family Mustelidae: subfamily Lutrinae), the sea otter (*Enhydra lutris*) of the North Pacific and the marine otter (*Lutra felina*) of western South America are strictly marine, and local populations of at least six other species feed in coastal marine waters. Two species of bats (order Chiroptera) also catch fish in coastal waters, the greater bulldog bat (*Noctilio leporinus*; family Noctilionidae) of the neotropics and the fishing bat (*Myotis vivesi*; family Vespertilionidae) of the Gulf of California. Finally, the most unexpected marine mammals were five species of large ground sloths of the genus *Thalassocnus* (order Phyllophaga: family Nothrotheriidae) which lived along the coast of Peru from the late Miocene to the late Pliocene (Pujos and Salas, 2004). They evidently grazed on algae or seagrasses.

Climate Change

SUE E. MOORE

Global climate change is shifting the state of the world ocean toward a future of increased acidity, reduced productivity and sea ice cover, higher sea levels and loss of marine biodiversity and ecosystem function (IPCC, 2007). Reduction in ocean productivity over the past decade has been driven chiefly by the warming and stratification of low latitude waters, which blocks nutrients necessary for phytoplankton growth (Behrenfeld *et al.*, 2006). Simultaneously, warming has resulted in dramatic reductions in sea ice at sub-polar and polar latitudes, with concomitant shifts anticipated in marine ecosystem structure (Bluhm and Gradinger, 2007). The impacts of these changes on marine mammals will be mainly indirect, often mediated through alteration of physical habitat and predator–prey dynamics. The concept of ecological scale, described as the interface between population biology and ecosystem science (Levin, 1992), is used here to interpret how climate change may affect marine mammals (Moore, 2005). Because many species of marine mammals migrate between feeding and breeding areas, the concept of phenology, or the relation between climate and periodic biological phenomena, is also invoked (Root *et al.*, 2003; Durant *et al.*, 2007). Finally, potential synergies between climate change and the rate and extent of marine mammal exposure to disease or natural toxins are considered (Harvell *et al.*, 2002; Van Dolah, 2005).

I. Ecological Scale

The effects of climate change on a given species will vary with the ecological scale on which that species exists. Ecological scale is determined by intrinsic life history characteristics and, for marine mammals, can extend from years to centuries in time and from tens to thousands of kilometers in space (Fig. 1). While individuals of some species roam across ocean basins for decades to centuries, others live shorter but more productive lives (in terms of number and frequency of offspring) within small freshwater, estuarine or coastal home ranges. This breadth of scale can confound attempts to predict and describe the effects of climate change on marine mammals as a group. A basic tenet of ecology is that community structure is influenced by (a) disturbance events that physically alter habitats and (b) competition among species for resources in those altered habitats. On the temporal scale, it is possible that marine mammals can adapt to disturbance introduced by climate change, given that most extant species have evolved over roughly the past 10 million years. However, it may be that ice-obligate species may not adjust as rapidly as more recent invading migrants that are evolved to more open water conditions. While description of the actual evolutionary steps that led to existing marine mammal fauna is outside the bounds of

Figure 1 Marine mammal ecological scale (shaded area) is determined by a species' intrinsic life history characteristics and, for marine mammals, can extend from years to centuries in time and from tens to thousands of kilometers in space. Reproduced from Moore (2005), with permission.

scientific measurement, impacts on marine mammals of anticipated warming over the next 50–100 years can be addressed with an eye toward the effects of disturbance anticipated across latitudinal zones.

A. Marine Mammals in Polar Regions

In polar regions, the loss of sea ice and glacial disintegration are the clearest signals of disturbance to the marine environment attributable to climate change. In the Arctic, polar basin multiyear sea ice has disappeared at a rate of 9% per decade over the past 30 years. If that rate continues or increases due to the absorption of heat by larger expanses of dark sea water (the albedo effect), the Arctic Ocean will be ice-free in September by sometime between 2040 and 2060. Of note, the rate of loss of seasonal sea ice measured to date varies among Arctic sub-regions and most models predict retention of sea ice during winter. The effects of the loss of seasonal sea ice, including declines in total ice cover and thickness as well as earlier breakup, will depend on the degree to which a species uses sea ice for basic life functions. Classifying the various species as ice-obligate, ice-associated, or seasonally migrant provides a conceptual model (Fig. 2). Clearly, the loss of sea ice will be most detrimental to those species, such as the polar bear (*Ursus maritimus*), the walrus (*Odobenus rosmarus*), and ice seals, that rely on ice as a platform for hunting and giving birth. For some ice seals, warmer temperatures and increased precipitation will further degrade sea ice habitat, including subnivean lairs that are required by ringed seals for rearing pups. Diminished sea ice could have cascading effects on the prey of ice-associated whales and seals. In some cases, loss of sea ice could be beneficial if it enhances productivity along the ocean basin slopes and shelves. In other cases, the decline of sea ice may result in the loss of preferred prey items, and the predators that cannot switch to alternative food will decline in numbers and perhaps range. The loss of sea ice may be most advantageous to seasonally migrant species, as it will give them opportunities to forage in Arctic waters earlier and stay later in the feeding season. Because humans live and exploit resources in the Arctic, changes in access as a result of climate change will complicate and compound the effects of sea ice loss on marine mammals. Importantly, all of the linkages shown in Fig. 2 are dynamic and interconnected. Sea ice loss will precipitate complex and cascading interactions among physical and biological components of the Arctic ecosystem. As top predators in this system, marine mammals are well positioned to function as well-observable indicators of climate change (Laidre *et al.*, 2008; Moore and Huntington, 2008).

Changes in marine mammal distribution and movements may also signal ecosystem shifts accompanying the loss of Antarctic sea ice. The dynamic relationship between sea ice and krill will mediate the impact of climate warming on whales, seals, and seabirds in the Southern Ocean. The density of krill, the primary prey of migratory baleen whales and many Antarctic seals, is positively correlated with extensive sea ice. Off the Antarctic Peninsula, years of extreme ice extent have been associated with high krill biomass and “good” years for penguins and seals. Conversely, reduced sea ice is associated with high salp biomass, few krill, and poor survivorship for young seals and penguins. Although the production–prey–predator dynamics among ice, krill, and whales remain poorly understood, feeding opportunities for large whales, at least in some regions of the Antarctic, are likely to decrease with the loss of sea ice.

B. Marine Mammals in Temperate and Tropical Regions

In temperate and tropical regions, ocean acidification and coral bleaching are the clearest signals of disturbance to the marine environment from climate change. Although these signs of environmental perturbation are alarming in their own right, the ultimate effects of these changes on marine mammals are not immediately evident. Although acidification will have cascading effects on trophic structure in the oceans, responses at the level of marine mammal prey cannot yet be predicted. Many climate models predict increases in sea level concomitant with thermal expansion of the warming oceans and melting of glaciers and ice caps. Rising sea levels can mean a loss of habitat for seals and sea lions that rely on low-lying coastal areas for rest, molting, pup birth and rearing, and courtship/mating. In the case of endangered and endemic fauna, such as Hawaiian monk seals (*Monachus schauinslandi*) in the Northwestern Hawaiian Islands, an evaluation of potential effects of sea level rise by 2100 found that maximum projected habitat loss ranged from 65% to 75% under median and maximum scenarios of sea level rise, respectively. For small isolated populations, such as those of monk seals (*Monachus* spp.), this loss of habitat increases extinction risk. Some climate change models predict increasing storm events, which may deepen the mixed layer and thereby increase nutrient availability in the upper ocean and ultimately enhance production of marine mammal prey. Storm effects are predicted to be most evident in temperate and sub-polar waters, and could result in more prey for marine mammals in these domains. At the same time, storms can severely

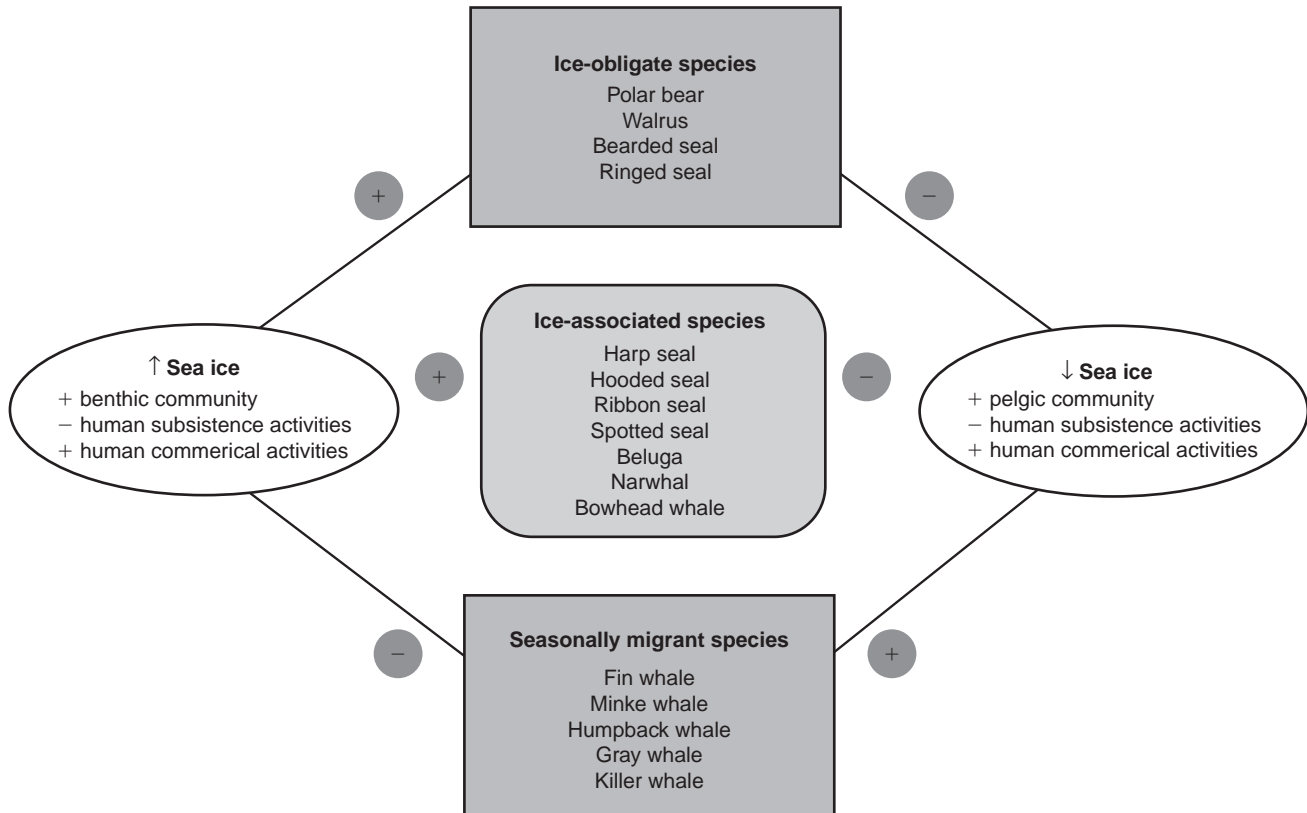

Figure 2 A conceptual model of sea ice impacts on ice obligate, ice associated and seasonally migrant marine mammal species. Dashed lines indicate uncertainty regarding potential impact of sea ice gain or loss for ice-associated species. Marine mammals will be affected by anticipated changes in productivity in both benthic and pelagic prey communities, and by changes in human subsistence and commercial activities in the Arctic. From Moore and Huntington (2008), with permission.

reduce the survival of young pinnipeds on land or ice, and have catastrophic effects on sirenian feeding habitat.

II. Phenology

Although marine mammal species have responded to climatic changes throughout their evolutionary history, the rates of those changes have been far slower than that measured during the past 100 years. Responses to recent global warming across a range of species from grasses and trees to mollusks and mammals have included poleward shifts in distribution and changes in the timing (phenology) of life history events such as migration, flowering, or reproduction. The broad-scale annual migrations by marine mammals between feeding and breeding areas have evolved to maximize foraging, reproductive success, and offspring survival. Although the environmental cues that initiate migration are not well understood, there is evidence to suggest that climate change is altering the timing of migrations in some marine mammal species. Such alteration in timing, or shifts in seasonal changes, to physical habitat, can lead to a mismatch between predator requirements and prey availability on the feeding grounds.

A. Migration Timing

Long-term data on migratory timing are available for only a few marine mammal species. One of the best records is that for the migration of Eastern North Pacific gray whales (*Eschrichtius robustus*) between feeding areas offshore Alaska and Siberia and breeding areas in the lagoons and coastal waters of Baja California, Mexico. The southbound migration for this population has been documented from

a census site in central California over the past 40 years, providing a rare opportunity to examine migratory timing. In doing so, researchers were able to define a week delay in migration that coincided with, and appeared to be a step-response to, the strong El Niño (periodic ocean warming) event that occurred in the North Pacific during 1998/1999. Prior to 1998/1999, the overall median date for gray whales passing southbound was 8 January, but since then the overall median date has shifted to 15 January. This shift in migration timing was accompanied by reports of more calves seen offshore California, well north of the Mexican calving areas. These observations suggest that gray whales have modified their migration timing, and possibly their breeding range, in response to a climate event in the ocean. In another less-well-documented case, belugas (white whales, *Delphinapterus leucas*) that migrate along the Alaskan coast in summer now arrive near the village of Point Lay roughly 2 weeks earlier than they did in the 1980s. Subsistence hunters have noted this change and altered their activities accordingly. Conversely, in the case of bowhead whales (*Balaena mysticetus*) that migrate between the Bering and Beaufort seas, the timing of the migration has not changed but whales appear to linger longer along the route, with more animals seen feeding near Barrow, Alaska, through early summer. This latter case also could be attributable to a growing whale population simply expanding its foraging range, and not necessarily to climate change.

B. Feeding

There is no doubt that the temporal aspects of feeding are important for marine mammals, especially in polar regions where the

productive season is short. In many cases, animals must consume a yearlong supply of food over the course of a few months because reproductive periods necessitate fasting, especially for species that haul-out on land, and those large whales that feed in high latitude waters and migrate to lower latitudes to mate/calve. The effects of climate warming on polar bears is a clear case where access to prey such as ringed seals (*Pusa hispida*) has been disrupted by earlier breakup and later formation of sea ice in some areas of the eastern Canadian Arctic. Long-term records show declines in population size and body condition for bears in Western Hudson Bay and Baffin Bay due to the extended fasting imposed on the bears by longer ice-free periods. There is no other species of marine mammal for which such a long-term record exists to investigate the potential effects of climate change on feeding opportunities. However, anecdotal observations suggest that rapid diminution of seasonal sea ice in the Arctic could also be affecting feeding opportunities and recruitment in Pacific walrus. In summer, female walrus and their calves ride the retreating sea ice north from the Bering Sea to the northern Chukchi Sea. In the recent past, at maximum recession the sea ice edge as approximately at the edge of the Chukchi Sea continental shelf and adult female walrus could make easy forays there to feed, then return to suckle calves while hauled out on sea ice. However, in recent years, sea ice has retreated rapidly and far into the deep water of the Canadian Basin. Adult walrus must undertake long swims (ca. 100+ km) between sea ice haul-outs and shallow-water feeding areas, at considerable energetic cost. In addition, the report of at least nine walrus pups separated from adult females in deep water habitat suggests that young may become separated from their mothers before they are weaned. Without the food or protection of their mothers, these pups would almost certainly die. Whether this situation is having a measurable effect on the Pacific walrus population is unknown, as population size and trend for these pagophilic (ice-associated) animals have not been accurately determined.

III. Disease and Toxins

Infectious diseases can cause rapid declines in wildlife populations. Rates of pathogen development, disease transmission, and host susceptibility are all influenced by climate, with a greater incidence of disease anticipated with warming. Marine mammal health and reproductive success are also adversely affected by toxins associated with harmful algal blooms (HABs). Marine mammal deaths associated with HABs appear to have increased over the past three decades, as have the frequency and geographic distribution of the events. Although coincident with climate warming, these apparent increases in HABs may also reflect improvements in the ability to detect HABs and in the capability to identify algal toxins in marine mammal tissues. While marine mammals may face greater risk of mortality due to disease outbreak or exposure to toxins in a warming ocean, the magnitude of these threats and their relationships to climate are difficult to judge. Fortunately, diagnostic tools to monitor and measure the effects of disease and HABs on marine mammal populations are in rapid development, and combined with access to satellite imagery of the oceans and geo-spatial modeling, there is some hope for rapid advances in this field.

Clymene Dolphin

Stenella clymene

THOMAS A. JEFFERSON

I. Characteristics and Taxonomy

The Clymene dolphin is a small, but rather stocky dolphin with a moderately long beak, separated from the melon by a distinct crease (Fig. 1). The dorsal fin is tall and nearly triangular to slightly falcate, and the flippers and flukes are typical of dolphins of the genera *Stenella* and *Delphinus*. The body shape is probably most similar to that of the striped dolphin, but coloration is very different. The color pattern is distinctly tripartite, with a white belly, light gray flanks, and dark gray cape (Fig. 1). The cape dips below the dorsal fin, somewhat lower than in the spinner dolphin. There is an eye stripe that runs forward to the upper beak and connects with a dark gray stripe running down the length of the top of the beak. The most distinctive feature is a black “mustache” marking of variable extent and intensity on the top of the beak. The lips are dark. Often there is a dark, indistinct band between the white belly and gray sides. With the exception of the mustache, most of the species’ external characters are very similar to those of the spinner dolphin. This is one of the reasons why the Clymene dolphin was not fully recognized as a distinct species until 1981 (Perrin *et al.*, 1981).

Not many individuals of this species have been examined in detail and measured, so data are limited. These small dolphins probably do not reach much over 2.0 m in length, with males somewhat larger and heavier than females (Jefferson, 1996). Adult-sized females have been between 171 and 190 cm, and males between 176 and 197 cm (Perrin and Mead, 1994; Jefferson, 1996). The maximum

Figure 1 A *Clymene* dolphin leaps at the bow wave of a research vessel in the northern Gulf of Mexico, showing the species' diagnostic characteristics. The dark vertical streak on the tail stock is not typical coloration. Photo by R. L. Pitman.

known weight is about 80 kg, but considering the few specimens that have been weighed, they probably reach somewhat greater weights than this.

The skull of this species is very similar to that of *Stenella longirostris* and *S. coeruleoalba* (especially the latter). It can be distinguished by its small size (CBL <415 mm), combined with a short, broad rostrum. Tooth counts range from 39–52 (upper) and 39–48 (lower) (Jefferson and Curry, 2003). Total vertebral counts for the small number of specimens examined so far have been 70–76.

The species was named after the Greek sea nymph, Clymene (daughter of Oceanus and Tethys), and therefore Clymene should always be capitalized in the common name (Jefferson and Curry, 2003). Other English common names include short-snouted spinner dolphin and helmet dolphin. Taxonomically, *S. clymene* is considered to be most closely related to *S. longirostris* and *S. coeruleoalba* (Perrin *et al.*, 1981; Perrin and Mead, 1994). However, genetic studies indicate that its cytochrome *b* sequence is actually closer to that of *S. coeruleoalba* (LeDuc *et al.*, 1999). Specimens thought to be hybrids between *S. clymene* and *S. longirostris* have been observed in the southwestern Atlantic (Silva *et al.*, 2005).

II. Distribution and Abundance

The Clymene dolphin is found only in the Atlantic Ocean, in tropical to warm-temperate waters (Fertl *et al.*, 2003). The exact range is not well documented, especially in South Atlantic, mid-Atlantic, and West African waters. Presumably it occurs continuously across the Atlantic Ocean. Recently, the known range off the coast of West Africa has been extended south to Angola (Weir, 2006). Most sightings have been in deep, offshore waters, although Clymene dolphins are sometimes observed very close to shore where deep water approaches the coast (such as around some islands of the Caribbean). It is present year-round in at least the northern Gulf of Mexico and probably throughout much of its tropical range.

No estimates of overall abundance exist, although there are estimated to be over 17,000 Clymene dolphins in the northern Gulf of Mexico (Mullin and Fulling, 2004). Considering this, it seems likely that the global abundance of the species is over 100,000 dolphins, and the species is not considered to be in danger of extinction. However, despite this, little is actually known about the status of its stock.

III. Ecology

There is very little known about the feeding ecology of this species, as very few stomachs have been examined. It apparently feeds mostly on mesopelagic fishes and squids, including some species that are vertical migrators (Jefferson and Curry, 2003).

External parasites include barnacles on appendages and whale lice in lesions and body grooves. Internal parasites have not been well studied but include various worms and flukes in the blubber and muscle, respiratory system, digestive system and brain and in the mammary glands of females. They can cause disease and have been implicated in the deaths of some animals.

Clymene dolphins associate with dolphins of other species on occasion, in particular spinner dolphins. Associations with tuna are known to occur off the West African coast (Cadenat and Doutre, 1958). Many Clymene dolphins bear bite marks and scars from cookie-cutter sharks on their bodies, and large sharks and killer whale are probable predators (although actual predation events have not been documented).

IV. Behavior and Physiology

Schools of this species are often moderately large, although most appear to consist of less than a few hundred individuals. In the Gulf of Mexico, where most information on school size comes from, the average group size is 42 dolphins (Mullin *et al.*, 1994). Schools may be segregated by age and sex class, as evidenced by several mass stranded herds that were composed largely of individuals of one or the other sex (Jefferson *et al.*, 1995).

Clymene dolphins are active bow riders, sometimes approaching ships from a distance for a free ride (Fig. 2). They are also often aerially active and they do spin on their long axes like spinner dolphins (something that only a few species of dolphins do), although apparently not as frequently or as elaborately as the spinner dolphin. Cooperative foraging techniques have been observed in the Gulf of Mexico (Fertl *et al.*, 1997).

Although there has been little work done on acoustic behavior (Mullin *et al.*, 1994), these animals often appear to be quite vocal, with whistles in the frequency range of 6–19 kHz (Wang, 1993). Virtually nothing is known about the species' physiology.

V. Life History

There have been no published studies on the life history of this species based on large samples of specimens. Most of what we know is based on scant information from strandings, mostly from the Gulf of Mexico. Both males and females appear to reach sexual maturity by a length of 180 cm (Jefferson and Curry, 2003). Nothing is known of other life history parameters, but they are thought to be broadly similar to those of other members of the genus *Stenella*.

VI. Interactions with Humans

Clymene dolphins have not been held captive, except for occasional animals that were kept temporarily after stranding alive. No major conservation problems are known for this species, but it is likely that some undocumented problems exist. Some dolphins are known to be killed in directed fisheries in the Caribbean, and others incidentally in nets throughout most parts of the range. This may be one of the species involved in the tuna purse seine fishery in the Gulf of Guinea area of West Africa (Maigret, 1981). It is possible that large, but undocumented, incidental catches may occur there, as they have in the eastern tropical Pacific. There has been almost no work on environmental contaminants in this species (Jefferson and Curry, 2003).

Coloration

WILLIAM F. PERRIN

Marine mammals are not as colorful as birds or fishes or reptiles, but many have striking and distinctive coloration patterns that are useful in their taxonomy, presumably have function and adaptive value, and can vary individually and with age, sex, geographic region, and even time of the year.

I. Terminology

A number of schemes have been proposed for naming the elements of color patterns in cetaceans; the usage here follows Perrin (1973, Perrin, 1997) and Perrin *et al.* (1991). In delphinids and phocoenids (Fig. 1), the *bridle* is composed of the *blowhole stripe* running from the blowhole to the apex of melon and the *eye stripe* from the eye to the apex of melon. Both stripes may have complex internal structure. An *eye spot* may be visible, and there may also be a small *ear stripe* or *spot*. The *eye-to-anus stripe* runs from the eye to the anal/genital region and may have *accessory stripes*. The *flipper stripe* runs forward from the base of the flipper variously to the eye (e.g., in spinner dolphin, *Stenella longirostris*), corner of the mouth (e.g., pantropical spotted dolphin, *S. attenuata*), or forward along the rostrum to join the *lip mark* ventrolaterally (common dolphins, *Delphinus* spp.).

The overall color pattern in at least some delphinids can be analyzed in terms of interacting independent components (Fig. 2). A basic *cape* is covered with a *dorsal overlay* of varying extent and intensity and may not be visible except in fetal or anomalously pigmented specimens. A crisscross of the boundaries of these two elements in *Delphinus* spp. yields a complex four-part pattern of a dark-gray *dorsal field* (cape and overlay combined), buff or yellowish *thoracic patch* (cape alone), light-gray *flank patch* (overlay alone), and white *ventral field* (outside both cape and overlay). In some anomalous individuals, the overlay may be absent, yielding a simplified pattern of cape only [e.g., in *Delphinus delphis* (Perrin *et al.*, 1995) and *Stenella longirostris* (Perrin, 1973)]. Spotting appears to be yet another independent component that develops with maturation in some species.

In pinnipeds, coloration can be a property of different *pelages* or pelage elements, through a range from white to silver, gray or bluish gray, brown, and black. The *lanugo* is a fetal pelage that develops and can be lost before birth, although in many species it is shed a few days or weeks after birth. Juveniles may undergo additional *molts* and changes of color. The coarse *guard hairs* can differ in color from

Figure 1 Typical appearance of bridge in 10 delphinid species: (A) *Steno bredanensis*, (B) *Lagenorhynchus obliquidens*, (C) *Tursiops truncatus*, (D) *Stenella frontalis*, (E) *S. attenuata*, (F) *S. longirostris*, (G) *S. coeruleoalba*, (H) *Delphinus delphis*, (I) *Cephalorhynchus eutropia*, and (J) *Peponocephala electra*. From Perrin (1997).

the hairs of the *undercoat*. Many seals are simply uniformly colored or counter-shaded, but some have bold patterns, such as the harp seal (*Pagophilus groenlandicus*) and ribbon seal (*Histiophoca fasciata*), and others are spotted.

II. Development

Coloration typically changes between birth and adulthood. In some cases appearance changes radically, whereas in others the change is more in contrast and distinctness of pattern elements. Only a few examples are discussed here.

The spotted dolphins, *Stenella attenuata* and *S. frontalis*, are unspotted at birth. Small dark spots appear in large juveniles in the throat region and spread over the ventral surface, enlarging as maturity approaches. Light spots appear on the back and spread in a similar fashion, although not in an even distribution over the back. In *S. attenuata* the dark ventral spots fuse and lighten to yield a light gray, faintly dappled ventral surface. In *S. frontalis*, both ventral and dorsal spots persist into maturity.

The beluga, *Delphinapterus leucas*, is dark gray at birth but lightens as it grows; adults are white. A similar trend is seen in Asian populations of the Indo-Pacific humpbacked dolphin, *Sousa chinensis*. The reverse of this trend is seen in many other cetaceans, such as pilot whales and beaked whales; calves are lighter at birth and darken with age, although neonates of the bottlenose dolphin and the finless porpoise, *Neophocaena phocaenoides*, in some regions are darker than juveniles and adults.

The development of coloration tends to take opposite courses in different groups of pinnipeds (Bonner, 1990). Otariids are born dark and become lighter as juveniles, most darkening again as adults. However, most Northern Hemisphere phocids (the phocinines), including *Phoca largha*, *Pusa* spp., *Pagophilus groenlandicus*, *Histiophoca fasciata*, and *Halichoerus grypus*, are born with a white or yellowish lanugo, which is shed at 2–5 weeks. This molt exposes either the adult pattern of spots or other marks or a juvenile counter-shaded coloration that later changes to the adult patterned state. The harbor seal, *Phoca vitulina*, and the hooded seal, *Cystophora*

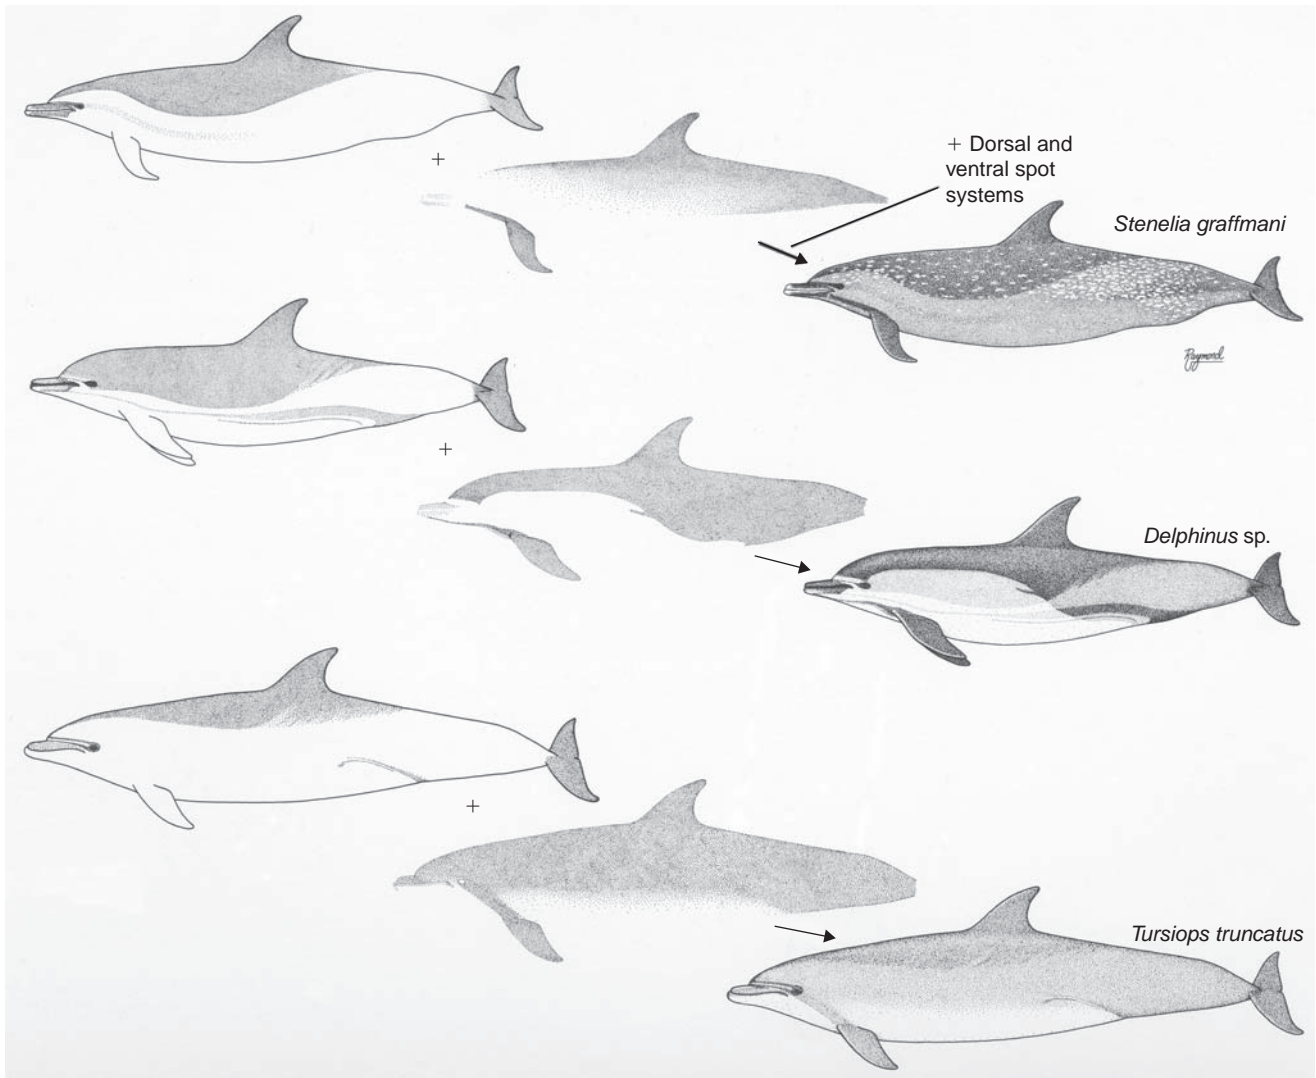

Figure 2 Component analyses of color patterns of *Stenella attenuata*, *Delphinus delphis*, and *Tursiops truncatus* (from left to right): basic cape plus dorsal overlay yields a complex color pattern. From Perrin (1973).

cristata, are unusual in that the lanugo is molted before birth (always in the hooded seal and usually in the harbor seal). The bearded seal, *Erignathus barbatus*, is born with a grayish-brown lanugo (with white muzzle and white blotches), and in the monk seals (*Monachus* spp.) and elephant seals (*Mirounga* spp.) the lanugo is black. In the southern phocids, the Weddell seal (*Leptonychotes weddellii*), Ross seal (*Ommatophoca rossii*), crabeater seal (*Lobodon carcinophaga*), and leopard seal (*Hydrurga leptonyx*), pups are born with pale-gray to brownish-gray coats; in the leopard seal the birth coat resembles the adult state in color and pattern. The walrus (*Odobenus rosmarus*) molts the lanugo *in utero* and has sparse whitish, yellowish, or silver-gray coat at birth. The lanugo, whether light or dark, is usually thick and woolly, and it has been suggested that it functions in heat conservation until a BLUBBER layer accumulates. Another suggested function, at least for the white lanugo, is camouflage against predators on the ice, although the southern ice-breeding monachines do not have white coats at birth. It has been posited that intrauterine loss of the lanugo in the harbor seal is a secondary adaptation to breeding

on land since its descent from an ice-breeding ancestor, implying a camouflage function. Why some birth coats are light and others dark is still a matter for speculation.

III. Sexual Dimorphism

In delphinid cetaceans, sexually dimorphic color-pattern elements are typically associated with the genital region. For example, a black tear-drop-shaped patch surrounding the genital slit in Commerson's dolphin, *Cephalorhynchus commersonii*, has its apex directed posteriorly in adult males and anteriorly (sometimes with a posterior invagination around the genital slit) in females (Fig. 3). A lateral stripe extending from the eye to the genital region in Fraser's dolphin, *Lagenodelphis hosei* is broader and darker in adult males than in females (Jefferson *et al.*, 1997). Adult male beaked whales (Ziphiidae) of many species tend to develop white areas on the head; in some species the entire head becomes white, whereas in others the white area may be confined to the front or top of the head or to the rostrum (Ridgway and Harrison, 1981–1999).

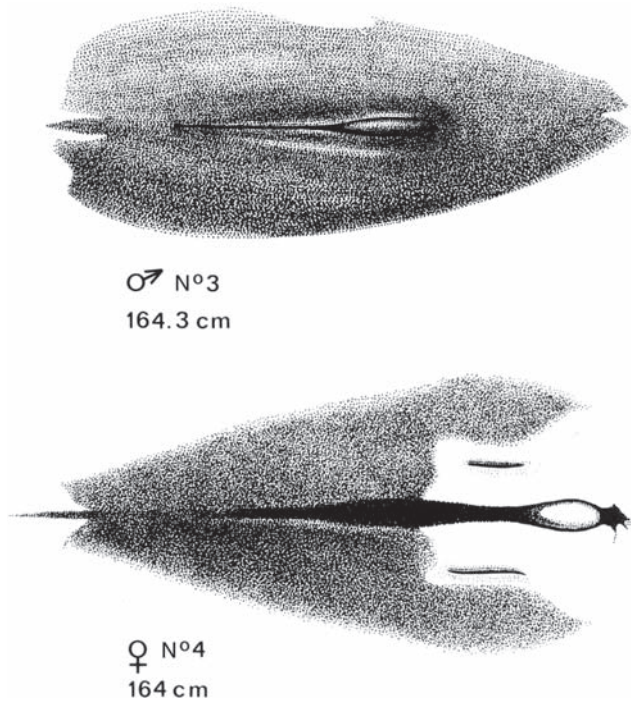

Figure 3 Sexual dimorphism in the form of a genital patch in *Cephalorhynchus commersonii*. From Robineau (1984).

Ventral coloration is dimorphic in the Mediterranean monk seal, *Monachus monachus*, from birth onward; as in some dolphins, the posterior boundary of a mark around the genital opening is arcuate in females and straight in males (Badosa and Grau, 1998). Adult males are also much darker than females. In other phocids, the color pattern is usually more distinct and with darker elements in males than in females, e.g., in the ribbon seal and harp seal. Some adult male gray seals are almost black, whereas females tend to be lighter colored. However, some species, e.g., the bearded seal and Weddell seal, are not noticeably dimorphic in coloration (Ridgway and Harrison, 1981). For walruses, the pattern seen in many phocids is reversed; old adult males tend to be lighter colored than females. The pattern is variable in the otariids; in some, e.g., the California sea lion, *Zalophus californianus*, and northern fur seal, *Callorhinus ursinus*, the adult male is darker than the female, whereas in others, e.g., the Steller sea lion, *Eumetopias jubatus*, there is no apparent dimorphism.

IV. Geographic and Individual Variation

Color patterns vary among adults in marine mammal species, both individually and geographically. Biologists use individual variations in coloration and other natural marks as “tags” in studies of abundance, movements, and life history. “Mark and recapture” studies using natural marks can estimate population size; this has been applied to a number of cetacean species, including killer whales (*Orcinus orca*), minke whales (*Balaenoptera acutorostrata*), fin whales (*B. musculus*), blue whales (*B. physalus*), humpback whales (*Megaptera novaeangliae*), right whales (*Eubalaena* spp.), bowhead whales (*Balaena mysticetus*), bottlenose dolphins, and others (Hammond *et al.*, 1990). Long-range movements of migratory whales have been documented using natural marks, clarifying migratory cycles and stock structure and affiliations. Longitudinal studies of individuals and groups over

generational time have been vital in arriving at estimates of such important life history parameters as age at first reproduction, calving interval, and survivorship, and these have been made possible by the use of natural marks to keep track of individuals (for the Atlantic spotted dolphin, *Stenella frontalis*, in the Caribbean, the killer whale in the Pacific Northwest, and a variety of other small cetaceans). Examples of coloration features that have been or could be used as natural marks include shape of the dorsal saddle and postocular spot in the killer whale (Visser and Mäkäinen, 2000), details of the eye and blowhole stripes in dolphins and porpoises, color and patterning of the underside of the flukes in the humpback whale, and patterns of spots, blotches and white areas on the body in right, gray (*Eschrichtius robustus*), bowhead, blue, and minke whales. Some naturally imposed marks, such as scars from intraspecific fighting and from bites by predators or cookie cutter sharks (*Isistius* spp.), have also proven useful, although factors such as fading and acquisition of new marks during a study must be taken into consideration (Blackmer *et al.*, 2000). For some drably colored marine mammals, e.g., manatees (*Trichechus* spp.), scars (including those from collisions with boats and fishing gear) are the only marks available for use.

The use of natural marks in individually identifying pinnipeds from their patterns of spots and blotches has been complicated by the difficulty of photographing seals from a standard angle or in a standard posture. This problem has been approached by the development of computer-aided matching of images using a three-dimensional model to correct for orientation and posture (Hammond *et al.*, 1990).

As for other morphological characters, coloration tends to vary geographically most in those features that vary individually most within a population. For example, in spinner dolphins in the eastern Pacific, the degree to which the dorsal overlay obscures the underlying cape is highly variable; in some animals the cape is prominent whereas in others it is invisible (Perrin *et al.*, 1991). It is in this feature of the color pattern that spinner dolphins vary most from region to region around the world. Similarly, adult spotted dolphins of both species (*Stenella attenuata* and *S. frontalis*) vary individually in the degree of spotting, and average spotting varies geographically as well; the offshore Gulf Stream form of *S. frontalis* is all but unspotted (Perrin *et al.*, 1987). The *truei* and *dalli* color morphs of Dall’s porpoise (Fig. 4), originally described as different species, typify regional populations but include the range of coloration in a single population (Ridgway and Harrison, 1981–1999), and an additional color-pattern morph has been recently discovered (Amano *et al.*, 2000). Baleen whales vary geographically in coloration of the baleen and in details of color pattern of the body and appendages, which also vary greatly within populations. Spotting is highly variable among individual harbor seals, and differences can be found between populations even on different islands in an archipelago (Hammond *et al.*, 1990). Humpback whales of the Southern Hemisphere tend to have more white pigmentation in their bodies than their Northern Hemisphere counterparts.

V. Genetics

Little is known of the genetic basis of coloration in marine mammals. Albinism is possibly an autosomal dominant trait as in humans. Analysis of populational data for the North Atlantic right whale, *Eubalaena glacialis*, suggests that the presence of white ventral skin patches is an autosomal recessive trait (Schaeff and Hamilton, 1999); it is not evident from data that the trait is subject to selection pressure.

Figure 4 Two color morphs of *Phocoenoides dalli*: *dalli* type (A) and *truei* type (B). Photos courtesy of T. A. Jefferson.

VI. Microanatomy

Pigmentation in cetaceans is limited to the occurrence of melanin in the epidermis. The distribution of melanin in the skin of *Delphinus delphis* (Gwinn and Perrin, 1975) is described here as an example. The pigment is usually concentrated around the bases of the dermal papillae and extends in bands from their apices. Portions of the skin that appear white show very small amounts of diffuse pigment (particles unresolvable at $1250\times$ magnification) and small granules ($<5\text{ mm}$ in diameter). The buff color characteristic of the thoracic patch is associated with an equal prominence of diffuse and small granules or higher density of diffuse pigment. The gray flank patch has some small granules but mostly large granules (5 mm). The black regions of the back and flukes have the highest density of large granules. It may be hypothesized that the type of melanin that produces the buff color is of a composition that does not allow further polymerization but favors its combination with a protein instead of aggregation into granules. In gray and black areas of the color pattern, the aggregation of particles proceeds, and melanocytes containing them migrate toward the surface of the epidermis until diffuse pigment is largely replaced by granular pigment.

VII. Function and Evolution

An early analysis of coloration in cetaceans (Yablokov, 1963) proposed several functions: acquisition of prey, protection from predators, and communication with conspecifics. Cetacean patterns were divided into three types: (1) uniform or finely spotted, adapted to planktonic feeding or feeding in murky water or great depths where vision is not important; (2) strongly spotted, striped, or patterned, for intraspecific recognition; and (3) counter shaded, as camouflage against predators in animals foraging near the surface. However, spots would seem also to be useful in camouflage, as the surface of the sea appears dappled when seen from below. Notably, spotted dolphins are strongly counter shaded at birth and only begin to develop

spots at about the age when they begin to forage on their own; in this case the likely function of the spots is camouflage against prey. This pattern of development is the reverse of that in many species of deer, which are spotted at birth and lose their spots as they become self-sufficient; there the function is camouflage against predators. The stripes and marks on the typical delphinid head (eye stripe, blowhole stripe, flipper stripe, eye spot, and lip mark) may also serve as camouflage against prey, obscuring the eye and mouth as in many terrestrial mammals and other tetrapods, including reptiles, amphibians, birds, and fishes. Many cetaceans have prominent white color-pattern elements or patches, often bordered with dark pigmentation; these may function in species recognition or serve to signal the positions of school mates in low-light conditions. Similar functions have been suggested for the bold color patterns seen in some phocid pinnipeds, together with possible uses in signaling sex and age. The patterns may also serve in disruptive coloration for camouflage against predator or prey.

The fin whale and dwarf minke whale (*Balaenoptera acutorostrata* unnamed subspecies) are unusual among marine mammals in being asymmetrically patterned. In the fin whale, the left anterior third of the body and the baleen on the left side are dark, but the lower jaw and the anterior baleen on the right side are white (Ridgway and Harrison, 1981–1999). The white area has been proposed to function to maintain counter shading when the whale rolls on its side during feeding or to startle prey during prey herding. A similar but lesser asymmetry obtains in the dwarf minke whale (Arnold *et al.*, 2005).

A simple counter-shaded pattern has been proposed to be the most primitive and generalized for the delphinid cetaceans (Mitchell, 1970) because it is a pattern shared by many taxa of marine organisms inhabiting near-surface waters and used for concealment through counter lighting. The crisscross pattern of *Delphinus* spp. is perhaps the most derived (as the most complex), with a possible function of obscuring the presence of a small calf swimming side by side with the mother.

The color pattern can evolve through paedomorphosis, the retention of fetal or juvenile characteristics into adulthood. The dark “hoods” on the heads of some dolphins and small-toothed whales may have evolved this way. The system of stripes on the head (eye stripe and blowhole stripe) in delphinid and phocoenid cetaceans develops from a single mark across the back of the head behind the blowhole in small fetuses (Perrin, 1997). A progressive forward invagination of the mark on each side of the head creates the two stripes, which are initially broad and then narrow to varying degrees. The stripes vary among species in width and definition, but in some species, e.g., *Cephalorhynchus* spp. and some of the globicephalini species such as *Peponocephala electra*, a fetal condition is retained and the “blowhole stripe” effectively covers the entire top of the head (Fig. 1). It is interesting to note that the *Cephalorhynchus* species are also paedomorphic in their osteology, convergent on the phocoenids in body and skull size and shape.

Paedomorphosis may account for geographic variation in the expression of color-pattern elements in some species. For example, the cape is visible in the fetus of the killer whale but is usually not expressed in the postnatal animal. However, the cape is distinctly visible in all whales in an Antarctic population (Pitman and Ensor, 2003). Similarly, the adult of the Kerguelen Islands form of Commerson’s dolphin, *Cephalorhynchus commersonii*, retains a grayish portion of the color pattern seen only in calves in the South American population (Robineau, 1984).

VIII. Coloration as a Taxonomic Character

Color-pattern features are useful in taxonomy, even lending themselves to cladistic analysis (Perrin, 1997 for Delphinoidea; Arnold *et al.*, 2005 for Mysticeti). In some cases, what were thought to be color variants of a single species have proved to be distinct species [e.g., the common dolphins *Delphinus delphis* and *D. capensis* (Heyning and Perrin, 1994); and the minke whales, *Balaenoptera acutorostrata* and *B. bonaerensis* (Best, 1985)]. However, in other cases, species defined on the basis of color-pattern differences have been subsequently lumped [e.g., the striped dolphin, *Stenella coeruleoalba*, and its nominal synonyms (Fraser and Noble, 1970) and the *dalli* and *truei* forms of Dall’s porpoise, *Phocoenoides dalli* (Ridgway and Harrison, 1999)], demonstrating that the same caution must be used in employing color-pattern characters as in the use of any other morphological characters. The contributions of ontogenetic, individual, and geographic variation must be delineated before species-level differences and higher level taxonomic relationships emerge.

IX. Ephemeral and Anomalous Variation

Real and apparent changes in coloration can be ephemeral or environmentally induced. For example, some dolphins (and old walrus) are at some times pink and other times white. The Amazon river dolphin, *Inia geoffrensis*, is also known as “*buceo colorado*” because of its pink color when seen in its natural habitat; in captivity in a temperate-latitude aquarium it is white. Some adult individuals of the Indo-Pacific humpback dolphin, *Sousa chinensis*, in the waters of Hong Kong have been observed to be bright pink (Fig. 5) whereas some other tropical dolphins sometimes exhibit pink bellies. This fact is even incorporated in the scientific name of one dolphin, the dwarf spinner dolphin of Southeast Asia, *Stenella longirostris roseiventris* (Perrin *et al.*, 1999, 2007). The pink color is due to dilation of subcutaneous blood vessels, presumably for purposes of thermoregulation; dolphins everywhere must dispose of excess heat generated by metabolism,

Figure 5 Adult Chinese humpback dolphin, illustrating pink coloration in response to excess heat load. Photo courtesy of T. A. Jefferson.

which is a greater problem in warm tropical water. Even the Arctic walrus, *Odobenus rosmarus*, must “dump” heat, and palely pigmented old males may appear “rosy” during relatively warm weather. In cetaceans, the pink coloration is visible only in animals or parts of animals that are normally white (lacking melanin), although light-gray dolphins, such as immature individuals of *Sousa chinensis*, may sometimes appear purplish because of the subcutaneous suffusion with blood. When a “pink” walrus enters the water, the skin becomes ischemic (deprived of blood) and the animal appears white.

Other pinnipeds change color when wet; e.g., the brown California sea lion becomes almost black. Seasonally molting pinnipeds change color, becoming drabber as the molt approaches. Reddish pelage in harbor seals can be the result of deposition of iron oxide precipitates on the hair shaft. Even conditions such as water color, cloud cover, and angle of sun can cause cetaceans to apparently change color in the water. The striped dolphin, also known as the blue-and-white dolphin, can appear brown and white in turbid water or under overcast skies. A sojourn in high latitudes can lead to an accumulation of a coat of yellowish diatoms in the blue whale, *Balaenoptera musculus*, leading to one of its other common names, “sulfurbottom.” In one minke whale taken in the Antarctic, the areas normally white were pinkish and the baleen, blubber, and connective tissue were orange; the cause of the “carotenoid” coloration was not apparent (Kato, 1979) but may have been metabolic. Cetaceans in captivity in shallow tanks can become darker when exposed to the sun. The intensity of coloration has been reported to vary seasonally in common dolphins in the Black Sea. In some cetacean species, apparent stripes or spots can be scars. Adult male beaked whales inflict long parallel rakes on each other with their teeth (the behavior also occurs in species in which the teeth erupt in females, although scarring is still usually more prevalent in males, e.g., in Amazon river dolphins, Martin and da Silva, 2006). Most cetaceans that frequent tropical waters bear oval or star-shaped scars from the bites of cookie cutter sharks; these can be so numerous as to give the animal an overall spotted appearance.

Anomalous conditions such as albinism (see chapter Albinism), melanism (Visser *et al.*, 2004) and pie-bald coloration have been recorded for many cetacean and pinniped species. In one anomalous color-pattern variety that has been seen in the short-beaked common dolphin in widely separated parts of the world, the dorsal overlay is missing, eliminating the typical crisscross pattern (Perrin *et al.*, 1995).

Coloration in cetaceans changes with death. Subtle elements of color pattern disappear quickly in a dead stranded animal as the skin dries, and a dolphin with a complex color pattern can turn solid black when long dead or frozen (careful thawing in water can

sometimes bring back some of the pattern). The outer layers of the skin can be abraded away during stranding, which has resulted in more than one report of a stranded “white whale.” The accounts of coloration in some original species descriptions of cetaceans were based on long-dead specimens and thus are defective (e.g., Heaviside’s dolphin, *Cephalorhynchus heavisidii*, is not uniformly black as originally described, but boldly patterned). Much remains to be learned about the color pattern of the living animal for many species.

Common Bottlenose Dolphin

Tursiops truncatus

RANDALL S. WELLS AND MICHAEL D. SCOTT

I. Characters and Taxonomy

Bottlenose dolphins (*Tursiops truncatus*) are arguably the best known of all cetaceans. They figured prominently in the legends of the ancient Greeks and Romans and were described in the writings of Aristotle, Oppian, and Pliny the Elder. Several books for scientific and public audiences have focused on this species (Caldwell and Caldwell, 1972; Shane, 1988; Leatherwood and Reeves, 1990; Thompson and Wilson, 1994; Reynolds et al., 2000), and a number of comprehensive review articles have been produced as well (Tomilin, 1957; Leatherwood and Reeves, 1982; Shane et al., 1986; Wells and Scott, 1999). The name *Tursiops* can be translated as “dolphin-like,” deriving from the Latin *Tursio* (“dolphin”) and the Greek suffix *-ops* (“appearance”); *truncatus* derives from the Latin

Figure 1 Lateral view of an adult male bottlenose dolphin (*Tursiops truncatus*, photo by R. S. Wells).

Figure 2 Ventral view of a bottlenose dolphin (*Tursiops truncatus*, photo by R. S. Wells).

truncato- (“truncated”), apparently referring to the flattened teeth used by Montagu (1821) as an identifying characteristic. The common English name is “common bottlenose dolphin,” distinguishing this species from the Indo-Pacific bottlenose dolphin, *T. aduncus*. It is still often referred to as “porpoise” in the southeastern USA.

Though no conclusive fossil evidence of the origin of *Tursiops* exists, fossil records extend back several million years (Barnes, 1990). The geographical distribution of the fossils falls within the range of the modern animals. Anatomical features suggest that *Tursiops* evolved from some ancestral group of extinct fossil Delphininae, perhaps related to the subfamily Steninae, which might have evolved from the Kentriodontidae.

Common bottlenose dolphins are cosmopolitan in distribution, and demonstrate a great deal of geographical variation in morphology. *T. truncatus* is found in most of the world’s warm temperate to tropical seas, in coastal as well as offshore waters. They are recognizable by their generalized appearance—a medium-size, robust body, a moderately falcate dorsal fin, and dark coloration, with a sharp demarcation between the melon and the short rostrum (Figs 1, 2). Adult lengths range from about 2.5 m to about 3.8 m, varying by geographic location (Mead and Potter, 1990; Read *et al.*, 1993). Body size appears to vary inversely with water temperature in many parts of the world, but not the eastern Pacific. Bottlenose dolphins are colored light gray to black dorsally and laterally, with a light belly (Fig. 2). A light blaze or brush

marking is sometimes observed on their sides. A distinct cape may be visible or may be obscured when the color pattern is very dark.

Variation in size, coloration, and cranial characteristics associated with feeding have led to descriptions of at least 20 nominal species of *Tursiops* (Hershkovitz, 1966; Rice, 1998). Recognition of the polymorphic nature of *Tursiops* and the existence of clinal variation had led to general agreement for many years that *Tursiops* was a single-species genus (Tomilin, 1957; Mitchell, 1975; Honacki *et al.*, 1982). However, recent genetic, morphologic, and physiologic studies suggest that revision of the genus may be necessary to acknowledge significant differences between forms from different oceans, as well as differences between forms in inshore vs offshore habitats within ocean basins (Hersh and Duffield, 1990; LeDuc *et al.*, 1999; Mead and Potter, 1995; Rice, 1998). Inshore bottlenose dolphins in the Atlantic and some other regions tend to be smaller, lighter in color, have proportionately larger flippers, and differ in hematologic and mitochondrial DNA features from offshore forms (Hersh and Duffield, 1990; LeDuc *et al.*, 1999); however, eastern Pacific offshore bottlenose dolphins are smaller and darker than inshore forms. The taxonomic status of *Tursiops* is made even more confusing by observations of hybridization with several other odontocete species (Sylvestre and Tanaka, 1985).

II. Distribution and Abundance

Common bottlenose dolphins are found in temperate and tropical marine waters around the world, with an estimated 600,000 animals world-wide (Fig. 3). In the North Pacific, they are commonly found as far north as the southern Okhotsk Sea, the Kuril Islands, and central California. In the North Atlantic, they are seen inshore during summer months off New England, offshore as far north as Nova Scotia, and they have been recorded off Norway and the Lofoten Islands. Bottlenose dolphins occur as far south as Tierra del Fuego, South Africa, Australia, and New Zealand. Limits to the species’ range appear to be temperature related, either directly or indirectly, through distribution of prey. Off the coasts of North America they tend to inhabit waters with surface temperatures ranging from about 10°C to 32°C. At the northern limit of the species’ range in the western North Atlantic, they are seasonally migratory, with a more southerly distribution in the winter.

III. Ecology

Tursiops inhabits most warm temperate and tropical shorelines, adapting to a variety of marine and estuarine habitats, even ranging into rivers. Common bottlenose dolphins are primarily coastal, but are also found in pelagic waters, near oceanic islands, and over the continental shelf, especially along the shelf break. In the Indian Ocean, *T. truncatus* tends to inhabit offshore waters, whereas *T. aduncus* is the more-common coastal species.

The diets of common bottlenose dolphins have been described from many regions (Barros and Odell, 1990). A large variety of fish and/or squid forms most of the diets, although bottlenose dolphins seem to show a consistent preference for sciaenids, scombrids, and mugilids. Most fish prey are bottom-dwellers, but some surface-dwellers or pelagic fish are also represented in the diets. Noise-producing fish make up a large part of the *Tursiops* diet, presumably because sound helps the dolphins to locate prey (Barros and Wells, 1998; Gannon *et al.*, 2005). Differences in diets have been found where both inshore and offshore *Tursiops* ecotypes have been identified. Across a population, common bottlenose dolphins may appear to be generalists with regards to prey, but individuals within the

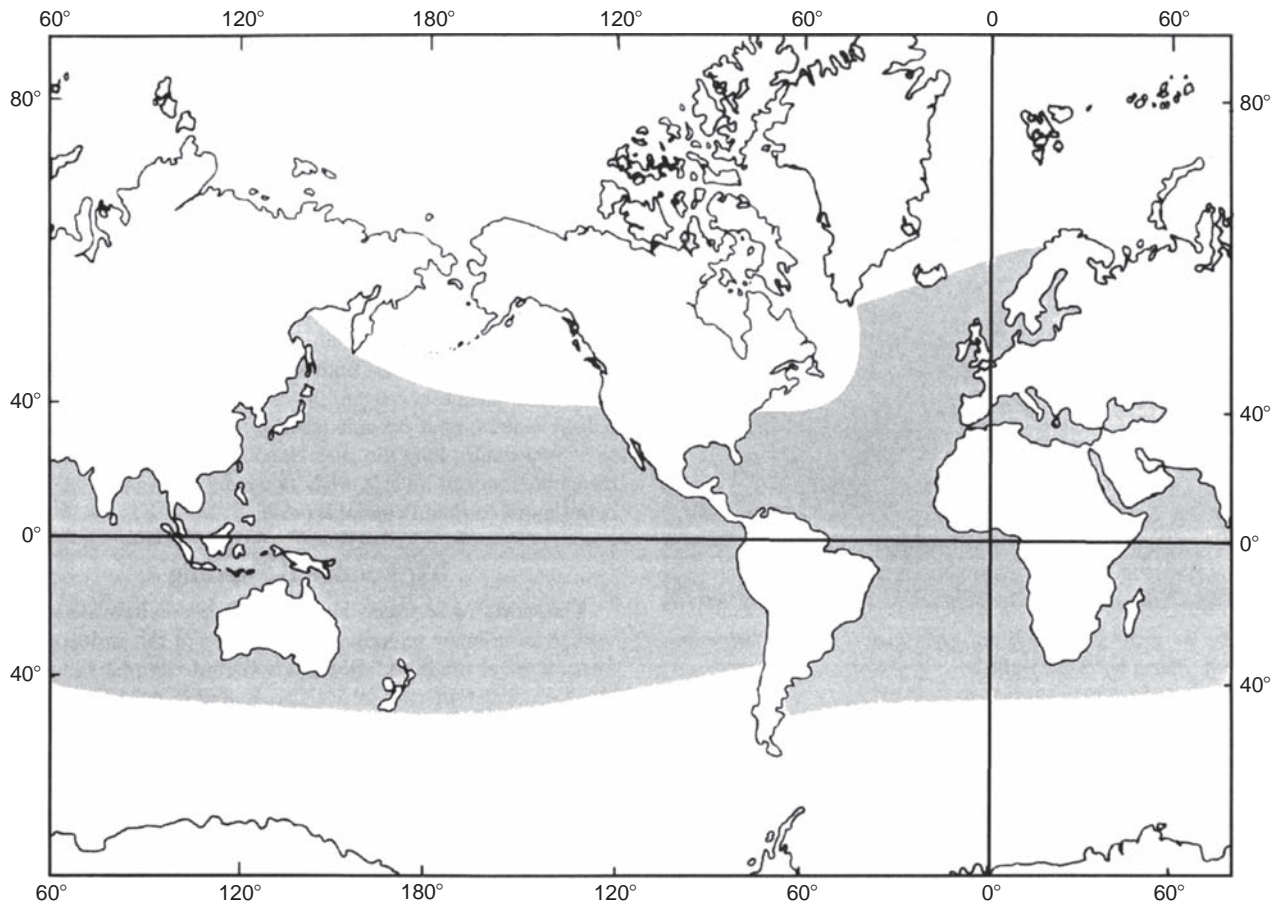

Figure 3 Species range of the common bottlenose dolphin (*Tursiops truncatus*).

population may show some degree of specialization. In some cases bottlenose dolphin groups feed in different areas depending on sex and size, with lactating females and their calves frequenting and feeding in the near-shore zone, adolescents feeding slightly farther offshore, and resting females and adult males feeding farther still.

Sharks are probably the most important predators of bottlenose dolphins, although killer whales (*Orcinus orca*) may also occasionally prey on them as well. Mutual tolerance during encounters between sharks and dolphins is probably typical, but as many as half of all bottlenose dolphins bear shark-bite scars as evidence of occasional encounters, depending on the region. In at least some areas, *Tursiops* appears to be a relatively minor and occasional part of the diets of sharks. Most wounds and scars from sharks tend to be found on the posterior and ventral regions of the dolphins, suggesting that the dolphins were ambushed from behind and below; some attacks may have been something other than a predation attempt (e.g., sharks defending a territory). The primary shark predators of common bottlenose dolphins are the bull shark (*Carcharhinus leucas*), tiger shark (*Galeocerdo cuvier*), great white shark (*Carcharodon carcharias*), and dusky shark (*Carcharhinus obscurus*) (Wood *et al.*, 1970). Observations of captive dolphins suggest that they may recognize certain species of sharks as potential threats (McBride and Hebb, 1948; Irvine *et al.*, 1973).

Anecdotal accounts describe common bottlenose dolphins attacking sharks by butting them with their rostra or by striking them with their flukes (summarized by Wood *et al.*, 1970). Defense may explain the apparently high survival rate indicated by the shark-bite scars on

living dolphins. The relatively infrequent occurrence of shark-bite scars on young dolphins indicates either that the calves are well protected by their mothers, or that attacks on young dolphins are generally fatal (Wells *et al.*, 1987; Cockcroft *et al.*, 1989a).

Stingrays are an increasing source of mortality for common bottlenose dolphins in some areas (Walsh *et al.*, 1988). The dolphins were wounded externally, or internally from ingestion of small rays, and deaths resulted from physical trauma as the barb migrated and penetrated vital organs, causing infection or toxicosis.

IV. Behavior and Physiology

Coastal common bottlenose dolphins exhibit a full spectrum of movements, including seasonal migrations, year-around home ranges, periodic residency, and a combination of occasional long-range movements and repeated local residency (Shane *et al.*, 1986; Wells and Scott, 1999). Much less is known about the ranging patterns of pelagic bottlenose dolphins. In some places, coastal dolphins living at the high-latitude or cold-water extremes of the species' range may migrate seasonally, as is the case along the Atlantic coast of the USA. Long-term residency has been reported from many parts of the world and may take the form of a relatively permanent home range or repeated occurrence in a given area over many years. For example, the year-round residents of several dolphin communities along Florida's west coast have maintained relatively stable, slightly overlapping home ranges during more than 37 years of observations and through at least five generations; seasonal changes in habitat

use may occur within the ranges (Scott *et al.*, 1990; Wells and Scott, 1999). Nearby ranges sometimes can be distinguished by genetic differences (Duffield and Wells, 1991, 2002; Sellas *et al.*, 2005; Parsons *et al.*, 2006). Home range bounds are often demarcated by physiographic features such as passes or abrupt changes in water depth. Some dolphins may use seasonal home ranges joined by a traveling range.

Longer-distance movements have been reported for some coastal common bottlenose dolphins, including range shifts of several hundred kilometers in apparent response to environmental changes such as an El Niño warm-water event (Wells *et al.*, 1990) and a 600-km roundtrip for several identifiable dolphins in Argentina (Würsig and Würsig, 1979). Average daily movements of 33–89 km, monitored through travel distances of as much as 4200 km, have been reported for bottlenose dolphins in offshore waters (Tanaka, 1987; Wells *et al.*, 1999a).

Common bottlenose dolphins are typically found in groups of 2–15 individuals, although groups of more than 1000 have been reported (Leatherwood and Reeves, 1982; Shane *et al.*, 1986; Scott and Chivers, 1990). In general, bottlenose dolphins in bays and estuaries tend to form smaller groups than those in offshore waters, but the trend does not continue linearly with increasing distance from shore (Wells *et al.*, 1999). Group composition tends to be dynamic, with sex, age, reproductive condition, familial relationships, and affiliation histories appearing to be the most important determining factors (Wells, 2003). Subgroupings may be stable or repeated over periods of years. Basic social units include nursery groups, mixed sex groups of juveniles, and adult males as individuals or strongly bonded pairs (Wells *et al.*, 1987; Owen *et al.*, 2002; Rogers *et al.*, 2004). Females bear calves sired by multiple males over the course of a lifetime; long-term monogamous bonds have not been observed (Duffield and Wells, 2002; Wells, 2003).

Dominance hierarchies have been observed in captivity, with large adult male common bottlenose dolphins dominating all other pool-mates, females forming a less-rigid hierarchy, with the largest females dominant over smaller animals. Aggressive behaviors including contact and posturing are used to establish and maintain hierarchies. Serious agonistic interactions have been noted in the wild between male conspecifics (Parsons *et al.*, 2003) as well as with other species of dolphins (Herzing *et al.*, 2003).

Bottlenose dolphins in the wild appear to be active both during the day and at night, interspersing bouts of feeding, traveling, socializing, and idling or resting (Shane *et al.*, 1986; Wells *et al.*, 1999b). The duration and frequency of activities are influenced by such environmental factors as season, habitat, time of day, and tidal state, and by physiological factors such as reproductive seasonality. Bottlenose dolphins feed in a large variety of ways and habitats, primarily as individuals, but cooperative herding of schools of prey fish also occurs (Leatherwood, 1975). Individual prey capture involves behaviors as diverse as high-speed chases with a pin-wheeling capture at the surface, “fishwhacking” in which a fleeing fish is struck with the dolphin’s flukes and often knocked clear of the water, pushing fish onto shore and then partially beaching to capture them, creating bubble bursts to drive prey to the surface, and herding and perhaps disorienting fish with percussive leaps and tail lobes referred to as “kerplunking.” Calves apparently learn foraging specializations from their mothers, and patterns may spread through a population from observation, as an indication of cultural transmission of knowledge (Mann and Sargeant, 2003; Wells, 2003).

Common bottlenose dolphins in shallow habitats tend to make relatively brief dives, surfacing on average twice every minute. In

deep water habitats, such as the Bermuda Pedestal, dives to more than 500 m and for longer than 5 min have been documented, correlating with reported nightly vertical migrations of mesopelagic prey (Klatsky *et al.*, 2007).

Common bottlenose dolphins produce three categories of sounds: whistles, echolocation clicks, and burst-pulse sounds. Dolphins produce a large variety of whistles, including largely stereotypic “signature whistles” that are individually specific and appear to be used to communicate identity, location, and possibly emotional state (Caldwell *et al.*, 1990; Sayigh *et al.*, 1990; Janik *et al.*, 2006). Once the signature whistle develops in neonates, it remains stable for many years. The signature whistles of many male calves are similar to the whistles of their mothers while those of female calves are not. Recent studies have demonstrated that common bottlenose dolphins spread over distances of hundreds of meters to kilometers may remain in acoustic contact with one another through whistles (Quintana-Rizzo *et al.*, 2006). Dolphin echolocation involves the production of “clicks,” with peak frequencies of about 40–130 kHz (Au, 1993). Echolocation is hypothesized to be used in navigation, foraging, and predator detection, among other possible functions (Nowacek, 2005; Quintana-Rizzo *et al.*, 2006). Burst-pulses (“squawks”) tend to be produced during social interactions.

V. Life History

Analyses of dentinal and cemental growth layer groups in teeth (Hohn *et al.*, 1989) have shown that female common bottlenose dolphins can live to more than 57 years, and males up to 48 years (Wells and Scott, 1999). Calves achieve most of their growth during the period of suckling, i.e., the first 1.5 to 2 years of life. Females typically reach sexual and physical maturity before males, leading to sexual dimorphism in some regions. Age at sexual maturity varies by region, but in general females usually reach sexual maturity at 5 to 13 years. Sexual maturity for males tends to occur at 9 to 14 years; paternity testing of common bottlenose dolphins in Sarasota Bay, Florida has shown that males 13 to 40 years of age have sired offspring (Duffield and Wells, 2002; Wells, 2003).

Although births have been reported from all seasons, calving tends to be diffusely seasonal, with peaks during spring–summer months (Urian *et al.*, 1996; Thayer *et al.*, 2003). Hormonal monitoring of captive common bottlenose dolphins indicates that females are spontaneous sporadic ovulators, ovulating repeatedly during a given season, while males may be active throughout the year with prolonged elevation of testosterone concentrations over the months that different females may be ovulating. The reproductive lifespan is prolonged; females up to 48 years of age have successfully given birth and raised young (Wells and Scott, 1999). Calves are born after a gestation period of about 1 year and range in length from about 84 to 140 cm (Perrin and Reilly, 1984), depending on the geographic region.

Lactation is the primary source of nutrition for the first year of life and may continue for several more years. Solid food has been found along with milk in the stomachs of calves as young as 4 months old. Maternal investment for free-ranging calves typically extends for about 3–6 years, with separation often coinciding with the birth of the next calf (Wells and Scott, 1999). Simultaneously pregnant and lactating females have been noted on occasion.

Common bottlenose dolphin mortality results from both natural and anthropogenic sources (Wells and Scott, 1999). Natural causes include old age, failure to thrive as a calf, intra-specific agonistic interactions, predation, stingray barb wounds, disease, and biotoxins from harmful algal blooms such as red tides. Threats of human

origin include entanglement in nets, entanglement in or ingestion of recreational fishing gear, pollution, boat collisions, noise, and drive or harpoon fisheries. In some cases, the distinction between natural and anthropogenic causes of death become blurred, e.g., when it is suspected that exposure to toxic environmental contaminants may increase a dolphin's susceptibility to natural pathogens or biotoxins.

VI. Interactions with Humans

Common bottlenose dolphins take advantage of human activities to facilitate prey capture in a variety of ways. In Mauritania and Brazil, dolphins regularly drive schools of mullet toward fishermen wading with nets in shallow water, and in many parts of the world dolphins collect discarded fish from behind shrimp trawls and small purse seines, or steal fish from various types of fishing gears.

Common bottlenose dolphins were publicly displayed first at the Brighton Aquarium in 1883, then at the New York Aquarium in 1914, and have been a regular attraction at Marineland of Florida since 1938. *Tursiops* continues to be the most common dolphin species maintained in collections and displayed throughout the world. According to a May 2000 National Marine Fisheries Service inventory, 35 US facilities held 392 common bottlenose dolphins; in addition, several hundred bottlenose dolphins were held in at least 16 other countries. Within the US, approximately 70% of the dolphins are held primarily for public display, whereas the remainder are used primarily for research or military purposes. Improved facilities and increased knowledge about the requirements for care of dolphins have led to increasing success in the long-term maintenance of the animals, to the point where birth and survivorship rates at the better facilities approach and, possibly in a few cases, surpass those of wild populations (DeMaster and Drevenak, 1988; Wells and Scott, 1990).

The largest of the historical fisheries for common bottlenose dolphins involved several countries surrounding the Black Sea, where dolphins were caught for oil, meat, and leather. Because of declines in dolphin populations, these countries have since outlawed the fishery. Directed takes still occur in other parts of the world, such as Peru, Sri Lanka, Faroe Islands, and Japan for human consumption, to reduce the perceived competition with commercial fisheries, or for bait (Wells and Scott, 1999). Live-capture fisheries for dolphins for public display have existed for more than 100 years. More than 1500 *Tursiops* were removed from the waters of the US, Mexico, and the Bahamas by 1980 for display, research, or military applications in many parts of the world (Leatherwood and Reeves, 1982). Though no bottlenose dolphins have been collected in US waters since 1989, some live-capture fisheries continue in Cuba, the Solomon Islands, Russia, and Japan.

Incidental catches of small numbers of *T. truncatus* have been reported for several fisheries, including purse-seine fisheries for tunas, sardines, and anchovetas (Wells and Scott, 1999). In some cases dolphins have been killed by fishermen to prevent damage to their fishing gear or stealing of the catch or bait (Leatherwood and Reeves, 1982). In the US, entanglement in, or ingestion of recreational fishing gear is resulting in increasing numbers of common bottlenose dolphin mortalities.

Though the impacts of habitat alteration and pollution on dolphins have not been studied systematically, anecdotal accounts suggest that human-caused degradation may have led to declines in some dolphin populations (Wells and Scott, 1999). Extremely high concentrations of chlorinated hydrocarbon residues have been found in the tissues of *Tursiops* in many parts of the world, with males accumulating higher concentrations than females with age (O'Shea, 1999; Wells *et al.*, 2005). Cockcroft *et al.* (1989b) suggested that

first-born calves of South African bottlenose dolphins, identified by the authors as *T. truncatus*, received 80% of their mother's body burden of contaminant residues (polychlorinated biphenyls and dieldrin), perhaps leading to increased neonatal mortality but also reducing levels of contaminants in the mothers. Studies along the west coast of Florida monitoring contaminant concentrations in identifiable resident dolphins supported these findings, with high concentrations in first-born calves and nulliparous females and lowered levels on females while lactating (Wells *et al.*, 2005). Accumulation of contaminants in tissues of males have reached levels that theoretically could impair testosterone production and thus reduce reproductive ability. Preliminary findings suggest that even relatively low levels of PCBs and DDT metabolites can result in a decline in bottlenose dolphin immune system function, health, and reproductive success (Lahvis *et al.*, 1995; Schwacke *et al.*, 2002). Other anthropogenic chemical contaminants, such as perfluoroalkyl compounds, are of emerging concern (Houde *et al.*, 2006).

Responses to other human use of dolphin habitat through dolphin feeding and swimming with dolphins are receiving increased attention (Samuels and Bejder, 2004; Cunningham-Smith *et al.*, 2006). It is clear that common bottlenose dolphins suffer mortality and serious injury from collisions with boats (Wells and Scott, 1997), relative abundance may decline with increased dolphin-watching tours (Bedjer *et al.*, 2006), and behaviors such as dive patterns, heading, synchronicity, aerial behaviors, and communications may change in the presence of vessels (Janik and Thompson, 1996; Nowacek *et al.*, 2001; Hastie *et al.*, 2003; Buckstaff, 2004; Goodwin and Cotton, 2004; Mattson *et al.*, 2005; Lusseau, 2006).

Although there are many threats operating on local populations, *T. truncatus* is widespread and abundant, and as a species it does not appear to merit concern for major global population decline. Therefore, the common bottlenose dolphin has been classified by the IUCN as "Least Concern."

Common Dolphins

Delphinus delphis and *D. capensis*

WILLIAM F. PERRIN

I. Characteristics and Taxonomy

The short-beaked common dolphin (*Delphinus delphis*) is the most abundant dolphin in offshore warm-temperate waters in the Atlantic and Pacific, often coming from a distance to join a boat and ride the bow wave. The closely related long-beaked common dolphin (*D. capensis*) is seen less often in most regions and is difficult to distinguish from its congener at sea. The very-long-beaked endemic Indian Ocean subspecies of the long-beaked common dolphin (*D. capensis tropicalis*) is poorly known; its taxonomic status has only recently been clarified (Jefferson and Van Waerebeek, 2002). There is also a distinct short-beaked form in the Black Sea, currently thought to be a subspecies, *D. delphis ponticus* (Amaha, 1994).

Figure 1 Short-beaked common dolphins, *Delphinus delphis*. Photograph by Robert Pitman.

Figure 2 Long-beaked common dolphin, *D. c. capensis*, off California. Photograph by Robert Pitman.

All the common dolphins are slender and have a long beak sharply demarcated from the melon (Figs. 1 & 2). The dorsal fin is high and moderately falcate, although in some areas it may be erectly triangular. The two species are distinguished from other dolphins by a unique crisscross color pattern formed by interaction of the dorsal overlay and cape, resulting in distortions of the usual delphinine lateral and ventral fields. The lower margin of the dorsal overlay passes high anteriorly and dips to cross the ventral margin of the low-riding cape, yielding a four-part pattern of dark gray to black uppermost portion or spinal field (cape under dorsal overlay), buff to pale yellow anterior portion or thoracic patch (undiluted cape), light to medium gray posterior portion or flank patch (undiluted dorsal overlay/lateral field), and white abdominal field. A dark flipper-to-anus stripe may parallel the lower margin of the cape and extend to the genital region. A dark flipper stripe runs forward to join the lip patch on the underside of the beak. In the short-beaked species, the color pattern is crisper, the thoracic patch is more yellowish, the sub-cape stripe tends to be anteriorly narrow and faint, and the flipper stripe tends to be narrow and pass low below the corner of the gape. In the long-beaked species including the Indian Ocean subspecies (Fig. 3), the pattern is more muted, the spinal field may be grayish, the thoracic patch tends to be pale buff, the flipper-to-anus stripe tends to be broad anteriorly and may be pronounced and contiguous with the flipper stripe, and the flipper stripe tends to wander toward the corner of the gape before passing ventrally to join the lip patch mark. In the short-beaked species, the dorsal fin and flippers may be all white

Figure 3 Extremely-long-beaked common dolphin in Indonesia; may be *D. c. tropicalis*. Photo courtesy of Danielle Krieb.

or have white centers. These relative features may not be evident in juveniles.

Full species status for the two forms has not been widely recognized until recently (Evans, 1994; Heyning and Perrin, 1994; Rosel *et al.*, 1994; Rice, 1998), and data on size and weight for the three species have been commingled in the literature for some parts of the world. Data exist for well-documented series of adults of two species from California waters. In the short-beaked species, males were 172–201 cm long ($n = 28$) and females were 164–193 cm ($n = 37$) vs 202–235 cm ($n = 15$), and 193–224 cm ($n = 10$), respectively, for the long-beaked species. The short-beaked species ranged to about 200 kg and the long-beaked species to about 235 kg. However, this pattern of differential size may not hold globally; a geographic form of the short-beaked species in the eastern tropical Pacific ranges in length to 235 cm, as large as the long-beaked species in California waters. Also, it has been impossible or difficult to identify definitively common dolphins to species in some areas based on morphology, e.g., South Africa (Samaai *et al.*, 2005) and the eastern North Atlantic (Murphy *et al.*, 2006), and the monophyly of *D. capensis* has been questioned on genetic grounds; various disjunct regional populations may have originated from *D. delphis* separately (Natoli *et al.*, 2006), possibly making the present taxonomy incorrect. Work remains to be done on the alpha taxonomy of the genus; there may be more than two species.

The SKULLS of *Delphinus* spp. are different from those of all the other delphinines (*Stenella* spp., *Tursiops* spp., *Sousa* spp., and *Lagenodelphis hosei*) in the combination of long narrow rostrum and deep palatal grooves. They are similar to the skulls of *Stenella longirostris*, *S. clymene*, *S. coeruleoalba*, and *L. hosei* in having a strongly dorsoventrally flattened rostrum with distally splayed teeth, about 40–60 teeth in each row, relatively small temporal fossae, and sigmoid mandibular rami. The two species in sympatry differ in proportional length of the rostrum in adults: the ratio of rostral length to zygomatic width in *D. delphis* is 1.21 to 1.47 and in *D. c. capensis* is 1.52 to 1.77 (Heyning and Perrin, 1994). Upper/lower tooth counts in California were 42–54/41–53 ($n = 49/47$) and 47–60/47–57 ($n = 53/51$), respectively. Vertebral counts were 74–80 ($n = 80$) in *D. delphis* and 77–80 ($n = 25$) in *D. capensis*. The osteology of *D. c. tropicalis* has not been well described, but the rostral/zygomatic ratio of the holotype specimen is 2.06 and the tooth counts 65–65/57–58, both well beyond the upper range of *D. capensis* for California. Six *Delphinus* skulls from the Arabian Peninsula ranged continuously from 1.72 to 1.94 in

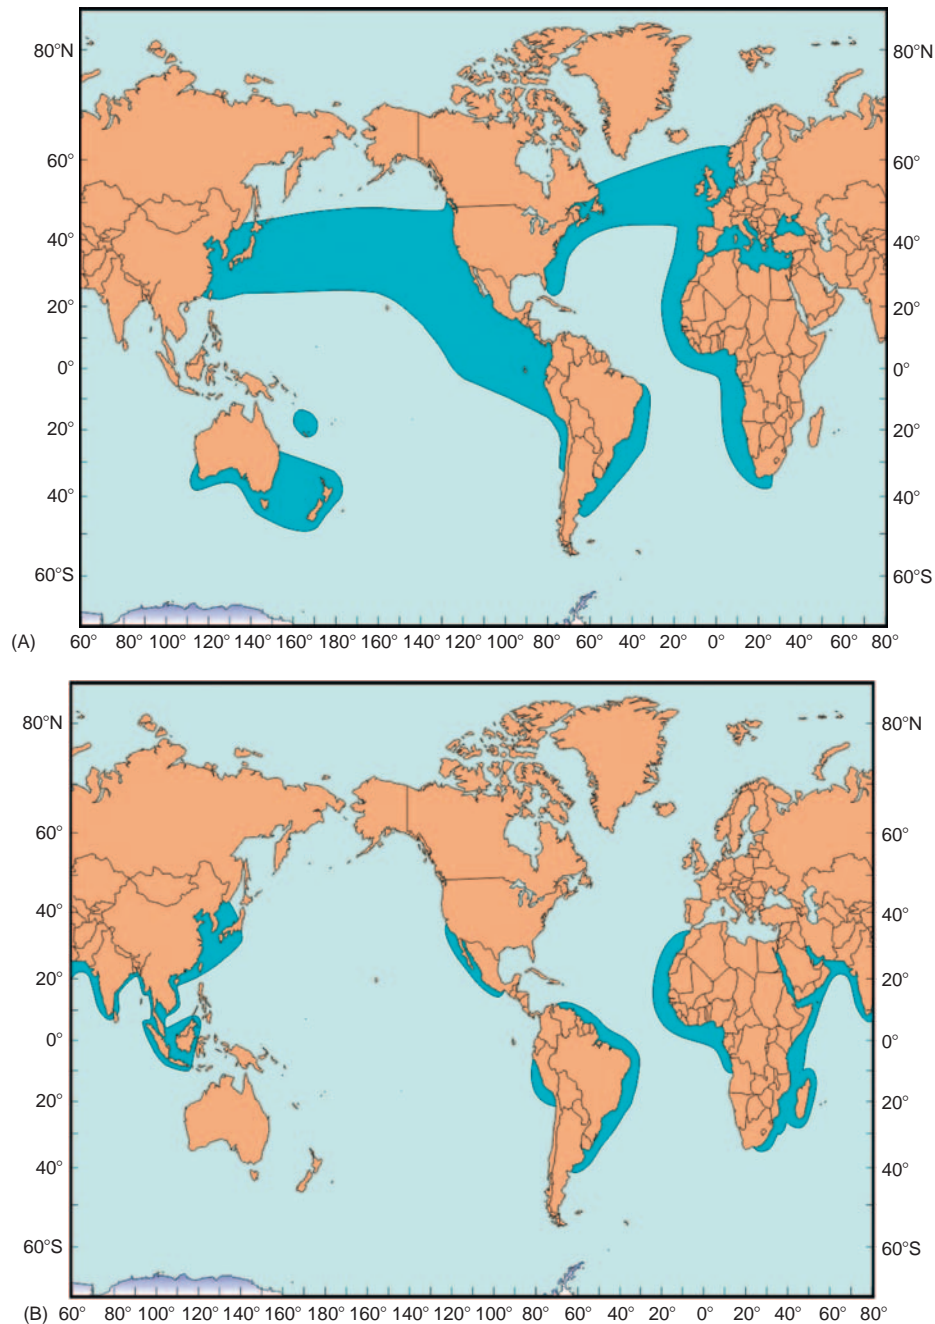

Figure 4 Distributions of (A) short-beaked and (B) long-beaked common dolphins.

rostral/zygomatic ratio. Three (with the lowest ratios) had been identified as “*D. capensis*” and the others as “*D. tropicalis*”; the range overlaps that of *D. capensis* from California (Smeenk *et al.*, 1996).

The common dolphins are members of the delphinid subfamily Delphininae *sensu stricto* (LeDuc *et al.*, 1999). In a cladistic phylogenetic analysis based on cytochrome *b* mtDNA, they share a strongly supported polytomic clade with *Stenella coeruleoalba* and *S. clymene* (sister taxa), *S. frontalis*, and *Tursiops aduncus*. *D. tropicalis* was basal in the *Delphinus* clade, with California *D. delphis*, Black Sea *D. delphis*, and *D. capensis* in a subsidiary three-part polytomy, making *D. delphis* seemingly paraphyletic. However, apparent paraphyly among terminal taxa can result from incomplete lineage sorting

in newly evolved species (LeDuc *et al.*, 1999); reciprocal monophyly has not yet had a chance to evolve in such cases. As noted earlier, *Delphinus* shares several skull features with *S. longirostris*, *S. coeruleoalba*, *S. clymene*, and *L. hosei*, but that grouping is not supported by the molecular results to date.

II. Distribution and Abundance

Common dolphins occur in warm-temperate and tropical waters worldwide from about 40–60°N to about 50°S (Jefferson *et al.*, 2007), but because the three species were considered to be forms of one until recently, many DISTRIBUTION records and much documentation

of range have not been identified to species (Rice, 1998). Based on records with diagnostic characters (Fig. 4; Heyning and Perrin, 1994), *D. delphis* occurs from southern Norway to West Africa in the eastern Atlantic (including the Mediterranean and Black Seas), from Newfoundland to Florida in the western Atlantic, from southern Canada to Chile along the coast and pelagically in the eastern Pacific; in the central North Pacific (but not in Hawaii); from central Japan to Taiwan and around New Caledonia, New Zealand, and Tasmania in the western Pacific; and is possibly absent from the South Atlantic and Indian Oceans. *D. c. capensis* occurs disjunctly in warm-temperate and tropical coastal waters in West Africa, from Venezuela to Argentina in the western Atlantic, from southern California to central Mexico, and in Peru in the eastern Pacific, around Korea, southern Japan, and Taiwan in the western Pacific, and in waters of Madagascar, South Africa, and possibly Oman in the Indian Ocean. The identification of the Oman specimens is in some doubt (Smeenk *et al.*, 1996). *D. tropicalis* is known only from the northern Indian Ocean and Southeast Asia.

Delphinus delphis is a very abundant species, with estimates available for several regions (IUCN, 2008): eastern tropical Pacific, 2,963,000; US west coast, 400,000; European continental waters, 63,400; portion of European offshore waters, 273,000; western North Atlantic, 121,000; western Mediterranean, 19,400. There has been a major decline in the Mediterranean during the last 30–40 years. Population size in the Black Sea is unknown. Only a few local abundance estimates exist for *D. capensis* (IUCN, 2008): off California, around 10,000; Pacific coast of Mexico, 55,000; Gulf of California, 69,000; South Africa, 15,000–20,000. There are no estimates for the subspecies *D. c. tropicalis*. Multiple stocks of *D. delphis* exist in the eastern tropical Pacific, identified by differences in size, shape, coloration and life-history characteristics (Perryman and Lynn, 1993; Danil and Chivers, 2006).

III. Ecology

D. delphis and *D. capensis* are narrowly sympatric in some near-shore waters; schools of the two species may be seen in the same general area on the same day. However, *D. capensis* seems to prefer shallower and warmer water and generally occurs closer to the coast. In the eastern North Pacific, substantial seasonal and inter-annual changes in abundance of *D. delphis* suggest migrations that vary with oceanographic conditions; the movements may be north–south and/or inshore–offshore (Forney and Barlow, 1998). In the tropical eastern Pacific, *D. delphis* occupies primarily upwelling-modified habitats with less tropical characteristics than surrounding water masses (Ballance *et al.*, 2006); separate northern, central, and southern stocks associated with different upwelling areas are recognized in the management of incidental mortality in tuna fisheries (Perrin *et al.*, 1985). *D. delphis* prefers coastal and upper slope waters in the Mediterranean (Bearzi *et al.*, 2003) and migrate between offshore and shallow coastal waters in the Black Sea (Birkun, 2006).

As would be expected for a species occupying a wide range of habitats, common dolphins feed on a variety of prey, including small mesopelagic fishes and squids found in the deep scattering layer and epipelagic schooling species such as small scombroids, clupeoids, and market squids (Evans, 1994; Ohizumi *et al.*, 1998; De Pierrepont *et al.*, 2005; Pusineri *et al.*, 2007). The diet varies taxonomically with region; in the western Atlantic, oceanic common dolphins consume more squid than neritic ones do (Lahaye *et al.*, 2005). Foraging dives to 200 m have been recorded. Diet varies with season as well as with region (Evans, 1994). FEEDING habits of the two species have not been compared.

IV. Behavior and Physiology

Schools of hundreds or thousands are thought to be composed of smaller subunits of about 20–30 perhaps closely related individuals (Evans, 1994). Differences between schools in cranial measurements and color pattern suggest that schools have temporal integrity at some level. There may be segregation in schools by age and sex. Association with schools of pilot whales (*Globicephala* spp.) and other dolphins (*Lagenorhynchus* spp., *Stenella coeruleoalba*, *Grampus griseus*) have been observed (Evans, 1994; Frantzis and Herzing, 2002), as has “bow riding” on mysticete whales, possibly the origin of bow riding on vessels. Common typical aerial behavior includes “pitch poling,” in which the dolphin leaps high vertically and falls lengthwise back into the water to create a large splash. In some areas in the eastern tropical Pacific, schools of *D. delphis* “carry” yellowfin tuna and are chased and captured by tuna fishermen using purse seines.

Seasonal migrations related to environmental change have been reported for *D. delphis* from the Black Sea (Birkun, 2006), New Zealand (Neumann, 2001) and the eastern tropical Pacific (Danil and Chivers, 2006). Individual long-beaked common dolphins may exhibit long-term local residency (Bernal *et al.*, 2003).

V. Life History

Gestation in *D. delphis* as estimated at 10–11.7 months for several populations around the world (Perrin and Reilly, 1984; Murphy and Rogan, 2006; Danil and Chivers, 2007; Westgate and Read, 2007). Estimated length at birth ranges from 80 to 93 cm. The calving interval varies from about 1 (Black Sea) to about 3 years (eastern Pacific). Weaning occurs at 5–6 months in the Black Sea, but possibly later in other areas. Estimates of age at sexual maturation vary with region from 3 years (Black Sea) to 7–12 years (eastern Pacific and western Atlantic) for males and 2–4 and 6–8 years, respectively, for females. Part of the range of variation may be a density-dependent effect due to exploitation. Maximum estimated age was 30 years for both sexes (western North Atlantic). Other possible factors explaining the variation include differences in age-determination methods and biases in sampling. Reproductive seasonality also varies with region, with cooler-water populations exhibiting more synchrony of breeding. The degree of sexual dimorphism and very large testes (translation of one Japanese name for the species is “testis dolphin”) suggest sperm competition and a promiscuous breeding system (Murphy *et al.*, 2005).

VI. Interactions with Humans

Short-beaked common dolphins have died in large numbers in tuna purse seines in the eastern tropical Pacific (e.g., 24,307 in 1986; IATTC, 2006) and, with long-beaked and Indian Ocean common dolphins, in gillnet, trawl and purse-seine fisheries around the world (Perrin *et al.*, 1994; IUCN, 2008); the impact of these kills on the populations is for the most part unknown. Common dolphins are also killed in nets enclosing tuna feedlots in Australia (Kemper and Gibbs, 2001). Use of pingers on gillnets has reduced gillnet mortality to an insignificant level in the eastern North Pacific (Carretta *et al.*, 2006). Direct take for human consumption and shark bait is a threat to *D. capensis* in Peru (IUCN, 2008). Prey depletion is thought to be a threat to the subspecies of *D. delphis* in the Black Sea (IUCN, 2008).

Common dolphins have been kept successfully in captivity for up to 8 years in eastern European oceanaria and reproduced successfully in captive facilities in the USA, New Zealand, and Russia

(Evans, 1994). *D. capensis* has hybridized with *T. truncatus* in captivity, producing viable offspring of unknown fertility (T. Goff, unpublished data). *D. delphis* is among the species exploited in whale watching in Europe and elsewhere (Hoyt, 2003).

Communication in Marine Mammals

KATHLEEN M. DUDZINSKI, JEANETTE A. THOMAS AND JUSTIN D. GREGG

Communication is a process by which a sender produces a signal, which alters the probability of a subsequent behavior in a receiver(s). Often, but not always, communication facilitates social behavior. Given the highly social behavior found in many marine mammals, the study of communicative behavior is essential to understanding the role that signaling plays in regulating social interactions for these species. To understand communication in a given species, it is important to view the mode of the signal (i.e., visual, acoustic, tactile, gustatory, or olfactory), medium in which the signal is transmitted (air and/or water), mechanisms of signal production (anatomical and/or physiological), function(s) of the signal (e.g., aggression/submission, mate attraction, parental care, TERRITORIAL defense), and whether signals are multi-modal.

This chapter is a brief overview of communication in marine mammals. Even with more than 40 years of focused studies on the social lives of marine mammals, relatively little is understood about the majority of species within marine mammal groups—cetaceans, pinnipeds, sirenians, sea otters (*Enhydra lutris*), and the polar bears (*Ursus maritimus*). Behavioral characteristics and social relationships are adapted to each species' unique ecology. Marine mammals are either amphibious or totally aquatic. Each life mode imposes different constraints on signaling and communication. A paucity of studies on communication exists for many marine mammals, especially polar bears, sea otters, dugongs (*Dugong dugon*), and manatees (*Trichechus* spp.). Even less is known about the marine otter (*Lontra felina*), so we do not discuss this species. The majority of research on communication has been conducted on pinnipeds (such as Weddell seals, *Leptonychotes weddellii*; and California sea lions, *Zalophus californianus*) and cetaceans (particularly bottlenose dolphins, *Tursiops* spp.; killer whales, *Orcinus orca*; and humpback whales, *Megaptera novaeangliae*). Thus, our discussion highlights and compares species predominantly represented in the literature.

I. Definition

A clear definition of communication is needed to facilitate consistency among studies and to avoid ambiguities in methods. Bradbury and Vehrencamp (1998) provided this definition: "communication involves the provision of information (via a signal) by a sender to a receiver, and subsequent use of this information by the receiver in deciding how or whether to respond." The signal is the vehicle by which the sender and receiver exchange information. Both the sender and the receiver rely on signals to meet individual challenges within a group setting, such as reproduction, predator defense, territory defense, foraging, maintenance of social bonds, and parental care. Signals are mechanisms or "tools" specialized over time to be informative, salient to interactions among individuals, and adapted for optimum transmission in their environment(s). In mammals, sensory channels can include chemical (i.e., taste and olfaction), mechanical (i.e., tactile and acoustic), photic (visual), and electromagnetic modes (Herman, 1980; Reynolds and Rommel, 1999). While most terrestrial mammals evolved signals in each

of these sensory channels (Hauser, 1997), marine mammals have not, primarily because of limitations of the aquatic environment. Amphibious marine mammals tend to use sensory modes similar to terrestrial mammals, but the strictly marine mammals have limited abilities for olfaction because water is not a good medium for long-term, site-specific use of scent. Likewise, marine mammals use vision only for short distances because water movement, plankton blooms, murky water, or darkness at depth limits the range and applicability of vision in water. In totally aquatic mammals, communication is achieved primarily through acoustic and tactile modes.

II. Chemical Communication

Chemoreception is common among terrestrial mammals, but little is understood about how marine mammals sense chemical signals in the water (Reynolds and Rommel, 1999). The olfactory sense and anatomy are not suited for communication in water and this sensation declines with greater adaptation to an aquatic lifestyle (Reynolds and Rommel, 1999). Jansen and Jansen (in Anderson, 1969) found that adult odontocetes lack olfactory nerves, bulbs, and tracts; the same are reduced greatly in adult mysticetes. Furthermore, cetaceans, pinnipeds, sea otters, and sirenians all close their nasal openings while in water, thus preventing smell. Chemoreception in water may be more taste than smell. The possibility that scents are pheromone based in nature and function has not been examined in marine mammals, although anecdotal accounts exist. It has been suggested that belugas (*Delphinapterus leucas*) release a "pheromone" when alarmed. Belugas react to blood in the water by either quickly escaping or becoming unusually excited. Trails of both feces and urine deposited by schools of dolphins could contain sexual pheromones. At times, spinner dolphins (*Stenella longirostris*) appear to swim deliberately through dispersing excrements deposited by schoolmates (Norris *et al.*, 1994).

1. *Cetacea* Whether under water or at the surface, cetaceans keep their blowholes closed, except during brief respirations at the surface. Most studied cetaceans have the ability to taste, although with somewhat different receptive qualities than terrestrial mammals (Reynolds and Rommel, 1999). Taste buds have been documented behaviorally and physiologically for both cetaceans and sirenians (Herman, 1980; Schusterman *et al.*, 1986; Reynolds and Rommel, 1999). Experiments on the taste sensitivities of common bottlenose dolphins (*Tursiops truncatus*) have shown that they can discriminate sour, sweet, bitter, and salty solutions. They were least sensitive to different salt concentrations, which seems adaptive given they live in a marine environment.

2. *Pinnipedia* Whether on land or under water, pinnipeds keep their nares closed, except to respire. The olfactory anatomy of pinnipeds is variably reduced, more for phocids and for odobenids than for otariids (Reynolds and Rommel, 1999). Pinnipeds employ scents to exchange or gain information about colony members; e.g., male northern fur seals (*Callorhinus ursinus*) sniff the hindquarters of females to assess their estrous state (Reynolds and Rommel, 1999). The largest glands of pinnipeds are around the vibrissae and could play a role in mother-pup recognition. Mothers and pups maintain a great deal of nose-to-nose contact and use odor cues for recognition in air. Little work has been conducted on pinniped taste sensations. Gustatory abilities also have been demonstrated in Steller sea lions (*Eumetopias jubatus*) and California sea lions. Both studies found similar taste abilities with some sensitivity to acidic, basic, and salty solutions, but not to sweet.

3. *Sirenia* Similar to cetaceans, sirenians keep their nasal openings closed under water or at the surface, except to quickly breathe at the surface. Sirenians have a rudimentary olfactory system (Reynolds and Rommel, 1999) and likely rely, to a limited degree, on chemicals for signal exchange among conspecifics. However, because aquatic plants are known to have different tastes and smells, manatees and dugongs could use this sense in foraging. No information is available on taste abilities in sirenians.

4. *Sea otter* Unlike other mustelids, known for their musky smell, the sea otter has no scent glands. This is likely a result of the aquatic environment in which scent marking would have limited usefulness. When under water, sea otters close their nares. Kenyon (1975) reported that sea otters in water commonly surface and sniff the air, and the male sea otter smells the genital area of an estrous female during pre-copulatory behavior. The common “nosing” behavior observed between sea otters is thought to involve scent recognition or chemoreception (Riedman and Estes, 1990). It is assumed that sea otters and polar bears have taste abilities similar to their terrestrial counterparts, although the exact extent of this sense is unknown for these species.

5. *Polar bear* Polar bears have a keen sense of smell, especially useful in foraging. While little is known about how olfaction is used for communication among polar bears, patterns are likely similar to those observed in other ursids and used by males to find potential mates (Ovsyanikov, 1996; Stirling, 1999). No studies are available on taste abilities of polar bears.

III. Visual Communication

Behavioral displays are well documented for many marine mammals with visual detection and acuity levels being good both above and under water for all species studied (Reynolds and Rommel, 1999). Under water, VISION is limited by light levels, the concentration and type of organic matter suspended in the water column, and depth (for a thorough discussion of light in the ocean and visual adaptations by marine mammal species for visual detection and acuity both above and below the water; Reynolds and Rommel, 1999; Mass and Supin, 2007). Visual displays can be simple, such as sexually dimorphic features, body postures or coloration patterns, or they can be elaborate sequences of behaviors that indicate a context, species, age, sex, or reproductive condition. Movements and postures often are highlighted in species with conspicuous color patterns. In clear water, visual signals provide cetaceans and other marine mammals a close-range alternative to acoustic signaling; however, displays could inadvertently alert predators or prey. Some marine mammals have adaptations for vision (e.g., large eyes, tapetum) that allow them to see and potentially communicate via visual signals in low light conditions. The anatomical adaptations for vision in water vary greatly among marine mammals (Mass and Supin, 2007).

1. *Cetacea* Visual displays for odontocetes include behaviors, coloration, and morphological traits. Several species possess distinct visual characters that might or might not be considered secondary sexual characteristics [e.g., male spinner dolphins have a forward sloping dorsal fin and bulging ventral keel, male Dall’s porpoise (*Phocoenoides dalli*) have a pronounced ventral hump, male narwhals (*Monodon monoceros*) have long spiral tusks and in several species of beaked whales males have lower teeth that protrude outside the mouth]. These sexually dimorphic characteristics may be used to regulate social signaling, and possibly mating. Recurrent

body color patterns (spots, saddle patches, capes, and longitudinal striping) are evident in several delphinids, especially species living in clear water where surface reflections may be important to social signaling. Disruptive coloration has likely evolved for social signaling, or to deceive prey and predators. Pelagic species tend to live in large, inter-specific schools and also seem to possess the most complex color patterns among small cetaceans. This complexity may be important for species and individual recognition, as well as social signaling (Thomas and Kastelein, 1990). Overt actions and gestures such as open-jaw threat displays, aerial leaps, tail lobbs, flared pectoral fins, and S-shaped postures form the majority of behavioral visual displays expressed by cetaceans. Changes in posture can be used to communicate to conspecifics, predators, and prey. Posture and behavioral signaling can also be used to synchronize actions among individuals or groups as a signal for group coordination or for social interaction (e.g., synchrony between male coalitions of bottlenose dolphins when herding a female). Whalers early on recognized that the shape and height of the “blow” associated with respiration at the water surface is quite distinctive in some species of odontocetes and mysticetes. Similarly, the blow could be used as a social signal among cetaceans, especially to indicate location and species.

2. *Pinnipedia* Several pinnipeds incorporate body coloration or postures into visual displays; e.g., TERRITORIAL BEHAVIOR of a Weddell seal patrolling the water underneath a crack in the fast ice consists of loud trill and teeth chatter sounds accompanied by an S-shaped posture that thrusts the chest forward and the hind flippers downward. When approached on the pack ice, Ross seals (*Omatophoca rossii*) assume a head-up posture that displays the stripes on their chest, an open mouth of teeth, and this is accompanied by noisy sounds. Interestingly, this species has been called the “singing seal,” but the postures and sounds indicate aggression toward an intruder.

3. *Sirenia* Sirenians have poor color vision and poor visual acuity for near-field objects. Often considered solitary, manatees may congregate at well-defined, traditional locations called “rendezvous sites” in Florida where tactile contact seems to be the primary form of close-range communication (Reynolds and Rommel, 1999). Little information is available on signal exchange for visual communication among manatees or dugongs.

4. *Sea otter* Riedman and Estes (1990) described a “head jerk” movement commonly seen in sea otters. This rapid side-to-side head movement is a visual display that may be involved in communicating social status, reproductive status, or other information. In general, little is known about the visual displays of sea otters.

5. *Polar bear* Polar bears exhibit visual displays on land, like other ursids, including bearing of teeth, upright sparring, chasing, and wrestling between males.

IV. Tactile Communication

Visual displays are useful for close-range communication among marine mammals and, because of close proximity, visual displays may readily become tactile signals. Extensive touching and rubbing occurs in both captive and free-ranging animals during PLAY, sexual, maternal, and social contexts using the nose or rostrum, flippers, pectoral fins, dorsal fin, flukes, abdomen, and the entire body. Tactile contacts often are observed during AGGRESSIVE BEHAVIOR, but are characterized by more overt actions, such as biting, raking, ramming,

wrestling, and butting. Tactile signals can be modified to increase the information content—who, where, and how animals touch, as well as the intensity of a touch, factor into the signal content. Often, tactile signals combine with other signals and grade into each other; e.g., a chase, then wrestle, teeth chatter, then nip, can escalate into a full biting and sparring match. The advantage of a graded signal is that the sender or receiver can choose to withdraw at any point along the progression.

A. Responsiveness to Touch

1. Cetacea An inclination for tactile responsiveness has been noted in studies of wild and captive individuals of all cetaceans. Among mysticetes, the “friendly” gray whales (*Eschrichtius robustus*) of San Ignacio Lagoon, Mexico are noted for approaching and rubbing under small boats and for tolerance of petting by tourists. In the wild, both Atlantic spotted (*Stenella frontalis*) and bottlenose dolphins rub body parts into the sand or along rocky edges, and are in frequent contact with each other (Fig 1). Gentle contact behavior between conspecifics (petting, stroking, nuzzling) has been recorded in many cetacean species [e.g., humpback and North Atlantic right whales (*Eubalaena glacialis*)] and is common among mothers and their calves. However, there is no evidence of allogrooming or mother grooming of a calf in cetaceans. Contact swimming bouts, where one dolphin lays its pectoral fin on the flank of a conspecific, have been recorded in bottlenose dolphins in Shark Bay Australia, with one bout reportedly lasting over 30 min (Connor *et al.*, 2006). All odontocetes in captivity seek and are receptive to gentle body contact. Mild tactile stimulation (e.g., rubbing of gums, flippers, or dorsal fin) serves as an effective re-enforcer in training of most odontocetes. Trainers suggest that tactile stimulation is reinforcing, and perhaps rubbing among dolphins might also be rewarding. Rubbing and touching serves a secondary function to help remove dead skin that continually sloughs in cetaceans. In addition, the flow of water across the body may help cetaceans judge swim speed or water depth. The bow-riding behavior exhibited by cetaceans in the family Delphinidae likely provides a tactile sensory experience.

2. Pinnipedia Pinnipeds vary in their degree of gregarious behavior and thus tolerance for tactile stimulation by conspecifics. Leopard seals (*Hydrurga leptonyx*) are solitary predators and rarely seen in close proximity. In contrast, Weddell seals congregate in breeding colonies, but each mother–pup pair maintains an individual space. The more polygynous pinnipeds, such as walrus (*Odobenus rosmarus*) and California sea lions, often crowd onto beaches, piling on top of each other, with little regard for “personal space.” This tolerance of body contact may provide a thermoregulatory advantage, as well.

Regardless of adult spacing, in pinnipeds a mother and pup maintain close tactile communication. Young pinniped pups often crawl over their mothers, and sleep touching their mother. There is, however, no maternal grooming of the young in pinnipeds.

3. Sirenia In Crystal River, Florida, some manatees seek physical contact with divers, whereas others avoid divers. Florida manatees (*Trichechus manatus latirostris*) sometimes “body surf” on currents generated below dams when floodgates are partially opened. This surfing can last for up to an hour, with manatees repeatedly riding the currents in parallel formation. Often, nuzzling and vocalizations accompany manatee body surfing (Reynolds and Odell, 1991). When not eating (nearly 8h/day), manatees curiously investigate objects, socialize by mouthing and rubbing against each other, and play together (Reynolds and Odell, 1991). The fact that manatees have a green tinge from the algae that grows on their skins suggests that they do not slough their skin often, but perhaps rubbing helps keep the amount of algae in check. Manatees are often seen mouthing or bathing in a water stream from a hose running off boats. Mothers do not groom their calves.

4. Sea otter Sea otters possess thick layers of fur for warmth and protection, and thus grooming is part of their social structure, as with many social terrestrial mammals. Unlike other marine mammals, sea otters do not have subcutaneous fat, they must rely on keeping their underfur dry and therefore groom themselves repeatedly to spread waterproofing squalene oil over the surface of their fur. Because grooming is essential to keeping warm, sea otters spend a large part of their day grooming. Like terrestrial mammals, sea

Figure 1 Two Atlantic spotted dolphins (*Stenella frontalis*) rubbing their bodies in the sand.

otter mothers groom their pups by licking their fur. They are the only marine mammal to have the ability to hold and manipulate their young for grooming. Mother sea otters float on their back and hold the pup on their abdomen and spend a great deal of time grooming their pup and remove feces and urine by licking the pup's urogenital region. Sea otter grooming behavior is probably at least partially hygienic in function; however, in other mammal species (e.g., primates, canids), grooming behavior signals affection, appeasement, or reconciliation. A variety of tactile behavior relating to grooming (rubbing, shaking, stroking) and other social interactions (shoving, pawing, wrestling) have been documented for sea otters (Riedman and Estes, 1990). When sleeping or resting, sea otters float on their back at the water surface; however, the water movement can "wash them out to sea" (Fig. 2). In Alaska, sea otters often synchronize their sleeping time and form a raft of bodies that bob together. Sea otters in groups often "hold paws" or otherwise keep close body contact to maintain the raft.

5. *Polar bear* More data are required to better understand how polar bears use touch in communication. As in other ursids, mother polar bears likely have close tactile contact with their young for nursing and grooming in the den. Adult males are seen in intense fights grasping each other with "bear holds," nose-to-nose open-mouth threats, growls, and biting. Small cubs are often seen sleeping together, perhaps for comfort and warmth.

V. Acoustic Communication

Marine mammals use both vocal and non-vocal acoustic communication. Richardson *et al.* (1995) summarized the hearing and acoustic abilities of marine mammals. Because of the ease with which sound travels in water and the large area over which sound can be transmitted, as opposed to in air, underwater acoustic signals evolved to be the principal mode of information transmission for fully aquatic mammals and a predominant mode of communication for amphibious marine mammals. Recording and analyzing sounds from marine mammals is relatively easy, but determining the

context and function of sounds is not. Deecke (2006) published a recent summary of studies using playback techniques to examine the function of sounds in marine mammals. The impact that anthropogenic underwater NOISE (Southall *et al.*, 2007) may have on the communicative signals of marine mammals has been highlighted in recent studies of many odontocetes (Foote *et al.*, 2004), endangered mysticete species (Croll *et al.*, 2002), sirenians (Miksis-Olds *et al.*, 2007), and pinnipeds (Southall *et al.*, 2000).

A. Non-vocal Communication

1. *Cetacea* Non-vocal communication can include noise from flukes or flippers striking the water surface, as well as the percussive sounds of jaw claps, teeth gnashing, or bubble emissions. Breaches, leaps, tail slapping, and chin slapping produce sounds under water that likely carry a communicative message. Most cetaceans are known to leap vigorously into the air, called breaching. A breach produces airborne and underwater sounds upon reentry that carry for several kilometers. Breaching could be a spacing mechanism or help cetaceans remain in acoustic contact. Breaching often indicates general excitement or arousal deriving from any of several causes, including sexual stimulation, location of food, or a response to injury or irritation. Calves and their mothers also breach on occasion and sometimes in unison. Clearly, there can be many immediate causes of breaching (e.g., parasite or dead skin removal) and further study is needed to clarify and understand the multiple contexts in which breaching occurs. Dusky dolphins (*Lagenorhynchus obscurus*) are well known for the three leap types they produce in association with three stages of cooperative feeding: head-first re-entry leaps, noisy leaps, and social, acrobatic leaps. The latter two create sounds that function to signal peers or, as for the noisy leaps, could act as a sound "barrier" to disorient prey and keep them tightly schooled. Upon water re-entry after a spin, a breach, a back slap, or a head or tail slap, spinner dolphins generate omni-directional noise that propagates over short to intermediate distances. Spinner dolphins' aerial behavior seems designed to

Figure 2 Typical behavior of a sea otter (*Enhydra lutris*)-floating on its back with a shell.

Figure 3 A group of Atlantic spotted dolphins (*Stenella frontalis*) socializing and exchanging vocal and behavioral signals modified by various postures.

produce noise, as many leaps are common at night, when visual contact is limited, or in daytime occur in fully alert, but dispersed schools (Fig. 3). Visual signals during leaps likely convey position information to schoolmates and could facilitate aerial inspection for feeding sites or for detecting environmental features.

Most observers agree that tail slaps often convey a threat or distress. Tail slapping, which produces extensive, low-frequency underwater and aerial sound, often occurs dozens of times in succession. It is likely that tail slaps among mysticetes and odontocetes often, but not always, have an agonistic component. Pectoral fin slapping is observed predominantly in humpback whales, although other baleen whales and some smaller delphinids also exhibit this behavior. The exact communicative nature of pectoral fin slapping is not clear,

although it may signal frustration or irritation, maintain individual spacing, or serve to invite PLAY or socializing.

The blow or sounds associated with respiration at the water surface are quite distinctive in both odontocetes and mysticetes. It is likely these sounds may be used incidentally by conspecifics to locate each other.

2. Pinnipedia Pinnipeds do not use non-vocal communication as much as cetaceans, i.e., pinnipeds exhibit fewer hind-flipper or fore-flipper slaps or breaches. However, harbor seals (*Phoca vitulina*) and Baikal (*Phoca siberica*) seals slap their fore flippers against their body when disturbed. This sound seems to warn intruders and is quite loud, especially from a wet seal. The most common example

of non-vocal communication in pinnipeds is teeth chattering, which provides both an acoustic and a visual aggressive sign. Many pinnipeds also produce a loud snort or hiss as they exhale, especially after a long dive. This exhalation could have communication significance because it is more forceful in some situations, such as when an intruder approaches while they are hauled out.

3. *Sirenia* Manatees are known to slap the water surface with their tail fluke as a form of communication.

4. *Sea otter* Riedman and Estes (1990) described sea otter behaviors involving contacting the water's surface ("splashing" and "porpoising"), although it is not known if this behavior is intended as non-vocal communication. Sea otters produce a distinctive and loud "tap, tap, tap" sound as they use a rock on their chest as an anvil to crack shellfish, but it is not known whether this may serve as a deliberate form of communication at times.

5. *Polar bear* Little is known about non-vocal auditory communication in polar bears, but as a top level predator it may be adaptive to minimize non-vocal sounds.

B. Vocal Communication

1. *Mysticete cetaceans* Generally, sounds of baleen whales are very different from those of odontocetes, with a wide range of types and quantity of phonation across mysticete species. Social functions proposed for mysticete sounds include long-range contact, assembly calls, sexual advertisement, greeting, spacing, threat, and individual identification; however, only rarely has a specific sound been associated with a given behavioral event. It is probable that sounds produced by mysticetes serve to synchronize biological or behavioral activities in listeners that promote subsequent feeding or breeding. Known and examined baleen whale sounds seem to fall into three basic categories: low-frequency moans, short thumps or knocks, and chirps and whistles. Additionally, the "songs" of humpback whales have been described in some detail.

A. MYSTICETE LOW-FREQUENCY MOANS Low-frequency moans are from 1 to 30sec in duration, with dominant frequencies between 20 and 200 Hz. These sounds can be either pure tones, as in the second-long, 20-Hz sounds of fin whales (*Balaenoptera physalus*), or more complex tones with a strong harmonic structure. Theoretically, these low-frequency, long-wavelength sounds are ideal for long-range communication. A 20-Hz moan from a fin whale has a wavelength of almost 75 m, which means that it passes unimpeded over most obstacles, only bouncing off something large, like a seamount, the water surface, or the ocean bottom. These sounds could travel hundreds of kilometers to reach conspecifics for signaling. Payne and Webb (1971) predicted that theoretically the low-frequency, high-amplitude signals of mysticetes could travel from pole to pole if it were not for interfering water surface and oceanic bottom topography.

Low-frequency sounds (20 Hz) of blue whales (*Balaenoptera musculus*) are recorded across ocean basins at distances of several hundred kilometers. Blue whales are the largest creatures to inhabit the earth; they traverse large expanses in a relatively short time. It is no wonder then that the social structure of these animals reflects a scale that we are only beginning to comprehend. However, tracking the distinctive vocal behavior of this species may provide important clues. "Old blue," a single blue whale, was tracked for nearly 80 days using its distinctive, repeated, 20-Hz signal received by bottom mounted SOSUS (Navy hydrophone) arrays off the coast of the eastern US.

B. MYSTICETE SHORT THUMPS OR KNOCKS Short thumps or knocks are less than 200 Hz, less than 1 sec long, and are currently known to be produced by right (*Eubalaena* spp.), bowhead (*Balaena mysticetus*), gray, fin, and minke whales (*Balaenoptera acutorostrata*). Clark (1983) recorded and studied southern right whale (*Eubalaena australis*) sounds in relation to behavior and found that their sounds were not random, but were related to social context and activity. Resting whales were least soniferous, whereas mildly social groups produced the most varied suite of sounds, including high, hybrid, and pulsive calls, body and flipper slaps, and forceful blows. Clark's work showed that "up calls" functioned as a request for contact between whales: lone swimming whales often produced up calls that were returned by other whales in the vicinity prior to joining.

C. MYSTICETE CHIRPS AND WHISTLES Mysticete chirps and whistles tend to be >1 kHz, but change frequency rapidly and are less than 0.10 sec in duration. These pure tones involve harmonics and seem to be produced by most baleen whales.

D. MYSTICETE SONG Humpback whale songs are probably the most recognized and well known of mysticete vocalizations. Humpback whale males produce what is considered true song because they use elements repeated in phrases and phrases repeated in themes. Songs are very long (up to 30 min), vary at different breeding grounds throughout the world, and change from year to year at a breeding ground. Only males sing while solitary and all sing the same song during each season in the same breeding ground. While males rarely sing outside of the breeding season, the song remains relatively constant from the end of one breeding season to the start of the next. The song could advertise each male's fitness as a mate and control male spacing when advertising to females. For whatever specific purpose, humpback songs represent an evolved signal used by males to communicate information about their internal (e.g., reproductive condition or fitness) and external (e.g., location, proximity) state to conspecifics, likely both females and other males.

2. *Odontocete cetaceans* Odontocete sounds can be divided broadly into two signal types: pulsed and narrow-band tonal sounds. Some pulsed sounds (clicks) are implicated in echolocation and can be of broad spectral composition as in the bottlenose dolphin, or of narrow-band composition as in the narwhal (Thomas *et al.*, 2004). Other burst-pulsed sounds, described in the literature as barks, squawks, squeaks, blats, buzzes, and moans, have social functions. Narrow-band tonal sounds are continuous signals called whistles. Limitations in audio equipment led to the suggestion that whistles, or frequency-modulated (FM) pure tones, were limited to the human mid-to-upper sonic range of frequency (5–15 kHz), and were of 0.5–2.0 sec in duration. Improvements in technology yielding a more complete bandwidth for recording dolphin sounds indicate that dolphins produce FM pure tones across a broad-frequency range, from 5 kHz to at least 85 kHz. Other FM tonal sounds include screams and chirps.

Research on sound communication in bottlenose dolphins and other delphinids has centered on whistle sounds for pragmatic reasons. The sonic range of whistles is recorded and analyzed easily. Also, whistles are produced by the most common captive species, the bottlenose dolphin, and appear to have no function other than communication. Because the number of non-whistling species, such as the harbor porpoise (*Phocoena phocoena*) and Commerson's dolphin (*Cephalorhynchus commersonii*), is relatively large, it is premature to regard whistles as the principal means for sound communication among odontocetes.

Stereotypical calls produced by members of a social group that vary among populations have been termed DIALECTS, and have been described in at least two species of odontocetes. In British Columbia, matrilineal groups of killer whales have repertoires of call types that are unique to each pod. Cultural transmission has been implicated in the development of orca dialects (Deecke *et al.*, 2000). In sperm whales (*Physeter macrocephalus*), codas are stereotyped sequences of 3–40 broad-band clicks usually lasting less than 3 sec in total (Watkins and Schevill, 1977). Rendell and Whitehead (2003) categorized these codas into six acoustic “clans” for populations in the South Pacific and the Caribbean. These vocal clans have ranges that span thousands of kilometers, are sympatric, and contain many thousands of whales. Like killer whale dialects, the codas produced by these clans may result from cultural transmission.

A. ODONTOCETE-PULSED SOUNDS All recorded toothed cetaceans produce pulsed underwater sounds. These sounds can be used for echolocation or communication (Herman, 1980; Au, 1993). They can be divided into two subclasses: pulse trains and burst-pulse sounds. Pulse trains, also called click trains, are sequences of acoustic pulses repeated over time. Individual pulses are about 50 μ sec, with varying peak frequencies of 5–150 kHz. The repetition rate of pulses within a click train can vary from 1–2 to several hundreds per second. Click trains are thought to function mainly for echolocation (Thomas *et al.*, 2004).

Burst-pulse sounds can be defined as high repetition rate pulse trains where the interpulse interval is less than 5 μ sec, which are similar in shape to echolocation pulses. Because of the high repetition rate in burst pulses, these sounds are not perceived as discrete sequences of sounds by the human ear, but are heard as a continuous sound. Their peak frequencies vary among species from 20 kHz in killer whales to above 100 kHz in Commerson’s dolphins. Burst-pulse sounds are proposed as functioning primarily for communication, and have been linked to the social interactions of some species (Herzing, 2004; Blomqvist *et al.*, 2005). The directional characteristics of many pulsed sounds, the relative ease with which they can be localized, their variability, and possibly the intensity with which they can be produced enhance their potential value as communication signals. Indeed, in situations described as alarm, fright, or distress, broad-band high-intensity squeaks have been heard from bottlenose dolphins and harbor porpoises. River dolphins in the family Platanistidae, some members of the family Delphinidae (i.e., killer whales, and Commerson’s dolphins), as well as Physteridae and Phocoenidae, which do not whistle, most likely communicate via pulsed sounds.

B. ODONTOCETE NARROW-BAND TONAL SOUNDS Narrow-band tonal sounds, i.e., whistles, are produced over a range of 5–20 kHz, are FM, and can last from milliseconds to a few seconds. These sounds sometimes have a rich harmonic content that extends into the ultrasonic range of frequencies up to 70–80 kHz for some dolphin species. Whistles vary greatly in contour from simple up-or-down sweeps to FM warbles to U-loops and inverted U-loops. Whistles often grade from one type to another. Whistles are thought to function only for communication, but are not produced by all odontocetes. In at least two odontocete species, false killer whales (*Pseudorca crassidens*) and belugas, whistle frequency shifts upward to avoid low-frequency ambient NOISE.

Of relatively low frequency, whistles travel longer distances in WATER than pulsed sounds. Although less directional than pulsed sounds, whistles probably are localized easily by cetaceans. Bottlenose dolphins and probably other whistling species can produce whistles and clicks simultaneously. Given these attributes, whistles provide a potential vehicle for maintaining acoustic communication and coordination during food search by echolocation. Also, whistles possess little overlap

with the major portion of the echolocation frequency spectrum, minimizing potential masking effects. If whistles have species, regional, or individual specificity, this would at least allow for the identification of schoolmates or familiar associates or aid in the assembly of dispersed animals and in the coordination, spacing, and movements of individuals in rapidly swimming, communally foraging herds.

Many different situations can elicit whistling. Whistling could appear as a simple phono-reaction in response to hearing another animal’s whistle. Mimicry of whistles or of artificial sounds has been documented in bottlenose dolphins by Peter Tyack (1986) and Louis Herman and colleagues (Richards *et al.*, 1984), and in belugas (Ramirez, 1999), revealing the plasticity of the sound production system (Kuczaj and Yeater, 2006). A correlation between whistling and feeding was noted among wild and captive delphinids; e.g., pods of false killer whales produce more whistles while feeding than during traveling. Dolphins accidentally captured in tuna seine nets whistle intensely. Captive bottlenose dolphins newly introduced into a tank or temporarily separated from a familiar pool mate whistle nearly continuously.

There have been several attempts to inventory the whistle repertoire of wild and captive delphinids. This is often difficult because the whistle contours are so variable. The size of a repertoire, including both whistles and pulsed sounds, is probably limited to fewer than 40 discrete types. However, it is possible that whistles are graded, rather than discrete signals. In a graded system, several basic types of signals transition to one another through a series of intermediate forms.

In 1965, the Caldwells presented the idea of SIGNATURE WHISTLES from observations indicating that each dolphin in a captive bottlenose group tended to produce whistles that were individually distinctive, stereotyped in certain acoustic features, and therefore called “signature” whistles. In the late 1980s and early 1990s, Tyack and colleagues proposed the hypothesis that dolphins use “signature whistles” to refer to each other and themselves (Caldwell *et al.*, 1990 in Leatherwood and Reeves, 1990; Tyack, 1986).

3. Pinnipedia Pinnipeds typically produce FM and pulsed sounds. Except for male walruses, pinnipeds do not whistle. The number of vocalizations produced by pinnipeds is correlated with their MATING SYSTEM and whether mating occurs under water or on land (Stirling and Thomas, 2003). Phocids tend to be more vocal under water, especially the true seals that mate under water. In general, otariids are much more vocal on land, often obtaining high densities that result in highly soniferous colonies. Polar pinnipeds are much more vocal under water than temperate or tropical pinnipeds. Early polar explorers reported hearing “eerie, ghost-like sounds from underneath the water.” Because of polar bear predation, Arctic pinnipeds are essentially silent while hauled out. In contrast, Antarctic pinnipeds are vocal when they haul out. Comparing the vocal repertoire size and MATING SYSTEM of three species of Antarctic phocids, Stirling and Thomas (2003) found distinctive differences. The Weddell seal congregates in colonies up to 100 mothers with pups, whereas males establish underwater territories beneath the fast ice that are vigorously patrolled and defended with an elaborate repertoire of 34 sounds. Mating in Weddell seals is polygamous; males mate with as many females as will enter their territory. Presumably, the 6-week period that males defend their underwater territory assists females, hauled out on the ice above, in mate selection. The polygynous, but solitary, leopard seal has an intermediate number of underwater vocalizations (9–12, depending on the region), apparently used to establish short-term underwater territories in the pack ice and attract females to mate. This large pinniped predator produces a surprisingly musical repertoire of sounds, but primarily during mating. This seal also

exhibits geographic variations in sounds around the Antarctic. The crabeater seal (*Lobodon carcinophaga*) is seasonally monogamous: a male hauls out on an ice floe with a female, guards her and her pup against attacks from predators, and then conveniently is available for mating when the pup weans. It is unlikely that this male is the pup's father, and the pair bond is well established for the season. Consequently, this pinniped has a single monotonous call.

In all pinnipeds, mothers and pups exchange vocalizations that are important in pup recognition and reuniting the mother and pup after she returns from a foraging bout. Recognition of one's pup is especially important in some otariid mothers that go to sea to forage for up to 7 days before returning to nurse their pup. In many pinnipeds, the vocal repertoire of the mother and pup is unique and distinct from their sounds during other social activities or their underwater sounds. This repertoire occurs mostly while hauled out, but is also used by mothers coaxing their pups into the water or to haulout.

The majority of documented pinniped sounds are within the range of human hearing. Only one study on a captive leopard seal has examined ultrasonic frequencies, with underwater sounds up to 164kHz (Awbrey *et al.*, 2004). Some species are nearly silent, whereas others have large repertoires that vary by season, sex, age, and whether the animal is in the air or water. Pinniped calls have been described as grunts, rasps, rattles, growls, creaky doors, warbles, trills, chirps, chugs, clicks, and whistles. Clicks are produced, but experimental attempts to demonstrate echolocation have not been successful. These studies, however, were on California sea lions and harbor seals and some researchers suggest that ECHOLOCATION, if present in pinnipeds, would more likely occur in the polar pinnipeds, which live in ice-covered waters and total darkness during the polar winters (Thomas *et al.*, 2004).

Phocid calls are primarily between 100Hz and 15 kHz, with peak spectra less than 5kHz. Typical source levels of underwater sounds are 130dB re 1 μ Pa, but are as high as 193dB re 1 μ Pa in a territorial Weddell seal. Northern elephant seals (*Mirounga angustirostris*) are reported to produce infrasonic vibrations while vocalizing in air (Fig. 4).

One of the most elaborate repertoire of sounds is from the Weddell seal, which has a separate repertoire of sounds for communicating while hauled out, from its sounds for underwater contexts (Terhune *et al.*, 2001). At the Hutton Cliffs colony in the Antarctic, Weddell seals had 34 types of underwater sound, including trills, chugs, chirps, guttural glugs, and knocks. Eleven types of trills are used exclusively

by males for territorial advertisement and defense and could be used in a graded context to convey the degree of warning, i.e., shortest, quietest trills are just a reminder, but long, loud trills are an emphatic warning to an intruder. This species also uses prefixes and suffixes with main call types, seeming to warn or emphasize a message. The trills are as long as 75sec. The repertoire on the opposite sides of the Antarctic (Palmer Peninsula and near Davis Station) shows geographic variations, including some unique usage of "mirror-image" calls, i.e., an upsweep followed by the mirror-image, downsweep. Male pups as young as 2 months try to perfect the long, loud trills, using comical, voice-cracking sweeps reminiscent of adolescent humans.

Otariid airborne sounds range from 1 to 4kHz, with harmonics up to 6kHz. Barks in water are slightly louder than in air, and both center around 1.5kHz. Individual California sea lion sounds have unique variations suggesting signal components for identity. Odobenid sounds are low in frequency, 500Hz, with a peak of 2kHz. Under water, walrus have a unique bell-like sound, but also produce clicks and whistles. Recent studies indicate that territorial male walrus have their own distinctive sound patterns.

4. *Sirenia* Sounds of sirenians are low in amplitude and probably only propagate short distances. From field observations of mother-calf manatee pairs, it appears that vocalizations play a key role in keeping the mother and calf together. Some researchers even describe this vocal exchange as dueting, where the mother and calf exchange chirps (Reynolds and Odell, 1991). Another example of communication in manatees included a mother-calf pair on opposite sides of a flood control gate. For nearly 3h, the mother placed her head in the narrow opening and vocalized to the calf until the gate opened enough for the calf to swim through. Although most evidence is anecdotal, sirenians (at least manatees) seem to use sounds to communicate with conspecifics.

Dugongs are highly social, occurring in groups up to several hundred animals. Sound probably plays the most important role in communication. Vocalizations of dugongs are low frequency, ranging from 1 to 8kHz and seem to be especially important in maintaining the mother-calf bond. Studies in the clear waters of Shark Bay Australia suggest that dugong males establish territories to attract estrous females. Reynolds and Odell (1991) suggested that low-frequency vocalizations play a role in mate attraction in dugongs.

Manatee and dugong sounds are described as chirps, whistles, squeals, barks, trills, squeaks, and frog-like calls. West Indian manatee (*Trichechus manatus* spp.) sounds range from 0.6 to 5.0kHz, whereas Amazonian manatees (*Trichechus inunguis*) produce sounds reaching 10kHz, with distress calls having harmonic structure up to 35kHz (Reynolds and Rommel, 1999). Manatee vocalizations appear to be stereotypical, with little variability between individuals and subspecies. Vocalizations consist primarily of short tonal harmonic complexes with small-frequency modulations at the beginning and end (Nowacek *et al.*, 2003). Nonetheless, there is evidence that variation in Amazonian manatee vocalizations could allow for individual recognition (Sousa-Lima *et al.*, 2002). Dugongs produce calls between 0.5 and 18.0kHz with maximum energy between 1 and 8kHz (Reynolds and Rommel, 1999).

5. *Sea otter* In sea otters, social interactions, pup care, and mating occur at the water surface; still, little is known about sea otter vocal behavior. No underwater vocal sounds have been reported for sea otters. The inter-tidal zone is a noisy, churning environment that would not be a good environment for exchange of sounds and would make recording difficult. In addition, sea otters forage singly and probably do not need to communicate while foraging. Kenyon (1975)

Figure 4 Bull northern elephant seals (*Mirounga angustirostris*) competing for territory.

provided a detailed summary of sea otter sounds heard in air. He described their sounds as (1) baby cry—a sharp, high-pitched “waah-waah” sound used by pups in distress situations or when wanting to attract mother’s attention; (2) scream—given by adults in distress or when a female has lost her young (it is an “ear-splitting” version of the pup cry detectable 0.5 miles away in the wild); (3) whistle or whine (“whee-whee”)—a high-pitched sound resembling a human whistle (denotes frustration or mild distress, given by captive sea otters when feeding is delayed, detectable 200 m away in the wild); (4) coo (“ku-ku-ku”)—produced by females before and after mating or while eating a “particularly pleasing food,” detectable only 34 m away; (5) snarl or growl—originating deep in the throat produced by a newly captured sea otter, audible only a few meters away; (6) hiss—short, explosive cat-like hiss used in startle situations; (7) grunt—soft groaning sound produced while eating; (8) bark—a staccato bark trailing off into a whistle, indicative of frustration produced by a young male; and (9) cough, sneeze, and yawn as in other mammals. A subsequent study by McShane *et al.* (1995) confirmed many of these vocal categories, and indicated that sea otters use a variety of graded signals that likely enhance the ability to share detailed and highly variable information between known individuals. Furthermore, the structural characteristics of the calls could easily allow for individual recognition.

6. *Polar bear* Polar bears have a variety of sounds used in different contexts. Growls serve as a warning to other bears and defense of a food source. Hissing, snorting, loud roars, and groans or grunts are aggressive sounds. Chuffing was documented as a response to stress, whereas mother polar bears will produce soft chuff sounds or low growls when scolding cubs (Ovsyanikov, 1996).

VI. Conclusions

Animals live in an ever-changing world. Reactions and responses to environmental and social variables must be flexible and adaptive for survival and reproduction. Examination of signaling behavior and subsequent receiver responses provides a window into nonhuman minds, as well as to the social complexity of other species. It can be assumed that evolutionary processes are at work on signals to keep them informative and useful to individuals. Ecological factors, coupled with social relationships and interactions, provide the principal force in the evolution of communication systems (Hauser, 1997). Foraging, mating, and parental strategies are examples of components that influence signaling behavior. In marine mammals, coastal or oceanic species living in relatively clear water may be more likely to use visual signals (e.g., postures, coloration patterns) than species inhabiting riverine or turbid environments. Similarly, amphibious species require a suite of signals useful both in air and under water. Differential communication is also evidenced in the foraging methods of several delphinid species. Communal foragers have more complex signals compared with more solitary hunters. Frequent interactions with conspecifics necessitate a higher rate of information exchange than for solitary species. Observing and examining the social and ecological differences among individuals and groups will help elucidate the mechanisms underlying the use and evolution of different signals to exchange information among individuals, i.e., to communicate.

Competition with Fisheries

ÉVA E. PLAGÁNYI AND DOUGLAS S. BUTTERWORTH

I. Introduction

From an ecological perspective, competition is a situation where the simultaneous presence of the two competitors is mutually disadvantageous. This review focuses on biological interactions (also known as trophic interactions), and specifically the competition for food and fishery resources between marine mammals

and fisheries, in contrast to operational interactions in which marine mammals damage or become entangled in fishing gear with negative consequences for both the fishery and the animals (Northridge, 1991, for a review).

Interactions due to bycatches in fisheries constitute one of the major threats to marine mammals (see Fisheries, interference with). These two forms of conflict are sometimes difficult to separate because e.g., animals may damage fishing gear in the process of removing fish therefrom. A third important marine mammal–fishery interaction concerns anisakid nematodes whose larvae use commercial fish and squid for transmission to marine mammals (see Parasites), but this is not of direct relevance to the current topic.

Competitive interactions between marine mammal populations and fisheries can either be “direct” or “indirect.” In the former case, the two groups share a common prey species whereas in the latter case, e.g., a marine mammal may prey on a species that is also an important component of the diet of a commercial fish species.

Perceived conflicts between marine mammals and humans in pursuit of common sources of food have come increasingly to the fore in recent years. Escalating pressures on shared resources are expected in the future because of both the increasing marine mammal populations and an increasing human population. Reductions in directed takes in response to recognition that several populations of marine mammals were heavily over-exploited in the nineteenth and earlier part of the twentieth century, as well as a widespread change in people’s perceptions of whether marine mammals should still be regarded as renewable resources available for harvest, have meant that several marine mammal populations are currently on the increase, sometimes by as much as 5–10% per annum (Bowen et al., 2006). From the human population perspective, the Food and Agriculture Organization of the United Nations (FAO, 2006) has estimated that over 2.6 billion people worldwide currently rely on fish and shellfish for more than 20% of their animal protein. Marine capture fisheries seem unlikely to much exceed the present global level, so that ability to meet the demands from an increasing human population will be heavily dependent on a continuation of the recent rapid increase in aquaculture production.

Commercial fisheries and marine mammals frequently target the same fish species, so that faced with possible shortages in marine food production in the future, it is likely that the possible impacts of growing marine mammal populations on the sustainable harvest of commercial fisheries will be vigorously questioned. Concerns about the consequences for fisheries of an increasing marine mammal population have already been expressed in southern Africa, e.g., where in 1990, Cape fur seals (*Arctocephalus pusillus pusillus*) were estimated to consume some 2 million tons of food a year. Considering that this amount was about the same as the annual human catch of fish in the region, and that the fur seal population was anticipated to increase further, the reasons for concerns and potential for conflict are obvious. A second example concerns the Pacific Ocean, where marine mammals are estimated to consume about 150 million tons of food per annum, which is some 3 times the current annual fish harvest by humans.

This chapter first presents a brief summary of some specific examples which address the question of whether marine mammal populations have negatively impacted the potential yields from fisheries through competition. Examples of perceived competitive interactions are included because the evidence is generally inconclusive. Secondly, some examples pertinent to the reverse—whether fisheries negatively impact marine mammals—are summarized.

II. Detrimental Effects of Marine Mammals on Fisheries

A. Pinnipeds (Seals, Sea Lions and Walruses)

In the early 1990s, catastrophic collapses occurred in the cod (*Gadus morhua*) fisheries on the East coast of Canada. Although several hypotheses have been posited to explain this, the most likely cause was overfishing. Harp seal (*Pagophilus groenlandicus*) populations off Newfoundland and Labrador increased at an estimated rate of 5% per annum over the 1980s and 1990s and are known to consume a substantial tonnage of juvenile cod. The socio-economic implications of the collapse of the cod fishery were huge, with some 40,000 fishers rendered out of work, and there is an obvious temptation to argue a causal relationship between the failure of the cod population to recover as rapidly as expected after its protection and the increase in harp seal abundance. Although the results of at least one ecosystem modeling study support the hypothesis that the recovery of these cod populations is being retarded to some extent by the increased abundance of harp seals, ecosystem models generally have poor predictive reliability, largely because of data limitations.

Demonstrating that either a fishery or a marine mammal will be adversely affected as a result of an increase in the removals by one party of a limited resource is not simple. Inferences based on assumptions of a linear relationship between predator and prey abundance are often incorrect because of the complex nonlinear interactions in an ecosystem. For example, off the west coast of South Africa, seals consume almost as much hake as is taken by the commercial fishery (Fig. 1). However, the commercially valuable hake consists of two species, a shallow-water (*Merluccius capensis*) and a deep-water species (*M. paradoxus*), with the larger of the shallow-water species eating the smaller individuals of the deep-water species. The results of multispecies models suggest that the net effect of a seal cull would be less hake overall because fewer seals would mean more shallow-water hake, and hence more predation on small deep-water hake (Punt and Butterworth, 1995). This study highlights the complexity of predation,

food-fish and fishery interactions and hence the difficulties of demonstrating conclusively that marine mammals are in direct competition with humans for food fish, as may superficially appear to be the case.

B. Whales

Numerous multispecies modeling studies have been employed to investigate the direct and indirect effects of common minke whales (*Balaenoptera acutorostrata*) on cod, herring (*Clupea harengus*), and capelin (*Mallotus villosus*) fisheries in the Greater Barents Sea. Minke whales are abundant in this region and prey on all three species, prompting the question of whether or not fishermen could expect greater catches if the populations of these marine mammals were reduced. The indications of these studies are that there is competition between the whales and the fishers in this region, and that the fisheries are likely to respond linearly to changes in whale abundance. The studies estimate that each minke whale reduces the potential annual catches of both cod and herring by some 5 metric tonnes. Similarly, studies off Iceland suggest that the piscivorous minke, humpback (*Megaptera novaeangliae*), and fin (*B. physalus*) whales may be having a considerable impact on the region's cod stock. The cod fishery is of key importance to the Icelandic economy, and the rebuilding of the cod population and catches are recognized as an important economic consideration. It is therefore not surprising that arguments have been put forward that there is a need to reduce whale populations to permit commercial fisheries to increase.

Marine mammals are thought to exert relatively minor influences on systems such as the North Sea and Baltic Sea, whereas they have been identified as potentially serious competitors off, e.g., the northeastern USA, a region that includes important fishery areas such as the Gulf of Maine and Georges Bank. The latter region exemplifies the conflicts that can arise between fishery management plans tasked with rebuilding prey populations and prescriptions, by the USA Marine Mammal Protection Act in this case, to facilitate an increase in the abundance of marine mammal predators.

Figure 1 Schematic showing the complexities of predation, food-fish and fishery interactions as summarized in a minimal realistic model of Cape fur seals and Cape hake interactions off South Africa. Reproduced with permission from Punt (1994).

C. Small Cetaceans

In many areas of the world, coastal fishermen consider dolphins as serious competitors, although retaliation by the fishermen usually has only minor effects on the populations or on their perceived damage. Common dolphins (*Delphinus delphis*) in the Mediterranean have often been perceived as a threat to the purse-seine and trawl fisheries operating in these waters, and as a result have been deliberately caught in direct retaliation. Declines in this population have been attributed to both direct and incidental catches by the fishery.

The largest hunt designed to reduce the perceived level of competition with fisheries took place in the Black Sea from 1870. In the mid-1900s, tens of thousands of dolphins and porpoises were killed every year as a result of fishing industry claims of competition. Other examples of cetacean kills due to perceived competition include the bombing of belugas (*Delphinapterus leucas*) from the air by the Quebec government in the 1920s and 1930s, the commissioning by the Icelandic government in 1956 of a US naval vessel to kill killer whales (*Orcinus orca*), and the use of explosives and firearms by Alaskan fishers in the mid-1980s to eliminate local killer whales.

D. Sea Otters

Sea otters prey on a variety of marine invertebrates such as urchins and abalone. Off southern California, southern sea otters (*Enhydra lutris nereis*) have been labeled by some as responsible for the decline of the abalone (*Haliotis* spp.) fishery, but there is little direct evidence to support this notion. The commercial abalone fishery in California was closed in late 1997, and factors such as commercial fishing, poaching, disease, and changing environmental conditions are all thought to have contributed to the decline of these commercially valuable shellfishes. Although the southern sea otter population is listed as federally threatened, southward movements of otters increased the overlap between otter fishing grounds and abalone fishing areas, and several conflicts exist with commercial and recreational abalone fisheries. Southern sea otters in some areas likely exert a greater impact on red abalone (*H. rufescens*) populations than human harvests.

III. Detrimental Effects of Fisheries on Marine Mammal Populations

A. Pinnipeds

The western Alaska population of Steller sea lions (*Eumetopias jubatus*) declined by 75% between 1976 and 1990, with subsequent continuing declines of the western stock resulting in its listing in 1997 as an endangered species under the US Endangered Species Act. Several groups have argued that this decline is due in part to the large fishery harvest of walleye pollock (*Theragra chalcogramme*), simultaneously a key source of food for sea lions and the most important US commercial fishery. There is considerable evidence to suggest that nutritional stress played a role in reducing both the recruitment and the reproductive rates of Steller sea lions (DeMaster and Atkinson, 2002). Measures to reduce the perceived competition between sea lions and fisheries for ground fish stocks include the establishment of “buffer” (no-trawl) areas to include important locations where the sea lions breed, feed, and rest, as well as specifying a pollock harvest which is more evenly distributed over the remaining areas and spread throughout the year. However, the results of modeling studies indicate that the observed sea lion population decline cannot be explained solely through trophic interactions, and rather is more likely linked to inadequate recruitment and shifts in environmental conditions which lead to changes in the favored complex of species

(DeMaster and Atkinson, 2002; Cornick *et al.*, 2006; Fay and Punt, 2006). Moreover, studies such as Trites *et al.* (1999) highlight the difficulties of predicting the direction and magnitude of a change in an ecosystem arising from a reduction in predation or fishing pressure. They posit that, paradoxically, Steller sea lion and northern fur seal (*Callorhinus ursinus*) populations might realize greater benefits if adult pollock and large flatfish were more heavily fished. This competitive release effect may result because, e.g., pollock are cannibalistic and hence decreased adult pollock abundance as a result of heavier fishing may result in increased numbers of juvenile pollock available to marine mammals.

B. Whales

Competition effects are difficult to quantify, but it has been proposed by Whitehead and Carscadden (1985) that the collapse of the eastern Canadian capelin fishery in the 1970s had a negative effect on fin whales. They suggest that a shortage of capelin might have allowed humpback whales to out-compete fin whales because the latter rely principally on capelin as a prey source.

If competitive predation between a marine mammal and fishery occurs, it implies that the marine mammal population is limited by food availability and hence it should be possible to demonstrate a response of some vital population parameters to a change in food availability. Past probable population increases of several krill-eating marine mammals, such as minke whales, crabeater seals, and fur seals, have been attributed by some investigators to a likely large increase in the availability of krill (*Euphausia superba*) in Antarctic waters (Mori and Butterworth, 2006). Following the substantial reduction through overexploitation of large whale populations during the early twentieth century, some 50–150 million tons of “surplus” krill is argued to have become available annually to other predators. This “krill surplus” hypothesis (Laws, 1977) is yet to be universally accepted, and questions remain concerning potential corroborative evidence, e.g., whether trends in the mean age at maturity of minke whales and crabeater seals (*Lobodon carcinophaga*) are fully consistent with the changes in food availability that the hypothesis suggests.

Trites *et al.* (1999) suggested that marine mammal populations can be quickly reduced through reductions in prey abundance but show a generally slow recovery when abundant food becomes available.

C. Small Cetaceans

Dolphin populations that have restricted or localized coastal distributions may be particularly susceptible to competition with fishers for limited food resources. Prey depletion is considered of primary or secondary importance in causing habitat degradation and loss of at least four small cetacean species in the Mediterranean and Black Seas (Notarbartolo di Sciara *et al.*, 2002). Prey depletion is the most likely proximate cause of declines in short-beaked common dolphins in the Mediterranean, with observed malnutrition in other marine mammals, such as bottlenose dolphins, also being attributed to overfishing of their prey stocks and intensive trawling (Bearzi *et al.*, 2003). Reduced prey availability due to fishing may also play a more indirect role in compromising animal health, which is suggested to have led to the large die-off of Mediterranean striped dolphins in 1990–1992 (Aguilar, 2000). As stocks of some preferred fished species, such as sardines and anchovies in the Mediterranean, are depleted, there is a concern that fishing will refocus on other small pelagic fish that are simultaneously the prey of common dolphins and important in meeting the growing demands of the aquaculture industry (Bearzi *et al.*, 2003).

D. Sea Otters

Recent declines—in excess of 50% since the mid-1980s—in northern sea otter (*Enhydra lutris kenyoni*) populations in Alaska have recently led to its listing as “Threatened.” Although the reasons for this decline are still subject to considerable debate, one hypothesis suggests the declines are indirectly linked to competition with fisheries (Doroff *et al.*, 2003). As discussed above, fishing is argued to be one of the factors contributing to the decline of pinniped populations (harbor seals *Phoca vitulina* and Steller sea lions) in some of Alaska’s Aleutian Islands. Killer whales preferentially feed on pinnipeds in this region, but as a result of the decline in pinnipeds, they have switched to sea otters as prey. Estes *et al.* (1998) argued that reduced populations of fish prey responsible for providing high caloric and nutritive value to pinnipeds, may impact not only directly on pinniped populations but also indirectly on killer whale and sea otter populations.

E. Sirenians (Dugongs and Manatees)

Although direct kills and incidental capture in fishery gear are problems, these mammals feed mostly on vascular aquatic plants so that there is no direct competition with humans for a shared food resource.

IV. Assessing the Competitive Effects

Commercial fishermen in many parts of the world perceive marine mammals as serious competitors for a scarce resource, whereas others argue that marine mammals are being used simply as scapegoats for failed fisheries management policies. Scientific evidence is therefore increasingly being sought to settle these disputes, but it is becoming increasingly appreciated that the scientific methodologies required to address them are complex, time consuming, data hungry, and beset with difficulties.

Initial attempts to quantify the impact of consumption by marine mammals on fish catches used a simple approach. They took account of the fact that, particularly for pinnipeds, the sizes of fish eaten tend to be smaller than are taken by commercial fisheries (Beddington *et al.*, 1985). Thus 1 ton of a commercially desired fish species eaten by seals say, does not translate exactly into 1 ton less in the allowable catch for fishers. This is because although a fish eaten by a seal would have grown larger by the time it became vulnerable to fishing, it might also have died before reaching the size as a result of other sources of natural mortality.

It is now acknowledged that such computations, which essentially treated marine mammals as the equivalent of another fishing fleet, are likely to be inadequate because of oversimplification. There are three complicating factors which need to be addressed in performing more realistic computations, while still accepting that both data and computing power limitations necessarily restrict the degree of complexity that is viable to incorporate in multispecies models. The first concerns how many of the large number of interacting species in any ecosystem need to be considered. Secondly, do age-structure effects need to be taken into account? One instance where this can become important is when one species that predated on the small juveniles of a second, finds itself the prey of the larger adults of that same species. For example, whiting *Merlangius merlangus* feeds extensively on the youngest (0+ and 1+) age classes of the commercially valuable cod, in turn an important predator on the smaller individuals of whiting. Finally, the customary modeling assumption that species interactions occur homogeneously over space may well be sufficiently

flawed to invalidate results. Moreover, the distribution of seal breeding and resting sites does not necessarily reflect their feeding distributions. Modern animal tagging technology has demonstrated, e.g., that gray seals (*Halichoerus grypus*) and southern elephant seals (*Mirounga leonina*) may travel hundreds of kilometers to a preferred feeding site.

However, with the development of several recent models (Koen-Alonso and Yodzis, 2005; Boyd *et al.*, 2006) as well as generalized multispecies modeling tools such as Ecosim and Ecospace (Walters *et al.*, 1997), groundwork is being laid to provide a more reliable basis for scientific evaluation of these competitive effects (Plagányi, 2007, for a review).

V. Considering the Influence of Fish and Krill Harvesting on the Ecosystem

The adoption of the Convention for the Conservation of Antarctic Marine Living Resources (CCAMLR) was a watershed in international fishing agreements in that it was the first to acknowledge the importance of maintaining the ecological relationships between harvested, dependent, and related populations of marine resources. Krill is the primary food source of a number of marine mammal species, and concern has been expressed that the rapidly expanding krill fishery might negatively impact or retard the recovery of previously over-exploited populations such as the large baleen whales of the Southern Hemisphere. Thomson *et al.* (2000) calculated, within a modeling procedure, the level of krill fishing intensity that would reduce krill availability, and hence the population of a predator to a particular level. Moreover, research is currently in progress regarding the subdivision of the precautionary catch limit for krill among 15 small-scale management units (SSMUs) in the Scotia Sea, to reduce the potential impact of fishing on land-breeding predators.

In general, initiatives such as these pursued under CCAMLR recognize the need to balance the needs of predators with the socio-economic pressures underlying fishery harvests and represent a realistic step forward in resolving some of the management quandaries resulting from competition for limited marine resources.

VI. Food Web Competition

Trites *et al.* (1997) and Kaschner *et al.* (2001) assessed the competition between fisheries and marine mammals for prey and primary production in the Pacific and North Atlantic Oceans respectively, concluding that marine mammals in these areas collectively consume about 3 times as much food as humans harvest. Kaschner (2004) presented similar arguments based on a global analysis of catch and food consumption by marine mammals and fisheries. In the Northern Hemisphere, the greatest overlaps occur with pinnipeds and dolphins and porpoises, whereas in the Southern Hemisphere overlaps between baleen whales and large toothed whales are the most substantial. The dietary overlap between the prey items of marine mammals and fisheries is however less than the foregoing might seem to suggest, because specialized feeding habits mean, e.g., that some of the targeted prey are either unfit for human consumption or are not currently viable for commercial harvest.

Trites and others argue that whilst direct competition between fisheries and marine mammals for prey appears limited, indirect competition for primary production may be a cause for concern. Such so-called food web competition may occur if there is overlap between the trophic flows supporting the two groups (see Fig. 2). Evidence in support of food web competition between marine mammals and fisheries

Figure 2 Schematic example of indirect competition for food by marine mammals and fisheries. The representation shows how top predators, such as marine mammals, may be affected by fisheries because of limits on the primary productivity available to support the two groups. Thus even though the mammals' prey and species taken by fisheries may not overlap, so-called food web competition occurs at the base of the food pyramids. Reproduced with permission from Trites et al. (1997).

is provided by a negative correlation between estimates of primary production required to support fisheries catches and to support the number of marine mammals estimated in the different FAO Statistical Areas in the Pacific Ocean.

VII. Additional Indirect Interactions

There are a number of additional instances, as summarized in Plagányi and Butterworth (2005), where fishing has impacted (or is likely to directly impact) marine mammals by damaging critical habitats upon which they depend, by altering the structure of ecosystems or by otherwise altering marine mammal population dynamics and/or population parameters. For example, trawling may have important effects on the fish populations upon which both fisheries and marine mammals depend. Fisheries-generated habitat destruction may impact most heavily on species such as the gray whale *Eschrichtius robustus*, which feeds primarily on benthic organisms such as amphipods, and the walrus which feeds on molluscs and other bottom-dwelling invertebrates. Other destructive fishing practices such as the use of explosives or cyanide in coral areas may seriously damage the habitat, with consequent repercussions for fish and dependent marine mammal populations.

Noise pollution from fishing vessels has been implicated in affecting marine mammals negatively both by interfering with the sensitive echolocation systems of toothed cetaceans and thereby indirectly reducing their foraging efficiency and by routing marine mammals away from preferred feeding areas (Roussel, 2002).

Fishing changes the overall size distribution of fish, and such changes over time may either increase the competitive overlap between fishers and marine mammals or may prove positive for marine mammals with a preference for smaller fish. However, a shift to preying on smaller fish may have negative effects on the bioenergetics of some species.

Several cetacean and pinniped species are known to feed in association with trawlers, as the resulting disturbance may bring prey species higher in the water column where they are easier targets for marine mammals, or alternatively trawlers might beneficially concentrate food (Fertl and Leatherwood, 1997). Although discards associated with trawling provide ready forage for several species (including dolphins and seals), the advantages of opening new feeding niches for marine mammals are likely offset by other negative impacts of trawlers and alterations in marine mammal foraging strategies.

Fishing may play yet another indirect role in increasing the mortality rates of a marine mammal species by forcing animals to either increase their foraging time or to forage further afield in areas where they are

themselves at higher predation risk. However, some shark fisheries may have a positive indirect effect on marine mammals because of the associated reduced predation on (in particular young) animals.

VIII. Summary

Despite a persistent notion worldwide that there is a mass-for-mass equivalence in the prey of marine mammals and the yields available to fishers, the evidence points to much more complicated situations in which this is hardly likely to be the case. Furthermore, the complexity of ecosystems could well be such that the response to a marine mammal cull, e.g., could be highly diffused through the food web, involving many other species (Yodzis, 2000). In some cases, competition effects are reduced because, e.g., one of the putative competitors in fact reduces the abundance of a predatory fish species, in turn affecting the abundance of the target prey species. It is worth noting that although marine mammals are the most obvious scapegoat of fishers because of their visibility, there is typically greater competitive overlap in the feeding “niches” of fish predators and fishermen.

Because of the difficulties of providing definitive scientific advice on such questions, scientists often equivocate. It is currently virtually impossible to wholly substantiate claims that predation by marine mammals is adversely impacting a fishery or *vice versa*. In the absence of definitive answers, fisheries managers are increasingly applying the “Precautionary Principle,” which requires that “where there are threats of serious or irreversible damage, lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation.” But this has been argued both ways in this context: either that marine mammal culls should not take place in the absence of clear evidence that they will benefit fisheries or alternatively that marine mammals should be culled in the absence of clear evidence that their consumption of fish will not possibly damage fisheries.

As more and better information on marine mammal diets becomes increasingly available, one of the key uncertainties in resolving questions as to the degree of competitive overlap between marine mammals and fisheries relates to limited understanding at present of the feeding strategies of marine mammals. There is a need to quantify not only spatial and temporal variability in diet but also the conditions under which predators switch to alternative prey species as the abundances of the various species change. It is important also to bear in mind that some marine mammals which are highly specialized (or conversely, highly specialized fishers) are most vulnerable to competition effects because they cannot readily change their diet in response to overfishing of a vital food source.

Conservation Efforts

RANDALL R. REEVES

Efforts to conserve marine mammals began early in the twentieth century. The impetus for these efforts came from the recognition that populations of several highly valued species—fur seals and the sea otter (*Enhydra lutris*)—had been nearly extirpated by hunting. In most instances, self-regulation through market feedback had been the only thing that prevented extinctions.

In other words, as the animal populations were reduced by overkill, it became increasingly difficult to hunt them profitably, so the hunting effort declined. This mechanism was clearly inadequate to protect the stocks of whales because modern whaling was a multispecies enterprise. As right whales (*Balaenidae*, *Eubalaena* spp.) and blue whales (*Balaenoptera musculus*) became scarce, the fleets simply redirected their attention to humpback, fin, and sei whales (*Megaptera novaeangliae*, *Balaenoptera physalus*, and *B. borealis*, respectively), but any right or blue whale encountered would still be killed. By the late 1920s and 1930s, the whaling industry had begun to place limits on oil production and had given some protection to the depleted right whales and gray whales (*Eschrichtius robustus*). Eventually, international agreements emerged to manage the industry on terms more favorable to conservation. It was not until the 1970s, however, that the multispecies problem in commercial whaling had been addressed properly. In fact, few serious efforts to conserve marine mammals for reasons other than as a response to stock depletion or exhaustion were made until the late 1960s and early 1970s.

A discussion of marine mammal conservation can be organized in a number of ways—according to different types of threat (e.g., directed hunting, bycatch in fisheries, chemical pollution), on a species or population basis, by geographical region, or chronologically (Twiss and Reeves, 1999; Whitehead *et al.*, 2000; Evans and Raga, 2001; Reeves and Reijnders, 2002; Reynolds *et al.*, 2005). The first part of this chapter is organized according to levels of governance. Conservation efforts have been and should be made at many different levels, from global international agreements all the way “down” to actions by local communities and individual citizens. Therefore, some efforts to conserve marine mammals at the international, regional, national, and local levels are reviewed, and this is followed by a discussion of some of the principal threats and how they are being addressed. Next is a brief overview of the geography of marine mammal conservation, which considers regional differences in the seriousness of threats and in how they are being addressed. Finally, an attempt is made to identify the most threatened marine mammal species and populations.

I. What Is “Conservation”?

“Conservation” is defined here as the preservation of wild populations so that they continue to replicate themselves in a natural context for an indefinite, but long, time into the future (i.e., at least hundreds of generations). This means that not only the animals themselves, but also the environments (habitats and “ecosystems”) that sustain them and the biotic communities to which they belong, need to be preserved. Neither the maintenance of a few individuals in zoo-like conditions, nor the preservation of frozen DNA, constitutes a conservation endpoint. Either of those approaches, however, can be part of a broader effort to achieve conservation goals.

The unit of conservation has traditionally been the species, classically defined as a group of interbreeding natural populations that is isolated reproductively from other such groups. In practice, conservation biologists generally agree that it is insufficient to be concerned only with preserving species. They argue that it is also important to preserve the natural variety within species, including genetic and behavioral variants. One way of achieving this more ambitious objective is by ensuring the survival of local or geographical populations (“stocks”). There is a substantial and growing body of literature on the “stock” concept as it applies to marine mammals (Taylor, 2005).

The term “conservation” has a long history and is often cast in three different perspectives: biocentric, economic, and ecologic.

Biocentric conservation emphasizes the intrinsic value of all life forms and is rooted in religious or philosophical beliefs that place humans on the same plane as other organisms. Although the concept of “animal rights” shares similar roots, it differs from biocentric conservation in that it focuses on the importance of individuals rather than on populations or genomes. Concerns about animal welfare and humane treatment also focus on individuals and are not always central to conservation, as defined here. *Economic* conservation regards wild animal populations as resources to be used for human benefit. A central tenet is sustainability: killing or other forms of extractive, or consumptive, use are allowed and perhaps even encouraged, but only on the condition that such use does not compromise the ability of a wild population to regenerate itself. Finally, *ecologic* conservation places a premium on the maintenance of natural systems and processes. Individuals, populations, and species derive importance from their functional relationships with the communities of which they are a part.

The term “conservation” is sometimes used as though it were synonymous with “protection,” particularly in the anti-whaling/pro-whaling debate. As used here, conservation does not rule out killing or other forms of use as long as the central goal—population persistence—is assured. Other terms that have tended to replace “conservation” in many forums over the last quarter-decade are “sustainable development” and “sustainable use” (Lavigne, 2006), which assume (questionably) that (a) there is no inherent conflict or incompatibility between human wishes and wildlife needs, (b) wild organisms *must* be used if they are to be preserved, (c) scientific understanding is sufficient to define sustainability, and (d) mechanisms exist to ensure against “over-use.”

II. International Conservation Efforts

Organized conservation efforts at the international level are carried out mainly by intergovernmental organizations established by treaties or conventions (Table I). A few non-governmental organizations (NGOs) also operate on a global basis. Some, such as the International Union for the Conservation of Nature (IUCN, actually a combination of inter- and non-governmental), International Fund for Animal Welfare (IFAW), and World Wide Fund for Nature (WWF), address a wide range of environmental issues.

The scale of any particular effort depends on the geographical distribution of the organisms (or phenomena) being conserved or the threat being addressed. Relatively few international conservation instruments focus solely on marine mammals. The best known is the International Whaling Commission (IWC), established under the International Convention for the Regulation of Whaling (ICRW) signed in Washington, DC, in 1946 (Gambell, 1999). A global conservation body was clearly necessary to manage the exploitation of the great whales, customarily defined as the baleen whales (Fig. 1) plus the sperm whale (*Physeter macrocephalus*). Most of these animals migrate over long distances and have been hunted on a truly worldwide scale for centuries (Reeves and Smith, 2006).

The IWC’s authority as the body responsible for managing whaling worldwide has been challenged in recent years, and there is ongoing controversy about its scope and reach. Some member states (e.g., Japan, Denmark, and Russia) have traditionally insisted that “small cetaceans,” meaning all toothed species except the sperm whale and the “bottlenose” whales (defined in the IWC schedule as the northern and southern bottlenose whales, *Hyperoodon ampullatus* and *H. planifrons*, respectively, Arnoux’s beaked whale, *Berardius arnuxii*, and Baird’s beaked whale, *B. bairdii*), are not covered by the ICRW

and that their exploitation and conservation are national, or at most regional, concerns. This interpretation of the Commission’s competence ignores the fact that many populations of small cetaceans move seasonally across national borders or onto the high seas. It also fails to acknowledge the close biological relationships among the cetaceans, which mean that they face common threats (e.g., bycatch in fisheries, bioaccumulation of pollutants) and are similarly vulnerable to over-exploitation (Fig. 2). In the absence of IWC oversight, various bilateral and multilateral instruments have been developed to manage takes of small cetaceans (see Section III), and national programs of full protection or managed exploitation are typical (see Section IV).

Any international agreement is effective only if the parties ensure compliance and enforcement. Typically, sovereign states are unwilling to accede to a convention unless they are allowed to opt out of provisions with which they disagree. Under the ICRW, e.g., member countries have 90 days to consider their options before any amendment to the regulations comes into effect. Once an objection has been lodged, the measure is no longer binding on the objecting country. On this basis, Norway has continued commercial whaling for common minke whales (*Balaenoptera acutorostrata*) despite the IWC’s global moratorium established in 1986. Japan and Iceland have used another “loophole” to continue (or resume) whaling. The ICRW allows contracting governments to grant special permits to take whales for scientific research. Although the IWC’s scientific committee reviews and comments on permit proposals, its advice is non-binding. Japan has kept its commercial whaling industry viable by issuing permits to kill hundreds of common and southern minke whales (*B. bonaerensis*), plus a growing array of other species (Bryde’s [*B. edeni/brydei*], sei, fin, and sperm whales) each year, allegedly for research purposes (but see, Gales *et al.*, 2005).

The United Nations Convention on the Law of the Sea (UNCLOS) was ratified in 1982. Rather than strengthening efforts to conserve marine mammals, however, this framework convention has tended to provide states with a rationale for opting out of agreements such as the ICRW. Under the convention, the idea that countries have exclusive sovereign rights to manage resources within 200 nautical miles of their coastlines became firmly entrenched. This has been interpreted to mean that the hunting of coastal stocks of marine mammals should not be subject to international oversight and regulation. Also, although Article 65 calls for member states to “work through the appropriate international organizations” for the conservation, management, and study of cetaceans, it leaves governments with considerable latitude to interpret what that means. Canada, e.g., withdrew from the IWC in 1982, arguing that a bilateral commission with Greenland sufficed as an “appropriate international organization” to manage the hunting of belugas (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*) (see Section III) and that the obligation of “working through” an appropriate international body to manage the hunting of bowhead whales (*Balaena mysticetus*) could be discharged by occasionally sending experts and observers to IWC meetings.

The Antarctic, an important seasonal feeding ground for migratory whale populations and home to several endemic seal species, is a global commons. As such, it requires its own international regime of protection and conservation (Kimball, 1999). The Antarctic Treaty system consists of four separate instruments: the initial framework treaty signed in 1959 (entered into force in 1961), the seals convention of 1972, the marine ecosystem-oriented Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR) of 1980, and a 1988 convention on mineral resources. As a whole, this system is nearly comprehensive, particularly taking into account the overlapping responsibilities of the IWC and other instruments

TABLE I
Current International Conservation Conventions and Institutions

<i>Name of Entity</i>	<i>Year of Initiation</i>	<i>Location of Secretariat or HQ</i>	<i>Primary Mandate or Responsibility in Relation to Marine Mammals</i>	<i>Comments on Effectiveness</i>
International Convention for the Regulation of Whaling (ICRW); International Whaling Commission (IWC)	Signed 1946, entered into force 1948; IWC established 1951	Cambridge, UK	Conservation of whale stocks (officially concerned only with baleen whales, sperm and bottlenose whales)	Very strong scientific component; controversial but highly effective in 1970s–1980s; suffered loss of credibility and authority in 1990s.
Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES)	Signed 1973, entered into force 1975	Geneva, Switzerland	Regulation and monitoring of international trade in products from species and populations classified as threatened	Highly politicized and rancorous, but continued through 1990s to be largely effective.
International Union for the Conservation of Nature (IUCN)	Established 1948	Gland, Switzerland (with country offices)	Maintains Red List of Threatened Species, sponsors specialist groups (e.g., Cetacean, Seal, Sirenia, Polar Bear, Otter), provides advice to CITES and IWC	Specialist groups provide scientific expertise, promote and coordinate conservation research.
World Wide Fund for Nature (WWF)	Established as World Wildlife Fund in 1961	Gland, Switzerland (with many national affiliates)	Lobbies for conservation, supports conservation research, and participates in international conservation fora	Influences policies of IWC and CITES, many national affiliates conduct local or regional marine mammal research and conservation programs (e.g., Philippines, USA, Canada, Hong Kong, Malaysia).
TRAFFIC Network (trade monitoring program of IUCN and WWF)	1976	Cambridge, UK (with regional or national offices)	Monitoring international trade in wildlife, works in close cooperation with CITES Secretariat	Important role in documentation of trade, with emphasis on threatened species.
Convention on the Conservation of Migratory Species of Wild Animals (CMS; or Bonn Convention)	Signed 1979, entered into force 1983	Bonn, Germany	Conservation of “entire populations or any geographically separate part of the population of any species or lower taxon . . . , a significant proportion of whose members cyclically and predictably cross one or more national boundaries.”	HAS RECOGNIZED CETACEANS, BUT NOT PINNIPEDS OR SIRENIANS, AS HIGHLY MIGRATORY SPECIES; see Table 2 for relevant regional agreements.
Convention for the Conservation of Antarctic Seals	1972, entered into force 1978	None, but scientific advice is provided by Scientific Committee on Antarctic Research's Group of Specialists on Seals, based in Cambridge, UK	Conservation of Antarctic seals, regulation of sealing, facilitation of scientific research on seals	First international conservation agreement to be established <i>prior to</i> the initiation of exploitation.
Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR)	1980, entered into force 1982	Hobart, Tasmania, Australia	Facilitation of recovery of depleted whale stocks; prevention of further irreversible human-caused changes in Antarctic ecosystem	Krill monitoring program, ecosystem focus, strong scientific base.
United Nations General Assembly Drift-net Resolution 46/215	1991, took effect end of 1992	None	Elimination of large-scale (longer than 2.5km), high-seas drift net fishing (and thus elimination of the large associated bycatch of marine mammals)	More than 1000 vessels were withdrawn from this type of fishing, but drift netting continues inside national 200nmi Exclusive Economic Zones (and probably to some extent illegally in international waters).

(B)

Figure 1 (A) A fin whale (*Balaenoptera physalus*) is butchered at a whaling station in Iceland on July 11, 1988. (B) A young Icelander poses with baleen. Iceland used a scientific rationale to justify continued whaling operations for a few years after the International Whaling Commission's moratorium took effect in 1986. Later, in 1992, Iceland withdrew from the commission, only to rejoin in 2002. Along with Norway and Japan, Iceland has been a strong advocate of resumed commercial whaling and the reopening of international trade in whale products. Photographs by Steve Leatherwood.

such as the 1972 Convention on the Prevention of Marine Pollution by Dumping of Wastes and Other Matter (the London Dumping Convention) and the 1973–1978 Convention for the Prevention of Pollution from Ships (the MARPOL Convention). It should provide an adequate legal basis for protecting Antarctic marine mammal populations. What it cannot do is reverse the devastation of the southern stocks of baleen whales caused by the whaling industry. Nor can it protect the seal and whale populations from the ongoing (and worsening) effects of climate change (see Section VIII).

(A)

(B)

Figure 2 (A) Sri Lankans begin butchering a Risso's dolphin (*Grampus griseus*; in August 1985). A diverse array of dolphins and whales are killed in Sri Lanka, partly as a bycatch of net fisheries and partly by direct harpooning. Estimates of the total annual kill of small cetaceans in Sri Lanka during the 1980s were in the tens of thousands. (B) Harbor porpoise (*Phocoena phocoena*) skin and meat are sold, along with other local wildlife, for domestic consumption in West Greenland. The annual reported catch of harbor porpoises in Greenland averaged about 2300 between 2000 and 2005. Photographs by Steve Leatherwood.

The Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES) has been in force since 1975. Although CITES has little relevance when the products of exploitation are only for domestic consumption or when animals are captured alive and placed in institutions within the country of origin, it becomes highly relevant when the animals or their products or derivatives cross international borders. The economic stakes can be high, and this is certainly true of the trade in whale meat and blubber, which are in demand by Japan. Under CITES, species and geographical populations can be listed in one of three appendices. Appendix I species or populations are threatened with extinction, and trade in their products for primarily commercial purposes is prohibited. Those in Appendix II are not considered to be in immediate danger of extinction but may become so unless trade is strictly regulated. The third appendix includes species or populations that are subject to national regulation and for which multilateral cooperation is necessary to avoid over-exploitation. The goals of monitoring and regulation are achieved through a system of permits and certificates for export or import issued by national governmental authorities. As of 2007, when the 14th Meeting of the Conference of the Parties took place in The Hague, all of the commercially valuable baleen whales were listed in CITES Appendix I, as were some of the odontocetes, including the sperm whale. Also, a series of resolutions, consolidated in 1979 and calling for CITES member states to honor IWC restrictions on whaling by prohibiting the trade of whale products, remained in force even though it had been challenged forcefully by Japan and Norway. In addition to its role in the whaling arena, CITES has been used to limit the trade in live cetaceans for public display and research (Fisher and Reeves, 2005).

The United Nations ban on pelagic drift nets was a major conservation achievement. In the early 1990s, at least 40 million non-target fish, sharks, seabirds, marine mammals, and sea turtles were being killed annually by the Japanese drift net fishery for squid. Altogether, the high-seas squid drift net fisheries in the North Pacific were killing approximately 15,000–30,000 northern right whale dolphins (*Lissodelphis borealis*), 11,000 Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), and 6000 Dall's porpoises (*Phocoenoides dalli*) each year. Drift nets set for salmon, tuna, and billfish were taking thousands more dolphins, porpoises, whales, and pinnipeds each year. The threats to populations of pelagic cetaceans, pinnipeds, seabirds, and many other organisms from large-scale, high-seas drift nets were judged sufficiently severe and widespread to necessitate action by the United Nations. A resolution passed by the General Assembly in 1991 called on member nations to enact a moratorium on such drift netting by the end of 1992. This global ban was a valuable step and undoubtedly helped avert catastrophic declines in some marine animal populations. However, the UN decree could not affect the use of these nets inside the 200 nautical mile limit of coastal states. Consequently, pinnipeds and cetaceans continue to be killed in large numbers by drift nets deployed in coastal waters. Also, the global proliferation of pelagic long lining (at times as a replacement for drift netting) has brought new problems, including both depredation (when mammals damage or remove caught fish) and bycatch (when mammals are hooked or entangled in the gear) (Read, 2005).

III. Regional and Bilateral Conservation Efforts

In cases involving species or populations with well-defined distributions that cross several national boundaries, multilateral regional bodies have sometimes been established to monitor and manage exploitation (Table II). Included among these are some “international”

instruments that are in fact regional because their scope is defined by the limited geographical ranges of the animals involved. For example, membership in the Inter-American Tropical Tuna Commission (IATTC), which is involved in managing the incidental mortality of dolphins in purse seines, has been geographically diverse since it was created in 1949 under a treaty between the USA and Costa Rica. Only states with an interest in fishing for tuna in the eastern tropical Pacific Ocean have joined the commission, and over the years this has included France, Japan, Vanuatu, the USA, and Mexico in addition to a number of Central and South American countries. Thus, while the commission is international in the sense of having a geographically varied membership, its purview is distinctly regional. Similarly, the International Agreement on the Conservation of Polar Bears and their Habitat involves only the northern circumpolar countries where polar bears occur, and it is therefore treated here as a regional agreement.

The 1911 Treaty for the Preservation and Protection of Fur Seals (often referred to as the North Pacific Fur Seal Convention) involved four countries: Great Britain (signing on behalf of Canada), the USA, Russia, and Japan. This was essentially an agreement among the states involved in the exploitation of northern fur seals (*Callorhinus ursinus*), which are endemic to the North Pacific Ocean. Pelagic sealing was banned, and as part of the agreement, Japan and Canada were allocated a portion of the profits from the controlled killing (mainly of “surplus” male seals) on the Pribilof (USA) and Commander (Russia) islands. This treaty lapsed in 1941, when Japan withdrew, and was replaced in 1957 by the Interim Convention on the Conservation of North Pacific Fur Seals. The northern fur seal is frequently cited as a conservation success story. Elimination of pelagic sealing, in combination with regulations limiting the kill at breeding rookeries, allowed the seal population to make a strong recovery from its depleted state in the early 1900s. The population reached about 2 million in the 1950s but had dipped below a million by the early 1980s. Numbers in US waters stood at about three-quarters of a million in 2006. The 1957 interim convention, having lapsed in 1984, has not been replaced.

The polar bear (*Ursus maritimus*) treaty mentioned earlier is often cited as an example of an effective international agreement. Discussions among the range states—Canada, the USA, Denmark (on behalf of Greenland), Norway, and the Soviet Union (now Russia)—began in the mid-1960s, when the future of the polar bear was of great concern because of overhunting and habitat deterioration (Lyster, 1985). The three main objectives of the agreement, which was signed in 1973 and took effect in 1976, were to ensure that appropriate restrictions were placed on hunting, that polar bear habitat was preserved, and that needed research was conducted in a coordinated fashion. The Polar Bear Specialist Group of the IUCN Species Survival Commission has served as a *de facto* scientific committee, meeting every few years to share information, discuss research needs, and assess the state of polar bear conservation. At its 14th working meeting in 2005, the group concluded that the total population of wild polar bears was between about 20,000 and 25,000, more than half of them in Canada. It stressed the serious implications of climate change and pollution, the need for better regulation of hunting and ship traffic, and the importance of identifying and protecting critical habitat.

The multinational hunt for harp and hooded seals (*Pagophilus groenlandicus* and *Cystophora cristata*, respectively) in the northern North Atlantic proceeded without meaningful regulation until the late 1950s, when Norway and the Soviet Union established a bilateral commission to set quotas for commercial catches of harp and hooded seals as well as walrus (*Odobenus rosmarus*) in the northeastern Atlantic. The reach of this agreement has been interpreted to include large areas of the Greenland and Barents seas, Denmark Strait, and waters

TABLE II
Regional or Bilateral Conservation Agreements Currently in Effect

Name of Entity	Year of Initiation	Location of Secretariat or HQ	Mandate or Objectives	Comments on Effectiveness
Inter-American Tropical Tuna Commission (IATTC)	1949	La Jolla, California	Initially to document and manage tropical tuna fisheries; since then, expanded to include documentation, mitigation, and regulation of dolphin mortality incidental to fishing operations in eastern tropical Pacific	Operates programs to: place observers aboard tuna vessels, reduce dolphin mortality through diagnosis and solution of gear problems, and training for captains and crews; provides mechanism for linking tuna industry with government agencies and environmental NGOs.
North Atlantic Marine Mammal Commission (NAMMCO)	1992	Tromsø, Norway	Sustainable use and management of marine mammals in the North Atlantic Ocean	Emphasis on ecological interactions (e.g., rationales for culling marine mammals to protect fish stocks), hunting rights of coastal communities, forum for scientific information exchange.
Canada/Greenland Joint Commission on Narwhal and Beluga	1989	None (Ottawa, Canada; Nuuk, Greenland)	Cooperative research and management related to "shared" stocks of narwhals and white whales	Forum for bilateral studies and sharing of information, with management measures left to national authorities and local "co-management" bodies.
Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas (ASCOBANS)	Signed 1991 (concluded under CMS, the Bonn Convention — see Table 1), entered into force 1994	Bonn, Germany	Cooperation to achieve and maintain a "favourable conservation status" for small cetaceans in the region	Most effort has been directed at estimating abundance and incidental takes of harbor porpoises and dolphins and at seeking ways to reduce bycatch.
Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and Contiguous Atlantic Area (ACCOBAMS)	1996 (concluded under CMS, the Bonn Convention — see Table 1), entered into force 2001	Monaco	Cooperation to achieve and maintain a "favourable conservation status" for cetaceans in the region, including the complete prohibition of deliberate taking and establishment of a network of "specially protected areas to conserve cetaceans"	Differs from ASCOBANS in that scope includes all cetaceans, not only "small" species; focuses on bycatch, disturbance and injury by recreational and industrial vessel traffic, prey depletion; planning basin-wide population surveys.
International Agreement on the Conservation of Polar Bears and their Habitat	Signed 1973, entered into force 1976	None; follows rotating chairmanship of IUCN Polar Bear Specialist Group	To prevent polar bear populations from becoming endangered because of hunting or other human activities	Provides a framework for communication and cooperation among circumpolar countries, emphasis on research and monitoring; signatory states are supposed to "enact and enforce such legislation and other measures as may be necessary to give effect to the Agreement."
U.S.-Russia Agreement on Cooperation in the Field of Environmental Protection	1972	None (Washington and Moscow)	Marine Mammal Project, under Area V of the Agreement, provides for information exchange, coordination of research activities, and joint or cooperative research	Annual scientific meetings, formerly focused on Bering and Chukchi seas regions, now also considers, e.g., Caspian seals, bycatch in Japanese salmon drift nets operating within Russian EEZ.

near the island of Jan Mayen. A similar bilateral agreement pertaining to the northwestern Atlantic was signed by Canada and Norway in 1971. A series of regional bodies have become involved in monitoring the North Atlantic seal hunt and assessing the harp and hooded seal populations to provide management advice. Starting in the 1960s, a

Sealing Panel of the International Commission for Northwest Atlantic Fisheries (later the Northwest Atlantic Fisheries Organization, or NAFO) recommended overall quotas and other conservation measures (e.g., opening and closing dates for sealing from ships) related to hunting of the western populations. In recent years, scientific advice

on harp and hooded seal stocks has come from a working group convened jointly by the International Council for the Exploration of the Sea (ICES) and NAFO. This group's advice is presented to the North Atlantic Marine Mammal Commission (NAMMCO), which in turn offers management advice to its members. Canada decides unilaterally on sealing quotas in the western North Atlantic, whereas Norway and Russia continue to allocate quotas in the West Ice (Jan Mayen) and East Ice (White Sea) on a bilateral basis.

NAMMCO is a regional body established in 1992 by several countries that had become frustrated by the IWC's unwillingness to allow the resumption of commercial whaling. Its membership consists only of Iceland, Norway, Greenland, and the Faroe Islands, the latter two belonging to the Kingdom of Denmark but with "home rule" governments. NAMMCO has devoted much of its attention to species for which there is little or no direct conflict with the IWC, notably harp and hooded seals, ringed seals (*Pusa hispida*), gray seals (*Halichoerus grypus*), walrus, long-finned pilot whales (*Globicephala melas*), and northern bottlenose whales.

An international treaty, the Convention on the Conservation of Migratory Species of Wild Animals (or Bonn Convention), provides a mechanism for developing regional conservation agreements. Three that deal explicitly with cetaceans have been concluded thus far. The Agreement on the Conservation of Small Cetaceans in the Baltic and North Seas (ASCOBANS) entered into force in 1994, with a membership that initially included Belgium, Denmark, Germany, the Netherlands, Poland, Sweden, and the UK (Finland, France, and Lithuania have joined since then). A major achievement has been the instigation, planning, and completion of two large-scale abundance surveys of cetaceans throughout the Baltic and North Seas, one of them (in 2005) extending westward to include a large area of the contiguous northeastern Atlantic. A second CMS-generated instrument, the Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and Contiguous Atlantic Area (ACCOBAMS), was concluded in 1996 and entered into force in 2001. Both of those agreements have tried to address a wide range of issues, including incidental mortality in fisheries, chemical pollution, and underwater noise. The development, and especially the implementation, of conservation plans for populations of special concern (e.g., harbor porpoises, *Phocoena phocoena*, in the Baltic; short-beaked common dolphins, *Delphinus delphis*, in the Mediterranean; Fig. 3) has been a major challenge. The third agreement is a memorandum of understanding for the Conservation of Cetaceans and their Habitats in the Pacific Islands Region. It was opened for signatures in 2006 and the first meeting was held in early 2007. As is true of most multilateral instruments, these ultimately depend on the willingness of sovereign state parties to enact and enforce any proposed measures.

Canada and Greenland have a bilateral agreement to manage the hunting of transboundary stocks of white whales and narwhals. In 1989, the two governments signed a memorandum of understanding that recognized the importance of hunting to the Inuit and called for "the rational management, conservation and optimum utilization of living resources of the sea" as reflected in the UNCLOS (see section II). The Joint Commission on Conservation and Management of Narwhal and Beluga meets annually, as does its Scientific Working Group. In addition to management advice directed at government agencies and, in Canada, the Nunavut Wildlife Management Board (a "co-management" body established under an aboriginal land-claims agreement), the commission's Scientific Working Group plans and undertakes collaborative research on narwhals and belugas.

Figure 3 Short-beaked common dolphins (*Delphinus delphis*) in Kalamos, western Greece, where they were plentiful as recently as the mid-1990s but are now rarely seen. The Mediterranean population of common dolphins is officially listed by IUCN as endangered. A conservation plan commissioned by UNEP's Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and Contiguous Atlantic Area has been available since 2004, but no significant implementation of measures outlined in the plan has occurred. IV. National Conservation Efforts

In the USA, the Marine Mammal Protection Act was passed by Congress in 1972, and it has been the cornerstone of a massive domestic commitment to conservation (Baur *et al.*, 1999). Although the MMPA is not the only such law in the world (many countries confer full legal protection to marine mammals), it is undoubtedly the most sweeping of its kind. At the time of the act's passage, a preeminent concern was the annual slaughter of more than 100,000 young harp and hooded seals on the spring pack ice off Newfoundland and in the Gulf of St. Lawrence. Public outrage at film footage of seal pups being clubbed to death was probably the most influential single factor in forcing Congress to pass legislation. In addition, however, there was growing concern about the deplorable condition of the world's stocks of large whales, especially the blue whale. Moreover, controversy swirled around the killing of pelagic dolphins by the American tuna fleet in the eastern tropical Pacific (Gosliner, 1999). The estimated kill from 1960 through 1971 had been more than 370,000 dolphins annually (totaling nearly 4.5 million by that time), and environmentalists were understandably outraged.

The resulting legislation was both comprehensive and innovative. An immediate embargo was placed on the importation of marine mammal products, with only a few specified exceptions. Deliberate taking was banned, although Alaskan Eskimos and other aboriginal people were allowed to continue hunting marine mammals for food, skins, and other products as long as the main purpose was to meet basic community needs. A strong emphasis in the act was placed on research, and science was accorded a prominent role in influencing how decisions were to be made. Existing federal departments were given the responsibility of implementing the new law, with the Department of Commerce to manage cetaceans and most pinnipeds and the Department of the Interior to manage polar bears, sea otters, sireniens, and walrus. In addition, however, an entirely new and independent federal agency, the Marine Mammal Commission, was established to oversee implementation.

The goals of management, as set forth in the Marine Mammal Protection Act, were to achieve and maintain “optimum sustainable populations” of marine mammals and to reduce incidental mortality from fishing operations (including tuna seining) to “insignificant levels approaching zero.” An optimum sustainable population has been defined operationally as having a lower bound at the maximum net productivity level and an upper bound at the unexploited population (carrying capacity) level. By defining population status in terms of productivity, the act emphasized the health and stability of ecosystems rather than economic yield. The ambitious and lofty goals of the act have been pursued over the past 35 years with what appears to be an undiminished national commitment to the conservation of marine mammals.

The European Union has used a more selective approach to achieve certain objectives related to marine mammal conservation. In 1983, the European Community (as it was then called) established a controversial ban on the importation of products from seal pups. The explicit goal was to stop the clubbing of young white-coated harp seals and blue-backed hooded seals, a concern related primarily to animal welfare. In combination with closure of the US import market from 1972, the European ban effectively destroyed the profitability of sealskin production in North America and Greenland, with serious unintended economic and social consequences in Eskimo communities where the hunting of ringed seals was a major source of income. Canada was forced to stop the commercial hunt for unweaned harp and hooded seals, essentially bringing the large-scale, ship-based sealing industry to a halt. For more than a decade, the populations of harp and hooded seals were allowed to increase. Since the mid-1990s, however, Canada’s commercial sealing industry has been reinvigorated with government subsidies and aggressive product marketing, particularly focused on the export of seal penises to China and other Asian countries, so the kill of harp and hooded seals has returned to levels not seen since the early 1970s.

The European Community also effectively banned the importation of whale products in 1982–1983 by declaring that all cetaceans would be treated as though they were in Appendix I of CITES (no commercial trade allowed). Greenland, with its special relationship to Denmark, was exempted from the ban, meaning that narwhal tusks could be imported to EU countries under the normal provisions of CITES Appendix II. Thus, although the EU measure caused a steep decline in the value of narwhal ivory from Canada (Fig. 4), it had comparatively little effect on the market for tusks from Greenland, which was traditionally centered in Europe. Having lost access to the American market and much of the European market for narwhal ivory, entrepreneurs in Canada found new buyers in Asia, a pattern similar to that seen with seal products.

National conservation efforts are often influenced by international law or governance, and such influence can be for either good or ill. The US government, in implementing the Marine Mammal Protection Act, has had to take account of what are sometimes conflicting commitments under international agreements. For example, the USA has always belonged to the IATTC, whose primary goal is to maximize tuna catches. A sometimes uneasy alliance has been forged over the years between the IATTC and the US National Marine Fisheries Service, the agency responsible for pursuing the “zero mortality rate” goal for dolphins mandated by the Marine Mammal Protection Act. Although substantial progress had been made toward that goal by the late 1980s, animal protection groups continued to mount legal challenges, insisting that the procedure of setting purse seines around dolphins to catch tuna should cease altogether. Their efforts led to the “dolphin-safe” labeling of canned tuna and

Figure 4 The long, spiraled tusk of the male narwhal (*Monodon monoceros*) has commercial value and is traded in the global marketplace. Here, Inuk hunters on northern Baffin Island, Canada, August 1975, have dragged a carcass onto a beach and are preparing to remove the valuable tooth, which will later be sold to a non-Inuk who will likely export it to Europe. The 1972 ban on imports of marine mammal products into the USA, and measures taken by the European Union since the early 1980s, have limited the international commerce in narwhal ivory, but the trade remains lucrative thanks to outlets in the Middle and Far East. Photographs by Randall Reeves.

to embargoes on US imports of tuna from countries continuing to “fish on dolphins.” The IATTC took the position that by redirecting all fishing effort away from “dolphin sets” and toward “school sets” and “log sets” (neither of which involve dolphin encirclement), the bycatch of other species (e.g., billfish and turtles) and the proportion of undersized tuna in the catch would both increase. In general, the Fisheries Service has tended to assign a higher priority to dolphin protection than has the IATTC, and the relationship between the two agencies has been strained because of this and other differences. To make matters worse, Mexico mounted a challenge to the tuna embargoes under the General Agreements on Tariffs and Trade (GATT), insisting that they were unwarranted and unacceptable impediments to free trade. The dispute-resolution panel ruled that the embargoes were indeed inconsistent with GATT provisions, and the USA consequently had to seek a balance between its commitment to marine mammal protection and its support for the principle of free trade (Gosliner, 1999).

In a more positive vein, the IWC has managed to influence the conservation of small cetaceans in Japan, despite Japan’s refusal to recognize the commission’s authority to impose measures related to dolphins, porpoises, and smaller species of toothed whales. A variety of small cetaceans have been hunted in Japanese coastal waters for many decades (Fig. 5). The IWC Scientific Committee’s standing Subcommittee on Small Cetaceans meets annually to review the status of species, particular threats, and technical approaches to eliminating or managing threats. In its reviews of stocks, the subcommittee has repeatedly found evidence of over-exploitation by the Japanese coastal cetacean fisheries. As a result, the government of Japan has been forced, through international pressure from governments and NGOs, to implement research programs and management measures.

The most glaring (but not only) example is the striped dolphin (*Stenella coeruleoalba*). A drive hunt for striped dolphins, in which entire schools are herded toward shore and killed *en masse*, has

Figure 5 Japanese fishermen have hunted small cetaceans for many decades, often driving hundreds of animals toward shore where they are killed en masse. Rough-toothed dolphins (*Steno bredanensis*), shown here, are rarely taken in drive hunts, and even more rarely is a photographer on hand to record the carnage. Photograph by Rusty White, courtesy of Hubbs Marine Research Institute.

taken place annually on Japan's Izu Peninsula for more than a century. Catches of as many as 22,000 animals occurred in some years during the 1940s and 1950s. By the 1980s, when the hunters introduced a voluntary catch limit of 5000 dolphins, the annual average catch had declined to less than 3000/year, presumably because the dolphin population was seriously depleted. Finally, in 1989, quotas were imposed. Although the hunt should have stopped entirely to allow the population to recover, the striped dolphin example at least helped demonstrate that stronger measures by the national government in Japan would be needed to prevent further over-exploitation.

V. Local and Individual Conservation Efforts

Top-down approaches to resource management have often failed. The cost of policing human actions is likely to be unacceptably burdensome when local people assign little or no legitimacy to the management regime. It is generally agreed that the greater the local or community involvement, the more likely it is that conservation efforts will succeed in the long run (Mangel *et al.*, 1996). Marine mammal hunting communities in the Arctic and in Australia [where dugongs (*Dugong dugon*) are the principal prey species] have forged cooperative management ("co-management") agreements with government agencies. Ideally, such agreements recognize the interests and rights of local people, and the broader national and international concerns are represented by the central government.

A prominent example is the Alaska Eskimo Whaling Commission (AEWC), which was established in 1977 by whalers in northern Alaska in reaction to the IWC's controversial decision to ban bowhead whaling. After several years of difficult negotiations, marked by threats, lawsuits, and even a grand jury investigation into violations of the agreed bowhead quota in 1980, a cooperative agreement was reached between the AEWC and the National Oceanic and Atmospheric Administration (NOAA), the federal body directly responsible by law for implementing IWC decisions within the USA. Under this agreement, the AEWC assumes responsibility for managing the hunt, monitoring compliance with the quota and other regulations, and reporting each year's results. Quotas on the number of strikes and landings of bowheads are still negotiated through the IWC.

Figure 6 A harbor porpoise (*Phocoena phocoena*) that had been trapped in a herring weir in Passamaquoddy Bay, New Brunswick, Canada (summer 1980), being lifted from a seine net before tagging and release. Efforts to extricate marine mammals from fishing gear and return them to the wild typically require that fishermen and scientists work together cooperatively. Photograph by Randi Olsen.

Singling out the contributions of individuals to the cause of conservation is an arbitrary undertaking. The conscientious daily efforts of bureaucrats, scientists, writers, educators, fishermen, engineers, veterinarians, lobbyists, lawyers, and political activists all merit recognition. Several individuals are mentioned here, but with the caution that their work, while it may be exemplary, is not necessarily exceptional.

As discussed further later (under Section VII), the rescue and rehabilitation of injured or otherwise incapacitated individual marine mammals may have little or no conservation value. Nevertheless, in some circumstances, especially when an endangered species is involved, intervention can be important. Jon Lien, a professor at Memorial University in Newfoundland, began working with fishermen in the late 1970s to devise ways of extricating whales from fishing gear. The problem of entrapment and entanglement was a concern of conservationists because, at the time, humpback whales in the North Atlantic were considered endangered (their status has improved since then). It was of concern to fishermen because of the economic losses associated with damaged gear and lost fishing time, as well as the personal danger involved when dealing with these large animals at sea. Lien gained the confidence of fishermen and developed a successful program for assisting in the safe release of entrapped or entangled whales. Subsequently, Charles Mayo, David Mattila, and their associates at the Center for Coastal Studies on Cape Cod began rescuing whales from fishing gear on the US coast, with an emphasis on endangered right whales (*Eubalaena glacialis*). Disentanglement teams are now integral to right whale recovery efforts in the eastern USA and southeastern Canada, thanks to the pioneering efforts of Lien, Mayo, and Mattila. A similarly successful program centered on rescuing harbor porpoises, minke whales, and occasionally right whales trapped in herring weirs has been in operation in Canada's Bay of Fundy for more than two decades (Fig. 6).

One of the greatest obstacles to conservation can be the difficulty of defining and demonstrating the significance of a threat.

Marine debris pollution provides a clear example (Laist *et al.*, 1999). Although it is widely accepted today that marine debris, such as derelict fishing gear and plastic packaging material, is a menace to wildlife, the problem's seriousness was not recognized until the early 1980s. Charles Fowler, a scientist with the National Marine Fisheries Service in Seattle, was engaged in research to determine the cause of the continuing decline of North Pacific fur seals (see Section III). Despite bureaucratic resistance and the skepticism of scientific colleagues, Fowler pressed ahead with the task of marshaling data to test the hypothesis that entanglement in debris was a major cause of juvenile mortality in fur seals. His painstaking compilation of evidence, together with mathematical models, finally convinced others that at least this one marine mammal species was being affected at the population level. Fowler's work provided the impetus for a chain of events, from beach clean-up campaigns to the signing of international treaties, intended to reduce the ocean's burden of debris and therefore lessen the risks to seals and cetaceans, to say nothing of seabirds, turtles, and other marine wildlife.

One final example of an individual's ability to change the course of conservation policy again relates to dolphin mortality in the eastern tropical Pacific tuna fishery. By the late 1980s, many conservationists had forgotten about this issue, assured that dolphin mortality had been reduced substantially as a result of changes in fishing techniques and the imposition of annual quotas on the number of dolphins from each species that could be killed before fishing would have to cease. In 1987–1988, however, Sam LaBudde, who described himself as an “itinerant biologist,” spent 5 months aboard a Panama-registered tuna boat. Although he had signed on as an ordinary seaman and cook, he carried a video camera and clandestinely recorded grisly footage of dolphins being killed. When the scenes were aired on national television, it galvanized public support within the USA for strong measures to be taken against the non-American tuna fleet. While LaBudde's actions can be viewed as either heroic or deceitful, depending on one's point of view, there is no doubting his courage or his influence on the course of conservation.

VI. Protected Areas

The designation of specially protected areas (e.g., reserves, sanctuaries, parks) is a tool increasingly used to achieve conservation goals. Of the many such areas around the world, relatively few exist for the explicit purpose of benefiting marine mammals (Hoyt, 2005). Mexico declared Scammon's Lagoon (Laguna Ojo de Liebre) a refuge for gray whales in 1971, and San Ignacio Lagoon was given similar status in 1979. Also, Mexico established a Biosphere Reserve in the upper Gulf of California in 1993 mainly to protect the highly endangered vaquita (*Phocoena sinus*) and the totoaba, an endangered sea bass (*Totoaba macdonaldi*). New Zealand created the Banks Peninsula Marine Mammal Sanctuary in 1988 to protect Hector's dolphins (*Cephalorhynchus hectori*), like the vaquita an endemic coastal species, from entanglement in gill nets. In 1999, the parliament of the North German state of Schleswig-Holstein established a sanctuary for small cetaceans off the islands of Sylt and Amrum in the North Sea, intended to protect harbor porpoises from the dangers associated with gillnet fishing, jet skiing, and high-speed motor boating. In the USA, the Hawaiian Islands Humpback Whale Sanctuary was declared in 1993, and several other marine sanctuaries were established in large part because of public interest in the marine mammals that use them for feeding, breeding, or both (e.g., the California Channel Islands, Gulf of the Farallones, Monterey Bay, and Stellwagen Bank sanctuaries).

In addition to those areas explicitly created to benefit marine mammals, there are many small sites in the Antarctic and on the sub-Antarctic islands that are designated as specially protected areas or sites of special scientific interest under the Agreed Measures for the Conservation of Antarctic Fauna and Flora (1964), or as nature reserves under national legislative instruments, many of which protect vital haul-out habitat for pinnipeds. Norway's Svalbard (Spitsbergen) archipelago in the northeastern North Atlantic was the site of some of the worst excesses of early whaling and walrus killing, yet since 1973 about half of the land area has been declared to be inside nature reserves and national parks, and the Svalbard population of walrus is expanding rapidly.

All too often, protected areas are created in response to a public outcry, but without an accompanying ongoing commitment to enforce meaningful restrictions on human activities within them. The marine sanctuary program in the USA, e.g., has failed to meet the public's high expectations, largely because no serious attempt has been made to regulate fishing within the sanctuaries. To the program's credit, though, the dumping of wastes and the exploration for oil and gas have been strictly regulated, and this may be seen as having conservation value for marine mammals and other organisms. So-called “paper parks” and “paper reserves” can be counterproductive for conservation because they provide false assurance that space and resources have been set aside for wildlife.

VII. Strategies to Enhance the Survival and Reproduction of Individuals

At times, human intervention can improve the chances for individual marine mammals to survive and reproduce. Organized programs for rescuing marine mammals that strand (come ashore) alive or that are injured and debilitated do manage to release some animals after rehabilitation. However, the success rate is low, and the conservation value of such programs has often been called into question. Many strandings represent “natural” mortality. Thus, while intervention may be justified as a humane gesture intended to improve the welfare of the stranded animals, it can also be argued that natural processes should be allowed to proceed without human interference. Only in a few special cases can rescue, rehabilitation, and release efforts be considered to have made a clear, positive difference for a marine mammal population.

Most of the rivers in southern Asia inhabited by river dolphins are partitioned by irrigation dams (called barrages). When dolphins on the upstream side of such dams get too close to the intake structures of adjacent canals, they run the risk of becoming marooned in the canals, unable to return to the safety of the main river channel. Wildlife officers and conservationists sometimes attempt to locate and rescue these ill-fated dolphins. Between January 2000 and July 2007, at least 46 Indus dolphins (*Platanista gangetica minor*) were trapped in canals near Sukkur Barrage in Pakistan (Gill Braulik and WWF-Pakistan/Uzma Khan, personal communication, 21 July 2007). The majority of them were successfully captured and returned to the river. Sindh Wildlife Department and WWF-Pakistan are developing a systematic procedure for notification and response, and are refining a protocol for rescuing river dolphins that enter irrigation canals. Also, on several occasions Ganges dolphins (*Platanista gangetica gangetica*) have become trapped in isolated pools, shallow streams, or rice paddies, and have been successfully captured and released into safer areas (Fig. 7).

In Florida, several facilities that display captive marine mammals have been collaborating for many years with the US. Fish

Figure 7 Interest in marine mammals, and concern about their conservation, is not limited to wealthy, countries. In Bangladesh, e.g., young conservationists are eager to contribute, and they collaborate with local and international scientists to study and conserve freshwater and coastal cetaceans (A). Here, a Ganges river dolphin (*Platanista gangetica*) is returned to the Sundarbans Delta after having been found stranded, its long beak fouled with monofilament gill netting (B). Photographs by Mowgliz, courtesy of Brian Smith.

and Wildlife Service to rehabilitate injured or orphaned manatees (*Trichechus manatus*). The animals are cared for and either maintained permanently in educational exhibits or, if judged healthy enough, released back into the wild. A single facility (Sea World in Orlando) was reported to have responded to 160 requests for assistance with distressed manatees from 1976 to 1995. More than half of the animals brought into captivity died, but nearly 60 individuals were eventually returned to the wild. Virtually all of the injuries to manatees in Florida waterways are caused by human activity (mainly boating), so the rehabilitation program is almost entirely compensatory in the sense of helping to offset human-caused mortality.

Rescue and rehabilitation programs can contribute to conservation in less direct ways, too. For example, as John Reynolds (1999) has pointed out, “Educating people about manatee conservation as they watch recuperating animals in a zoo setting can make a strong impression that may do more to encourage actual conservation than reading an article or watching a documentary about manatees.” The whale and river dolphin rescue efforts mentioned earlier also serve to heighten awareness, educate people about conservation issues, and inspire actions to prevent further entanglement and entrapment. Reynolds also points out that manatees in captivity have allowed scientists to study their species’ reproduction, osmoregulatory capabilities, and sensory abilities. Knowing more about manatee biology and physiology is important for conservation.

Finally, rescue and rehabilitation programs offer opportunities to instrument and monitor animals after release. This can lead to new discoveries about the animals and allow researchers to test new study methods. There are many examples, but one in particular stands out. In 1997 an adult male bottlenose dolphin (*Tursiops truncatus*), nicknamed “Gulliver,” stranded in Florida. He was treated for a variety of ailments and, after about 4 months in captivity, released far offshore bearing a satellite-linked transmitter. Gulliver’s travels were impressive. After a week moving northward along the continental shelf, he headed southeast, swimming against the North Equatorial Current. He traversed waters more than 5000 m deep and reached an area northeast of the Virgin Islands before his transmitter stopped working, having covered 4200 km in 47 days. This study showed that bottlenose dolphins can be extremely mobile and that previous assumptions about the distributional limits of pelagic stocks needed to be reconsidered.

Another example of human intervention to enhance survival comes from the northwestern Hawaiian Islands, where biologists from the US National Marine Fisheries Service have captured and translocated endangered monk seals (*Monachus schauinslandi*). In one program on Laysan Island, they caught some adult males that had been seen participating in “mobbing,” or collective attacks on adult females and juvenile seals. The males were moved by ship to Johnston Island, some 600 miles south of Laysan, and released in the hope that they would survive but not return to carry on their destructive behavior toward other monk seals. In another program, called “Headstart,” female pups at Kure Atoll have been collected after weaning and kept in a fenced beach enclosure for several months. The watered portion of the enclosure is kept well stocked with fish taken from nearby reefs, and the young seals have a chance to learn to forage in safety from large sharks, adult male monk seals, and hazardous fishing gear—all potential causes of mortality. The idea is that by the time they are released, they will have survived a critical stage in the life cycle and be ready for independence.

Captive breeding, with the intention of using captive-born young to reestablish a species in its former range or to supplement and reinvigorate a depleted wild population, is sometimes employed as a conservation strategy when necessary and feasible. However, only one serious attempt has been made to restock a wild population of marine mammals with animals that were conceived, born, and reared in captivity. A number of captive-born harbor seals (*Phoca vitulina*) were released into the Dutch Wadden Sea, where their species had been depleted (although harbor seals are not threatened globally). The released seals were monitored with telemetry devices, and early results suggested that they had survived and adapted reasonably well.

Although captive breeding programs have been discussed in relation to Yangtze River dolphins, or baiji (*Lipotes vexillifer*), and Mediterranean monk seals (*Monachus monachus*), both gravely endangered, none of these programs have come to fruition.

A much-publicized “seminatural reserve” was established for river dolphins in a Yangtze River oxbow, but this facility was stocked primarily with finless porpoises (*Neophocaena phocaenoides*) rather than dolphins. The single female baiji introduced to the reserve became entangled in fishing gear and died. No attempt was made to place this female with the lone male baiji in captivity (which itself later died), so there was no prospect of captive breeding. Efforts to capture additional baiji for captivity or for stocking the seminatural reserve failed, and a recent survey led investigators to conclude that the baiji is likely extinct and that further capture and translocation efforts would be pointless (Turvey *et al.*, 2007).

Translocation efforts played a role in the sea otter’s reoccupation of parts of its original range. More than 700 otters were taken from high-density areas in Alaska during the 1960s and early 1970s and released at unoccupied sites in British Columbia, Washington, and Oregon. Populations are now well established in British Columbia and Washington. A controversial attempt was made during the 1980s to establish a new population of sea otters in the California Channel Islands in view of the risk that an oil spill could destroy the mainland population. More than 135 otters were captured and translocated to San Nicolas Island, but their numbers did not increase as expected and by the mid-2000s only about 30–35 remained.

VIII. Reduction of Environmental Pollution (Chemical and Acoustic)

The role of POLLUTION in impairing the productivity and survival of marine mammals was first realized in the 1970s, when a correlation was found between the rate of reproductive failure (premature births, still births, and abortions) in California sea lions (*Zalophus californianus*) and elevated tissue levels of DDT (Vos *et al.*, 2003). Also during the 1970s, studies of seals in the Baltic and North seas provided suggestive evidence that organochlorine pollutants pose serious risks to the health and reproductive potential of marine mammals. The production and use of DDT, PCBs, and some other dangerous persistent organochlorine chemicals began to be restricted in North America and western Europe in the 1970s, and there has been a general trend toward further restrictions since then. Unfortunately, however, the problem is far from solved. For example, India continued to produce 4000 metric tons of DDT at least as recently as the mid-1990s, and at least some of the former Soviet states have continued to manufacture and use PCBs. Moreover, the persistent nature of these chemicals means that they continue to be present in the environment, either temporarily sequestered in sediments or recycling in food webs, and therefore marine mammals continue to be vulnerable to their effects. While it must be acknowledged that the principal motivation for banning the release of harmful substances into the environment has had less to do with protecting marine mammals than with protecting human health (and birds, in the case of DDT), there is no doubt that reports of high levels of contaminants in marine mammals have contributed to public concern (O’Hara and O’Shea, 2005).

Acoustic pollution is thought to be especially damaging to cetaceans, as they depend heavily on sound for information about their environment, for foraging, and for communication. Military sonar has been implicated in numerous mass strandings of cetaceans, particularly beaked whales (Hildebrand, 2005). Noise associated with the offshore exploration, development, and transport of oil and gas has been a particular source of concern, and many millions of dollars have been invested in studies of effects (Richardson *et al.*, 1995). In some instances, notably those involving seismic and drilling noise in the

Figure 8 *The franciscana (Pontoporia blainvillei) is one of several marine mammal species with a restricted distribution (coastal waters of eastern South America between approx. 18°30’S and 41°10’S) that experience substantial incidental mortality in fisheries. Although progress has been made toward assessing the impact of such mortality on franciscana populations in some areas, nowhere has significant progress been made at reducing the bycatch rate. This image shows franciscanas killed incidentally in the coastal gill net fishery for demersal fish (sciaenids) based in the port of Rio Grande, southern Brazil, 1994. Photograph by Eduardo Secchi.*

Arctic, steps have been taken to minimize the exposure of whales and seals to high-energy sounds. In some countries, government agencies and companies have conducted monitoring programs to determine when marine mammals are present in an area so that operations can be suspended or moved to protect them. In a similar vein, the sites and timing of military exercises have, in a few instances, been planned with the safety of marine mammals and other marine wildlife as a primary consideration.

It has become increasingly clear that human-induced changes in global climate will have (and probably already have had) significant effects on marine mammal populations. The effects will be most obvious for ice-associated species: the phocid seals in the Arctic and Antarctic and the walrus and polar bear in the Arctic. These animals use sea ice as a platform for resting, giving birth, or, in the case of polar bears, hunting. As the extent and thickness of pack ice decrease from global warming, these species will lose critical habitat. Once again, as in the case of toxic chemical pollution, the primary motivation for taking steps to reduce emissions of greenhouse gases and ozone-depleting substances has been concern about human welfare rather than a desire to conserve marine mammals.

IX. Reduction of Conflicts with Fisheries

Fishery policies are the key to many of the most pressing marine mammal conservation problems. While there are examples of effective action to reduce marine mammal mortality in fishing gear, such as the UN ban on high-seas drift netting, the seasonal or permanent closure of certain areas to gill netting, and the development and implementation of deterrence programs using pingers and similar devices, the sad truth is that many critical situations simply continue to deteriorate (Fig. 8). For example, although some legal limits

have been placed on gill netting and commercial fishing in a portion of the northern Gulf of California, there has been little effective enforcement, and vaquitas remain in jeopardy (Rojas-Bracho *et al.*, 2006; Jaramillo-Legorreta *et al.*, 2007). In China's Yangtze River, it is illegal to fish with electricity and explosives, yet there is almost no enforcement, and river dolphins (if any survive, which seems unlikely) and finless porpoises continue to be killed and injured as unintended victims (Turvey *et al.*, 2007).

X. Reduction of Disturbance and Direct Harm from Vessel Traffic

Manatees living in Florida's motorboat- and barge-infested waterways are frequently struck and injured, if not killed outright, by watercraft (also see section VII). On average, about 50 Florida manatees are killed by boat collisions each year, and many more are injured and harassed by vessel traffic. Although this problem had long been recognized, it was not until the late 1970s and early 1980s that serious efforts were made to reduce the risk of collisions and disturbance. More than 20 areas have been designated as protection zones for manatees, where vessel speed is regulated and signs warn visitors of the need to exercise caution. In some key manatee congregation areas, all waterborne human activity, including diving, boating, and swimming, is prohibited.

Another marine mammal species that is clearly threatened by ship strikes is the North Atlantic right whale. Where thousands of right whales were present in the past, all that remains is a small population of about 350 to 400 centered along the east coast of Canada and the USA. Several right whales are killed by ship collisions each year. This mortality, combined with that caused by entanglement in fishing gear, is considered sufficient to have stalled population recovery (Kraus *et al.*, 2005). Efforts have been made in both Canada and the USA to map the seasonal distribution and movements of right whales and to caution vessel captains to watch for and avoid them. Both countries have also modified the official shipping lanes into key ports in the hope that this will reduce the risk of ship strikes.

It remains to be seen whether manatees and right whales will be able to withstand the effects of human activities in the coastal and inshore waters we share with them. Thus far, our own species' recreational and commercial use of the marine environment has been regarded as sacrosanct, and the few gestures made to accommodate the needs of these other species have had to overcome strenuous resistance from boaters, the shipping industry, military authorities, and others.

XI. Giving Economic Value to Living Wild Marine Mammals

In the 1950s, a few nature enthusiasts in southern California began venturing into near-shore waters to watch gray whales. At the time, scientists were just beginning to document the remarkable recovery of this whale population—a result of the protection from whaling afforded by the IWC and, in recent years, Mexico's protection of the breeding lagoons in Baja California. Interest in watching whales grew steadily, and by the mid-1970s, conservationists were suggesting that the “non-consumptive” use of whales as objects of tourism might eventually rival whaling in economic value. The 1980s and 1990s saw the rapid proliferation of tour enterprises for observing whales and dolphins. Even in the whaling countries of Norway, Iceland, and Japan, whale watching has become a popular and remunerative form of recreation. In eastern Canada, helicopter tours to the pack-ice pupping grounds of harp seals have been encouraged by

animal-welfare groups as a way of demonstrating that seals also can generate income (tourism revenues) without having to be killed. In the Antarctic and Arctic, opportunities to observe marine mammals are an important aspect of nature-oriented tourism.

XII. Zoogeography of Marine Mammal Conservation

Threats to marine mammal species and populations are relatively well understood and are being addressed to some degree in North America, Europe, South Africa, Australia, and New Zealand. However, even in those parts of the world, serious problems remain. In fact, North Atlantic and North Pacific (*Eubalaena japonica*) right whales, Hawaiian monk seals, northern (or Steller) sea lions (*Eumetopias jubatus*), and sea otters in US waters, Mediterranean monk seals and some local populations of bottlenose dolphins, harbor porpoises, and short-beaked common dolphins in Europe, dugongs in parts of Australia, and Hector's dolphins in New Zealand are still in trouble. Elsewhere in the world, marine mammal populations are slipping away even before there has been a chance to document their distribution and abundance, or to elucidate their ecological roles.

Table III lists 20 of the world's most threatened marine mammal taxa. The list is by no means authoritative, or exhaustive. Some species, such as the franciscana dolphin (*Pontoporia blainvillei*) and Caspian seal (*Pusa caspica*), might merit inclusion except for the fact that their total numbers are still believed to be in the tens of thousands. For other species, such as the West African manatee (*Trichechus senegalensis*) and Amazonian manatee (*T. inunguis*), we have very little understanding of how many there are or the extent to which their distribution has been reduced by over-exploitation, incidental mortality in fishing gear, and habitat deterioration. For these and many other situations, there has been little or no active conservation. Another concern is that by limiting the list to recognized species and subspecies, geographical populations are left out. In particular, numerous geographically isolated populations that are known to be in serious trouble are missing simply because they have not been accorded a subspecies designation. Among the more obvious examples are several freshwater populations of Irrawaddy dolphins (*Orcaella brevirostris*), the western Pacific population of gray whales, and the Cook Inlet (Alaska) population of belugas, all of which number in the tens or low hundreds and are listed by IUCN as Critically Endangered.

Endemism is a feature that is often associated with vulnerability. Many of the species and subspecies in Table III are on the list because they occur in only one place. For example, the baiji was confined for the last several decades of its existence (it is likely now extinct) to the main stem of the Yangtze River, and the Indus river dolphin to the main stem of the Indus. The vaquita is limited to the upper portion of the Gulf of California, and the Saimaa, Ungava, and Ladoga ringed seals occur only within single networks of freshwater rivers and lakes. The effects of endemism are, of course, scale dependent—the smaller the range, the more vulnerable the population tends to be. A species or population that ranges throughout, or on both sides of, an ocean basin is usually less vulnerable than one limited to a single stretch of coastline or a single river or lake. However, an extensive range and great mobility also mean that management for conservation (e.g., protection from hunting, entanglement in fishing gear, exposure to ship strikes, and other threat factors) must be pursued on a large spatial scale and, often, across multiple jurisdictions.

The conservation challenges that lie ahead are truly endless. As the global economy becomes more integrated and as the human appetite (and capacity) for consuming our planet's resources expands,

TABLE III
Twenty of the world's most threatened marine mammal taxa, including recently extirpated ones
 (subspecies taxonomy follows Rice, 1998, except as noted)

<i>Taxon</i>	<i>Range States</i>	<i>Approx. Abundance</i>	<i>Main Threats</i>
1. Caribbean monk seal, <i>Monachus tropicalis</i>	Mexico, USA, Bahamas, Jamaica, Cuba, Haiti, Dominican Republic, Guadeloupe, and other Caribbean states	Probably extinct	Deliberate killing, loss of habitat due to development
2. Baiji or Yangtze river dolphin, <i>Lipotes vexillifer</i>	China	Probably extinct	Fishery bycatch, loss and degradation of habitat due to development, contamination and depletion of prey resources, vessel strikes and disturbance
3. Vaquita, <i>Phocoena sinus</i>	Mexico	100s	Fishery bycatch
4. Mediterranean monk seal, <i>Monachus monachus</i>	Turkey, Greece, Italy, Mauritania, Morocco, Western Sahara, Libya, Madeira (Portugal)	500	Fishery bycatch, shooting by fishermen, loss of pupping and pup-rearing habitat
5. North Atlantic right whale, <i>Eubalaena glacialis</i>	Canada, USA, Iceland, Norway, UK, Spain, Portugal, France	350–400	Ship strikes, fishery bycatch, possibly effects of small population size (depletion from past over-exploitation)
6. North Pacific right whale, <i>Eubalaena japonica</i>	Russia, Japan, Korea, China, Canada, USA, Mexico, Canada	Mid to high 100s	Ship strikes, fishery bycatch, possibly effects of small population size (depletion from past over-exploitation)
7. Hawaiian monk seal, <i>Monachus schauinslandi</i>	USA (Hawaiian archipelago)	1,000	Fishery bycatch, disturbance on pupping beaches, debris entanglement, possibly prey depletion by commercial fisheries
8. Hector's dolphin, <i>Cephalorhynchus hectori</i>	New Zealand	7,000	Fishery bycatch, vessel strikes
9. Japanese sea lion, <i>Zalophus californianus japonicus</i>	Japan, Korea, Russia	Probably extinct	Deliberate killing, fishery bycatch
10. Maui's (North Island Hector's) dolphin, <i>Cephalorhynchus hectori maui</i> (new subspecies recognized in 2002)	New Zealand	100	Fishery bycatch
11. Saimaa ringed seal, <i>Pusa hispida saimensis</i>	Finland	280	Fishery bycatch, changes in habitat due to water management policies, chemical contamination
12. Ungava harbor seal, <i>Phoca vitulina mellonae</i>	Canada	Low to mid 100s	Loss and fragmentation of habitat due to water management policies, hunting
13. Red Sea dugong, <i>Dugong dugon hemprichii</i>	Egypt, Saudi Arabia, Yemen, Eritrea, Sudan	Probably low 1,000s at most, possibly only 100s	Fishery bycatch, hunting
14. Bhulan or Indus river dolphin, <i>Platanista gangetica minor</i>	Pakistan	1,200	Loss and fragmentation of habitat due to water management policies, accidental movement into canals and other unsafe areas, fishery bycatch, chemical contamination
15. Yangtze River finless porpoise, <i>Neophocaena phocaenoides asiaeorientalis</i>	China	1,500–2,000	Fishery bycatch; loss, degradation, and fragmentation of habitat due to water management policies and sand mining; possibly contamination and depletion of prey resources
16. Southern sea otter, <i>Enhydra lutris nereis</i>	USA	2,800–3,000	Fishery bycatch, human-mediated disease
17. Susu or Ganges river dolphin, <i>Platanista gangetica gangetica</i>	India, Bangladesh, Nepal	At least low 1,000s	Fishery bycatch, deliberate hunting, loss and fragmentation of habitat due to water management policies, accidental movement into canals and other unsafe areas, chemical contamination
18. Florida manatee, <i>Trichechus manatus latirostris</i>	USA, Bahamas (occasionally)	3,500	Vessel strikes, fishery bycatch, exposure to toxic organisms (probably related to human activities), habitat modifications due to water management and energy policies
19. Antillean manatee, <i>Trichechus manatus manatus</i>	Caribbean and Atlantic mainland coastal states from Mexico to Brazil, Cuba, Puerto Rico, Trinidad, Dominican Republic, and other Caribbean island states	Unknown but probably 1,000s	Fishery bycatch, deliberate hunting and trapping
20. Ladoga ringed seal, <i>Pusa hispida ladogensis</i>	Russia	About 5,000	Fishery bycatch, disturbance at haul-out sites

marine mammals will inevitably experience new threats, even while long-standing ones persist. We are in danger of losing numerous populations, some species, and a few genera (e.g., *Monachus*). One entire family of cetaceans, the Lipotidae, appears to have been lost very recently (Turvey *et al.*, 2007). Another river dolphin family, the Platanistidae, is far from secure, particularly given the ever-mounting pressure on the freshwater systems inhabited by the two extant subspecies in southern Asia. However impressive the array of conservation efforts may seem on paper, it is far from adequate (Bearzi, 2007). Only with a genuine, broad-scale change in how we value the remnants of the world's natural variety and abundance, and thus in how we use and care for the Earth's precious resources, can we hope to head off a cascade of marine mammal EXTINCTIONS in the coming decades.

Crabeater Seal

Lobodon carcinophaga

JOHN L. BENGTSON

I. Characteristics and Taxonomy

The crabeater seal may be the most abundant pinniped in the world, existing in the millions around Antarctica. The scientific name, *Lobodon carcinophaga* (Hombron and Jacquinot, 1842), is derived from Greek, and means “lobed tooth” (*Lobodon*) “crab eater” (*carcinophaga*). Crabeater seals have finely divided, lobed teeth, presumably an adaptation to their specialized diet of krill. The multiple cusps of upper and lower postcanine teeth interlock to form a sieve that can be used to filter crustaceans from seawater. A bony protrusion on the lower jaw behind the most posterior postcanine tooth fills the gap in this sieve so that prey cannot escape at the rear of the mouth.

Adult crabeater seals are generally about 205 to 240 cm long, with some older male and female individuals reaching lengths of up to 264 and 277 cm, respectively (Laws *et al.*, 2003). During the summer molting period, adults typically exhibit average weights of about 200 kg (males) and 215 kg (females). Pups weigh about 35 kg at birth but can grow to more than 100 kg by the time they are weaned.

The pelts of crabeater seals usually have medium brown to silver hair over most of their body, although darker coloration and spotting is not uncommon on the front and rear flippers and flanks (Fig. 1). The hair fades in color throughout the year, so recently molted seals may appear darker than those about to begin their molt, whose pelts can appear silvery-white. The body form is relatively slender compared to other phocids, and crabeater seals' faces have a somewhat pointed snout. Crabeater seals have a high incidence of obvious scarring on their bodies, mostly caused by leopard seal (*Hydrurga leptonyx*) attacks (Fig. 2). Adults typically also have small scars from bites around their front and rear flippers (both sexes) and around their lower jaw and throat (mostly males) from intra-specific interactions during the breeding season.

Crabeater seals are highly mobile on ice, and when disturbed often raise their heads and arch their backs. They can move surprisingly quickly over ice and snow, and on a cold day (i.e., when not subject to overheating) they may be capable of outrunning a fit human.

II. Distribution and Abundance

Crabeater seals have a circumpolar Antarctic distribution, spending the entire year in the pack ice zone as it advances and retreats seasonally. Occasionally crabeater seals are found along the southern fringes of South America, Australia, New Zealand, and Africa, but such sightings or strandings are rare. Genetic analyses suggest that the circumpolar crabeater seal population is panmictic; there are no known subspecies of crabeater seals.

Crabeater seals migrate over large distances in association with the annual advance and retreat of the pack ice. Although they can be found anywhere within the pack ice zone, it is typical to find higher densities of crabeater seals over and at the edge of the continental shelf, as well as in the marginal ice zone (Burns *et al.*, 2004; Southwell *et al.*, 2005). Crabeater seals sometimes congregate in large groups (i.e., hundreds of individuals), which may be associated with migration or foraging.

Figure 2 Nearly all crabeater seals possess long, raking scars on their torsos resulting from attacks in their first year of life by leopard seals. Photo by J. L. Bengtson.

There is presently no reliable estimate of the total abundance of crabeater seals. Past estimates have ranged from 2 to 75 million individuals, although a population estimate in the range of 5–10 million is likely to be more reasonable. The observed densities of crabeater seals censused in the 1980s were lower than densities observed in the late 1960s and early 1970s (4.3 vs 11.4 seals/nm² in the Weddell Sea and 1.9 vs 4.9 seals/nm² in the Pacific Ocean Sector, respectively) (Erickson and Hanson, 1990). However, it is unclear whether these differences in densities reflected a change in population abundance or a shift in distribution within the sea ice zone. An international research initiative, the Antarctic Pack Ice Seals (APIS) Program, is evaluating survey data to refine estimates of the abundance and distribution of crabeater seals (Southwell *et al.*, 2008).

III. Ecology

In their first year, crabeater seals experience a surprisingly high mortality rate that may be as high as 80%, which is perhaps double that which might normally be expected (Boveng and Bengtson, 1997). For the approximately 20% of crabeater seals that survive past their first birthday, as many as 78% exhibit large, raking scars on their bodies resulting from attacks by leopard seals (Fig. 2), suggesting that leopard seals may have a significant negative impact on crabeater seal populations. Most attacks by leopard seals on crabeater seals occur in the crabeater seals' first year; fresh wounds, indicating

a recent attack, are rarely seen on crabeater seals that are older than 1 year (Siniff and Bengtson, 1977).

Studies of crabeater seal diet have shown that these seals depend almost exclusively on Antarctic krill (*Euphausia superba*). Most investigators have reported that krill comprise over 95% of the crabeater diet, with the remainder being made up of small quantities of fish and squid (Øritsland, 1977). As specialist krill predators, crabeater seals do not appear to switch their prey seasonally.

IV. Behavior and Physiology

In a peculiar behavioral twist, crabeater seals likely hold the record for any pinniped wandering inland from the coast. Carcasses have been found up to 113km from open water and as high as 1100m above sea level. Seals that wander inland, become lost, and die; they may eventually become mummified in the cold, dry, Antarctic air, and can remain in this “freeze-dried” state for many decades or centuries (Stirling and Kooyman, 1971).

Similar to other Antarctic pack ice seals, crabeater seals exhibit a daily haulout pattern in summer that generally involves hauling out on ice floes during the middle of the day (Bengtson and Cameron, 2004). However, usually less than 80% of crabeater seals haul out simultaneously on the ice, even during the height of the molting period in January and February. Haulout patterns also vary markedly among seasons, with as few as 40% of seals hauling out at the peak of daily haulout during winter months.

During daily foraging periods in summer, which normally occur during the night, crabeater seals dive nearly continuously for periods of up to 16h. In one study, a single crabeater seal continued diving for 44h without interruption. Although crabeater seals have been recorded diving to depths of over 600m, most dives are less than 100m deep and less than 5min in duration (Bengtson and Stewart, 1992; Nordøy *et al.*, 1995; Burns *et al.*, 2004; Wall *et al.*, 2007). Foraging dives made during crepuscular periods are often deeper than those made during the darkest hours, suggesting that the seals may prefer dark conditions when catching their principal prey, Antarctic krill.

V. Life History

During the breeding season, crabeater seals form “family groups,” consisting of a female, her pup, and an attendant male who guards the female from other males until she completes lactation (Siniff *et al.*, 1979). The peak of pupping is in mid- to late-October, with pups still observed with adults as late as mid-December (Southwell *et al.*, 2003b; Southwell, 2004). Pups are born with a light brown lanugo that is molted about 2 weeks later. Following weaning at about 2–3 weeks of age, the attendant male and the female form a “mated pair” and remain together for an estimated 1 to 2 weeks. Estrus, ovulation, and copulation occur approximately 4 days after the pup weans (Laws *et al.*, 2003b). Females without pups also form mated pairs as they come into estrus. Crabeater seals can live up to 40 years, but adults dying at about 20–25 years is more typical.

A large group of crabeater seals experienced an incident of mass mortality in 1955 in the vicinity of an Antarctic base where sledge dogs were active (Laws and Taylor, 1957). Up to 97% of mixed-age aggregations died during that event. It was speculated that a viral infection may have been associated with the die-off, and circumstantial evidence suggests that it may have been caused by a distemper-like virus. Blood samples taken from crabeater seals in the late 1980s confirmed that populations of crabeater seals along the Antarctic Peninsula had antibodies similar to those related to canine distemper and phocine distemper viruses that were responsible for major

epi-zootic die-offs of harbor seals (*Phoca vitulina*) in the Northern Hemisphere in the late 1980s (Bengtson *et al.*, 1991).

VI. Interactions with Humans

Crabeater seals were harvested commercially twice during the past century: in 1964/1965 by Norway, and in 1986/1987 by the former Soviet Union. In both cases, the sealing ventures were judged to be economically unsuccessful. However, the concern generated by the earlier harvest was sufficient to mobilize an international effort to prevent potential over-exploitation of the seals. This concern resulted in the Convention for the Conservation of Antarctic Seals, which came into effect in 1978, and provides international oversight for the conservation and management of crabeater seals throughout their range.

Culture in Whales and Dolphins

HAL WHITEHEAD

Evidence is growing that culture is an important determinant of the behavior of whales and dolphins (Rendell and Whitehead, 2001). Among the many definitions of culture, one that is commonly used by evolutionary biologists and is useful when studying the phenomenon in whales and dolphins, is behavioral variation between sets of animals maintained and transmitted by social learning (Laland and Hoppitt, 2003). As clearly shown in the case of humans, when culture becomes an important determinant of behavior, then evolution and ecology are channeled into unusual paths (Richerson and Boyd, 2004).

There are two principal approaches to the study of nonhuman culture (Laland and Hoppitt, 2003). Because some scientists will only ascribe culture to a behavioral pattern if it can be proved to be transmitted between animals by imitation or teaching, they investigate transmission mechanisms experimentally. Others, who use a broader definition of culture encompassing any form of social learning, not just imitation or teaching (Whiten and Ham, 1992), look for patterns of behavioral variation in wild populations that cannot be explained by either genetic factors or environmental differences

plus individual learning. This has been called the “ethnographic” approach to the study of culture.

The bottlenose dolphin, *Tursiops* spp., has been shown experimentally to possess sophisticated social learning abilities, including vocal and motor imitation (Herman, 2002), but these have not been closely tied to observed patterns of behavior in the wild. Although social learning of other cetacean species has not been studied experimentally, there is observational evidence for imitation and teaching in some other whales and dolphins, especially killer whales, *Orcinus orca* (Guinet and Bouvier, 1995).

Using the second, ethnographic, approach to the study of culture, there is good evidence for cultural transmission in several cetacean species. Most notable are the complex and stable vocal (call dialects) and behavioral (foraging patterns and techniques) cultures of sympatric pods, clans, communities, and types of killer whales (Boran and Heimlich, 1999; Yurk *et al.*, 2002; see KILLER WHALES). The parallel slow evolution of calls in neighboring pods not only demonstrates cultural evolution, but also indicates that killer whales actively delineate their social structures using cultural markers (Deecke *et al.*, 2000).

The sperm whale, *Physeter macrocephalus*, another large odontocete with a matrilineally based social system, also has important matrilineally transmitted cultures. In the South Pacific, social units of female sperm whales are members of clans that are distinguished by the types of coda vocalizations that they use (Rendell and Whitehead, 2003). Although clans are sympatric, units form groups only with other units from their clan. The clans, which span several thousands of kilometers and might contain ten thousand members, have distinctive movement patterns, foraging success, and seem to differ in their reproductive rates (Whitehead and Rendell, 2004; Marcoux *et al.*, in press).

Sympatric cultural variants seem to be quite common in odontocetes. In Shark Bay, Australia, there are at least 13 foraging strategies that are not used equally by individual bottlenose dolphins, at least some of which are likely socially learned (Mann and Sargeant, 2003; Krützen *et al.*, 2005). In several parts of the world, inshore and riverine odontocetes have developed fishing cooperatives with local human populations, in which both humans and dolphins benefit (Simões-Lopes *et al.*, 1998).

Perhaps most remarkable of all cetacean cultures is the song of male humpback whales, *Megaptera novaeangliae*. All males in any ocean basin sing nearly the same song, but it evolves over periods of months and years (Payne, 1999). This evolution is usually gradual, but over a 2-year period, the males off eastern Australia adopted the radically different western Australian song, which they had heard from a few itinerant males, making this the first known instance of a non-human cultural revolution (Noad *et al.*, 2000; Fig. 1).

The case that culture is the sole cause of these differences in cetacean behavior varies in strength, being perhaps strongest for humpback whale songs and weakest for bottlenose dolphin foraging strategies (Rendell and Whitehead, 2001; Laland and Janik, 2006). While it is very likely that culture has a role in all cases, ecological or genetic influences may also be present, making the exclusionary approach of studying culture in the wild ineffective. New techniques are being developed that, instead of only ascribing culture when other influences can be ruled out, apportion behavioral variation to genetic, ecological and cultural causes (Laland and Janik, 2006), and these may be particularly important in the future study of cetacean culture.

Several factors may be implicated in the apparent importance of cultural transmission of behavior among cetaceans. Long lives, prolonged parental care, and substantial cognitive abilities are often associated with the evolution of cultural faculties, and these are generally characteristic of cetaceans, as well as other cultural animals,

Figure 1 The revolution in humpback (*Megaptera novaeangliae*) song type off the east coast of Australia during 1995–1998, as males from the east coast population adopted the west coast song (adapted from Noad et al., 2000).

such as primates and some birds. The wide movements of cetaceans and the greater variability of the marine biotic environment relative to that on land, as well as the stable matrilineal social groups of some species, are potentially important factors in the evolution of some of the more unusual aspects of cetacean culture (Rendell and Whitehead, 2001).

Culture can affect the evolution of other aspects of the lives of animals. There have been a number of suggestions for gene-culture coevolution in cetaceans, and culture may be implicated in some of their unusual behavioral and life history traits. For instance, it has been proposed that the separation between “resident,” fish-feeding and “transient,” mammal-feeding forms of killer whales (which now show morphological and genetic differences) was originally driven by culture (Boran and Heimlich, 1999). Another suggestion is that cultural selection may have caused the remarkably low diversity of mitochondrial genes found in matrilineal whales, as these genes and beneficial cultural traits may have been inherited in parallel by daughters from their mothers (Whitehead, 1998). Culture may also be implicated in mass strandings, as well as in the pronounced menopause shown by killer and pilot whale (*Globicephala* spp.)

females which is known only from humans among non-cetaceans (Rendell and Whitehead, 2001).

Culture potentially affects ecology and population biology in a variety of ways. It can increase feeding success, the diversity of diet, and either promote or inhibit population structure. Thus, cetacean culture may need to be included into considerations of the conservation and management of whales and dolphins (Whitehead et al., 2004). As an example, the bottlenose dolphin population in Hervey Bay, Australia, includes two sympatric communities, one that feeds extensively on the discards from trawlers and one that does not (Chilvers and Corkeron, 2001). Management of the fishery will have complex repercussions for this population.

The focused study of culture in whales and dolphins is just beginning. Despite denials from those who demand experimental proof of imitation or teaching before attributing culture, there are strong indications that, in common with humans (*Homo sapiens*) and chimpanzees (*Pan troglodytes*), much of the behavioral repertoire of many cetaceans is learned socially and constitutes culture. Culture may also be an important attribute of other marine mammals, with the foraging techniques of sea otters (*Enhydra lutris*) perhaps forming the clearest example (Estes et al., 2003).

The cultures of whales and dolphins possess features that have no known parallel outside humans. Examples are the sympatric multifaceted cultures of killer whales, and the giant physical scales such as ocean-wide songs of humpback whales and clans of sperm whales. They represent an independent evolution of cultural faculties outside the primate line, and thus help us understand both how culture evolved and what its consequences may be.

Cuvier's Beaked Whale

Ziphius cavirostris

JOHN E. HEYNING AND JAMES G. MEAD

I. Characteristics and Taxonomy

The original description of *Ziphius cavirostris* is based on a partial cranium collected near the village of Fos, France, in 1804. In his species description, Cuvier mistakenly identified the specimen as a fossil because he thought the skull was “petrified.” The specimen actually represents part of a skull, including a densely ossified rostrum, with a well-developed prenarial basin of an adult male. This basin, or cavity, on the top of the skull just anterior to the bony nares led to the trivial name of *cavirostris*. The densely ossified rostrum is found in adult males of Cuvier's beaked whale and mesoplodont beaked whales (Fig. 1). The function of this rock-hard snout is unknown, but it has been postulated to either reinforce the skull when males fight or serve as a sound conduit. The most common English names for *Z. cavirostris* are Cuvier's beaked whale and the goose-beaked whale, both of which are in wide usage.

The general body shape of *Z. cavirostris* is similar to that of other beaked whales with a rather robust, cigar-shaped body (Heyning,

Figure 1 As males of *Ziphius cavirostris* become sexually mature, they begin to resorb bone in front of the nasal passages, creating over time a distinct cavity or prenarial basin seen easily in this dorsal view (right). Adult females and immature males lack this basin (left).

1989). The falcate dorsal fin is relatively small and set approximately two-thirds of the body length posterior to the rostrum. The flippers are also relatively small, narrow, and can be tucked into a slight depression or pocket along the body wall. This flipper pocket is also found in other ziphiids and is assumed to allow the flippers to be held tight against the body while swimming. As with other ziphiids, the flukes are proportionately large and, as a rule, lack the distinctive medial notch found in all other cetaceans. The head is rather blunt in profile with a small, poorly defined rostrum that grades into a gently sloping melon region. There is no significant difference in total length between sexes for *Z. cavirostris*, with an average adult size of 6.1 m. There are several reports of specimens that exceed 7.0 m in length, but virtually all of these appear to be either estimates of lengths or based on misidentified animals. The largest accurately measured specimen of *Z. cavirostris* is an adult male that measured 6.93 m from the Falkland Islands. There is one pair of throat grooves that converge, but do not meet anteriorly. Beaked whales feed primarily by suction and these grooves allow the throat region to expand as they slurp in their prey.

The pigmentation pattern for male *Z. cavirostris* is a dark slate gray over most of its body with a distinctively white head. This white coloration continues slightly posterior along the dorsum. This appears to be the pattern found in most mature males (Fig. 2). Adult females tend to vary in general color from a dark gray to a reddish-brown, with a slight lightening of the skin on the head. This is not as dramatic a contrast as in males and does not appear to extend posteriorly on the dorsal aspect of the body. Usually there are some distinctive patterns of dark pigment on the head of adult females. The eye is typically dark, and there is a highly variable pair of dark crescents surrounding the eye, one anteriorly and one posteriorly. Newborns are dark black or bluish-black above and lighter below. This pigmentation pattern is very similar to that found on young beaked whales of the genus *Mesoplodon* and may represent the primitive pigmentation pattern for the calves of many ziphiids. Light oval patches and linear marks are quite common on the skin of *Z. cavirostris*, which can give an animal a mottled appearance.

Figure 2 This dead, stranded *Z. cavirostris* shows lime whitish head characteristic of adult males. Photo by W. Perrin, National Marine Fisheries Service.

The oval patches on ziphiids have been attributed to scars left by lampreys or cookie-cutter sharks of the genus *Isistius*. Linear marks have been attributed to scars resulting from the teeth of males raking along the skin during intraspecific fighting. The only erupted teeth are the apical pair in adult males, and linear scars are most prevalent in mature males.

II. Distribution and Abundance

As with most uncommon cetaceans, the distribution of *Z. cavirostris* is known primarily from strandings. This type of information may be somewhat biased, especially with regard to the abundance for a particular area. Stranding records indicate that *Z. cavirostris* is the most cosmopolitan of the beaked whales and is distributed in all oceans and most seas except in the high polar waters (Heyning, 1989). Strandings of *Z. cavirostris* are the most numerous of all beaked whales, indicating that they are probably not as rare as originally thought. Observations of live animals in the field reveal that the blow of *Z. cavirostris* is low, diffuse, and directed forward, making sightings more difficult, and there is some evidence that they avoid vessels by diving. These two facts may explain why these whales are rarely seen at sea. Single animals are frequently observed with pods ranging in size up to seven animals. There are several records of mass strandings.

III. Ecology

Although most general accounts of *Z. cavirostris* list squid as the primary prey item, very few actual stomach contents have been analyzed, and care must be invoked in any interpretation. Stomach contents from *Z. cavirostris* caught off Japan varied consistently, with a predominance of squid from animals taken in waters slightly under 1000 m in depth, but fish are the most abundant prey item found in animals in deeper waters. This evidence has been interpreted to suggest that *Z. cavirostris* is somewhat opportunistic in its feeding habits. Most of the prey items listed are open ocean, mesopelagic, or deep-water benthic organisms, concurring with the idea that *Z. cavirostris* is an offshore deep-diving species. Ectoparasites that have been reported include the barnacles *Xenobalanus* sp. from the flukes and dorsal fin and *Conchoderma* sp. on the erupted apical teeth. The following internal parasites have been reported from *Z. cavirostris*;

Nematoda, *Anisakis* sp., *Crassicauda boopis*, and *Crassicauda crassicauda*; and Cestoda, *Phyllobothrium* sp.

IV. Behavior and Physiology

Recent studies have demonstrated that *Ziphius* can dive to 1888 m and stay submerged for up to 85 min while foraging using echolocation clicks and buzzes.

V. Life History

The minimum length at sexual maturity is 527 cm for females, which average 580 cm at sexual maturity (Heyning, 1989). Males average 550 cm at sexual maturity. There are no detailed studies of age, though females have been estimated at 30 years of age and males at 36 years. The mean length at birth is 270 cm.

VI. Interactions with Humans

In the past, there have been few small cetacean fisheries that have taken *Ziphius*. In the Japanese *Berardius bairdii* fishery, *Z. cavirostris* have been taken on an opportunistic basis with catches of varying from 3 to 35 animals taken yearly. Although the *Berardius* fishery continues, there has been no takes of *Z. cavirostris* in recent years. It is probable that killer whales occasionally prey on *Z. cavirostris*.

Association of mass stranding of *Ziphius* and naval sonar exercises leads one to speculate that repeated deep dives lead to supersaturation of the blood with nitrogen and abnormal behavioral responses resulting in stranding (Cox *et al.*, 2006). In addition, ship noise may disrupt their behavior.

Dall's Porpoise

Phocoenoides dalli

THOMAS A. JEFFERSON

I. Characteristics and Taxonomy

Typical of the porpoise family, Dall's porpoise has a stocky body, and it has a short, wide-based, triangular dorsal fin (Fig. 1). The dorsal fin is slightly falcate at the tip, but the entire fin may be canted forward in adult males (Jefferson, 1990). The tail stock is deepened, especially in adult males, and males also have a prominent post-anal hump of connective tissue. There is an extremely short, poorly defined beak. The flippers and flukes are small, and the fluke blades may also be canted forward in older individuals.

The color pattern is diagnostic. "Dall's" are largely dark gray to black with a large, ventrally continuous white patch that extends up about halfway on each flank. In addition, there is light gray to white frosting, or trim, on the upper part of the dorsal fin and on the trailing edges of the flukes. Some other light patches may exist, particularly around the base of the tail stock. Newborn animals are muted in color and do not have the fluke and dorsal fin frosting, which develops with age in older animals.

There are two major color morphs, one with a flank patch that extends forward to about the level of the dorsal fin (*dalli* type) and the other with a flank patch extending to about the level of the flippers (*truei* type). These forms were variously considered as separate species and subspecies in the past, but most recent work suggests that they are in fact color variants, with few or no other phenotypic

Figure 1 Dall's porpoise mother and calf killed in a Japanese salmon driftnet south of the Aleutian Islands in the mid-1980s. Such large-scale kills have now been much reduced, due to a United Nations ban on oceanic driftnet fishing.

differences. However, genetic analyses have confirmed that they do form separate populations (Escorza Trevino *et al.*, 2004), and Rice (1998) still considered them as separate subspecies. Other color types (all-black, all-white, and forms intermediate between *dalli* and *truei* types) have also been observed.

Dall's porpoises reach maximum known lengths and weights of about 239 cm and 200 kg. Males grow longer and heavier than females, and adult males have secondary sexual characteristics (as discussed earlier). There is a great deal of geographical variation; size, shape, and coloration differences have been documented among different areas of the species' range (Amano and Miyazaki, 1992).

The **SKULL** of Dall's porpoise is larger than that of most other phocoenids and may reach 340 mm in length. The rostrum is wide at the base and relatively short. There are prominent "maxillary shields" that make an angle of about 130° with the rostrum axis (Houck and Jefferson, 1999). Tooth counts are highly variable, but generally number 21–28 per tooth row. The **TEETH** are shaped like grains of rice (not strongly spatulate, as in *Phocoena*) and are extremely small, the smallest of any species of cetacean. They often do not rise above the level of the gums and are considered by many to be rudimentary. Dall's porpoises have an unusual skeleton, with extremely long, slender dorsal, and lateral processes on the vertebrae. Total vertebral counts generally number 92–98.

Recent studies of mtDNA and morphology suggest that the previous classification of Dall's porpoise and the spectacled porpoise (*Phocoena dioptrica*) in the same subfamily was erroneous (Rosel *et al.*, 1995; Fajardo-Mellor *et al.*, 2006). These two species do not appear to be closely related, and their similarities may be the result of **CONVERGENT EVOLUTION**.

Intergeneric hybrids between Dall's porpoises and harbor porpoises (*Phocoena phocoena*) have been examined and described (Baird *et al.*, 1998; Willis *et al.*, 2004). Free-ranging hybrids are regularly observed around Vancouver Island, British Columbia, suggesting that such hybridization events may not be all that rare and supporting the hypothesis of a close relationship between these two species.

The species was named after William H. Dall, who collected the type specimen in Alaska in 1873. Other English common names include True's porpoise, white-flank porpoise, and spray porpoise.

II. Distribution and Abundance

Dall's porpoise is found only in the North Pacific Ocean and adjacent seas (Bering Sea, Okhotsk Sea, and Sea of Japan), from about 32–35°N (southern California and southern Japan) in the south to about 63°N (central Bering Sea) in the north. When water temperatures are unseasonably cold, they may extend down to around Scammon's Lagoon, Baja California, Mexico (Morejohn, 1979). On rare occasions, they may also go through the Bering Strait into the Chukchi Sea. Up to 10 different stocks are recognized, based on studies of morphology, genetics, and ecological parameters (see review in Houck and Jefferson, 1999). Sex-biased dispersal and migration patterns have been elucidated from molecular genetic analyses (Escorza Trevino *et al.*, 2004).

Dall's porpoise is a cold-water species, avoiding tropical/subtropical waters. This is an oceanic species that is found in deep offshore waters, but also in deeper nearshore and inshore waters along the west coast of North America. There are seasonal inshore–offshore and north–south movements in both the eastern and western North Pacific (Forney and Barlow, 1998; Houck and Jefferson, 1999), but in most areas these are poorly defined.

Current global abundance is not well established (due to lack of survey data for some areas and probable biases in available estimates),

but it was thought to number over 1.2 million individuals in the 1980s (Buckland *et al.*, 1993). There are thought to be around 104,000 along the Pacific coast of Japan, 554,000 in the Okhotsk Sea, 83,000 in Alaska, and 100,000 along the US west coast.

III. Ecology

Prey of Dall's porpoise include a wide variety of small fishes and cephalopods (several dozen species have been identified—see Houck and Jefferson, 1999). The most common prey items include schooling fishes (such as herrings, anchovies, mackerels, and sauries), mesopelagic fishes (such as myctophids and deep-sea smelts), and squids. KRILL, decapods, and shrimps have been found in some stomachs, but these are not considered to be common prey items. Amano and Miyazaki (1992) found that the skulls of Dall's porpoises grew to larger sizes in areas with higher productivity, suggesting that food availability may affect growth. Dall's porpoises in some areas appear to feed preferentially at night on vertically migrating fish and squid associated with the deep scattering layer (DSL).

Dall's are thought to be deep divers and capable of feeding at great depths; however, very few dives have been measured directly. The first dive depth data were obtained from a single individual in the transboundary area between British Columbia and Washington State. Seventeen dives were recorded, the deepest to 94 m (Hanson and Baird, 1998). However, Dall's porpoises are probably capable of much deeper dives.

Several internal parasites have been identified from various areas of the body of this species, and these parasites can cause disease and pathology which can even lead to death (see review in Houck and Jefferson, 1999). The trematode fluke, *Nasitrema*, appears to be particularly serious and has been implicated in the stranding and subsequent deaths of several specimens. Whale lice have also been found on the external surface of the body.

Large sharks, and especially killer whales, are predators. Several attacks by killer whales on Dall's porpoises have been observed in recent years, and it appears that killer whales may be major predators on this species, at least in Alaskan waters.

IV. Behavior and Physiology

Small groups are most common, although large aggregations of several hundred to about one thousand have been reported on occasion (Houck and Jefferson, 1999). Groups of over 20–30 are rather uncommon. Very little is known of the group structure of this species, except that group composition appears to be quite fluid. Recently, evidence of mate guarding behavior, whereby a male maintains longer associations with females (presumably to exclude other males from mating with them) has been documented (Willis and Dill, 2007). This is probably related to a polygynous mating system.

Dall's porpoises are very fast swimming and active animals. They are often seen moving very quickly, slicing along the surface, creating a sloppy, V-shaped splash. These are called rooster tail splashes (Fig. 2). However, aerial behavior, such as breaching and leaping out of the water, is virtually nonexistent. Dall's porpoises are willing and capable bow riders and will converge on the bow of a fast-moving boat from all around. They have even been seen to “snout ride” on bow waves pushed forward by the heads of large whales (like blue and humpback whales). When moving more slowly, they roll at the surface in a subdued behavior more typical of other species of porpoises (Fig. 3).

The physiology of this species has not been extensively studied, but some work mostly related to diving physiology has been done.

Figure 2 Most often when Dall's porpoises are seen at sea, they are swimming very fast and “roostertailing,” as this porpoise is doing while riding the bow wave of a research vessel in Southeast Alaska.

Figure 3 A Dall's porpoise slow rolls in Monterey Bay, California. This is an adult male, based on the forward-canted dorsal fin (the animal is moving left to right).

Dall's have a thin blubber layer, large skeletal muscle mass, thick tracheal cartilage rings, deeply folded vestibular sacs, fatty pads lining the lungs, relatively small brain, and large adrenal and thyroid glands. They also have relatively high blood oxygen content. In addition, they appear to have a relatively high metabolic rate and interestingly, captive animals were never seen to sleep (see review in Houck and Jefferson, 1999).

V. Life History

Growth and reproductive parameters have been estimated for several populations in the central and western North Pacific, based on large samples of specimens killed in various fisheries. Length at birth is about 100 cm. Estimates of length and age at sexual maturity range from about 172 to 187 cm and 4–7 years for females, and from 175 to 196 cm and 3.5–8 years for males (Ferrero and Walker, 1999; see Houck and Jefferson, 1999 for a review). Gestation lasts about 10–12 months. The length of lactation is not well known (but is most likely <1 year). The calving season is in the summer for all populations that have been studied to date, although sometimes calves may be born outside of the main calving season (Jefferson, 1989). There appears to be significant geographic variation in growth and life history parameters.

VI. Interactions with Humans

Small numbers of Dall's porpoises have been kept in captivity in oceanaria and research institutes in the United States and Japan, but most individuals have not survived very long. Due to their poor record of survival in captivity and their apparent intractability, they are not currently a species that is sought after for captive display.

A number of human-caused threats to Dall's porpoise populations have been identified, including environmental POLLUTION and habitat alteration. However, the most serious threats are clearly the various fishery kills of this species (review in Houck and Jefferson, 1999). These include directed kills in Japanese waters and INCIDENTAL CATCHES in various fisheries (most prominently several drift gillnet fisheries) throughout the range. The most heavily impacted populations were those in the central and western North Pacific. Between 1981 and 1990, over 45,000 Dall's porpoises were killed in Japanese driftnet fisheries, and between 1981 and 1994, more than 247,000 were directly taken in a Japanese harpoon fishery (Houck and Jefferson, 1999). Fortunately, these kills have been greatly reduced in recent years.

Delphinids, Overview

RICK LEDUC

I. Introduction

For most species of delphinids, basic aspects of their evolution, physiology, ecology, behavior, and population structure are virtually unknown. Even abundance estimates for many species are very imprecise. For the biologist, dolphin research presents challenges and opportunities in trying to understand individual species and how they fit into marine ecosystems.

II. Taxonomic Overview

The family Delphinidae is one of three extant families (with Phocoenidae and Monodontidae) in the cetacean superfamily Delphinoidea (which also includes two extinct families, Kentriodontidae and Albireonidae). Delphinids likely arose in the mid- to late Miocene (11–12 mya) from kentriodontid-like ancestors and quickly radiated into many different morphological and ecological types. This early radiation produced precursors of many modern forms; many of the early delphinid fossils can be assigned to extant genera, particularly *Tursiops*. Today the Delphinidae is the most speciose family of marine mammals, with 33–35 recognized extant species arranged into 17–19 genera. At present, there is much uncertainty about the evolutionary relationships among the species of delphinids. Of the many recent classifications that have been proposed, two are depicted here. One represents a more traditional view of dolphin taxonomy (Table Ia), and the other is a revised classification based on various recent molecular and morphological phylogenetic analyses (Table Ib). Some of these analyses have led to changes in the number of species in certain genera (*Orcaella* and *Sotalia*) (Beasley *et al.*, 2005; Caballero *et al.*, 2007). In fact, some of the best known genera, such as *Orcinus*, may undergo revision in the number of recognized species (Pitman and Ensor, 2003). There is still uncertainty surrounding the deeper relationships, such as those among the different subfamilies. Also, there will no doubt be additional revisions proposed in the future at the genus level, especially involving the apparently paraphyletic genera *Stenella* and *Tursiops*. In part, this changing nature of delphinid taxonomy is due to the new molecular and analytical tools available to researchers, but it also reflects the uncertainties about evolutionary relationships that have long been recognized by morphological systematists but have yet to be addressed.

III. Morphology

Dolphins have the typical morphological characteristics of toothed whales, such as spindle-shaped bodies, single external blowholes, telescoping of the skull such that the maxillary bones overlap the frontals in the supraorbital region, left-skewed cranial asymmetry, polydonty, and homodonty (in most). In some species, there has evolved a secondary reduction in the number of teeth, often seen as an adaptation for feeding on squid. The evolution of the delphinoid lineage saw the development of elaborate systems of pterygoid sinuses and better-isolated ear bones, probably increasing their ability to echolocate and perhaps giving them an advantage over some of the other odontocete groups of the Miocene. The presumed ancestors of the delphinids, the kentriodontids, were small dolphins

with short to medium length rostra and, unlike most modern delphinoids, had symmetrical cranial vertices. The development in the Delphinidae of asymmetry in the cranial vertex and in the premaxillary bones suggests a further refinement of their echolocation capabilities and may partly explain their evolutionary success. The most noticeable difference between delphinids and their closest relatives, the phocoenids (true porpoises), is that the latter have spade-shaped teeth while delphinids have conical or peg-like teeth, as do most other odontocetes (toothed whales). They also differ from phocoenids in the shape of the facial region of the skull, including having a more distinct vertex. Within the Delphinidae, the most obvious variation among species relates to the feeding apparatus—the development of the rostrum, jaws, and teeth. There is a broad spectrum

of rostrum lengths and widths, tooth counts, and tooth sizes, reflecting the range of ecological niches occupied by the different species. For example, total tooth counts range from less than 10 in *Grampus griseus* (which has no teeth in the upper jaw) to 250 in *Stenella longirostris*.

Delphinids also show wide variation in their external morphology. Only a few species (e.g., *Orcinus orca*, *Globicephala* spp.) are dramatically sexually dimorphic, although many others may have subtler dimorphism in body size and shape, coloration, and dorsal fin shape. In size they are small to medium cetaceans, with adults ranging from less than 1.5 m (*S. longirostris* from the Gulf of Thailand, some species of *Cephalorhynchus*) to over 9 m (*O. orca*). External rostrum (beak) length varies widely, from very long on some (e.g., *Delphinus delphis tropicalis*) to very short on others (e.g., *Lagenorhynchus albirostris*). The external beak is completely absent in a number of delphinids with short bonyrostrum in the skull, particularly in *Orcinus*, *Globicephala*, *Feresa*, *Pseudorca*, and *Peponocephala*. Those species that lack an external rostrum often have heads that are rounded or even bulbous in profile. In most delphinid species, the dorsal fin is pointed and falcate, although it is triangular in some subspecies of *S. longirostris* and in male *O. orca*, round in *Cephalorhynchus hectori*, and even forward canted in males of *S. longirostris orientalis*. The dorsal fin is completely missing in *Lissodelphis* spp., and *Sousa* spp. has a pronounced hump at the base of its dorsal fin. The color patterns of delphinids are similarly varied, from bold black and white patterns (e.g., *O. orca* and some of the *Cephalorhynchus* spp.) to complex patterns of black, white, and gray (e.g., *Delphinus* spp. and *Stenella* spp.) to rather simple patterns of black (e.g., *Globicephala* spp.) or gray (e.g., *Sousa* spp.). The complex color patterns exhibited by some delphinids are composites of various elements, including stripes, capes, overlays, spots, and blazes (Perrin, 1973). Regardless of their overall color and pattern, all dolphins tend to have a countershaded aspect, where the ventral surface is lighter than the dorsum. This countershading reduces an animal's visibility in the marine environment, where the ambient light comes from above. Besides being a mechanism for species recognition, the more complex patterns may also play a role in camouflage against waves at the surface or against the dappling of light penetrating the water.

IV. Distribution and Habitat

As a group, the family Delphinidae reaches its highest diversity in tropical and warm-temperate latitudes. There are numerous species with pantropical distributions and others that occur in tropical waters but are limited to one or two ocean basins (Rice, 1998). For example, *Stenella frontalis* and *S. clymene* are limited to the lower latitudes of the Atlantic Ocean, while *Tursiops aduncus* and *Orcaella brevirostris* only occur in the Indian and west Pacific Oceans. In colder areas one can find species in the genera *Globicephala*, *Cephalorhynchus*, *Lissodelphis*, and *Lagenorhynchus* (including *Sagmatias* and *Leucopleurus* of Table Ib). Interestingly, genetic evidence suggests that the majority of these cold-temperate species appear to be closely related (subfamily Lissodelphininae in the classification of Table Ib). Only one recognized species (*Globicephala melas*) has an antitropical distribution, although some antitropical species pairs [e.g., *Lissodelphis* spp., *Lagenorhynchus* (or *Sagmatias*) *obscurus/obliquidens*] have been hypothesized as being single species with antitropical populations. Only one species, *O. orca*, ranges into high latitudes near the polar ice. Indeed, occurring also in mid- and low latitudes, this species is probably the most cosmopolitan of all the cetaceans.

Within this broad range of geographic distributions, delphinids occupy an equally diverse array of habitats. Many species occur far

offshore in deep water, where the specifics of their ecological requirements are poorly known. In fact, in tropical seas, only the cetacean fauna of the eastern tropical Pacific has been extensively and systematically studied; here some differences in the species composition have been observed in different water masses (Au and Perryman, 1985). Areas with a stable mixed layer and a shallow thermocline are frequented by *Stenella attenuata*, *S. longirostris*, and *Steno bredanensis*, while areas with more variable conditions and some amount of upwelling contain species such as *Globicephala macrorhynchus*, *Delphinus delphis*, *Stenella coeruleoalba*, and *Peponocephala electra*. In any ocean, some of the offshore species may also range closer to the coast (e.g., *D. delphis*), or even have populations or sister species that are restricted to the coastal waters or the nearshore habitat (e.g., *D. capensis*, coastal populations/species of *Tursiops*). In a few cases, coastal populations may ascend a short distance up rivers, but only two species (*Sotalia fluviatilis* of South America and *O. brevirostris* of the Asian Indo-West Pacific) regularly occur far upstream. These two species also present a contrast in patterns of divergence. The former has a sister species occurring in coastal waters of middle and South America on the Atlantic side (*S. guianensis*), while the latter has shown no such divergence between coastal and riverine species, instead having a sister species in Australia and New Guinea (*O. heinsohni*). These cases illustrate how speciation can occur across ecological boundaries or across discontinuities in geographical distribution.

V. Social Organization and Behavior

All dolphin species are social to some degree. However, characteristic group sizes for the different species range from small pods of just a few individuals to large schools numbering in the thousands. Due to the difficulty of observing dolphins in the wild, especially those occupying offshore habitats, very little is known about the behavior and social organization of most species. The populations that have been studied over longer time scales (e.g., *O. orca* in the northeast Pacific and *Tursiops truncatus* in the western Atlantic) are those that form relatively stable and small social groups within a short distance of the coast. By using photos to identify individuals via fin markings and color patterns, and by supplementing observations with genetic data, associations of individuals and their genealogical relatedness have been recorded and monitored over generations. In these populations, some long-term associations and patterns have been noted. For example, it appears that bonds between individuals in a pod and/or between individuals and a particular area (philopatry) tend to be stronger for females than males; the society can even be considered matrilineal for *O. orca*. A similar pattern was inferred from molecular data on *G. melas* in the North Atlantic. However, one must be cautious in extrapolating these social patterns to other delphinid species. For example, some species that occur on the high seas are found in schools that number in the thousands, and these associations appear much more fluid in their composition. In fact, social patterns observed for inshore groups of species like *T. truncatus* and *O. orca* may not even reflect the organization of offshore populations of the same species. What little is known about the social organization of offshore dolphins comes from direct observations of school sizes and from life history data collected from mass strandings and fishery kills. In the few pelagic species studied (primarily *S. attenuata* and *S. longirostris*), there is evidence for promiscuity, strong mother-calf bonds, and some segregation by age and sex both within and between schools.

In addition to their intraspecific social organization, most dolphin species are seen at least occasionally in the company of other species. One famous association is between *S. attenuata* and *S. longirostris* in

the eastern tropical Pacific, an aggregation that also includes yellowfin tuna (*Thunnus albacares*) and numerous species of seabirds. Other associations are frequently observed, such as *P. electra* associated with *Lagenodelphis hosei*, or *T. truncatus* with *G. macrorhynchus*. A few species, such as *Lissodelphis borealis*, have been observed with a wide variety of marine mammals, including mysticetes and pinnipeds.

Most of the information on the behavior and cognition of individual dolphins comes from studies of captive animals, primarily of *T. truncatus*. Apart from humans, dolphins have the highest ratio of brain size to body mass of any animal. Their intelligence and behavioral versatility is legendary and is still being explored. Using controlled experiments, dolphins have been shown to be capable of understanding complex commands, including the incorporation of abstract concepts and variations of syntax, of devising novel behaviors of their own volition, and of self-recognition. Although behavioral activities in the wild are more difficult to interpret, there are well-documented observations of cooperative hunting (e.g., *O. orca*), play behavior (e.g., *T. truncatus*), and even tool use (*T. truncatus*). In fact, *T. truncatus* has been observed surfing in many coastal areas, and many dolphin species are avid riders of the bow-wakes of ships and large whales. Some species regularly perform aerial maneuvers such as high leaps and flips and, in the case of *S. longirostris*, spins. At the present time, the function of many of these behaviors can only be guessed at. Dolphins also have an array of vocalizations such as clicks, whistles, and squeals, which are used in part for their well-developed echolocation and in part for communication. However, only those species kept in captivity have been extensively studied. For the rest, due to the logistic difficulties of collecting data on fast-swimming dolphins in the pelagic realm, the vocalizations of those species that have been recorded are difficult to understand in terms of functionality. There has been recent progress made in developing methods to use recorded vocalizations to identify dolphin species, but the complexities and similarities of the calls of certain species (e.g., *Stenella* and *Delphinus* spp.) make this a difficult endeavor.

VI. Feeding

Ecologically, dolphins have also radiated dramatically. There are species that forage on fish, squids, and/or other invertebrates. A few species (e.g., *O. orca*, *Pseudorca crassidens*) even take mammalian prey, including large whales and pinnipeds. While some have fairly specific diets, a few species have rather broad tastes. In those species that eat a wide variety of prey items, one type of food (e.g., fish vs squid) may predominate. For some species (e.g., *S. coeruleoalba*), the preferred food type varies among populations, while in others (e.g., *S. attenuata*), it may even vary among individuals within a population depending on their sex and life history stage. Perhaps the most dramatic segregation of foraging strategies is seen in the populations of *O. orca* in the eastern North Pacific, where two distinct groups exist in sympatry, one specializing on mammals and the other on fish (mostly one species of salmon). Individual species of delphinids usually forage in a particular part of the water column, specializing in epipelagic prey (e.g., *S. attenuata*), mesopelagic prey (e.g., *Lissodelphis* spp.), or even benthic prey (e.g., some species of *Cephalorhynchus*). The few measurements of swimming speeds (often anecdotal) suggest that some may exceed 20 knots in short bursts, although prolonged cruising speeds are generally on the order of 5–9 knots (9–17 km/h). Direct data on diving depths for wild delphinids are practically nonexistent. However, *S. longirostris*, a relatively small species, is thought to dive to at least 200–300 m, based on an analysis of prey items. Greater depths are no doubt possible for larger species (e.g., *Globicephala* spp.) that feed mainly on larger squid. In fact, a trained pilot whale

(*Globicephala* sp.) is thought to have reached 610 m in an experimental situation. At the other extreme, certain populations of two dolphin species have been known to intentionally beach themselves in pursuit of prey. In one case, groups of *T. truncatus* drive and pursue schooling fish onto the beach and in the other, *O. orca* beach themselves to take pinnipeds hauled out near the water's edge. The behavioral adaptability of dolphins may be best illustrated by those species that incorporate human activities into their foraging, such as the *Sousa chinensis* that feed on trawl discards or the *O. orca* that raid longlines for their catch. Along the Gulf of Mexico coast of the United States, there are even some *T. truncatus* that feed within shrimp trawl nets, many of whom are "caught," released, and netted again.

VII. Reproduction

As with many aspects of dolphin biology, there is much that is unknown about the reproductive biology of most species, although many of the parameters seem to be correlated with body size. Estimated ages at attainment of sexual maturity range from about 6 (*D. delphis*) to 16 (*O. orca*). Like most mammals, when the age at sexual maturation differs between the sexes, it is usually the females that reach maturity at a younger age. Like other cetaceans, dolphins bear single young. Gestation periods are rarely well documented and are thought to range from about 9 months to 16 months, although most last less than a year (16 months was an estimate for *G. melas*). Most species appear to show at least some seasonality in their breeding, although this varies in degree. Estimates of calving intervals similarly vary, even among populations within species or among studies, ranging from just over a year for many species to approximately 8 years in one study of *O. orca* from the eastern North Atlantic. Reliable estimates of longevity are quite rare, but range from around 20 years for the smaller species up to about 60 years for females of the larger species. In the large species, which tend to be more sexually dimorphic, females may live 15–20 years longer than males. The causes of natural mortality, when they can be ascertained, are usually parasites, pathogens, or predation by killer whales or sharks.

VIII. Abundance and Conservation

Some delphinid species are no doubt the most numerous of cetaceans, occurring in schools of thousands in large portions of the world ocean. Reliable global estimates for most species do not exist, but in the eastern tropical Pacific alone, some species (*S. attenuata*, *D. delphis*) number in the low millions. At the other end of the spectrum, species with restricted ranges (e.g., *C. hectori*) may have total populations of only a few thousand. In spite of (and in some cases because of) their general abundance, dolphins face numerous anthropogenic threats. They are still hunted in some parts of the world by harpoon, drive fisheries, or nets. Two well-known examples are the drive fisheries for *S. coeruleoalba* in Japan and for *G. melas* in the Faeroe Islands. There are many other smaller dolphin fisheries still in operation, mostly in developing countries, often in spite of the protection of assorted laws and treaties. Usually the meat from intentional takes is for human consumption, although in some areas it is used as bait for crab pots or shark longlines. In addition to the mortality from directed fisheries, many dolphins are also taken incidentally in the course of other fishing operations. The dolphin mortality from the eastern tropical Pacific tuna purse-seine fishery has been well studied and greatly reduced in recent years. However, many dolphins of a variety of species are still caught in coastal and offshore gillnets all over the world (Perrin *et al.*, 1994). It is difficult to accurately assess the severity of these threats to dolphin

populations, given that the extent of the mortality can only be roughly guessed at in most cases and the sizes of the affected populations are largely unknown. Nevertheless, mortality from fisheries bycatch may present major threats to some dolphin populations.

Compounding the impact of these direct kills are indirect effects from human activities. In some areas, large-scale fishing operations may adversely affect dolphin populations, either by direct competition for prey or by alteration of a region's ecology. Pollution also undoubtedly takes its toll on dolphin health, particularly in coastal areas, either by direct poisoning effects or by making the animals more susceptible to pathogens and parasites. Subtle effects on fitness like decreases in reproductive capacity or shortened lifespans are almost impossible to detect, but large-scale mortalities are difficult to ignore and are not at all unusual. There have been mass strandings in recent years along the Mediterranean coast, in the southeastern United States, and in the Gulf of California in Mexico. These large-scale die-offs often involve multiple species (although one species usually predominates) and may occur over periods of several months. It is difficult to determine if such mass mortalities are increasing in frequency in recent years because historical events may not have been adequately documented. It is also difficult to assess their impact on dolphin populations. Nevertheless, they are a cause for concern if for no other reason than as indicators of the declining health of marine ecosystems.

Dental Morphology, Evolution of

MARK D. UHEN

Modern marine mammals exhibit some of the most highly derived dentitions in all of Mammalia. Among cetaceans, living odontocetes exhibit a wide variety of conditions from the polydont delphinids to the complete lack of teeth in some ziphiids. Living mysticetes completely lack teeth as adults. Add to this even more divergent conditions in fossil mysticetes, odontocetes, and their early forebears, the archaeocetes, and the result is a broad range of conditions in which is embedded the story of how modern cetacean dentitions arose from the more typically mammalian teeth of early artiodactyls (Fig. 1).

The herbivorous Sirenia and Desmostylia are distinct but related orders. Modern dugongids lack functional teeth as adults and modern trichechids have a highly derived pattern of serial dental eruption. Desmostylian teeth are also highly derived, but in a very different fashion when compared to sirenians (Fig. 1, 2).

Pinniped dentitions (Fig. 2) are general, simplified compared to other those of their relatives, terrestrial carnivores, and they lack the carnassial pair typical of carnivoran dentitions (fourth upper premolar, P4/, and the lower first molar, M/1). Different pinniped dentitions have become specialized for various feeding modes from the large peg-like teeth of molluscivorous odobenids to the delicate, denticulate cheek teeth of the crabeater seal for filter feeding on krill.

I. Cetacea

A. Archaeocetes

Archaeocetes are diphyodont and heterodont with their incisors in line with the cheek teeth and separated by diastemata (a gap between teeth). The anterior teeth are conical and single rooted, and the premolar series forms a morphological gradient from the anterior teeth to the posterior premolars, and usually smaller molars. The molars have basins, where teeth occlude during chewing, but these are smaller than in related land mammals. Archaeocetes often exhibit vertical wear facets on the buccal (cheek side) surfaces of the lower molars that resulted from contact with the lingual (tongue side) surfaces of the upper cheek teeth during chewing (O’Leary and Uhen, 1999). Clementz *et al.* (2003) studied diet using isotopes.

I. Non-Basilosaurid Archaeocetes Non-basilosaurid archaeocetes have a dental formula of 3.1.4.3/3.1.4.3 (three incisors, one canine, four premolars, and three molars per half jaw), that they share with early artiodactyls and other early mammals and that distinguishes them from the later basilosaurids. Non-basilosaurid archaeocetes have two

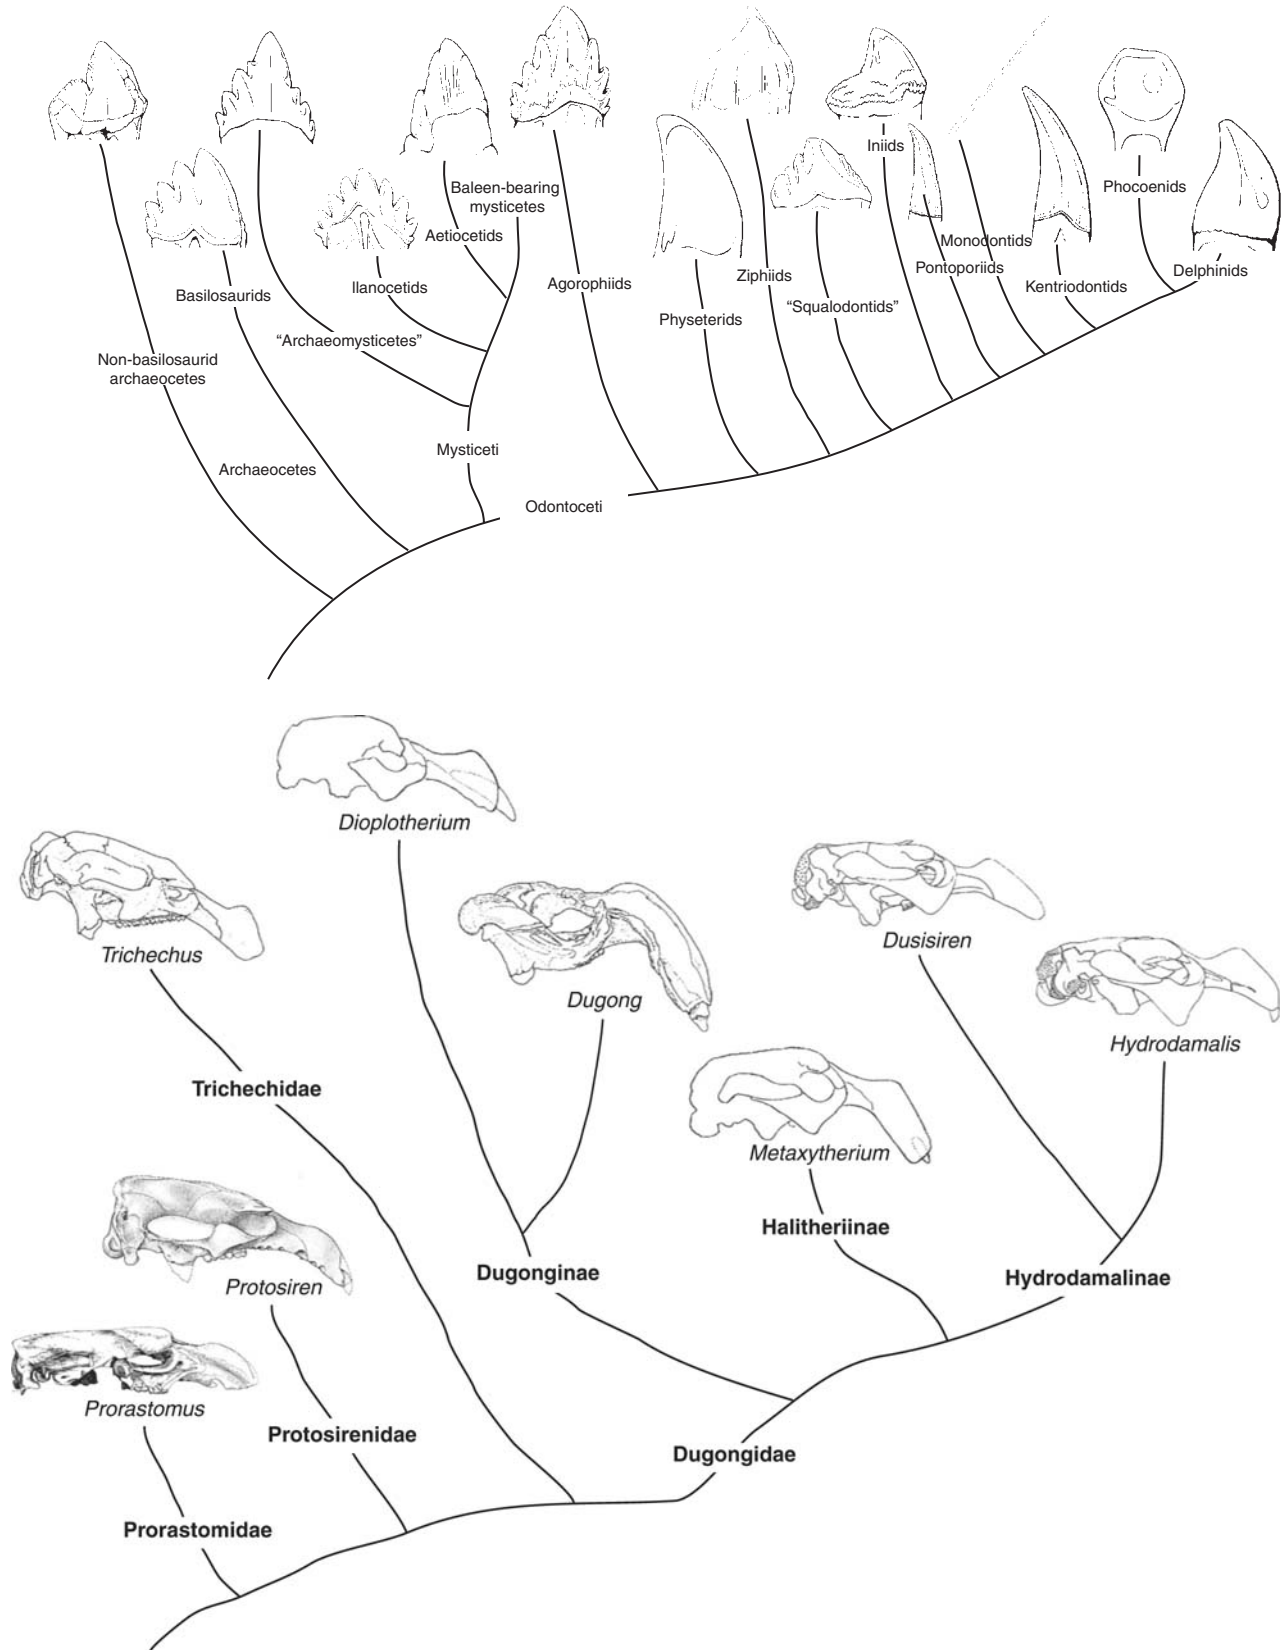

Figure 1 Phylogenetic relationships of cetaceans with examples of dental morphology. For those cetaceans with heterodont teeth, molars (posterior cheek teeth) are shown (top). Phylogenetic relationships of Sirenia (after Domning, this volume; bottom).

cusps on the buccal side and one on the lingual side. Between these cusps (elevated areas) are basins (depressed areas) in which a cusp from the opposite side (upper or lower) occludes. Ambulocetids have a protocone lobe on the lingual side of the upper molars that is smaller than that in pakicetids, and larger than that in remingtonocetids and protocetids (Thewissen *et al.*, 1996). Remingtonocetids have labiolingually narrow incisors and premolars; upper molars large and narrow, sometimes lacking a lingual third root, and crenulations on the cutting edges of the teeth, which distinguishes them from other non-basilosaurid archaeocetes (Gingerich *et al.*, 1995; Kumar and Sahni, 1986). Protocetids have robust teeth with upper molars having three roots and the cheek teeth lacking accessory denticles.

2 *Basilosauridae* Basilosaurids differ from other archaeocetes in that upper and lower first premolars are replaced in dorudontine basilosaurids, but it is unclear how broadly this character is distributed within the archaeocetes (Uhen, 2000). Basilosaurids lack M^3 , giving them a dental formula of 3.1.4.2/3.1.4.3. The cheek teeth of basilosaurids have accessory denticles (small cusps) along their crests. It is unclear whether any (or all or none) of the accessory denticles are homologous with more primitive mammalian cusps. Basilosaurid molars lack basins in which teeth occlude.

B. Neoceti

The fossil record of archaeocetes ends in the late Eocene. Mysticeti and Odontoceti can be distinguished from archaeocetes. Even though modern mysticetes lack teeth as adults, they develop embryonic tooth buds that are later resorbed (Karlsen, 1962). In addition, early fossil mysticetes have well-developed teeth as adults (Emlong, 1966; Mitchell, 1989; Barnes and Sanders, 1996). Even a late-occurring archaeocete has been described that may be monophyodont (Uhen and Gingerich, 2001). Early mysticetes and odontocetes are similar to archaeocetes in that they are heterodont, with a morphological gradient from conical, single-rooted anterior teeth to triangular (or rounded) multi-rooted cheek teeth with accessory denticles.

1. *Odontoceti* Modern odontocetes can be generally characterized as being polydont, monophyodont, with single-rooted teeth that grow throughout life, but there are numerous counter examples to these generalizations, in both modern and fossil cetaceans discussed below. The earliest odontocetes show only limited polydony, with *Agorophius* having eight, and *Xenorophus* with ten (Fordyce, 1982 and references therein). Polydony could have originated by intercalation of deciduous and permanent teeth, and could have been further increased in later odontocetes by the addition of supernumerary teeth, but it would be difficult to explain why no odontocete is known that exceeds three teeth in the premaxilla under this scenario (Fordyce, 1982). The description of early mysticetes with one extra molar in each quadrant (Barnes and Sanders, 1996) may indicate that polydony arose prior to the split of Mysticeti and Odontoceti by terminal addition of teeth, although many other toothed mysticetes are not polydont (Emlong, 1966; Fordyce, 1982).

All modern and fossil odontocetes are thought to be monophyodont (Fordyce, 1982). It is unclear whether the teeth of modern odontocetes are homologous with the deciduous or adult teeth (or both), of archaeocetes. One archaeocete that appears to possess adult teeth in a skeletally juvenile individual suggests that the teeth of all Mysticeti + Odontoceti may be adult teeth (Uhen and Gingerich, 2001), but Karlsen (1962) suggested that the embryonic

tooth buds of mysticetes were homologous with the deciduous dentition of more primitive mammals.

The early odontocetes Agorophiidae (including *Xenorophus*), Simocetidae, Waipatiidae, Squalodontidae are all considerably heterodont. Their anterior teeth are conical with long, single roots. These teeth grade into teeth with a more triangular shape with multiple accessory denticles on the anterior and posterior edges of the teeth and two roots. The most posterior lower cheek teeth may lack accessory denticles on their anterior edges. These differences in tooth form are reminiscent of the differences along the tooth rows of archaeocetes, but the teeth are smaller compared to the size of the skull.

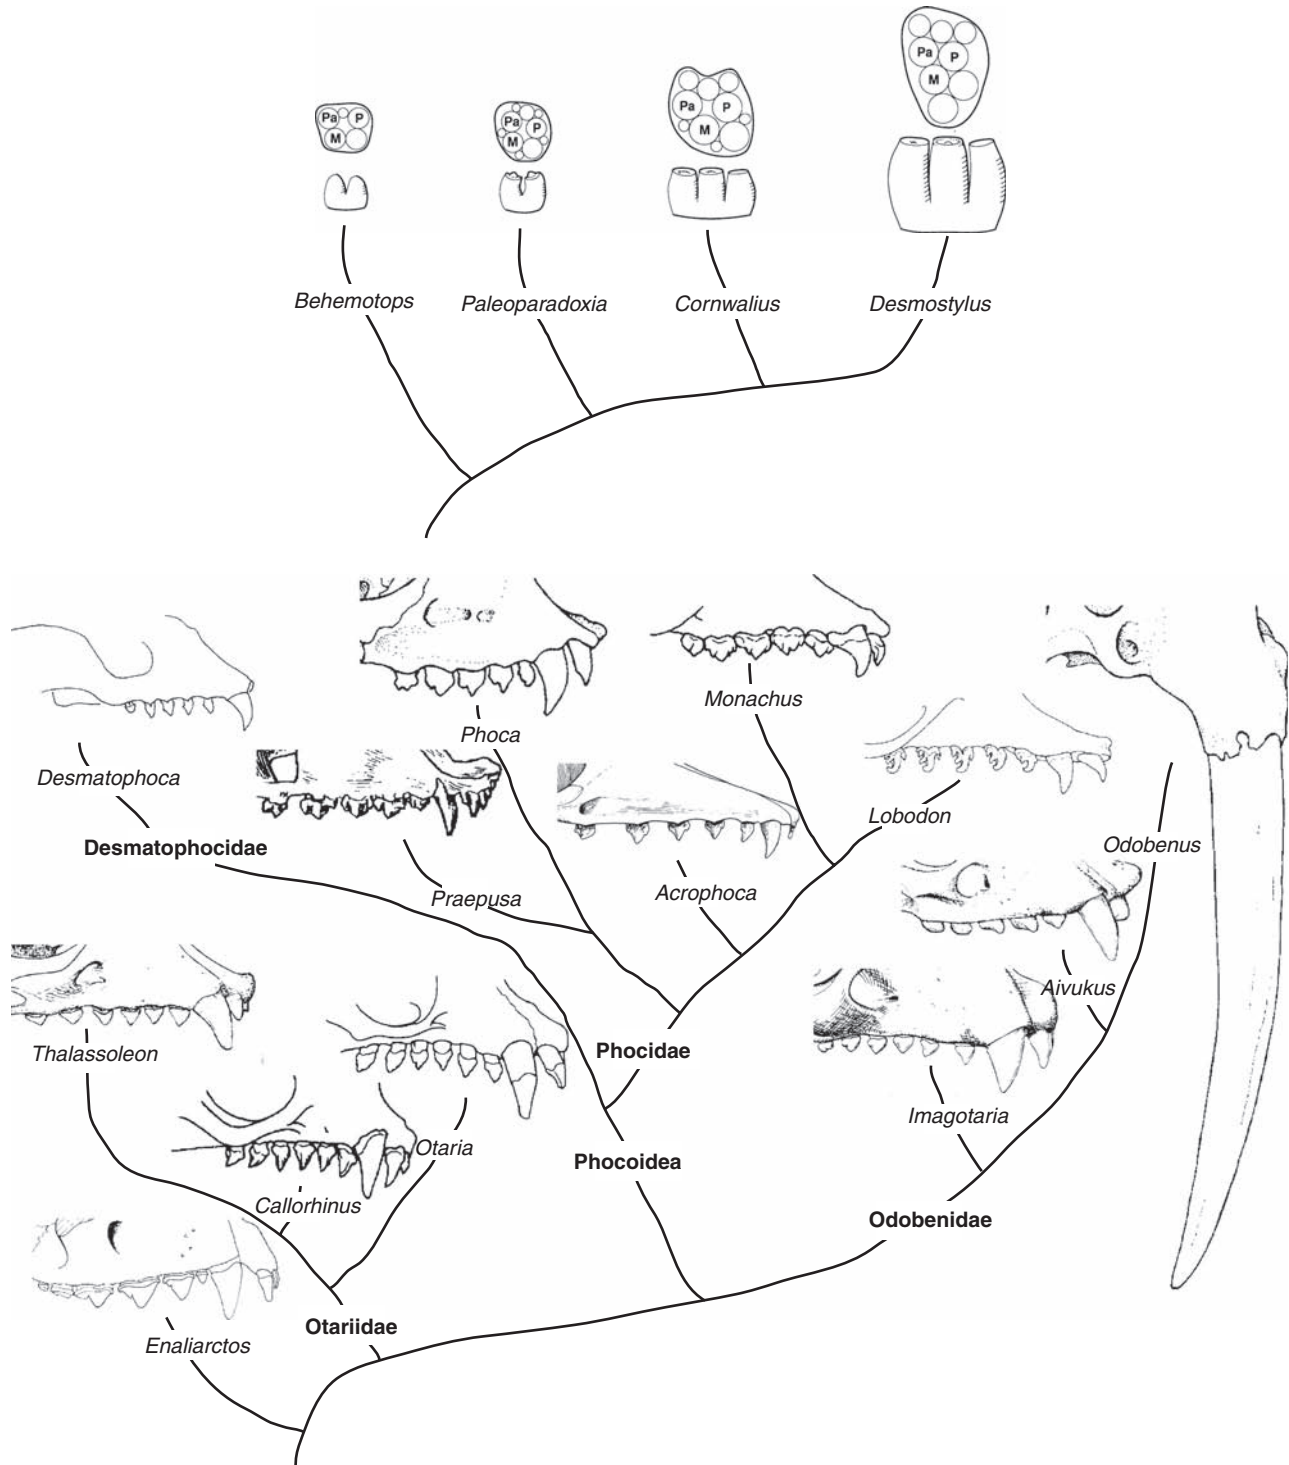

Modern physeteroids lack upper teeth (although some anomalous specimens have tiny upper teeth that do not erupt), but some fossil representatives (like *Scaldicetus* have similarly sized teeth in the lower and the upper jaws (Hirota and Barnes, 1995). Ziphiidae are thought to have secondarily reduced the dentition from a primitively polydont condition. One modern species, *Tasmacetus shepherdi*, and additional fossil species are polydont. In other modern species, the female usually lack teeth entirely, and males have one tooth on each side of the lower jaw, and none in the upper jaw. Iniidae have rugose heterodont teeth that are expanded lingually in the posterior portion of the jaw. Monodontidae have very reduced dentitions. Male narwhals (*Monodon monoceros*) have a single, long, spiral tusk, usually on the left side with a small unerupted tooth on the right. Females usually have two unerupted teeth. One fossil monodontid, *Odobenocetops*, has a walrus-like skull with one large tusk-like tooth, and another shorter tusk on the opposite side (de Muizon, 1994). Members of the extinct Kentriodontidae have small conical teeth that are generally homodont, a feature shared with one of their likely descendants, the Delphinidae, but not with another, the Phocoenidae, which have numerous small spatulate teeth that are embedded in the gums.

2. *Mysticeti* Despite the lack of teeth in modern mysticetes they are thought to have evolved from toothed ancestors in part because they develop tooth buds as embryos that are later resorbed (Karlsen, 1962) and many tooth-bearing early mysticetes are known from the Oligocene epoch (Fordyce and Barnes, 1994). All post-Oligocene mysticetes are baleen bearing and lack teeth (Fordyce and Barnes, 1994).

One group of toothed mysticetes includes species with archaeocete-like teeth (Fordyce, 1989; Barnes and Sanders, 1996). *Llanocetus denticrenatus* from the late Eocene of Antarctica (Mitchell, 1989) has teeth that are similar in size to those of archaeocetes and the cheek teeth are similarly double rooted and have accessory denticles. Some species have an extra molar in each quadrant over the count of basilosaurids, yielding three upper and four lower molars (Barnes and Sanders, 1996). These teeth may have been used to filter food from seawater, since the teeth generally lack wear resulting from tooth/food contact (Mitchell, 1989). Fitzgerald (2006) suggested that the large-toothed mysticetes (archaeomysticetes, *Mammalodon*, and *Janjucetus*) were not filter feeders, but were macrophagous predators.

The second group of toothed mysticetes includes species that all have tiny teeth that are conical anteriorly and have tiny denticles posteriorly, but are all single rooted, the Aetiocetidae. Some aetiocetids have the plesiomorphic number of teeth for archaeocetes (11), while others are polydont. Aetiocetids may have had some form of proto-baleen, and may have used this baleen and their small teeth for filter feeding.

The earliest baleen-bearing mysticetes that lack teeth are the Eomysticetidae, from the early Oligocene of South Carolina. All

D

Figure 2 Phylogenetic relationships of Desmostylia with examples of molar dental morphology. (after Domning, this volume; top). Phylogenetic relationships of pinnipeds (after Berta, this volume; bottom).

baleen-bearing toothless mysticetes belong to the Chaemysticeti. All known post-Oligocene mysticetes belong to the Chaemysticeti, and are thus toothless. Modern mysticetes use several modes of feeding, and have different sizes and shapes of baleen plates, but they are all bulk feeders, and use their baleen for prey capture.

II. Sirenia

All Eocene sirenians have a dental formula of 3.1.5.3/3.1.5.3. Unfortunately, sirenian cheek teeth are relatively similar and not diagnostic of specific clades. These teeth are low crowned with two rows of large, rounded cusps (see SIRENIAN EVOLUTION). Some

sirenians, particularly within the Dugongidae, developed tusks which were used for feeding on seagrass rhizomes, even though modern *Dugong* uses its tusks primarily for interactions with other individuals. (Domning and Beatty, 2007).

The Dugongidae diversify and some show a tendency to evolve large, blade-like incisor tusks (Domning, 2001). Modern *Dugong* is unusual in that it has reduced its cheek teeth to open-rooted, ever-growing pegs whose enamel crowns wear off, leaving flat surfaces of dentin. Modern *Dugong* has 5 or 6 functional cheek teeth per quadrant, and the teeth are replaced from the rear, with new teeth erupting in the rear of the tooth row, and the anteriormost tooth being resorbed and lost (Husar, 1978a). Steller's sea cow, *Hydrodamalis gigas* completely lacked teeth, and instead had keratinous pads for mastication.

Trichechidae (Manatees) are derived from basal dugongids that were diphyodont. In contrast, modern *Trichechus* have 5–7 functional cheek teeth per quadrant at one time. Teeth are replaced in the rear, and migrate forward, yielding a significant number of supernumerary teeth, but it is not clear how many teeth eventually erupt (Husar, 1978b). The earliest fossil form to exhibit this type of tooth replacement is *Ribodon*, from South America and North Carolina (Domning, 2001).

III. Desmostylia

Desmostylia are diphyodont and heterodont with a large diastema separating the anterior teeth from the cheek teeth. The procumbent incisors are caniniform and the canines are tusk-shaped in some desmostylians. The premolars become more complex and molariform from anterior to posterior. The cheek teeth are bunodont, with large cusps and thick enamel. As the teeth wear, the tips of the cusps wear away, leaving a ring of thick enamel surrounding an area of dentine (Domning, 2002), and eventually evolving in teeth that look as an agglomeration of a large number of conical enamel tubes (Fig. 2; Inuzuka *et al.*, 1995).

The dental formula of desmostylians changes over their history. *Behemotops*, has a dental formula of 3.1.4.3 (Inuzuka *et al.*, 1995); *Paleoparadoxia* has a dental formula of 3.1.3.3; *Desmostylus japonicus* has a dental formula of 0.1.2.3/2.1.2.3 (Kohno, 2002); and *Desmostylus hesperus* has a dental formula of 0.0.2-1.3/2.1.1.3 (Kohno, 2002). Thus, desmostylians undergo a pattern of upper incisor loss over their evolutionary history.

IV. Pinnipedia

The earliest known pinniped is *Enaliarctos* (Berta *et al.*, 1989). *Enaliarctos* has a dental formula of 3.1.4.2/3.1.4.2, which represents a loss of M^3 compared to basal Carnivora, as well as basal Arctoidea. *Enaliarctos* also has small upper molars relative to the premolars when compared to other arctoids, and to other pinnipeds as well (Berta, 1991). *Enaliarctos* shares with other pinnipeds a reduction and/or loss of the M_1 entoconid, reduction and/or loss of the M_1 hypoconid, and reduction and/or loss of the upper molar cingulum, suggesting a reduction in the carnassial function of the teeth (Berta, 1991).

Crown group Pinnipedia (to the exclusion of *Enaliarctos* and *Pteronarctos*) is characterized by the loss of the embrasure pit between P^4 and M^1 , loss of the P^4 protocone, and the loss of M_2 , indicating a further reduction in the carnassial function of the teeth (Berta, 1991).

Otariidae have a dental formula of 3.1.4.0-3/2.1.4.1-2, including a molar count that varies both within and among the genera (Kubota

and Togawa, 1964; Repenning and Tedford, 1977; Nowak, 1999). Otariid third incisors are enlarged and caniniform (Nowak, 1999). The premolars and molars are similar in morphology. Cheek teeth in *Thalassoleon* are double rooted (Repenning and Tedford, 1977), as they are in some modern otariids (Repenning, 1977). All otariids have relatively homodont, generally conical cheek teeth (Repenning, 1977).

Phocoidea (Phocidae + Desmatophocidae) have a dental formula of 2-3.1.4.0-2/1-2.1.4.0-2 (Nowak, 1999; Deméré and Berta, 2002). Most phocids retain more complex tooth crowns than most other pinnipeds, with at least three distinct cusps on each crown (Nowak, 1999). The earliest known named phocid, *Devonophoca*, retains an M^1 with three roots, which is similar to the condition in the M^1 of *Enaliarctos* (Koretsky and Holec, 2002). Long-snouted phocids such as *Acrophoca* have relatively small cheek teeth with large diastemata between them, which also sport embrasure pits (de Muizon, 1981). Modern *Lobodon* has elongate, recurved cusps on the cheek teeth which it uses to filter feed krill from sea water when the lower and upper dentitions are occluded (Adam, 2005).

Odobenidae are characterized by a progressive reduction and simplification of the dentition. More basal odobenids, such as *Imagotaria*, retain a plesiomorphic dental formula (3.1.4.2/3.1.4.1 or 2) and a plesiomorphic dental morphology, with single roots on P_{2-4} , which are however, bilobed. (Repenning and Tedford, 1977). *Aivukus* has a more reduced dental formula (2.1.4.1/2.1.4.1) and more simplified, peg-like teeth as well. All of the lower teeth are circular in cross-section, single-rooted, solid columns of dentine with a heavy layer of cementum (Repenning and Tedford, 1977). *Aivukus* also possessed an enlarged canine which eventually closed its root, so was not ever growing (Repenning and Tedford, 1977). Modern *Odobenus* has a variable number of teeth, with the most common dental formula being 1.1.3.0/0.1.3.0. The teeth are reduced to dentine pegs except for the greatly enlarged canine tusks. The tusks can reach 100-cm long in males and 80-cm long in females (Nowak, 1999).

Desmostylia

DARYL P. DOMNING

The Desmostylia are the only completely extinct order of marine mammals. They were hippopotamus-like amphibious herbivores (Fig. 1) that were confined to the North Pacific Ocean and are known only as fossils of Oligocene and Miocene age. [For comprehensive references to the published literature on desmostylians, see Domning (1996).]

I. Desmostylian Relationships, Origins, and Distribution

Desmostylians have undergone more of a taxonomic odyssey than perhaps any other mammals. Although they were placed initially (and afterward, most commonly) among either the Sirenia or the Proboscidea, various authors later assigned them to the Monotremata, Marsupialia, Multituberculata, or an order of their own. The latter view prevailed only in 1953. Today they are classified in the supraordinal group Tethytheria together with the living Sirenia and Proboscidea; the Proboscidea are probably their sister group. The teeth of the most primitive desmostylians closely resemble those of anthracobunids, early tethytheres which are sometimes considered true proboscideans (Domning *et al.*, 1986; Gheerbrant *et al.*, 2005).

Since the most primitive known desmostylians, as well as other early tethytheres, are found in Asia, this continent, bordering the eastern part of the ancient Tethys Sea, is likely to have been the area where this order arose, probably during the Paleocene or Eocene. However, desmostylians do not appear in the fossil record until the early Oligocene, about 30 million years ago. By that time they had already spread to the North American shore of the Pacific; and from then to their extinction some 20 million years later, they inhabited the North Pacific littoral from Japan to Baja California.

Figure 1 Skeleton of *Paleoparadoxia tabatai*, a Miocene desmostylian, in terrestrial pose. Total length about 2.2m. Note hyperextension and anterolateral direction of front toes, anterior direction of hind toes, and strong abduction of knees. From Domning (2002), reproduced with permission of the Smithsonian Institution Press.

II. Anatomy and Mode of Life

The desmostylian skull (Fig. 2) features a more or less long, narrow, and little-deflected rostrum; dorsally protruding orbits; a stout paroccipital process; an external auditory meatus nearly enclosed ventrally by contact of the posttympanic and postglenoid processes; and a large epitympanic sinus opening into the temporal fossa. The dental formula is primitively 3.1.4.3, with procumbent, transversely aligned incisors and canines; the lower canine is especially enlarged. The fourth lower deciduous premolar is primitively trilobed. The body (Fig. 1) is stout and compact, with a relatively short neck, a deep thorax, a broad sternum with paired plate-like sternbrae, a strongly arched lumbar spine, and a very reduced tail. The limbs are robust, with considerable torsion in the tibia and an ankle joint that is oblique to the tibial shaft (conditions also seen to varying degrees in many noncursorial land mammals). The metacarpals are longer than the metatarsals. The bones show some osteosclerosis (increased density) but no pachyostosis (increased volume).

Controversy over desmostylians' structure and posture has even surpassed the disagreements over their classification (Inuzuka *et al.*, 1995). Once complete skeletons were discovered, showing that they possessed four stout limbs and were capable of some sort of locomotion on land, paleontologists and artists created a startling variety of reconstructions, including ones resembling hippopotami, tapirs, sea lions, crocodiles, and creatures unlike anything else (Inuzuka, 1982). The interpretations presented most recently and defended in the most detail have portrayed them as hauling out in the manner of sea lions (Repenning; see Repenning and Packard, 1990), as walking with the limbs sprawled in a "herpetiform" stance (Inuzuka; e.g., Inuzuka *et al.*, 1995), or as keeping the legs under the body in a more conventional land-mammal fashion, with resemblances to ground sloths (Domning, 2002; Fig. 1).

In contrast, their aquatic behavior has occasioned little argument. Their style of swimming is generally agreed to have been like that of polar bears; i.e., alternate paddling with the forelimbs while the hind limbs were used for steering. Because desmostylian fossils are found exclusively in marine deposits, there has also never been any doubt expressed that they were strictly marine mammals, despite the lack of clearly aquatic specializations in their skeletons.

The peculiar, heavily enameled tooth structure of the more highly derived desmostylians has occasionally led to suggestions that they fed on molluscs or other shelled prey. However, these teeth tend to be high crowned, like those of grazing ungulates, rather than low, broad, and pavement-like as seen in animals that do crush shellfish. Moreover, the teeth of earlier desmostylians closely resemble those of undoubted herbivores. Hence a diet of marine plants for all desmostylians is now generally conceded.

III. Diversity

Only about seven genera and fewer than a dozen species are currently recognized in this order (Table I). They are currently grouped into two families, Paleoparadoxiidae (*Behemotops*, *Paleoparadoxia*) and Desmostylidae (*Ashoroa*, *Cornwallius*, *Kronokotherium*, *Desmostylus*, and *Vanderhoofus*). All these taxa, so far as is known, had broadly similar postcranial skeletons, and they are distinguished mainly by details of skull and dentition.

The most primitive form named so far is the Oligocene *Behemotops*, an animal nearly the size of a Nile hippopotamus and with low crowned, anthracobunid-like teeth (Ray *et al.*, 1994). The Miocene *Paleoparadoxia* is similar, but has a more retracted nasal opening, fewer premolars, and a long postcanine diastema. *Cornwallius*, another late Oligocene genus, shows a tendency for the molar cusps to become more columnar. This trend continued

Figure 2 Skull and mandible of *Desmostylus hesperus*, a Miocene desmostylian, in dorsal, lateral, and ventral views (immature specimen). The left mandibular angle is broken and the large right dental capsule is visible. Note the columnar cusps of the molars. A, nasal aperture; B, basisphenoid; Ch, choana; Cn, nuchal crest; Cnh, hypoglossal canal; Coc, occipital condyle; Cs, supraorbital canal; F, frontal; Fasq, anterior squamosal foramen; Fio, infraorbital foramen; Fj, jugular foramen; Fl, foramen lacerum; Fmd, mandibular fossa; Fmg, foramen magnum; Fov, foramen ovale; Fpa, parietal foramen; Fpma, greater palatine foramen; Fpmi, lesser palatine foramen; Fpz, postzygomatic foramen; Fst, stylomastoid foramen; Lt, temporal crest; M, maxilla; M1, M2, upper first and second molars; N, nasal; O, occipital; Or, orbit; P4, upper fourth premolar; Pae, external auditory meatus; Pal, palatine; Par, parietal; Pm, premaxilla; Pp, paroccipital process; Sd, dental capsule; Sep, epitympanic sinus; T, squamosal (temporal); Ta, articular tubercle; Tm, muscular tubercle; Tp, pharyngeal tubercle; V, vomer; Z, zygomatic (jugal). From Inuzuka (1988), reproduced with permission of the Geological Survey of Japan.

TABLE I
Genera of Desmostylia and Their Temporal Range

Genus	Range
<i>Behemotops</i>	Early to late Oligocene
<i>Paleoparadoxia</i>	Early to late Miocene
<i>Ashoroa</i>	Late Oligocene
<i>Cornwallius</i>	Late Oligocene
<i>Kronokotherium</i>	?Early to ?middle Miocene
<i>Desmostylus</i>	Early to late Miocene
<i>Vanderhoofius</i>	Middle Miocene

in the Miocene with the genera *Kronokotherium*, *Vanderhoofius*, and *Desmostylus*; the latter name, meaning “bundle of columns,” expresses the appearance of a molar in these most highly derived and characteristic members of the group (Fig. 2). The procumbent incisors and canines are variously reduced, sometimes leaving only the large lower canines as digging organs, and the adult cheek dentition comprises only molars.

The diversity of desmostylians was constrained by their limited geographic range and dietary opportunities. Apparently they were adapted to cooler climates than the tropical sirenians, but they seem to have succumbed to competition from these more fully aquatic herbivores as soon as hydrodamaline sirenians evolved the ability to spread into the cool home waters of the desmostylians.

Dialects

JOHN K.B. FORD

Consistent variations in the underwater vocalizations of marine mammals can exist among individuals, groups, or populations. Differences in vocal patterns between geographically isolated populations have been described in several species of pinnipeds and cetaceans. Examples are regional variations in the vocal repertoires of the Weddell seal, *Leptonychotes weddellii* (Thomas and Stirling, 1983), the trill vocalizations of the bearded seal, *Erignathus barbatus* (Risch *et al.*, 2007), and the songs of humpback whales, *Megaptera novaeangliae*, in different ocean areas (Payne and Guinee, 1983). Although these types of variations have occasionally been referred to as *dialects*, they are more appropriately termed *geographic variations* (Conner, 1982). Such differences may result from long-term geographic and, therefore, reproductive isolation leading to genetic distinctions among populations. However, cultural variations may also contribute to acoustic distinctions between marine mammal populations. Pinnipeds and cetaceans are among the few mammalian orders in which vocal mimicry and learning has been documented (Janik and Slater, 1997, 2000). Transmission of vocal patterns across generations may thus depend more on cultural than on genetic mechanisms. Copying errors and other forms of cultural mutation and drift may be responsible for at least a portion of the vocal differences between distant populations. Geographic variation in vocal patterns most likely represents epiphenomena, or byproducts, of social and genetic isolation.

Dialects, which are consistent differences in the vocal repertoires of local, neighboring populations, or groups that can potentially mix and interbreed, likely arise primarily through social learning. Generally rare among mammals, dialects have been described in two cetacean species to date, killer whales (*Orcinus orca*) and sperm whales (*Physeter macrocephalus*). Among pinnipeds, there is evidence for vocal dialects between neighboring sites in Weddell seals (Morrice *et al.*, 1994) and harbor seals, *Phoca vitulina* (Van Parijs *et al.*, 2003).

In coastal waters of the northeastern Pacific, matrilineal kinship groups, or pods, of “resident” killer whales have repertoires of 7–17 call types that vary among pods (Ford, 1991; Yurk *et al.*, 2002). All pods have distinctive features in their call repertoires, and thus each has a unique dialect. Certain pods share a portion of their call repertoires with others, and these are considered to belong to the same acoustic clan; each clan is acoustically distinct. Pods belonging to different clans have overlapping ranges and interact frequently, despite having very different call repertoires. New pods form by gradual fission of older, larger pods, along maternal lines. This process appears to be accompanied by divergence of common dialects, thus dialects reflect the historical matrilineal genealogy of pods within clans. Differences in fine-scale features of call structure exist among closely related matrilineal pods (Deecke *et al.*, 2000; Miller and Bain, 2000). Dialects likely serve as acoustical “badges” that help maintain cohesion and integrity of matrilineal groups and may also serve as an inbreeding avoidance mechanism (Ford, 1991; Barrett-Lennard, 2000). Group-specific dialects have also been found among killer whale groups off Norway (Strager, 1995) and Kamchatka (Filatova *et al.*, 2006).

The other cetacean species with group-specific dialects, the sperm whale, tends also to live in matrilineal groups, although these lack the long-term stability seen in “resident” killer whales. Sperm whale

Diet

NÉLIO B. BARROS AND MALCOLM R. CLARKE

groups were found to have repertoires that consistently varied in the proportional usage of different coda types and classes (Weilgart and Whitehead, 1997). As in killer whales, groups of sperm whales with distinct dialects regularly interact. Geographic variations in coda repertoires was also noted in different oceans and in different areas within oceans (Whitehead *et al.*, 1998), but such variations were weaker than those observed in group-specific dialects within local regions. In the South Pacific, sperm whale groups were grouped into six sympatric acoustic clans based on coda sharing (Rendell and Whitehead, 2003). These clans differed in patterns of movement, habitat use patterns, and feeding success (Whitehead and Rendell, 2004).

The ancestors of present-day marine mammals moved into water, possibly to escape competition on land for food resources, escape predation, or take advantage of relatively abundant food supplies in the seas. Most likely, it was a combination of factors. Eventually, the development of echolocation capabilities in odontocetes (toothed whales) and physiological adaptations for deep and prolonged dives allowed for the exploration of deep waters in search for food. Some groups of cetaceans, such as beaked whales and several phocid seals were able to evolve the ability to dive to great depths and take advantage of food resources unavailable to other predators. From a presumed terrestrial insectivore diet, marine mammals switched largely to fish, squid, and shrimp as main prey (in addition to other crustaceans, mollusks, and zooplankton organisms) (Bowen and Siniff, 1999).

I. Methods of Study

Various methods have been used to gain insight into what marine mammals eat. Their aquatic lifestyle usually limits direct observations of feeding, except in shallow waters in geographical areas where water visibility is good. The following methods have been used to draw inferences on marine mammal diet.

A. Direct Observations of Feeding

This method has been limited to what can be observed above the surface, from a vessel, a vantage point on land, or the air. Although much can be learned from these observations, especially when made systematically in a particular area, subsurface feeding behavior is generally not observed, and the picture obtained on feeding is incomplete, at best. Prey that present aerial behavior (e.g., mullet, flying fish) tend to be overrepresented, whereas bottom-dwelling species (e.g., toadfish, flatfish, octopus) are underrepresented. Modern “crittercam” video cameras mounted on marine mammals (quite successfully on several pinniped species) promise to give us much more direct information on food ingested.

B. Traditional Methods

The traditional method to study marine mammal food habits has been the analysis of food remains present in vomit or scat from living animals, and the stomachs and intestines of stranded animals. This method relies on the finding and identification of structures representing a typical meal, e.g., fish bones and the jaws of cephalopods, often referred to as “beaks” due to their superficial resemblance to beaks of parrots. Fish ear stones (or otoliths), in particular, are diagnostic structures in the identification of prey because their size and shape vary considerably from species to species (Fig. 1) (Härkönen, 1986; Nolf, 1993).

Fish otoliths are calcareous structures (their primary composition is calcium carbonate) and are more resistant to digestion than bones. In life, they are housed in capsules inside the fish’s skull, and their main function in a fish is to provide information on balance and sound reception. Each species of fish has three pairs of otoliths (the sagitta, lapillus, and asteriscus). With a few exceptions (e.g., catfish), the largest pair of otoliths (the sagitta) is also the one most distinctive and recognizable, and the one used in species identification (Smale *et al.*, 1995; Furlani *et al.*, 2007). Similarly, cephalopod beaks possess

Figure 1 Fish ear stones (otoliths) of different sizes and shapes retrieved from stomachs of bottlenose dolphins stranded in Florida.

Figure 2 Cephalopod lower (left) and upper (right) jaws or “beaks” from a giant squid (*Architeuthis*).

morphological features that vary and can be used in the identification of species (Fig. 2). Although the upper beaks have some taxonomic value, the lower beaks are generally the ones used in prey identification (Clarke, 1986a). Beaks are composed of chitin, a similar material to our fingernails and mammal horns, and are not dissolved by digestive processes. Otolith and cephalopod beak lengths correlate well with the length and weight of the animal from which they came; relationships with their weights are described by a power curve. These allow reconstruction of the original meal by weight. Estimates can then be made of consumption of particular prey species by single mammals and, sometimes, their populations. The relationships relating otolith/beak length to animal length are best described by straight lines, which indicate the target lengths of prey species.

The advantages of the otolith/beak method are (1) knowledge of prey composition and size classes allows for understanding spatial and temporal distribution of predators; (2) studies of predator-prey dynamics are possible; (3) prey species may be very poorly sampled by humans using other methods, and diets can give considerable information on the species in an area available to predators; (4) changes in diet during growth and over time can be monitored;

(5) analysis requires low cost or little equipment; and (6) samples can be collected from carcasses in an advanced stage of decomposition.

The disadvantages of this method are (1) prey with no hard parts (e.g., invertebrates) will be underrepresented; (2) different digestion rates of prey can make calculations of reconstructed meal sizes complicated (fish otoliths can last for about 1 day in the gastrointestinal tracts of marine mammals, whereas squid beaks may accumulate for several days or longer); (3) there can be potential bias in using feeding data gathered from stranded (possibly sick) animals, as they may not be representative of the population at large; (4) analyses of food matter present in fecal material (e.g., scats) may present biases, as prey structures can be partially or completely digested through passage in the gastrointestinal tract; correction factors may be necessary to account for such limitations (Bowen, 2000); and (5) a comprehensive reference collection of hard structures (fish otoliths and cephalopod beaks) of the most common prey in a particular area is of great advantage in species identification, but is not always available.

C. Use of Novel Tools (New Technology) to Understand Feeding Ecology

Several new methods of studying diets are likely to become more important with time (Read, 1998).

1. Stable Isotopes The principle of this method is that ratios of heavier vs lighter isotopes of particular elements (carbon, nitrogen, oxygen, sulfur) in tissues of predators can be traced to those of their prey as they are assimilated through the diet (Latja and Michener, 1994; Walker and Macko, 1999).

The following are the advantages of this method: (a) it is ideal to detect shifts in diet; (b) different tissues of the predator yield information reflecting the feeding history relative to the last days, months, or the entire life of the animal; these data can be used to gain insights into the distribution, movements, and migratory habits of the animal; (c) isotopic ratios of carbon reflect those of the primary producers in the area; isotopic ratios of nitrogen are indicative of the trophic level occupied by the organism, which are helpful in understanding habitat utilization and trophic relationships; and (d) historical reconstruction of values through time can yield intraannual and interannual variability in feeding. The disadvantages of this method are that a reference database for the isotopic signature of prey is needed and the cost of the equipment used in the analyses is high.

2. Fatty Acids The fatty composition of a prey is species specific and, as these compounds are assimilated through the diet and accumulated in the fatty tissues of predators (e.g., blubber of marine mammals), they can be used as tracers of diet (Iverson *et al.*, 1997; Wetzell and Reynolds, 2004; Budge *et al.*, 2006). Fatty acid analysis can be useful in (a) reconstructing diets in time and space; (b) population studies of various marine mammal species using different feeding grounds; (c) studies of energetic transfers between mother and their offsprings; and (d) the application of the technique to free-ranging animals, which can be done by the relative noninvasive collection of tissue (e.g., through biopsy darts). Similarly in stable isotopes, this method requires a reference database for the chemical signature of the various prey species, and the cost of the equipment is high. In addition, there is stratification of fat in the outer and inner blubber layer of marine mammals, and incomplete sampling of the blubber layer may yield misleading results of dietary information. Additional variability may be associated with from what part of the body the sample is taken, making interstudy comparisons difficult.

3. *Molecular Identification of Prey* This method involves the genetic identification of material from scats, stomach contents, and gut bacteria, which must be separated prior to analysis. The disadvantages of this method are that a reference database for the genetic signature of prey is needed and there might be biases associated with prey DNA survival during digestion (Deagle and Tollit, 2007). However, the increased application of this method to marine mammal dietary studies (Purcell *et al.*, 2004; Casper *et al.*, in press; Dunshea *et al.*, in press) reflects the potential of this tool.

4. *Video-Taping Studies (Using "Critttercams") of Animals Feeding at Depth* This method has the following advantages: (a) it documents the actual feeding behavior of the predator, and the identity of the prey species can be verified by the images; (b) prey behavior during detection and capture can be documented; and (c) different feeding strategies can also be observed (e.g., cooperative feeding). Among the disadvantages (a) only captures of a few species can be observed; (b) ambient light must be relatively bright and the water must be clear; (c) there is difficulty in the attachment and recovery of the equipment (video camera); and (d) there are high costs associated with the equipment and its operation.

5. Acoustics

A. **DIGITAL ACOUSTIC RECORDING TAGS (D-TAGS)** Placing of acoustic tags in deep-diving cetaceans, such as beaked and sperm whales, has allowed the recording of ultrasonic clicks and the returning echoes of potential prey (Johnson and Tyack, 2003; Johnson *et al.*, 2004; Madsen *et al.*, 2005; Zimmer *et al.*, 2005; Watwood *et al.*, 2006). The computerized instruments record whale movements, depth, and sounds on dives, which shed light into whales' foraging behavior at great depths.

B. **PREY TARGET STRENGTH** This method estimates the abundance of prey in the wild by measuring the target strength of the individual organisms that potentially comprise the prey spectrum (Benoit-Bird and Au, 2001; Benoit-Bird *et al.*, in press). The advantages of acoustic sampling vs other direct methods, such as trawling, are cost-effectiveness, a less biased assessment of overall biomass and relative composition of the prey field, and the potential of examining prey variability in larger spatial and temporal scales.

In summary, although identifying and measuring items in vomit, scats, and stomach contents have many disadvantages, it provides more information at considerably less cost than other methods and cannot be replaced effectively by any other method at present.

II. Diets in General

Marine mammals, all together, eat a great variety of animals from minute crustaceans, less than 1-mm long, to giant squids, over 15 m in length. These disparate prey live in a wide range of habitats, from the shallow shelf seas and estuaries to over 2000-m deep in the deepest oceans, from near the water surface to the ocean bottom. The animals consumed vary in texture from soft-skinned and gelatinous octopods to hard-scaled, muscular fish and vary in mobility from sedentary clams to jet-propelled squids. The three species of manatees (*Trichechus* spp.) and the dugong (*Dugong dugon*) of the order Sirenia rely on sea grasses and river plants; they are grazers in the true sense.

All this variety in food organisms has led to many specializations in structure. Most obviously, the mouth has developed a great variety of tooth numbers, sizes, and shapes or, for those eating very small organisms, a special filter made of horny plates, frayed on one edge, the baleen. Various species dive to greater depths, thus permitting

an extension of their feeding grounds from the continental shelves, down the continental slopes, to depths exceeding 2000 m. Similarly, thickening of their fatty blubber layer has permitted further extension of their feeding grounds into the cold waters of the Antarctic and the Arctic. The diet of any species reflects its adaptations; its mouth adaptations make it possible for it to catch certain types and sizes of prey. The actual species that compose the diet depend on its own and on the prey's depth and geographic distribution.

Another property of the food is quality. Crustaceans, fish, and cephalopods vary in protein, fat, and mineral constituents and proportions. Marine mammal species can sometimes shift between these three groups during a year, as supply fluctuates or during their own migrations, but this may drastically affect their physical condition and health. Even within one of these major groups, the protein content, for instance, may vary greatly so that change to another species of prey as the main food item might markedly affect the predator. This is likely to be important when the mammal shifts from a diet of shellfish, which are very muscular, to deep-living oceanic fish, which are generally lower in protein content. Similarly, shelf-living cephalopods are mainly soft-bodied, have weak muscles, and are low in protein so that twice as much has to be eaten. The high acidity and presence of ammonium salts in high concentration in some soft-bodied squids also probably require special adaptations of digestive processes.

The food of rarer marine mammals, and species that have not been caught for their oil, is not well known. Knowledge depends on information from occasional strandings, and stomach contents are often difficult to collect because of the size of the carcass. Debris from the stomachs only occasionally includes complete, readily identifiable, prey animals. Usually information on diet has to be obtained from hard pieces, mainly fish otoliths and cephalopod beaks.

A. Cetaceans

1. *Baleen Whales (Mysticeti)* These possess baleen plates, and all but the gray whales (*Eschrichtius robustus*) collect swarming animals by skimming through the water or by gulping. They therefore primarily eat shoaling plankton or small nekton together with a few larger animals, such as fish and squids, caught with the shoals (Kawamura, 1980).

A. **RIGHT WHALES (BALAENIDAE AND NEOBALAENIDAE)** These five species (three right whales, *Eubalaena* spp., the bowhead whale, *Balaena mysticetus*, and the pygmy right whale, *Caperea marginata*) have very long baleen plates hanging from the roof of the mouth, whose finely frayed inner edges can trap very small plankton. They mainly eat small crustaceans ranging from minute copepods less than 1-mm long, favored by the bowhead whale of the northern seas and the pygmy right whale to small euphausiid crustaceans called "krill" as much as 25-mm long, eaten by the southern right whale (*Eubalaena australis*). The bowhead is also known to eat a small molluscan called a pteropod.

B. **GRAY WHALE** This species has very tough baleen plates that become worn, particularly at the right side, by rubbing on the sea floor from which it principally sucks, by piston action of its tongue, bottom amphipod crustaceans and mollusks and bristle worms.

C. **RORQUALS (BALAENOPTERIDAE)** These species have shorter baleen plates than right whales and generally favor larger prey than copepods. Blue whales (*Balaenoptera musculus*) eat midwater crustaceans, mainly krill, in the Antarctic and other euphausiid species in the North Pacific and the North Atlantic. The fin whale

(*B. physalus*) eats krill in the Antarctic but in the North Pacific it broadens its diet to include fish such as clupeids, muscular squids, and a copepod. It eats the fish capelin in the North Atlantic. Humpback whales (*Megaptera novaeangliae*) eat mainly krill or “lobster krill” in the Southern Hemisphere, but mainly anchovies and cod in the Northern Hemisphere. Assorted squid are also eaten by humpback whales. The sei (*B. borealis*) whale eats 20 species of densely shoaling midwater crustaceans, including krill and copepods, in addition to anchovy, cod, and assorted oceanic squids. Minke whales (*B. acutorostrata* and *B. bonaerensis*) eat assorted crustaceans in the Arctic and the Antarctic seas, and also fish, including anchovy, in the North Pacific and herring in the North Atlantic. They also take assorted midwater squid in the south tropical seas and appear to rely more on fish than other baleen whales. Bryde’s whales (*B. brydei* and *B. edeni*) eat crustaceans, including krill, but also various fish, including mullet and anchovy in the Southern Hemisphere and anchovy in the North Pacific.

2. *Toothed Whales (Odontoceti)* Within this group, comprising 7 families and 52 species, teeth are developed and the main prey items are fish and cephalopods. The cetacean species that live on the continental shelf eat muscular fish, such as herring (*Clupea* spp.), pilchards, whiting, and soles; muscular cephalopods, such as inshore squid, cuttlefish, and octopods, are occasionally taken as well. Odontocetes living in the deep ocean eat mainly lantern fishes and soft-bodied, often gelatinous, squids. Around oceanic islands, both lantern fishes and more muscular species, such as horse mackerel and trumpeter fish, are often taken.

A. **DOLPHINS (DELPHINIDAE)** In 45% of the species in this family, cephalopods comprise over 75% and fish less than 25% of the diet (Clarke, 1986b). In 24% of the species, cephalopods comprise 50–75% and fish 25–50%. Depending on the species of dolphin, the diet can be muscular species living on the continental shelf, as for many populations of the short-beaked common dolphin (*Delphinus delphis*) and the common bottlenose dolphin (*Tursiops truncatus*); or as in spinner (*Stenella longirostris*) and spotted dolphins (*S. attenuata* and *S. frontalis*) the diet may include many soft-bodied oceanic species. However, on the whole, dolphins favor muscular squid rather than soft-bodied ones, even in oceanic waters; this also applies to pilot whales (*Globicephala* spp.). A few species include other prey groups in their diet, e.g., Commerson’s dolphins (*Cephalorhynchus commersonii*) eat some krill and killer whales (*Orcinus orca*) also prey on seals and other cetaceans.

B. **PORPOISES (PHOCOENIDAE)** In half of the species in this family, cephalopods comprise over 75% and fish less than 25% of the diet. In the other half of the species, cephalopods comprise 50–75% and fish 25–50%. Being inshore cetaceans, food consists of common (often economically important to humans) species including muscular inshore squid, cuttlefish, and octopus, as well as fish such as herrings, whittings, and bottom-living soles.

C. **BEAKED WHALES (ZIPHIIDAE)** In over half the species of beaked whales, more than half of the food is cephalopod and the rest is fish. These whales are deep divers and at least one species favors soft-bodied squids. The number of teeth is much reduced in this family and, in one species, the strap-toothed beaked whale (*Mesoplodon layardii*), the two teeth in the lower jaw grow over the upper jaw and limit it to a narrow gape. It is remarkable that this does not seem to inhibit capture of oceanic squids.

D. **NARWHAL (MONODON MONOCEROS) AND BELUGA (DELPHINAPTERUS LEUCAS), MONODONTIDAE** The diet of the narwhal includes

fish such as Greenland halibut (*Reinhardtius hippoglossoides*) and polar cod (*Boreogadus saida*), muscular squid, and shrimp. The suggestion that the long tooth of male narwhals is regularly used to stir prey from the mud is unlikely to be true. Beluga feed on fish such as capelin (*Mallotus villosus*) and sand lance, as well as larger species such as cod and flounder. Sand- and bottom-living worms show that they probably feed on the bottom as well as in midwater.

E. **SPERM WHALES (PHYSETERIDAE AND KOGIIDAE)** All three species feed mainly on squids, although a few fish are taken, including large sharks. Sperm whales (*Physeter macrocephalus*) eat mainly deep-living oceanic squids, and most of these are soft-bodied or gelatinous, luminous, and weak swimmers. Contrary to common belief, the average weight of their prey is not great, varying from 0.5 kg off South Africa to 7 kg in the Antarctic, although some large sperm whales can eat squids over 15 m in length. Pygmy and dwarf sperm whales (*Kogia breviceps* and *K. sima*) eat some of the same species as their larger relative but, because they spend some time on continental shelves, they also include muscular, shelf-living squids and octopods (Clarke, 1996).

F. **RIVER DOLPHINS (INIIDAE, PONTOPORIIDAE, LIPOTIDAE, PLATANISTIDAE)** This group includes four species of dolphins, three of which inhabit the freshwater systems of major rivers in South America, China (but recently declared extinct), and the Indian subcontinent. The fourth species has a marine distribution and is found in coastal waters of the Atlantic coast of South America. The riverine species feed on a variety of freshwater fish (including sharks) and prawns, and occasionally also prey on other groups, such as freshwater turtles. As cephalopods are strictly marine in distribution, they are not part of the diet of riverine dolphins. The marine species in this group (the “franciscana,” *Pontoporia blainvillei*) eats mainly bottom-dwelling fish, coastal species of cephalopods, and several species of shrimp.

B. Pinnipeds [Seals, Sea Lions, Walruses (*Odobenus rosmarus*)]

All but 2 of the 36 species of pinnipeds (seals and sea lions) probably include both fish and cephalopods in their diet. The exceptions inhabit freshwater systems where cephalopods do not occur. Most pinniped species inhabit coastal regions or seas close to oceanic islands, which partly influences their choice of diet (Klages, 1996).

1. *Fur Seals and Sea Lions (Otariidae)* Of the 16 species, 10 take benthic cephalopods and 11 eat midwater squids. At least 14 eat muscular cephalopods and 3 of these eat oily squids whereas only 1 eats soft-bodied squids. Three species consume all these on the continental shelf, whereas 8 eat them in oceanic waters.

A. **NORTHERN FUR SEAL (CALLORHINUS URSINUS)** On the continental shelf this species eats primarily small shoaling fish and muscular squids. In offshore waters, they eat mainly muscular oceanic squids.

B. **GUADALUPE FUR SEAL (ARCTOCEPHALUS TOWNSENDI)** They eat oceanic cephalopods and lantern fish.

C. **JUAN FERNANDEZ FUR SEAL (A. PHILIPPII)** They apparently eat muscular, oceanic squids.

D. **GALÁPAGOS FUR SEAL (A. GALAPAGOENSIS)** This species mainly eats muscular, oceanic squids.

E. **CAPE AND AUSTRALIAN FUR SEALS (A. PUSILLUS)** They eat both shelf and oceanic fish and cephalopods, as well as both midwater and bottom species. They favor muscular rather than soft-bodied cephalopods.

F. NEW ZEALAND FUR SEAL (*A. FORSTERI*) This species eats not only midwater fish and muscular cephalopods, but also takes penguins.

G. ANTARCTIC FUR SEAL (*A. GAZELLA*) They eat mainly krill in the Antarctic, but further north take oceanic fish, as well as muscular and soft-bodied squids.

H. SUBANTARCTIC FUR SEAL (*A. TROPICALIS*) They eat oceanic squids, both muscular and soft-bodied.

I. STELLER SEA LION (*EUMETOPIAS JUBATUS*) They eat muscular, bottom octopods as well as oily oceanic squids, and polar cod.

J. CALIFORNIA, GALÁPAGOS, AND JAPANESE SEA LIONS (*ZALOPHUS CALIFORNIANUS*, *Z. WOLLEBAEKI*, AND *Z. JAPONICUS*) These species eat shelf-living, muscular squids, and octopods, as well as muscular, oceanic squids.

K. SOUTH AMERICAN SEA LION (*OTARIA FLAVESCENS*) They eat mainly bottom and midwater shelf fish and also take some shelf cephalopods.

L. AUSTRALIAN SEA LION (*NEOPHOCA CINEREA*) This species eats shelf octopods and cuttlefish.

M. NEW ZEALAND SEA LION (*PHOCARTOS HOOKERI*) This species eats shelf fish, cephalopods, and crustaceans.

2. *Earless (true) Seals (Phocidae)* This group eats a variety of fish, cephalopods, and crustaceans of both inshore and oceanic species, depending on their locality. Of the 19 species, at least 15 eat muscular cephalopods, 5 eat oily species, and 4 eat soft-bodied squids. Some slight deviations from this pattern are given.

A. HARP SEAL (*PAGOPHILUS GROENLANDICUS*) This species eats mainly fish and crustaceans, especially amphipods and euphausiids, although both bottom and midwater oceanic cephalopods are also taken.

B. BEARDED SEAL (*ERIGNATHUS BARBATUS*) They eat mainly bottom shelf invertebrates, such as clams, and also fish, in addition to a few species of octopods.

C. GRAY SEAL (*HALICHOERUS GRYPUS*) Gray seals eat schooling fish, squids, octopods, and occasionally sea birds.

D. CRABEATER SEAL (*LOBODON CARCINOPHAGA*) They eat krill almost exclusively.

E. ROSS SEAL (*OMMATOPHOCA ROSSII*) Ross seals eat oceanic species of fish and squids of both muscular and soft-bodied species.

F. LEOPARD SEAL (*HYDRURGA LEPTONYX*) This species eats krill, fish, soft-bodied squids, and occasionally mammals.

G. WEDDELL SEAL (*LEPTONYCHOTES WEDDELLII*) They eat mainly cephalopods, including muscular and soft-bodied species, and bottom octopods.

H. ELEPHANT SEALS (*MIROUNGA ANGUSTIROSTRIS* AND *M. LEONINA*) These species eat oceanic species, including muscular, soft-bodied, and oily species and, seasonally shelf squids.

3. *Walrus* These are benthic feeders in shallow Arctic seas at depths less than 100m. Their main food is clams but they also eat a small quantity of bottom octopods and have been known to attack other seals.

C. Sea Otter (*Enhydra lutris*)

These generally eat bottom invertebrates on the continental shelf, usually very close to shore, including clams, sea urchins, and other

invertebrates. However, especially in the northern distributions of their range, they also feed on fishes.

D. Polar Bear (*Ursus maritimus*)

This species eats mainly harp seals and also feeds on other seals, young beluga and narwhal, young walrus or sick animals, and fish such as Arctic char (*Salvelinus alpinus*). Polar bears also feed on terrestrial species of mammals and birds, on carcasses of bowhead and gray whales, and occasionally on humans. Polar bear males are known to kill and eat cubs of their own kind, possibly in part to incite the female to come into estrus again rapidly.

E. Sirenians

The manatees and dugong feed on tropical grasses and roots and rhizomes in nearshore areas in saline environments and on water hyacinths (*Eichhornia* spp.), water lilies, and other vegetation in rivers and lakes. The extinct Steller's sea cow (*Hydrodamalis gigas*) was a cold-adapted species, last found off the Kamchatka Peninsula in far east Russia; it fed on cold-water kelp.

on land or ice also characterize their distribution. In the polar bear, breeding and cub-rearing terrestrial habitats are also relevant.

In freshwater environments, marine mammals are found in rivers and lakes. Examples of riverine species are the river dolphins (Platanistidae, Iniidae, Lipotidae, and Pontoporiidae) and the manatees. A few Phocidae live in freshwater inland lakes: the Saimaa seal (*Pusa hispida saimensis*) in Finland, the Caspian seal (*Pusa caspica*) in the Caspian Sea, the Baikal seal (*Pusa sibirica*) in lake Baikal, and the Ungava (common) seal (*Phoca vitulina mellonae*) in freshwater lakes of the Hudson Strait.

In marine environments, distribution can be generally described as coastal (in estuarine or near shore waters), neritic (in waters on the continental shelf), or oceanic (in waters beyond the continental slope, in the open seas or oceans). Examples of marine mammals that reside primarily in coastal waters are populations of bottlenose dolphins (*Tursiops* spp.), sea otters (*Enhydra lutris*), and dugongs (*Dugong dugon*). Primarily neritic species include gray whales (*Eschrichtius robustus*), harbor porpoise (*Phocoena phocoena*), and California sea lions (*Zalophus californianus*). Primarily oceanic species include the sperm whale (*Physeter macrocephalus*) and beaked whales (family Ziphiidae). These generalizations should be used with caution, as many species occur in multiple habitats. Some species shift from one habitat to another seasonally, such as the switch from neritic feeding grounds to coastal migratory routes and breeding grounds by gray whales. Some species have populations that reside in a variety of habitats, such as the bottlenose dolphin, which occurs in coastal, neritic, oceanic, and, occasionally, riverine habitats.

Marine mammal distribution can also be classified according to general geographic areas. These are characterized by latitudinal bands and average water temperatures. Thus, marine mammals have tropical and/or subtropical, temperate, Antarctic, or Arctic distributions. Some species can be strictly included in just one of these categories, such as exclusively Arctic species [bowhead whales (*Balaena mysticetus*), polar bear (*Ursus maritimus*), narwhal (*Monodon monoceros*), and beluga (*Delphinapterus leucas*)], but, again, other species often have multiple classifications. A clear example is the baleen whales that migrate from cold high latitudes to tropical low latitudes. Some species, such as the killer whale (*Orcinus orca*) are found in all the marine waters of the world, from the equator to the Arctic and the Antarctic. Finally, similar and closely related species may occupy different latitudinal (hemispheres, ocean basins) or longitudinal (different oceans and seas) ranges. Examples of pairs of similar species that occur in different hemispheres are the northern (*Hyperoodon rostratus*) and southern (*Hyperoodon planifrons*) bottlenose whales and the northern (*Mirounga angoustirostris*) and southern (*Mirounga leonina*) elephant seals. An example of very similar cetacean species with different distribution preferences within the same ocean basin are the long- and short-finned pilot whales (*Globicephala melas* and *G. macrorhynchus*).

Detailed data on distribution are provided in the species account of this encyclopedia and therefore only overall patterns by taxa are given in this section to avoid redundancy. Additional detailed description of marine mammal distribution can be found in the chapters for cetaceans, the sea otter (*E. lutris*), pinnipeds, sirenians, and the polar bear.

A. Cetaceans

Cetaceans live permanently in aquatic environments. They can be found in all the oceans and most of the seas of the world, and distribution patterns vary between and within families. The Balaenidae, the Balaenopteridae, the gray whale, the sperm whale, and the killer

Distribution

JAUME FORCADA

I. Distribution Patterns and Preferences

Marine mammals are found in almost all the different marine environments, and their distribution varies according to the physical, chemical, and biological characteristics of the water masses they use. The effects of oceanographic phenomena, wind-induced movements (e.g., water currents, local divergence, and upwelling areas and water fronts, thermocline depth), and the topography can be used to characterize distribution. In the case of pinnipeds, the haul-out and breeding and molting habitats

whale are found in polar, temperate, and tropical waters. They are found in the Northern and Southern Hemispheres, except gray and bowhead whales, which are only found in the Northern Hemisphere. As noted earlier, other strictly northern and also Arctic species are the narwhal and beluga. The pygmy right whale (*Caperea marginata*) is only found in the Southern Hemisphere. Most delphinids live in tropical and temperate waters of both hemispheres. More tropical Delphinidae are *S. attenuata*, *S. longirostris*, *S. frontalis*, *Steno bredanensis*, *Sotalia fluviatilis*, *Globicephala macrorhynchus*, *Pseudorca crassidens*, *Peponocephala electra*, and *Feresa attenuata*. Other tropical odontocetes are the pygmy (*Kogia breviceps*) and dwarf (*K. sima*) sperm whales, Irrawaddy dolphin (*Orcaella brevirostris*), and many Ziphiidae. Most Phocoenidae live in temperate or subtropical waters with some species exclusively in the Northern Hemisphere (*P. phocoena*, *P. sinus*, and *Phocoenoides dalli*) and some exclusively in the Southern Hemisphere (*P. spinipinnis* and *P. dioptrica*). All Delphinidae of the genus *Cephalorhynchus* live in temperate waters of the Southern Hemisphere. Of the river dolphins, the Amazon River dolphin, *Inia geoffrensis*, lives in the large lakes and tributaries of the Amazon and Orinoco basins. The franciscana (*Pontoporia blainvillei*) lives in the coastal central Atlantic waters of South America, but is commonly found in the mouth of the rivers and ocean waters surrounding estuaries. Similarly, the tucuxi is distributed in both fresh and marine waters. The two subspecies of the family Platanistidae (*Platanista gangetica gangetica* and *P. gangetica minor*) live in the major rivers of India and Pakistan, the Indus and Ganges, and the baiji (*Lipotes vexillifer*), at present considered extinct, lived in the Yangtze river and formerly lived in some of the lakes along this extremely large inland river system.

B. Pinnipeds

Pinnipeds are amphibious mammals and spend most of their life in aquatic environments. However, they must return to land or ice for breeding (giving birth and rearing their offspring) and molt after breeding. Other possible reasons for hauling out are resting, thermoregulation, and escape from predators. Some common characteristics of nonaquatic habitats are space availability, isolation from predators, and proximity to food supply. Pinnipeds with tropical and temperate distributions find these conditions in isolated rookeries or beaches of remote places, which often are on islands. In the Mediterranean monk seal (*Monachus monachus*), terrestrial habitats are secluded spaces and caves with preferably underwater entrance. Ice characteristics condition the distribution and activity patterns of pinnipeds; pack ice offers a more constant substrate than fast ice, which varies highly seasonally in extent. Some pinnipeds reproduce in fast ice, such as the hooded seal (*Cystophora cristata*), and the leopard seal (*Hydrurga leptonyx*) and the duration of lactation and rearing of their young strongly depend on ice conditions. In general, seasonal changes in oceanographic conditions and ice cover condition the distribution of pinnipeds in the pack ice.

Among the Phocidae, geographical or latitudinal distributions include the Arctic, subarctic, and temperate areas, subtropical and tropical areas, and subantarctic and Antarctic areas. Antarctic seals are the Weddell (*Leptonychotes weddellii*), crabeater (*Lobodon carcinophaga*), leopard, and Ross (*Ommatophoca rossii*) seals. A subantarctic and Antarctic seal is the southern elephant seal. In the Northern Hemisphere, tropical and subtropical species are the Hawaiian (*Monachus schauinslandi*), Mediterranean, and the extinct Caribbean (*Monachus tropicalis*) monk seals. Subarctic and temperate-water seals are the gray (*Halichoerus grypus*), harbor (*Phoca vitulina*), and northern elephant seals. Arctic and subarctic seals are the harp (*Pagophilus*

groenlandicus), hooded, bearded (*Erignatus barbatus*), ringed ribbon (*Histiophoca fasciata*), spotted (*Phoca largha*), Baikal (*Pusa sibirica*), and Caspian seal. Among phocids, harp, hooded, bearded, ribbon, spotted, Ross, and leopard seals breed in the pack ice; the crabeater and ringed seals breed in pack and fast ice; the southern elephant seal breeds on land and fast ice; the Baikal and Caspian seals on fast ice; the harbor and gray seals on land and ice; and the northern elephant and the monk seals breed on land. Phocids with coastal and continental shelf distribution are the harp, harbor, gray, bearded, ringed, ribbon, spotted, Weddell, crabeater, leopard, and Mediterranean monk seals. Continental slope and oceanic seals are the Hawaiian monk, northern and southern elephant, Ross, and hooded seals. The walrus (*Odobenus rosmarus*, family Odobenidae) breeds on the pack ice and occurs in waters of the continental shelf. All the Otariidae breed and rear their offspring on land. Most of them disperse after breeding and therefore have neritic and oceanic distributions depending on season and reproductive status. Many Otariidae have subtropical or tropical distributions, such as the California (*Z. californianus*) and Galapagos (*Z. wolfebaeki*) sea lions and the Guadalupe (*Arctocephalus townsendi*) and Galapagos (*A. galapagoensis*) fur seals. The Steller sea lion (*Eumetopias jubatus*) is found from Arctic to temperate waters of the eastern North Pacific. The other sea lions are distributed in tropical and subantarctic waters in the Southern Hemisphere: the Australian (*Neophoca cinerea*), New Zealand (*Phocarctos hookeri*), and South American (*Otaria flavescens*) sea lions. In the Southern Hemisphere, all the fur seals are found in temperate or subantarctic waters: the New Zealand (*Arctocephalus forsteri*), South African (*A. pusillus pusillus*), subantarctic (*A. tropicalis*), Australian (*A. pusillus doriferus*), Juan Fernandez (*A. philippii*), and South American (*A. australis*) fur seals. Only the Antarctic fur seal (*A. gazella*) can be strictly considered subantarctic and Antarctic. In the Northern Hemisphere, the northern fur seal (*Callorhinus ursinus*) is found in the subarctic and temperate North Pacific.

C. Sirenians

All the Sirenia are found in tropical or subtropical waters. The manatees have restricted ranges in different oceans and river systems. The West Indian manatee (*Trichechus manatus*) is found from southern North America and the Caribbean to northern South America in the western Atlantic, and the Amazon manatee (*T. inunguis*) in the Amazon drainage. In the eastern Atlantic, the African manatee (*T. senegalensis*) is found in western Africa, from Senegal to Angola. Manatees are coastal, although they may be found in continental shelf waters, transiting between islands, in the Caribbean. The dugong (*Dugong dugon*) is the most widely distributed sirenian, in the Indian and the western Pacific oceans, with a preference for shallow coastal bays.

D. Polar Bear and Sea Otter

The polar bear has a circumpolar distribution, mostly above the Arctic circle. It uses coastal, neritic waters, and breeds and rears its offspring on ice, inside snow lairs. Ice is also important for polar bears as a platform to travel, especially in the ice floes, between foraging areas and areas where they give birth and rear their young and as a substrate to hunt seals. The time of spring sea-ice breakup is important for polar bear feeding. After hibernation, bears start looking for food for them and their offspring, and an important component of the diet are seals. Sea ice is essential habitat for seals. Without it the seals move to other places, restricting the bear's food supply. The sea otter is found in the Pacific coasts of North America and Russia, essentially in temperate and subarctic waters. It lives

near shore and comes ashore on Aleutian Islands. Its distribution is conditioned by predators (e.g., killer whales) and food availability, such as the prey they usually use in kelp forests (e.g., sea urchins and abalone).

II. Factors Affecting Marine Mammal Distribution

Marine mammal distributions are affected by demographic, evolutionary, ecological, habitat related, and anthropogenic factors. Demographic factors include the abundance, age, and sex structure of the populations and the reproductive status and life cycle of individuals. Evolutionary factors include morphological, physiological, and behavioral aspects of the species' adaptations. Ecological factors include biological production and use of prey, distribution of prey and predators, and competitors. Habitat includes factors such as water temperature, salinity, density, thermocline depth, and the type of substrate and the bathymetry. Anthropogenic factors are the human effects that alter the natural distribution of marine mammals, including pollutants, human-induced sounds, habitat encroachment, modification by global warming (sea-ice habitat), and incidental and direct kills. Distribution is the product of factors that act in a parallel or interactive way over different scales of space and time on each species, and sometimes on groups of species. As an example, baleen whale distribution depends on their ability to exploit planktonic organisms (evolutionary), the oceanographic characteristics of the water masses where they feed (habitat), and the trophic level they exploit (ecological).

A. Demographic Factors

The dynamics of marine mammal populations can determine distribution changes and patterns. The number of individuals that live in particular areas depends on the capacity of those areas to sustain their biological requirements. In general, the most critical requirements are prey availability and energy. The depletion of food resources by marine mammal populations influences the movement or dispersal to other areas. The age and sex structure of marine mammal aggregations also affect the distribution patterns. Habitat requirements for breeding females or females with offspring are not the same as those of adult males. In the case of odontocetes, females with calves may require coastal areas with locally abundant food resources and protection from predators. Adult males, not having to care for their offspring, are less limited in movements and distribution range. In offshore dolphins, large cohesive aggregations may be required by breeding females for protection in the open ocean, and foraging distances will be greater due to patchiness of their prey. In the case of pinnipeds, distributional differences according to age and sex classes and reproductive status are related to the seasonality of their life cycles, their adaptation to aquatic feeding, and their need to periodically return to land to breed. In breeding colonies, individuals will gather seasonally to mate, give birth, and nurse their pups over variable periods of time according to species. After the breeding season, pinnipeds often display age- and sex-related differences in habitat use and foraging areas. Dispersal according to age and sex classes is often associated with these characteristics.

B. Evolutionary Factors

All factors related to the secondary aquatic adaptation of marine mammals influence their distribution to some extent. Diving capacities in terms of duration and maximum depths allow particular species to exploit different habitats. In sperm whales and elephant seals, deep diving allows access to prey unavailable to the shallower diving

dolphins or porpoises. Hence, their distributions are associated with deep canyons and other deep ocean areas. In sperm whales, this ability also requires complex social systems that insure the protection of newborns or youngsters, particularly while mothers spend long times underwater in search of prey. Another notable physiological adaptation is thermoregulation, which allows marine mammals to extend their distribution ranges from the warm equatorial waters to the coldest high latitudes. Efficient insulation and body temperature regulation systems allow the polar bear and the sea otter to spend a substantial part of their life at sea and survive in cold waters. The relative inability to regulate body temperature adequately in colder water of neonates is a hypothetical factor that leads baleen whales to migrate from the cold feeding grounds to the warmer calving grounds. Morphological adaptations, such as the feeding apparatus of baleen whales, also influence their distribution. As active filter feeders, they can capture planktonic (e.g., copepods, krill) or schooling (e.g., sand lance, capelin, herring) prey, which are abundant in the particular areas where whales distribute. Finally, the cohesiveness of large dolphin schools and the sensorial integration of individuals allow them to range in offshore areas, find food actively and efficiently, and obtain protection from predators.

C. Ecological Factors

Marine mammal distribution is in great measure related to prey distribution. The ability to exploit different trophic levels and resources classifies different marine mammals from top predators, such as the killer whales or leopard seals, to low-trophic level feeders, such as northern right whales or manatees. Marine mammals can be considered as either specialists or generalists, and these two aspects imply differentiated distribution patterns, although it is very likely that it is an abundant prey source like copepods for northern right whales and Antarctic krill for many whales migrating seasonally to the Southern Ocean that renders them specialists. Manatees, being specialist feeders, have restricted distributions where sea grass meadows provide continued food. Despite often being categorized as specialists, odontocetes or phocids tend to use a wide range of prey items. Thus, they can be distributed over wider ranges and change their distribution seasonally according to the availability of their prey. The killer whale, as a species, has a broad diet, yet different populations have more specialized diets, transient killer whales feed mainly on pinnipeds and other marine mammals but must range widely to maintain this diet, whereas resident killer whales feed on large fishes such as salmon. In both instances, the distributions of the whales are synchronized to the life cycles of their prey. In the eastern North Pacific, the transients concentrate seasonally near pinniped rookeries, whereas residents live near the mouth of salmon-spawning rivers. In other cases, marine mammals tend to use the same home range, such as coastal bottlenose dolphins, feeding on different prey species that change their distribution seasonally. In this case, distribution patterns must be studied and interpreted at a finer scale. Interspecific competition is an additional ecological factor determinant of variable distribution. Violent attacks on harbor porpoises by bottlenose dolphins have been reported in their common range in the North Sea. Finally, predation plays an important role in the selection of habitats and distribution areas by marine mammals, especially those of smaller size, such as ringed seals. This species appears to select the fast ice to avoid predation by polar bears.

D. Habitat-Related Factors

Marine mammals are usually found in waters with high densities of principal prey species. These waters are characterized by

the physical conditions that facilitate the accumulation of the prey. Relevant oceanographic variables characterizing marine mammal habitats are water temperature, salinity, density, chlorophyll concentration, and thermocline depth. These characteristics are related to upwelling fronts, often related to differences in species distribution. As an example, spinner and spotted dolphins range in the same areas of the eastern tropical Pacific, often traveling in the same schools. They occur in the same overall ocean area as common and striped dolphins but appear to have preferences for water masses of different oceanographic characteristics (Reilly, 1990). Ocean topography and bathymetry are often related to local oceanographic phenomena that influence marine mammal distribution. Underwater canyons, marine ridges, and irregular topographies concentrate prey for deep divers such as sperm whales or elephant seals. In contrast, mysticetes often have preferences for shallow waters (Elwen and Best, 2004) and sometimes with high topographic variation. In these waters their prey accumulates at frontal interfaces between mixed and stratified waters. Temperature is also an important factor limiting waters of specific characteristics. For instance, warm water boundaries like convergence zones are important for northern right whales (Keller *et al.*, 2006). The ice is also a critical habitat element for marine mammals; the seasonal and highly dynamic changes of ice cover determine their patterns of change in distribution. It provides shelter during reproduction for pinnipeds, access to seasonally abundant food, and also delimits the distribution ranges of some cetaceans, such as the bowhead whale.

E. Anthropogenic Factors

Human alteration of habitats can change marine mammal distributions significantly. Marine mammals that haul out on land are particularly affected by habitat encroachment by human development. The three species of monk seals have suffered substantial changes in their original distributions, and one of them, the Caribbean monk seal, became extinct because of this. In the case of the Mediterranean monk seal, a major change in habitat preferences occurred as a result of human development but also of deliberate kills for human uses. The seals changed their haulouts from open beaches to difficult-to-access caves, often with underwater entrance. This has created severe habitat fragmentation. Commercial exploitation has also affected marine mammal distributions greatly. Whale stocks were reduced to the point that many original distribution areas are not used anymore. Overfishing of prey items has led to changes in marine mammal distributions. Pollution of coastal areas has degraded many original marine mammal habitats, thus affecting their original distributions. Human-induced changes in local water temperature have changed the seasonal distribution of the Florida manatee (Reynolds and Odell, 1991). This population previously migrated to warmer waters in winter but now uses the thermal vents in waters close to power plants and has changed migration patterns substantially. Expanding sources of sound in the ecosystem (e.g., large ship traffic, naval experiments) and pollution may also affect marine mammal distribution. A recently new indirect human impact is global warming, which is altering the distribution of species very attached to critical habitats. For example, the dependence of polar bear in certain areas of the seasonal sea ice to access their prey has been affected by changes in the air-temperature-sea-ice relationships. These have caused an earlier spring sea-ice breakup and late sea-ice formation in autumn. In addition, the more extensive melting of sea ice in certain regions may extend the range of predatory species like killer whales, giving them access to new prey sources. In contrast, the contraction of sea ice brings about reductions in prey,

like the Antarctic krill in the South Atlantic sector of the Southern Ocean, which have repercussions for distribution and abundance of Antarctic fur seals and crabeater and leopard seals, and possibly many baleen whale species.

III. Movements and Seasonality

The distribution of marine mammals changes seasonally as their biological and ecological requirements change. Marine mammals respond to changes in the environment, such as in temperature, ice coverage, and prey availability. Daily requirements in terms of energy or protection against predators depend on the reproductive status and the season; these are clearly not the same for females with nursing offspring as for solitary males. Movements are a response to changes in the environment and the biological requirements of a species. In tropical areas, movements are expected to vary according to the patchiness of the environment. Distances covered in short periods of time may vary depending on the conditions, but a very marked seasonality is not commonly found. In high latitudes, changes during the cold winter affect the distribution of marine mammals, their tolerance to physical conditions, and their life history requirements. Thus, seasonality is more marked.

Movements can be classified as migration, dispersal, and daily travel. Migration is the seasonal change between two geographic locations that is related to species reproductive cycle, changes in the physical environment, like water temperature or ice coverage and extent, and prey availability. Dispersal is the movement from the place of birth to other areas in which individuals reach a feeding area, join a breeding population, or find another group of individuals with which to spend the next stage of its life. The classification of movements may be somewhat arbitrary because marine mammals do not always follow strict periodic patterns. They instead respond to the limitations of the environment in providing constant food or other requirements. Short-scale movements are difficult to detect and must be put in the context of the species life cycle before being classified. A typical example of migration is the one of baleen whales; humpback, right, and gray whales undertake long-distance travels, often thousands of kilometers, between the tropical calving grounds in winter and the high-latitude feeding grounds in summer. In contrast, most otarids have dispersal movements from their birth colonies toward different feeding areas or other breeding colonies when they reach sexual maturation. In any case, movement patterns vary among individuals, according to their age, sex, and reproductive condition. A prereproductive young whale may delay its departure from the high-latitude feeding grounds to extend the feeding season, whereas a pregnant female must leave for the low-latitude calving grounds to give birth to its offspring.

A. Cetaceans

Cetaceans spend their entire life in aquatic habitats and are in constant movement. Understanding their seasonal distribution is more difficult than in pinnipeds for technical and logistical reasons, the manipulation and tagging of animals is less efficient and more expensive. Thus, classifying movements as dispersal or migration is even more confusing, except in some well-studied populations of baleen whales. Their life patterns and cycles make the concept of dispersal a little ambiguous, however, because seeming residency, site fidelity, or habitat discreteness may be just apparent, short-term attributes of their distribution. Only migration in large whales is known from long-term studies. Studies on migration range from the examination of catch statistics of whaling operations to the use of modern telemetry technology.

Contrary to classic accounts of whale migration, the most recent studies show how movements vary across whale populations and species. Mysticetes appear to have periodical migrations with relatively consistent patterns over the years. Seasonal movements in odontocetes are far less consistent over time, including those of the sperm whale, which has been classified as a migratory species with marked seasonal patterns. However, only males appear to be involved in the long latitudinal migrations between the tropics and the poles, while females, calves, and young stay year round in tropical areas. In general, as in other marine mammals, factors inducing migration are the biological cycle, greatly determined by reproductive needs, and factors in the environment (e.g., prey availability, changes in water temperature). These factors may trigger the start of seasonal movements, although not all individuals will respond in the same way.

Annual migrations are best known for species with more coastal ranges, such as the gray, right, or humpback whales. However, virtually all mysticete species are known to migrate. No data are available for the pygmy right whale. Most mysticetes have latitudinal migrations, from tropical breeding grounds to high(er) latitude feeding grounds. In breeding grounds, mating and calving take place. Migratory species are right, blue (*Balaenoptera musculus*), fin (*B. physalus*), sei (*B. borealis*), humpback, and gray whales. Bowhead whales also migrate, but their longitudinal movements are equal to or greater than their latitudinal changes, and they never leave Arctic waters. Bryde's (*Balaenoptera edeni*), common minke (*B. acutorostrata*) and Antarctic minke (*B. bonaerensis*) whales, however, have less clear movement patterns. Bryde's whales, often confused at sea with sei whales, spend most of the year in warm tropical waters and calving does not have the same marked seasonality seen in other balaenopterids. This indicates a possibly different reproductive cycle, in which whales feed and mate year round. In this case, whale movements are more similar to those of many odontocete species, in constant search for food, with variable utilization of prey, and different prey types through the year. Among the best known migrations are those of the gray and humpback whales. Gray whales migrate annually from feeding grounds in the Arctic to their calving areas in the lagoons of Baja California in Mexico. Interannual changes in the timing and numbers reaching the different migratory destinations have been observed. The migration of humpback whales is also very well studied, and male sperm whales are the best example of long-range migration in odontocetes.

Movements in odontocetes have different scales depending on geographical areas, family, and species. It is generally accepted that most movements are in response to prey availability, and the largest movements, often called migration, occur in oceanic odontocetes. In the eastern tropical Pacific, movements are reported to be wide. Several species of *Stenella* had daily movements of 53km/day and hundreds of kilometers over months, and these reflected seasonal changes in distribution. Dolphins moved inshore, toward the American continent, in fall and winter and offshore in spring and summer. Other methods, such as line transect surveys in California, have shown how several dolphin species have different patterns of abundance and distribution depending on the season. Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), Risso's dolphins (*Grampus griseus*), common dolphins (*Delphinus* spp.), and northern right whale dolphins (*Lissodelphis borealis*) were less abundant in summer than in winter, and significant north/south shifts in distribution were reported for Dall's porpoises and common and Pacific white-sided dolphins. Significant inshore-offshore differences were found for the northern right whale dolphin. Some dolphin species show variable distribution patterns, such as bottlenose dolphins or killer whales. Difference in patterns has been attributed to different varieties or ecotypes of the

same species. In the case of bottlenose dolphins, a well-studied coastal population (Scott *et al.*, 1990) showed a year-round residency with slight seasonal changes within the population home range. It has been argued that dolphins in Florida follow the mullet migrations into the Gulf of Mexico during the fall. Short-term movements have also been observed in a resident bottlenose population in east Scotland. In contrast, Atlantic offshore bottlenose dolphins, described as a possible different form, have wider movements and a broader distribution (Wells *et al.*, 1999).

B. Pinnipeds

Migration is not uncommon in pinnipeds, and the advent of new telemetry has helped describe the migratory movements of several species. Dispersal is very common in pinnipeds and depends on the abundance of prey, its energy content, and the seasonality of prey distribution. In addition, their reproductive cycle mandates that individuals return to land or ice to give birth, nurse, and rear their offspring and molt. Pinnipeds also haul out for resting, thermoregulation, and to escape predators, among other reasons. If the environment provides constant food resources, such as in some tropical areas, there will not be a clear need to disperse. In contrast, pinnipeds living in high latitudes will be more dependent on ice cover, availability of seasonally changing prey, reproduction, and population size. These will create density-dependent effects, such as dispersal and distributional changes. Thus, dispersal can vary with latitude, based on the stability of prey resources.

Phocids appear to migrate more than otariids, as they generally live in higher latitudes, where the environment (e.g., the ice cover) is more variable. For otariids that live in tropical areas with a more constant environment, habitat regulates the growth of the standing colonies and conditions of dispersal. Otariids also have longer lactations and rearing periods than true seals. Their breeding behavior and requirements in terms of habitat are also different, allowing them to stay longer in the breeding colonies. Periodic events that lead to drastic changes in food availability or other environmental limitations, such as the El Niño southern oscillation (Trillmich and Ono, 1981), also favor dispersal. In Antarctic fur seals of the South Atlantic, the lagged effects of El Niño-Southern Oscillation (ENSO) reduce prey availability and affects the life history of breeding mothers. This promotes breeding abstention, low return of breeders, and causes low survivorship among mothers after severe El Niños. Among otariids, only the northern fur seal has a well studied and distinctive migration.

Both elephant seal species and the hooded and the harp seals are good examples of migratory seals. Northern and southern elephant seals spend between 8 and 10 months at sea each year, with long-distance migrations between breeding and molting sites. Both species have two long migration trips between postbreeding and postmolting areas. The northern elephant seal migration, of between 18,000 and 21,000 km, is the longest reported for any mammal.

Harp and hooded seals have interannually variable distribution patterns, dependent on the time of the year, the geographic location, and the density of individuals in the breeding colonies. Harp seals live in colonies in the subarctic pack ice, where breeding takes place. The largest population of this species is in Newfoundland. Individuals from this population start their southward migration in late September along the coast of the Baffin Islands and go eastward through the Hudson Straits, reaching Labrador between October and December. There are variations in migration timing and patterns between age classes.

Gray seals from numerous colonies in the British Isles and gray seal pups disperse widely during the first year. Adult seals show high variability in their movements along the coasts of Scotland, especially

in postbreeding periods and after the molt, from March to May. Although long-distance travel by adults occurs, short travel at close range from particular haul outs is more common. Juveniles tend to spend longer periods at sea (Hammond *et al.*, 1993).

C. Sirenians

The best-studied movements by sirenians are of manatees in waters of Florida. Water temperature is a major determinant of seasonal movements of Florida manatees, and dispersal is higher in warmer months. In winter, manatees tend to aggregate in areas of warmer waters, such as natural freshwater springs or the outfalls of power plants (Reynolds and Odell, 1991).

D. Polar Bear

Seasonal movements in polar bears have been reported in all their distribution range. Long-range movements also occur and are mostly related to the ice cover and extent. Predation on seal pups also influences movements, and bears disperse more during pinniped pupping seasons. In summer, when ice melts in many areas, bears move to land, where they remain for a few months, before leaving in November–December. Pregnant females stay longer on land than males.

IV. Study of Marine Mammal Distribution

The study of distribution depends on each species' habitat and its abundance, so that scale is a significant factor. Distribution changes have to be interpreted in space and time, and different methods are to be used according to species range and density. The distribution of a species occupying an extensive ocean area is best studied by air or shipboard surveys following systematically placed transects. In surveys, visual and/or acoustic data on species are collected according to predetermined protocols. Oceanographic variables and data on position of individuals can be incorporated in spatial modeling (Hedley *et al.*, 1999). Results of this modeling on repeated surveys can be compared to study seasonal patterns and changes over time. In species that live in fragmented habitats and that are not abundant, knowledge of the location of animal aggregations is essential. In these cases, the best possible information is obtained from telemetry studies using high-frequency radio tags, satellite-linked radio tags, and geolocation time-depth recorders, GPS tags, and geolocation tags. The use of telemetry devices is also essential in understanding seasonal movements and patterns. The life of the batteries and permanence of the tags in the animals are critical to the duration of the studies. The study of habitat, an integral part of distribution, changes with the species life time because of the above-mentioned factors. It is difficult to monitor a cohort of animals, ideally tagged since birth, because of the long average life span of marine mammals. In practice, the general distribution patterns of a marine mammal population are the sum of the individual specific movements over space and time. Monitoring just a few animals over a restricted time duration (e.g., that of a telemetry device battery) produces partial information on the overall patterns and may show a high variability between individuals. Therefore, inferences at the population level must be made cautiously to avoid biased perceptions of the species distribution.

Diving Behavior

BRENT S. STEWART

Except for the polar bear (*Ursus maritimus*), all marine mammals feed exclusively in aquatic environments, and mostly in the world's oceans (Reeves and Stewart, 2003). The depths at which they hunt for and capture prey and the time spent submerged vary among pinnipeds, cetaceans, sea otters, and sirenians as a function of physical and physiological adaptations among these taxa, environmental conditions (e.g., coastal or pelagic, tropical or polar, season), and body size, age, and health of individuals. All are ultimately tied to the sea surface to periodically breathe, yet natural selection has operated to minimize the time needed there and to maximize the amount of time that can be spent submerged hunting and capturing prey. What has become known in recent years is that these animals spend substantial parts of their lives moving within

the water column to relatively great depths and some over vast geographic areas in search of food. Among the amphibious pinnipeds, these aquatic foraging bouts can extend, with minor interruptions, for several weeks to several months, punctuated by periods of several days to weeks on land or ice when no feeding occurs when these animals rest, molt, or breed. For the less amphibious sea otters (*Enhydra lutris*), diving and foraging periods may be separated by periods spent sleeping or resting at the sea surface rather than on land. Among the wholly aquatic cetaceans and sirenians, foraging bouts may last several hours or perhaps days, interrupted by periodic resting periods at the sea surface.

Individuals of some species, particularly sperm whales (*Physeter macrocephalus*) and many mysticete cetaceans, evidently fast during migrations or in particular breeding areas. Although the diving performance and the patterning of individual dives or sequences of dives vary among species, what has become apparent for all marine mammals is that little time is spent at the surface between successive dives to exchange gases (i.e., unload carbon dioxide from tissue and blood and restore tissue oxygen stores). This allows for sustained, repetitive diving and hunting, and is made possible by physiological adaptations for conserving heat and oxygen and by anatomical adaptations that promote effective movement in the aquatic environment (e.g., reducing drag through streamlining and efficient propulsion mechanisms; Reeves and Stewart, 2003).

I. Methods of Studying Diving Behavior

The simplest method for studying the diving behaviors of marine mammals is direct observation of the timing and location of appearances of individuals at the sea surface, the number of breaths taken there, and the duration of the animal's disappearance under water before reappearing. With some assumptions and strong inference, much can be deduced about what animals are doing while hidden beneath the ocean surface. Indeed, most early knowledge of diving, feeding, traveling, and migratory behaviors was based on such interpretations.

Other techniques for documenting diving behavior have used radio transmitter and telemetry instruments, operating at various radio frequencies. Sonic transmitters, operating at relatively low frequencies or wavelengths, allow the tracking of animals when they are submerged by placing a microphone (hydrophone) beneath the sea surface to listen for and orient to these signals. Higher frequencies are used for in-air detection and tracking but generally yield less detailed observations, mostly when an animal reached the surface and how long it spent there. Durations of dives are inferred from periods of radio silence, as transmissions that occur when the animal is submerged will rapidly be attenuated in salt water. When vocalizing underwater, some marine mammals may also be tracked with hydrophones to detect and localize those sounds. All of these techniques require constant tracking and observers must be within a few hundred meters (surface observers) or kilometers (observers in aircraft), as the signals attenuate quickly.

During the past several decades, and in particular since the early 1990s, an enormous amount of information has been added to those simple observations due to technological developments and their application to free-ranging marine mammals. For example, in the late 1960s and the early 1970s, an encapsulated mechanical device was used in the Antarctic to study the diving patterns of Weddell seals (*Leptonychotes weddellii*). That instrument provided a continuous trace on photographic film of the depth of the seal vs time. The

spooled film was pulled at a known rate past a small radioactive particle, which rested on a pressure-sensitive arm. Thus a two-dimensional record was made on the film of depth vs time. From these records came the first long-term (about 7 days continuous, based on film capacity) data on the vertical movements of free-ranging marine mammals (Kooyman, 2006). Those instruments, called time-depth recorders (TDRs), were later deployed on a number of species of fur seals and some sea lions to study the effects of variation in body size and environment on the foraging patterns of lactating females. However, because the instruments were rather large and because they were attached with harnesses, they likely had some influence on the recorded durations of dives because of the effects of drag on swimming that they imposed, particularly for fur seals. Other simple instruments used capillary tubes with pressure sensors attached to record the maximum depth of a single dive or the maximum depth achieved during a period of diving.

Mechanical instruments were replaced in the late 1980s with much smaller electronic instruments, armored to keep seawater out under extreme hydrostatic pressures. These instruments could collect and store substantially more data on depth and duration of dives and also had less impact on behavior. Indeed, today most of these instruments weigh less than 50g and can be glued (Figs 1 and 2) to the hair or fur of pinnipeds for long-term (up to a year) monitoring, attached to the dorsal fin of small cetaceans (Fig. 3), attached to the skin surface of large whales with subdermal anchors or deeply embedded into their blubber, or attached with suction cups to the skin of cetaceans for shorter term (to several days) study. Because these instruments may now also collect data other than just water depth as a function of time (e.g., swim speed, ambient light level, compass bearing, seawater temperature, salinity), they are called time-data recorders. These instruments are generally controlled by small microprocessors that can be programmed to record measures of various parameters at particular intervals that are then stored in electronic memory for several months or more. Thus, detailed records (e.g., at 1-sec intervals) of a marine mammal's position in the water column, in addition to other environmental and behavioral data, can be collected continuously for months or more.

Even more recently, technological developments and improvements have involved remote sensing of diving patterns and geographic movements of marine mammals using radio transmitters that communicate with earth-orbiting satellites, most notably the

two polar-orbiting satellites of the ARGOS Data Collection and Location System (DCLS). These transmitters are known as platform transmitter terminals (PTTs) and packaged instruments that include microprocessor-based data recorders in addition to the PTT are known as satellite relay data recorders (SRDRs). They allow animals to be located several times each day, and also allow small amounts of behavioral and environmental data to be transmitted through the DCLS. Further continuing improvement and miniaturization of film and digital video equipment are allowing the underwater diving, social, and hunting behaviors of marine mammals to be visually documented (Parrish and Littnan, 2008).

Most of what is now known and summarized below on the diving behaviors of marine mammals is based on two-dimensional (i.e., depth vs time) data from electronic TDRs, which are occasionally supplemented by geographic locations of the animals at the sea surface. Some data have been collected recently on the movements of animals in a three-dimensional ocean space beneath the sea surface for several hours to a couple of days (Harcourt *et al.*, 2000; Simpkins *et al.*, 2001). But the seductiveness of representations of a single spatial vector (depth) vs time as a trace in a two-dimensional, linear

Figure 4 Gluing a satellite-linked data recorder to a physically restrained ribbon seal (*Histriophoca fasciata*). Photo by B. S. Stewart.

spatial format has led some researchers to infer the geographical form of large numbers of dives in three-dimensional space. Moreover, some researchers have extended inferences even further to assign physiological and behavioral function to those guessed three-dimensional spatial forms. Though those inferences and conclusions of function have yet to be substantively validated, they are nonetheless interesting hypotheses for further rigorous inspection (*cf.* Brillinger and Stewart, 1997; Fedak *et al.*, 2001).

A substantial amount of information has been collected on diving patterns of a number of pinniped species compared to relatively little progress in the study of cetacean diving patterns. The primary reason for the difference in quantity and quality of data between these taxa is principally due to the greater difficulty of keeping instruments attached to cetaceans compared to the long-term attachment of instruments, up to 1 year, to pinnipeds by gluing them to their hair (Fig. 4). Regardless, the dive patterns of virtually all species were limited to particular times of the year and even to particular classes of individuals (e.g., lactating female pinnipeds). Nearly year-round monitoring of northern and southern elephant seals (*Mirounga angustirostris* and *M. leonina*, respectively) has been the exception. Consequently, any discussion of diving patterns is conditioned on these important constraints. Moreover, it has not been confirmed for all cases whether hunting or feeding occurs whenever animals are submerged and diving. The incorporation of additional environmental and physiological sensors to TDRs and PTTs will likely help refine studies of diving patterns to more rigorously evaluate spatial form and function of subsurface movements and to enhance the summaries of dive patterns presented here.

II. Pinnipeds

A. Otariids

California sea lion females (*Zalophus californianus*) dive mostly to depths of around 75 m for about 4 min during summer and then deeper and longer the rest of the year (maximum depth of 536 m and longest dive of 12 min). When at sea for several days at a time and up to 1–2 weeks at some seasons, California sea lions dive virtually continually and rest at the surface for only about 3% of the time.

Juvenile Steller sea lions (northern sea lion, *Eumetopias jubatus*) dive to average depths of 21 m (maximum 200 m). Most dives last less than 2 min. They are generally shallower at night and deeper in spring

and summer than in winter. Adult females dive deeper than juveniles and dives are deeper in winter than in autumn (Pitcher *et al.*, 2005).

Southern sea lions (*Otaria flavescens*) dive mostly at night, apparently to the sea bed, where they hunt at depths down to 250 m. While at sea near the Falkland Islands, these sea lions dive virtually continually. Near Patagonia along the Argentina coast, over half of the time that lactating females are at sea they are diving. Their dives are mostly to depths of 19–62 m (maximum of 97–175 m) and for 2–3 min (maximum of 4.4–7.7 min). Diving is continuous during these bouts, and time spent at the surface between successive dives is brief, around 1 min.

Lactating New Zealand sea lions (Hookers sea lions, *Phocarctos hookeri*) also dive almost continually when at sea, averaging about 7.5 dives per hour, varying little with time of day. Dive depths average about 123 m (maximum of 474 m) and last between 4 and 6 min (maximum of 11.3 min). Most dives are evidently to the sea bed to forage on demersal and epibenthic fish, invertebrates, and cephalopods.

A few lactating Australian sea lion (*Neophoca cinerea*) females were reported to repeatedly forage on the sea bottom (~150 m deep) on the continental shelf of South Australia within 30 km of the coast.

Northern fur seals (*Callorhinus ursinus*) can be at sea continuously for several months or more from autumn through spring, but their diving behavior has not been studied then. Most data come from lactating female fur seals that are foraging near ROOKERIES in the Bering Sea in summer. Then they forage in bouts that mostly occur at night. Seals mostly make shallow dives to depths of 11–13 m, lasting around 1–1.5 min (Baker and Donohue, 1999). These dives tend to be at night when seals are in pelagic habitats.

Depths and durations of dives of Galapagos fur seals (*Arctocephalus galapagoensis*) increase as they get older. Six-month-old seals dive to depths of around 6 m for up to 50 sec and dives occur at all hours. One-year-old seals reach depths of 47 m and durations average 2.5 min. Most of those dives occur at night. When 18 months old, seals are at sea mostly at night, diving continually for periods lasting around 3 min and reaching depths of 61 m (Horning and Trillmich, 1997).

Lactating Juan Fernandez fur seal (*Arctocephalus philippii*) females dive mostly at night to depths of 50–90 m, although most dives are shallower than 10 m. They last, on average, 1.7–2.0 min (longest 3.46 min).

Lactating female New Zealand fur seals (*Arctocephalus forsteri*) dive as deep as 274 m, and their longest dives have been measured at around 11 min. Median dive depths are around 5–10 m. They occur in bouts with the longest bouts at night. The deepest dives occur around dawn and dusk. Dives are shallowest (30 m) and shortest (1.4 min) in summer and get progressively deeper and longer through autumn (54 m, 2.4 min) and winter (74 m, 2.9 min; Mattlin *et al.*, 1998).

Most dives of female Australian fur seals (*Arctocephalus pusillus doriferus*) are to the sea bed on the continental shelf at depths of 65–85 m. The median depth of one foraging male fur seal was 14 m and the median duration of dives was 2.5 min. The deepest dive was to 102 m and the longest was 6.8 min, and the seal spent about one-third of its time at sea diving and foraging, with little variation in activity with time of day.

Lactating female subantarctic fur seals (*Arctocephalus tropicalis*) at Amsterdam Island dive predominantly at night. These foraging dives get progressively deeper and longer from summer (10–20 m and about 1-min long) through winter (20–50 m and about 1.5-min long). The deepest dive recorded was 208 m and the longest was 6.5 min (Georges *et al.*, 2000).

Lactating female Antarctic fur seals (*Arctocephalus gazella*) dive mostly at night when they are at sea for periods of 3–8 days at a time in summer. Those dives are shallower at night (to ~30 m) than dives made during the day (40–75 m), closely matching the vertical distribution of krill. Maximum depths and durations of dives have been measured at 82–181 m and 2.8–10 min, respectively, for individual females. Seals apparently adjust their diving behavior to maximize the proportion of time that they spend at depth. Young pups dive mostly to depths of about 14 m, depending on their body size, for mean durations of 20 sec. Their diving abilities continue to develop during their first couple of months of life, and by the time they are weaned at around 4 months of age, they are able to dive to the same depths and for about the same amount of time as adult females.

B. Odobenids

The diving patterns of the walrus (*Odobenus rosmarus*) are not well studied. It is known, however, that its dives may last 20 min or more, although most may be less than 10 min and not exceed 100 m. The longest dive recorded lasted about 25 min and the deepest was to 133 m. Most dives are likely shallower than about 80 m, as its benthic prey of mollusks are generally found in relatively shallow coastal or continental shelf habitats. Near northeast Greenland, walrus may be submerged about 81% of the time when they are at sea and are presumably diving and foraging most of that time.

C. Phocids

Phocid seals generally are at sea continually for weeks to months and appear to dive, and perhaps forage, virtually constantly (Reeves *et al.*, 1992; Reeves and Stewart, 2003). Elephant seals are perhaps the best studied of marine mammal divers. The dives of weaned southern elephant seal pups are to about 100 m for about 6 min and they dive virtually continuously when at sea for several months. Heavier pups dive deeper (to ~130 m) and longer (7 min) than smaller pups (88 m and 5 min). Dives of juvenile southern elephant seals last around 15.5 min (maximum of 39 min) to depths averaging 416 m (deepest 1270 m) and they spend about 90% of their several months at sea diving. Intervals between dives are brief, rarely lasting more than 2 min. Adult southern elephant seal dives on average 400–600 m and 19–33 min (deepest 1444 m and longest 113 min) and also occur continuously while they are at sea for up to 7–8 months (Campagna *et al.*, 1999).

Northern elephant seals also dive continually when at sea for several months or more, with only brief periods at the surface (1–3 min) between dives. Dives of adults are to modal depths of 350–400 m and 700–800 m (maximum of 1567 m), and average 20–30 min (maximum of 77 min). Depths and durations of dives differ between adult males and females depending on season and geographic location (Stewart and DeLong, 1995). Generally, these seals feed on pelagic fish and squid, although some seals may also dive to and feed near the sea floor near the coastlines of continents and islands.

Dives of Hawaiian monk seals (*Monachus schauinslandi*) are between 3- and 6-min long and mostly shallow, between 10- and 40-m deep, where the seals forage near the sea bed on epibenthic fish, cephalopods, and other invertebrates. Adults may occasionally dive to greater depths of up to 550 m when foraging outside of the shallow atoll lagoons of the northwestern Hawaiian Islands (Stewart *et al.*, 2006).

Weddell seals forage for much, if not most, of the year beneath the unbroken fast ice and the more open pelagic pack ice zones of the Antarctic. Diving and foraging occur in bouts of about 40–50

consecutive dives over a several hour period, usually to depths of 50–500 m. Dives of young pups are relatively shallow and brief but get progressively deeper and longer as pups age. They plateau when the pups are weaned when about 6–8 weeks old. The dives of 1 year olds are somewhat shallower, to around 118 m, compared to adult females (163 m). The deepest dive recorded is about 750 m and the longest over 73 min. Dives are shallower (350–450 m) in spring (October–December) than in summer (January; 50–200 m) evidently reflecting a shift in preferred hunting depths.

Among the Antarctic pack ice seals, Ross seals (*Ommatophoca rossii*) are also relatively deep divers. One female that was monitored near the Antarctic Peninsula in summer dove exclusively at night, mostly to depths of 110 m (maximum of 212 m) and for about 6.4 min (longest 9.8 min). Diving was continual while the seal was in the water with about 1 min between dives. The deepest dives (175–200 m) occurred near twilight and the shallowest (~75–100 m) at midnight (Bengtson and Stewart, 1997).

In summer, crabeater seals (*Lobodon carcinophaga*) dive primarily at night and haul out on pack ice during the day, although some diving bouts may last up to 44 h without interruption. Most dives are 4–5 min long to depths of 20–30 m, with maximum depths and durations of 430 m and 11 min, respectively. Dives near twilight are deepest and those near midnight shallowest (Bengtson and Stewart, 1992). Diving patterns in other areas of the Antarctic are similar (cf. Nordoy *et al.*, 1995; Wall *et al.*, 2007).

Baikal seals (*Pusa sibirica*) apparently dive continually from September through May, when the freshwater Lake Baikal is frozen over, and haul out only infrequently then (Stewart *et al.*, 1996). Most dives are 10–50 m deep in the middle of Lake Baikal where the water depth is around 1000–1600 m. Occasionally, seals descend to more than 300 m. Dives last between 2 and 6 min but some have been measured at more than 40 min.

Dives of another closely related freshwater seal, the Saimaa seal (*Pusa hispida saimaensis*) of Lake Saimaa in eastern Finland, last about 6 min in spring and increase to about 10–11 min by autumn. In summer and autumn, long series of sequential dives lasting more than 10 min each may occur over 3 h or more. The longest dive recorded is about 23 min, when the seal may actually have been resting on the bottom rather than feeding.

Modal dive depths for breeding age, male ringed seals (*P. hispida hispida*) are 10–45 m and for subadult males and postpartum females 100–145 m. Durations of dives for adult males are around 4 min and around 7.5 min for adult females.

Harbor seal (*Phoca vitulina*) diving behaviors have been studied in several areas throughout their range in the North Pacific and North Atlantic Oceans. Dives in the Wadden Sea (northeast Atlantic) average from 1–3 min (maximum of 31 min) with little variation between night and daytime behavior. When in the water, about 85% of their time is spent diving. In the western Atlantic, foraging dives of adult males are mostly deeper than 20 m but are shallower during the mating period, when they are defending aquatic territories or searching for females to mate with instead of foraging (Bowen *et al.*, 1999). Dives of lactating females are 12–40 m and occur in bouts lasting several hours, mostly during the day. In southern California, dives are as deep as 446 m. Most, however, are to modal depths of 10, 70, or 100 m with an occasional mode at around 280. Harbor seals near Monterey dive to and forage at depths between 5 and 100 m for up to 35 min (Eguchi and Harvey, 2005).

Bearded seal (*Erignathus barbatus*) adult females near the coast of Spitzbergen, Norway, dive mostly at night to depths of around 20 m (deepest at 288 m) and for 2–4 min (longest 19 min). Nursing

pups may dive to around 10 m (maximum of 84 m) for about 1 min (maximum of 5.5 min). Pups spend about 40% of their time in the water diving. Depths and durations of dives increase as the pups age (Kraft *et al.*, 2000).

Most dives of lactating female gray seals (*Halichoerus grypus*) are to the sea floor and last about 1.5–3 min (maximum of 9 min). Most foraging dives of juvenile gray seals in the Baltic Sea are to depths of 20–40 m (Sjoberg and Ball, 2000).

Lactating female harp seals (*Pagophilus groenlandicus*) dive about 40–50% of the time that they are at sea. Dives average about 3 min (maximum of 13 min) to depths of up to 90 m.

Hooded seals (*Cystophora cristata*) repeatedly dive to depths of 1000 m or more and for 52 min or longer. Most feeding dives appear to be to depths of 100–600 m.

III. Cetaceans

A. Odontocetes

Limited data for odontocete cetaceans so far indicate that short-beaked common dolphins (*Delphinus delphis*) may forage at depths of up to 260 m for 8 min or more, although most dives are around 90-m deep, last about 3 min, and are mostly at night. Pantropical spotted dolphins (*Stenella attenuata*) dive to at least 170 m; most of their dives are to 50–100 m for 2–4 min and most feeding appears to occur at night. Atlantic common bottlenose dolphins (*Tursiops truncatus*) near Grand Bahama Island off southeastern Florida often dive to the ocean bottom (7–13 m depth) and burrow into the sediment (“crater-feeding”) to catch fish dwelling or hiding there. Long-finned pilot whales (*Globicephalus melas*) dive to over 500–600 m for up to 16 min. Northern bottlenose whales (*Hyperoodon ampullatus*) regularly dive to the sea bed at depths of 800–1500 m for more than 30 min per dive and occasionally for 2 h (Hooker and Baird, 1999).

Harbor porpoise (*Phocoena phocoena*) near Japan have dived almost continuously when observed for short periods. Maximum dive depths are around 70–100 m, although about 70% of dives may be less than 20 m. These porpoises descend to and ascend from depth at greater rates when diving deeply than when the dives are shallow. In waters near Denmark, porpoises dive as deeply as 84 m and for up to 7 min from spring through late autumn.

Female beluga (white) whales (*Delphinapterus leucas*) dive more often between 2300 h and 0500 h than during the day, although males may dive at the same rate at all hours. Dive rates and time spent at the surface decline whereas dives deepen and lengthen from early through late autumn. Most dives are deep (400–700 m), with the deepest recorded at 872 m, and last about 13 min on average (maximum of 23 min). Dive duration increases with body size (Martin and Smith, 1999).

Narwhals (*Monodon monoceros*) regularly dive to more than 500 m and occasionally deeper than 1000 m, but most dives are to depths of 8–52 m and last less than 5 min, although as long as 20 min on occasion. The rate of diving varies between adult males and females. When diving shallowly, narwhals descend and ascend relatively slowly (<0.05 m/sec) compared with deeper, longer dives (1–2 m/sec) where substantially more time is spent at maximum depth.

Killer whales (*Orcinus orca*) along the northern coast of North Island, New Zealand, dive to the ocean bottom (~12-m depth or less) after stingrays and perhaps probe into the sediment to catch them.

Sperm whales are deep and long-duration divers. Near Kaikoura, New Zealand, the average duration of dives is about 41 min with

about 9 min spent at the surface between dives. Both durations and surface intervals are longer in summer than in winter. Males spend little time at the surface compared to females (Jaquet *et al.*, 2000). Average dive durations have been measured at 36 min near Sri Lanka and about 55 min near the Azores. Sperm whales in the Caribbean were reported to make dives averaging 22–32 min during the day (longest 79 min) and 32–39 min at night (longest 63 min). Off Japan, sperm whales dive to around 550–650 m along the Kumano coast with no differences between day and night patterns, whereas dive patterns are strongly diurnal to around 470 m at night and to around 850 m at night near the Ogasawara Islands, evidently related to differences in behaviors of their prey (Aoki *et al.*, 2007).

B. Mysticetes

As yet there is no evidence for a taxonomic relationship between body size and maximum dive depths for mysticete cetaceans, although preliminary correlations have been reported between maximum dive durations and body size.

While in shallow coastal lagoons during the spring breeding season, gray whales (*Eschrichtius robustus*) dive for about 1–5 min (maximum of 28 min) to average depths of 4–10 m (maximum recorded of 20.7 m). It is not clear what the function of these dives may be other than perhaps subsurface resting, as breeding whales are presumed to fast. In the Bering Sea in summer, when whales are feeding on the bottom, dives average 3–4 min at depths ranging from less than 10 to 79 m (Würsig *et al.*, 1986).

Fin whales (*Balaenoptera physalus*) in the Ligurian Sea dive repeatedly to depths around 180 m (maximum 474 m) for around 10 min (longest 20 min) while they prey on deep-dwelling krill. Elsewhere, fin whale dives have been reported to last about 5 min near Iceland and about 3 min in the North Atlantic and near Long Island, New York, in summer. Elsewhere, fin whales dive to around 98 m for 6 min when foraging and to around 59 m for 4 min when not foraging (Croll *et al.*, 2001).

When chased by commercial whalers, dives of blue whales (*Balaenoptera musculus*) lasted up to 50 min. Blue whales off central and southern California otherwise spend about 94% of their time submerged. Dives lasting longer than 1 min are 4.2–7.2 min, on average (longest 18 min), and to around 105 m (deepest 150–200 m). When foraging, blue whales dive to around 140 m for 8 min and to 68 m for 5 min when not foraging (Croll *et al.*, 2001). Dives of pygmy blue whales (*B. musculus brevicauda*) have been measured to average 9.9 min (longest 26.9 min).

Humpback whales (*Megaptera novaeangliae*) in Frederick Sound, Alaska, make rather brief (most less than 3 min) and shallow (60 m or less) dives, although some may exceed 120 m on occasion.

When on summer feeding grounds in the Beaufort Sea, dives of bowhead whales (*Balaena mysticetus*) last 3.4–12.1 min and some are to the relatively shallow sea bed. Dives of calves are very short compared to adults and they also spend more time at the surface between dives. Most dives of juveniles last about 1 min (longest 52 min) to depths of around 20 m. Longer dives, up to 80 min, have been observed for bowhead whales that were harpooned and being chased by whalers. Dives lasting longer than 1 min (“sounding dives”) average between 7 and 14 min. Dives made while whales are migrating through heavy pack ice are deeper and longer than those made while in open water. Lactating females dive less often and for shorter periods than other adult whales.

Dives of North Atlantic right whales (*Eubalaena glacialis*) near Cape Cod, Massachusetts, last around 2.1 min.

IV. Other Marine Mammals

Manatees (*Trichechus manatus*, *T. inunguis*, and *T. senegalensis*) feed on floating and submerged vegetation in shallow nearshore habitats, so it is unlikely that their dives often exceed 25–30 m. Direct observations of free-ranging animals have shown that most dives are less than 5 min, although a few have been timed at more than 20 min. These longer dives may have periods of rest at the bottom rather than feeding activity. Dugongs (*Dugong dugon*) also feed on submerged vegetation, most often in coastal and offshore seagrass beds either on the sea bottom to depths of 20 m or in surface canopies. The longest foraging dives observed are around 6 min, but most have been reported to last only between 2 and 4 min.

Sea otters dive and forage mostly on the seafloor in shallow near-shore waters. Dives may be in bouts lasting several hours during the day and night, interrupted by periods at the surface to groom, process food, or rest. Juvenile males often dive in deeper water, for longer periods, and further from shore than juvenile and adult females (Ralls *et al.*, 1995). In southeast Alaska, sea otters spend about 11–12 h each day diving, about 9 h of that actively foraging. Adult males in recently occupied habitats spend less time foraging than do adult females and also less time foraging than do sea otters in less recently colonized habitats (Bodkin *et al.*, 2007).

Polar bears are powerful swimmers and probably make some dives while moving among ice floes, the fast-ice edge, or coastlines, but nothing is known of the details of such diving performance. They prey mostly on ringed seals and whale carcasses on the surface of the ice or along shorelines and also on white whales and narwhals that they may attack and kill at the sea surface and then drag out of the water to consume.
