Females typically give birth to their first viable calf at 12–14 years of age (Olesiuk *et al.*, 2005). Intervals between viable calves average about 5 years (range 2–14 years). Females have an average of about 5 viable calves over a 25-year reproductive life span, which ends at approximately 40 years of age. Females then become reproductively senescent for an average period of 10 years, although this post-reproductive period may extend to more than 30 years. Mean life expectancy for females (calculated at age 0.5 years, following the period of high neonate mortality) is estimated to be approximately 50 years, and maximum longevity is 80–90 years. Males attain sexual maturity at about 15 years of age, as indicated by a rapid growth of the dorsal fin, and continue to grow until they reach physical maturity at about 21 years of age. Mean life expectancy for males (calculated at age 0.5 years) is estimated to be about 30 years, with maximum longevity of about 50–60 years. Mortality curves for both males and females are U shaped, although the male curve is narrower.

VI. Interactions with Humans

Although the species has long been held in high regard by many aboriginal maritime cultures, other societies feared the killer whale as a reputedly ruthless and a dangerous predator, and the animals were commonly vilified and persecuted. Attitudes toward killer whales have fortunately improved over the past few decades. The killer whale has been an admired display species in aquaria for over 30 years and has been featured in numerous movies, documentaries, and other forms of popular media. It has recently become the focus of commercial whale-watching operations in several regions.

Orcinus orca was listed by the IUCN in 2008 as Data Deficient (DD). Should the taxon be revised into two or more species, this will need to be reevaluated. Some regional populations of killer whales are small and highly specialized, and may therefore be vulnerable to over-exploitation and habitat deterioration. The Strait of Gibraltar population of killer whales is critically threatened due to its small population size (<50 individuals) and evidence of recent declines in whale numbers and their primary prey, bluefin tuna. The “southern resident community” or population of killer whales that inhabits the northwest coast of the mainland US and British Columbia is listed as Endangered under the US Endangered Species Act and the Canadian Species-at-Risk Act. Additional small, reproductively isolated populations of killer whales may exist but have not yet been identified, and it is likely that some of these may qualify for a threatened category.

Historically, killer whales in several regions have been the target of directed fisheries, culling, and persecution. An average 43 whales per year were taken by Japanese whalers from their coastal waters during 1946–1981, mostly for human consumption. Norwegian whalers took an average 56 whales per year during 1938–1981 in a government-subsidized hunt aimed at reducing killer whale numbers to reduce competition for other fisheries. The killer whale meat from this fishery was used only for animal consumption. An average of 26 was taken annually by Soviet whalers in the Antarctic from 1939 to 1975, with an exceptionally large take of 916 animals in the 1979/1980 season. Killer whales are still taken in small numbers in coastal fisheries in Japan, Greenland, Indonesia, and the Caribbean islands (Reeves *et al.*, 2003).

Killer whales have long been feared as dangerous predators or vilified as perceived or real threats to fisheries in many regions and were often harassed or shot opportunistically. Although much reduced, some persecution continues today. Killer whales have been shot illegally by fishermen in Alaska to prevent them from taking sablefish (*Anoplopoma fimbria*) from longline fishing operations (Matkin and Saulitis, 1994). Shooting by bluefin tuna fishermen in response to depredation is also considered to be a potential threat to the highly endangered killer whales residing in the Strait of Gibraltar. Killer whale depredation of longline fisheries involving various fish species has also been reported in northern and southern Pacific equatorial waters, the North Atlantic, off Brazil and Tasmania, and in the Southern Ocean.

Live-capture fisheries for killer whales represent another threat to some populations. After the first successful capture and display of the species in Vancouver in 1964, a demand arose for the acquisition of killer whales for public display in aquaria, and a live-capture fishery developed in coastal waters of British Columbia and Washington State in the mid-1960s. During 1964–1977, 63 killer whales were taken in this fishery to supply aquaria in many parts of the world (Olesiuk *et al.*, 1990). There is now evidence that the populations of resident killer whales involved in this fishery were already depressed from shootings related to depredation. During the late 1970s to mid-1980s, live captures shifted to the waters of Iceland, where over 50 whales were taken. Improved success of captive breeding during the

past decade has reduced the need for capture from wild populations, though periodic live captures continue.

Other conservation concerns include direct effects of oil spills and other forms of toxic pollution on killer whale survival. The *Exxon Valdez* oil spill in Alaska was strongly correlated with the subsequent loss of 14 whales from a pod that was seen swimming through light oil slicks early in the spill, although it was not possible to directly attribute the deaths to this cause. Oil spills may also have indirect effects on killer whales by reducing prey abundance. Their high trophic position in the food web makes killer whales susceptible to bioaccumulation of organochlorine pollutants. Levels of PCBs in resident and, in particular, transient killer whales in British Columbia and Washington state have been shown to be among the highest observed in any cetacean, and are higher than levels found to affect health in European harbor seals. It is not known whether there is a direct impact of PCBs on health in these killer whales, though such effects as immunosuppression and reduced reproductive success are possible (Ross *et al.*, 2000).

Other potential impacts of human activities on killer whale status are reduced prey availability and disturbance caused by vessel traffic. As an example, many stocks of chinook salmon, the principal prey of resident killer whales, have declined significantly in British Columbia and Washington State as a result of overfishing, degradation of spawning grounds, and reduced ocean survival. Vessel disturbance is of particular concern in areas of intensive whale-watching, though many forms of boat traffic have the potential to affect whales. The physical presence of fast moving boats near killer whales can disrupt their activities, particularly during resting, as well as put them at risk of collision. Underwater noise from vessels has the potential to interfere with social or echolocation signals, or to mask passive acoustic cues that may be important in finding prey.

On their own, many of these potential impacts on killer whales are likely insufficient to negatively affect killer whale survival. However, there is a potential for more serious cumulative effects that could displace killer whales from critical habitats or result in reduced survival.

Krill and Other Plankton

ROGER HEWITT AND JESSICA D. LIPSKY

I. Introduction

Plankton is the collective name given to the assemblage of free-swimming or suspended microscopic organisms considered too small to move independently of ocean currents. Large animals that are able to disperse under their own power are called nekton. The distinction between plankton and nekton, however, is sometimes blurred. For example, larger animals that are capable of limited self-propulsion, such as jellies and salps, are often included in the plankton. Large euphausiids, such as Antarctic krill (*Euphausia superba*), have been referred to as either macroplankton or micronekton. Phytoplankters are plants, and zooplankters are animals.

Phytoplankton consists of microscopic unicellular plants and forms the basis of marine ecosystems; nearly all life in the sea derives from the solar energy fixed in photosynthesis by these plants. Two factors control phytoplankton growth, light irradiance and nutrients.

Figure 1 Photograph of adult *Euphausia superba*. Photo by Tadashi Mizowaki, Courtesy of Inter-Research Science Center.

Light is only available in the top layers of the oceans (200 m or less) whereas nutrients are more abundant in the deeper layers. Highest concentrations of phytoplankton occur where light and adequate nutrients are coincident (e.g., areas of coastal upwelling, oceanic fronts, and transition zones). Evolution of small size has enabled phytoplankton to absorb scarce nutrients through maximizing the ratio of surface area to volume. Small size, down to 2 μm , also confers high buoyancy and a low sinking rate, keeping the cells near the surface.

Zooplankton consists of animals from several taxonomic groups from Protozoa to Vertebrata and is a main source of food for many marine mammals. Carnivorous, omnivorous, and herbivorous zooplankters have been found in the stomach of baleen whales. Three groups of crustaceans are the most important: copepods, amphipods, and euphausiids. These planktonic animals have developed a wide variety of specialized mechanisms and techniques for feeding on smaller plankton and suspended particulate matter, including appendicular nets and guiding whorls in copepods, ciliary movements in pteropods, and finely structured appendages used for filtering by euphausiids. Nektonic animals have also developed filters by modifying gillrakers into functional sieves [e.g., basking shark (*Cetorhinus maximus*) and whale shark (*Rhincodon typus*)]. Buccal teeth with well-developed accessory cusps also function as sieves in crabeater seals (*Lobodon carcinophaga*) and leopard seals (*Hydrurga leptonyx*), which feed on krill. The most highly derived filtering system among the vertebrates is that of baleen in whales.

Euphausiids, or krill (Fig. 1), have long been recognized as a critical element of the natural economy of the world’s oceans (Sars, 1885; Brinton, 1962; Marr, 1962; Mauchline and Fischer, 1969; Mauchline, 1980). Early fishery biologists repeatedly stressed the importance of various species of euphausiids as food for exploited fish and whale stocks (Lebour, 1924; Hickling, 1927; Hjort and Rund, 1929). Norwegian whalers referred to the euphausiids found in large numbers in the stomachs of whales caught in the North Atlantic as *stor krill* (or large krill, referring to *Meganctiphanes norvegica*) and *små krill* (or small krill, referring to *Thysanoëssa inermis*); the word “krill” is now used in reference to euphausiids in general (Mauchline and Fisher, 1969). Laws (1985) estimated that 190 million tons of Antarctic krill (*Euphausia superba*) were consumed annually by baleen whales in the Southern Ocean prior to their exploitation. It is estimated that current populations of whales, birds, pinnipeds, fish, and squid consume

Figure 2 Scale drawings of eight most important krill species. (A) *Euphausia superba*, (B) *E. pacifica*, (C) *E. crystallophias*, (D) *Meganyctiphanes norvegica*, (E) *Thysanoëssa macrura*, (F) *T. inermis*, (G) *T. raschii*, (H) *T. longipes*. From Mauchline and Fischer, 1969.

250 million tons of Antarctic krill annually (Miller and Hampton, 1989). Of the 85 species of krill, Mauchline and Fisher (1969) list only 8 of primary importance in terms of their distribution range, biomass, and dominance in the diets of vertebrate predators. They note that these species constitute a large fraction of the plankton where they are found and that their biomasses are largest at high latitudes. In addition to their numbers, the habit of euphausiids to form large swarms makes them particularly important as prey to marine vertebrates.

The krill species considered most important to the trophodynamics of marine ecosystems are: *M. norvegica*, *T. raschii* and *T. inermis* in the North Atlantic Ocean, *E. pacifica*, *T. inermis*, *T. raschii*, *T. longipes*, and *T. inspinata* in the North Pacific Ocean, and *E. superba*, *E. crystallophias*, and *T. macrura* in the Southern Ocean (Figs 2 and 3). Mauchline and Fisher (1969) list another seven species of importance in more restricted geographical areas and/or seasons: *Nyctiphanes couchii* in the North Atlantic Ocean, *T. spinifera* and *E. similis* in the North Pacific Ocean, *N. capensis* near the southern part of Africa, *N. australis* and *Pseudo euphausia latifrons* from western Australia to New Zealand, and *E. vallentini* in the Southern Ocean. In addition, the following seven species are often cited in predator diet samples from restricted locales and time periods: *Nematocelis megalops* in the North Atlantic, *E. recurva*, *E. lucens*, *E. hemigibba*, *T. gregaria*, *E. spinifera*, and *N. megalops* from western Australia to New Zealand, *E. recurva*, *E. lucens* and *T. gregaria* near the southern part of Africa, and *N. simplex* along the western coast of North America.

Although many of these species are broadly dispersed, they exhibit their highest densities in areas of enhanced seasonal primary and secondary production. These areas include eastern boundary currents, coastal and oceanic upwelling regions and sea ice edge zones as well as estuaries, fjords, and small-scale eddies where physical mechanisms

may enhance the aggregation of krill. It is not surprising therefore to find krill predators, including baleen whales and crabeater seals, concentrated in these areas as well.

Krill species differ in their geographic distribution, body size (ranging from <1 cm to 14 cm), and longevity (ranging from <1 year to as many as 10 years) but share many other characteristics that contribute to their importance as prey for baleen whales. Furthermore, baleen whales have not shown strong species or size selectivity among krill when foraging in an area where more than one species and/or developmental stage are present. Krill are therefore described here in general terms with species-specific references only where appropriate.

II. General Morphology and Life History of Krill

The body plan of krill (Fig. 4) is divided into two main regions, the cephalothorax and the abdomen. The cephalothorax, a fused head and thorax, contains the internal organs including the digestive system, the heart, and the gonads. It is about one-third of the body length and is covered by a thin shell or carapace. The muscled abdomen is made up of six segments ending with a telson and two pair of uropods, which together form a fan shape at the tail. At the head there are a pair of eyes and two pair of antennae with tactile and olfactory sensors; excretory organs open near the second set of antennae. The mouth is made up of several parts whose function is to filter, macerate, and manipulate food prior to ingestion. Six to eight pairs of limbs are connected to the thorax and are used to filter particles out of the water and pass them to the mouth. Unlike decapod crustaceans (crabs, lobsters, prawns, shrimps) the gills of krill are exposed, hanging below the carapace. The first five abdominal segments each have a single pair of limbs (pleopods) attached, which are used for swimming; the sixth abdominal segment has no appendages. On a mature adult male the first pair of pleopods is modified to form a petasma which is used during copulation to clasp and transfer spermatophores to the female. The thelycum, or female copulatory organ, is located on the anterior underside of the thorax near the opening of the oviducts.

The exoskeletons of krill are translucent, allowing a view of the internal organs, including the heart, stomach, and hepatopancreas, which is often colored dark green or red. Krill are also luminescent with light-emitting photophores located at the bases of their pleopods, near the thelycum, close to the mouth and in the eye stalks. The photophores are a deep red color but emit electric blue light in the water. Many species are also pigmented with red chromatophores that expand when the animal is stimulated. As a result swarms of krill often appear to be bright red, particularly when under attack by a predator. The guano of krill-eating birds is often pink in color and the feces of krill-eating marine mammals are characteristically dark red.

As krill mature sexually, males elaborate packets of sperm called spermatophores and females develop clusters of eggs or broods. During spawning the male grasps the female with his petasmae and transfers spermatophores to her body where they adhere in the vicinity of her thelycum. Among the various species of krill, brood size ranges from tens of eggs to several thousand and some species have been observed to spawn several broods during a single breeding season. When a female releases a brood of eggs, they are fertilized by spermatozoa now liberated from the spermatophores. For some species the female carries the fertilized eggs in brood pouches until they hatch, thereby protecting them from predation. For most species, however, eggs are released into the open sea. In some cases the eggs are neutrally buoyant, but often they are heavier than water and sink before hatching into nauplius larvae, which in turn develop and molt through a series of larval stages each resembling the adult morphology

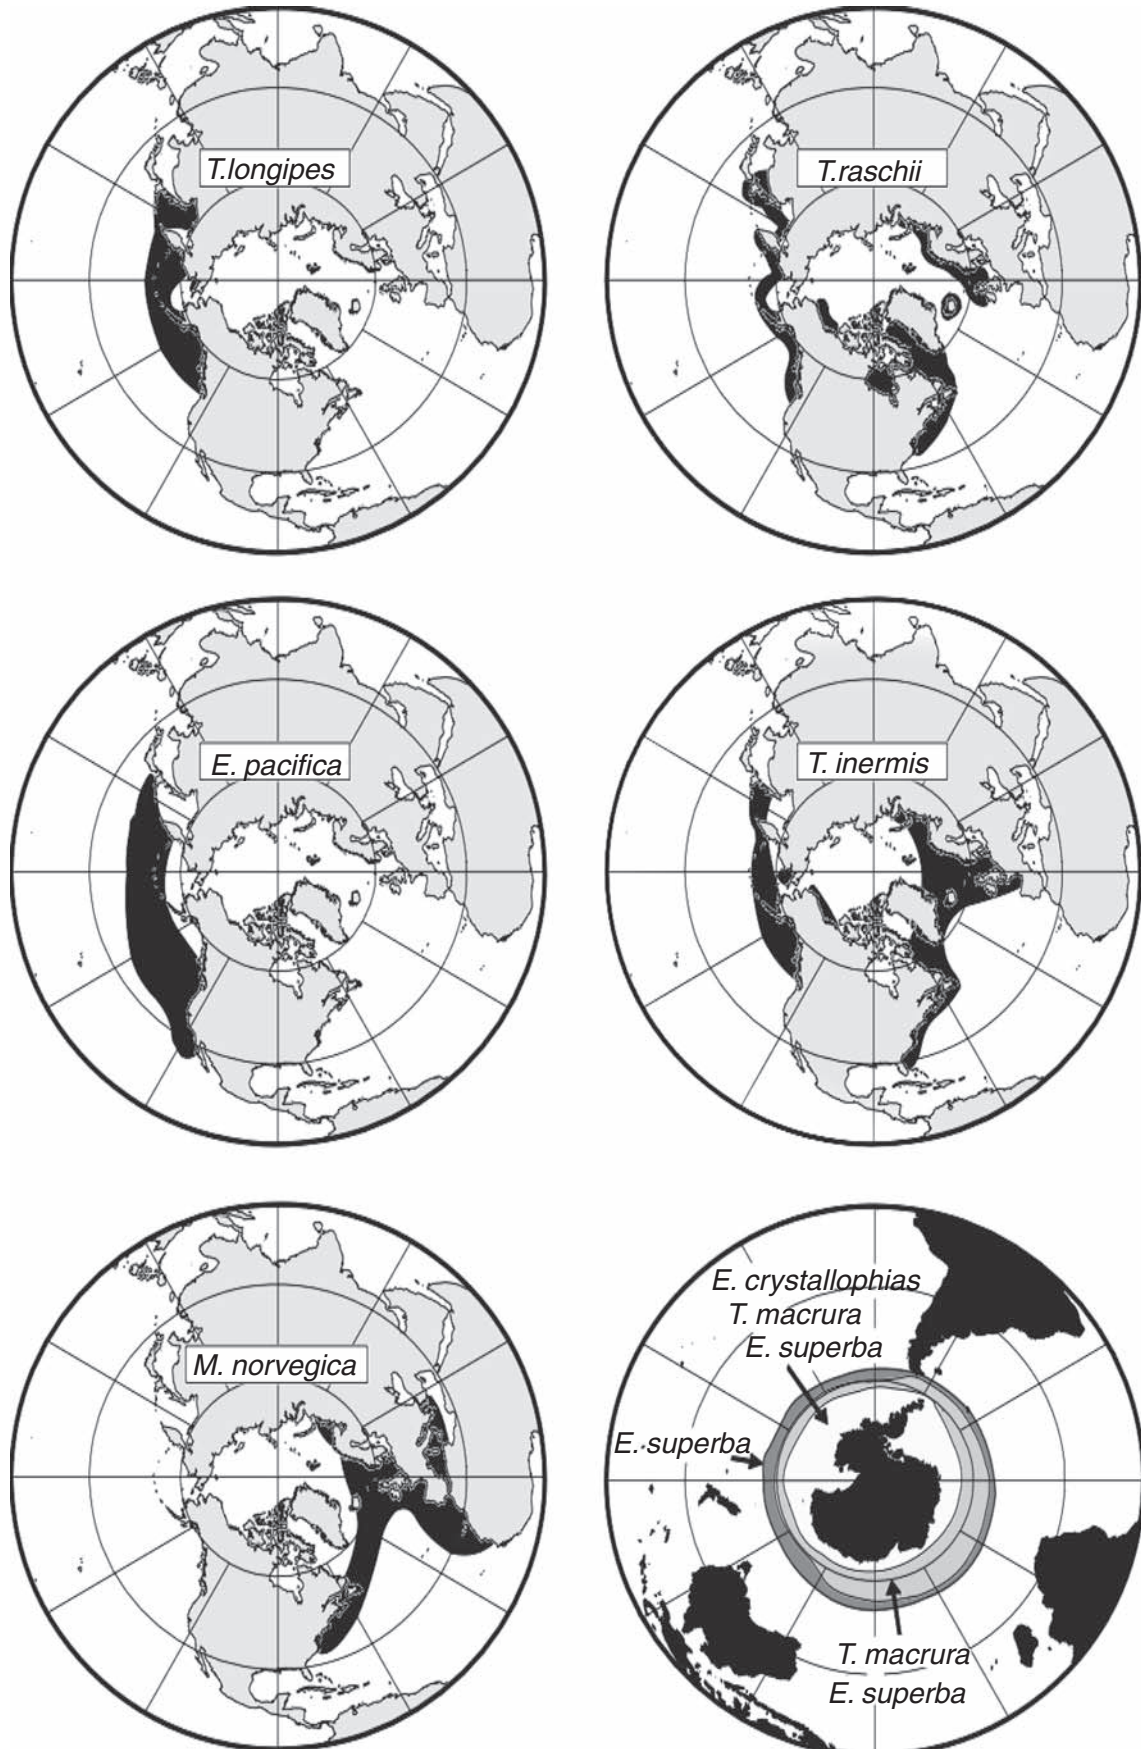

Figure 3 Northern and Southern hemisphere maps showing dispersion of important krill species (redrawn from Mauchline and Fischer, 1969).

K

Figure 4 General krill body plan.

more than the previous stage. In the case of *E. superba*, a brood of 10,000 fertilized eggs may be released by a single female in a near-surface swarm of spawning adults; the eggs sink to depths of greater than 1000 m, incubate and hatch. The nauplius has no swimming appendages and continues to sink as it grows, molts, and gives rise to more advanced larval forms. Once it can swim, the larva begins its ascent into the surface waters, progressing through several more molts and ultimately emerging as a calyptosis larva. Calyptoses continue to eat, grow, and molt through additional stages in preparation for the winter when food is less available. Sometime in the late winter or the early spring the calyptoses finally metamorphose into juvenile krill, but it may be as long as another year before they are ready to spawn themselves. In the case of *E. pacifica*, this process is compressed to a few months, with spawning occurring during the spring and recruitment into the adult population occurring during the fall.

Except for rich fat stores invested in developing eggs, larval and post-larval krill do not develop high levels of fat reserves. Consequently they must eat constantly in order to offset the energy costs of swimming, growth, and reproduction. In addition, krill periodically shed their exoskeletons throughout their life, adding substantially to their energy requirements. Krill are generally thought to be filter-feeding herbivores, grazing on phytoplankton in the surface layers of the ocean. Many species, however, are reported to be omnivorous, filtering and/or capturing copepods and other small zooplankton. *E. superba* has been observed in the cavities and cracks on the underside of winter sea ice presumably feeding on interstitial ice algae. Krill growth and reproductive activity have been directly linked to available food supplies. Negative growth and regression of sexual characteristics has been observed in several species and related to lowered availability of food.

III. Swarming

Krill are heavier than water and must continually swim in order to maintain their position. They aggregate into dense swarms, which can take on a variety of shapes from discreet balls to extensive layers. The swarms may range in thickness from one meter to several tens of meters and may extend horizontally tens of meters to several thousand meters. Individual animals appear to be in constant movement, and a sharp gradient in density is often observed at the periphery of a swarm. Within the swarm, volumetric densities may range up to several thousand animals per cubic meter. Near the shelf break surrounding islands in the southwest Atlantic sector of the Southern Ocean it is not uncommon to observe large swarms of *E. superba*, each estimated to contain several thousand tons of krill. Most krill species migrate vertically each day, moving into the upper waters at night and dispersing; just before dawn they move downward and aggregate into denser concentrations. It is generally thought that this behavior is the result of a

trade-off between avoiding predation (dense swarms deep in the water during the day) and maximizing feeding efficiency (dispersed individuals in the more particle-rich surface water at night). Although this is a regular pattern, vertical migration behavior varies among species and within a species depending on location and season. Daytime surface swarms have been observed for several species; they often contain reproductively mature individuals.

Highest densities of krill have been reported near areas of strong vertical mixing and enhanced primary production. These include coastal upwelling zones, ocean frontal boundaries, and topographic features that interrupt or modify currents such as continental shelf breaks, underwater canyons, and escarpments and seamounts. Krill swarms also tend to aggregate in areas of water flow discontinuity such as eddies and shear zones between opposing currents.

IV. Recruitment Variability

Recruitment of young animals into adult euphausiid populations is highly variable in space and time. Production of spawn and survival of larvae may vary widely within the distribution range of a species as well as between reproductive events. In his review of euphausiid life histories, Siegel (2000a, b) notes that most species reduce their growth phase and extend their reproductive phase toward the center of their distribution ranges. Closer to their distribution limits, krill put more time into growth and less into reproduction.

There is no apparent relationship between the stock size and the production of new recruits for most species studied. Relatively large adult stocks can produce few new recruits and small adult stocks are capable of producing enough new recruits to increase the stock abundance several fold. The intensity of spawning, survival of eggs and larvae, and the rate of growth have been shown to vary widely between years for several species, resulting in large year-to-year variability in abundance. Interannual variability in abundance has been estimated as 10-fold for *E. pacifica* and *N. simplex* off the west coast of North America, 25-fold for *T. inermis* in the Barents Sea, and 5- to 60-fold for *M. norvegica* at different parts of its range in the North Atlantic.

Recruitment success is affected by exogenous factors, which act to enhance adult reproduction, survival of eggs, and growth of larvae. The best documented of these is the influence of coastal upwelling, which enhances the primary production and the subsequent growth and maturation of young krill. Temperature affects the incubation rate of eggs and growth rate of larvae exposing them to longer or shorter periods of predation. Fluctuations in currents may also transport animals into unfavorable areas. Near the Antarctic Peninsula, *E. superba* spawn earlier in the spring and for a longer period following winters of extensive sea ice development; their larvae enjoy a higher survival rate if sea ice is extensive during the following winter

(Loeb *et al.*, 1997). Four to five year cycles are apparent in the seasonal extent of sea ice and the recruitment of krill in this region of the Southern Ocean. The postulated affect of seasonal sea ice is to provide a refuge, access to a wintertime food source (ice algae), and to inhibit rapid springtime population growth of a potential competitor to krill, *Salpa thompsoni* (Loeb *et al.*, 1997). *Salpa thompsoni* is a pelagic tunicate and obligate filter feeder, which requires open water access to springtime phytoplankton blooms in order to reproduce.

V. Foraging Tactics of Baleen Whales and Crabeater Seals

The two characteristics of euphausiids described earlier—(1) an immediate response, in terms of individual growth and reproductive output, to favorable conditions and (2) highest densities in predictable locales—allow efficient exploitation of krill by baleen whales. In general, baleen whales migrate between high latitude summer feeding grounds and low latitude winter breeding and calving grounds. Exceptions are bowhead whales, which are restricted to Arctic regions, and Bryde's (*Balaenoptera edeni*) and Omura's whales (*B. omurai*), which usually range from subtropical to temperate waters. Blue (*B. musculus*), fin (*B. physalus*), and sei (*B. borealis*) whales tend to migrate in offshore waters, whereas gray (*Eschrichtius robustus*), right (*Eubalaena* spp.), and humpback (*Megaptera novaeangliae*) whales tend to use a more coastal migration route. Adult whales are thought to feed less during migration than immature or undernourished animals. Off the western coast of North America, blue, fin, Bryde's and humpback whales have been observed feeding on euphausiids aggregated along underwater escarpments and canyons during both winter and summer. The location and timing of whale foraging follows the appearance of high densities of euphausiids and tends to progress from south in the winter to north in the summer. In recent years, aggregations of euphausiids and foraging whales have been a predictable event in the Gulf of California during late winter, near underwater seamounts and canyons off northern California in the summer, and along the shelf break surrounding the Channel Islands in the fall.

Actively feeding whales have been observed to lunge through surface swarms of krill, engulfing large quantities of water and distending their throats, before expelling the water and extruding as much as several hundred kilograms of krill. Similar feeding behavior on subsurface swarms has been inferred from acoustic records of krill layers superimposed with dive tracks simultaneously recorded by instruments attached to foraging whales. There are many reports of humpback and fin whales herding and concentrating their prey before lunging through an aggregation of krill. Bryde's and minke whales (*B. acutorostrata* and *B. bonaerensis*) have also been observed gulping large quantities of aggregated euphausiids. Foraging by right whales has been described as skimming a continuous stream of water rather than gulping; this behavior may be more efficient with dispersed prey (Nemoto, 1970). Sei and gray whales appear to use both methods.

Despite their name, crabeater seals (*Lobodon carcinophaga*) eat very little other than krill. They are found in the sea ice zone in the Southern Ocean and constitute 50% by number (75% by weight) of the world pinniped population. Crabeaters have lobed cusp teeth with spaces between them. It is presumed from the shape of the mouth, tongue, and spacing between the teeth, that crabeater seals engulf a portion of an aggregation of krill and then strain the water similar to a baleen whale. Crabeaters tend to feed at night when krill are in the upper layers and more dispersed than during the day.

VI. Marine Mammal Diets and Euphausiid Consumption by Ocean Basin

A. North Pacific

Blue whales in the eastern North Pacific, foraging from the British Columbia to the Californias, feed principally on three species of krill in the California Current; *Euphausia pacifica* and *Thysanoëssa spinifera*, the more inshore species, which is replaced by *Nyctiphanes simplex* moving south. Fin whales have been observed feeding from the Gulf of California to the northern parts of the Bering Sea from April to September respectively. During the late winter and the spring fin whales feed on *N. simplex* in the southern portion of their foraging range; moving north in the summer they feed on *E. pacifica*, *T. raschii*, *T. longipes*, and *T. inermis*. Fin whales have also been observed to feed on copepods, the change in prey type related to changes in local relative densities of prey. During the summer months sei whales consume a variety of euphausiid species including *T. gregaria*, *E. pacifica*, *E. recurva*, *E. diomedea*, *E. tenera*, *T. inermis*, *T. spinifera*, *N. difficilis*, and *N. gracilis*. South of Japan less than 2% of sei whale diet has been reported to consist of fish. Prey species consumed near the Aleutian Islands include copepods, amphipods, decapods, fishes, and squids. Sei whales, in comparison to blue whales and fin whales, appear to be more opportunistic feeders willing to switch prey type more readily in response to local availability. Bryde's whales have been observed consuming *E. similis*, *N. difficilis*, and *T. gregaria* as well as amphipods, copepods, and fish in the western Pacific and both euphausiids and fish in the Gulf of California. Humpback whales have been observed foraging on euphausiids, including *E. pacifica*, *T. raschii*, *T. longipes*, and *T. spinifera*, from Southeast Alaska to Baja California, although a substantial part of their diet includes clupeoid fish as well. Bowhead whales forage primarily on *T. raschii* and *T. inermis* in the Bering and the Beaufort Seas during summer and fall, although copepods, mysids, and amphipods also form a part of their diet. Common minke whales (*B. acutorostrata*) have been observed foraging on euphausiids but appear to prefer fish throughout the North and the northeastern Pacific. Gray whales are thought to consume primarily benthic amphipods in the Bering Sea during the summer months, although there are reports of gray whales consuming *T. raschii* in the Bering Sea and *E. pacifica* off northern California. Prey selectivity among ringed seals appears to be dependent on seasonality and location. Ringed seals (*Pusa hispida*) have been reported to eat *T. raschii*, *T. longipes*, and *T. inermis* in offshore waters in the Northern Hemisphere in spring and summer when krill abundance is greatest; in the winter they consume Arctic cod and other fish species in inshore waters.

B. South Pacific

Bryde's whales have been observed feeding on *E. diomedea*, *E. recurva*, and *T. gregaria* and occasionally fish in the Coral Sea (western South Pacific) during the austral spring. In the eastern South Pacific Bryde's whales consume euphausiids during the austral summer between 35° and 40° south latitude. Humpback whales have been observed off the east and west coasts of Australia feeding on euphausiids, including *E. hemigibba*, *P. latifrons*, and *E. spinifera*.

C. North Atlantic

Fin whales feed primarily on *M. norvegica*, *T. inermis*, and *T. raschii* during the summer months, switching between prey species in response to local availability. Common minke whales consume

T. inermis and *M. norvegica* in the North Atlantic, where euphausiids form a much larger portion of the diet than in the Pacific. Northern right whales feed primarily on copepods, although consumption of euphausiids has been observed, particularly when associated with copepods. Harp seals (*Pagophilus groenlandicus*) feed on a variety of prey including decapods, amphipods, euphausiids, and pelagic fishes; however, newly weaned pups and young seals have been reported to feed mainly on *Thysanoëssa* species.

D. Indian Ocean

Fin and Antarctic minke whales (*B. bonaerensis*) have been observed feeding on euphausiids in the southwest Indian Ocean during their spring and fall migrations to and from the Southern Ocean; prey species include *E. recurva*, *E. lucens*, *T. gregaria*, *E. spinifera*, *N. capensis*, and *E. diomedae*. Bryde's whales forage on these euphausiids species as well in the southwest Indian Ocean. Near Durban, South Africa humpback whales have been observed feeding on *E. recurva* and *T. gregaria* and a single pygmy blue whale was reported to be feeding on *E. recurva* and *E. diomedae*. Sei whales were observed to consume euphausiids as well as copepods, amphipods, pteropods, and fish.

E. Southern Ocean

Fin and Antarctic minke whales consume several species of krill in the Southern Ocean throughout the austral summer. Species preference appears to be related to local availability, with *T. macrura* and *E. vallentini* more prevalent in the diets of animals foraging in open waters and *E. frigida* and *E. crystallorophias* more prevalent near the continental shelf and ice edge regions. The numerically dominant euphausiid in the Southern Ocean, *E. superba*, is consumed in all areas. Southern right whales (*E. australis*) have been observed foraging on *E. superba* in the Atlantic sector of the Southern Ocean. Humpback whales have been frequently observed foraging on *E. superba* in bays and in fjords along the Antarctic Peninsula. Crabeater seals consume *E. superba* and *E. crystallorophias* in the sea ice zone and in coastal fjords and bays; Antarctic silverfish have been reported as seasonal constituents of their diet but krill has been estimated to provide over 90% of their prey requirements. Much smaller portions of the diets of leopard (*Hydrurga leptonyx*) and Ross (*Ommatophoca rossii*) seals and Antarctic (*Arctocephalus gazella*) and subantarctic (*A. tropicalis*) fur seals have been reported to be composed of krill.

F. Summary

From these observations some generalizations may be drawn: (1) blue and fin whales appear to have a higher preference for euphausiids than minke, humpback, or bowhead whales; (2) sei and Bryde's whales appear to be more opportunistic feeders; (3) gray whales and northern right whales prefer prey other than euphausiids but will consume them; (4) crabeater seals have a higher preference for euphausiids than other seals in the Southern Ocean; and (5) ringed and harp seals in the Northern Hemisphere include euphausiids in their diets during certain times of the year and life cycle.

Gross estimates of the consumption of euphausiids by marine mammals are summarized in Table I. Estimates of stock abundances were obtained from working papers and reports of the International Whaling Commission, reports from the US National Marine Fisheries Service, and the primary literature. In some cases no reliable estimates are available and broad ranges were used. Daily ingestion rates for baleen

whales during the feeding season were estimated from energetic requirements as a function of body weight following Sigurjonsson and Vikingsson (1997). A daily ingestion rate for seals was estimated as 7% of body weight. Average body weights, the percentages of euphausiids in the diets, and the caloric value of euphausiids (0.93kcal/g) were taken from the primary literature. The duration of the feeding season was assumed to be 180 days for Northern Hemisphere baleen whales and seals, 120 days for Southern Hemisphere baleen whales and Antarctic and subantarctic fur seals, and 335 days for crabeater, leopard, and Ross seals.

Although Table I is based on several simplifying assumptions, some general conclusions may be drawn. Total consumption of euphausiids by marine mammals is on the order of 10–20 million tons per year in the North Pacific, 15–25 million tons per year in the North Atlantic, and 125–250 million tons per year in the Southern Hemisphere, with the bulk of the latter portion consumed in the Southern Ocean. In the North Atlantic, the largest portion is consumed by fin whales, followed by common minke whales. In the North Pacific, consumption is more evenly distributed, with fin and bowhead whales consuming the most, followed by blue, sei, Bryde's, and common minke whales, all of which consume similar portions. In the Southern Hemisphere, comparable proportions of euphausiids are consumed by crabeater seals and baleen whales. Of the estimated total krill consumption by baleen whales in the Southern Ocean, Antarctic minke whales consume approximately two-thirds. Crabeater seals consume more krill than any other marine mammal population in the world.

These crude calculations suggest that baleen whales consume a substantial amount of euphausiids. Moreover, their food requirements must have been several times higher prior to commercial whaling. Unfortunately, there is little information on which to judge whether krill production was higher prior to the onset of commercial whaling or whether other krill predators (e.g., crabeater seals) benefited as a result of the decline in baleen whale stocks.

What is more apparent is that krill abundance can vary dramatically over relatively short periods of time and that baleen whales have adapted to this variability. Their size and ability to accumulate substantial energy stores allow them to integrate over large distances and periods of time in their search for food. Their longevity allows them to spread reproductive effort over several years. It is reasonable to expect, however, that the supply of euphausiids will not be sufficient in all years to meet total energy requirements, and that reproductive success and population growth among krill-dependent baleen whales may vary from year-to-year in response to the availability of their prey.

VII. Anthropogenic Affects

The production of euphausiids can be very sensitive to environmental conditions. This raises two concerns with regard to the influence of human activities. The first is that highly productive euphausiid populations may be able to sustain large fisheries (Fig. 5). The second is that climatic change (whether man-induced or not) may affect the frequency of environmental conditions that are favorable for reproductive success. Because these are relatively recent developments, we cite three studies below as entries into a larger body of literature (Nicol and Foster, 2003; Croxall and Nicol, 2004).

Fisheries on euphausiids have the potential of being the largest in the world. In their review of krill fisheries, Nicol and Endo (1999) describe the harvest of *E. pacifica* off the coasts of Japan and

TABLE I
Marine Mammal Stock Abundance, Average Body Weight, Daily Ingestion Rate, Duration of Feeding Season, Proportion of Krill in Diet, and Total Krill Consumption by Ocean Basin

<i>Ocean basin</i>	<i>Whale species</i>	<i>Abundance</i>	<i>Average body weight (t)</i>	<i>Summertime ingestion rate (10³ kcal/day)</i>	<i>Feeding period (days)</i>	<i>Krill in diet (%)</i>	<i>Krill consumed (10³ tons)</i>
North Pacific	Blue whale	3,000–4,000	69.2	2,136	180	100	1,240–1,654

western Canada, *T. inermis* off the coasts off Japan and eastern Canada, *E. nana* off the coast of Japan, *T. raschii* and *M. norvegica* off the coast of eastern Canada, and *E. superba* in the Southern Ocean. In recent years, the harvest of *E. pacifica* off Japan (~60,000 tons per year) and *E. superba* in the Scotia Sea region of the Southern Ocean (~100,000 tons per year) comprised over 90% of the world harvest of euphausiids. Nicol and Endo (1999) note that

these yields are well within their theoretical potentials, although expansion of the coastal fisheries is unlikely because of ecological, economic, and political considerations. They further note, however, that as conventional fisheries decline and demand for krill as aquaculture feed increases, fishing pressure is likely to shift to *E. superba* in the Southern Ocean, where current harvests are far below current estimates of sustainable yields.

Figure 5 Japanese krill trawlers operating off the north coast of Elephant Island, South Shetland Islands, Antarctica Photograph by (R.P. Hewitt).

Recent evidence suggests that the production of euphausiids may be affected by long-term climatic change. Warming of the surface waters of the California Current since the mid-1970s has been accompanied by a reduction in the depth of the thermocline, reduced nutrient input via coastal upwelling, reduced primary production and an overall decrease in macrozooplankton biomass by as much as 80% (Roemmich and McGowan 1995; Lavaniegos and Ohman, 2007). Euphausiids are the dominant taxa in the macrozooplankton fauna of the California Current and have shown decreased abundances during warm (El Niño) years and increased abundances during cold (La Niña) years. A 50-year warming trend in the Antarctic Peninsula region has been associated with a decrease in the annual production of sea ice. Loeb *et al.* (1997) and Nicol *et al.* (2000) correlated the reproductive success of *E. superba* with the wintertime extent of sea ice and suggested that the warming trend may cause a decrease in the frequency of strong year classes of Antarctic krill, a decrease in the mean population abundance of krill, and a change in the carrying capacity of vertebrate krill predators in the region.

L

Language Learning and Cognitive Skills

LOUIS M. HERMAN

No single trait has been linked more closely with the human species than language. However, the definition of language, its relation to animal communication, and its origins continue to be areas of study and debate. One of the most contentious areas is the degree to which there is evolutionary continuity between human language mechanisms, and characteristics and mechanisms extant or tutored in selected animal species. Mechanisms include brain structures and processes as well as articulatory and receptive systems; characteristics include such human language features as semanticity, reference, syntactic structure, and openness as well as the pragmatic characteristics that typify a child's acquisition of language.

The linguist Noam Chomsky (Chomsky, 1972, 1975) viewed human language as a unique development supported by a "language acquisition device" (LAD), whose embodiment in the brain was to be found only in humans. He later elaborated on this idea, postulating the existence of a hard-wired "Universal Grammar" that provides a basic grammatical template that can be modified by exposure to fit the grammar of any language heard by the child. Chomsky asserted that animals do not have a LAD or a universal grammar module, and therefore cannot have language. In these views, human language appeared as a *saltational* event, an abrupt evolutionary development, likely occurring through a genetic mutation and as a by-product of the pattern of growth and development of the human brain. Alternatively, these views maintain, language could have appeared as an *exaptation*, a by-product of a mechanism or function evolved for some purpose other than language. As an example of an exaptation, bird feathers might have evolved originally as an adaptation for thermal insulation but were later co-opted for flight. Pinker (1994), although favoring a discontinuity position—there is no relation between human language and animal communication—believes that the language faculty did not arise *de novo*, but evolved as a unique *adaptation* that followed the laws of Darwinian natural selection, arising relatively gradually. The view that language is a uniquely human "instinct" with no continuity with any form of animal communication is emphatically contested by several other linguists. Lieberman (2000, 2006), a prominent critic of Chomskian notions of a language organ and a linguistic gene, contends that the roots of human language are present in other species. He cites evidence that the human functional language system is distributed widely across many subsystems of the brain, including

subcortical areas present in many animal species, and posits that the evolution of a language capacity was a gradual process stretching over 2 million or more years.

Some other recent work appears to attempt to meld properties of human language and animal communication, at least partially by hypothesizing that almost everything essential to human language can be found in other animals, in particular the sensory-motor systems and the cognitive systems ("conceptual-intentional systems") (Hauser *et al.*, 2002). What humans added, these authors contend, is a key computational process, *recursion*, "the capacity to generate an infinite range of expressions from a finite set of elements" (p. 1569). Recursion refers to the hierarchical structure of human language: morphemes combine into words, words into clauses, clauses into sentences, and moreover, for example, sentences can be embedded within sentences. Recursion, coupled with syntactic devices that allow for determining the grammatical relation between words (e.g., as subject vs object), gives language its rich open-ended generative capacity. Jackendoff and Pinker (2005), however, reject recursion as the sole discriminator of human language and animal communication, while at the same time viewing language "as a combination of components, some special to language, others rooted in more general capacities in human or animal cognition" (p. 223). They are therefore supportive of experimental work on animal communicative abilities in efforts to connect theories of grammar to evolutionary principles.

It is within these diverse contexts and disputes that the study of cognitive processes in animals and their competencies for learning forms of communication that have language-like properties take on special meaning and value. As Lieberman (1984, p. 333) stated, "the nature and evolution of the biological basis of language can ultimately be ascertained only by actually studying the cognitive, linguistic, and communicative behavior of human beings and the other animals to whom we are all related." The developing body of work on animal cognition indeed testifies to the depth and the breadth of cognitive skills that may be demonstrated in many large-brained mammals, not only the close relatives of humans, the great apes, but also in the evolutionarily divergent but large-brained common bottlenose dolphin (*Tursiops truncatus*) and several other cetacean species. Within this work, the ability of animals to learn some defining properties of language has been a subject of intense study.

I. Human Language and Ape Language

The work on teaching language-like systems to apes, by Beatrice and Alan Gardner, David Premack, Duane Rumbaugh, and others, beginning in the mid-1960s and continuing throughout the decade of the 1970s, seemed to provide a genuine link between human and ape in fundamental language competency (see reviews in Ristau and Robbins, 1979; Herman, 1987). This early work reported that common chimpanzees (*Pan troglodytes*) were able to learn to understand and use not only individual words but also words strung together into sentences. Sentences give human language its vast communicative power through the infinite variety of meanings that can be constructed by the combination and recombination of words. To understand a sentence, the human listener must take account not only of the meaning and referents of the words but also their grammatical relationship to one another, as governed by some syntactic device such as word order. This early work on teaching language to apes was thrown into disarray, however, by additional studies and criticisms from other researchers, such as Herbert Terrace (Terrace *et al.*, 1979) and Carolyn Ristau (Ristau and Robbins, 1979). These researchers argued that the putative "sentences" produced by the apes were largely an artifact of

context, imitation, or social cueing. Further, although sequences of symbols were indeed produced by the apes, the sequences often had no syntactic structure that enhanced, explained, or modified meaning.

Historically, this work with apes focused primarily on language production and paid scant attention to language comprehension. Investigators attempted to teach the apes to produce requests or statements through learned gestures, or the pressing of keyboard symbols, or the use of other types of artificial symbols, assuming that if the ape produced a gesture or other learned symbol, or a sequence of such productions, that it understood what it was communicating—that it understood what the word or sequence meant or represented. A further assumption was that the ape would understand those same words or sequences when produced by the human partner. These assumptions, when later tested, proved largely false. It was found, instead, that comprehension did not flow automatically from production. The preeminence of language comprehension over language production, only relatively recently appreciated by ape language researchers (Herman and Morrel-Samuels, 1990), has long been appreciated among those studying child language. Language comprehension by young children develops earlier than language production, and even into adulthood, comprehension vocabularies exceed speaking vocabularies (Bloom, 1974).

More recent language work with bonobo chimpanzees (*P. paniscus*), pioneered by Savage-Rumbaugh *et al.* (1993), emphasized language comprehension and has progressed well beyond the findings from the earlier ape language studies. The bonobos have shown an ability to learn to understand instructions given in spoken English sentences, with at least a rudimentary appreciation that sentence structure affects meaning. Further, Savage-Rumbaugh has shown that both common and bonobo chimpanzees can learn to appreciate that symbols (words) of the language can function as references to objects and actions. This understanding that words *refer* is one of the key characteristics of human language. Referential understanding enables us, for example, to discuss objects or events that are not immediately present or that happened at a different place or time.

II. Dolphins and Language

A. Natural Language?

Dolphins (including the common bottlenose dolphin) produce various types of sounds including clicks and burst-pulse emissions, and, for some species, whistles. Clicks are used for ECHOLOCAION (Au, 1993). Through echolocation, the dolphin can examine its underwater world by listening to the echoes returning from its emitted clicks as they strike reflective surfaces. Dolphin echolocation apparently can yield an “image” or mental representation of an ensonified object that is functionally similar to the image derived through vision (Herman *et al.*, 1998; Pack *et al.*, 2004). Burst-pulse sounds may indicate the dolphin’s emotional state, ranging from pleasure to anger (Herman and Tavolga, 1980; Herzing, 1996). However, burst-pulse sounds have been relatively little studied and much remains to be learned about them. Whistles may be used for COMMUNICATION, but it is still an open question as to whether or how much of whistle production is communicative and intentional (thus, rapidly repeated whistling may be elicited by stress, without any apparent intention to convey that emotional state to others). During the 1960s, researchers attempted to determine the diversity of whistles from dolphins (principally bottlenose dolphins, *Tursiops* spp.), whether these whistles were tied to specific contexts or events, and whether they might support a language (see review in Herman and Tavolga, 1980). Estimates of the number of distinct whistles produced by bottlenose dolphins have varied widely across studies, and the validity and reliability of the different techniques for separating

and classifying samples of whistles still remain an unsettled issue (*cf.* Janik, 1999; McCowan and Reiss, 2001). Some early work pointed to the stereotype of the whistles from individual dolphins, leading to the hypothesis that the whistle functioned principally as a “signature,” with each individual dolphin producing a unique and predominant whistle type (Caldwell and Caldwell, 1965). Presumably, this signature quality enabled that individual to identify itself to others, knowingly or not. McCowan and Reiss (2001), however, contended that there was no individually unique signature. Instead, many different whistles are produced (see also McCowan *et al.*, 1999), but under the conditions of isolation studied by the Caldwells, most dolphins typically produce a single shared whistle that the authors describe as rising in frequency (an upsweep) and which they term “Type 2.” Individual recognition was still present, these authors contended, in the distinctive “voice” characteristics of the individual dolphin producing the Type 2 whistle. Janik *et al.* (2006), proponents of the signature whistle hypothesis, have, however, recently presented evidence that individual recognition was not based on voice characteristics but on the contour or shape of the whistle, as it varied in frequency over time. Clearly, additional study is needed to resolve these differences in theory and in evidence.

Richards *et al.* (1984) demonstrated that a bottlenose dolphin could use its whistle mode to imitate a wide variety of sounds of different frequencies and waveforms generated by a computer and broadcast underwater into the dolphin’s habitat and could also use learned whistles to “label” objects (see also Reiss and McCowan, 1993). Tyack (1986), studying wild dolphins in Sarasota Bay, Florida, reported that one dolphin could imitate another’s typical whistle, thereby possibly referring to or calling that individual. Janik (2000) provided additional evidence for whistle matching in wild dolphins in the Moray Firth in Scotland, and suggested an analogy to the presumptive earliest stage of the development of human language—when a vocalization (or gesture) was invented to refer to some object or event and that symbol was then shared with others. Janik’s dolphin analogy was that signature whistles are “invented” individually, and that the imitation of one dolphin’s whistle by another dolphin was, in effect, symbol sharing of an invented self-reference. We do not know, however, to what extent the dolphin’s imitations are *intentional* references to another or whether whistles, or other dolphin vocalizations, may be used to refer to things other than themselves or another dolphin. This is a fruitful area for additional study.

Although the available evidence strongly suggests that dolphins do not possess a natural language sharing the basic characteristics of semanticity and syntactic structure of human language (Herman, 1980), it is nevertheless important for a deeper understanding of animal communication and its relation to human language to investigate whether they might be able to learn to utilize those fundamental characteristics if tutored in a language-like symbolic system. Any demonstration of language-learning competency by dolphins would bear on questions of the origins of human language, shifting the emphasis from a search for language precursors only in other hominoid species or ancestors to an examination of common or convergent cognitive or social characteristics shared by ape and dolphin that might lead to advanced communicative skills in both species. A large number of behavioral studies of bottlenose dolphins have in fact revealed extensive cognitive skills, both in laboratory settings (reviewed in Herman, 2006) and in the wild (reviewed in Connor, 2007), many of which are shared with the apes. Similarly, the complex social structure of dolphin societies, including higher-order alliances, has also been amply documented (reviewed in Connor *et al.*, 2000, 2007) and has resemblances to some of the complexities of chimpanzee social organization.

B. Dolphin Cognitive Skills

If language depends in part on rich cognitive structures, then a capacity for learning some elements of a language system might be attainable by large-brained animals exhibiting wide ranging and flexible cognitive skills. The literature demonstrating such skills in the great apes is vast (Tomasello and Call, 1997), and it is no coincidence that these skills combined with the close phylogenetic relationship of humans and apes have motivated the quest for exploration of language-learning capabilities in these species. This quest has met with interesting recent successes, particularly among bonobo chimpanzees, as noted earlier. Bottlenose dolphins share many of the cognitive skills demonstrated in apes (see reviews in Herman, 1980, 1986, 2006).

1. *Memory* Language and indeed all learning skills rest on a strong foundation of memory. Studies of dolphin short-term or “working” memory—the processing of new information and retaining it in conscious memory—show that auditory memory (memory for things heard) and visual memory (memory for things seen, including objects and behaviors) are well developed and robust in bottlenose dolphins (reviewed in Herman, 1980; see also Herman *et al.*, 1989). Dolphin short-term memory is similar in its fidelity and characteristics to demonstrated short-term memory capabilities of nonhuman primates (D’Amato, 1973), or in the case of probe memory—memory for lists of items—comparable to memory characteristics demonstrated in humans (Thompson and Herman, 1977; Herman, 1980).

2. *Rule Learning, Concept Formation, and Representation* Language proficiency is intimately interwoven with rule learning, concept formation, and representation. Bottlenose dolphins can learn a variety of governing rules for solving abstract problems (Herman *et al.*, 1994) including reliably classifying pairs of objects or sounds as “same” or “different” (Mercado *et al.*, 2000). They can learn that arbitrary symbols can represent objects, actions, agents, relationships, and locations. Dolphins can also understand representations of the real world, as illustrated by their spontaneous (untrained) ability to respond to gestural instructions from the small images of televised trainers with the same fidelity that those responses are made to “live” trainers (Herman *et al.*, 1990).

3. *Imitation* Imitation is a key component of the child’s early mastery of spoken words. Dolphins (and possibly some other cetacean species) appear to be the only nonhuman animal capable of imitating both arbitrary sounds and arbitrary behaviors including an understanding of the abstract concept of “imitate” (see review in Herman, 2002).

4. *Shared Attention and the Indicative* In the human infant, gazing and pointing as communicative devices often precede more sophisticated language skills. Dolphins tested for “shared attention” reliably choose the object pointed to by a human informant or gazed at with a turn of the head (Tschudin *et al.*, 2001; Pack and Herman, 2006, 2007), and under certain conditions, they will spontaneously use their rostrum and body alignment to point at objects that they desire from a human companion (Xitco *et al.*, 2001).

5. *Creativity* In language, creativity allows for the development of novel sentences and new words. Dolphins have been shown capable of innovating motor behaviors, either individually or in close synchrony with a second dolphin (Pryor *et al.*, 1969; Herman, 2006). Innovations in feedings strategies are also well documented (Smolker *et al.*, 1997).

6. *Cross-modal Transfer* In humans, language can involve transfer from one modality to another, for example the written word to the spoken word. Dolphins have been shown capable of spontaneous transfer of object shape information across the senses of echolocation

and vision (Pack and Herman, 1995; Herman *et al.*, 1998;). An ability to transfer information across sensory modalities has been linked to a variety of intellectual functions in humans and nonhuman primates (Rose and Wallace, 1985; Gunderson *et al.*, 1990).

7. *Cultural Transmission* The child learns the language of its community through such mechanisms as imitation and tutoring within the scope of its predispositions toward language in general. Thus, language is passed from generation to generation. Cultural transmission of group-specific vocalizations or vocal dialects also occurs in some cetacean species, such as the pod-specific vocal dialects of killer whales (*Orcinus orca*) and sperm whales (*Physeter macrocephalus*), and the changing songs of humpback whales (*Megaptera novaeangliae*) that evolve collectively among male humpbacks throughout a winter season in a particular breeding ground. Other non-vocal examples of cultural transmission are the unique sponge-feeding techniques passed on from mother to daughter among subsets of bottlenose dolphins in Shark Bay, Australia, and the cooperative fishing techniques of dolphins and humans in Laguna, Brazil (Rendell and Whitehead, 2001).

There are other demonstrated cognitive abilities that illustrate the breadth of intellectual competence that can be attained, such as the ability to learn a concept of “numerically less” (Kilian *et al.*, 2003; Jaakkola *et al.*, 2005) or to exhibit meta-cognition, “sometimes described as an awareness of one’s personal knowledge or lack of knowledge” (Smith *et al.*, 1995).

In summary, this impressive suite of cognitive abilities demonstrates considerable intellectual flexibility that could be applied toward an understanding of some of the elementary features of an imposed language.

C. Early Attempts at Teaching Language to Dolphins

From the mid-1950s to the mid-1960s, Lilly (1961, 1967) promoted the idea that bottlenose dolphins might possess a natural language. He based this supposition on this species’ exceptionally large brain with its richly developed neocortex. He reasoned that the large brain must be a powerful information processor having capabilities for advanced levels of intellectual accomplishment, including the development of a natural language. He set about to uncover the supposed language. Failing in that quest, he then attempted, also without success, to teach human vocal language (English) to dolphins he maintained in his laboratories. Dolphins have a rich vocal repertoire, but not one suited to the production of English phonemes. The procedures used by Lilly and the data he obtained were presented only sketchily, blunting any detailed analysis of his efforts at teaching language. Lilly’s language work and his often freewheeling speculations were met with harsh criticisms by several prominent researchers (Wood, 1973; Wilson, 1975).

In the mid-1960s, Duane Batteau developed an automated system that translated spoken Hawaiian-like phonemes into dolphin-like whistle sounds. The sounds were projected underwater into a lagoon housing two bottlenose dolphins (reviewed in Herman, 1980). Batteau attempted to use these sounds as a language for conveying instructions to the dolphins. A major flaw in his approach, however, was that individual sounds were not associated with individual semantic elements, such as objects, actions, or properties, but instead functioned as holophrases (complexes of elements). For example, a particular whistle sound instructed the dolphin to “hit the ball with your pectoral fin.” Another sound instructed the dolphins to “swim through a hoop.” Unlike a natural language, there was no unique sound to refer to *hit* or *ball*, or *hoop*, or *pectoral fin*, or any other unique semantic element. Hence, there was no way to recombine sounds (semantic

elements) to create different instructions, such as “hit the hoop (rather than the ball) with your pectoral fin.” As was noted earlier, human language achieves its great communicative power through its ability to combine and recombine words in infinite ways (governed by syntactic structures) to achieve distinct meanings. After several years of effort, Batteau’s dolphins were able to reliably follow the holophrastic instructions conveyed by each of 12 or 13 different sounds. However, because of the noted flaw in the approach to construction of a language, the experiment failed as a valid test of dolphin linguistic capabilities.

Bastian (1967) took a different approach, asking whether dolphins might develop arbitrary symbols to refer to some event—the language feature of “openness” (Hockett, 1960; Hauser *et al.*, 2002)—if a situation were structured requiring it. Food reward for each of two dolphins, a male and a female housed in the same pool, was made contingent on an apparent cooperative exchange of information between the pair. Each dolphin had available a pair of paddles and each dolphin was required to press a paddle to its left if an out-of-water light was flashing or a paddle to its right if the light held steady. Both had to press the correct paddle for either to obtain reward, but the male had to press his paddle first. Through a series of steps, Bastian altered the situation so that an opaque screen separated the two and now only the female was able to see the light. Yet, both had to continue to press the appropriate paddle, but with the “blind” dolphin, the male, required, as before, to press his first. Under those conditions, surprisingly, the two dolphins continued to perform almost without error. Bastian noted that the female vocalized at the start of most trials, suggesting that she was intentionally transmitting information to the male about the state of the light or which paddle to press. However, additional tests by Bastian *et al.* (1968) negated this conclusion: the female’s vocalizations persisted even when the barrier was removed and the male could again see the light, and also continued even when the male was removed entirely from the pool. Further, subsequent reversal of the contingencies between the state of the light and which paddle to press disrupted joint performance although each dolphin learned the reversal readily. The most likely explanation for the initial high level of joint performance was that the female adopted some stereotyped location in the pool while she vocalized (technically, called a “superstitious” behavior—a behavior correlated with reward but unnecessary for reward) which differed for each state of the light, and the male simply learned to use that unintentional cue (locus of the female’s vocalizations) to make his choice. This was confirmed in a replication study carried out in the dolphinarium at Harderwijk by Dudok van Heel (pers. comm.). Evans and Bastian (1969) in a review of the original Bastian study reached a similar conclusion to that of Dudok von Heel. For a fuller description, see Herman and Tavolga (1980).

D. Kewalo Basin Dolphin Studies of Language Comprehension

The work at the Kewalo Basin Marine Mammal Laboratory in Honolulu examining dolphin language-learning competencies was begun in the mid-1970s and emphasized language comprehension from the start. These researchers tested the capabilities of two female bottlenose dolphins, Akeakamai and Phoenix, to understand instructions given them within artificial languages, including novel requests. Akeakamai was trained in a visually based language and Phoenix in an acoustically based language. Although the vocabularies of the two languages overlapped greatly, the grammars were different, a linear (left-to-right) grammar for Phoenix and an inverse (right-to-left grammar) for Akeakamai. Each dolphin was proficient in its particular language form, as described in detail in Herman *et al.* (1984).

After 1984, the researchers concentrated primarily on analyzing and expanding the language work with Akeakamai. In her language, “words” were produced by gestures of a person’s arms and hands. The words referred to floating and fixed objects in the dolphin’s habitat, to actions that could be taken to those objects, and to relationships that could be constructed between pairs of objects—taking one object to another or placing one object on top of or inside of another object. There were also location words, *left* and *right*, expressed relative to the dolphin’s location, that were used to refer to a particular one of two objects having the same name, e.g., *left hoop vs right hoop*. And, there were gestural names for Phoenix, for the dolphin’s own body parts, and for abstract concepts, like “mimic,” “create,” “negate,” “tandem,” and “question,” most of which could be used in combinations with other gestural symbols.

Syntactic rules, primarily word-order rules, governed how words could be combined to extend meaning. For the gestural language, an inverse grammar was used in which the relation between the order of words in a sequence and the order in which response to them were taken were uncorrelated. This required that the dolphin attend to the whole sequence as a unit before responding, as later terms in the sequence could not be reliably predicted from earlier terms. The vocabulary, together with the syntactic rules, allowed for many thousands of unique combinations of words. Sentences up to five words in length could be created, with each sentence a unique instruction to the dolphin. The simplest sentences were instructions to take named actions to named objects. For example, a sequence of two gestures glossed as *surfboard over* directed the dolphin to leap over the surfboard; a sequence of three gestures glossed as *left Frisbee tail-touch* directed the dolphin to touch the Frisbee on her left with her tail. More complex sentences required the dolphin to construct a relationship between two objects, such as taking one named object to another named object or placing one named object in or on another named object. To interpret these “relational” sentences correctly, the dolphin had to account for both word meaning and word order. For example, a sequence of three gestures glossed as *person surfboard fetch* instructed the dolphin to bring the surfboard to the person (who was in the water), but *surfboard person fetch*, the same gestures rearranged, required that the person be carried to the surfboard. By incorporating *left* and *right* into these relational sentences, highly complex instructions could be generated. For example, the sequence of five gestures glossed as *left basket right ball in* asked the dolphin to place the ball on her right into the basket on her left. In contrast, the rearranged sequence *right basket left ball in* meant the opposite, now asking the dolphin to put the ball on her *left* into the basket on her *right*. The results (Herman *et al.*, 1984, Herman, 1986, 1987; Herman *et al.*, 1993b) showed that the dolphin was proficient at interpreting these various types of sentences correctly, as evidenced by her ability to carry out the required instructions, including instructions new to her experience. These were the first published results showing convincingly an animal’s ability to process *both* semantic and syntactic information in interpreting language-like instructions.

As a test of Akeakamai’s grammatical knowledge of the language she had been taught, Herman *et al.* (1993a) constructed *anomalous* gestural sentences. These were sentences that violated the syntactic rules of the language or the semantic relations among words. The researchers then studied the dolphin’s spontaneous responses to these sentences. For example, the researchers compared the dolphin’s responses to three similar gestural sequences: *person hoop fetch*, *person speaker fetch*, and *person speaker hoop fetch*. The first sequence is a proper instruction; it violates no semantic or syntactic rule of the learned language. It directs the dolphin to bring the hoop to the person, which the dolphin does easily. The second sequence is a syntactically

correct sequence but is a semantic anomaly inasmuch as it directs the dolphin to take the underwater speaker, which is firmly attached to the tank wall, to the person. The dolphin typically rejects sequences like this by not initiating any action. The final sequence is a syntactic anomaly in that there is no sequential structure in the grammar of the language that provides for three object names within a sequence. However, embedded in the four-item anomaly are two semantically and syntactically correct three-item sequences: *person hoop fetch* and *speaker hoop fetch*. The dolphin, in fact, typically extracts one of these subsets and carries out the instruction implicit in that subset by taking the hoop to the person or to the underwater speaker. These different types of responses revealed a rational analysis of the sequences. Thus, the dolphin did not terminate her response when an anomalous initial sequence such as *person speaker* was first detected. Instead, she continued to process the entire sequence, apparently searching mentally backward and forward for proper grammatical structures as well as for proper semantic relationships, until she found something she could act on or not. This analytic type of sequence processing is characteristic of sentence processing by human listeners, as illustrated by so-called “garden-path” sentences that lead the listener into an initially false assumption about meaning, as they wend their way through a sentence, such, for example, “Fat people eat accumulates.” For a fuller exposition of dolphin grammatical competencies, see Herman and Uyeyama (1999).

Herman and Forestell (1985) tested Akeakamai’s understanding of symbolic references to objects that were not present in her habitat at that time. They constructed a new syntactic frame consisting of an object name followed by a gestural sign glossed as “question.” For example, the two-item gestural sequence glossed as *basket question* asks whether a basket is present in the habitat. The dolphin could respond *yes* by pressing a paddle to her right or *no* by pressing a paddle to her left. Over a series of such questions, with the particular objects present being changed over blocks of trials, the dolphin responded to approximately 80% of the questions, with correct “absent” responses (83.3%) and correct “present” responses (79.6%) showing no significant statistical difference. These results gave a clear indication that the dolphin understood the gestures assigned to objects referentially, i.e., that the gestures acted as symbolic references to those objects. Further tests revealed the dolphin’s creativity with language tasks. When the dolphin was asked to construct a relationship between two named objects, such as “bring the Frisbee to the hoop,” but the destination object, the hoop, was absent, she spontaneously created a new response, by taking the indicated transport object (e.g., the Frisbee) to the “no” paddle. This response communicated her knowledge of the presence of the transport object but the absence of the destination object (Herman *et al.*, 1993b).

The television medium can display scenes that are representations of the real world, or sometimes of imagined worlds. As viewers, we understand this and often respond to the displayed content similarly to how we might respond to the real world. We of course understand that it is a representation and not the real world. It appears, however, that an appreciation of television as a representation of the real world does not come easily to animals, even to apes. Sue Savage-Rumbaugh (1986) wrote in her book, “Ape Language,” that chimpanzees show at most a fleeting interest in television, and that from their behavior it was not possible to infer that they were seeing anything more than changing patterns or forms. Her own language-trained chimpanzee subjects, Sherman and Austin, learned to attend to and interpret television scenes only after months of exposure in the presence of human companions who reacted to the scenes by exclaiming or vocalizing at appropriate times. Herman *et al.* (1990) tested whether the dolphin Akeakamai might respond appropriately to language instructions delivered by a trainer whose

image was presented on a television screen. Akeakamai had never previously been exposed to television of any sort. Then, for the first time, the researchers simply placed a television monitor behind one of the underwater windows in the dolphin’s habitat and directed Akeakamai to swim down to the window. On arriving there she saw an image of the trainer on the screen. The trainer then proceeded to give Akeakamai instructions through the familiar gestural language. The dolphin watched and then turned and carried out the first instruction correctly and also responded correctly to 11 of 13 additional gestural instructions given to her at that same testing session. In further tests, Akeakamai was able to respond accurately even to degraded images of the trainer, consisting, for example, of a pair of white hands moving about in black space. The overall results suggested that Akeakamai spontaneously processed the television displays as representations of real-world trainers and of the gestural language she had been exposed to for many years previously.

E. Studies of Language Production

As noted earlier, studies of language development in humans have shown that comprehension both precedes and exceeds production. A few studies have examined the dolphins’ ability to produce symbols that are associated with objects, locations, and outcomes. Richards *et al.* (1984) showed that the dolphin Akeakamai could learn to vocally produce the appropriate acoustic label (in Phoenix’s acoustic language system) for each of several objects presented to her. Reiss and McCowan (1993) developed a keyboard with six visual symbols as keys. Each key was associated with a particular acoustic associate and also with a particular outcome (e.g., the presentation of a specific toy like a ball or ring, a reinforcing action like the trainer rubbing the dolphin, etc.). After striking a key or producing the associated sound themselves, a human agent provided the dolphins with the associated outcome. Two of four dolphins showed consistent use of the keyboard in this manner, producing the sounds that gained them the associated item. Finally, Xitco *et al.* (2001) also showed that a dolphin could learn to use an underwater electronic keyboard to make requests of humans, in this case divers present in the dolphin’s habitat. Keyboard symbols referred to objects or locations. For example, on seeing fish available at a particular location, the dolphin could press the associated key, alerting the diver to accompany it to that location and to retrieve and offer the fish that was there.

Labeling or naming an object is a necessary but not sufficient act to contend that the name is understood referentially, as a surrogate for or a reference to that object. Further tests for productive naming would be needed, such as establishing that the animal understands the name as a reference to an object even if that object is absent (*cf.* Herman and Forestell, 1985).

F. Sea Lion Language Competencies

The only other marine mammal that has been trained and tested in a language-learning paradigm is the California sea lion (*Zalophus californianus*). Schusterman and Krieger (1984) tested whether a sea lion named Rocky might be able to learn to understand sentence forms similar to those understood by the dolphin Akeakamai. Rocky was able to carry out gestural instructions effectively for simpler types of sentences requiring an action to an object. The object was specified by its class membership (e.g., “ball”) and, in some cases, also by its color (black or white) or size (large or small). In a later study, Schusterman and Gisiner (1988) reported that Rocky was able to understand relational sentences requiring that one object be taken to another object. These reports suggested that the sea lion, like the dolphin, was capable of semantic processing of symbols and, to some degree, of syntactic

processing. As noted by Herman (1989), however, a shortcoming of the sea lion relational work was the absence of contrasting terms for relational sentences such as the distinction between “fetch” (take to) and “in” (place inside of or on top) that was easily understood by the dolphin Akeakamai. Without that contrast the symbol is not necessary and likely not processed semantically, as the sentence form itself tells the animal what to do. Additionally, unlike the dolphin, the sea lion’s string of gestures were given discretely, each gesture followed by a pause during which the sea lion looked about to locate specified objects before being given the next gesture in the string. In contrast, gestural strings given to the dolphin Akeakamai were without pause, analogous to the spoken sentence in human language. Further, Rocky did not show significant generalization across objects of the same class (e.g., different balls). Unlike the dolphin, Rocky seemed to regard a gesture as referring to a particular exemplar of the class rather than to the entire class. Thus, although many of the responses of the sea lion resembled those of the dolphin, the processing strategies of the two seemed different, and the concepts developed by the sea lion appeared to be more limited than those developed by the dolphin.

G. Conclusions

Human language, though unique as a whole, may depend in part on general cognitive processes that are also available to with some nonhuman animals. Language, like other biological traits, is best understood as having its genesis and development within the rules of Darwinian evolution, so that there should be some features that are homologous with features found in other hominoid species, and analogous to features found in some cognitively advanced nonprimate mammals. There is ample evidence for advanced cognitive skills in dolphins, as reviewed earlier. Dolphins can learn concepts and abstract rules and, like apes, are able to learn symbolic systems that have language-like features, particularly semantic and syntactic features. Sea lions can attain the semantic features, but their competency for acquiring syntactic rules has not been well studied. There is evidence that the artificial symbols used in language-like tasks with dolphins are understood referentially, as surrogates for or references to real-world objects, actions, or relationships. There is no evidence for a natural language in dolphins. Although whistle vocalizations have long been targeted as a primary means of vocal communication for bottlenose dolphins, their complexity and function are issues of intense dispute and study. At the same time, vocal learning and vocal mimicry is well developed in dolphins, as illustrated by laboratory behavioral studies and by studies and observations in the wild of vocal imitation by group-specific dialects in some cetacean species.

Finally, the results of the language work with the bonobo chimpanzee and the dolphin show some similarities, especially in the receptivity of the animals to the language formats used and in their proficiency at responding to sequences of symbols. The similarities in these language skills are mirrored by many other convergent cognitive traits in dolphin and in primate (Marino, 2002). An early conclusion by Herman (1980, p. 421) still seems appropriate to accommodate these convergent cognitive and language-learning skills of ape and dolphin: “The major link that cognitively connects the otherwise evolutionarily divergent delphinids and primates may be social pressure—the requirement for integration into a social order having an extensive communication matrix for promoting the well-being and survival of individuals.”

Locomotion, Terrestrial

THOMAS A. DEMÉRÉ AND JOSHUA H. YONAS

Among the obligate marine mammals (Cetacea, Sirenia, and Pinnipedia), only pinnipeds are able to locomote on land. They were the last to invade the seas, with the earliest forms known from the latest Oligocene (~24 Ma). Even today, pinnipeds retain a close tie to the land (or ice) for mating, birthing, and molting. In a sense, their bodies represent a compromise between the requirements for aquatic locomotion and the necessity for some form of terrestriality. Some pinnipeds have retained a higher degree of terrestriality than others (i.e., the “walking” otariids and odobenids in contrast to the “wriggling” phocine and monachine phocids).

Extant pinnipeds exhibit a general body plan consisting of a streamlined torso with major portions of the appendicular skeleton concealed within the body contour (i.e., the “armpit” is positioned near the wrist and the “crotch” is positioned near the ankle). The knee joint is held in an obligate flexed posture and proximal limb elements (i.e., humerus and femur) are shortened, whereas distal limb elements (i.e., manus and pes) are elongated. In addition the feet are modified as flippers with retention of five digits and elongation of the “thumb,” “big toe,” and “little toe.” Three patterns of combined aquatic and terrestrial locomotion are recognized: forelimb propulsion and quadrupedal walking (otariids); hindlimb propulsion and quadrupedal walking coupled with sternal lunging (odobenids); and hindlimb propulsion and essentially limb-free undulation (phocids).

Otariids have retained the greatest degree of terrestriality and, surprisingly, represent the latest diverging group of crown pinnipeds. Their fore- and hindlimbs are capable of quadrupedal support and locomotion. The feet are held in a plantigrade stance with the flippers extended laterally. The hind feet are able to rotate under the body. Although some researchers have suggested that Otariids can both walk and gallop, English (1976) has emphasized that in a true gallop there are periods when all feet are off the ground. This condition does not occur in otariids, which never have less than 1 ft on the ground during terrestrial locomotion. Thus otariids can be said to have two gaits; a walk and something between a fast walk and a true gallop. During the otariid walk the forelimbs are alternately in protraction and retraction and rely on flexion and extension of the elbow and dorsoflexion of the wrist. The axial skeleton contributes to the walk with the head and neck swinging from side to side to shift body weight from the side of the raised, flexed, and protracted forelimb to the side of the planted, extended, and retracted forelimb. The hindlimb serves primarily a support role during locomotion, whereas the posterior axial skeleton undergoes flexion on the recovery stroke and extension on the propulsive stroke. The upper ankle joint and transverse tarsal joint remain acutely flexed throughout the walking phase, with the pes turned to the side.

Odobenids also retain a high degree of terrestriality relative to phocids. Like otariids, their fore- and hindlimbs are capable of quadrupedal support and locomotion, their feet are held in a plantigrade stance, and their hind feet are able to rotate under the body. However, rather than being able to completely hold the body off the ground, the limbs of an adult walrus act more like stilts while the venter (primarily represented by the sternum) acts like a “fifth leg” to support the majority of the animal’s weight. Odobenids move on land in a slow, blubbery lateral sequence walk punctuated by a forward lunge (Gordon, 1981). First, the forelimb is positioned under the body; with the foreflippers laterally oriented, while the forearm is almost vertical and slightly protracted. The limbs are holding a limited amount of body weight at this stage with the bulk supported by the venter. Next, the forward lunge is facilitated by an initial lift of the body by a “push-up” of the forearm. Here the limb is in full extension and is being used to propel the animal. With the body partially suspended, locomotion occurs by a lateral swing of one forelimb at a time, in the direction of travel. The hindlimb is tucked under the body and pointed cranially, only holding a limited amount of body weight. The hindlimbs then extend and push the body forward. As a forelimb swing goes through completion, and once planted, the hindlimb on the same side is swung laterally and forward in the direction of travel. In this manner the adult walrus swings the left limbs, then the right. The axial skeleton and head also contribute to terrestrial locomotion. With the head aligned with the body axis and the sternum supporting the bulk of the weight, the venter is thrust forward aided by extension of the posterior axial skeleton. Although the forelimbs and hindlimbs swing and are placed in the direction of travel, the head is used as a counterbalance and shifted to the opposite side to allow for less weight on the fore- and hindlimbs, thus acting as a lateral “see-saw.”

Phocids have a very divergent mode of terrestrial locomotion. Their fore- and hindlimbs are, for the most part, incapable of supporting the body, the feet are typically held free of the substrate, and the hind feet cannot be rotated forward under the body and instead are held in a relatively hyperextended posture and directed backwards with palmar surfaces opposed. The unique structure of the phocid tarsal bones (e.g., elongate astragalus with hypertrophied calcaneal process) and the position and orientation of the tendon of the flexor hallucis longus prevent the foot from being brought into a plantigrade position (Howell, 1929; Polly, 2008). Phocids have been called “beach maggots” in reference to their inchworm-like undulatory mode of terrestrial locomotion. With the limbs rather useless on land (or ice) most phocids primarily rely on the sternum and pelvis for support and locomotion (Backhouse, 1961). Planting the sternum on the substrate, the posterior part of the axial skeleton is ventroflexed to draw the pelvis forward. When planted the pelvis then serves as an anchor as the axial skeleton is extended forcing the body forward. The forelimbs are generally held against the torso but can sometimes be used to assist in scrambling on land or ice. This is accomplished by flexion of phalanges and extension of metacarpals to form a terminal hook with which the seal can drag its body forward as both forelimbs are retracted (Backhouse, 1961). In elephant seals the forelimbs provide some support of the body and propulsive force as the animal undulates across the land or ice (O’Gorman, 1963). Some Antarctic phocids (e.g., Ross, crabeater, and leopard seals) utilize a sinuous mode of progression to “swim” across soft snow. The forelimbs are alternately retracted whereas the posterior lumbar region, pelvis, and hindlimbs are strongly flexed laterally (O’Gorman, 1963).

Concerning extinct pinnipeds, we are forced to rely on features of fossil bones (e.g., limb proportions, size and position of bony processes, and muscle and ligament attachment sites) to formulate and test hypotheses about ancestral patterns of terrestrial locomotion. Based

on fossil limb bones of *Enaliarctos mealsi* from the earliest Miocene of California, United States, it is clear that this stem pinniped had already evolved many of the aquatic limb adaptations of extant otariids (e.g., shortened proximal limb elements and elongate feet), while retaining a greater degree of terrestriality (Berta and Ray, 1990). The same can be said for fossils of the middle Miocene dematopochids, *Desmatophoca* and *Allodesmus*, from the North Pacific region. Extinct odobenids including the stem taxon, *Proneotherium repenningi* from the middle Miocene of Oregon, United States, were also capable of terrestrial quadrupedal walking (Deméré and Berta, 2001). The later evolving designathine and odobenine walruses, although diverging in mode of aquatic locomotion (fore- and hindlimb swimming, respectively), retained the ability for terrestrial quadrupedal walking. The phocid fossil record, although in need of rigorous modern analysis, does contain important stem taxa such as the middle Miocene *Leptophoca lenis* from Maryland, United States, that indicate an early evolutionary loss of the ability for terrestrial quadrupedal walking.

Leopard Seal *Hydrurga leptonyx*

TRACEY L. ROGERS

I. Characteristics and Taxonomy

Leopard seals are a large sexually dimorphic species (Kooyman, 1981; Laws, 1984; Bonner, 1994). The females are larger than the males, growing up to 3.8 m in length and weighing up to 500 kg, whereas males grow up to 3.3 m in length and weigh up to 300 kg.

II. Distribution and Abundance

Although the majority of the leopard seal population remains within the circumpolar Antarctic pack ice, the seals are regular, although not abundant, visitors to the subantarctic islands of the southern oceans and to the southern continents (Erickson *et al.*, 1971; Heller *et al.*, 1977). The most northerly leopard seal sightings are from the Cook Islands. Juveniles appear to be more mobile, moving farther north during the winter. Because it does not need to return to the pack ice to breed, the leopard seal can escape food shortages during winter by dispersing northwards. Every 4–5 years, the number of leopard seals on the subantarctic islands oscillates from a few to several hundred seals. The periodic dispersal could be related to oscillating current patterns or resource shortages in certain years (Testa *et al.*, 1991).

The leopard seal population is estimated to be 222,000–440,000. During summer, leopard seals breed on the outer fringes of the pack ice where they are solitary and sparsely distributed. Their density is inversely related to the amount of pack ice available to the seals as haul-out platforms. Pack ice cover varies with the season, from a maximum between August and October to a minimum between February and March. Population densities are greatest in areas of abundant cake ice (ice floes of 2–20 m in diameter) and brash ice (ice floes greater than 2 m in diameter), whereas they are least in areas with larger floes. Densities range from 0.003–0.151 seals/km², and there is an age-related difference in their spatial behavior. Due to intraspecific aggression there is a greater degree of spatial separation among older seals (Rogers and Bryden, 1997).

III. Ecology

Leopard seals take a diverse range of prey (Lowry *et al.*, 1988; Hall-Aspland and Rogers, 2004) including fish, cephalopods, sea birds, and seals. Different food sources are used when available or when opportunities to take other more sought-after prey are few. Krill makes up the largest proportion of their diet, particularly during the winter months when other food types are not abundant. At this time the leopard seals must compete directly with krill-feeding specialists, such as the crabeater seal (*Lobodon carcinophagus*) and Adélie penguin (Siniff and Bengtson, 1977). This is believed to be a time of potential food shortage and causes some juvenile leopard seals to move north from the pack ice during the austral winter. The leopard seal is responsible for more predation on warm-blooded prey than any other pinniped. Leopard seals capture and eat juvenile crabeater seals in particular but also prey on Weddell (*Leptonychotes weddellii*) Ross (*Ommatophoca rossii*) and southern elephant (*Mirounga leonina*) seals, subantarctic and Antarctic fur seals (*Arctocephalus tropicalis* and *A. gazella*) and southern sea lions (*Neophoca cinerea* and *Phocarctes hookeri*). Newly weaned crabeater seals are the most vulnerable and are taken from November to February. Crabeater seal survivors bear characteristic parallel paired scars from leopard seal attacks; approximately 78% of adult crabeater seals display such marks. The teeth of the leopard seal have a dual role; the large recurved canines and incisors are designed for gripping and tearing prey, whereas the upper and lower tricuspid (three cusped) molars interlock to provide an efficient krill sieve.

IV. Behavior and Physiology

Acoustic behavior is important in the mating system of the leopard seal (Rogers *et al.*, 1996; Stirling and Siniff, 1979; Rogers and Cato, 2002). Leopard seals become highly vocal prior to and during

Figure 1 Leopard seal. Photo by Jaume Forcada, British Antarctic Survey.

their breeding season (Fig. 1). Lone male leopard seals produce highly stereotyped vocalizations for long periods each day, from early November through January. Female leopard seals also use long-distance acoustic displays during the breeding season. However, female seals vocalize for a brief period only from the beginning of estrus until mating, presumably to advertise sexual receptivity. The calls of the leopard seal are at low-to-medium frequencies and so powerful that they can be heard through the air–water interface and felt through the ice.

V. Life History

Male leopard seals are sexually mature by 4.5 years and females by 4 years of age (Kooyman, 1981; Bonner, 1994). Females give birth to their pups and wean them on the ice floes of the Antarctic pack ice. Males do not remain with the females; only mother–pup groups are observed on ice floes. Length at birth is approximately 120 cm, with rapid growth through the first 6 months postpartum. Births are believed to occur from October to mid-November and mating from December to early January, after the pups have weaned. Lactation is believed to last for up to 4 weeks. Mating in the wild has been observed rarely, but captive seals mount only when in the water. There is a period of delayed implantation from early January to mid-February. Implanted fetuses are found after mid-February when the corpus luteum (glandular structure in the ovary) has begun to increase in size and the corpus albicans (scar from ovarian glandular structure) from the previous pregnancy has continued to regress.

VI. Interactions with Humans

There are many reported interactions between humans and leopard seals, mainly involving scientists working in Antarctica (Muir *et al.*, 2006). However, with the number of tourists visiting the Antarctic continent and surrounding islands on the increase, this number is bound to rise. Of all the interactions there has only been one reported death associated with a leopard seal encounter. Generally, the leopard seal behavior during in-water interactions is described as being curious.

Historically leopard seals have never been exploited commercially, however small numbers have been taken for scientific research and for use as pet food.

Leopard seals are currently listed as lower risk, least concern by the International Union for Conservation of Nature (IUCN). The main conservation issue facing leopard seal populations today is the reduction in krill stocks, which is being exacerbated by the rapid increase in climate change.

M

Male Reproductive Systems

SHANNON ATKINSON

Studies of the reproductive biology of male marine mammals have not received the attention that has been focused on their female counterparts. In part this is due to the limited numbers of male marine mammals kept in captivity, but also to the difficulty of measuring the anatomical and physiological parameters of free-ranging males. This account focuses on the anatomy of male reproduction, with emphasis on features unique to the various marine mammal groups. Aspects of reproductive life history and behavior, such as endocrine systems, mating systems, territoriality, and sociobiology, are covered elsewhere in this encyclopedia. The effects of environmental and pharmacological factors on reproduction are also briefly reviewed here.

Genitalia are internal in whales, dolphins, and porpoises (Fig. 1; Ommanney, 1932; Harrison Matthew, 1950; Green, 1972; Perrin *et al.*, 1984; and Kenagy and Trombulak, 1986); this contributes to hydrodynamic efficiency. There is no os penis or baculum. The penis is fibroelastic, similar to that in artiodactyls, such as cows, pigs, and antelopes. Cetacea are included in the Artiodactyla, or Cetartiodactyla, by some taxonomists (Slijper 1966; Berta and Sumich, 1999; Rommel *et al.*, 2007). It originates in two crura from the caudal part of the free pelvic bones or from the entire surface of

these bones (Fig. 2; Rommel *et al.*, 2007). The two arms fuse into a long rope-like body, round or oval in cross section. In large rorquals it may be 2.5- to 3-m long and 25–30 cm in diameter. The distal part of the penis tapers smoothly to the tip and is covered with ordinary skin; this may be homologous with the glans penis of some terrestrial mammals. When retracted the penis rests in an S-shaped horizontal loop. Because enlargement through engorgement with blood is limited by the tough tunica albuginosa (modified skin covering) during arousal, this loop allows protrusion of the organ without its lengthening (Ommanney, 1932; Perrin *et al.*, 1984; Rommel *et al.*, 2007). A flat retractor penis muscle runs from its ligamental or rectal wall origin to insert on the ventral surface of the penis; it serves to withdraw the penis back into the penile slit. The prostate is primitive among eutherian mammals, resembling that of marsupials and monotremes in consisting of diffuse urethral glands unlocalized to form a discrete prostate gland.

The testes are intra-abdominal (or cryptic) and mesial/ventral in position, a condition known as secondary testicondy (Rommel *et al.*, 2007). This feature is thought to be synapomorphic in Cetacea but is shared with some marsupials. The position varies among the cetacean taxa, from nearly renal in some odontocetes to ventral in baleen whales (Ommanney, 1932). In *Mesoplodon* spp., the organs are sunk in recesses of the abdominal cavity connected to the main cavity by short vagioperitoneal canals. The organs are long and cylindrical with a smooth shiny white surface. Seminiferous tubules located in the testicle lobe are mostly composed of Sertoli cells. (Honma *et al.*, 2004). In Bryde's and Minke whales, the seminiferous tubules of mature whales only contained a single layer of spermatogonia (Watanabe *et al.*, 2004). Relative testis size varies widely among the cetacean groups, being greater in those species thought to engage in sperm competition (Mate *et al.*, 2005), such as right whales (*Eubalaena* spp.) than in polygynous species such as the sperm whale (*Physeter macrocephalus*). Odontocetes in general have testes 7–25 times larger than would be predicted for “average” mammals of their size, ranging to 8% of body weight in the dusky dolphin (*Lagenorhynchus obscurus*), as compared to 0.08% in humans. The largest mammalian testes known are found in right whales, weighing up to 1000 kg (Mate *et al.*, 2005). Testicular activity (and size of some muscles associated with the penis) varies seasonally, and weight increases substantially with breeding

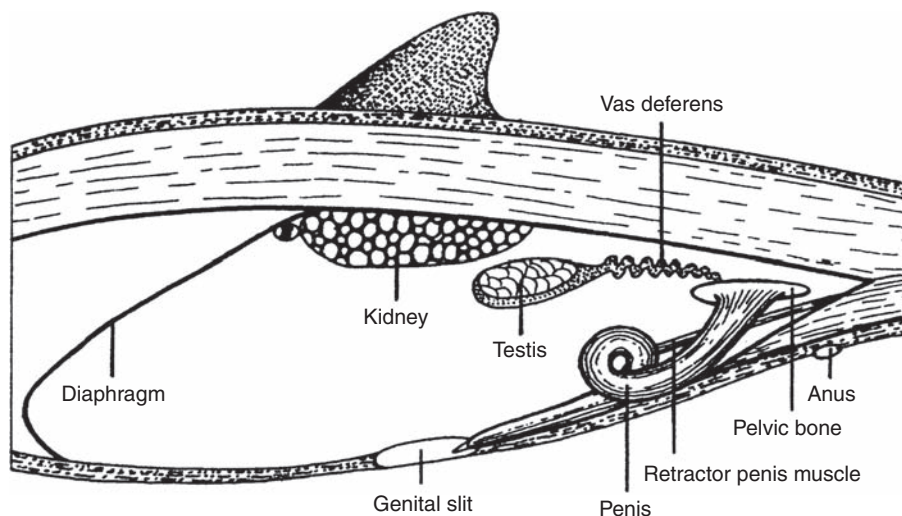

Figure 1 Cetacean male reproductive system. From Berta and Sumich (1999), adapted from Slijper (1966).

Figure 2 Pelvis and male genitals of bowhead whale (*Balaena mysticetus*) in ventral view (top of drawing is anterior). This figure shows the close relation between the internal hind limb bones (pelvis, femur, and tibia), the rectum, and the penis. Retractor penis and bulbospongiosus are penile muscles. Modified after Struthers (1893).

season in at least some delphinid odontocetes (e.g., the spinner dolphin *Stenella longirostris*). In bowhead whales mean testis mass and mean testis length were correlated as was body length and mean testis mass (O'Hara *et al.*, 2002). The latter correlation had a break point at 12.5–13.0 m suggesting the onset of sexual maturation occurs at that size (O'Hara *et al.*, 2002). In many cetacean species, the spermatic tubules (vasa differentia) are more highly convoluted than in most terrestrial mammals. A distal spiral valve exists in the blue whale (*Balaenoptera musculus*), and mucosal folds have been described in the pygmy sperm whale (*Kogia breviceps*).

The scrotum functions in terrestrial mammals in part to lower ambient temperature to ensure viability of the sperm. Loss of the scrotum in Cetacea in the interest of hydrodynamic efficiency thus introduces a new thermoregulatory problem (Pabst *et al.*, 1998 and 1999). The rete testis is the site where numerous anastomosing tubules are located, whereby cooling through a cardiovascular countercurrent mechanism takes place (Honma *et al.*, 2004). Blood cooled in superficial veins of the dorsal fin and flukes feeds directly into a deep venous plexus closely juxtaposed to a similar arterial plexus that supplies the testis (Rommel *et al.*, 1992). Thus, heat is drawn into the venous blood from the arterial blood before it reaches the testis, cooling the testis to below body core temperature.

All pinnipeds, the polar bear (*Ursus maritimus*), and the sea otter (*Enhydra lutris*) possess a baculum, or penis bone, which is the ossified anterior end of the corpus cavernosum of the penis (Green, 1972; Morejohn, 1975; Atkinson, 1997). The baculum is largest in the walrus (*Odobenus rosmarus*) and smallest in otariid pinnipeds, or fur seals and sea lions. The distal shape varies widely among species and is more complex in phocids (true or earless seals) than in otariids (Morejohn, 1975). As most of the phocids are aquatic copulators, relatively large bacula may function in preventing water damage to sperm after copulation or to facilitate sperm competition in

species where the females mates with more than one male. Bacular size may also be adaptively constrained by a large body size in terrestrial copulators due to the risk of bacular fracture. The penis is vascular, as in terrestrial carnivores (Fig. 3). In phocids, the baculum is surmounted by a fleshy claviform glans. In otariids, it is covered by only a thin layer of epithelium. The prostate gland is bulky, weighing up to 760 g in the southern elephant seal (*Mirounga leonina*) and is similar in anatomy in all seals.

Phocid seals lack a scrotum; the testes are external to the abdominal muscles but covered by the posterior part of a superficial muscle (Laws and Sinha, 1993; Atkinson, 1997). Otariid pinnipeds possess a scrotum, but in some species, e.g., the Antarctic fur seal (*Arctocephalus gazella*), the testes are usually withdrawn into the inguinal position and the scrotum is visible only as two areas of hairless skin; the testes descend into the scrotum only during the need to avoid hyperthermia. Seasonal changes in testis and epididymis size and function occur with breeding season in pinnipeds in which this has been examined (Fig. 4). The testes in the sea otter and polar bear are scrotal (Ramsay and Sterling, 1988).

Sirenians do not possess a baculum. The penis is vascular and retracted when not engorged. The testes are abdominal. The prostate is lacking in the dugong (*Dugong dugon*) and is composed of erectile muscle tissue in the manatees (*Trichechus* spp. Marsh *et al.*, 1984).

Testosterone is the main androgen in male mammals and stimulates spermatogenesis (Atkinson, 1997; Atkinson and Yoshioka, 2007). Testosterone concentrations have been measured in many odontocetes and pinnipeds. In all species for which there are published data, testosterone concentrations increase around the time of sexual maturity, making it a useful diagnostic tool (Desportes *et al.*, 1994; Kita *et al.*, 1999; Kjeld *et al.*, 2003; Robeck and Monfort, 2006; Kjeld *et al.*, 2006; Atkinson and Yoshioka, 2007). A seasonal pattern of circulating testosterone concentrations exists with elevated concentrations during the

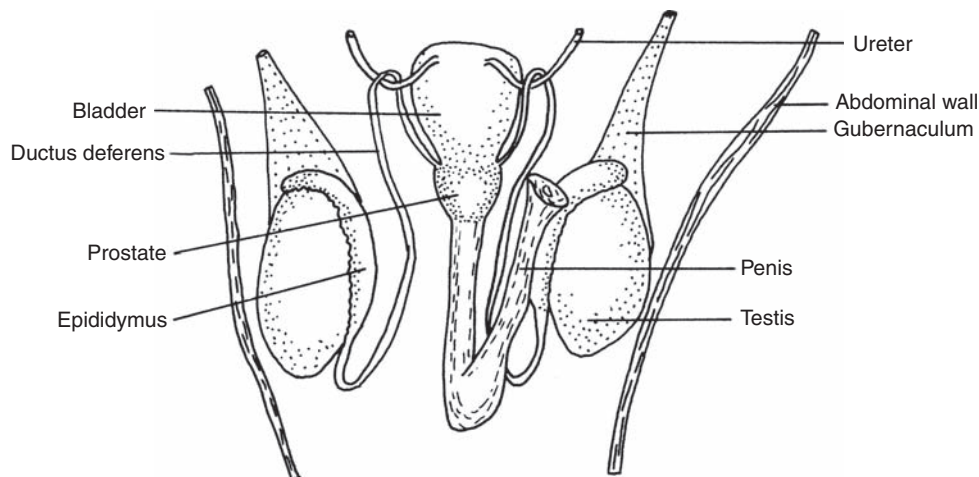

Figure 3 Male reproductive tract of an otariid in ventral view (top is anterior). Modified after Boyd *et al.* (1999).

Figure 4 Weight of nonspermiogenic testes of walrus in relation to age. Modified from Fay (1982).

breeding season (typically in spring, but a few species are autumnal or multiseasonal breeders). In species with a short, tightly synchronized breeding season, testosterone concentrations are increased for 1–3 months at the start of the season but decline to baseline levels by the time breeding ends. Seasonality is also apparent in most male marine mammals in increased size of the testes and accessory reproductive glands (even muscles in some cetaceans) and increased spermatogenesis. Increased size of the testes is due to an increased diameter of the seminiferous tubules and epididymes, resulting in increases in the volume of sperm. Spermatogenesis usually lags behind testosterone production, as production of testosterone by testicular Leydig cells is necessary for germ cell differentiation in the seminiferous tubules. However, testis weight and circulating testosterone concentrations were correlated in minke whales (Suzuki *et al.*, 2001; Atkinson and Yoshioka, 2007).

A few marine mammals, such as dugongs and sea otters, lack a distinct breeding season. A few older male dugongs that were examined were found to be aspermic, suggesting long periods of sterility (Marsh *et al.*, 1984).

During seasonal quiescence in many cetaceans and pinnipeds, spermatogenesis ceases, although the testes retain relatively large seminiferous tubules with spermatocytes present (Watanabe *et al.*, 2004; Honma *et al.*, 2004). Shrinkage of anterior pituitary cells that produce gonadotrophins is thought to be ultimately responsible for the seasonal testicular regression.

Some environmental factors simply cue physiological events, whereas others have the potential to hasten or disrupt the system. The three most important are photoperiod, nutrition, and social factors.

Seasonal reproduction requires that males have adequate numbers of viable sperm when the females enter estrus. Hence the spermatogenic cycle must be initiated months before breeding (Atkinson, 1997; Atkinson and Yoshioka, 2007). Photoperiod is the most commonly cited environmental cue for synchronizing reproductive processes in both males and females; it appears to function months before the breeding season begins. The pineal gland is responsible for the neuroendocrine communication of photoperiod to the rest of the body (see Endocrine Systems). Melatonin secretion, which is activated during short photoperiods, acts to relay photoperiodic cues to the target organs. In many species, melatonin is inhibitory to the gonadotrophic-releasing hormones (GnRH) that stimulate testosterone production and spermatogenesis. Thus, reproductive processes in most species are stimulated during increasing daylength (i.e., spring). Conversely, increased melatonin concentrations due to a decreased photoperiod lead to inactivation of the testes (see Endocrine Systems).

Both sea otters and sirenians lack a defined breeding season, and the Australian sea lion (*Neophoca cinerea*) has a nonannual, non-seasonal reproductive pattern (Atkinson, 1997). Spermatogenesis in these species may be continuous. The lack of correlation between testicular activity and season in the dugong may relate to the absence of a pineal gland (Marsh *et al.*, 1984). No published studies have accounted for the lack of a defined breeding season in sea otters.

There is little published information of nutritional effects on the reproductive biology of male marine mammals. A high plane of nutrition is known to advance the onset of puberty in females and could be expected to have the same effect in males (Atkinson, 1997). It is also safe to assume that the plane of nutrition of an individual male will affect its position in a dominance hierarchy. For species in which there can be severe natural impacts on food resources, adult males may have lower blubber thickness during years of poor feeding, resulting in reduced stamina during the breeding season. Although the functional or mechanistic nature of the nutrition–reproduction relationship remains unclear, it can safely be concluded that the measurement of body condition and its effects on various reproductive events, especially during natural environmental perturbations, will continue to be important areas of marine mammal research.

Physiology and the environment influence the development of mating systems by affecting the relative distribution and availability of males and females, thereby altering the reproductive success of an individual male. After sexual maturation, serum testosterone concentrations may vary independent of testis weight, indicating that social factors play a role in reproductive processes (Atkinson and Yoshioka, 2007). It is not uncommon to find captive situations with cetaceans that are of the same age but at very different reproductive states (i.e., one or more males remain sexually immature much longer than the others). Changing the social structure in an enclosure will often stimulate puberty in those lagging behind in sexual development.

The most common reproductive reason for prescribing pharmacological agents is to reduce fertility. The three species for which this has been needed in captivity are the bottlenose dolphin (*Tursiops truncatus*) the California sea lion (*Zalophus californianus*), and the harbor seal (*Phoca vitulina*). All of these can be prolific breeders in captivity, and the need regularly arises to control numbers in some facilities. Until recently, physical separation and contraception of females were the only practical methods. GnRH agonists has been demonstrated to be an effective, reliable, and reversible contraceptive in harbor seals (Siebert *et al.*, 2007). Antiandrogens have been tried unsuccessfully with bottlenose dolphins.

A second reason to prescribe pharmacological agents is to suppress aggression among males. The need to control behavior in the captive setting is obvious, especially with adult male bottlenose dolphins during the breeding season. It is less obvious, but equally, if not more important in the management of the Hawaiian monk seal (*Monachus schauinslandi*), a declining species in which males attempt mass matings, usually with a breeding-aged female, sometimes to the point of killing her (Atkinson *et al.*, 1994; Atkinson *et al.*, 1998).

GnRH agonists work by stimulating the anterior pituitary to release GnRH, which stimulates the testes to produce testosterone and initiate spermatogenesis. Paradoxically, the pituitary quickly becomes refractory and ceases its production of GnRH, which inhibits the testes. Injections of GnRH agonists have been used with some success with harbor seals and effectively decrease circulating testosterone concentrations to prepubertal levels in Hawaiian monk seals (Atkinson *et al.*, 1993; Atkinson *et al.*, 1998).

Marine top predators are likely targets for xenobiotic compounds that act either as estrogens or as antiandrogens. The most common of these are the polychlorinated biphenyls (PCBs) and dichlorodiphenyltrichloroethanes (DDTs). These compounds bioaccumulate up the food chain, making marine mammals highly susceptible to their biological effects. Male marine mammals continue to accumulate organochlorines throughout their lives, whereas females tend to reduce their body burden via transplacental transfer and lactation (Willcox *et al.*, 2004; Meyers *et al.*, 2008). The range of PCB concentrations reported for arctic marine mammals is highest in the walrus (*Odobenus rosmarus*), although the absolute concentrations are highest in polar bears. The effects of organochlorines on male reproductive physiology have not been well studied, as most research has focused on females. The known effects are pathologies related to structural changes and thickening of tubules in organs such as the kidneys, adrenals, and reproductive tract. The most striking possible example has been the occurrence of pseudohermaphroditic polar bears with a normal vaginal opening, a small penis with baculum, and no Y chromosome (Ramsay and Sterling, 1988). The syndrome is hypothesized to be due to either excessive androgen secretion by the mother or endocrine disruption from environmental pollutants.

The impacts of all the detected pathologies are unknown. However, there are widespread reports that xenobiotic compounds are also strongly immunosuppressive, rendering contaminated animals more vulnerable to bacterial and viral infections. Experimental studies using minks (mustelids) indicate that the enzymatic pathways that metabolize steroids are disrupted, but the detailed biosynthetic pathways of the organismal response have not been elucidated.

Management

JAY BARLOW

Management refers to those regulations, laws, treaties, and policies which govern human interactions with marine mammals (Twiss and Reeves, 1999). Marine mammal management may promote a wide variety of human objectives: conservation of marine mammal populations for their intrinsic value, maintenance of marine mammal populations from human exploitation, protection of human health interests, humane treatment of captive animals, reduction of direct or competitive interference with commercial fisheries, and so on. This article concentrates on the general approaches used for marine mammal management.

I. Management Units

“Management unit” refers to the group of animals that is the target of some management action. It may refer to a colony, subpopulation, population, or species. The term “stock” has traditionally been used instead of “management unit,” but this term has evolved to be synonymous with both “population” and “management unit,” so, to avoid confusion, “management unit” is preferred. The appropriate definition of a management unit depends on the management objective. Laws to prevent the extinction of a species might have a species or a subspecies as a management unit; however, the likelihood of achieving this management objective may be increased by managing on the basis of populations. Laws may not always explicitly define management units, but the stated goals of that law may give some clues as to how the term should be interpreted. For example, if the goal is to maintain marine mammal populations as functional elements of their ecosystems (one of the goals of the US Marine Mammal Protection Act, MMPA), management units might necessarily be smaller than the entire population to ensure that range contractions would not prevent the attainment of this goal (Taylor, 1997). Knowledge of population structure is critical to defining management units. Population structure has been studied using tagging, radio and satellite tracking, allozymes, DNA fingerprinting, DNA sequencing, photo-identification, morphometrics, and chemical markers. Most of these methods are limited—they can only show that two samples differ and thus that population structure is present, but they cannot be used to demonstrate that population structure is absent. There is almost always some uncertainty in deciding how finely to divide management units, and one of the current challenges in marine mammal management is dealing with this uncertainty.

II. Methods of Marine Mammal Management

A. Traditions, Taboos, and Practices

Prior to modern times, management took the form of culturally enforced practices. Ancient Greeks, natives in the Amazon Basin, and many sea-going cultures held dolphins in especially high regard and had proscriptions against killing or eating dolphins. Monk seals (*Monachus monachus*) were considered by the early Greeks to have prophetic powers and to be protected by Poseidon; however, the popular views toward this species included antipathy and hostility. The societies that did harvest whales and seals (including Inuit and Aleut cultures) often had elaborate rules that determined who could hunt these animals and when they could be hunted. It is not known whether traditions and taboos were important in conserving marine mammals, but there

is no evidence of marine mammal EXTINCTIONS caused by humans prior to that of the Steller's sea cow (*Hydrodamalis gigas*) in the 1700s. Traditions based on superstitions have been increasingly ignored as human populations have increased (Johnson and Lavigne, 1999).

B. Harvest Bans

The most common method of protecting marine mammals from overexploitation has been a complete ban on harvesting. Most often, this has been practiced after a catastrophic decline that has already occurred. Gray whales (*Eschrichtius robustus*), northern elephant seals (*Mirounga angustirostris*), and Guadalupe fur seals (*Arctocephalus townsendi*) were protected by Mexico after their near extinction. A complete ban on whaling for gray whales and right whales (*Eubalaena* spp.) was instituted early in the history of international whale management. Australia, Mexico, New Zealand, South Africa, and the United States have banned the commercial harvest of all marine mammal species in their waters. The European Union members of ASCOBANS (Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas) have agreed to ban the intentional harvest of all small cetaceans. Exceptions to harvest bans are commonly made for aboriginal or subsistence harvests and for incidental mortality pursuant to other commercial enterprises such as shipping and fishing.

C. Age/Sex Limitations on Harvests

Age and/or sex limitations on harvest are commonly employed in the management of terrestrial species. The US North Pacific Fur Seal Act of 1910 outlawed the harvest of northern fur seal (*Callorhinus ursinus*) females and pups. This, together with the provisions of the North Pacific Fur Seal Treaty of 1911, effectively reversed the marked declines of the populations that breed on islands in the Bering Sea. Because many marine mammals do not exhibit marked sexual dimorphism (as do fur seals), similar regulations are not practical for all species. The 1931 Convention for Regulation of Whaling and later regulations of the International Whaling Commission (IWC) prohibited the commercial harvest of dependent calves and their mothers. Because most whales have a 2- or 3-year reproductive cycle and are nursing for only 6–12 months, females were not protected for the majority of time. Minimum size limits were also established for various whale species. These and other regulations were not effective in preventing the depletion of most of the world's whale populations.

D. Seasonal Area Closures

The seasonal closure of certain areas or all areas is another common practice in wildlife management. The 1931 Convention for the Regulation of Whaling established a closed season for factory ships in Antarctic waters from April 7 to December 8. Seasonal area closures have also been used to reduce the number of gill net entanglements of Hector's dolphins (*Cephalorhynchus hectori*) in New Zealand and harbor porpoises (*Phocoena phocoena*) in the US Gulf of Maine.

E. Restrictions on Methods and Fishing Gear

Regulations may limit the methods by which marine mammals are killed. The Fur Seal Treaty of 1911 eliminated the at-sea pelagic harvest of northern fur seals (*C. ursinus*), which were commonly considered to be wasteful (many carcasses could not be recovered) and which were more difficult to monitor. Methodological restrictions are not limited to direct, intentional harvests. Many gear restrictions have been applied to reduce marine mammal bycatch in commercial

fishing operations. Finer mesh panels (Medina panels) were added to tuna purse seine nets in the eastern tropical Pacific to reduce dolphin ENTANGLEMENT. The use of acoustic warning devices (pingers) is required to reduce cetacean bycatch in several US fisheries. Similarly, pinger use in gillnet fisheries was recently mandated by the European Union in the North Sea and English Channel, but compliance and enforcement have been low. Regulations may also address how a particular gear is used; the adoption of a “backdown” procedure greatly reduced the mortality of dolphins in tuna purse seines. In addressing marine mammal bycatch problems, restrictions sometimes take the form of a complete ban on a particular gear type. In 1989 the states and territories of the South Pacific banned the use of large-scale (>2.5 km), drift gill nets in their exclusive economic zones, and in 1992 the United Nations General Assembly extended this ban to all international waters. Drift gill net fishing for tuna is banned in the Mediterranean. In the United States, Florida, Louisiana, Texas, and California have banned gill nets in all or part of their waters in response to marine mammal and other bycatch issues.

F. Quota-Based Restrictions

The most direct method to manage removals from a wild population is to set a limit on the number of animals that can be taken in a given time period (usually 1 year). Quota-based management was first applied to the directed harvest of marine mammals and was later adapted to regulation of bycatch. This method requires some method for estimating annual mortality, such as from a mandatory program placing observers on whaling or fishing vessels. Whaling on the high seas has been regulated with quotas since 1931, but early quotas were designed only to limit oil production and were based on a “blue whale unit” [the oil equivalent of one blue whale (*Balaenoptera musculus*) being two fin whales (*B. physalus*), six sei whales (*B. borealis*), etc.]. The lack of species- or population-specific whale quotas lasted until 1972 and is widely blamed for the near extinction of most large whale populations. The failure of IWC to effectively manage whaling resulted in an international moratorium on commercial whaling that started in 1986 and continues today. Since 1986, the IWC has devised and adopted a revised management procedure that incorporates a new, well-tested catch limit algorithm (CLA) for setting population-specific quotas. Aboriginal subsistence whaling continues under population-specific quotas that are based on biological considerations and on “cultural and nutritional needs.” Quotas were first used in 1976 to limit bycatch in the US tuna purse seine fishery to 78,000 dolphins per year. The US quotas gradually decreased to 20,500 by 1981, but, like the blue whale unit, still had not adequately addressed species- and population-specific conservation concerns. The gradual conversion of the tuna purse seine fishery from a US industry in 1970 to a largely international fleet by 1990 further complicated conservation efforts. The Inter-American Tropical Tuna Commission (IATTC) and several nongovernmental organizations have negotiated with IATTC signatory nations to impose vessel-specific quotas on total dolphin bycatch (1993) and stock-specific quotas (2000). Although the management of dolphin mortality in the tuna fishery has remained a special case, the United States has adopted a more general approach to setting stock-specific quotas on the maximum allowable levels (potential biological removal, PBR) of human-caused mortality for marine mammal populations in its exclusive economic zone. The PBR approach (Wade, 1998) is like the IWC's CLA in that it sets allowable removal rates that are conservative in the face of uncertainty but which can increase as uncertainties are resolved. New Zealand uses a similar approach to setting annual

bycatch limits for Hooker's sea lions (*Phocartos hookeri*) and has closed its squid trawl fishery when this limit was exceeded. Several countries, including the United Kingdom, are investigating similar approaches to setting limits on fishery bycatch.

G. Market Monitoring and Trade Restrictions

Enforcement of laws on the high seas is often difficult or impossible; therefore, market monitoring and international trade restrictions may be necessary to prevent the illegal harvest and marketing of protected marine mammal. The Convention on International Trade in Endangered Species (CITES) is the primary implement for international trade restrictions and currently bans all trade in whale products, including some species that are not considered "endangered" but whose meat might be confused with that from endangered species. Genetic methods now can distinguish between all species, and CITES is under pressure from pro-whaling countries to lift the "look-alike" ban on non-endangered whales. Surreptitious market surveys by nongovernmental organizations and subsequent genetic analyses have shown that Japanese and Korean markets contain a wide variety of cetacean products (Baker *et al.*, 2002, 2006), many of which are mislabeled and some of which may have been illegally imported (some cetaceans taken within EEZ waters of those countries and whales taken under "scientific whaling" can be legally marketed). Because marine mammal products can be extremely valuable, there will be a strong incentive to cheat. Some IWC member countries are insisting that a system of market monitoring precedes the resumption of commercial whaling, possibly by genetically "fingerprinting" every legally taken whale.

H. Treatment of Wild and Captive Animals

Marine mammals, especially cetaceans, are regarded by many cultures as deserving special treatment by humans. These attitudes may stem from their similarities to humans (large brain, play behavior, etc.), from their representation in popular media, or from the endangered status of some species. Whatever the reason, the special treatment is often evident in national laws that afford more protection for marine mammals than for similar terrestrial mammals. For example, the US MMPA prohibits "harassment" of marine mammals (defined as any pursuit, torment, or annoyance that has the potential to disrupt the natural behavioral patterns of the animal) unless a specific permit is obtained. Virtually any research on marine mammals (except passive observation) has a potential for harassing the subject and therefore requires an MMPA permit. National laws are also frequently implemented to regulate the public display of marine mammals to ensure that adequate space and care are provided to those animals. Some laws and regulations are expressions of public concern for individual animals (rather than concern about species or populations) and are derived more from the animal rights movement than from a conservation ethic, but this distinction is not clear in many cases. Stranding programs that rehabilitate beached animals may aid individuals and, for endangered species, the survival of the species.

I. Marine Sanctuaries

There is a long-standing and growing interest in the use of protected areas or sanctuaries as a management tool for marine species. The first marine mammal refuge [for pinnipeds and sea otters (*Enhydra lutris*) on Afognak Island, Alaska] was established in 1892, but most have been established since 1975. Protected areas are a useful management tool because the concept is so simple (easy to

understand and to enforce). For marine mammals, established sanctuaries and protected areas are taxonomically limited: the Indian Ocean and Southern Ocean whale sanctuaries (established by the IWC) protect only large whales, the Irish whale and dolphin sanctuary (established by Ireland) protects only cetaceans, and the Banks Peninsula sanctuary (established by New Zealand) was designed to protect only Hector's dolphins. The level of protection varies among sanctuaries; the Irish whale and dolphin sanctuary does not prohibit porpoise and dolphin bycatch in commercial fisheries (although the existence of the sanctuary has focused efforts on reducing bycatch). The utility of protected areas as a management tool depends critically on characteristics of the animals they are designed to protect (residency patterns, home ranges, mating strategies) and on the size of the protected area. The enormous Southern Ocean whale sanctuary (generally, all waters south of 40° but excluding the Indian Ocean sanctuary) is currently recognized as being too small to effectively protect its whales (which migrate out of this area during the southern winter). In contrast, small protected areas are quite effective in sheltering breeding colonies of pinnipeds or essential warm spring habitats of manatees. To conservation biologists, a "marine protected area" refers to an area of complete protection at all ecosystem levels. Existing marine protected areas are too small to afford much protection for marine mammal species, although they may protect some critical habitat.

J. Pinniped Control Programs

The recovery of many pinniped populations from a legacy of hunting and near extermination is one of the success stories in marine mammal management, but this recovery is hardly viewed as a success by fishermen and aquaculturists who share their waters. Even conservationists are faced with a dilemma in some situations, such as when California sea lions (*Zalophus californianus*) (protected, but now numbering ~250,000) are threatening the survival of a depleted steelhead run in Washington State. Laws protecting marine mammals can and have been modified to deal with such small-scale problems by authorizing the lethal or captive removal of specific problem animals. In some areas, the use of acoustic harassment devices (AHDs) has been authorized to deal with the economic loss to seals by aquaculture facilities or commercial fishermen. Although some of these "fixes" appear to be successful in the short term, their long-term utility is questionable and there is concern about the impact of AHDs on other elements of the ecosystem. Even more controversial are programs designed to reduce entire pinniped populations by culling. Government-sanctioned culling programs to improve fisheries have been practiced in many countries, including Norway and the United States. In Canada, the high annual quota on harp seals (*Pagophilus groenlandicus*) and hooded seals (*Cystophora cristata*) is justified, in part, as a means to reduce seal predation on depleted cod stocks. This approach has been criticized on theoretical grounds because it oversimplifies ecosystem interactions; pinnipeds may feed on a commercially important fish species but may also feed on predators of that species. Management of culling programs would typically fall under national regulations, but the IUCN Marine Mammal Action Plan has established a protocol to evaluate culling proposals.

K. Ecosystem Management

Ecosystem management refers to approaches ranging from simply considering the impact of a management decision on other elements of the ecosystem to the simultaneous optimization of management strategies to meet management goals of all elements of an ecosystem. There are no examples of the latter approach, although

Norway and the signatory nations of the Convention for the Conservation of Antarctic Marine Living Resources are pursuing this goal by promoting multispecies considerations in the management of marine mammal, fish, and seabird resources. Although it is unarguably true that improvements can be made in resource management by considering ecosystem interactions (sometimes called an ecosystem approach to management), it is also true that predicting the implications of even a simple ecosystem perturbation is far beyond our current capabilities. Significant progress in implementing ecosystem management may be left to future generations.

III. Trends in Marine Mammal Management

In recent years, there has been a movement toward management procedures that determine quotas for allowable harvests or incidental mortality based on rigid formulae. Both the IWC's CLA and the US PBR approaches are based on formulae that estimate the allowable removals from a management unit based on measurable attributes (such as estimated population size, population growth rates, catch histories, and the precision of the various estimates that are used). The advantage is that all parties can reach *a priori* agreement on the management objectives and on the rules that will be used to reach those objectives without divisive arguments about the effect on anyone's quota. Biological data are inherently imprecise and full of other uncertainties. For both CLA and PBR approaches, computer simulation studies were used to "tune" the quota formulae to achieve their goals even in the presence of imprecision and bias in available data (Wade, 1998). With the increasing emphasis on rigid quota-based management, debates about management practices are changing. Instead of concentrating on which values of biological parameters and which analytical models should be used, managers are now more concerned with how management units should be defined.

Coincident with the movement toward rigid formula-based quota schemes is an increasing reliance on direct approaches to measuring population parameters and a decreasing reliance on industry statistics, such as catch per unit effort. Advances in survey methodology (line-transect and mark-recapture) have greatly improved our ability to estimate the size of cetacean populations. Photo-identification studies, combined with mark-recapture analysis, have refined our understanding of marine mammal life history. Observer programs have increased the reliability of bycatch and harvest estimates. Satellite tagging and the recent revolution in molecular biology have contributed to an explosion of new information on the structure of marine mammal populations. Although all these recent trends promote the potential for effective marine mammal management, the real impediment to effective management is now the lack of collective willpower to implement regulations and to enforce existing regulations.

There has been increasing interests in applying the "precautionary principle" in marine mammal management. In the face of uncertainty, management decisions should be made to minimize the damage caused by being wrong. In most resource protection issues, there are two types of damage: the damage caused to a regulated industry by providing more marine mammal protection than is needed and the damage done to the populations and the industry by providing too little protection. A look at the catastrophic history of marine mammal management illustrates the disastrous economic and ecological results of management approaches that are not precautionary. One way to add precaution is to reverse the legal burden of proof to ensure that any action will *not* adversely affect the population before that action is permitted. Clearly, the future challenge is how to make marine mammal management appropriately precautionary.

Manatees

Trichechus manatus, *T. senegalensis*, and *T. inunguis*

JOHN E. REYNOLDS, III, JAMES A. POWELL AND
CYNTHIA R. TAYLOR

I. Characteristics and Taxonomy

The manatees (order Sirenia, family Trichechidae, subfamily Trichechinae) represent one of the most derived groups of extant mammals. Although ancestral forms were terrestrial, descendant forms have occupied aquatic habitats since the Eocene Epoch, providing the group with a long period of time over which to evolve. Apart from their suite of unusual morphological attributes (adaptations) associated with their herbivory and aquatic habitat, manatees have many behavioral and life history traits that are similar to those of other mammals. For most aspects of species biology, the Florida manatee is the best-studied taxon, and without data to the contrary, scientists assume that other manatees may be similar to the Florida subspecies.

The three species and their subspecies are *Trichechus inunguis*, Natterer, 1883 (*Amazonian manatee*); *Trichechus manatus*, Linnaeus, 1758 (West Indian manatee); *T. m. manatus* (Antillean manatee); *T. m. latirostris* (Florida manatee); and *Trichechus senegalensis*, Link, 1795 (West African manatee).

The generic name of the manatees, *Trichechus*, comes from the Greek words *trichos* (hair) and *ekh_* (to have), referring to the sparse body hairs and abundant facial hairs and bristles. *Inunguis* refers to the lack of nails on the pectoral flippers of the Amazonian manatee. At least two possible origins for *manatus* have been suggested: It could refer to the hand (*manus*) since manatees sometimes use their front, or pectoral, limbs to push food into their mouths. More likely, the term comes from the Carib Indian word *manati*, which means woman's breast, perhaps referring to the fact that the manatee's mammary glands are located in the axillary region in approximately the same anatomical location as the breasts of a human female; this particular anatomical feature contributed to the association of the manatee with the mythical mermaid. *Senegalensis* denotes that the West African species is found along the coast of Senegal, although it also occurs in waters of other west-central African countries.

Vernacular names for the manatees vary by region. In English-speaking areas, they are typically referred to as sea cows; similarly, in German, a manatee is referred to as a *Seekuh* or *Manati*, in Dutch as a *zeekoe*, in French as a *lamantin*, in Spanish as a *manati* or *vaca marina*, and in Portuguese as a *peixe-boi*, or ox fish. In some West African countries, a manatee is called a "mamivata," which refers to a water deity. Diverse indigenous names are also in use in Africa and South America.

Unlike some marine mammals (e.g., pinnipeds, polar bears, and sea otters), manatees and the other living member of the order Sirenia, the dugong (*Dugong dugon*), are totally aquatic. They inhabit shallow waterways and feed primarily on plants, a diet that makes the sirenians unique among modern marine mammals.

Although manatees do not dive to great depths or for prolonged periods as many cetaceans and pinnipeds do, they are anatomically well adapted to aquatic habitats (Fig. 1). They lack hind (pelvic) limbs have reduced, paddle-like front (pectoral) limbs, and have fusiform (streamlined, spindle-shaped) bodies with few external protuberances and thick, tough skin, and are very large (an adaptation that facilitates heat conservation). Their heads are somewhat streamlined, and the nostrils are located on the dorsal side of the muzzle. A dorsal fin is lacking. Internally, manatees have extremely thick, heavy (pachyosteosclerotic) bones and an unusual arrangement of the

diaphragm and lungs that facilitates buoyancy control. Manatees, like other marine mammals, have sensory and other adaptations that enhance diving, osmoregulatory, and thermoregulatory abilities.

Unusual adaptations accommodate the manatee's herbivorous diet. These include (1) enlarged lips (especially the upper lip) equipped with prehensile as well as tactile vibrissae and moved by a muscular hydrostat; (2) the presence of supernumerary (polydont) molariform cheek teeth that are replaced via horizontal migration along the jaws throughout the lifetime of each manatee; and (3) a greatly expanded gastrointestinal tract (specialized for hindgut fermentation, as in horses and elephants) with several unusual gross and microscopic features.

Manatees differ sharply from their close relative, the dugong. Manatees have a rounded fluke, whereas dugongs have split flukes similar to those of cetaceans. Dugongs have tusks, which manatees lack, and the mode of tooth replacement in the two differs. The rostrum of the dugong is much more sharply deflected downward than is the rostrum in any manatee species. In addition, dugong skin is smoother than is the case for West African and West Indian manatees.

The West Indian manatee is the largest living sirenian, with individuals approaching 1500 kg in weight and 4 m in length. Females tend to be somewhat larger than males, but body size cannot be used to determine either the sex or the age of an individual. West Indian manatees are euryhaline (can tolerate both salt and freshwater) but may require periodic access to fresh water to drink. West African manatees are generally very similar to West Indian manatees in terms of their size, general body form, and habitat, but the West African manatee has a blunter snout, somewhat protruding eyes, and a slightly more slender body. The Amazonian manatee is the smallest trichechid, measuring about 3-m long or less and weighing less than 500 kg. Its "rubbery" skin is smoother than that of its congeners, and it lacks nails at the tips of the pectoral flippers, which are proportionately longer than in the other species. In addition, white or pink belly patches are common. The Amazonian manatee is confined to freshwater habitats.

Manatee species also vary in the degree of rostral deflection, corresponding to the predominate location in the water column of food plants in their natural habitats. West African manatees have the least deflected snouts, and Florida manatees the most deflected.

The only species for which subspecies have been identified is the West Indian manatee. The two subspecies differ most obviously in their skeletal (especially skull) morphology.

However, Garcia-Rodriguez *et al.* (1998) examined mitochondrial DNA control regions from 86 individual West Indian manatees from 8 different locations. They found 15 different haplotypes that could be clustered into three, rather than two, distinctive lineages for the species. These authors also noted for three presumed West Indian manatees from Guyana that their mtDNA haplotypes were more consistent with that of the Amazonian manatee. Vianna *et al.* (2006) sequenced the mitochondrial DNA control region from 330 *Trichechus* to compare phylogeographic patterns. In *T. manatus* three haplotype clusters were identified showing distinct spatial distribution. A single expanding population cluster was observed for *T. inunguis*. Analysis revealed a hybrid between the *T. manatus* and *T. inunguis* species at the mouth of the Amazon River in Brazil, extending to the Guyanas and possibly to the mouth of the Orinoco River, Venezuela. Systematics of manatees is a topic that requires additional study.

Sirenians probably arose in the Old World (Eurasia and/or Africa) not later than the early Eocene Epoch, 50–55 million years ago. The oldest fossils are from Jamaica. Within a few million years (i.e., in the

Figure 1 Although manatees may not swim as fast or dive as deep as some cetaceans do, manatees have the fusiform bodies, the reduced or absent limbs, and the powerful locomotory fluke that cetaceans also have. This particular animal has been fitted with a belt attached to a floating canister containing telemetry equipment. Photograph by Patrick Rose.

middle Eocene, 45–50 million years ago), several genera of sirenians existed. Peak diversity of sirenians occurred during the Oligocene and Miocene Epochs (5–35 million years ago).

The first truly manatee-like (i.e., trichechine) sirenian was *Potamosiren*, fossils of which are about 15 million years old (Miocene of Colombia). During the Pliocene Epoch (about 2–5 million years ago), trichechids also inhabited the Amazon Basin and the Caribbean. The Amazonian trichechids gave rise to the Amazonian manatee, and the Caribbean trichechids are thought to have given rise to the West Indian and West African manatees, which are sister taxa.

Due to at least in part to their dense bones, sirenians in general are well preserved in the fossil record, but true manatees are rare until the Pleistocene.

Various lines of evidence (e.g., genetic analyses, electrophoresis of serum proteins, and morphological studies) suggest that the order Sirenia (manatees and dugong) is most closely related to a group of mammalian orders called the Paenungulata. The extant paenungulates include the elephants (order Proboscidea) and hyraxes (order Hyracoidea). The sirenians appear to be most closely related to elephants and the extinct, hippopotamus-like desmostylians.

II. Distribution and Abundance

All extant manatees occupy subtropical and tropical waters (Figs. 2–5).

A. West Indian manatee, *T. manatus*

This species occupies coastal and riverine habitats from the mid-Atlantic region of the United States, throughout the wider Caribbean Sea and Gulf of Mexico, and into coastal parts of northeastern and central-eastern South America. The Florida manatee, *T.m. latirostris*, occurs from eastern Texas to Virginia in the summer with occasional sightings as far north as Massachusetts, but occupies waters of Florida and southeastern Georgia year-round (Fig. 2). Although its distribution is not continuous, the Antillean manatee, *T.m. manatus*, occupies the remainder of the species' range, from southwestern Texas to South America. It occupies the waters of 19 countries (Fig. 3). The range of the Antillean manatee may overlap with that of the Amazonian manatee around the mouth of the Amazon River (Fig. 4).

Scientists estimate that there may be 3000 or more Florida manatees. Some recent analyses of population trends of manatees

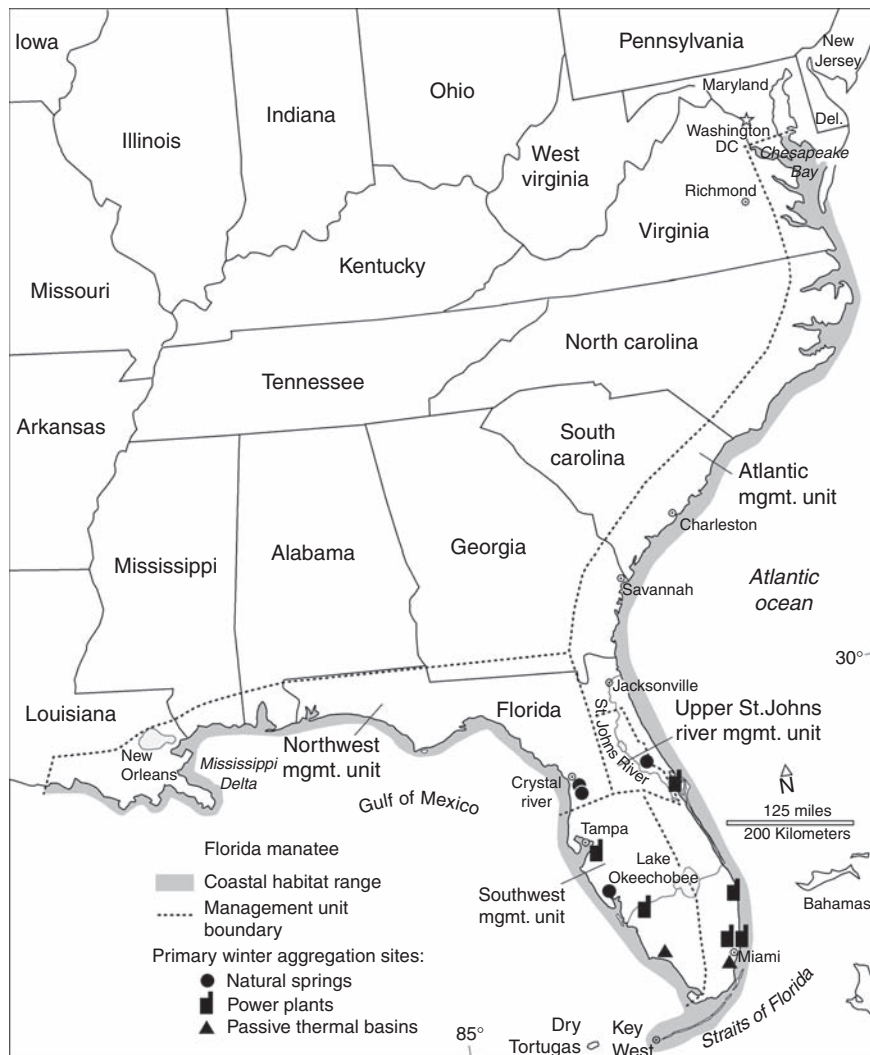

Figure 2 Range of the Florida manatee, *T.m. latirostris*. Map produced by Ellen McElhinny.

Figure 3 Range of the Antillean manatee, *T.m. manatus*. Map produced by Ellen McElhinny.

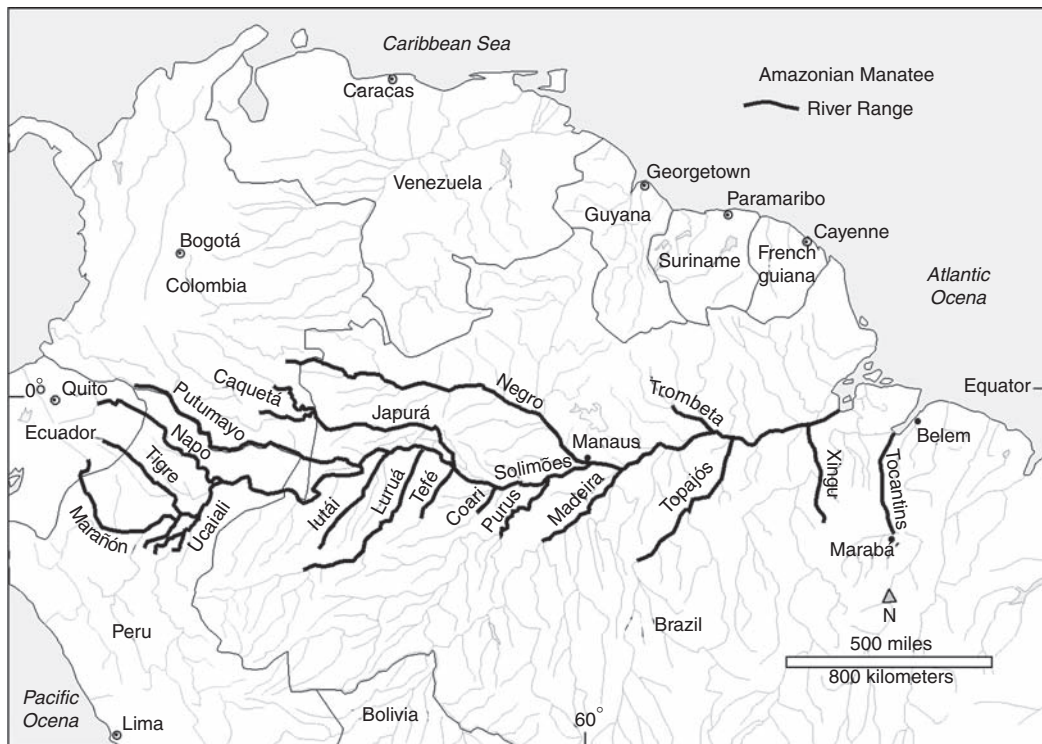

Figure 4 Range of the Amazonian manatee, *T. inunguis*. Map produced by Ellen McElhinny.

occupying different regions of the species' range suggest that the population grew through the 1980s and early 1990s but leveled off in at least some locations during the mid-1990s. As the twentieth century ended, other recent analyses suggested that the population may be relatively stable or may even be increasing slightly in some regions, but the statistical uncertainty associated with the data and models leaves open the possibility that the overall population may be declining.

The number of Antillean manatees is unknown. Aerial surveys of Belizean waters and waters of southern Quintana Roo, Mexico, have documented more than 400 manatees. The corridor between Belize and southern Mexico is considered to be a stronghold for the subspecies.

B. Amazonian manatee, *T. inunguis*

This species occupies freshwater habitats throughout the drainage of the Amazon River and its tributaries, including rivers and lakes in Brazil, Peru, Ecuador, and Colombia (Fig. 4). There are no reliable population estimates.

C. West African manatee, *T. senegalensis*

This species is found in the coastal and riverine waters of 21 countries in central and West Africa, from Senegal to Angola (Fig. 5). Manatees inhabit the upper reaches of the Niger River to Guinea and occur throughout the inland delta of Mali. Manatees in the upper Niger River are cut off from the sea by cataracts and a

hydroelectric dam. In Ghana, manatees caught above a dam on the Volta River are also now permanently cut off from the ocean. Manatees inhabit two tributaries of Lake Chad, the Logone and Chari rivers, but are not found in the lake itself. The Logone and Chari rivers do not communicate with the sea; during times when water levels were higher, manatees in these rivers probably were able to mix with other manatees by moving through interconnecting lakes to the Benue River, a tributary of the Niger River. There are no reliable population estimates.

III. Ecology

All manatees are herbivores, and as hindgut digesters (like horses and elephants), they can subsist on low-quality forage. Because they are such large mammals, manatees would be expected to have a low weight-specific metabolic rate, but their metabolism is 20–30% lower than one would expect. The best-studied species, the West Indian manatee, consumes more than 60 species of plants (almost exclusively angiosperms) and may ingest a mass of food that approximates up to 7% of its body weight each day. In some locations, 50–90% of the plant biomass may be eaten or uprooted by grazing animals, but the overall effects on local plant productivity of manatee feeding are not well understood. The dugong has been described as a cultivation grazer, and the manatee may serve the same role.

Although manatees subsist primarily on plants, they also consume flesh. They have been reported to consume fish caught on longlines, and tunicates have been found in large numbers in some manatee

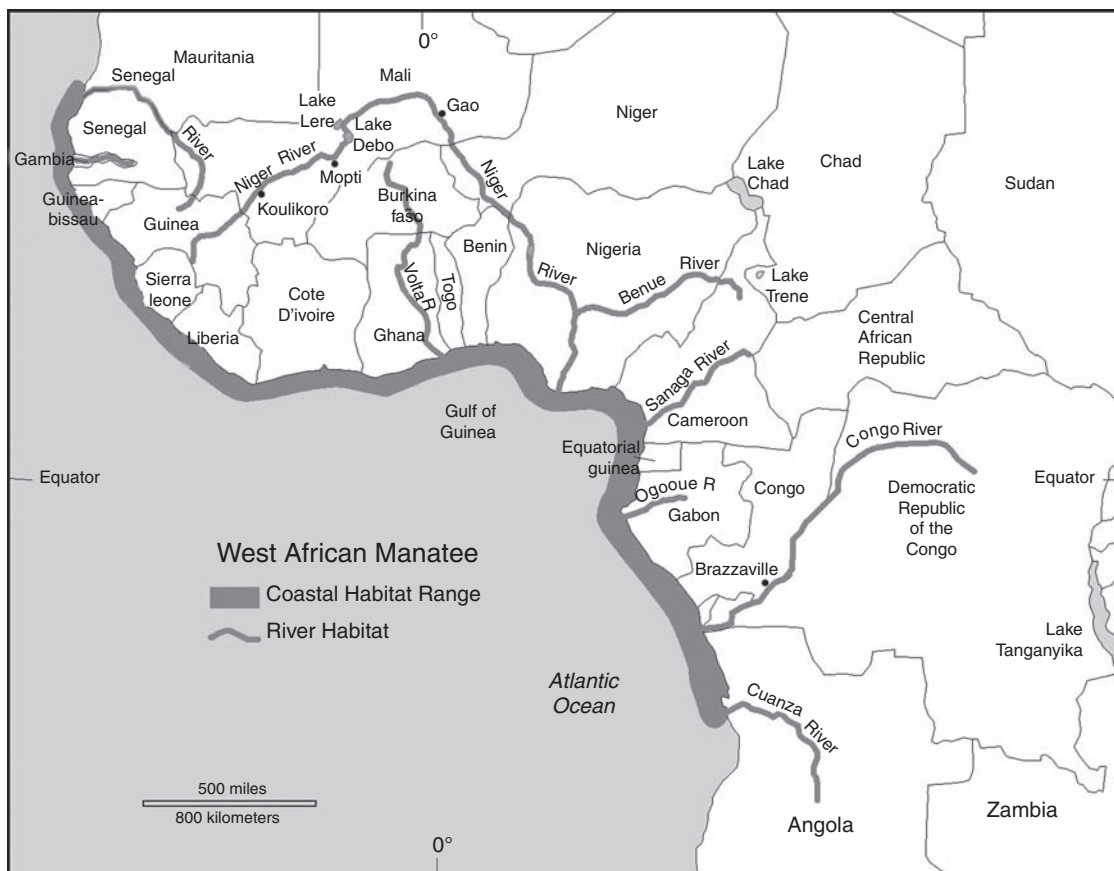

Figure 5 Range of the West African manatee, *T. senegalensis*. Map produced by Ellen McElhinny.

stomachs. Of course, the plants manatees consume have epiphytic organisms growing on their leaves.

The distribution of the Florida manatee is influenced by temperature and, perhaps, by access to fresh water to drink. In cold weather, manatees tend to migrate south and/or seek refuge at natural and artificial warm-water refugia (Fig. 6). The distribution of other manatee species or subspecies appears to be governed to at least some extent by the availability of water and suitable habitat during the wet and dry seasons. Antillean manatees, for example, may move upstream in coastal rivers during the wet season, when water levels are high, and return to lower reaches of rivers during the dry season. Amazonian manatees occupy lakes during the dry season, when rivers and streams dry up. Because the lakes are murky and lack bottom vegetation, manatees may fast during the dry season for up to 200 days when water levels drop and shoreline vegetation is no longer available for them to eat.

The habitat requirements of West African manatees are similar to those of West Indian manatees. Although manatees along the coast of Africa tend to move up rivers and out of estuaries during the dry season, they can occasionally be found in any aquatic habitat. In the upper reaches of the Niger River and some other large rivers, West African manatees, like Amazonian manatees, may remain in lakes during the dry season, when water levels drop, and stay there until waters rise and they can move back into the rivers.

Predation on manatees has not been well documented, but it appears that they have few natural enemies and that predation levels are very low. There is some evidence to suggest that crocodilians and sharks may account for some manatee mortality in different parts of the world; in Florida, such reports are reinforced by the rare presence on living manatees of wounds caused by alligators or sharks (Falcón-Matos *et al.* 2003). Especially, but not exclusively, when aggregated in lakes during the dry season, Amazonian manatees may also be preyed upon by jaguars.

Natural factors that have been documented to kill large numbers of Florida manatees include cold weather and red tides.

IV. Behavior and Physiology

Manatees feed on bottom vegetation, plants in the water column, and floating or shoreline vegetation. Their flexible pectoral flippers and prehensile lips, which are equipped with bristles, are used to push vegetation into the mouth. The most striking and well-documented migrations occur in Florida in response to cold weather. Aggregations of more than 300 manatees occur at each of several natural and artificial sources of warm water in winter (Fig. 6). On very cold mornings, the majority of Florida manatees may be found at a few warm-water refugia scattered along the coast. Florida manatees disperse widely in warm weather. Amazonian manatees also migrate seasonally, from rivers and streams in the wet season to deeper waters, such as lakes, in the dry season. In some areas, West African and Antillean manatees show movement patterns similar to those of Amazonian manatees in response to low water and lack of freshwater flow.

Mating herds, composed of a female in estrus and a consort of several (up to 22) males, may remain together for periods of up to a month, typically outside the winter season. The cow is receptive to mating for only a day or two during that time. Although “fighting” does not occur, the males vigorously push and shove one another to gain access to the female. Females mate with several males during the estrous period. The mating system is an example of scramble competition polygamy (specifically polyandry).

Cues that males use to locate estrous females are not known, but it is possible that the males detect olfactory, gustatory, and acoustic signals produced by the females. Males tend to have larger home ranges than females do; thus, wandering males may routinely encounter a number of females. Females in estrus have a larger range of movement than do non-estrous females.

Figure 6 Florida manatees aggregate in large numbers around natural and artificial sources of warm water in winter. In this photograph, approximately 230 manatees huddle in the discharge of the Riviera power plant. Photograph by John Reynolds and Florida Power & Light Company.

Calves tend to stay close to their mothers for some time after birth. Weaning generally occurs when the calf is 1–2 years old, although calves up to 4 years old may still nurse. When traveling, calves swim parallel and close to their mothers, presumably in a position where they are easy to protect, where communication is facilitated, and where hydrodynamic drag is minimized. During the long period of maternal care, calves apparently learn the locations of important resources such as warm-water discharges or fresh water. The learning process causes groups of manatees, including young animals that have recently become independent from their mothers, to use the same areas year after year.

Details of the social structure of manatees are lacking. Florida manatees appear to have a simple fission–fusion society in which individuals come together in a series of temporary groups. G. B. Rathbun has stated that although such societies may be relatively unstructured, the lack of social structure is not the same as a lack of social complexity.

Communication among manatees appears to involve acoustic signals (squeaks and squeals, mostly in the 3–5 kHz range), tactile cues (rubbing and “kissing”), visual cues, and possibly chemical cues (suggested by repeated use of “rubbing posts” and by individuals mouthing one another).

Manatees appear to play. Body surfing and follow-the-leader have been observed.

Manatees have a suite of unusual morphological and physiological adaptations. We note here some features of a variety of organ systems.

The bones, especially the ribs, are dense and heavy (osteosclerotic), and the ribs and some other bones are swollen (pachyostotic). As in other marine mammals, the long bones are shortened and the phalanges in the pectoral appendage are more elongated than are those of “typical” terrestrial mammals. Hyperphalangy, however, does not occur. The first digit is reduced and the fifth digit is enlarged. Pelvic limbs are absent, although vestigial pelvic bones that are sexually dimorphic remain embedded in hypaxial musculature. Erythropoiesis (formation of red blood corpuscles) and granulopoiesis (formation of certain white blood cells) occur primarily in the vertebral bodies. The skull is elongated but not telescoped. Nares and nasal bones have migrated dorsally. The zygomatic arch, which abuts the periotic bone on each side of the skull, is relatively light and porous and is permeated with oil. However, compared to the bones of the zygomatic arches of most marine mammals, the bones of the manatee’s arch are huge, reflecting their importance as an attachment for powerful chewing muscles.

The muscle color is of several shades, from almost white to red, apparently due to differences in myoglobin concentration in particular muscles or muscle groups. Axial muscles to the fluke are extremely powerful. The panniculus muscles are very well developed, as are muscles to the pectoral flipper (presumably to facilitate both dexterity and strength).

The skin is extremely heavy and thick and may provide some of the ballast needed for buoyancy control. Body hairs are sparse (~1 every cm²); sweat glands are lacking; and nerve plexuses associated with some hairs suggest that the hairs are important in detecting pressure or in tactile communication. Instead of having one layer of blubber as many other marine mammals do, manatees have alternating layers of panniculus muscle and blubber (somewhat resembling bacon).

The lungs are long and unlobed, and they occupy virtually the entire dorsal region of the trunk. Manatees exchange about 90% of the air in their lungs in a single breath. The branching pattern of the bronchi is monopodial, and the terminal airways are reinforced with cartilage. The diaphragm is large and powerful, is located in a

horizontal (coronal) plane, constructed as two independent hemidiaphragms, and instrumental in maintaining buoyancy control.

The large intestine is enormous (>20-m long in large animals), a feature that is not surprising in a hindgut fermenter. The stomach has a large accessory organ of digestion (the cardiac gland), and the capacious duodenum has two prominent diverticulae. The cecum is small and bicornuate. The life-long, horizontally oriented tooth replacement is a very unusual feature and may be an adaptation to facilitate the consumption of the gritty plant material that manatees consume. Histology of the various portions of the gastrointestinal tract shows some unusual cellular arrangements. The accessory organs of digestion (liver, pancreas, salivary glands) are unremarkable. Manatees have taste buds but no vomeronasal organ.

The heart is not unusual except for a persistent interventricular cleft, the presence of notable amounts of cardiac fat, and the large amount of pericardial fluid. Circulatory adaptations (retia, arteriovenous anastomoses, counter-current heat exchangers) facilitate overall heat conservation, while also allowing for the cooling of the reproductive organs and nervous tissues.

The brain is small (the encephalization quotient for *T. manatus* is 0.27), and the cerebral hemispheres lack extensive convolutions. Notably large trigeminal (cranial nerve V) and facial (cranial nerve VII) nerves are associated with the facial vibrissae.

The uterus is bicornuate. The ovaries are rather flattened and diffuse, and in mature individuals, the ovaries have numerous corpora. The penis and testes are located inside the body wall. The testes are relatively small, but the seminal vesicles are very large. The testes abut the kidneys along the caudal part of the diaphragm.

The kidneys are lobular, are located on the ventral surface of the caudal part of the diaphragm, and are often encapsulated in fat. Their microscopic structure suggests an ability to produce concentrated urine and therefore to go for prolonged periods without access to fresh water.

Manatees can remain submerged for more than 20 min but generally dive for much shorter periods of time (2–3 min or less). Because the plants manatees consume grow close to the surface where sunlight is available, dives are usually shallow.

Scientists have historically suggested that temperatures below about 19°C induce sufficient stress to cause at least some manatees to seek warm water as a refuge. Some recent evidence suggests that this temperature may be a little high and that 17°C is perhaps a more realistic point at which stress occurs. Even though scientists may be uncertain of the precise point at which thermal stress occurs, it is clear that both chronic and acute exposure to low temperatures may cause death.

The extent to which manatees physiologically *need* fresh water is unclear. It is clear, however, that Florida manatees *like* fresh water to drink. Functional morphology suggests that the kidney should be able to produce hyperosmotic urine and be able to rid the body of excess salt following seawater ingestion. Manatees, like other marine mammals, are K-strategists when compared to most other animals. In some ways, however, manatees appear to be less K-selected if the comparison group is just the marine mammals. Table I provides life history information on Florida manatees.

V. Life History

Aspects of life history are known for the Florida manatee based on long-term research (Lefebvre and O’Shea, 1995; Runge *et al.*, 2004). Maximum age was 60 years. The gestation period was 11–13 months. The sex ratio at birth was 1:1. Calf survival to year 1 was 0.81 at Blue Spring and 0.67 at Crystal River. Adult annual survival was

0.937 on the Atlantic coast, 0.96 at Crystal Spring, and Blue Spring and 0.908 on the southwest coast. Earliest age at first reproduction was 3–4 years, mean is 5 year. Thirty-three percent of salvaged female carcasses were pregnant, as were 41% of living adult females at Blue Spring. The mean proportion with nursing calves during the winter season was 0.36. The mean period of calf dependency was 1.2 year. The mean inter-birth interval was 2.5 year. The highest number of births was in May–September, and the highest frequency of mating herds was in February–July.

VI. Interactions with Humans

Humans have interacted with the various manatee species in a number of ways, most of them harmful to the manatees. The following information includes both well-documented and presumed interactions.

Manatees have historically been hunted throughout their ranges. In Florida, hunting pressure has virtually ceased within the past few decades, although animals are occasionally still taken illegally for meat. The best-documented and most extreme example of manatee hunting occurred in Brazil from 1935 to 1954, when between 80,000 and 140,000 Amazonian manatees were killed for their meat and hides. Primary products included *mixira* (fried manatee meat preserved in its own fat), uncooked meat, lard, and the tough hides, which could be used for a range of products including whips, shields, and machine belts. Although the market for hides diminished after 1954, several thousand manatees were killed each year through the late 1950s, and probably beyond.

In certain countries such as Peru and Ecuador (Amazonian manatee) and possibly in some West African countries, military patrols hunt manatees, or hire local hunters to catch manatees, for food.

Manatees are also hunted for reasons other than the products they provide. In Sierra Leone, the Mende people hunt manatees, in part, to reduce the number of manatees and thereby to keep them from tearing fishing nets, destroying fish that have been netted, and plundering rice fields.

However, local traditions may work in favor of manatees and prevent their harvest in particular areas. In the Korup region of Cameroon, e.g., villagers fear manatees and have no taste for the meat, so they generally do not hunt the animals.

An interesting presumed effect of manatee hunting in tropical America and West Africa is that some manatees have become nocturnal and/or crepuscular.

Manatees are captured accidentally in fishing gear (crab pot lines, trot lines, fishing nets) in the United States and other countries. The extent of serious injury or mortality is unknown.

Collisions with boats and barges account for about 25% of all manatee mortality in the United States (Fig. 7). The number rose at a rate of about 7.5% per year between 1976 and 1996, and currently more than 70 animals die annually in this way. The number of registered boats in Florida alone exceeds 1 million. Based on observations of scarred animals, collisions with boats appear to be occurring with increasing frequency in other parts of the world, but the extent to which those collisions kill manatees outside the United States is unknown. Also unknown is how seriously boat-inflicted injuries debilitate manatees and affect reproduction, without causing immediate death (Fig. 8).

The propeller scars and increased turbidity caused by boats negatively affect the health and distribution of sea grasses and other vegetation eaten by manatees. Boats also make noise, which may affect manatee distribution, habitat use, and energetics. Boats can, therefore, affect manatees both indirectly, by contributing to diminished

Figure 7 Categories of manatee mortality in Florida. This pie chart shows manatee mortality categories based on 6180 carcasses recovered or reported to federal or state agencies from 1974 through 2007. The highest percentage of deaths remains undetermined ($n = 1802$) and includes unrecovered, badly decomposed, and other carcasses that were not badly decomposed but for which cause of death could not be assigned. Total human-related mortality is high ($n = 1897$, 31% of total) and includes watercraft-related deaths ($n = 1551$), trauma, or drowning caused by canal locks or flood gates ($n = 191$), and other human-related factors such as entanglement ($n = 155$). Non-human-related causes of death ($n = 1158$, 19% of total) are related to cold exposure ($n = 359$), red tide outbreaks ($n = 460$), or other factors ($n = 339$). Perinatal mortality ($n = 1323$) refers to the death of a small animal (≤ 150 cm long) for which cause of death can not be determined; perinatal mortality can be either human or non-human related. Watercraft-related mortality continues to rise annually and is the single highest known category of death. Produced by James Powell/Cynthia Taylor.

food resources, and directly, by disturbing, injuring, or killing them. In Florida, manatees sometimes become trapped in flood control structures and canal locks and die. About 4% of the manatees known to die between 1974 and 1996 were crushed and drowned in flood gates or canal locks. Increasingly, scientists and environmentalists at the national, state, and regional levels are concerned about the effects of pollution on both the health of individual animals and the status of populations. Levels of certain chemical pollutants have been assessed in some marine mammal tissues, but the effects of these chemicals are unclear. In only one case did scientists experimentally demonstrate a clear cause-and-effect relationship between a toxicant and a reproductive impairment (in harbor seals). Based on toxicological studies of laboratory animals, scientists suspect that chemical pollution is harming the endocrine and immune systems of at least some stocks of marine mammals, but this has yet to be demonstrated.

Scientists have found elevated levels of copper in the tissues of Florida manatees from certain locations, but levels of other metals and of organochlorines have been considered unremarkable, and have not been the focus of many studies. However, Pulster *et al.* (2007) and Wetzel *et al.* (in press) have examined levels of polychlorinated biphenyls (PCBs) and chlorinated pesticides in manatees from southeastern Mexico and southwestern Florida; the scientists found that PCBs in some individuals are surprisingly high, exceeding toxic threshold values for cetaceans (such values are not known for

Figure 8 Although several dozen Florida manatees die each year because of collisions with watercraft, many animals survive such encounters, albeit with considerable pain and disfigurement. The extent to which reproduction and longevity of survivors is compromised is unknown. Photograph by Sirenia Project, US Geological Survey.

sirenians), and that pesticide residues in the blubber are both diverse and higher than expected. No other toxicants have been examined, and the effects of contaminants on manatees are unknown.

In Central America, run off of pesticides and herbicides, and the ingestion of plastic debris, have been suspected of causing the death of Antillean manatees. In the Amazon basin, the water pollution associated with mining activities may be harming manatees.

Noise pollution is a problem of which people around the world have become increasingly aware, but about which few data exist. Many scientists suspect that noise pollution negatively affects manatees, but studies examining this relationship are needed. Underwater noise of anthropogenic origin has been demonstrated or suggested to cause some marine mammals to vary their normal patterns of habitat use, and to expend more energy than usual to avoid disturbance, and these behavioral changes could logically be expected in manatees too. In the coastal waters of Florida, where more than 1 million boats are registered and many additional boats are also found, any cumulative effects of anthropogenic noise are a real cause for concern. Even in Costa Rica, where boat traffic is sparse compared to that in Florida, hunters and scientists have noted that manatees react to the noise of approaching boats and that manatee distribution is inversely related to the amount of boat traffic.

Behavioral and anatomical evidence suggests that manatees hear boat motors, but a recent audiogram suggests otherwise. Nevertheless, the suggestion (unwise in our opinion) has been made to put noise makers or acoustic alarms on boats to alert manatees. Not only may such devices be unnecessary if manatees do, indeed, already hear boats, but because their use would greatly increase existing levels of underwater noise, they would most probably disturb or harm not only manatees but many other organisms as well.

Disturbance can occur in ways besides those associated with boat traffic or boat noise as described above. At Crystal River and nearby springs in Florida, tourists gather in large numbers to swim with manatees when the animals aggregate in winter. Although most

people behave responsibly, some stand on, ride, or tie ropes to the manatees. Such behavior by humans could cause manatees to avoid seeking refuge at warm-water springs in winter, which could lead to even higher-than-usual manatee mortality in very cold weather. Disturbance of females accompanied by calves could lead to abandonment of a calf, contributing to escalating levels of “perinatal” mortality.

In Southern Lagoon, Belize, and other locations, ecotourism focusing on manatees has developed. Although the financial benefits to local residents may be significant, such activities should be carefully planned to minimize the negative effects upon the manatees residing in and using the resources of such locations.

As noted above, disturbances from hunting pressure have apparently induced nocturnal or crepuscular behavior in manatees in certain parts of the world.

We have discussed many of the harmful ways that humans have affected manatees—noise, chemical contamination, boat traffic, and ecotourism, e.g.—but in at least one way, we humans may be helping manatees. Most biologists feel that thermal discharges from power plants and other sources have provided winter habitat that has helped the populations of manatees in Florida to survive and even to grow in at least some areas. But these plants have finite lifetimes, and manatee dependence on them creates a long-term dilemma for managers. What will the manatees do if warm water is no longer available at a spot where they have learned to depend on it? Industry (primarily Florida Power & Light Company) and the US Fish and Wildlife Service have initiated discussions to attempt to solve this problem.

Another way in which people have helped manatees is by the introduction of exotic aquatic plants into Florida’s waterways. Such plants as *Eichhornia crassipes* (water hyacinths) and *Hydrilla verticillata* have proliferated to such an extent that they provide important and abundant food resources for manatees in certain regions of the state. In fact, the exotics displace native vegetation and may grow

so luxuriantly that they create navigation problems in some waterways, manatees in Florida have been suggested as possible economical weed-clearing agents, a role that they fill well in some canals in Guyana.

Other human-related habitat modifications have not been helpful to manatees. Dams or other structures prevent manatees from pursuing normal migration routes along rivers in South America and West Africa. And finally, the eradication of millions of hectares of rainforest each year in Amazonia cannot help but negatively affect ALL species occupying that area because of factors such as reduced productivity, siltation, and changes in hydrological cycles.

Manatees are maintained in nearly 20 different facilities worldwide. They breed in several of the facilities. In certain facilities in Florida, injured or diseased manatees are routinely rehabilitated and released back into the wild, thereby assisting wild populations.

Without entering the debate about the appropriateness of captivity, we simply note here that facilities that display manatees to the public provide important venues for educating people about manatees and their conservation, as well as for conducting basic and applied research on the different species.

The various manatee species are protected by laws specific to the countries they occupy, but enforcement of these laws is generally minimal. Several countries (e.g., US, Mexico, Belize, Guatemala, Ivory Coast, Cameroon, and Nigeria) have created manatee reserves and sanctuaries, and others (Brazil and Peru) have “protected” areas that include important manatee habitat.

The following list provides examples of broader-scale protection efforts.

<i>Trichechus inunguis</i> :	CITES: Appendix 1 World Conservation Union (IUCN): listed as vulnerable USA, Endangered Species Act (ESA): listed as endangered
<i>Trichechus manatus</i> :	CITES: Appendix 1 World Conservation Union (IUCN): listed as vulnerable USA, Endangered Species Act (ESA): listed as endangered
<i>Trichechus manatus latirostris</i> :	CITES: Appendix 1 World Conservation Union (IUCN): listed as endangered USA, Endangered Species Act (ESA): listed as endangered
<i>Trichechus manatus manatus</i> :	CITES: Appendix 1 World Conservation Union (IUCN): listed as endangered USA, Endangered Species Act (ESA): listed as endangered
<i>Trichechus senegalensis</i> :	CITES: Appendix 2 World Conservation Union (IUCN): listed as vulnerable USA, Endangered Species Act (ESA): listed as threatened Protected under Class A, African Convention for the Conservation of Nature and Natural Resources

Marine Mammal Evolution

J.G.M. THEWISSEN AND BOBBI JO SCHNEIDER

The front and back inside cover of this volume presents interpretative summaries of the phylogeny of cetaceans, pinnipeds, sirenians, and desmostylians, plotted against the geological timescale. These phylogenies are meant to give the non-specialist an introduction to the confusing array of systematic names of marine mammals by providing a family attribution, an approximate phylogenetic position, and an approximate age range for many genera. They do not represent a conclusive, or even consensus, view of marine mammal evolution.

Most of the topology of these diagrams is based on the entries in this volume (Archaic Archaeocetes, Basilosaurids; Cetacean Evolution; Pinniped Evolution; Sirenian Evolution; Desmostylia; Fossil record), supplemented by data provided by the Paleobiology database (<http://paleodb.org>) and some technical papers (e.g., Geisler *et al.*, 2005; Fitzgerald, 2006; Steeman, 2007). Modern genera are based on the list of Marine Mammal Species provided in this book, which is mostly consistent with Rice (1987). There are clearly differences of opinion between authorities, for instance in the validity of the right whale genus *Eubalaena* or in whether the dolphin genus *Lagenorhynchus* should be divided into multiple genera (LeDuc *et al.*, 1999). Resolution of these inconsistencies can only be reached with further research.

Marine Parks and Zoos

DANIEL K. ODELL AND LORAN WŁODARSKI

I. The History of Zoological Parks

Humans have exhibited animals from the wild in marine life parks, zoos, and aquaria for hundreds if not thousands of years. The earliest zoos were not meant for the average

citizen but for the elite, as wealthy rulers collected unusual animals for their enjoyment. Slowly, these private collections turned public, such as when animals gathered at Schloss Schönbrunn, Vienna, Austria, were first exhibited to the public in 1765. This park is considered the first modern zoo. Solski (2006) gives an historical perspective on public aquariums from 1853–1914. Polar bears (*Ursus maritimus*) and various pinnipeds were probably among the first marine mammals to be held by humans. Polar bears may have been held since about 1060, and harbor porpoises (*Phocoena phocoena*) since perhaps as early as the 1400s, but the majority of marine mammals seen more commonly in marine facilities today (2007) were not displayed until the late 1800s and early 1900s. Many species of cetaceans have never been displayed and some have only been seen recently in marine parks. Killer whales (*Orcinus orca*), for example, were first displayed in a sustainable manner in 1961.

II. Zoos and Marine Parks Worldwide

How many zoos, aquaria, and marine zoological parks exist worldwide? More specifically, how many of these facilities display marine mammals? It is likely that no one has an exact count. New facilities are being built, some facilities close, and some facilities change the animals that they have on display. In 2001, the Conservation Breeding Specialist Group (CBSG) of the World Conservation Union (the IUCN) maintained a global zoo directory on its worldwide web page that listed nearly 1800 institutions but does not give information on marine mammals in the collections (CBSG no longer maintains this directory). A similar list is published in each annual issue of the International Zoo Yearbook (Anonymous, 2006). This list includes postal, phone, fax, and email addresses for the institutions. Kislung (2001) is the most recent review of zoo and aquarium history and includes an admittedly incomplete listing of over 900 zoos and aquaria worldwide. For example, 230 facilities are listed for the United States (The US Department of Agriculture's Animal and Plant Health Inspection Service [APHIS] licenses ~130 facilities to exhibit marine mammals.), 140 for Japan, 56 for India, and 155 for Asia (Table 1). As of July 2007, 216 zoos and aquariums were listed as accredited members of the Association of Zoos & Aquariums (AZA, formerly the American Zoo and Aquarium Association). A full list of these facilities can be found at www.aza.org. A survey by Couquinaud-Douaze (1999) of facilities holding cetaceans lists 166 institutions in 42 countries located on all continents except Antarctica (Table 1). If pinnipeds and polar bears were added, the number of institutions would grow considerably. For example, a 1995 survey (Andrews *et al.*, 1997) of the United States and Canada listed 109 facilities that held 1460 marine mammals, including 11 species of cetaceans, 11 species of pinnipeds, the sea otter (*Enhydra lutris*), and the Florida manatee (*Trichechus manatus latirostris*). Polar bears were not included. In 2007, members of the AZA (2007c) listed more than 700,000 animals at their facilities, of which 1260 were marine mammals. Zoological parks can be found through web sites maintained by regional organizations. The following list is representative and not necessarily all inclusive: Alliance of Marine Mammal Parks and Aquariums (Alliance) www.ammpa.org; American Zoo and Aquarium Association www.aza.org; Australian Regional Association of Zoological Parks and Aquariums www.arazpa.org.au; Canadian Association of Zoos and Aquariums www.caza.ca; European Association of Zoos and Aquaria www.eaza.net; Fish Link Central www.fishlinkcentral.com/links/Public_Aquariums/; Japanese Association of Zoological Gardens and Aquariums www.jazga.or.jp; PanAfrican Association of Zoological Gardens, Aquariums and Botanical Gardens www.paazb.com; South East Asian Zoos

Association www.seaza.org; World Zoo Organization www.waza.org; Zoological Society of London <http://www.zsl.org/research/>; and Zoos Worldwide www.zoos-worldwide.de.

III. Challenges

As zoos and aquaria learned more about the marine mammals in their care, there is no question that the quality of the facilities and animal husbandry improved dramatically, especially over the past several decades and especially in developed countries. Enclosure and pool sizes have increased and have gone from caged to cageless exhibits. Governments have enacted (or are considering) legal standards for the care, maintenance, and display of captive animals (e.g., the United States Animal Welfare Act) and these standards are continually evolving. The Animal Welfare Act (including minimal pool size requirements for marine mammals, animal transportation regulation, and so on) is discussed in detail on the United States Department of Agriculture web site www.aphis.usda.gov/. Marginal facilities, including most traveling or temporary exhibits, have been eliminated. However, on a worldwide basis, there remains room for improvement. These improvements and the expert staff necessary for good animal care have a high financial cost and there is often an unavoidable trade-off with funding for other human activities (e.g., health care in the case of publicly funded institutions). If facilities cannot provide proper care for their animals, they should be closed and the animals relocated to responsible facilities. Unquestionably, it is in the best interests of all zoo and aquarium staff to provide the best possible care for the animals in their charge. Whether institutions are formally “for profit” or “not for profit,” it still takes large amounts of money to build, operate, maintain, and expand exhibits.

Breeding at zoological parks and aquariums is becoming more important for marine mammal facilities. These programs often require additional separate facilities (e.g., maternity pools) and additional animals. Another challenge is the acquisition of high-quality marine mammal food (primarily fish and squid) on a reliable basis. As fish stocks are depleted around the world, marine mammal facility managers must plan accordingly. Some are considering the development of a mass-produced fish replacement for marine mammal food. Such a product could be produced as needed and would not require the storage of a year's supply.

Facilities exhibiting marine mammals argue that introducing people to living dolphins and other marine mammals is a proven way to promote wildlife conservation, instills an awareness of ecological and conservation issues, and inspires a strong, active commitment to marine mammal conservation. However, the ethics of keeping wild animals (or, for that matter, any animal) in marine life parks, zoos and aquaria for any purpose is an issue for some (Mench and Kreger, 1996). Worldwide, one will encounter any number of animal rights groups dedicated to the elimination of facilities holding cetaceans for any purpose. Interestingly, one seems to see little, if any, opposition to holding pinnipeds. Marine parks and zoos are often targeted by protests when new exhibits are proposed or opened or when new animals are acquired. The effectiveness of these protests and similar activities remains unclear. Ultimately, each person will have to reach her/his own conclusions on the ethics of keeping animals in marine life parks, zoos, and aquaria. One can only ask that people seek factual information even if they choose to ignore it, before making their personal decisions. Zoos and aquariums have an obligation to provide the best available information on the animals in their charge.

The ethics of displaying animals at zoos and aquariums is a topic that more parks are directly discussing. Organizations representing

marine life parks, aquariums, and zoos have developed numerous member requirements to assure that the well-being of their animals is the top priority and that they receive state-of-the-art care. For example, members of AZA promote a code of professional ethics that is based on respect and dignity for the care of all animals at these parks (www.aza.org/AboutAZA/CodeEthics/). The Alliance of Marine Mammal Parks and Aquariums (www.ammpa.org) has an accreditation program based on professional standards and guidelines that are updated regularly as the knowledge base expands to integrate advancing science and technologies.

IV. Research

The mission statements of most zoological parks and aquaria include “recreation, education, conservation, and research” in one form or another. For all institutions, the recreation component is the most visible to the public. The extent to which these institutions are involved in research and conservation programs varies and is, to some extent, dependent on financial resources. However, even the smallest of institutions, in size or in financial resources, can participate in local or multi-partnered national or international research and conservation projects.

Research on wild marine mammals, especially cetaceans, is often expensive and subject to the vagaries of environmental conditions (i.e., weather) among other things. Modern technology (radio and satellite tags, time-depth recorders, GPS tags, “critter cams,” hydrophone arrays, etc.) have made huge contributions to our knowledge of free-ranging marine mammals. Nevertheless, it is our opinion that there is still much that cannot be learned from wild animals that can be learned from marine mammals in zoological parks and aquariums. Behavior, including acoustic emissions, can be observed and recorded in 24 h/day if desired. Animals can be trained to hold position for body measurements, collection of body fluids (blood, urine, milk), various medical procedures (i.e., ultrasound examinations), and collection of exhaled breaths for air composition analyses. Animals can be trained for a variety of visual, acoustic (hearing, echolocation), locomotion, and learning studies. The birth, growth, and development (behavioral and physiological) of offspring can be detailed. Therefore, studies on animals in public display facilities are not a replacement for, but a supplement to, studies on free-ranging animals, and the results must be applied with the limits of these “laboratory” studies in mind.

One measure of the involvement of zoos and aquaria in research can be obtained from annual reports of individual institutions and regional organizations. For example, the American Zoo and Aquarium Association's (AZA) annual report on conservation and science for 1996–1997 biennium (Hodskins, 1998) lists over 1100 publications of all types (abstracts, magazine articles, journal articles, etc.) for all animal groups produced by the AZA member institutions during that time period. The Association of Zoos and Aquariums' (2007a) report for CY 2006 lists a total of 866 publications produced by 194 of its 216 member institutions. The Alliance of Marine Mammal Parks and Aquariums publishes a biennial research report that summarizes its members' projects that involve marine mammals (AMMPA, 2005b).

V. Education

Marine parks, zoos, and aquaria offer a wide variety of education programs, in-park graphics, exhibit narrations, behind-the-scenes tours, curriculum-specific programs for various age and grade levels

from preschool through college, camp programs, classroom programs, off-site outreach programs, and, in the electronic age, satellite television and internet (worldwide web) offerings. In fact, US facilities holding marine mammals for public display are required by federal law to have an education program based on professional standards. The US Department of Commerce (1994) published, for reference purposes, the AZA's and Alliance's professionally accepted standards on which their members base their education and conservation programs.

The world we live in might be remarkably different if everyone could travel to the plains of Africa to view cheetahs (*Acinonyx jubatus*) stalking their prey, to view diminutive Humboldt penguins (*Spheniscus humboldti*) basking in the South American shorelines, or perhaps see meandering Florida manatees slowly grazing on vegetation along the coasts of the state of Florida. However, for most people around the planet, such encounters will never occur. In a 1995 Roper poll, 87% of those who participated stated that their only opportunity to see wild animals came from visiting zoological facilities (Roper Starch Worldwide, 1995). Harris Interactive, Inc. [(Rochester, NY) www.harrisinteractive.com] conducted a poll for the Alliance of Marine Mammal Parks and Aquariums (AMMPA) in 2005 (AMMPA, 2005a). Results indicated that 97% of respondents agree that marine life parks, aquariums, and zoos play an important role in educating the public about marine mammals which they might not otherwise have the chance to see.

AZA (2007b) recently completed a 3-year, nationwide study to determine the impact of marine life parks, zoos, and aquaria on the people that visit such facilities. The key results of this study were that visitors felt a stronger connection to the environment after visiting a zoological facility, visitors felt an enhanced public understanding and awareness of conservation issues facing animals in the wild, and overall visitors recognized the value and importance of modern of marine life parks, zoos, and aquaria in the fields of conservation education and animal welfare. Given the fact that most people cannot afford the time and money of a jet-set lifestyle, zoological parks are vital links to connect mankind with the plethora of animals on the planet.

Zoological parks alert people to the increasing threats these animals face. For example, because most people will not travel to view wild cheetahs in Africa, they may not see how these creatures are slaughtered for their hides, how Humboldt penguins are disappearing due to the mining of their guano (feces) deposits where they nest, or how Florida manatees are highly endangered thanks to an ever-increasing presence of humans in their habitat. Zoological facilities may be entertaining, but education, research, and conservation are now cornerstones of major parks. The same Roper poll revealed that 92% of those surveyed agreed that zoological parks are vital educational resources.

Although approximately 71% of the planet is covered by oceans, this realm and its inhabitants remain a mystery to a majority of people. Marine life parks help (1) educate the public about the seas and (2) clear up long-rooted misconceptions about ocean animals. A prime example of this is how killer whales were perceived in the past and how they are viewed today.

Some cultures, like aboriginal tribes of the Pacific Northwest, respected killer whales, although several major whaling countries feared these animals. Indeed, the name *Orcinus* is probably derived from Orcus, an ancient mythological Roman god of the netherworld—a reference to the ferocious reputation of this animal. In 1835, Hamilton wrote that the killer whale "... has the character of being exceedingly voracious and warlike. It devours an immense

number of fishes of all sizes ..., when pressed by hunger, it is said to throw itself on every thing [*sic*] it meets with ..." (Hamilton, 1835). In modern civilization, many still envisioned killer whales as terrifying threats to humans, with a 1973 United States Navy diving manual warning that killer whales "will attack human beings at every opportunity." In the not too distant past, governments such as Japan, Greenland, Canada, and the United States sanctioned the use of lethal force to be used against killer whales. Killer whales were hunted for commercial use and despised by whalers who would "... often carry a rifle expressly for the Killer's benefit," according to Bennett (1932) in his book "Whaling in Antarctica." In 1961, a killer whale was displayed publicly for the first time in recent history, and afterward the perception of these animals began to change. Coupled with a growing environmental awareness in the 1960s, public sentiment rallied to protect cetaceans like killer whales from hunting. Cetaceans are now protected by various national laws and international agreements, and killer whales are generally perceived in a positive way thanks in part to the educational programs of zoological parks.

Conservation programs are linked inextricably with both research and education programs. Zoos, aquaria, and marine parks that hold marine mammals can incorporate conservation messages (i.e., do not feed or swim with wild dolphins or manatees, proper field etiquette, and trash disposal) into static graphics and show and exhibit scripts and narrations, as well as in classroom programs and the electronic media. The American Zoo and Aquarium Association's annual report on conservation and science for the 1996–1997 biennium (Hodskins, 1998) listed over 1200 conservation projects in which the AZA's 185 members were involved during that time. A similar report for CY 2006 lists over 1800 conservation projects reported by 194 member institutions (Association of Zoos and Aquariums, 2007b).

Facility staff experienced in handling marine mammals can provide advice and assistance to field workers, and many of these institutions are actively involved in marine mammal stranding programs. Facilities located near an endangered species' habitat can assist with rescue and rehabilitation of sick or injured animals [e.g., monk seals (*Monachus* spp.) in Hawaii and the Mediterranean/eastern Atlantic, manatees in Florida, sea otters in Alaska and California, and Steller sea lions (*Eumetopias jubatus*) in Canada and Alaska]. No facility is large enough to handle a blue (*Balaenoptera musculus*) or right whale (*Eubalaena* spp.), although SeaWorld California had remarkable success with an orphan gray whale (*Eschrichtius robustus*) calf (Antrim *et al.*, 1998). It may even be possible for facilities to start breeding colonies of severely endangered marine mammals [e.g., the vaquita (*Phocoena sinus*)] if field conservation efforts prove inadequate. In addition, institutions can make direct monetary contributions to conservation programs and encourage their visitors to make their own contributions to *bona fide* programs.

associated flora, fauna, historical, and cultural features, which has been reserved by law or other effective means to protect part or all of the enclosed environment. Marine protected area, or “MPA,” is the common generic term, although in various jurisdictions, MPAs are called marine reserves, marine parks, special areas of conservation (SACs), marine wildlife refuges, or national marine sanctuaries. The term “sanctuary,” however, in reference to marine mammals, usually refers to the protection of a country’s entire EEZ waters in a “national sanctuary” or to an “international sanctuary” on the high seas, e.g., the Indian Ocean Sanctuary. Such national and international sanctuaries typically ban cetacean or marine mammal hunting but rarely have in place detailed conservation measures, or a management plan.

MPAs have been set up to protect vulnerable species and ecosystems, to conserve biodiversity and minimize extinction risk, to re-establish ecosystem integrity, to segregate uses to avoid user conflicts and to enhance the productivity of fish and marine invertebrate populations around a reserve (Pauly *et al.*, 2002; Hooker and Gerber, 2004). MPAs are also useful in terms of providing a public focus for marine conservation (Agardy, 1997). A given MPA may have any one or several of the above goals. A highly protected MPA set aside as a fishery no-take zone, e.g., could be useful for marine mammal conservation by helping predators and prey to recover (Bearzi *et al.*, 2006). Also, setting up an MPA around marine mammals which function as umbrella species can often result in positive effects for many other species (Simberloff, 1998; Hoyt, 2005).

MPAs for marine mammals require targeted management measures to address marine mammal and ecosystem threats either as part of the MPA itself or through existing laws and regulations. Currently, in terms of conservation of most marine mammal populations, MPAs are too small, too few in number, and too weak in terms of protection, and most are “paper reserves”—MPAs in name only (Hoyt, 2005). Yet MPAs hold some promise for marine species and ecosystems when they include substantial highly protected (IUCN Category I) zones, use ecosystem-based management (CBM) principles, and function as part of larger MPA networks.

I. The Recent Growth and Development of Marine Protected Areas

Even though 71% of the surface of the Earth is ocean, the concept of MPAs is relatively recent, lagging far behind land-based protected areas. The Durban Accord and Action Plan from the V World Parks Congress in 2003 stated that approximately 11.5% of the world’s land area has protected status compared to less than 1% of the world ocean and adjacent seas. The first notable MPA of appropriate scale was the Great Barrier Reef Marine Park (GBRMP), established in 1975, although it only achieved a strong level of protection in 2003. Its size, at 340,000 km², makes it one of the largest MPAs in the world managed on a zoned basis. In 2003, nearly a third of it, 111,700 km², became a highly protected, “no take” zone. Although created to protect the world’s largest coral reef, GBRMP also contains cetacean populations including mating and calving humpback whales (*Megaptera novaeangliae*) and various dolphins.

The world’s first MPA set up specifically for marine mammals was Laguna Ojo de Liebre, or Scammon’s Lagoon, established by the Mexican Government in 1971 to protect a prime gray whale (*Eschrichtius robustus*) mating and calving lagoon in Baja California (see Fig. 1). In 1988 the surrounding area of desert and coast was brought together with the San Ignacio and Guerrero Negro lagoons

Marine Protected Areas

ERICH HOYT

A marine protected area is defined by the International Union for the Conservation of Nature (IUCN) as any area of intertidal or subtidal terrain, together with its overlying water and

Figure 1 El Vizcaino Biosphere Reserve. In 1971 Laguna Ojo de Liebre was made a whale refuge by Presidential decree; protection of Laguna San Ignacio and Laguna Guerrero Negro followed in 1979 and 1980; in 1988, the entire lagoon complex was officially designated a MAB biosphere reserve and UNESCO World Heritage site status followed in 1993. Map by Lesley Frampton.

to form El Vizcaino Biosphere Reserve. Among cetaceans, gray whales have easy-to-define habitat requirements because they bring their calves every winter to semi-enclosed salt-water lagoons.

Worldwide, as of 2008, there were more than 4500 MPAs, most of them declared in the past two decades. At least 375 MPAs feature or include marine mammals, while a further 200 have been proposed (Hoyt, 2005). Some notable MPAs are shown in Table I. Only an estimated 0.0001 (one ten-thousandth, or 0.01%) of the world ocean is set aside in highly protected IUCN Category I areas.

New Zealand MPA pioneer Bill Ballantine says that we should aim for at least 10% of the world ocean to be in highly protected MPAs (Ballantine, 1995). In a 1998 statement entitled “Troubled Waters: A Call to Action,” more than 1600 scientists and conservationists declared that we should aim for 20% of the sea as highly protected MPAs by the year 2020 (Roberts and Hawkins, 2000). Other calls, mainly to address the worldwide collapse of commercial fisheries, have suggested between 20% and 50% of the sea to be protected to enable over-exploited fish stocks to recover. The consensus from MPA practitioners around the world at the V World Parks Congress was that at least 20–30% of each marine and coastal habitat should be in highly protected areas.

II. Criteria for Selecting MPAs for Marine Mammals

Protecting mobile, wide-ranging marine mammals such as cetaceans and pinnipeds presents unique challenges using the tool of a fixed-boundary protected area. A number of marine mammal species migrate thousands of kilometers twice a year to feeding or breeding areas. Even the feeding or breeding grounds of a population may be spread over a wide area. Although some populations have site fidelity, there may be considerable movement within individual feeding or breeding grounds. Such dispersion is partly due to the peculiarity

of ocean habitat. Besides static topographic features defined largely by slope and depth (the marine equivalent of mountains and valleys), there are persistent yet ever-moving hydrographic features such as currents and frontal systems and ephemeral habitats created by wind- or current-driven upwellings and eddies (Hyrenbach *et al.*, 2000). The option is to conserve large areas and build in flexible boundaries for intra-seasonal protection to accommodate uncertainty, as well as to build networks of MPAs as described in Section VII.

The starting point for establishing marine protected areas should be long-term research of populations of marine species and ecosystems (Simmonds and Hutchinson, 1996; Twiss and Reeves, 1999). “Snapshot” boat or aerial surveys or single season studies are not enough; a several year research period, with dedicated surveys and quantified effort, is ideal. Spatial habitat preference modeling, combining marine mammal sightings, and behavioral observations with oceanographic/environmental and physiographic data, can then be used to characterize cetacean habitats, e.g., as has been done in the western Mediterranean Sea in studies of various dolphins and fin whales (*Balaenoptera physalus*) (Cañadas *et al.*, 2002; Cañadas *et al.*, 2005; Cañadas and Hammond, 2006). The resulting work has lent a strong scientific basis to the choice of marine habitat suitable for protection: the so-called cetacean critical habitat.

However, the dilemma is that time is short for protection and studies can be costly and time-consuming. Partial knowledge must often dictate action to protect populations or ecosystems, with additional research employed as it comes in to refine boundaries and extent of coverage. In Australian waters, governments have taken the approach of seeking to identify critical habitat for marine species, including whales and dolphins, before awarding formal habitat protection (Prideaux, 2003b). This approach, as long as it does not become an excuse for delay, could significantly increase the potential value of future MPAs with cetaceans.

TABLE I
Notable Marine Protected Areas, National & International Sanctuaries for Marine Mammals^a

Name	Location	Size	Date	Species	Notes
Abrolhos National Marine Park	58 km off southern Bahia State, Brazil	913 km ²	1984	Humpback whale, large coral reef	First national marine park protects coral reef & humpback breeding areas; pioneer seismic protection zones around the park have recently been withdrawn
Auckland Islands Marine Mammal Sanctuary & Marine Reserve	Auckland Islands, New Zealand subantarctic, 460 km south of New Zealand	4,840 km ²	1993; add'l protection: 2003	Southern right whale; New Zealand sea lion; various endemic fauna & flora	Important sea lion colony & right whale breeding area; high level of protection
Bunaken Marine National Park	off Manado in Minahasa Province, on north Sulawesi, Indonesia	790.6 km ²	1991	Sperm, short-finned pilot & other tropical whales & dolphins; large coral reef	At first a paper park but improving with tourism interest; allows fishing & other development
Banks Peninsula Marine Mammal Sanctuary	Banks Peninsula, east coast of South Island, New Zealand	1140 km ²	1988	Hector's dolphin	Commercial gill nets banned but protected area may need to be larger so as not to fragment populations
El Vizcaino Biosphere Reserve	Baja California, México	25,468 km ²	1971	Gray whale	Mating & calving grounds
Galápagos Marine Resources Reserve & Galápagos Whale Sanctuary	Galápagos Islands, 975 km west of Ecuador, in the equatorial Pacific, Ecuador	158,000 km ²	1979; Whale Sanctuary: 1990	Galápagos sea lion, Galápagos fur seal; sperm, short-finned pilot, humpback whale & tropical dolphins; various endemic fauna & flora	High protection for wildlife but concern about tourism impacts
Gerry E. Studds Stellwagen Bank National Marine Sanctuary	Southern Gulf of Maine off Massachusetts, USA	2,181 km ²	1993	Humpback, North Atlantic right, fin, minke, pilot whales	Pop-ups to monitor noise levels (ensonication); no discharge or mining but fishing unrestricted
Great Barrier Reef Marine Park & World Heritage Area	Queensland, Australia	340,000 km ²	1975	Humpback whale, dwarf minke whale, dugong; large coral reef	1/3 highly protected area; intensive management
Hawaiian Islands Humpback Whale National Marine Sanctuary	Hawaiian Islands, USA	3,368 km ²	1997	Humpback whale; tropical dolphins	MPA based around humpback whale; no restrictions on fishing or military activities
Ilhas Desertas Natural Reserve	Desertas Islands, Madeira	96.7 km ²	1990	Mediterranean monk seal (also: bottlenose dolphin)	High level of protection & small seal population has increased
Commander Islands Biosphere Reserve (Zapovednik)	Commander Islands, 50 km east of Kamchatka Peninsula, Russia	36,490 km ²	1993	Sperm & killer whales; fur seal; Steller sea lion; spotted harbor & ringed seals; sea otter	Protected zone extends 50 km around Commander Islands; largest Russian MPA; local fishing, hunting & tourism allowed
Marine Mammal Sanctuary of the Dominican Republic	Northeast of the Dominican Republic including Silver Bank, Navidad Bank & part of Samaná Bay, Dominican Republic	2,500 km ²	1986, 1996	Humpback whale; Bryde's, pilot & sperm whales; bottlenose & pantropical spotted dolphins; manatee	Law of the Environment & Natural Resources (2000) strengthens environmental standards & protects coral reefs with breeding areas for humpbacks. From Feb–Apr, Silver Bank has densest concentration of humpbacks in North Atlantic (up to 3,000 present); humpbacks from 5 feeding stocks in the w. North Atlantic aggregate on the bank.

(continues)

TABLE 1 (continued)

Name	Location	Size	Date	Species	Notes
Monterey Bay National Marine Sanctuary	North central California coast, USA, adjoining Gulf of the Farallones NMS	13,802 km ²	1992	Gray, fin, blue, minke, humpback whales; various dolphins; sea otter; Steller & California sea lions	Largest US NMS (part of growing California state & national MPA network) prohibits oil & gas exploration & waste dumping but no fisheries restrictions
Northeast Greenland National Park	Northeast Greenland	Land: 846,100 km ² ; water: 110,600 km ²	1974, expanded 1988	Beluga, narwhal, minke whale, white-beaked dolphin, walrus, polar bear	Commercial hunting & mineral development banned but concern remains about high levels of subsistence hunting
Papahānaumokuākea Marine National Monument	Northwest Hawaiian Islands, USA	340,000 km ²	2006	Humpback whales; tropical dolphins	World's largest highly protected MPA; to allow no commercial fishing & limited tourism
PELAGOS Sanctuary for Mediterranean Marine Mammals	Ligurian Corsican & northern Tyrrhenian seas, western Mediterranean Sea, Italy, Monaco, France & High Seas	87,492 km ²	1999; SPAMI, 2001	Fin, sperm, minke, Cuvier's beaked whale; bottlenose, striped, common & Risso's dolphin	More than 50% on the high seas of the Mediterranean; first high seas as well as tri-national MPA
Saguenay-St. Lawrence Marine Park	St. Lawrence River, Québec, Canada	1,138 km ²	1998	Beluga, fin, humpback & minke whales; Atlantic white-sided dolphin & harbor porpoise	Multiple-use zoning with heavy traffic; protects most southerly population of belugas from tour boats
Seal Bay Conservation Park	Kangaroo Island, South Australia, Australia	49.5 km ²	1971	Australian sea lion (also: New Zealand fur seal)	Intensively managed to protect population & for tourism
Shark Bay Marine Park & World Heritage Area	Shark Bay, Western Australia	23,000 km ²	1990	Indo-Pacific bottlenose dolphin, humpback whale, dugong, green & loggerhead turtles	High visitor level especially to Monkey Mia; tourism controlled
National EEZ Sanctuaries for Marine Mammals	21 countries & territories (10 in the South Pacific)	120,000 km ² to 16 million km ²	Various	Mainly all cetaceans; some include all marine mammals plus turtles	No hunting. These are not MPAs, but with management plans & enhanced protected zones could help conservation.
International Whale Sanctuaries	Indian Ocean Sanctuary, Southern Ocean Sanctuary, Eastern Tropical Seascape	IOS: 103.6 million km ² ; SOS: 50 million km ² ; ETS: 2.1 million km ²	Various	Mainly baleen whales & sperm whale	No commercial hunting

^aFor a complete directory of more than 600 proposed & existing MPAs & sanctuaries for cetaceans, see www.cetaceanhabitat.org

Defining critical habitat is the crux of the matter. Governments and other agencies have adopted various definitions for critical habitat, but, it is essentially the places, or conditions, where marine mammals feed, socialize, rest, breed, and raise their young as well as where their prey lives. Some times part of migration routes are included, too. The challenge is determining the level of protection needed as well as when areas are essential for day-to-day survival, as well as for maintaining a healthy population growth rate.

The actual selection process for MPAs starts with defining the goals of any proposed MPA in view of marine mammals found and threats to their existence paired with the need to devise the rationale for the proposal (Hoyt, 2005; Notarbartolo di Sciara, 2007). Threats include fishing conflicts (overfishing, bycatch, entanglements), ship

collisions, pollution, habitat degradation, and the chronic, high noise levels (ensonification) from shipping traffic as well as acute loud sounds from seismic activities, and low- and mid-frequency Navy sonar. To date, few management plans for MPAs have addressed fishing conflicts, pollution, or habitat degradation, and noise in a comprehensive way.

Then the question must be asked: Is an MPA the most effective tool—the answer or part of the answer—in terms of addressing threats to marine mammals and ensuring that a favorable conservation status is maintained? At the same time, stakeholders must be brought on board from the start so that the MPA selection process ideally grows out of a community, taking into account socio-economic and other concerns. The most effective MPAs proceed from the bottom up;

top-down approaches usually only work if they institute bottom-up procedures early in the process. Even then, it is sometimes impossible to orchestrate public participation and such MPA proposals may ultimately fail.

The next steps are to compile bibliographic information, collect updated scientific data on the animals, human activities, and the threats; and to recommend highly protected zones or core areas as within the MPA. A comprehensive proposal with maps and information on every aspect should then be presented to stakeholders as well as authorities involved in the legal process. This is rarely a one-time process but usually involves a lengthy consultation phase during which stakeholders examine the proposal and help to shape it until conflicts are resolved and acceptable proposals can be formulated.

III. Designing MPAs for Marine Mammals

MPAs either tend to be managed for multiple- or zoned use. Management for multiple-use is found to a great extent in the flagship US national marine sanctuaries, as well as in the special areas of conservation created under the European Union (EU) Habitats and Species Directive. Multiple-use allows or in some cases tries to regulate a wide variety of uses, from shipping and tour boat traffic to sports and commercial fishing, at “acceptable” levels of use throughout the marine protected area. Of course, some uses may be entirely excluded if deemed too harmful—e.g., oil and gas exploration, waste dumping, and certain kinds of fishing.

In contrast, zoned use, or zoning, attempts to create zones in locations and at sizes appropriate for one or more compatible uses, excluding other uses, but attempting to accommodate all or most uses within a number of zones located within a single MPA. Of course, not every MPA can accommodate every use; many are too small and are most suited to a high level of protection throughout the MPA.

Multiple-use management has had a long history on land, with mixed, often poor results, but land-based protected areas have now employed zoned use successfully for several decades and this is the widely accepted model for many national parks and protected areas. The biosphere reserve concept uses zoning for land-based protected areas and this has also been adapted for MPAs (Batisse, 1990). Biosphere reserves feature a zoned architecture with substantial key core areas reserved for strict protection, surrounding zones for research, tourism, education, and other “light use,” and still other zones open for sustainable use of marine resources and as transition areas to the wider community (see Fig. 2).

Highly protected core areas are easy to define for marine mammals spending time on rookeries and haul-outs, and with confined home ranges such as for bottlenose dolphins (*Tursiops* spp.) or humpback and gray whales on winter breeding grounds. But what about marine mammals with less well-defined breeding habitat or on feeding grounds subject more to changing oceanographic conditions? One solution could be to employ adaptable time and area closures such as are used for salmon or other fisheries in various parts of the world. It would be possible to use the biosphere reserve concept to create large overall MPAs with a number of moveable, highly protected “core areas” corresponding to marine mammal critical habitat with boundaries that can be adjusted as needed. Such adjustments would be constantly reviewed and sensitive to seasonal and annual signals from the wider environment. To achieve this fine-grained kind of critical habitat management, however, it is necessary to try to understand ecosystem processes and the impacts that humans have on such processes. An appropriate tool for this is EBM.

IV. Ecosystem-Based Management

EBM, or ecosystem management, is the management of the uses of ecosystems. An ecosystem *per se* needs no management. It is the escalating human interactions with ecosystems and the damaging human impacts on ecosystems and species that need to be managed. Still, it has become clear that human uses must be accommodated within ecosystem capacities. EBM is a regime that recognizes that ecosystems are dynamic and inherently uncertain yet seeks to manage the human interactions within ecosystems to protect and maintain ecological integrity and to minimize adverse impacts. EBM is widely talked about and is being attempted by some managers but it remains at an embryonic stage, though Australia, e.g., is building its regional marine planning on EBM (Smyth *et al.*, 2003).

To embark on EBM, fundamental shifts in management thinking and research must take place (Hoyt, 2005):

- Management must move from a *reactive* to a *proactive* style. This requires ongoing scientific analysis and the ability to adapt management practice quickly when new information signals the need for a change.
- Research has to re-orient itself to view the ecosystem as a whole, using multiple components such as stability of reef or sea floor, predator presence and water quality as indicators of management success.
- Risk assessments of management choices must be reviewed regularly and adapted to new information.
- Multiple sectoral uses (e.g., commercial and sports fishing) as well as the resulting impacts (e.g., cetacean bycatch), must be viewed as cumulative rather than isolated.
- Managers, policy makers and the public must be alert to the misuse of the term “EBM,” particularly by those seeking to justify the culling of predators.
- The ultimate aim is to maintain the ecosystem as it naturally occurs—not to adapt it to human needs but to enable it to accommodate an acceptable level of human use.

Thus, it is important to understand more about the whole ecosystem, rather than focusing on one or other isolated area or species. Without doubt, these are major tasks to undertake in any large marine area, but they are necessary steps to manage human involvement with marine ecosystems.

EBM as a management regime grew out of the widely acknowledged failure of single species management, primarily of fisheries. EBM requires an ongoing research commitment to unravel and model the complex linkages in marine ecosystems. But where knowledge is lacking, it is accepted that a precautionary approach should be invoked to protect ecosystems (Hoyt, 2005). Part of this precautionary approach is creating MPAs as safeguards built into the system from an early stage to secure ecosystem integrity in the absence of scientific certainty.

V. The Legal Process for Setting up MPAs

To achieve legal status, MPA proposals situated within a country's waters must seek state/provincial/local and/or national approval in law. Such legal status along with appropriate enforcement provisions can be difficult and time-consuming to establish; some governments have only recently approved MPA legislation and others have weak or even no legislation available (Scovazzi, 1999; Hoyt, 2005).

In most parts of the world, regional treaties and international organizations are available to assist with the MPA designation process. These bodies include the IUCN World Commission for

Figure 2 The Architecture of a Biosphere Reserve. This map shows the various zones of a hypothetical marine- and land-based biosphere reserve area. Core areas (IUCN Category I) are devoted to strict nature reserve protection; these are surrounded by buffer zones (Category II–V) where activities compatible with the conservation objectives occur, and the buffer zones are in turn surrounded by a more or less defined transition zone (Category VI) which integrates the local people and sustainable resource management into the fabric of the overall reserve. To be effective, the biosphere reserve model must include zoned highly protected areas that are declared and enforced through legislation with management plans formulated by the community, including all stakeholders. Map by Lesley Frampton.

Protected Areas (WCPA, Marine) with its many regional offices, as well as regional agreements such as ACCOBAMS (the Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea and contiguous Atlantic Area), the SPAW Protocol in the Caribbean, and the SPREP Convention in the South Pacific.

In addition, international recognition and further protection of an MPA can be valuable. The International Maritime Organization

(IMO), e.g., has granted the status of “particularly sensitive sea area” (PSSA) to parts of the GBRMP; such a PSSA requires a compulsory pilotage system through the most sensitive parts of the park. MPAs can also be awarded further protection through World Heritage Site or MAB Biosphere Reserve status (UNESCO), or at the regional level, e.g., designation as a Special Protected Area of Mediterranean Interest (SPAMI). These and other designations are helpful in terms

TABLE II
Developing Networks of MPAs for Marine Mammals

Name	Location	Action	Species
1. Wadden Sea Conservation Area	SE North Sea off Germany, Denmark, Netherlands	Series of national parks & nature reserves	harbor seal; also harbor porpoise present
2. Sister sanctuaries of Gerry E. Studds Stellwagen Bank National Marine Sanctuary & Marine Mammal Sanctuary of the Dominican Republic	Southern Gulf of Maine off Massachusetts & Caribbean Sea off NE Dominican Republic	Bilateral "sister sanctuary" relationship formally established 2007 with education, research & other planned links	humpback whale on feeding & breeding grounds
3. Natura 2000 network	European Union (EU) waters	Special areas of conservation (SACs) declared for <i>Tursiops</i> & <i>Phocoena</i> but no protection yet for all other cetaceans	bottlenose dolphin, harbor porpoise
4. MPAs proposed for the ACCOBAMS MPA Work Program (the Agreement on the Conservation of Cetaceans of the Black Sea, Mediterranean Sea & contiguous Atlantic Area)	Mediterranean & Black seas	18 MPAs proposed 2007 by the Scientific Committee to the Parties to protect cetaceans throughout the ACCOBAMS region; countries have agreed in principle to begin work to establish the MPAs	bottlenose, common, Risso's & striped dolphins; harbor porpoises; fin, sperm, Cuvier's beaked, killer whales
5. 21 manatee sanctuaries	Gulf of Mexico, west coast of Florida	Several protected areas for the critical habitat of manatees	West Indian manatee
6. Various protected areas & recovery plans	Western North Atlantic including Bay of Fundy & Gulf of Maine & approaches	Several marine sanctuaries, conservation zones, species recovery plans & IMO & pilot controls on shipping off NE US & Canada but remains to be seen if this will reduce mortalities from ship strikes.	North Atlantic right whale
7. 9 national (EEZ) marine mammal sanctuaries established among SPREP (South Pacific Region Environment Program) Convention members	South Pacific Ocean: American Samoa, Cook Islands, Fiji, French Polynesia, New Caledonia, Niue, Papua New Guinea, Samoa, Vanuatu	National sanctuaries set up to protect marine mammals & ban whaling in national waters; countries through SPREP plan to devise management &/or zoned conservation plans	Humpback whale, tropical dolphin species including blackfish species; dugongs; turtles in some countries

of expanding the remit of an MPA into an important component of an international network.

Whatever designations are obtained, it is useful to consider achieving protection status not as a final goal but as a *first* stage or step toward conservation (Hoyt, 2005).

In some countries, MPAs are situated and must also be considered in the broader context of a general management plan for coastal and marine resources, that is, an umbrella program for conservation of renewable resources as well as implementation of EBM principles (Salm and Clark, 2000; Augustowski and Palazzo, 2003).

VI. Management Plans, Monitoring, and Evaluation

The management plan is at the heart of the success or failure of an MPA. It is the working plan for what the MPA hopes to do and accomplish along with the time frame for its activities and the schedule for its review.

Many MPAs exist only or mainly on paper. It is fair to say, however, that all MPAs begin as a piece of paper, and it is up to government and stakeholders to devise, put in practice, and enforce their

management plan (Hoyt, 2005). Creating effective protected areas, whether marine- or land-based, is an iterative, participatory process, and is bound to fail if the management plan is seen as set in stone or as a fixed law imposed from the outside. As with MPA design, management must be both top-down and bottom-up. The following are the key steps leading to effective management (Hoyt, 2005; Notarbartolo di Sciara, 2007):

- (1) engaging stakeholder involvement from the beginning and throughout the process;
- (2) formulating clear management objectives for the proposed MPA;
- (3) creating a management body;
- (4) developing a management plan, subject to periodic re-examination and revision;
- (5) offering management training;
- (6) conducting research for baseline numbers, inventory, status and monitoring purposes;
- (7) promoting and offering educational programs for the local community and visitors;
- (8) developing effective enforcement regimes; and
- (9) conducting periodic management review and other evaluations to assess whether objectives are being met.

The last provision is essential to the long-term success of the MPA. Without such evaluations, even MPAs that start out with considerable success may decline in value and fail. An MPA must have clearly defined objectives against which its performance is regularly checked, and a monitoring program to assess management effectiveness and recommend changes (Kelleher, 1999). A number of methods are available for conducting a review (Pomeroy *et al.*, 2004).

Management of an MPA for cetaceans and pinnipeds is similar to managing any other type of MPA (Notarbartolo di Sciara, 2007) but there are several differences that must be kept in mind. MPAs for marine mammals require large sizes to accommodate these highly mobile animals, with all the attendant complications and added problems from size alone. The movement of populations across many national borders and even to opposite ends of an ocean dictate the necessity of creating MPA networks to ensure comprehensive protection. Finally, the use of high seas habitat by many populations of cetaceans and pinnipeds, means that effective legal measures—as well as practical mechanisms for implementation and enforcement—will need to be devised for the high seas (see Section VIII).

VII. Networks of MPAs

An MPA network can be defined as “an organized collection of individual MPAs operating co-operatively and synergistically, at various spatial scales and with a range of protection levels, to fulfill ecological aims more effectively and comprehensively than individual sites could alone.” (WCPA/IUCN, 2006). The idea of creating networks of MPAs is particularly suited to marine mammals. In addition to their long migrations, marine mammals may depend on food webs whose critical habitats are widely separated. Thus, networks are essential to create an effective conservation plan for these wide-ranging species, as well as for the marine ecosystems that help to support them.

A number of MPA networks are beginning to be assembled to confer population-level protection to marine mammals (Reeves, 2000; Hoyt, 2005) (see Table II.) Establishing a network is mainly a “top-down” exercise with governments or regional associations acting as the main initiators and mechanisms. In Table II, individual governments with large territories or undertaking bilateral agreements (United States, Canada, Dominican Republic) have been responsible for nos. 2, 5, and 6. Regional associations, including political and economic unions such as the EU, and conservation agreements and treaties such as ACCOBAMS which draw on the Barcelona Convention are responsible for 1, 3, and 6.

VIII. High Seas MPAs

Many marine mammal species, including sperm (*Physeter macrocephalus*), beaked, and other toothed whales, large baleen whales and a number of pinnipeds spend part or even most of their life cycles in pelagic waters off the continental shelves and far from the coasts. Large portions of their critical habitats may be in the 50% of the world ocean classed as international waters, or high seas, i.e., outside the 200nm limits declared by most countries under the United Nations Convention on the Law of the Sea (UNCLOS) (Hoyt, 2005). In such areas—where no single state or authority has the power to designate MPAs, adopt management schemes, or enforce compliance—new strategies must be devised to protect and manage high seas habitats (Thiel and Koslow, 2001).

Various international agreements have the potential to be used to create high seas MPAs. For example, UNCLOS says that States

are in a position to take strong conservation measures on the high seas, as long as they cooperate with other States, show that the measures they want to take would enhance the conservation of resources, and that they are based on the best scientific evidence available (de Fontaubert, 2001). Article 194 of UNCLOS establishes a mandate for high seas MPAs by stipulating measures to protect rare and fragile ecosystems as well as the habitat of depleted, threatened, or endangered species and other forms of marine life while Article 197 asks for cooperation on a global basis (Prideaux, 2003a).

Another key treaty, the Convention on Biological Diversity (CBD), has with the work of its scientific advisors, the Subsidiary Body on Scientific, Technical, and Technological Advice (SBSTTA), planned a program of work that includes the creation of high seas MPAs. UNCED: Agenda 21, although it is a “soft-law” instrument, also recognizes the possibility of enacting MPAs on the high seas.

The Convention on the Conservation of Migratory Species of Wild Animals (CMS) may also become an important instrument for high seas critical habitat protection. The harmonization of work plans between CBD and CMS integrates CMS and migratory species into the work program and implementation of CBD with regard to protected areas, as well as the ecosystem approach, and the drive to develop indicators, assessments, and monitoring. In addition, CMS focuses on the establishment of regional agreements (such as ACCOBAMS), which increases its adaptability to regional circumstances. If high seas and multi-jurisdictional cetacean critical habitats are to be protected, CMS and CMS regional agreements may be the most appropriate framework to develop this regime (Prideaux, 2003b).

Besides all of the above approaches (UNCLOS, CBD, CMS, and UNCED: Agenda 21), the IWC whale sanctuaries provide a useful precedent of nations working together to agree on conservation on the high seas. Future IWC agreements could embrace, or even create themselves, highly protected high seas MPAs, though current divisions in the IWC make this unlikely in the near future. In any case, it is important to recognize that those states that are not party to the various conventions and treaties are not bound by them. Yet most states now recognize or are party to at least two of the important conventions for future high seas MPA development: UNCLOS and CBD. Still, it is a huge challenge for the world's nations to come together with the necessary foresight and imagination to create a comprehensive network of MPAs on the new frontier of the high seas.

In 1999, an agreement to create the world's first high seas MPA was signed by France, Monaco, and Italy. The PELAGOS Sanctuary for Mediterranean Marine Mammals, located partly in the national waters of these three countries and partly on the high seas, contains resident populations of sperm, fin, and Cuvier's beaked whales (*Ziphius cavirostris*), as well as striped (*Lagenorhynchus coeruleoalba*), common bottlenose (*Tursiops truncatus*), Risso's (*Grampus griseus*) and short-beaked common dolphins (*Delphinus delphis*.) (see Fig. 3). In 2001, a high seas agreement was forged under the Barcelona Convention, making PELAGOS a SPAMI which confers the official protection of all signatory Mediterranean countries in both national waters and on the high seas (Notarbartolo di Sciara *et al.*, 2008). It could take several years for PELAGOS to come up to speed and to function as a valuable conservation tool. The marine mammals of the Mediterranean are important of course, but no less important is the precedence of both transborder and high seas cooperation by this designation and the implications for other potential areas and cooperation by States. For these reasons, it is hoped that the management plan put in place will employ EBM principles and be effective in terms of identifying and protecting marine mammal critical

Figure 3 Map of the PELAGOS Sanctuary for Mediterranean Marine Mammals. The PELAGOS Sanctuary for Mediterranean Marine Mammals is the world's first high seas MPA. It was designated in 1999 as a transborder MPA in the national waters of France, Italy, and Monaco. In 2001, it was declared a Special Protected Area of Mediterranean Interest (SPAMI) under the Barcelona Convention which gives it protection on the high seas of the Mediterranean. Map by Lesley Frampton.

habitat core areas as well as responsive to new data and management strategies as they arise in future.

Mark–Recapture

PHILIP S. HAMMOND

I. Introduction

The capture, marking, release, and recapture of individual animals can be used to study movement patterns, the size and structure of populations, survival and recruitment rates (Hammond *et al.*, 1990). It is thus an important method for marine mammal researchers interested in ecology, life history, conservation, and management.

Mark–recapture analysis is widely used in ecology to estimate abundance and survival rates. The basic data required are a set of capture histories of individually identified animals. A capture history is simply a string of 1s and 0s representing whether an animal was (1) or was not (0) captured in a series of sampling occasions. A sampling occasion is a finite period of time during which data are collected, e.g., a survey day, but in studies of marine mammals sampling occasions are often taken to be longer, e.g., a season.

Mark–recapture analyses make a number of assumptions, the violation of which may lead to biased estimates of survival and, especially, abundance. Although it is straightforward to apply mark–recapture analysis to capture history data, great care must be taken to consider the effects of failing to meet these assumptions. This is especially true for studies that were not originally designed for such analyses. Although analytical models exist that allow some assumptions to be relaxed, there is no substitute for a well-designed field study.

II. Capturing and Identifying Individuals

Mark–recapture methods were initially developed, and have mostly been used, for studies in which individual animals are physically captured in traps of some kind, marked either by the application of a tag or by mutilation, released, and then recaptured or resighted without capture. Pinnipeds can be captured on land during pupping and molting periods and at other times when they are hauled out on land or ice. They can also be captured in nets but are vulnerable to drowning. Typical ways to mark pinnipeds have been the application of flipper tags, and branding methods that are commonly used on terrestrial mammals, and, for short-term studies, gluing plastic numbered “hat-tags” on the heads of animals (Hall *et al.*, 2001).

Cetaceans are difficult to capture and may be vulnerable to being handled, and it has been necessary to develop additional ways of capturing and marking individuals. When whaling was still commonplace, large whales were marked by firing Discovery tags (metal bolts about 30-cm long) into the blubber and recaptured by recovering the tag when the animal was butchered in whaling operations. Some

more recent studies have physically captured and branded or tagged small cetaceans, but the associated logistical and welfare issues mean that this is not usually a viable method.

A. Photo-Identification

The most commonly used technique for capturing and marking cetaceans is to take photographs of the natural markings of individual animals (Hammond *et al.*, 1990). Clearly, this is only appropriate if individuals of a species/population are sufficiently well marked. The use of photo-identification has the great advantage of avoiding physical capture, handling, or application of a mark. However, “photo-id” can also make it more challenging to meet the assumptions of analytical methods (see Assumptions). For example, the future recognition of a naturally marked individual may depend on the amount of information in the mark, how long the mark lasts, and the quality of the photograph.

Good photographs are essential for photo-identification; good enough that animals that are considered marked will be recognized with certainty if seen again later. Not all photographs will be of sufficient quality and in most studies photographs are graded according to quality, and only the best are used in analysis.

The list of cetacean species marked through photo-identification is long. It includes humpback (*Megaptera novaeangliae*), right (*Eubalaena* spp.), fin (*Balaenoptera physalus*), blue (*B. musculus*), sperm (*Physeter macrocephalus*), northern bottlenose (*Hyperoodon ampullatus*), killer (*Orcinus orca*) and pilot whales (*Globicephala* spp.), and several species of dolphins, particularly bottlenose dolphins (*Tursiops* spp.). Much of what we know about the biology of these species has come through photo-identification studies. This technique is also used for seals (Hiby and Lovell, 1990; Forcada and Aguilar, 2000; Forcada and Robinson, 2006; Gerondeau *et al.*, 2007).

B. Genetic Tagging

Individuals can be uniquely identified by genotyping tissue obtained via a biopsy sample. Such genetic tags have been used in a large-scale mark–recapture analysis of North Atlantic humpback whales (Palsbøll *et al.*, 1997; Smith *et al.*, 1999).

C. Other Marking Methods

Telemetry devices (radio tags) can also be used to mark individuals and provide mark–recapture data (Ries *et al.*, 1998). A recent development involves using mobile telephone technology to send SMS text messages from a tag attached to a seal, which are received when the animal is within range of the coast (McConnell *et al.*, 2004).

III. Movement Patterns

The simplest information to come from mark–recapture is that an animal marked at a particular place and recaptured in another has clearly moved from one place to the other during the intervening time. This basic information can be used to explore animal movement patterns at a range of spatial and temporal scales from small-scale habitat use to long-distance seasonal migrations (Wilson *et al.*, 1997; Whitehead, 2001; Calambokidis *et al.*, 2001; Stevick *et al.*, 2003a).

IV. Mark–Recapture Analysis to Estimate Survival Rates and Abundance

Mark–recapture analysis is widely used in ecological studies to estimate survival rates, and arguably it is for this purpose that it is best suited. However, in marine mammal science, although it has been used to estimate survival rates in a variety of species, it is most often considered as a tool for estimating population size (abundance). Time series of data that are sufficiently long to estimate survival rates are relatively rare for marine mammals, but there are many shorter datasets, particularly from relatively small and local photo-identification studies of cetaceans, which are, at least in principle, amenable for estimating abundance.

A. Survival Rates

To estimate survival rates, cohorts of marked animals are sampled over a period of time, several years if the aim is to estimate annual survival rates. An animal that is not recaptured on a particular sampling occasion may either have died or still be alive but simply not recaptured. The basic task in analysis is to simultaneously estimate two quantities: the probability that an animal survived from one sampling occasion to the next; and the probability of recapturing an animal given that it was alive. Resulting estimates of survival probabilities (rates) are representative of the marked animals in the cohorts. The researcher must then infer population survival rates by assuming that the marked animals are representative of the wider population.

The conventional analytical approach for estimating survival rates is to use the Cormack–Jolly–Seber model. This allows not only time-dependent survival rates to be estimated but can also be collapsed to estimate the average survival rate over a period of time. This model and an expanding range of other more complex models can be implemented in the software MARK <http://www.phidot.org/software/mark/>, which is accompanied by an excellent guide (Cooch and White, 2007) containing statistical details and references. The other models include the “robust design” for estimating survival rate between primary sampling occasions (e.g., years) and estimating abundance within primary occasions from secondary sampling occasions (e.g., months). This model also allows parameters related to temporary emigration from the study area to be estimated (Bradford *et al.*, 2006). Also useful are models that utilize recaptures additional to those obtained from the designed sampling occasions, such as opportunistic live and dead recoveries, as used by Hall *et al.* (2001) to estimate gray seal (*Halichoerus grypus*) first-year survival rates. If covariate data are available for individuals, e.g., sex, size, age, body condition, analysis can investigate their effects on survival rates.

Survival rates have been estimated using mark–recapture methods for a variety of marine mammal species including humpback, blue, bowhead (*Balaena mysticetus*), right and gray (*Eschrichtius robustus*) whales, elephant (*Mirounga* spp.), monk (*Monachus* spp.), grey and Weddell (*Leptonychotes weddellii*) seals, subantarctic and New Zealand fur seals (*Arctocephalus* spp.), and manatees (*Trichechus manatus*) (Caswell *et al.*, 1999; Pistorius *et al.*, 1999; Schwarz and Stobo, 2000; Hall *et al.*, 2001; Zeh *et al.*, 2002; Bradshaw *et al.*, 2003; Larsen and Hammond, 2004; Langtimm *et al.*, 2004; Mizroch *et al.*, 2004; Cameron and Siniff, 2004; Beauplet *et al.*, 2005; Bradford *et al.*, 2006; Ramp *et al.*, 2006; Baker and Thompson, 2007).

B. Abundance

Mark–recapture methods estimate the number of animals in a population of individuals that mix together (Hammond, 1986). Obtaining a representative sample of data therefore means sampling individuals representatively (see Assumptions). The estimate is of the population of animals that uses the study area. Note the difference between this and the situation for line-transect sampling, which estimates the density of animals in a defined area at the time of the survey and for which a representative sample of the survey area is required.

The basis of estimating abundance using mark–recapture is as follows. A sample of individuals is captured, marked and released (n_1) and on a subsequent occasion, a second sample of individuals is captured (n_2) of which a number (m_2) are already marked. If a number of assumptions are met (see Assumptions), the proportion of marked individuals in the second sample should equal the proportion of marked animals in the population at large (N)

$$\frac{m_2}{n_2} = \frac{n_1}{N}$$

which allows population size to be estimated as:

$$\hat{N} = \frac{n_1 n_2}{m_2}$$

This simple two-sample estimator is known as the Petersen estimator. As well as other basic assumptions, it assumes that the population being estimated is closed to births, deaths, immigration, and emigration. To reduce small sample bias and allow a finite estimate of variance to be estimated, a more commonly used estimator is Chapman's modification of the Petersen estimator,

$$\hat{N} = \frac{(n_1 + 1)(n_2 + 1)}{(m_2 + 1)} - 1$$

with estimated variance

$$\text{var}(\hat{N}) = \frac{(n_1 + 1)(n_2 + 1)(n_1 - m_2)(n_2 - m_2)}{(m_2 + 1)^2(m_2 + 2)}$$

Note that estimates of variance are correlated to the estimates themselves, an undesirable feature of mark–recapture abundance estimates.

In essence, the data on animals that have been captured at least once are used to estimate the number of animals that have never been captured. This inference is what makes mark–recapture abundance estimates so sensitive to the analytical assumptions (see Assumptions). The same idea applies when there are multiple sampling occasions; in this situation each sample (except the first) provides information on recaptures as well as on animals caught for the first time. An important consideration when estimating abundance from multiple samples is whether or not the population being estimated can be considered closed or not. If the sampling occasions are sufficiently close in time that any change in population size is likely to be small, multi-sample closed population models can be used. A variety of models are available in program MARK, including those implemented by the well-known program CAPTURE that allow capture probabilities to vary by time and due to trap dependence and individual heterogeneity (see Assumptions).

If the population is not closed, the most obvious option is to use an open population model to estimate abundance. Program MARK provides a number of options based around the Jolly–Seber model. These models are very flexible and also provide estimates of survival, recruitment, and population growth rates as well as abundance. However, they are not able to take into account individual heterogeneity of capture probabilities, which can be a substantial source of bias (see Assumptions). Another option is to use a series of two-sample estimates (Stevick *et al.*, 2003b).

Not all animals in the population may bear distinguishing markings. For example, bottlenose dolphins acquire nicks as they get older, so younger animals are typically not well marked and will be excluded from a population estimate of well-marked individuals. Data on the proportion of well-marked animals in each school encountered can be used to estimate the proportion of markable animals in the population (Williams *et al.*, 1993; Wilson *et al.*, 1999).

Abundance has been estimated using mark–recapture methods for a number of marine mammal species/populations including humpback, blue, sperm, and northern bottlenose whales; bottlenose, humpback (*Sousa* spp.), and Hector's dolphins; Weddell, leopard (*Hydrurga leptonyx*), elephant, monk (*Monachus* spp.), and gray seals; and Australian and New Zealand fur seals (*Arctocephalus forsteri*) (Williams *et al.*, 1993; Whitehead *et al.*, 1997a,b; Cerchio, 1998; Smith *et al.*, 1999; Wilson *et al.*, 1999; Forcada and Aguilar, 2000; Shaughnessy *et al.*, 2000; Bejder and Dawson, 2001; Read *et al.*, 2003; Stevick *et al.*, 2003b; Calambokidis and Barlow, 2004; Cameron and Siniff, 2004; Larsen and Hammond, 2004; Garcia-Aguilar and Morales-Bojorquez, 2005; Forcada and Robinson, 2006; Boren *et al.*, 2006; Stensland *et al.*, 2006; Gerondeau *et al.*, 2007).

C. Assumptions

Analyses to estimate survival rates and abundance make assumptions about the data that, if violated, may lead to bias in estimated population parameters.

There are three fundamental assumptions about the marked individuals:

1. Marks are unique (i.e., there are no twins, triplets, etc.);
2. Marks cannot be lost (to ensure that a marked animal will be recognized on recapture);
3. All marks are correctly recorded and reported.

The uniqueness of a mark can be assured with the application of a numbered tag/brand or the use of genotyping, but it must be inferred for natural markings from the amount of information represented by the marks. For example, the color pattern on the ventral surface and the indentations along the trailing edge of tail flukes of humpback whales, in the Northern Hemisphere at least, are generally believed to contain enough information for the markings to be unique. Similarly, it is usually assumed that the pattern of nicks and notches on the trailing edge of the dorsal fin allows bottlenose dolphins to be uniquely identified. However, not all animals possess such markings so it is important to define what is meant by the markable population.

The issue of mark loss is an important one. Flipper tags may fall off, brands may fade, and natural markings may change. Whether or not mark loss could occur should be determined in any mark–recapture study. If it is, the rate of mark loss should be estimated, e.g., by double tagging (Stobo and Horne, 1994; Bradshaw *et al.*, 2000; Pistorius *et al.*, 2000)

The correct recording and reporting of marks from captured animals may seem a trivial assumption to meet; however, two aspects of this are important. First, it is surprisingly easy to make mistakes in the field or in transcribing field notes or in laboratory processing of data. Researchers should pay particular attention to avoiding making such errors because they can potentially have a big effect, especially in datasets with few recaptures. Second, the correct identification of recaptures is critical to mark–recapture. The chance of making an error with numbered tags is small, but there are important issues concerning matching individuals using photo-identification, and a strict protocol is essential to minimize false negative errors (missing a match) or false positive errors (calling two different individuals the same). Most researchers implement protocols to avoid making false positive errors. Stevick *et al.* (2001) investigated the rate of false negative errors and found it to increase with decreasing photographic quality. The effects of false negative or false positive errors in matching are again most severe in the analysis of datasets with few recaptures.

The simplest models also make assumptions related to the behavior of the animals or the researcher. These assumptions are often stated as:

1. Marking does not affect future survival or catchability;
2. Animals must have an equal probability of being captured within each sampling occasion.

In many, but not all, circumstances models are available that do not require these assumptions to be made. As a general rule, it is wise to explore datasets with a range of models to determine the level of model complexity needed to minimize bias and maximize precision in population parameter estimates. Model selection and goodness-of-fit testing are important components of mark–recapture analysis; these are well covered in Cooch and White (2007).

Failure of the assumption that marking does not affect future catchability can result in trap dependency where animals become “trap-happy” or “trap-shy” after first capture, which causes bias unless accounted for in estimation models. This is not uncommon in trapping studies of terrestrial animals where capture depends on an animal entering a trap but is less likely to be a problem in studies of marine mammals, which must be actively captured. In particular, animals that have been captured by photo-identification should not become more or less likely to be captured again. However, in analysis, trap dependency may act as a proxy for some other feature of the data (Ramp *et al.*, 2006).

Failure of the assumption that all animals have an equal chance of being captured in each sampling occasion is often referred to as heterogeneity of capture probabilities. This can occur for a variety of reasons: behavioral responses to marking (as described above); failure of animals to mix completely between sampling occasions caused by area preferences of individuals; inability of sampling design to give each animal an equal chance of being captured even within the study area; behavioural aspects making some animals inherently more difficult to catch than others; some animals having more distinguishable marks than others (especially for photo-identification studies).

Heterogeneity of capture probabilities causes bias, which can be severe in abundance estimates. Achieving equal capture probability in each sampling occasion for all individuals in a study population is a practical impossibility; all datasets will suffer from heterogeneity to a greater or lesser extent. The important point is to recognize this and to be prepared to explore the impact in analysis. Notwithstanding this, it is good practice to minimize heterogeneity of capture

probabilities in the field as much as possible; this can simplify analysis. The most obvious way to do this is to implement a sampling design that ensures high average capture probability. If a large proportion of the animals in the population can be captured there is less scope for variation in the probability of capture among individuals. How well this can be achieved is a matter of the size and extent of the population, data collection logistics, and the resources available.

V. Birth Rates

A birth-interval model in which mark–recapture data are used to estimate fecundity and survival rates, and hence population growth rates, was developed by Barlow and Clapham (1997). The model was applied to humpback whales in the Gulf of Maine, but its wider application may be limited because of the requirement for fairly complete data on calving histories of individual females.

Mass Mortalities

AILSA HALL AND JOHN HARWOOD

The term “mass mortality” has been used rather imprecisely in the scientific literature. In general, it is an event which involves the death of many hundreds of individuals in a relatively short interval (usually 1–2 months). Mass mortalities of rare species may involve smaller numbers of individuals, but the use of this term can be justified if a large proportion of the population is involved in the die off. Strandings of groups of social cetaceans, such as pilot whales (*Globicephala macrorhynchus* and *G. melas*) and pygmy killer whales (*Feresa attenuata*), should probably not be regarded as mass mortalities (Geraci et al., 1999). However, large numbers of carcasses may wash up along a short section of coast during a mass mortality and this

may, initially, resemble a stranding event. Marine mammals spend most of their lives at sea and only a fraction of the number of individuals which die during a mass mortality are likely to be observed. As a result, the true magnitude and effect of these events cannot be assessed from a simple body count. The scale of the mortality is usually best estimated by comparing abundance estimates made before and after the event.

I. Diagnosis

The fact that marine mammals spend most of their lives at sea not only makes it difficult to determine how many individuals have died during a mass mortality, but it also makes it difficult to diagnose the cause. Many days may elapse between an individual's death and the recovery of its carcass. To make matters worse, many mortalities occur along remote stretches of coastline where access is difficult, further increasing the time between death and examination. Some large cetacean carcasses may float off-shore, necessitating at-sea necropsies. The problem is further complicated because many of the agents which can cause mass mortalities, such as viral infections, also affect immune function and reduce resistance to secondary infections. As a result, the ultimate cause of death may be a pathogen that would otherwise be relatively harmless (Gulland and Hall, 2007).

Despite these problems, it has proved possible to identify the causes of many of the mass mortalities observed since the 1980s. Three causal factors appear to be particularly prevalent: infectious diseases, naturally occurring biotoxins, and environmental events (Harvell *et al.*, 1999; Gulland and Hall, in press). Several of these factors may act together, and the effects of any one of them can be amplified by exposure to anthropogenic factors such as environmental pollutants.

II. Infectious Disease

Infectious disease of one kind or another is a frequent cause of mortality in marine mammal populations, and highly virulent pathogens (particularly viruses) can cause the death of large numbers of animals in a very short period. One of the first infectious disease outbreaks to be identified involved an influenza virus that probably caused the death of at least 450 harbor seals (*Phoca vitulina*) along the New England coast of the United States in 1979–1980. But the viruses which are most often associated with mass mortalities are those in the Morbillivirus family. *Canine distemper virus* (probably contracted from domestic dogs [*Canis lupus*] or farmed mink [*Mustela* spp.]) caused the death of several thousand Baikal seals (*Phoca sibirica*) in the Russian Federation in 1987–1988. In the spring of 2000, more than 10,000 Caspian seals (*Phoca caspica*) were estimated to have died during an outbreak of canine distemper. Terrestrial carnivores such as wolves or feral dogs appear to be the most likely source of this virus. The closely related *Phocine distemper virus* caused the death of 18,000 harbor seals in the North Sea during 1988, and a second outbreak in the same geographic region in 2002 probably affected almost 30,000 animals. A *Cetacean morbillivirus* caused the death of several thousand striped dolphins (*Stenella coeruleoalba*) in the Mediterranean Sea between 1990 and 1992. The death of more than 700 bottlenose dolphins (*Tursiops truncatus*) along the Atlantic coast of the US in 1987 was initially attributed to poisoning by biotoxins (discussed later), but more recent evidence suggests that this was also caused by *Cetacean morbillivirus*.

Other notable infectious diseases that have caused mass mortalities in pinnipeds include two bacterial infections. Between 2001 and

2003, a marked reduction in the number of New Zealand (Hooker's) sea lion (*Phocarcos hookeri*) pups born on the Auckland island rookeries were followed by very high neonatal mortality. A single highly pathogenic clonal lineage of the opportunistic bacterium *Klebsiella pneumoniae* was identified as the major causative agent of this 2-year mass mortality. Since 1970, California sea lions (*Zalophus californianus*) along the west coast of the USA have been increasingly affected by outbreaks of leptospirosis, caused by *Leptospira interrogans* serovar pomona, that result in death through renal failure.

III. Biotoxins

Some species of single-celled algae (notably the diatoms and dinoflagellates) produce poisonous compounds (known as phycotoxins) which can accumulate in any fish or invertebrate animals that eat them. When environmental conditions are particularly suitable, these organisms multiply rapidly, creating "blooms" (also sometimes called "red tides" due to the high density of algae in the surface water). The resulting high concentrations of biotoxins can cause mass mortalities of fish and fish predators. The best documented event of this kind involving marine mammals caused the death of over 400 California sea lions along the central California coast during May and June 1998 (Scholin *et al.*, 2000). This coincided with a bloom in the same area of the algal diatom *Pseudo-nitzschia australis*, which is known to produce domoic acid—a dangerous neurotoxin. Domoic acid was detected in northern anchovies, which are plankton feeders and a well known prey of sea lions, and in the body fluid of sick sea lions. These sea lions also showed many of the neurological symptoms, such as seizures and convulsions, commonly associated with domoic acid poisoning.

Biotoxins produced by dinoflagellate protozoa have been implicated in the deaths of many marine mammals. Ciguatoxin and maitotoxin were the suspected causative agents in the deaths of Hawaiian monk seals (*Monachus schauinslandi*) in 1978, and 14 humpback whales (*Megaptera novaeangliae*) died from saxitoxin exposure in Cape Cod Bay in 1987. Large numbers of Florida manatees (*Trichechus manatus*) have been affected by exposure to brevetoxin produced by the dinoflagellate *Karenia brevis*. The first mass mortality occurred in 1982 and was followed by a second outbreak in 1996. Between 2002 and 2007, this has been an annual occurrence that has also caused the additional death of hundreds of Florida bottlenose dolphins.

However, identifying the primary cause of a mass mortality is not always straightforward. In May and June 1997, the bodies of over 100 Mediterranean monk seals (*Monachus monachus*) were found along a short stretch of the west African coast near the border between Mauritania and the former Western Sahara. Initial investigations revealed that at least some of these individuals had been infected with a morbillivirus, which most closely resembled *Cetacean morbillivirus*, and the mass mortality was originally attributed to this agent. However, most of the seals died quickly with few, if any, overt signs of disease. This was very different from what had been observed in other morbillivirus-induced events. Subsequent analysis provided evidence of the presence of several biotoxins in dead seals (largely saxitoxin and its derivatives), and high concentrations of a dinoflagellate known to produce at least one of these toxins had been observed in local coastal waters. It is possible that both agents were involved in the mortality, but on the basis of the available evidence it is not possible to say with any confidence that either was responsible (Harwood, 1998).

IV. Environmental Effects

Unusual environmental conditions can cause high levels of mortality, particularly among young animals. For example, severe storms coupled with unusually high tides during the winter of 1982 and 1983 resulted in the death of up to 80% of all northern elephant seal (*Mirounga angustirostris*) pups born at some Californian colonies.

Even more dramatic effects can be caused by changes in oceanographic conditions. For example, El Niño southern oscillation events can dramatically alter the availability of prey species around marine mammal colonies. The severe 1982–1983 El Niño event had wide-ranging effects on fur seal and sea lion colonies throughout the eastern Pacific. Its effects were even evident in populations of seals in the Antarctic.

An intrusion of low oxygen content water into the coastal waters of Namibia in early 1994 resulted in a massive reduction in the availability of fish. Colonies of Cape fur seals (*Arctocephalus pusillus pusillus*) in Namibia suffered the highest levels of pup mortality ever observed: approximately 120,000 pups had died by the end of May 1994. There was also very high mortality among those sub-adult males which remained on the breeding grounds.

In 1992, two floods and a cyclone caused the loss of 1000 km² of sea grass from Hervey Bay in Queensland, Australia, an important habitat for a population of over 2000 dugongs (*Dugong dugon*). By 1993, the dugong population had declined to approximately 600 animals, and many of the recovered carcasses indicated that the animals were severely emaciated and probably died of starvation.

V. Anthropogenic Effects

Deliberate killing by humans can cause mass mortalities of marine mammals, but the effects of such activities are dealt with elsewhere. However, human activities can also result in mass mortalities through indirect effects. The most obvious of these is the exposure of marine mammals to harmful chemicals which are spilled or discharged into the marine environment. Although marine mammals are probably less vulnerable to the effects of oil spills than seabirds, species that rely on dense fur for insulation, such as the sea otter (*Enhydra lutris*), can be seriously affected. Indeed, it is estimated that 3500–5500 sea otters died in 1989 after the tanker *Exxon Valdez* spilled 42 million liters of oil in Prince William Sound, Alaska. Other chemicals may have a more insidious effect. A wide range of man-made halogenated organic compounds are preferentially soluble in fat and can accumulate at high concentrations in the blubber of predatory marine mammals. These compounds can reduce resistance to disease, and individuals with high tissue levels may be particularly vulnerable during mass mortalities caused by infectious disease agents. High persistent organic and other pollutant levels (DDE, DDT, PCB) may well have been a contributory factor to mortality during the morbillivirus epidemics in the North Sea and Mediterranean.

Between January and May 1992, 220 bottlenose dolphins died in the coastal bays of mid-Texas, USA. Although no definitive cause was established, the low salinity of the coastal waters at that time indicated that there had been unusual levels of agricultural runoff due to record levels of rainfall, and this runoff resulted in elevated concentrations of carbamate pesticides (atrazine and aldicarb). After all other potential causes had been excluded, it was concluded that a combination of pesticide exposure and increased dermal absorption due to low water salinity may have been responsible for the dolphins death.

A combination of environmental factors and fishing activity may also result in mass mortality. For example, large numbers of harp seals (*Phoca groenlandica*) appeared off the north coast of Norway between 1985 and 1988, probably as a result of the collapse of the stocks of capelin, an important prey species, in the Barents and Norwegian Seas. Many of these seals became entangled in fishing nets and subsequently drowned. The Norwegian government compensated fishermen for the damage this caused, and these statistics indicate that at least 79,000 seals died in 1987 and 1988 alone.

VI. Effects on Populations

Determining the effect of mass mortalities on the marine mammal populations is often difficult, because baseline data on the size and status of the affected populations are lacking. However, their impact can be substantial. For example, the 1988 and 2002 morbillivirus epidemics in the North Sea killed approximately 40% of the harbor seal population, and local mortality rates were as high as 60%. The mass mortality of Mediterranean monk seals in 1997 killed 70% of the local population and about one-third of the world population of this species.

Some marine mammal populations have shown a remarkable ability to recover from the effects of these events. The North Sea harbor seal population returned to its pre-epidemic level within 10 years of the 1988 epidemic, although some local populations (e.g., those along the eastern seaboard of England) are still depleted. However, species whose populations are already small (such as the Mediterranean monk seal, whose world population was less than 1000 individuals at the time of the 1997 mortality) may be reduced to such low levels that they are more susceptible to other problems associated with low population size, such as increased levels of inbreeding and the loss of genetic diversity through genetic drift. As a result, their risk of extinction may be substantially increased.

VI. Future Trends

There are a number of grounds for predicting that the frequency of mass mortalities will increase during this century (Harvell *et al.*, 1999; Gulland and Hall, 2007). Like many other species, marine mammals will be exposed ever more frequently to novel pathogens as a result of the increased movement of humans and their domestic animals, who can act as vectors for these agents. Climate change is also likely to lead to new movement patterns which will increase the exchange rate of these pathogens.

Exposure to biotoxins, particularly those produced by dinoflagellate algae, is also likely to increase. Levels of nutrients and minerals, which are normally in short supply, are periodically increased in coastal waters by large-scale runoff of rainwater from agriculture land. This occurs more frequently now because of modern drainage techniques and can create conditions that are favorable to algal blooms. In addition, dinoflagellates are particularly well adapted to transportation in the ballast water of large ships, because when conditions are unfavorable they become encased in a protective cyst. As a result, many species that once had a very restricted distribution now have a global one. For example, *Gymnodinium catenatum* (one of the species implicated in the mass mortality of Mediterranean monk seals) was originally confined to the east coast of the US. Since 1970, it has been recorded in Japan and Australia, as well as off the west coast of Africa.

Mating Systems

SARAH L. MESNICK AND KATHERINE RALLS

I. Introduction to Mating Systems

Marine mammal mating systems are diverse and variable. The key to understand this variation is the fundamental idea that individuals behave so as to maximize their lifetime reproductive success and that males and females are subject to different selective pressures (Trivers, 1972). In general, female mammals invest heavily in rearing a limited number of young during their lifetimes whereas males tend to maximize reproductive success by mating with as many females as possible to increase the number of offspring they sire. Recent reviews have both questioned this general conceptual framework (Roughgarden *et al.*, 2006), and supported it, although acknowledging that there is more complexity than originally envisioned (Clutton-Brock, 2007). Males and females do not necessarily always cooperate during mating, and sometimes may be in conflict. Together, the mating strategies of males and females define the mating system of a species. This article presents an overview of male and female mating strategies and describes how the different groups of marine mammals solve the problem of finding mates.

Mating systems have traditionally been categorized on the basis of whether the female and male form pair bonds, the duration of those bonds and the number of partners each sex copulates with during a breeding season or lifetime. To facilitate comparisons among marine mammals, in which males do not remain with their mates after mating (with rare exceptions, Danilewicz *et al.*, 2004), we focus on the number of partners for each sex during a breeding season. In *monogamous* systems, each individual has a single partner during the breeding season and in *polygamous* systems, some individuals have multiple partners. There are several types of polygamy: *polygyny*, in which some males have more than one partner; *polyandry* in which some females have more than one partner; and *polygynandry*, in which some females and some males have multiple partners.

Marine mammals, like most mammals, are predisposed to polygyny because of the fundamental disparity in reproductive biology between the sexes (Clutton-Brock, 1989). Females can produce only a limited number of offspring in their lives and they bear the energetic costs of gestation, lactation, and parental care. Males, however, provide little or nothing to the care of offspring and are free to devote their time and energy to competing for access to mates.

The potential for polygyny, and the extent to which that potential is realized, is determined to a great extent by the degree to which receptive females are aggregated in space and time. The distribution of females, in turn, is determined by phylogenetic constraints (such as the retention of terrestrial birthing in pinnipeds) and by ecological and social conditions. Among the most important of these conditions are the distribution of resources necessary for breeding, predation pressure, and the costs and benefits of group living. Several types of polygynous mating systems have been identified in marine mammals. In populations where females are clustered and their movements are limited in space and time, males generally compete to monopolize females. They may defend resources that are vital to females such as parturition sites (territoriality or resource defense polygyny) or they may defend females directly (female defense polygyny). When females are spatially or temporally dispersed, or are highly mobile, males are less able to control access to potential mates. In these situations, males may aggregate on traditional display sites and advertise for females (lekking) or they may search widely and spend little time with females except to mate (roving).

Females of many species also mate with more than one male during a breeding season and they may benefit in many ways by doing so (see below). Polygynandrous (or "promiscuous") mating systems have been described for a number of species. Frequent copulation may have a variety of functions, but not all mating behavior is for procreation; in many species, sexual behavior is an important component of the social fabric and often has little to do with fertilization.

II. Male Mating Strategies

Male competition for access to mates takes at least three general forms: aggressive interactions to limit the access of other males to females (contest competition), competition to disperse and find sexually receptive females (scramble competition), and competition in courtship to be chosen by the female (mate choice competition). Each of these behavioral strategies has, in turn, generated a number of morphological and physiological adaptations. For example, males are often distinguished by large body size, big canines, or tusks that can be used as weapons in combat with other males (Fig. 1). Among mammals, males generally disperse more widely than females and there is an increasing evidence that the pattern holds in marine mammals [e.g., Dall's porpoise (*Phocoenoides dalli*) and beluga (*Delphinapterus leucas*)]. Males are typically more persistent in courtship and are the more conspicuous and ornamented sex. They may attempt to entice and attract females through visual acoustic, and pheromonal displays (Fig. 2).

Several additional forms of male competition have also been described. Males may attempt to out-compete other males by producing higher quality or greater quantities of sperm or by removing other male's sperm (sperm competition). When a male cannot monopolize access to females by himself, males may cooperate and form alliances. These alliances, comprised of pairs of males or small groups, compete with each other for access to females and have been described in Indian Ocean bottlenose dolphins (*Tursiops aduncus*) from Shark Bay, Australia (Connor *et al.*, 1996), and common

Figure 1 Adult male northern elephant seals (*Mirounga angustirostris*) fight for positions in a dominance hierarchy that confers access to receptive females. Photograph by Sarah L. Mesnick.

Figure 2 A singing adult male humpback whale (*Megaptera novaeangliae*). Singing by humpback males presumably acts to attract females, although whether songs contain cues to mate quality remains in dispute. Singing may also function to space males in a breeding area or to aid in the establishment of dominance hierarchies. Maui. © Flip Nicklin (Minden Pictures). Photograph obtained under N.M.F.S. Permit No. 987.

bottlenose dolphins (*Tursiops truncatus*) from Sarasota Bay, Florida (Wells *et al.*, 1987), and are likely to occur in other species as well. Males may also form consortships, maintaining close proximity to a female until she comes into estrus. In common bottlenose dolphins from Sarasota Bay, Florida, such consortships have been found to correlate with the birth of offspring several months later. Species in which males are larger than females, possess dangerous weapons and aggressively pursue copulation, some males may forcibly coerce the female to mate (forced copulation), e.g., northern elephant seals (*Mirounga angustirostris*), Le Boeuf and Mesnick (1990). Males which are not competitive, because of their size, age, or experience, may employ alternative strategies to obtain access to females. Males may sneak copulations when alpha bulls are distracted or abduct females from the territories of dominant males (kleptogyny) as observed in northern fur seals (*Callorhinus ursinus*), Gentry (1998). Although competition between males receives the most attention, the possibility of male choice—the notion that males may prefer to mate with particular females—is an area that deserves further attention.

III. Female Mating Strategies

Females of most marine mammals produce only a single offspring at a time. The interbirth interval ranges from 1 year in most pinnipeds and small cetaceans to 5, 6, or even 7 years in larger toothed whales such as sperm whales (*Physeter macrocephalus*), killer whales (*Orcinus orca*), and short-finned pilot whales (*Globicephala macrorhynchus*). While females may maximize their reproductive success by being good mothers, they may also enhance their fitness by choosing males as mates that offer resources, protection, or genetic benefits. Multiple mating is also an important female strategy that may function to ensure insemination or to confuse paternity and reduce potential aggression directed toward young. Multiple mating may also enable females to promote sperm competition and exert cryptic female choice.

In other well-studied taxa, such as birds, females are highly discriminating in their choice of sexual partners. Moreover, females often choose in a similar way, so that a few males achieve many copulations and most other males achieve few or none. Females may choose among potential mates directly (based on resources, size, strength, dominance, or display) or indirectly (by mating with the winner of contests for access to females). Some marine mammal females actively seek out particular males and mate. For example, in California sea lions (*Zalophus californianus*), some females were observed to change pupping locations from one year to the next to remain with a territorial male who changed territory location (Heath, 1989). Females may also incite male–male competition. As a result of protesting male sexual advances loudly, female northern elephant seals instigate fights among males, and subsequently mate with the winner of these battles (Cox and Le Boeuf, 1977).

In marine mammals, it is difficult to establish the existence of female choice and even more difficult to determine why females might choose particular males with which to mate or to quantify the benefit to females of exercising choice. Direct benefits to the female, in the form of nutritional resources or parental care, are not known to exist in marine mammals. Females can benefit, however, by choosing males with higher quality territories, which provide better parturition or thermoregulatory sites, or by choosing males that provide protection from harassment by subordinate males (the bodyguard hypothesis; Mesnick, 1997). Females can also benefit by discriminating among potential mates on the basis of genetic benefits (Mays

and Hill, 2004). These include choosing males of the correct species, males with immunologically compatible genes, and males with “good genes” who can produce offspring of higher quality. Females can also choose males with better fertilization ability or virility.

Females may make very different decisions regarding which males they associate with, which males they mate with, and which male ultimately sires their offspring. In land-breeding pinnipeds, for example, a female may reside with one dominant or territorial male during lactation but later leave this male’s territory to copulate with another male elsewhere (extra-territorial copulation). In some species, such as the common bottlenose dolphin, sexual behavior is a frequent and important component of nonreproductive social life and has little to do with fertilization. As with males, female strategies need not be mutually exclusive and it is likely that different females will utilize different strategies depending on their age, dominance rank, and the number and quality of available mates.

IV. Taxonomic Descriptions

A. Pinnipeds

For all pinnipeds studied to date, the data support, or are highly suggestive of, a polygynous mating system (Boness *et al.*, 2002). Pinnipeds are predisposed to polygyny because they give birth on land, which results in the spatial clustering of females, and have an annual birthing cycle, which results in reproductive synchrony among females. The degree of polygyny varies both within and among species with the extent of reproductive synchrony and spatial clustering. Most species have a peak availability of receptive females lasting about 1 month but the availability of receptive females ranges from 10–15 days in harp (*Pagophilus groenlandicus*) and hooded (*Cystophora cristata*) seals to a period of several months for species that breed in tropical habitats such as monk seals (*Monachus* spp.) and Galapagos sea lions (*Zalophus wollebaeki*).

Variation in the degree of spatial clustering within and among species is due to a variety of factors including the spatial distribution of suitable breeding sites, whether mating takes place on land or at sea, the intensity of male harassment, predation pressure, and thermoregulatory pressures. Polygyny and sexual dimorphism are generally much more extreme in species that mate on land than in those that mate in the water and in species that reside in high latitudes than those that reside in lower latitudes (see article on Sexual Dimorphism).

1. Otariids Otariid females feed during lactation. Lactation is energetically costly, so females must raise their young on sites near highly productive marine areas. Because these sites are limited, and the season of maximum marine productivity may be short, females typically occur in dense aggregations (numbering from a few individuals to more than one thousand) on beaches or rocky shelves on islands. Mating occurs on land, although evidence of at least some mating at sea exists for a few species [e.g., Juan Fernández fur seal (*Arctocephalus philippii*) and the California sea lion]. The combination of dense female aggregations and terrestrial mating gives some males the opportunity to monopolize mating with many females. Sexual dimorphism among otariids is correspondingly extreme; males are on average 3 times, and up to 10 times, heavier than females and have other traits favored in physical combat over females: large canines, heavy chests, and dense manes.

The northern fur seal is among the most polygynous of the otariids: a single male at the St. George Island rookery mated with 161 females while hundreds of other males had no copulations at all (Gentry, 1998). The lowest levels of polygyny probably occur in

species such as the Juan Fernández fur seal, the South American sea lion (*Otaria flavescens*), the Galapagos fur seal (*Arctocephalus galapagoensis*), and Hooker’s sea lion (*Phocarctos hookeri*), in which the ratio of sexually active adults ranges from two to six females per male (Boness *et al.*, 1993).

Male otariids typically defend territories containing resources needed by females—parturition and thermoregulatory sites—rather than individual females (Fig. 3). However, female defense has been demonstrated in at least one otariid, the South American sea lion. The two types of polygyny are difficult to distinguish and are not necessarily mutually exclusive. There is some evidence suggestive of lekking in at least three species, the California sea lion, the South American fur seal (*Arctocephalus australis*), and Hooker’s sea lion.

A male’s ability to acquire and defend a territory depends on his size and age, his ability to compete with other males, and his ability to fast during his tenure (contest competition). Under most circumstances, the boundaries of territories are fixed and are often delineated by natural breaks in the substrate. Males use a species-specific threat display when defending the boundaries of their territory. A male that secures a territory will probably, but not necessarily, mate with many of the females that give birth on his territory. Climate and topography also play an important role in determining a male’s mating success. Those males defending territories containing access to the water, tide pools, or shade typically acquire a disproportionately large number of females.

Most otariid bulls fast while maintaining their territories, sometimes for the entire 2–3-month breeding season [e.g., Steller sea lions (*Eumetopias jubatus*) and northern fur seals]. Some males return to the same territory in subsequent years, with remarkably high site fidelity, whereas others move to new territories or are not seen again. Territorial males may try to herd females to prevent them from leaving their territories but in most species, females determined to leave generally can do so. The males of some species, however [e.g., northern fur seal and the South American and Australian (*Neophoca cinerea*) sea lion], are able to prevent females from leaving their territories by threats, herding, and sometimes physical aggression leading to injury.

Figure 3 A Steller sea lion (*Eumetopias jubatus*) territory. Adult males defend resource-based territories that encompass female parturition and thermoregulatory sites. Females choose among males in a surprisingly consistent way. As a result, some males holding territories never or rarely mate, while a few males mate with many females. Photograph by Sarah L. Mesnick.

The importance of male courtship displays in otariids is not well understood. For example, it is not known whether male displays, such as the incessant barking of male California sea lions, function as threat displays directed at other males, as courtship displays to attract females, or both. Alternative male mating strategies are widespread and generally thought to be practiced by subadult or subordinate males. These include gang raids by groups of non-territorial males to abduct or mate with females in the main breeding territories (observed in South American and Australian sea lions), males stealing females from the territories of their neighbors (kleptogyny; northern fur seals) or males trying to sneak copulations or mate at sea (several species). How successful these strategies are in inseminating females is generally not known. In Antarctic fur seals (*Actocephalus gazella*), a large DNA-based paternity study found that females who pupped on the study beach in the year of conception almost certainly conceived to territorial males and males did not appear either to sneak copulations or mate aquatically, although probability of paternity was strongly influenced by maternal state at conception (females who come to the beach but do not pup appear less likely to conceive with males from that beach) and the authors could not entirely preclude the possibility that a few males might employ alternative strategies (Hoffman *et al.*, 2003).

Female mating strategies are less well understood than male mating strategies but several lines of evidence, including genetic studies, suggest that females exercise more choice among males than previously suspected. Female otariids choose which territory to haul out in and usually, but not always, move freely in and out of a male's territory. Estrus occurs within 1–2 weeks postpartum in all but one species (California sea lion, about 21–27 days). When it is time to mate, a female may leave the male's territory in which she gave birth and mate with another male. This behavior has been observed in California sea lions, South American fur seals, and between the territories of sympatric Antarctic fur seals (Goldsworthy *et al.*, 1999).

Climate, rookery topography and the intensity of male herding and harassment influence the ability of females to exercise mate choice. In hot climates, females have more opportunity for mate choice due to their frequent thermoregulatory movements between their birthing site and the water. In contrast, in colder climes, intense male herding restricts female choice and may injure females. Female northern fur seals are thought to successfully reduce the risk of injury from males by forming dense aggregations and competing for central locations within these groups, which minimizes contact with males, and by acting submissive around males. In this species, females do not appear to choose males directly. Rather, by gathering on traditional mating grounds, the result is that males fight for access for these sites, and females subsequently mate with the winners of these contests. Female otariids may also directly solicit and initiate copulation from males. In Steller sea lions, e.g., a female gains the sexual attention of a male by laterally swinging her neck, dragging her hindquarters and sinuous movements of her body against his body. While females tend to direct most solicitation behavior toward the older “proven” territorial males, the extent of female choice remains unclear. Multiple mating is known in 30% of otariids studied (Boness *et al.*, 1993) and suggests an important and variable role for sperm competition and mate choice across species.

2. *Phocids* Most phocid females are thought to fast during a short and concentrated lactation period and are generally thought not to return to sea to feed until after weaning their pup. However, smaller individuals of some species may supplement fat stores by foraging to sustain lactation (Bowen *et al.*, 2001). Many species

live in high latitudes, and a number of species give birth on ice. Females of most phocids are spatially dispersed during lactation; they may be solitary or occur in small-to-moderate-sized well-spaced colonies. In 16 of 19 species, the majority of mating takes place in the water near or after the end of lactation (Boness *et al.*, 2002). As a consequence, males have less opportunity to defend and mate with multiple females. Aquatically mating phocids are less polygynous and less sexually dimorphic than terrestrially mating phocids or otariids.

For most species, the breeding season is relatively short and, in species that breed on ice, mating takes place when temperatures are well below freezing. Reverse sexual dimorphism, with females larger than males, occurs in several species. Large female size may help a mother provide greater quantities of fat-rich milk to her pup and protects her from low polar temperatures. Small size in males is also thought to facilitate agility underwater where males may defend aquatic territories, display, and mate with females. Nevertheless, aquatically mating species are considered to be slightly or moderately polygynous. Mating takes place within a few days of the weaning of the pup.

A common feature of the behavior of aquatically mating phocids is the production by males of simple or complex underwater vocalizations and stereotypical dive displays during the breeding season (Van Parijs *et al.*, 2003). These vocalizations are thought to be used predominantly in male–male competition and are also likely to play a role in attracting females. “Eerie but melodious” songs have been described for male bearded seals (*Erignathus barbatus*) and trills, knocks, buzzes, and chirps for male Weddell seals (*Leptonychotes weddellii*). Harbor seal (*Phoca vitulina*) males produce broadband growls. Hooded seals males make numerous sounds underwater and also produce sounds in air as they inflate and deflate their hood and red nasal sac. The number and diversity of underwater vocalizations is correlated with various social and environmental factors, including mating system, female gregariousness and predation intensity, and is geographically variable (Stirling and Thomas, 2003). In leopard seals (*Hydrurga leptonyx*), both males and females produce underwater broadcast calls thought to serve in mate attraction.

In aquatically mating phocids, there is considerable variability in male mating strategies displayed by each species as well as plasticity within and between populations. In some species, such as crabeater seals (*Lobodon carcinophagus*), spotted seals (*Phoca largha*), and hooded seals, males directly defend the lactating female and her immediate vicinity, a strategy akin to roving and mate guarding of a single female or small group of females. A typical group consists of a female and her pup and an adult male who may have to wait before the female comes into estrus and is receptive to mating. Presumably, the male will mate with the female when she enters the water after weaning her pup. This strategy can be described as sequential female defense polygyny since the male may leave after mating to search for another receptive female. Other males may surround these triads and may compete with the attending male for access to the female, typically with threats and sometimes bloody fights.

In other species, males defend aquatic territories (called “maritories”) off the beach or ice where females haul out to raise their pups. Males spend considerable time in these territories giving underwater vocal and visual displays and may mate with any receptive female that enters the territory. This characterizes the behavior of Weddell, harp, bearded, and harbor seals, although there is considerable variation within and between breeding colonies. In the geographically wide-spread harbor seal, colonies occur in diverse habitats and males adjust their mating strategies depending on the topography. Some males defend adjacent discrete territories offshore from female

haulout areas, others defend territories near female foraging areas or along route to foraging areas, and still others do not defend territories but display in the vicinity of female haulouts. Studies from all habitats observe that males perform stereotypic vocal and dive displays during the period the females is in estrus and raise the possibility of a lek-type mating system in which females select males (Boness *et al.*, 2006).

The northern and southern (*Mirounga leonina*) elephant seal and some populations of the gray seal (*Haliocoeris grypus*) are unusual among phocids in that mating takes place on land. These species exhibit forms of female defense polygyny. Harassment by subordinate males is widespread, costly to females, and may be an important factor contributing to spatial and temporal synchrony among breeding females (Le Boeuf and Mesnick, 1990, Boness *et al.*, 1995). In all the three terrestrially breeding species, males that are unable to maintain control over access to females may attempt to “sneak” copulations or capture, sometimes aggressively, and mate with females as they leave the colony.

In elephant seals, males use visual and acoustic threats as well as physical fighting to compete for dominance in a social hierarchy that confers access to females (Le Boeuf, 1974). Female elephant seals may exercise mate choice by competing for central positions in harems where dominant males reside and by inciting male–male competition and subsequently mating with the winner of these battles. Polygyny in elephant seals is among the most extreme recorded in all mammals; lifetime reproductive success of most males is nil or low. Many die before reaching breeding age and higher-ranking males prevent many of those that survive from breeding. DNA paternity analyses confirm that the proportion of pups sired by alpha males is consistent with that expected from observed mating success in southern elephant seals but show that behavioral observations overestimate the success of some northern elephant seal alpha males (Hoelzel *et al.*, 1999). The relatively lower success of northern elephant seal males may be due in part to the behavior of the northern elephant seal females which copulate more frequently than southern females and may mate during departure from the harem, the greater success of non-alpha males, and/or reduced virility of specific alpha males.

Mating behavior among the geographically wide-spread populations of the gray seal is difficult to categorize because of their varied habitat and social organization. Gray seal females typically do not cluster as tightly and are more mobile in the colony than elephant seal females. Males exhibit state-dependent reproductive strategies, a primary mating tactic involving prolonged female defense and three alternative strategies have been identified (Lidgard *et al.*, 2004). Although males exhibiting the primary strategy achieve the greatest mating success, males that exhibit alternative tactics have been shown to achieve some success. At North Rona, Scotland, genetic studies show that over 80% of assigned paternities agree with behavioral observations in which a female in estrus mates with the local dominant male. However, about 10–20% of females do not have their pups sired by local males and may instead seek preferred sires outside the local male’s range or mate with unobserved males, during their departure, or at sea (Twiss *et al.*, 2006). Among gray seal colonies, North Rona has a relatively stable social organization; a lower correlation between observational and genetic measures of success would be expected in colonies with a more fluid social structure and increased female mobility (Pemberton *et al.*, 1992).

3. *Walrus (Odobenus rosmarus)* Walruses have the most elaborate courtship displays of all pinnipeds. Walruses show marked sexual size dimorphism and are thought to be strongly polygynous. Atlantic

walruses (*O. r. rosmarus*) in the Canadian High Arctic exhibit a mating system that resembles female defense polygyny in which males appear to monopolize access to female herds. Pacific walruses (*O. r. divergens*) in the Bering Sea may have a lek-like mating system. Groups of males cluster around females, which form dense aggregations on pack ice. Males are aggressive toward one another and produce intricate visual and vocal displays, consisting of barks, whistles, growls, and underwater bell-like sounds. The massive tusks of the male walrus appear to play an important role as a symbol of rank used to threaten other males and as a visual signal to females who may choose among males partly by the size of their tusks.

B. Cetaceans

1. *Odontocetes* In contrast to pinnipeds, which are relatively sedentary and clustered during the breeding season, female odontocetes are mobile and dispersed. This has two important consequences for male mating strategies: males have less opportunity to control access to aggregated females and less assurance of paternity. It is not surprising, therefore, that the basic mating strategy of male odontocetes appears to be one of searching for receptive females and spending little time with them other than to mate. It is likely that mate guarding, or monopolization of females long enough to increase assurance of paternity and to reduce extra pair copulations, also occurs, although the phenomenon has been noted only in bottlenose dolphins and Dall’s porpoise.

Female mating strategies in odontocetes are little understood. Given their mobility and three-dimensional habitat, it is generally thought that females are able to exercise choice by out-maneuvering males or by rolling belly-up. Observational and hormonal evidence suggests that females of several species copulate frequently both during and outside the breeding season and may be polyestrous. Frequent copulation may function to ensure fertilization, induce sperm competition, obscure paternity, and help to establish social bonds with potential future partners. In many odontocete species, sexual behavior is an important component of nonreproductive social interactions and often has little to do with fertilization, making it difficult to infer mating strategies from incomplete observations. An example is the intriguing “wuzzling” behavior of Hawaiian spinner dolphins (*Stenella longirostris longirostris*). Wuzzling refers to the interweaving, caressing, and copulating dolphins of both sexes and all ages and is especially common in the summer months, when many females come into estrus. Is the behavior social? Sexual? Or both?

We know little about mating systems in the vast majority of odontocetes. However, there are substantial data on bottlenose dolphins, sperm whales, and killer whales. A mating strategy of female defense or sequential defense polygyny has been suggested for two species of bottlenose dolphin. In Indian Ocean bottlenose dolphins in Shark Bay, Australia, males in pairs or trios cooperate to form temporary consortships with individual females, often through aggressive herding (Connor *et al.*, 1996). “Second-order alliances,” teams of pairs or trios, attack other alliances in contests over female consorts. In common bottlenose dolphins in Sarasota Bay, Florida, individual males and members of long-term male associations form temporary consortships with females without obvious aggressive herding (Wells *et al.*, 1999). The extent to which this sequential female defense strategy is successful is uncertain; individual females are polyestrous and associate with several males during the season in which they conceive. These behaviors may facilitate female mate choice, promote sperm competition, and obscure paternity. In Moray Firth, Scotland, common

bottlenose dolphin males apparently do not form alliances or aggressively herd females, although single males may accompany groups of females throughout the breeding season. Among these three sites, the level of male bonding may be inversely related to male body size and the degree of sexual dimorphism (Tolley *et al.*, 1995). In Shark Bay, individuals are small in size, not noticeably dimorphic and alliance formation enables males to gain and maintain access to females. In Moray Firth, males are larger than females and can do this on their own.

Most sperm whales in the Galápagos Islands appear to rove between groups of females searching for potential mates. One or more large males may attend a group of females (sometimes simultaneously) for short periods of time ranging from a few minutes to several hours (Fig. 4). Rather than males herding female groups, females were observed to alter course and speed so that they could join a large male hundreds of meters away. Males did not interact aggressively with each other within female groups, despite several accounts in the literature of males fighting outside of groups. Given the apparent roving strategy of males, the role of the tremendously large nose of the male sperm whale and its possible use as a sound generating organ remains unclear. The loud clicks may function in male–male competition or advertisement to attract females.

Pods of resident killer whales in the Pacific Northwest are frequently observed associating with one another in the summer months when prey (and observer) abundance is high. In these multi-pod

groups, there is much sexual activity amongst all pod members, young, and old alike. Since no dispersal of either sex occurs from resident pods, it is thought that mating takes place during these encounters. Considering that the entire pod engages in these ceremonies, it is likely that the function of multi-pod encounters is both sexual and social. Similarly, genetic analyses of long-finned pilot whales captured in a Faroese fishery indicate that males remain in their natal groups but do not mate within them (Amos *et al.*, 1993). Young were sired by males not captured with the group, implying that pilot whales must mate when two or more groups meet or when adult males pay brief visits to other groups.

Very little is known about mating systems in the remaining species of toothed whales. However, we can infer something about the mating strategies of these species from the type and degree of sexual dimorphism and its association with other characteristics such as body scarring and relative testis size (see article on Sexual Dimorphism). For example, relative testis size ranges nearly two orders of magnitude among odontocete species, from less than 0.05% [several Mesoplodon species, the franciscana (*Pontoporia blainillei*), the baiji (*Lipotes vexillifer*), and sperm whale] to nearly 5% [harbor porpoise and dusky dolphin (*Lagenorhynchus obscurus*)] of body weight. These data suggest the importance of sperm competition in several odontocete species, and especially among some of the delphinids and porpoises. The importance of mate choice competition, attempts to entice and attract females through elaborate visual or acoustic displays, is suggested by differences between the sexes in vocalizations and exaggerated visual signals such as the post-anal hump or enlarged dorsal fins. At present, sexually dimorphic acoustic signals are known only in sperm whales. However, because odontocetes produce a wide range of sounds, acoustic displays are likely to occur in several other species as well. The importance of contest competition for access to mates is suggested by sexual dimorphism in size, weaponry (teeth and tusks) and the presence of scarring of conspecific origin (tooth rake marks). Sperm whales, the beaked whales, and bottlenose whale (*Hyperoodon* spp.) exhibit these traits.

2. *Mysticetes* Among the mysticetes, substantial data on breeding behavior exist only for the humpback (*Megaptera novaeangliae*), right (*Eubalaena* spp.), and gray (*Eschrichtius robustus*) whales. Even in these species, little is known about female behavior. The humpback whale has been studied most intensively. Male humpbacks adopt one or more of the three primary strategies: display by singing long, complex songs; direct competition with other males for females in “competitive groups;” and escort of females, including those with newborn calves. It is possible that males escorting females are waiting for mating opportunities or are guarding females after copulation. Two secondary strategies, roving and sneaking, have also been suggested.

Female humpbacks sometimes aggressively reject subadult males and they may incite competition among males. Although molecular analysis of paternity has shown that females are mated by different males between years (Clapham and Palsbøll, 1997), it is unknown whether females mate multiply within a given breeding season. Singing by male humpbacks is an intriguing phenomenon, since songs change over time yet all members of a population sing essentially the same song at any one time. Singing by humpback males may serve to attract females, signal status to other males, or both. Additional suggestions for the function of song include a means to synchronize estrus and a basis for organizing males during breeding season (Darling *et al.*, 2006). Whether the aggregation and displaying

Figure 4 Adult male sperm whales (*Physeter macrocephalus*) rove among female groups searching for receptive individuals and staying with each group for only a few hours at a time. Dominica. © Flip Nicklin (Minden Pictures).

of humpback whales at specific sites constitutes a lek also remains controversial (see article on Song).

Little else is known about the mating systems of baleenopterid whales. Blue (*Balaenoptera musculus*), fin (*B. physalus*), Bryde's (*B. edeni*), and minke (*B. acutorostrata*) whales have patterned calls, termed songs, which are geographically variable and thought to function in mating, although the mechanism is unclear. Species recognition, male–male competition, and female choice are possibilities. In the Gulf of California, male fin whales may sing while guarding feeding territories (Croll *et al.*, 2002).

Right whales show sexual activity throughout the year, although calving is strongly seasonal. Since the gestation period is 1 year and there is no evidence of diapause, mating leading to conception presumably occurs primarily in the winter. The function of sexual activity during other seasons is unknown. Observations of multiple male right whales mating with single females, together with the huge (1 ton!) testes, strongly suggest that sperm competition is a principal mating strategy in this species, and also probably in bowhead (*Balaena mysticetus*) and gray whales (Brownell and Ralls, 1986). The level of aggression in male–male interactions in these species is low compared to that observed in humpback whales, an observation that is also consistent with the predominance of sperm competition as a mating strategy.

C. Sirenians, Sea Otters (*Enhydra lutris*) and Polar Bears (*Ursus maritimus*)

Male manatees (genus *Trichechus*) and dugongs (*Dugong dugong*) tend to be solitary and search for potential mates by roaming over large areas that include the home ranges of several females. Groups of males sometimes follow and try to mate with a single female, forming a “mating herd.” In both manatee and dugongs, males in these herds threaten and fight with each other but it is still unknown whether this behavior is a form of scramble competition or is more akin to a type of lekking. In Shark Bay, Australia, dugongs associate in a more classical kind of lekking, with several males patrolling exclusive areas and engaging in activities usually indicative of both male competition and mate attraction, including acoustic signaling. In both manatees and dugongs, the mating season extends over several months and sexual dimorphism is slight. Interbirth intervals are at least 2 years and may be as much as 5 years in some cases.

Female sea otters typically give birth annually. Births generally peak in the spring, although females in warmer areas may give birth in any month. Adult males are larger than females. Male sea otters establish territories that contain food resources and sheltered resting places and usually overlap the home ranges of one or more females. Males may defend territories seasonally or all year. Other males congregate in groups outside of the areas occupied by territorial males. Courtship and mating, as are typical for many mustelid species, is physically aggressive and females may be injured or killed by males. Copulation occurs with both the male and female on their backs near the water's surface and the male grasps the female's head or jaws, including the nose, in his own jaws. Recently mated females typically have red, swollen noses. After mating, the pair may stay together for a few days in which they feed, groom, play, and rest in close company.

Polar bears are highly sexually dimorphic and polygynous; adult males may be over twice as heavy as adult females. Females have extensive home ranges and males are forced to travel over large areas when searching for mates. Males apparently fight among themselves for access to females. Specific courtship behaviors are lacking or are as yet undescribed. The largest and strongest males apparently do most of the

mating while other males sometimes wait in the distance. Polar bears are notable among marine mammals in that they are the only species in which females give birth to multiple young (1–2 is the most common litter size and rarely 3–4). The interbirth interval is about 3 years.

IV. Mating System Studies and the Future

Our knowledge of marine mammal mating systems has increased dramatically in recent years due to technological advances in the use of molecular markers, animal-borne cameras and underwater acoustic recording devices which provide new insights and make it possible to investigate previously inaccessible behaviors and species. Long-term field studies continue to be sources of deepening understanding and new analytical methods such as social network studies and investigations of genetic kinship will likely reveal more complex patterns of social structuring than is currently known. Female mating strategies, including the role of multiple mating and the importance of cryptic female choice are gaining increasing attention. As our understanding of the physiology of female receptivity grows, we will be better able to interpret both female and male mating behavior. At the same time, our increasing ability to hear and see underwater will enable us to tap into the little known realm of underwater acoustic and visual displays.

Melon-Headed Whale

Peponocephala electra

WAYNE L. PERRYMAN

I. Characteristics and Taxonomy

The melon-headed whale is one of a group of small, dark-colored whales that are often referred to as “blackfish.” It is mostly dark gray in color with a faint darker gray dorsal cape that is narrow at the head and dips downward below the tall, falcate dorsal fin (Fig. 1). A faint light band extends from the blowhole to the apex of the melon. A distinct dark eye patch, which broadens as it extends from the eye to the melon, is often present and gives this small whale the appearance of wearing a mask. The lips are often white, and white or light gray areas are common in the throat region and stretching along the ventral surface from the leading edge of the umbilicus to the anus. At sea, this species is difficult to distinguish from the pygmy killer whale (*Feresa attenuata*). It differs externally from the pygmy killer whale by having a more pointed or triangular head and sharply pointed pectoral fins. Both of these characters are difficult to recognize at sea unless these small whales are seen from above. Experienced observers often rely more on behavioral than on physical characters to separate these two blackfish in the field. In stranded specimens, the melon-headed whale can be distinguished from all other blackfish by its high tooth count, 20–26 per row, compared to generally less than 15 teeth per row for pygmy killer whales.

Asymptotic length for males (2.52 m) is greater than for females (2.43 m), and males also have comparatively longer flippers, taller dorsal fins, broader tail flukes, and are more robust (Best and Shaughnessy, 1981; Miyazaki *et al.*, 1998). In addition, some males exhibit a pronounced ventral keel that is found posterior to the anus. The longest specimen reported was a 2.78-m female that stranded in Brazil (Lodi *et al.*, 1990); a 2.64-m male that stranded in Japan weighing 228 kg is the heaviest specimen reported (Miyazaki *et al.*, 1998).

The skull of the melon-headed whale is typically delphinid in shape, with the exception of a very broad rostrum and deep antorbital notches. It is similar to the skull of the common bottlenose dolphin (*Tursiops truncatus*), but the teeth of the melon-headed whale are

Figure 1 Melon-headed whales underwater.

much smaller and more delicate. The high tooth count of this species separates its skull from those of the other small beakless whales.

The melon-headed whale is a member of the subfamily Globicephalinae where it is closely allied with the very similar pygmy killer whale and the larger pilot whales (*Globicephala melas* and *G. macrorhynchus*), false killer whales (*Pseudorca crassidens*), and Risso's dolphin (*Grampus griseus*). Investigations regarding the interrelations of these species have yet to produce definitive results.

II. Distribution and Abundance

Melon-headed whales are found worldwide in tropical to subtropical waters. They have occasionally been reported from higher latitudes, but these sightings are often associated with incursions of warm water currents (Perryman *et al.*, 1994). They are most often found in offshore, deep waters, and nearshore sightings are generally from areas where deep oceanic waters are found near the coast. Systematic line transect surveys have produced estimates of abundance of 45,000 (CV = 0.47) for the eastern tropical Pacific (Wade and Gerrodette, 1993), 3451 (CV = 0.55) in the northern Gulf of Mexico (Mullin and Fulling, 2004), and in the Philippines, 921 (CV = 0.83) in the eastern Sulu Sea and 1383 (CV = 0.82) in Tañon Strait between the islands of Cebu and Negros (Dolar *et al.*, 2006).

III. Ecology

Squids appear to be the preferred prey of this species, but small fishes and shrimps have also been found in their stomachs (Jefferson and Barros, 1997). In the eastern tropical Pacific, aggregations of melon-headed whales have frequently been seen in association with Parkinson's petrels (*Procellaria parkinsonii*) which likely feed on scraps of large prey items that the small whales dismember below the surface (Pitman and Balance, 1992).

IV. Behavior and Physiology

Melon-headed whales are most often found in large aggregations, a behavior that separates them from the very similar pygmy killer whale. They are often seen in large mixed aggregations with Fraser's dolphin (*Lagenodelphis hosei*). They have also been sighted in mixed herds with spinner dolphins (*Stenella longirostris*), common bottlenose dolphins, and rough-toothed dolphins (Dolar *et al.*, 2006). Although they are reported to flee from approaching vessels in the eastern Pacific, it is not uncommon for melon-headed whales to briefly ride the bow wave of passing ships in other areas. They may bow-ride for longer periods if the vessel slows to a speed of a knot or less.

Mass strandings of melon-headed whales have been reported on several occasions and it appears that strandings of this species, at least in the North Pacific, are becoming more common (Brownell *et al.*, 2007). The causes of the strandings are unknown. In two strandings from Japan and one in Brazil, the specimens had high loads of internal parasites, which might have caused some animals to strand. It has been suggested that mass strandings of these highly social animals may be caused by a panic response in the school when a few members accidentally strand (Miyazaki *et al.*, 1998). In a recent stranding event in Hawaii, active sonar transmissions from military vessels were considered as a contributing factor in the stranding (Southall *et al.*, 2006).

V. Life History

Melon-headed whales are about 1.1 m in length at birth (Perrin, 1976; Bryden *et al.*, 1977) and continue to increase in length until

they are 13–14 years old. Females reach sexual maturity at about 11.5 years and a length of about 235 cm. Males appear to mature later, at an age of about 15 years.

VI. Interactions with Humans

When captured live and transferred to aquariums, melon-headed whales have not thrived and have been difficult to train. They have been aggressive toward keepers and have caused injuries by ramming individuals with their heads or raking them with their teeth. Although melon-headed whales were reported to approach divers in an aggressive manner in Hawaiian waters, several other reports of interactions between these small whales and divers or swimmers found them to be mildly evasive to curious toward people in the water.

Melon-headed whales are taken in small numbers in directed harpoon fisheries and as bycatch in drift net fisheries in the Philippines (Dolar, 1994; Dolar *et al.*, 1994), Indonesia, Malaysia, and in the Caribbean near the island of St. Vincent. Schools of melon-headed whales have been taken in the drive fishery operated from the port of Taiji, Japan. On rare occasions, a member of this species is taken in the purse seine fishery for yellow-fin tuna in the eastern tropical Pacific. Because most of these fisheries are not extensively monitored, the effect of these direct and incidental takes on local populations is unknown.

Mesoplodont Whales (*Mesoplodon* spp.)

ROBERT PITMAN

Mesoplodont whales are found in nearly all of the deeper, oceanic waters of the world and they are by far the most speciose genus of marine mammal. But despite this, they remain among the least known large animals on the planet. Several species have never been identified alive in the wild, and at least one species is known only from skeletal remains. Although they are fairly common in some parts of the ocean, because of their shyness around vessels and unobtrusive behavior, they are rarely observed, even by those who study cetaceans at sea.

I. Characters and Taxonomic Relationships

The genus name *Mesoplodon* (Greek: *mesos*, middle; *hopla*, arms; *odon*, tooth; i.e., armed with a tooth in the middle of the jaw) was coined by Gervais in 1850. Ziphiids (beaked whales), including mesoplodonts, appeared suddenly in the fossil record in the lower Miocene (26 Mya), are well represented by the upper Miocene (5 Mya), and their diversity has declined steadily since then. Currently, there are 14 recognized species in *Mesoplodon* (Table I) and new species are still being discovered. In the Pacific Ocean, *M. peruvianus* (Reyes *et al.*, 1991) and *M. perrini* (Dalebout *et al.*, 2002) were recently described; *M. traversii* was resurrected as a distinct species (van Helden *et al.*, 2002), and another unidentified form from the central Pacific is perhaps a new species also (Dalebout *et al.*, 2007). Species limits in the group have been confirmed through a concordance of morphological characters and molecular genetics analyses (Dalebout *et al.*, 2004). Although no subspecies currently recognized within the group, *M. mirus* has disjunct populations in the North Atlantic and the southern Indian Ocean which have markedly different color patterns and they are genetically as distinct as some recognized species of mesoplodonts, suggesting at least a subspecific level of divergence. Longman's beaked whale (*Indopacetus pacificus*) was up until very recently known only from two skulls and has often been included within *Mesoplodon*, but is it now considered to be a separate, monotypic genus.

TABLE I
Living Species of *Mesoplodon*

Latin name	English name(s)	Length* (m)	Distribution
<i>M. hectori</i>	Hector's beaked whale; New Zealand beaked whale	4.4	Temperate waters of the Southern Hemisphere
<i>M. mirus</i>	True's beaked whale	5.3	Warm temperate waters of North Atlantic and southern Indian Ocean
<i>M. europaeus</i>	Gervais' beaked whale, Antillean beaked whale, Gulf Stream beaked whale	5.2	Warm temperate and tropical waters of the Atlantic
<i>M. bidens</i>	Sowerby's beaked whale; North Atlantic beaked whale; North Sea beaked whale	5.5	Temperate North Atlantic
<i>M. grayi</i>	Gray's beaked whale; Haast's beaked whale; scamperdown whale; small-toothed beaked whale	5.6	Temperate waters of the Southern Hemisphere
<i>M. peruvianus</i>	Pygmy beaked whale; Peruvian beaked whale; lesser beaked whale	3.9	Mostly tropical waters in the eastern Pacific
<i>M. bowdoini</i>	Andrew's beaked whale; deep-crest beaked whale	4.4	Temperate waters of the Southern Hemisphere
<i>M. traversii</i>	Spade-toothed beaked whale	?	Known from 3 strandings: islands off Chile and New Zealand
<i>M. carlhubbsi</i>	Hubbs' beaked whale; arch-beaked whale	5.3	Temperate North Pacific
<i>M. ginkgodens</i>	Ginkgo-toothed beaked whale; Japanese beaked whale	5.3	Tropical and warm temperate waters of Indian and (mainly western) Pacific oceans
<i>M. stejnegeri</i>	Stejneger's beaked whale; Bering Sea beaked whale; saber-toothed beaked whale	5.7	Subarctic and temperate North Pacific
<i>M. layardii</i>	Layard's beaked whale; strap-toothed beaked whale; long-toothed beaked whale	6.2	Temperate and subantarctic Southern Hemisphere
<i>M. densirostris</i>	Blainville's beaked whale; dense-beaked whale	4.7	Circumglobal in warm temperate and tropical waters
<i>M. perrini</i>	Perrin's beaked whale	4.4	Known only from strandings in California, USA

Figure 1 Selected Mesoplodon skulls and mandibles, the latter showing the diversity of tooth shape, size and placement within adult males of this genus (not to scale). (A) Dorsal view of *M. grayi* skull, (B) Lateral view of *M. grayi* skull; lower jaws of (C) *M. mirus*, (D) *M. hectori*, (E) *M. perrini*, (F) *M. grayi*, (G) *M. carlhubbsi*, (H) *M. stejnegeri*, (I) *M. bidens*, (J) *M. traversii*, (K) *M. layardii*, and (L) *M. densirostris*. Modified from Jefferson et al. (2008).

Historically, mesoplodont species have been diagnosed by features of the skull, relying mainly on the length of the rostrum, and the shape, size, and placement of teeth, especially of adult males (Moore, 1968; Fig. 1). However, due to anatomical similarities (especially of females and young), specimens have often been misidentified, even by experts, and molecular genetic analyses have become increasingly important for identifying individual specimens and even uncovering “cryptic” species (Dalebout et al., 2002, 2007; van Helden et al., 2002).

Mesoplodonts are small whales, ranging in size from 3.9 (*M. peruvianus*) to 6.2 m (*M. layardii*) (Table I); there are too few data to determine if there are consistent size differences between males and females, although in at least some cases females appear to be slightly larger, as is the case for most ziphiids. The body is spindle shaped, with a small, usually triangular dorsal fin located approximately two-thirds of the way back on the body (Fig. 2). The flippers are small and narrow and fit into pigmented depressions in the body. The unnotched flukes are usually straight across the trailing edge or even slightly convex. A single pair of external throat grooves is present between the mandibles that apparently assist in suction feeding (discussed later). The head is small and tapered; the melon is small and blends without a crease into

Figure 2 A rare photograph of a strap-toothed beaked whale (*Mesoplodon layardii*), the most distinctively patterned of all the mesoplodonts, lofting out over the Southern Ocean. This is an especially long-beaked species of Mesoplodon. Photography by S. N. G. Howell.

Figure 3 A Hubbs' beaked whale (*Mesoplodon carlhubbsi*) that stranded in Kanagawa, Japan in 2005. The erupted tooth (one on each side) identifies it as an adult male, and the white, linear scars on its head are tooth marks from skirmishes with other males; the red flesh is from beach abrasion. the beak. The blowhole is a half circle with the ends pointed forward and not always symmetric. Beak length is variable depending on the species, ranging from short (e.g., *M. densirostris*) to very long (e.g., *M. grayi*, *M. layardii*, and *M. bidens* Fig. 2).

Most species show three sexually dimorphic traits, all of which relate to male aggressive behavior at the onset of sexual maturity: (1) only adult males have functional teeth (tusks), (2) only adult males have extensive secondary ossification of the mesorostral canal, and (3) only adult males show extensive and conspicuous body scarring. These features are discussed.

Males apparently use their teeth for intraspecific fighting with other males to establish breeding hierarchies (Heyning, 1984). In fully mature males, a single pair of teeth erupts from the mandibles, projecting up, outside of the mouth. Depending on the species, the teeth are located anywhere from the tip of the lower jaw (apical), to about halfway back along the jaw, and they vary markedly in size and shape depending on the species (Fig. 1). The teeth are usually laterally compressed, although in *M. mirus*, which has the most apical teeth, they are oval in cross section. The tooth usually develops a sharp denticle on top for inflicting wounds, but this often worn down smooth in older males. In some species, the tooth is raised up on a high bony arch in the lower jaw (Fig. 3); in other species, the mandible is relatively straight and the tooth is surrounded and supported mainly by gum tissue.

A hypothesized evolutionary trend for mesoplodonts proposes that the occurrence of apical teeth is a primitive condition and more posterior locations are derived. Teeth positioned further back on the mandible apparently allow animals to attack more forcefully with their rostrum with less risk of damage to the mandibles or teeth. However, teeth positioned further back along the lower jaw need to be elevated or elongated so that they are not obstructed by the rostrum, which gets wider and deeper toward the base. Although it has been suggested that the different sizes and shapes of teeth could be used for species recognition among the various mesoplodonts,

Figure 4 The skull of an adult male strap-toothed whale *Mesoplodon layardii* showing asymmetrical blowhole and the remarkable way the teeth wrap around the upper jaw.

it is just as likely that tooth position and mandible development within this group correlate with differing amounts of male aggression among the different species. As an extreme example of tooth development, *M. layardii* has some of the most bizarre teeth of any known animal. They are long (at least to 34 cm) and curl back and over the rostrum so that they sometimes overlap each other, clamping the jaws nearly shut (Fig. 4). These teeth have dorsally projecting denticles and, judging by the amount of scarring on adult males, they are still effective for intraspecific fighting. However, in many individuals, tooth wear also results from the rostrum rubbing against the inner sides of the teeth. This clearly indicates that jaw movement is impaired, and the adaptive significance of tooth development in this species has never been adequately explained.

The mesorostral canal is a narrow groove in the midline of the upper rostrum that is filled with cartilage in most cetaceans. This cartilage is continuous with the mesethmoid and homologous to the nasal septum of terrestrial mammals. In adult male mesoplodonts, the cartilage is displaced by expansion of the vomer from below, which is composed of extremely dense bone, in some cases more dense than elephant ivory. When males attack, they make contact with the top of their rostrum and use their teeth with the mouth in

the closed position. It has generally been assumed that the heavily reinforced rostrum was selected to allow fighting males to be more forceful with their attacks while reducing the possibility of damage to the rostrum. A recent study, however, suggested that the bone of the rostrum, although very dense, was too brittle to provide mechanical reinforcement and that it might, e.g., have a hydrostatic role to assist in deep diving. Why this would be necessary for males and not females is not clear.

Color patterning among mesoplodonts is gradually becoming known. In general, females and young of most species are indistinguishable either at sea or stranded on the beach because they all tend to be nondescript gray or brown dorsally and somewhat paler ventrally. On the other hand, adult males of most species if seen well are often identifiable in the wild based on tooth shape and location and body coloration. For example, *M. mirus* (Southern Hemisphere form) has an all-white tail stock, dorsal fin, and flukes; *M. layardi* has a very distinctive black and white pattern (Fig. 2), and adult male *M. peruvianus* from the eastern tropical Pacific have a broad white swathe across the body that forms a conspicuous chevron when viewed from above.

The more conspicuous color patterning that most male mesoplodonts exhibit can be due either to normal pigment deposition (e.g., white beak and top of melon of *M. carlhubbsi*; Fig. 3) or to adventitious coloration caused by scarring. Most of the (often numerous) scars on mesoplodonts are attributable to either tooth rake marks from adult males or are the healed scars from the bites of cookiecutter sharks (*Isistius* spp., see below). Both sexes tend to collect the oval cookiecutter shark bite scars as they age but only the adult males acquire the numerous long, linear scars from encounters with other males. All mesoplodonts, except apparently *M. ginkgodens*, form white scar tissue over external wounds so that the body retains a permanent visual record of past injuries. As a result, among groups of mesoplodonts, adult males are usually easily recognizable by their prominent linear scarring (Fig. 3), which may be important for social signaling. In addition to heavy scarring, adult males (and, to a lesser extent, females) of some species have white pigment patches that may serve to highlight important anatomical landmarks, including the beak tip, head, lips, and genital area.

II. Distribution and Abundance

Mesoplodonts are so difficult to approach and identify under normal conditions that there are several species that have almost never been identified alive in the wild, including, e.g., *M. bowdoini*, *M. perrini*, *M. traversii*, *M. ginkgodens*, and *M. hectori*. Consequently, nearly everything known about their distribution and abundance has been inferred from relatively infrequent stranding events. As a group they are widespread, occurring in all of the world's oceans except for the coldest waters of the Arctic and Antarctica. They normally inhabit deep oceans waters (>2000 m) or continental slopes (200–2000 m), and only rarely stray over the continental shelf. The distribution of most species tends to be somewhat localized (limited to single ocean basins or a hemisphere within an ocean basin; Table I), although *M. densirostris* is found in all tropical and warm temperate oceans and is probably the most widespread and perhaps most abundant mesoplodont. Seasonality of stranding records suggests that at least some high-latitude species (e.g., *M. layardii*) may undergo some limited migration to lower latitudes during the local winter. *M. stejnegeri* in the Bering Sea sometimes have fresh cookiecutter shark bites suggesting that they probably moved up from warmer waters (discussed later).

III. Ecology

Very little is known about prey preferences of mesoplodonts. Based on stomach contents of stranded animals, they appear to feed primarily on relatively small (~500 g), mesopelagic squid (e.g., *Histioteuthis* spp., *Taonius* spp., *Gonatus* spp.). Meso- and benthopelagic fish are also taken (at least some of these fish, however, maybe secondary, i.e., squid prey) and in some species (e.g., *M. bidens*, *M. mirus*, and *M. grayi*), fish may comprise the most important prey items. Most prey are probably caught at depths of well over 200 m or more, using high-frequency echo-location clicks to detect them.

A reduced dentition among various species of odontocetes (toothed cetaceans) is generally interpreted as an adaptation for feeding on squid. Most squid-feeding cetaceans, including mesoplodonts, are thought to be suction feeders: prey is sucked in and swallowed whole. Large muscles at the back of the tongue (hyoglossus and styloglossus) are anchored to an enlarged hyoid bone; this allows the tongue to be retracted in a piston-like manner while the paired throat pleats allow distention of the mouth floor, creating the necessary vacuum for sucking in prey. Because ziphiids in general no longer need their teeth for feeding, this has freed them up to evolve for other purposes, i.e., as fighting weapons for males, or to be functionally lost altogether (females). It has been hypothesized that white pigmentation on the anterior floor of the mouth of many beaked whale species may serve as an attractant for bioluminescent squid.

IV. Behavior and Physiology

Until recently, almost nothing was known about mesoplodont behavior, partly because they are so rarely observed, but also because their behavioral repertoire at the surface is very limited and stereotyped. The most commonly reported behavior has been slow swimming, usually away from a vessel, and often a mile or more away. When undisturbed, they roll quietly several times at the surface and disappear, usually not to be seen again. Most groups surface simultaneously and within a few body lengths of each other, indicating that they are probably communicating as they forage in total darkness of the deep ocean. While at the surface, either traveling or stationary, individuals in groups usually remain within a couple body lengths of each other. Breaching (leaping out of the water; Fig. 2) has been recorded on only a very few occasions. Long-beaked forms (e.g., *M. grayi*, *M. bidens*, and *M. layardii*) often bring their beak up out of the water at a 45° angle when they surface. Normally there is no visible blow, and no species are known to lift their flukes when diving. Tail slapping has been observed on a couple of occasions. Although adult males are assumed to use their erupted teeth as tusks to fight with each other, none of these battles have ever even reported by human observers, even though the extensive scarring found among males of this group suggests that it must be of fairly frequent occurrence (Fig. 3). Photo-identification studies of *M. densirostris* in the Bahamas and around Hawaii indicate long-term site fidelity with individuals re-sighted in the same general area over a period of at least 15 years.

Recent technological advances, including DTAG (acoustic recording tags) and electronic time/depth recorders, have vastly improved our understanding of what these animals are doing during their long absences from the surface. Mesoplodonts are deep divers: suction cup time/depth recorders on *M. densirostris* in Hawaii indicated regular dive times from 48–68 min and reaching a maximum depth of 1408 m. Another study showed that between deep foraging dives, *M. densirostris*

spent about twice as much time near the surface undertaking a series of shallow dives, which, it was suggested, allows them to recover from an oxygen debt.

Vocalizations have been reported for only two species: *M. densirostris* and *M. carlhubbsi*. Recently, vocalizations recorded with a suction-cup acoustic recording tag indicate that *M. densirostris* uses two distinct click types associated with different phases of foraging: long duration, frequency-modulated clicks were used for detecting prey and short duration “buzz” clicks used when capturing prey (Johnson *et al.*, 2006). Mesoplodonts are also suspected of producing mid-frequency tonal sounds, similar to those used by other cetacean species for communication. This is apparently rarely used, at least near the surface, which may be a behavioral adaptation for avoiding detection by predatory killer whales (“acoustic crypsis”).

V. Life History

Because of their shy nature, oceanic habitat, and apparent rarity, very little is known about the biology of mesoplodonts, and nearly everything that is known has come from the examination of stranded animals. As in all cetaceans, females give birth to a single calf. Reported mean body length for calves at birth has ranged from 2.1 m for *M. europaeus* to 2.5 m for *M. carlhubbsi*, representing from 40–48% of the adult female body lengths (these are neither the largest nor the smallest mesoplodonts). The smallest mesoplodont calf reported to date was 1.9 m (*M. hectori*), although *M. peruvianus* will probably prove to be smaller. There is no information on gestation or lactation periods.

Longevity data for mesoplodonts are virtually nonexistent, although they may be quite long lived: a count of tooth layers in a specimen of *M. europaeus* suggests that it was at least 27 years old. A female *M. densirostris* estimated to be 9 years old (based on tooth layer counts) had just recently become sexually mature. Very little has been recorded in the way of diseases, parasites, or commensals (Mead, 1989). Osteomyelitis has been reported twice. Endoparasites recorded have included cestodes and occasional heavy infestations of nematodes (*Crassicauda* sp.) in the kidneys. Ectoparasites recorded include *Penella* sp. (a parasitic copepod) and cyamids. The erupted teeth of males often have stalked barnacles (*Conchoderma* sp.) attached to them; bunches of these often appear as “tassels” on the teeth of live animals at sea. A pseudo-stalked barnacle, *Xenobalanus* cf. *globicipitis*, sometimes attaches to the trailing edges of the flukes or dorsal fin.

Mesoplodonts occur in small groups typically ranging in size from 1 to 6 animals, although groups of up to 15 have been reported, and a mass stranding of 28 *M. grayi* occurred in New Zealand. Mean school size for 125 *Mesoplodon* sightings (including at least three different species) from the eastern tropical Pacific was 3.0, with 2 being the most common. Although mixed groups of adult males with females and calves have been observed at sea, there is some evidence from both sightings and strandings data that there may be some segregation by sex or age class at times. Predators of mesoplodonts probably include killer whales and large sharks, although direct observations are lacking. Mesoplodonts often have numerous white oval scars (diameter to about 8 cm) caused by the bites of cookiecutter sharks (*Isistius* sp.); one study in Hawaii counted 120 separate bite marks on the visible part of just one side of a *M. densirostris*. These are small (to about 50 cm), mesopelagic sharks that feed by snatching mouthfuls of flesh of larger fish and cetaceans. Although presumably painful, they do not appear to contribute to mesoplodont mortality.

VI. Interactions with Humans

So few mesoplodonts have been reliably identified at sea that it has been impossible to accurately determine the population status of any species, although based on stranding data, at least some species may not be as rare as the sighting records indicate. *M. grayi* and *M. layardii* appear to be widespread and fairly common in the Southern Ocean, as is *M. densirostris* in tropical oceans; these may be the most abundant mesoplodonts. Most species, however, appear to be neither numerous nor widespread, and some may be quite rare (e.g., *M. bowdoini*, *M. hectori*, *M. perrini*, *M. traversii*). The large number of species in this group suggests a high rate of endemism with naturally small populations and restricted ranges, all of which increases the vulnerability of individual species.

The two main human-caused threats to mesoplodonts are probably bycatch in fishing gear and anthropogenic noise. Although there has never been any directed fishery, a few are occasionally harpooned opportunistically by whalers, and unknown but potentially significant numbers are killed by high seas drift nets and longline fishing gear. Only stranded specimens have ever been kept in captivity and these have usually died within a few days (usually from pre-existing conditions).

Currently, the biggest threat to mesoplodonts, and beaked whales in general, may be anthropogenic noise sources, particularly those associated with airgun arrays (seismic surveys) and military mid-frequency sonar (2–10 kHz). Necropsies of mass-stranded beaked whales exposed to these sound sources have led to a hypothesis that mortality may be caused by gas-bubble disease induced by behavioral responses to acoustic exposure (Cox *et al.*, 2006).

Migration and Movement Patterns

S. JONATHAN STERN

Migration and movement are hallmarks of marine mammal behavior. Whether engaged in localized diving or ocean basin-scale displacements, marine mammals use their three-dimensional world in fascinating ways. One of the best ways to view how they use their world is through their movement. The focus of this chapter is to discuss migration and movement patterns in a general sense, using various species as examples, rather than to provide a species by species account.

Movement encompasses a hierarchy of displacements, ranging from a few meters to thousands of kilometers (Fig. 1). A *step* is a relevant distance moved, such as distance between surfacing sites

or distance traveled between fluke or flipper beats. A step should relate to some relevant distance. *Kinesis* refers to changes in turning or movement rates. *Foraging* is search for resources within a patch. A patch is an area within which resources are randomly distributed. The patch itself may be spatially constant while resource availability and distribution varies temporally. *Commuting* is movement between adjacent patches. *Ranging* is movement between regions. After searching patches in a region, an animal then moves to another region, spatially separated and defined by a different local set of oceanographic conditions. *Dispersal* is permanent movement from one area to another. It is impossible to talk about movement without an environmental context.

As an animal moves greater distances, it experiences greater environmental variability. Variability relates to, among other things, areas of high and low resource concentration, or patchiness. Resources include food, conspecifics (including mates), and space. Mates may only be seasonally receptive or available, or sexes may have a different spatial distribution in a particular season. Space is a variable resource because not all habitats are suitable, or available at all times. For example, high tide may cover rocks used for hauling out. In territorial species, once a territory is occupied, other individuals of the same species are excluded. In non-territorial species, crowding often occurs, and while suitable habitat is nearby, individuals crowd.

Foraging animals rely on predictable resources at a specific place at a specific time (scale). Resource variability requires a movement tactics that allows an individual to maximize its fitness. In a constant environment, an individual is likely to find food on most days, while in a high-variance environment, an individual may have difficulty finding food from one day to the next and for considerable stretches of time. This animal is essentially living in an energy sink environment with few areas of energy sources (Stern, 1998). Unless significant energy stores are available, that individual is going to run out of energy.

Marine mammals, by virtue of their large body sizes, require large home ranges (Calder, 1984). And given that resources distribution is variable in space and time, some home ranges are enormous. As home range increases in size, an individual experiences spatial and temporal environmental variability.

Consider a parcel of water with properties of temperature, salinity, dissolved oxygen, and nutrients. Two parcels of water 10 cm apart are more similar, in terms of temperature, salinity, dissolved oxygen, and nutrients than two parcels of water 100 km apart. In terms of depth, one parcel of water at the surface differs from a parcel of water at 100 m. Therefore, a diving animal experiences greater small-scale spatial variability than an individual moving along the surface. In addition, a single parcel of water may have similar oceanographic conditions 2 days apart but may differ significantly 2 weeks apart. And oceanographic conditions in early summer may be very different than those in mid or late summer. The timing of oceanographic conditions favoring primary production must coincide with periods of high hours of sunlight. Thus, resources are variable in space as well as time. Disparity in resource availability results in the necessity to move between places in the home range. Some parcels of water have food, but most do not. The parcels of water with food are rare so an individual has to move to find it. The term *variance* means that food is patchy.

Patchy prey resources require animals adapt to this spatial and temporal variability. The strategy is to conserve energy, since available energy is reduced during parts of the year. One tactic is to stay in a home area and tough out the hard times by somehow reducing the effects of variability. An individual that stays knows the area,

Figure 1 Different types of movements are described in the text.

reduces the energetic cost of moving, and does not encounter potentially adverse conditions along the way. Survival requires formation of denser fur, thicker BLUBBER layer for thermal protection and energy storage, or adopting a strategy such as hibernation. Female polar bears (*Ursus maritimus*) hibernate over winter, giving birth and feeding cubs until emerging from the den in spring. Other segments of polar bear populations do not hibernate, but make large-scale movements in search of food. For cetaceans, the cost of moving long distances while on migration is probably not very different than moving around in one location. Some pinnipeds conserve energy by hauling out or lying at the surface for extended periods. Energy is also conserved during dives by slow or no tail beats, or gliding. Ranging is a second strategy where an animal moves to another part of their home range where conditions are more favorable, such as a higher resource density, or where environmental conditions are better. Feeding generally occurs along the way. For example, Caribbean manatees (*Trichechus manatus*) move in relation to seasonal changes in water temperature preferring waters warmer than 68°F.

Migration is defined as regular, repeated, and large-scale movement between different sites of the home range (Dingle, 1996). Migration is at the extreme end of a continuum of large-scale displacements. The difference between migration and other large-scale displacements is that migration consists of persistent linear travel not distracted by resources. The goal is to move between sites each serving in a different life history role. Leaving a migration terminus is marked by a decrease in turning angles, resulting in linear travel. Upon arriving at the other migration terminus, turning angles increase in size and frequency resulting in station keeping. In addition, some form of energy re-allocation sustains migration, and time away from feeding grounds (Dingle, 1996). For marine mammals, these destinations are areas for feeding, breeding, birth, lactation, and molting. Pinnipeds generally forage between haul-out sites and feeding grounds. However, some phocids rely on stored energy while hauled out (Table I). Marine mammals have a suite of physiological adaptations for energy allocation and fasting, as well as storage and mobilization of fats to and from blubber stores. Fats are the most important

energy source, as lipids hold more energy per unit weight than other forms. Lipids are also less bulky than protein or carbohydrates because no water is required for storage. During feeding on productive feeding grounds, hyperphagia promotes increased lipid synthesis, fat uptake, and rate of fatty acid synthesis. Fats are stored when supply in blood exceeds metabolic demand and mobilization occurs when the demand for energy in blood exceeds supply.

Feeding in highly productive areas results in an increased fat store to support reproduction. Based on stomach contents analysis of whales killed on winter grounds, mysticetes are thought to feed little on migration routes and breeding grounds, living off stored blubber. However, recent evidence suggests that feeding occurs on the winter grounds, at least opportunistically. Some phocids such as elephant seals (*Mirounga* spp.) move long distances. They feed continuously to store energy to support time spent on breeding and molting haul outs. Stored energy is used for lactation in females and for mating and agonistic displays in males. Elephant seals lose much of their fat when hauled out and need to begin storing energy as rapidly as possible upon reentry into the water. Elephant seal movement can be viewed as migration, though feeding does occur along the migration route. Telemetry studies suggest areas with a higher frequency of deep dives, suggesting intense, localized feeding. Some of these highly productive areas are associated with seamounts. Hauling out for extended periods reduces energy loss to locomotion. Therefore, most of the stored energy can be used for reproductive activities and metabolism.

True migrating marine mammals are the mysticete whales, and their general migration patterns are shown in Fig. 2. However, energetic models suggest that mysticetes might have to feed at a reduced level while away from their feeding grounds (Lockyer and Brown, 1981). Migration was historically assumed to occur based on the occurrence of a particular species at given locations at different times of the year. However, documenting individual movement between locations was the only way to prove migration. Whaling provided the first real evidence for migration in large whales. Numbered darts were fired into dorsal blubber and muscle. If that individual was killed during subsequent whaling operations, tagging and killing dates and locations were compared and some assessment of movements were made. Some pinnipeds are marked with numbered flipper tags. Censuses were conducted on a number of haul-outs that documented tagged individuals moving between haul-out sites. Movement and migration patterns have been described in varying levels of detail using photo-identification and satellite telemetry. For example, locations of individual northern elephant seals (*Mirounga*

Figure 2 Generalized migration patterns of baleen whales in the Northern and Southern Hemispheres. Whales spend summers on productive feeding grounds and then migrate to the winter breeding/calving grounds in warmer waters. Most species of whales are believed to feed little, if at all, while away from their feeding grounds.

angustirostris) sent by satellites every 2 days revealed fascinating information on movement to and from areas of high food productivity, inferred by persistent signals from a relatively confined location, such as over a seamount. Intricate underwater movement has been described using telemetry devices showing that marine mammals do not swim in straight lines between surfacing locations.

The following scenarios are not migrations but are often labeled as such in literature. Seasonal movement may be a response to changing prey distribution. The occurrence of some groups of killer whales (*Orcinus orca*) in the inland waters of the Pacific Northwest correlates with the seasonal migration of salmon (*Oncorhynchus* spp.). Because these fish ultimately go upstream to die, the whales must find other prey during the winter. It is not clear if they feed on other species during the winter or go offshore to find other salmon schools. Gray seals (*Halichoerus grypus*) move to distinctly different areas on a seasonal basis to feed in productive areas in the Northwest Atlantic. Other large-scale movements are also not truly migration. For example, movement may be in relation to shifting environmental conditions, such as the seasonal advance or retreat of an ice edge. While geographic location of an individual changes, it is essentially maintaining itself in the same general environment.

Dispersal is not migration, as there is no return to the original area. Dispersal is colonization of new or re-colonization of historic breeding habitats. For example, breeding sites of northern elephant seals were historically on islands off the mainland of California, likely due to the presence of terrestrial predators on the mainland. In association with post-exploitation recovery and the decline of terrestrial predators, elephant seals returned to all historic breeding islands and invaded new sites on the mainland. Another example of a dispersal event was observed off California in response to the 1982–1983 El Niño Southern Oscillation event. Common bottlenose

dolphins (*Tursiops truncatus*) moved from southern California to San Francisco with the northward advance of warmer waters. This group of dolphins remained after the warm waters retreated back south.

Baleen whales require large quantities of high quality food. Such resources are found in productive cold waters so it is clear why they migrate to these areas. However, these areas have not been consistent over very long temporal scales. The poleward retreat of productive oceanic waters over the past 20,000 years changed regional productivity, migration routes, destinations, and foraging areas of many marine mammals. Increased ice extent and land emergence of the Pleistocene made current feeding grounds unavailable to gray whales (*Eschrichtius robustus*), bowhead whales (*Balaena mysticetus*), beluga whales (*Delphinapterus leucas*), narwhals (*Monodon monocerus*), walrus (*Odobenus rosmarus*), Northern fur seals (*Callorhinus ursinus*), and other seals. The North Atlantic north of 45° was an ice-bearing polar sea with conditions similar to the Antarctic Convergence, resulting in a larger, more productive sea than at present. The reduced distance between productive cold water and warmer water meant large-scale movement was not necessary (see Fig. 3). In the Southern Ocean, an equatorward shift in isotherms was in response to a northward extension of ice. The Antarctic convergence was 5° north of its current position. As cold, nutrient-rich waters retreated toward the poles, sunlight for photosynthesis became more seasonally variable leading to intense seasonal peaks in production followed by reduced production in winter. Over time, whale distribution followed the poleward retreat of fronts of productive oceans. Along with this the need to store massive amounts of energy for time away from feeding grounds.

A question remains as to why they migrate to warm waters for reproduction. Four reasons have been suggested for migration to

Figure 3 Post-Pleistocene distribution of the polar front in the North Atlantic Ocean. Lines represent the southern extent of sea surface temperature relating to the polar front. Numbers associated with each line are thousands of years before present. Whale movement from warm-water calving/breeding waters to cold productive feeding waters would have been similarly truncated toward the equator in the past. The equator-ward extension of cold water meant that productive seasons were probably longer in the past than at present due to increased hours of daylight.

warm water breeding and calving areas. The first is to minimize thermal stress on calves. This is likely not a problem for a newborn calf. Smaller mammals with less insulation are able to survive in those conditions. Because of its large body size, a calf is not likely thermally stressed.

The second reason to move to warm waters is resource tracking, i.e., following prey. By definition, this is not migration since foraging occurs along the way. Energetic models suggest that migrating (fasting) baleen whales need to feed, albeit at low levels while away from the feeding grounds. Whales likely feed on whatever they encounter, rather than tracking prey.

Killer whale predation on calves has been a suggested reason for mysticete migration. By migrating to warm, relatively killer whale-free waters to give birth, calf mortality would be reduced. Killer whales have recently been observed feeding on gray whale calves caught along their northward migration. These attacks occur where calves are most vulnerable, far from shore where the mother can lead the calf into the coastal kelp beds. Killer whales exploit this opportunistic but reliable resource.

The final reason to migrate is essentially an evolutionary holdover—individuals migrate because their ancestors did. The evolutionary holdover hypothesis includes feeding and reproduction into a life history strategy. Intense feeding leads to energy storage thus maximizing reproductive success. Natural selection favors individuals that are successful at migrating, feeding, reproducing, and responding to changing environmental conditions.

Resource distribution explains the summer distribution of baleen whales, and for whatever reason, they migrate to warm waters for reproductive activities. How do marine mammals initiate large-scale movement? Many species of marine mammals, and mammals in general, have highly seasonal reproductive strategies to time births relative to optimal environmental conditions. Day length is a cue for seasonal breeding in a number of birds and mammals and is invariant from year to year. The advantage is that an individual can maximize its use of seasonal prey resources as well as seasonally available mates.

Both circadian (daily) and circannual (yearly) cycles use light as a cue; however, the specific cues from light, or *zeitgebers*, vary. Circadian signals are dawn and dusk, whereas circannual signals are perceived as the ratio of number of light to dark hours in a 24-h period. Thus, both cycles are used for seasonal cues. Other cues may act as secondary synchronizers, although these, such as food availability, are more variable.

The pineal gland is responsible for time keeping in birds and mammals via the production of melatonin, as well as other compounds. The number of hours of darkness per 24 h is “counted” by the biosynthesis of melatonin, which is produced more in hours of darkness. At seasonal scales, as winter approaches, the hours of daylight decrease and hours of darkness increase. In a given 24-h period, the amount of melatonin produced increases, suppressing gonadal activity. In many mammals, the breeding season of females corresponds to periods of decreasing daylight per 24 h. Increasing daylight after the winter solstice is responsible for triggering estrus. Pineal glands are exceptional in size in polar species such as the Weddell seal (*Leptonychotes weddellii*) northern fur seal, and walrus, species that live where day length is most variable.

Testosterone and its metabolites trigger migratory behavior in some animals. Male California sea lions (*Zalophus californianus*) spend the bulk of the year hauled out in large bachelor groups. By June, they have left their haul-outs in central and northern

California, Oregon, Washington, and Alaska and migrated to the Channel Islands off southern California. Here, breeding occurs as males set up territories and defend females against other males with whom they spend most of the year in relatively peaceful coexistence. Once migration back to the feeding grounds is triggered in July, an individual is exposed to increasing hours of daylight per 24 h as it swims poleward. One benefit from such a signal is that it is invariant from year to year.

Since their entire migration take place close to shore, documenting migration in the Eastern Pacific Gray Whale is relatively easy. Given that the peak migration of gray whales is variable from year to year, environmental cues must be only partly responsible for onset of migration. If endogenous cues play a role, their influence may be at least partly overridden. It is enticing to speculate what will happen to gray whale migration, as well as arctic species as arctic ice retreats.

The mechanisms of orientation, plotting their location at any time, and navigation, directing movement from one location to another, are not known. Individuals are often seen in the same locations from one year to the next. In the interim, they have traveled thousands of kilometers, indicating that marine mammals use some type of cues for orientation and navigation between migratory destinations. Organisms tend to meander if they lack orientation and navigation cues. Therefore, marine mammals must know where they are at a given time (orientation) and where they are going next (navigation).

At the initiation of migration, a direction must be selected. Advancing ice may simply eliminate certain directions as a choice, displacing individuals toward the equator. In higher latitudes, changes in sea conditions influence prey availability, which may also trigger the migratory response. If either or both of these change, individuals will react accordingly.

Cues may vary over time and the course of migration. For example, once migration is initiated, the only cue necessary is which overall direction to travel: north, south, east, or west. Celestial navigation has been suggested as one mechanism of navigation. In the north–south directions, the relative location of the sun in the sky can be monitored. This may be as simple as “keep sunrise on the left side when migrating to the breeding ground and on the right side when migrating to the feeding ground” or as complicated as estimating latitude as a function of position of the sun. Navigation by star location has also been suggested as a mechanism.

Another possible large-scale cue is the direction of a major current if an animal is moving against it. Near the equator in the Northern Hemisphere, western boundary currents move from south to north, while eastern boundary currents move from north to south. Coastal processes and minor currents cause the deformation of major currents, resulting in the formation of gyres and eddies. Migrating whales may use these currents for a free ride and gyres, eddies, and smaller-scale features as landmark.

Magnetite in the brains of some species has been implicated as a mechanism by which individuals could track changes in the earth's magnetic field. Mass STRANDINGS often occur at the same location. These locations may have anomalies in the local earth's magnetic field, which cause whales to become disoriented and strand. A tantalizing example of the possibility of using magnetic cues is seen in humpback whales (*Megaptera novaeangliae*) migrating from Hawaii to Southeast Alaska. Tracks were within 1° of magnetic north.

At smaller scales, other cues could be used. For example, while mysticetes do not have a true sense of smell, they do have a well-developed Jacobsen's organ. This may allow them to “taste” differences

in water mass composition. For example, freshwater from ice melt or riverine input might provide a “taste trail” to a rich feeding ground, as a lens of fresh water floats on denser salt water.

Routes to and from feeding and breeding grounds may be variable or essentially a retracing of the migratory path. Male humpback whales migrate south from the Gulf of Maine relatively far offshore, while the return trip is much closer to shore. Gray whales along the west coast of North America probably migrate between calving lagoons in Baja California and feeding grounds in the Bering, Chukchi, and Beaufort Seas by following contours of the coastline. Gray whales migrate along the same nearshore corridor in both migratory directions. There is spatial or temporal segregation based on age class or gender. Northern elephant seals disperse from haul-out sites into the Gulf of Alaska; however, males go further north than females. Another way to look at this is male and female elephant seals are segregated on their feeding grounds, and migrate to haul-outs for breeding and molting.

In cases where a baleen whale species has a sufficiently long lactation period, offspring can learn migration routes and feeding locations from their mothers. In instances where offspring are weaned prior to reaching the feeding grounds, offspring are left to make exploratory migrations in hopes of finding suitable feeding grounds.

However, little is known about hormonal activity in relation to migratory movements. Prolactin is a hormone responsible for promoting milk production and lactation in mammals. It has the effect of increased fattening in birds. If there were a similar effect on mammals, it would be of importance. For pinnipeds, where lactating females leave pups for one to a few days, increased fat storage for milk is vital. A lactating female mysticete on the feeding ground would store fat relatively faster. This would not only provide for milk for the offspring but also help in restoring the female’s blubber layer for subsequent migration back to the breeding-calving grounds.

Within an ocean basin, stocks can be viewed as a metapopulation, which is a number of populations connected by the dispersal of individuals between them. If a species is distributed into populations spread over a sufficiently large area, environmental conditions are more or less independent between areas; therefore, a catastrophe in one area will not affect other populations. Dispersal reduces the risk of population extinction by minimizing the effects of chance environmental changes or changes in population demography. Further, genetic heterozygosity is maintained and the population is less likely to exhibit genetic problems. The probability of dispersal between metapopulations is an important thing to know.

A Steller sea lion (*Eumetopias jubatus*) metapopulation structure has been explored in Alaska. In the Aleutian Islands and Gulf of Alaska, these sea lions have declined by 50% since the 1960s. However, Steller sea lions from Southeast Alaska south to Oregon have remained stable or slightly increased during this time. Evidence from Alaska and the Aleutian Islands suggests that fragmentation will occur, with rookeries being reduced in size and eventually becoming extinct. One reason for hope would be if the population in Southeast Alaska became a source of dispersers into the Aleutian population. The Mediterranean monk seal (*Monachus monachus*) experienced a recent population decline with habitat fragmentation throughout its range. Large expanses of unsuitable habitat separate major pupping sites, with little chance of dispersal between the two remaining large populations, although each separate population may be viable over time.

Movement and migration models can be used to study the effects of changing environmental conditions. Migration in marine mammals evolved within the context of an environment that changes

over many spatial and temporal scales. The *rate* of change is as much a concern as the amplitude of the change. If populations are not able to adapt to the rate at which the environment changes, it will not survive. Species had to adapt to deal with novel situations and conditions. A polar front in the Pleistocene as described earlier retreated at a rate that allowed individuals to adapt to its changing distribution. Climatologists predict that global temperatures will increase by as much as 4.5°C in the next century. While it is clear that marine mammals are capable of adapting to changing environments, they might not be able to adapt at a rate commensurate with that of the change in environmental conditions in the near future. The potential implications are profound, and the environmental effects are not entirely clear.

Global warming will vary by latitude and environment, with polar and temperate regions affected to a greater extent than more tropical areas. Because these areas represent feeding grounds for migratory as well as resident species, understanding these effects is of considerable importance. The effect on marine mammals will likely be through changes in the distribution of resources in space and time. Key to survival will be how individuals respond to changes in resource distribution over space and time, and how this affects reproductive success. This hinges on an individual’s ability to move in response to changing environmental conditions.

Mimicry

PETER L. TYACK

The words “mimicry” and “imitation” often have a negative connotation in English of being an unoriginal fake. A mimic is often an annoying copycat, while an imitation can be a second-rate copy of a more valuable original. However, mimicry and imitation are based on special cognitive abilities that are rare among

animals and that form the basis of culture. Humans learn most cultural traits—from the words in our language to the way we prepare food or hold a tool—through observational learning and imitation. We must learn thousands of these cultural traits through imitation before we can make an original contribution to our culture.

Imitation is a form of social learning—it requires an animal to observe a “demonstrator” performing a behavior and then to be able to perform that behavior itself (Galef, 1988; Whiten and Ham, 1992). Many psychologists distinguish between vocal learning, in which an animal modifies the sounds it produces based on the sounds it hears, and motor imitation, which involves an animal watching a posture or movement of another animal and then copying that movement—“monkey see, monkey do.” Some also distinguish between motor imitation of something like clapping, where the animal can watch its hands in the same way that it watches the demonstrator, versus facial gestures or whole body movement, where the actor cannot receive sensory input about its own performance that directly parallels the observation of the demonstrator. However, the discovery of neurons in the premotor cortex of monkeys (Rizzolatti and Craighero, 2004) that fire either when the monkey sees a specific action performed by another monkey or when it performs the same action itself suggests that specialized neural mechanisms may facilitate the ability of animals to equate their own actions with observation of the actions of others.

There is strong evidence for vocal learning and imitation among a variety of animals, including marine mammals and birds (Janik and Slater, 1997). Perhaps the simplest evidence involves vocal mimicry, where an animal demonstrates the ability to produce sounds after exposure to model sounds that were not part of its pre-exposure repertoire. Animals such as parrots (Todt, 1975; Pepperberg, 2000), starlings (West *et al.*, 1983), and a harbor seal (*Phoca vitulina*) named Hoover (Ralls *et al.*, 1985) have demonstrated abilities to imitate the sounds of human speech. Other animals such as dolphins have been trained to imitate acoustic features of artificial sounds (Richards *et al.*, 1984).

Humpback whales, *Megaptera novaeangliae*, have not been kept in captivity where one could most easily study imitation of manmade sounds, but their songs have a structure that cannot be explained by any mechanism other than vocal imitation. At any one time, most singing humpback whales within a population sing songs that are similar (Tyack, 1999). These songs change week by week, month by month, and year by year, and individual whales have been shown to track these changes. Humpback songs have been recorded for decades, with no suggestion that the songs repeat. This suggests that humpback whales learn to produce the current song and to track the progressive changes that make up such a distinctive feature of this signal.

Vocal imitation has also been reported for the natural sounds of bottlenose dolphins (*Tursiops truncatus*). Most dolphins studied in either captive or wild settings develop an individually distinctive signature whistle. Dolphins can imitate the whistles of social partners (Tyack, 1986). Three male Indian Ocean bottlenose dolphins (*T. aduncus*) that formed a strong social bond were reported to modify their whistles over 3 years as the bond formed, such that all three converged on a shared whistle (Smolker and Pepper, 1999). Watwood *et al.* (2004) showed that five pairs of male bottlenose dolphins in Sarasota, Florida each had developed whistles more similar to their partner than to the other pairs. The functions of this imitation are currently not known, but similar imitation has been suggested to function as a name for reference (Tyack, 1999), as a threat (Janik and Slater, 1997), or as an affiliative signal (Smolker and Pepper, 1999).

It has been controversial whether animals can perform motor imitation (Galef, 1988). This stems in large part from the difficulty of proving that a display of which the demonstrator was capable was not part of the pre-exposure repertoire of the animal. Ethologists expect that many animal displays represent fixed action patterns that are inherited. If an action pattern is simply triggered by sensing a conspecific performing the same action, that triggering alone does not demonstrate observational learning. There are many anecdotes about motor imitation in marine mammals which are difficult to explain via any mechanism other than observational learning. Tayler and Saayman (1973) provided some of the most interesting examples. They reported captive bottlenose dolphins swimming with postures and motor patterns similar to those of seals, turtles, fishes, and penguins which were housed in the same pool. These postures and swimming patterns are so awkward and different from normal dolphin locomotion that it is scarcely credible that they represent anything other than learned behaviors. The most striking example of imitation involved a calf Indian Ocean bottlenose dolphin that observed through an underwater window a human blowing out a cloud of cigarette smoke. The calf swam over to its mother, suckled, swam back to the window, and expelled a mouthful of milk into a cloud that looked similar to exhaled tobacco smoke! This kind of anecdote clearly suggests that it would be worth conducting careful experimental tests of motor imitation in cetaceans.

A good teacher can shape our behavior in ways that may look like imitation, but only demand associative learning on the part of the student. Animal trainers can shape the behavior of animals in the same way. If wild animals were to train one another in this way, this could create a faulty appearance of imitation, but this is thought not to be a problem for there is little evidence that one animal will train another to perform an action it has mastered (Caro and Hauser, 1992). However, there are some indications of what might be called teaching in cetaceans. Tyack and Sayigh (1997) provided suggestive evidence for possible teaching of signature whistles in wild bottlenose dolphins, and Guinet and Bouvier (1995) suggested that killer whales (*Orcinus orca*) teach the young how to strand to catch pinnipeds on the beach. Rather than being an alternative to passive observational learning, teaching appears at least in our own species to function in tandem with observational learning. This potential synergy between teaching and imitation would be most likely to benefit highly social animal groups, such as carnivores, primates, and cetaceans, in which cultural traditions for foraging provide a strong selective advantage. These kinds of observations in wild cetaceans, coupled with careful experimental tests with captive cetaceans, suggest that cetaceans are promising subjects for the study of mimicry in the development of cultural traits in animals.

late 1990s (Rice, 1998; IWC, 2001), but a few workers have withheld judgment about the best taxonomic arrangement pending further studies (Kato and Fujise, 2000). The two species are partially sympatric in the Southern Hemisphere, where a small form (unnamed subspecies) of the common minke whale, the dwarf minke whale, is much smaller than the Antarctic minke whale and possesses the distinct white flipper mark that is characteristic of the species in the Northern Hemisphere and absent in the Antarctic species (Fig. 1). The two species also differ in relative size and shape of several cranial features (Arnold *et al.*, 1987) and in mitochondrial DNA sequences (Pastene *et al.*, 1994). Based on genetic data, the two species are hypothesized to have diverged less than 5 million years ago in the Southern Hemisphere (Pastene *et al.*, 2007).

Phylogenetic relationships of the minke whales to other Cetacea are yet unsettled. In a recent mtDNA control-region tree and in an earlier study including mtDNA and nuclear genes, the two species were sister taxa, in turn sister to the rest of the balaenopterids and the gray whale, *Eschrichtius robustus* (Sasaki *et al.*, 2006; Rychel *et al.*, 2004). In other trees and studies based on cytochrome *b* sequences, nuclear introns and sines, their position was more ambiguous. In a cladogram based on color-pattern characters, they were sister to the fin whale, *B. physalus* (Arnold *et al.*, 2005).

Rice (1998) recognized three subspecies of the common minke whale: the North Atlantic minke whale (*B. a. acutorostrata*), the North Pacific minke whale (*B. a. scammoni*, formerly *B. a. davidsonii*), and the unnamed Southern Hemisphere dwarf minke whale. The dwarf minke whale is genetically closer to the North Atlantic than to the North Pacific form.

The common name comes from Norway. One story has it that a hapless whale spotter named Meincke identified a minke whale as a blue whale, and thereafter small rorquals were called "Minkie's whale." Other common names that have been applied to the minke whales include "lesser rorqual," "little piked whale," "sharp-headed finner," and "lesser finback." Somewhat confusingly, the Antarctic minke is also called "ordinary minke whale" in older IWC literature.

In both species, the rostrum is very narrow and pointed and there is a single ridge on the head. The dorsal fin is relatively tall and falcate and is located relatively far forward on the posterior one-third of the body (in comparison to the larger rorquals). The average length of the common minke whale in the North Atlantic at physical maturity has been estimated variously at about 8.5–8.8 m in females and 7.8–8.2 m in males (Horwood, 1990). One estimate for the North Pacific is 8.5 in females and 7.9 in males. Female Antarctic minke whales are estimated to average 9.0 m at maturity and males 8.5 m. The dwarf minke whale of the Southern Hemisphere is on average about 2 m shorter than the Antarctic minke whale (Kato and Fujise, 2000). The white flipper mark of the common minke whale extends up onto the shoulder in the dwarf subspecies of the Southern Hemisphere (Fig. 1). The BALEEN is white in the northern subspecies of the common minke whale but appears dark-gray or brown posteriorly in the dwarf subspecies due to a narrow dark fringe. In the Antarctic minke whale, the baleen plates are black on the left beyond the first few plates and on the right they are white in the first third and black in the rear two-thirds of the row. The baleen filaments in both species are coarser than in the sei whale but finer than in fin, blue, and Bryde's whales, about 3.0 mm in diameter (Kato and Fujise, 2000). The SKULL (Fig. 2) is larger in *B. bonaerensis* than in both northern and southern forms of *B. acutorostrata*. The modal number of vertebrae in both species is about 49, ranging from 46 to 51.

Minke Whales

Balaenoptera acutorostrata and *B. bonaerensis*

WILLIAM F. PERRIN AND ROBERT L.
BROWNELL, JR.

Until relatively recently, only one species of minke whale was thought to exist (common minke whale); all minke whales were referred to *Balaenoptera acutorostrata* (Lacépède, 1804) (e.g., in Stewart and Leatherwood, 1985). Morphological and genetic evidence of a second species accumulated through the last quarter of the twentieth century, and the Antarctic minke whale, *B. bonaerensis* (Burmeister, 1867) came to be fully recognized in the

I. Distribution and Abundance

In the North Atlantic, the common minke whale is found in summer as far north as Baffin Bay in the Canadian Arctic, Denmark Strait, Franz Josef Land, and Novaya Zemlya (IUCN, 2008). The wintering grounds are poorly known but extend at least to the Caribbean in the west and the Straits of Gibraltar in the east. It is considered as a visitor to the Mediterranean. Affinities of minke whales reported from farther south to Senegal are unknown. In the North Pacific, the summer range extends to the Chukchi Sea. In the winter, common minke whales are found south to within 2° of the equator, although those south of central Baja California, Mexico, in the eastern North Pacific are of unknown relationship to the whales farther to the north. It has been seen off Hawaii. It is not known to occur in the northern Indian Ocean. In the Southern Hemisphere, the distribution of the dwarf subspecies is poorly known. It extends as far north as 11°S in the western Pacific off Australia and 2°S off South America in the Atlantic nearly year-round. It has been reported from Chilean waters (Acevedo *et al.*, 2006). In the far south, it is seasonally sympatric with the Antarctic minke whale on the FEEDING grounds during austral summer and occurs off South Africa during the fall and winter. Where sympatric with the Antarctic minke whale, it tends to occur in shallower, more coastal waters over the continental shelf.

Antarctic minke whales are abundant from 60°S to the ice edge during the austral summer, some occurring in the loose ice pack and in polynyas (IUCN, 2008). Some have been recorded to over-winter in the Antarctic. During the austral winter, most retreat to breeding grounds at mid-latitudes: 10–30°S in the Pacific between 170°E and 100°W, off northeastern and eastern Australia, off western South Africa, and off the northeastern coast of Brazil. In these areas their distribution is primarily oceanic, beyond the continental shelf break. One specimen is known from Suriname in the Northern Hemisphere.

Abundance has been estimated for four stocks of common minke whales in the North Atlantic (IUCN, 2008): Northeast Atlantic, about 81,000; Central North Atlantic, about 94,000; West Greenland, about 3500; Canada/US East Coast, about 4000. These total about 182,000. Abundance estimates exist for some areas of the North Pacific (areas may have substructure): Okhotsk Sea (West Pacific), about 25,000; west coast of US, about 1000; central and southeastern Bering Sea, about 2000. Abundance of the Southern Hemisphere dwarf minke whale has not been estimated. Population substructure in the eastern North Pacific is suggested by different calls recorded east and west of 135° (Rankin and Barlow, 2005).

Antarctic minke whale stocks in the Southern Hemisphere have been thought to be still in good condition and stable. However, the older estimates in the neighborhood of 750,000 have been abandoned because a substantial decline may have occurred in recent decades. A new assessment is underway to estimate the current abundance of this species (IWC, 2008).

II. Ecology

Common minke whales inhabit both coastal and offshore waters. Density of Antarctic minke whales in the austral summer is greatest near the edge of the pack ice, but they also occur within the pack ice (Shimada and Kato, 2006). Both species of minke whales are catholic feeders but specialize with season and area. In the North Atlantic, reported diet items include sand lance, sand eel, salmon, capelin, mackerel, cod, coal fish, whiting, sprat, wolffish, dogfish, pollack, haddock, herring, euphausiids, and copepods (Stewart and

Leatherwood, 1985); krill (euphausiids) are important off West Greenland, whereas capelin and cod are dominant prey in eastern Newfoundland. In the North Pacific, major food items include euphausiids, Japanese anchovy, Pacific saury, and walleye pollack. In the Antarctic, dwarf minke whales feed mainly on myctophid fishes (Kato and Fujise, 2000), whereas Antarctic minke whales feed mainly on euphausiids.

Killer whales (*Orcinus orca*) prey on minke whales of both species. By one Russian estimate, Antarctic minke whales make up 85% of the diet of killer whales in the Southern Ocean, although this may relate to the diet of only one of the two forms of killer whales found there (Pitman *et al.*, 2007).

III. Behavior and Physiology

Common minke whales are noted for their curiosity about ships, often coming from afar to cross the bow or run with the vessel for minutes or hours. Their sudden appearance on the bow or alongside has startled many an observer. They are difficult to spot at a distance because of their small inconspicuous blow and brief surfacing behavior. Antarctic minke whales are reported to be easily approachable while feeding. Dwarf minke whales in the Great Barrier Reef region of northeastern Australia readily approach and stay with divers and are the subject of a WHALE-WATCHING tourist operation.

Single animals are often seen and groups are usually small, consisting of two or three individuals, although larger aggregations of up to 400 may form on occasion in high latitudes.

Minke whale sounds recorded in the North Atlantic included grunts, thumps, and frequency down sweeps ranging to 200 Hz. Similar down sweeps have been recorded in the Ross Sea. In the Pacific, the long-mysterious “boing” heard by acousticians has been identified as produced by common minke whales (Rankin and Barlow, 2005).

IV. Life History

Differential migration by sex and age leads to segregation by sex and breeding condition. Mating behavior has not been directly observed. Breeding is diffusely seasonal in the common minke whale in the Northern Hemisphere, with calves of 2.4–2.7 m appearing approximately 10 months after conception. Lactation lasts 5–6 months. Age at attainment of sexual maturity has been estimated at about 7 years in males and 6 years in females. The pregnancy rate among adult females in some populations approaches 90%; suggesting an annual reproductive cycle. Little is known of the life history of the dwarf minke whale, but limited data available suggest similarity with that of the northern forms. The Antarctic minke whale also exhibits similar life history parameters (Horwood, 1990). Age at attainment of sexual maturity is 8 years in males and 7–8 years in females (although it may have been higher when overall whale densities were much higher earlier in the twentieth century). Pregnancy rates remain at or near 90% for most of the year, again suggesting an annual cycle on average. Generation time is estimated at 23 years (IUCN, 2008). Peak births are in July and August. During the feeding season, mature females are found closer to the ice than immature females, and immature males are more solitary than mature males.

V. Interactions with Humans

The minke whales in the Southern Ocean were largely ignored in the early days of modern industrialized whaling because of their small size, but as the larger rorquals (blue, fin, and sei) were successively

depleted, attention turned to the still abundant minke whales in the early 1970s. After 1979, only minke whales were allowed by the IWC to be taken in factory-ship operations. Annual catches in the Antarctic ranged to about 8000 (details on all world catches are given in Horwood, 1990) by Japan and the USSR. Hundreds were also taken from land stations in Brazil and small numbers in South Africa. As of the 1985/1986 Antarctic season, all commercial whaling was banned under an IWC moratorium. Meanwhile, Japan has continued to take Antarctic minke whales annually under a research permit issued under the terms of the whaling convention. The annual research catch limit was increased in the 2005/2006 season to 935, up from 400 (IUCN, 2008).

Common minke whales have also been exploited commercially in the North Pacific and North Atlantic, in both land-based and pelagic whaling operations. Some stocks were depleted and became fully protected under IWC regulations, including the west Greenland, north-eastern North Atlantic, and Sea of Japan—Yellow Sea—east China Sea stocks. The main whaling nations involved were Norway and Japan, with catches also by Korea, China, and the USSR. Catches from land stations in Japan continued until the moratorium on commercial whaling in 1987. In the 1990s, Norway recommenced commercial whaling on minke whales in the North Atlantic under an objection to the 1986 moratorium; the take in 2006 was 521 out of a self-imposed quota of 1052 (IUCN, 2008). In the North Pacific, Japan began taking minke whales under a scientific research permit in 1994; the nationally established annual limit for 2006 was 220. Minke whales in the region are also subject to significant bycatch (100s of animals) in set nets in Japan and Korea.

Aboriginal subsistence whaling is exempt from the IWC moratorium on commercial whaling, and localized whaling for North Atlantic minke whales has continued under this provision in West Greenland. In 1999, 165 minke whales were landed, and the current IWC annual catch limit for the years 2003–2007 was 175. The impact of this whale fishery on the West Greenland stock is not known.

In summary, most minke whale stocks are in better condition than most stocks of the other large whales, but questions remain about the status of some populations and the effects of continued whaling. Also, there may be threats to their habitats due to global warming, e.g., a great reduction of extent of sea ice is expected in this century as mean Antarctic temperatures rise faster than the global average (Turner *et al.*, 2006); the implications of this for minke whales are unclear but need to be monitored.

Northern common minke whales are the subject of whalewatching in Europe and the far east, including Japan (Hoyt, 2003, 2005), and dwarf minke whales off northeastern Australia (Arnold *et al.*, 2005).

Molecular Ecology

A. RUS HOELZEL

Molecular ecology explores the interrelationship between ecological and evolutionary processes. From a practical point of view, this often means the application of molecular methods to ecological studies. Applications include individual-based genetics (e.g., assessing kinship to better understand evolutionary strategy), population studies (e.g., to understand the ecological context of population genetic structure), and inter-specific analyses (e.g., to better understand the ecological drivers of speciation). Mammals in the marine environment have adapted to the challenges of aquatic life with some dramatic changes in anatomy, physiology, and behavior. This is especially relevant to molecular ecology when characteristics of the marine habitat, or behaviour enabled by these adaptations, affect patterns of dispersal, reproductive behaviour, and demographics.

For example, while many cetacean species can move great distances and have broad tolerance for different habitats with respect to breeding and foraging, pinnipeds are tied to suitable terrestrial habitat for breeding (e.g., isolated from predators), but must forage at sea. Characteristics of the resource exploited by pinnipeds means that some populations can forage near breeding grounds, while others must travel great distances in search of prey. Resources can also limit the distribution of suitable breeding grounds. These factors affect population genetic diversity and structure through an impact on dispersal range and the “effective size” of populations. The effective population size (N_e) is the size of an ideal population (random mating and unaffected by processes such as mutation and selection) that would show the same rate of decay in genetic diversity as the observed population. Population size can be very large at a breeding colony where the resource is local and abundant (and therefore genetic diversity can be high), as seen especially for some otariid species. Phocid seals, on the other hand, often travel great distances on foraging excursions, and breeding colonies are often smaller than for otariids (or restricted to breeding pairs).

The following sections will briefly address the main aspects of molecular ecology in marine mammal species, with a focus on the most abundant taxonomic groups, the cetaceans and the pinnipeds.

I. Genetic Diversity

Genetic diversity decays by genetic drift more quickly over time in populations with smaller effective population size. Within populations, reproductive strategy can impact the level of diversity, since reproductive skew (such as polygynous mating) reduces N_e . The potential for polygyny has been suggested to depend on various aspects of resource exploitation, and in pinnipeds on the consequences this has for the clumping of females (see Boness, 1991). If females are clumped and not too synchronous in estrus, males can monopolize the mating of multiple females to the exclusion of other males (polygyny). Most of the otariid species are polygynous, but only a few of the phocid seals. The phocid elephant seals provide a good illustration of both the potential role of polygyny and the impact of excessive hunting on the loss of genetic diversity. There are two closely related species, the northern (*Mirounga angustirostris*) and the southern (*M. leonina*) elephant seals. Behavioral and genetic studies have shown that these species are among the most polygynous of mammals (LeBoeuf, 1972; Hoelzel *et al.*, 1999).

In the ninetieth century elephant seals were exploited heavily for their blubber in both hemispheres. The southern species retained relatively large population numbers, but the more accessible northern species was forced through a severe population bottleneck (Bartholomew & Hubbs, 1960; Hoelzel *et al.*, 1993). Molecular genetic variation in the northern elephant seal is now low at mtDNA, allozyme, immune system, and repetitive DNA loci (see review in Hoelzel, 1999), consistent with predictions based on simulation models given the severity of the bottleneck (Hoelzel *et al.*, 1993; Hoelzel, 1999). The direct loss of diversity, due to the bottleneck, was shown through the comparison of samples collected before and after the bottleneck (Hoelzel *et al.*, 2002). By comparing post-population bottleneck genetic diversity with demographic simulation models and historic data, Hoelzel *et al.* (1993) estimated the severity of the population bottleneck to be fewer than 30 seals over a 20-year period, or a single-year bottleneck of fewer than 20 seals.

Simulation studies illustrate the role of polygyny in further reducing genetic variation during the period of recovery (Hoelzel, 1999). A survey of 54 allozyme loci at an average of 99 individuals per locus revealed no variation (Bonnell and Selander, 1974; Hoelzel *et al.*, 1993). The estimated bottleneck of 20 seals would not have been sufficient to eliminate variation at these loci in a monogamous species, but polygynous mating results in high variance in male reproductive success, and this increases the impact on diversity. The reason is simply that relatively few males are contributing to the gene pool. Figure 1 illustrates how a bottleneck of less than 20 seals can account for the loss of allozyme diversity when you take into account the observed level of polygyny. Only those simulations based on polygynous mating (open bars) predict a level of post-bottleneck diversity that is low enough to be consistent with the measured levels of diversity.

Many other marine mammal species have also been the subject of intensive hunting. Molecular methods can help assess the impact and track recovery. For example, an interspecific comparison of right whale species showed reduced variation in the North Atlantic right whale (*Eubalaena glacialis*) compared to the Southern Hemisphere species (*E. australis*). Waldick *et al.* (2002) analyzed 13 microsatellite DNA loci developed from the *E. glacialis* genome, and found all 13 to be polymorphic in *E. australis*, but only nine were polymorphic in *E. glacialis*. Average heterozygosity was also reduced in the North Atlantic right whale. Long- and short-term estimates of effective population size (N_e) suggested an N_e of approximately 100–300 for this species since the eightieth century, and about 4–8 times larger between the eleventh and eighteenth centuries. However, Waldick *et al.* (2002) found only weak evidence of a population bottleneck using methods that detect recent events (though these do not reliably detect all bottleneck events). This and a study showing relatively high mtDNA diversity in historical samples (late ninetieth and early twentieth century) suggest that diversity could have been decaying over time prior to the intensive hunting of the ninetieth century (Rosenbaum *et al.*, 2000).

In studies on a related species, also heavily impacted by whaling, Rooney *et al.* (1999, 2001) showed that the modern BCB stock (Bering–Chukchi–Beaufort Seas population) of the bowhead whale (*Balaena mysticetus*) has relatively high diversity at both microsatellite DNA and mtDNA markers. They suggest that the recent intensive whaling on this stock did not significantly reduce genetic variation. This population is understood to have been isolated from the now nearly extinct Spitsbergen stock (Greenland, Norwegian, Barents, and Kara Seas) during periods since the last glaciation by the M’Clintock Channel ice plug. Bjørge *et al.* (2007) investigated mtDNA diversity for the Spitsbergen stock over a Holocene timescale, sequencing 99 historical samples ranging in age from 30–51,000 years

Figure 1 This graph illustrates for the northern elephant seal the predicted impact of population bottlenecks of various sizes (along the x-axis) on a measure of genetic diversity (heterozygosity) following the bottleneck. The shaded bars are based on simulations that assume monogamous mating, while the open bars are based on simulations assuming observed levels of polygyny. No allozyme heterozygosity was found in the modern population, but the arrow indicates the average heterozygosity that would have been seen (0.00018) if just one individual had been heterozygous at just one locus. After Hoelzel (1999).

old. (Increasingly studies are incorporating the analysis of ancient DNA, which can greatly enhance our understanding of patterns of change over time.) In this case the samples had been preserved by cold weather and the success rate was comparatively high. They found comparable levels of diversity in the historical Spitsbergen and modern BCB stocks, consistent with the idea that diversity in the BCB stock had not been substantially depleted, and they found a low but significant level of genetic differentiation between these stocks. Comparing early and late Spitsbergen samples suggested little change in this pattern over time.

A direct comparison between samples from before and after periods of hunting and population depletion in the sea otter (*Enhydra lutris*) showed a loss of diversity directly attributable to the anthropogenic bottleneck (Larson *et al.*, 2002), as had a similar study on the northern elephant seal (Hoelzel *et al.*, 2002). Other studies on pinnipeds have either indicated lost diversity due to hunting pressure (e.g., for the Mediterranean monk seal, *Monachus monachus*; Pastor *et al.*, 2004) or suggested that sealing-induced pressure has not had a substantial impact on diversity (e.g., for the Cape fur seal, *Arctocephalus pusillus*; Matthee *et al.*, 2006). The latter study used a coalescent method to detect a much older population expansion in that species and suggested that this was related to abundant food resources in the South Atlantic during the last glacial period. Other studies have used coalescent methods to estimate past population sizes, e.g., pre-whaling populations of baleen whales (Roman & Palumbi, 2003). However, these estimates are complicated by their dependence on parameter estimates (especially mutation and migration rates) which are not well known but can influence N_e estimates substantially (Baker & Clapham, 2004).

II. Individual Genetics

Molecular methods can also enhance our understanding of the relationships among individuals within populations. At the most basic level, genetic markers can help us identify individual animals. The identification of individuals has been a fundamental method contributing to our better understanding of marine mammal species and has typically been based on acquired or congenital distinguishing markings (e.g., pigmentation patterns and scars) or tags. However, sometimes individuals are hard to tag or are not naturally well marked,

or despite good individual markings numbers of animals are so large as to make visual identification difficult. The latter case is exemplified by a very large-scale survey of humpback whales (*Megaptera novaeangliae*) in the North Atlantic using genetic tags (Palsbøll *et al.*, 1997). This study genetically identified nearly 2400 individual whales (using six polymorphic microsatellite DNA markers) and “recaptured” 692 of them. The 692 repeat-sampling events provided new information on migration patterns and evidence of mixing on feeding grounds, and because it was genetically based, also permitted the identification of the sex of each individual.

Another important application at the individual level is to consider fitness in the context of genetic diversity (measured, e.g., as the proportion of loci heterozygous in that individual). There are many studies showing impact on survival or some indirect measure of fitness (such as fluctuating asymmetry) for a diversity of animal species (see review in Hansson and Westerberg, 2002). Comparatively few such studies exist for marine mammals, but they show consistent results. For example, Acevedo-Whitehouse *et al.* (2003) showed that pathogen susceptibility was correlated to genetic diversity in the California sea lion (*Zalophus californianus*), while less diverse striped dolphins (*Stenella coeruleoalba*) appeared to have been affected more severely by a morbillivirus outbreak (Valsecchi *et al.*, 2004). With respect to indirect measures, fluctuating asymmetry was shown to increase in the northern elephant seal directly after a severe population bottleneck (that also severely reduced genetic diversity; Hoelzel, 1999; Hoelzel *et al.*, 2002).

Perhaps the most common application is toward the assessment of kinship. For pinnipeds the focus has been on testing paternity, e.g., to assess the comparative success of harem holders in the highly polygynous northern and southern elephant seals. Variance in reproductive success among males of the northern species was high and not always consistent with copulatory success (Hoelzel *et al.*, 1999). However, behavioral and genetic assessments of male paternal success were generally consistent for the southern species (Hoelzel *et al.*, 1999; Fabiani *et al.*, 2004). The authors suggest that some northern elephant seal males may have been reproductively compromised following the severe bottleneck event, as has been seen for other species (e.g., lions, *Panthera leo*; Wildt *et al.*, 1987). Although many pinniped species are highly gregarious during the breeding season, there is little evidence that kin typically associate over extended periods. In a study on the southern elephant seal, Fabiani *et al.* (2006) found that females at the colony were more closely related than males, but while there was evidence for some long-term association among female kin, these associations were rare. There were also no indications that females choose harem males to which they are either more or less closely related than expected by chance.

Some of the most interesting studies involving kinship analysis have been on the highly social species in the delphinid radiation. Bottlenose dolphins (*Tursiops* sp.) exist in fission/fusion social groups, but male associations in “alliances” can be long-lasting. Krützen *et al.* (2004) tested the paternity success of alliance members at Monkey Mia in Australia and found that independence from alliances did not preclude paternity, though membership in some alliances could lead to greater success. In a number of species, associated male kin pursue access to females together, perhaps gaining indirect fitness benefits (e.g., in lions; Packer *et al.*, 1991). This may have been the case for some bottlenose dolphin alliances in the Bahamas (Parsons *et al.*, 2003), but apparently not at Monkey Mia (Möller *et al.*, 2001). However, evidence for adult female kin associations has been found for bottlenose dolphins at Monkey Mia (Möller *et al.*, 2006) as well as for striped dolphins in the Mediterranean Sea (Gaspari *et al.*, 2007).

Among the baleen whales, the humpback whale shows highly social behaviors on the breeding grounds, including the association of males into “consorts” pursuing access to females. However, extensive surveys showed no evidence for kin association beyond mother/calf pairs in humpback whales on either the breeding grounds (Pomilla and Rosenbaum, 2006) or during migrations (Valsecchi *et al.*, 2002).

III. Population Genetics

Dispersal (and hence gene flow) among populations can be restricted by geographic barriers (such as continents) or by habitat specialization and energetic considerations. However, marine mammal species are highly mobile and some are capable of movement over vast distances. For example, the sperm whale (*Physeter macrocephalus*) shows little genetic variation even among different ocean basins (Lyrholm *et al.*, 1999). Other species have been shown to be composed of geographically isolated populations that are genetically differentiated, such as Pacific vs Atlantic populations of humpback whales (Baker *et al.*, 1994) and walrus (*Odobenus rosmarus*; Cronin *et al.*, 1994). This “allopatric” pattern of differentiation is common among both marine and terrestrial species. What is more unusual, but perhaps quite important for the evolution of population structure in marine mammals, is the partitioning of the environment in a way that shows differentiation among sympatric (living in the same geographic region) and parapatric (neighboring regions) populations. This can happen when populations that differentiated in allopatry come back together, or by processes that lead to choosing particular mates in preference to others (“assortative mating”) in sympatry.

One mechanism for differentiation in sympatry is called “resource specialization,” and this has been described in detail for various terrestrial and aquatic species (see Smith and Skulason, 1996). It means that individuals of a species specialize on habitat or prey choice. Note, however, that these specializations can only lead to genetic differentiation if they also lead to assortative mating. Various studies show genetic differentiation between resource specialists in dolphin species. For example, the killer whale (*Orcinus orca*, the largest dolphin) travels in highly stable social groups (“pods”). Pods tend to specialise on prey resources, with some pods and populations of pods focussing on marine mammal prey and others on fish prey (two different “ecotypes”). Sympatric populations of marine mammal and fish specialists in the eastern North Pacific were found to be genetically differentiated (Hoelzel and Dover, 1991; Hoelzel *et al.*, 1998a). The level of differentiation was great enough to suggest the possibility of two “cryptic” killer whale species, differing especially in foraging behavior. However, the application of non-equilibrium evolutionary models to test for ongoing migration suggested that current dispersal among ecotypes was at a similar level as that seen within ecotypes (Hoelzel *et al.*, 2007), implying multiple populations of a single species. This study further showed that there are clearly two mechanisms differentiating populations of killer whales in the North Pacific: differentiation among ecotypes in sympatry or parapatry, and an “isolation by distance” pattern within ecotypes. The timing of population origins was assessed using a coalescent method, and this suggested that these regional populations had been established after coastal habitat became available when glaciers retreated after the last ice age, emphasizing the likely importance of local habitat in defining genetically isolated populations.

One striking result was the existence of population structure on a geographic scale that is clearly smaller than the dispersion range of the species (see Hoelzel *et al.*, 2007). The southern elephant seal

provides another example. In this case male-mediated dispersal can be over a range of thousands of kilometer, and yet significant population genetic structure exists among breeding colonies that are only hundreds of kilometer apart (Fabiani *et al.*, 2003). Satellite tracking studies have further shown that both males and females travel thousands of kilometer on foraging excursions, regularly overlapping the ranges defined by population genetic structure (Biuw *et al.*, 2007). In this case it seems likely that philopatry is driven by the limited availability of suitable breeding habitat. In the case of the killer whales, the key factor may be differences in prey resource among regional habitats. A similar pattern was seen for bottlenose dolphins distributed between the Black Sea and Scotland. Genetic structuring (defined by genotypes without *a priori* assignment to putative populations) matched apparent habitat boundaries between the Black Sea, eastern Mediterranean, western Mediterranean, North Atlantic and Scotland (Natoli *et al.*, 2005; Fig. 2). The implication that local habitat defines population structure in this species was further reinforced by a study that investigated fine-scale population structure around the UK incorporating a now extinct population at the Humber river estuary. The data could rule out an historical range shift or contraction; they instead indicated that this regional population was isolated from neighboring populations and went extinct sometime between 100–1000 years ago.

A number of dolphin species inhabit both coastal and offshore environments, which can differ with respect to the type and distribution of potential prey. Especially in regions where there is upwelling, the habitat in the marine littoral zone can be very different from the offshore habitat. Several studies of nearshore and offshore dolphin populations indicate intraspecific morphological, and in some cases genetic distinctions. For example, nearshore and offshore subspecies of the spotted dolphin (*Stenella attenuata*) can be distinguished by tooth and jaw structure, and the Atlantic spotted dolphin (*S. frontalis*) is also found in nearshore and offshore populations. Two forms of common dolphin (*Delphinus delphis*) have been classified by the proportional length of the beak. In this case, ranges overlap, and both forms are sometimes found in the nearshore habitat. Rosel *et al.* (1994) found genetic differentiation between these forms; they are now considered by most workers to comprise two species: *D. delphis* and *D. capensis* (but see complications described below).

The best known example is that of the bottlenose dolphin, which occurs in coastal and offshore populations throughout its range. In the eastern North Pacific, nearshore and offshore forms were originally classified as two different species: *T. gilli* (the nearshore form) and *T. nuuanu*, though a reappraisal recognizing extensive overlap in morphotypes later reclassified both as *T. truncatus*. In the western North Atlantic, the nearshore and offshore forms have been described in some detail and show both morphometric (Mead and Potter, 1995) and genetic differentiation (Hoelzel *et al.*, 1998b). There were consistent differences between the two types in feeding behavior with the nearshore form feeding primarily on coastal fish, while the offshore form concentrated on deep water squid (Mead and Potter, 1995). The genetic distinction indicated low levels of gene flow (or no gene flow in the recent past) between the two populations.

Marine mammals are highly mobile, and in many cases they show seasonal differences in distribution, such as the annual migration between breeding and feeding sites seen in baleen whales. This is an important consideration for the identification of populations for protection and management, especially when breeding “stocks” mix on feeding grounds where they may be hunted (see review in Hoelzel, 1998). For example, minke whale (*Balaenoptera acutorostrata*) populations on either side of Japan (off Korean and in the western North

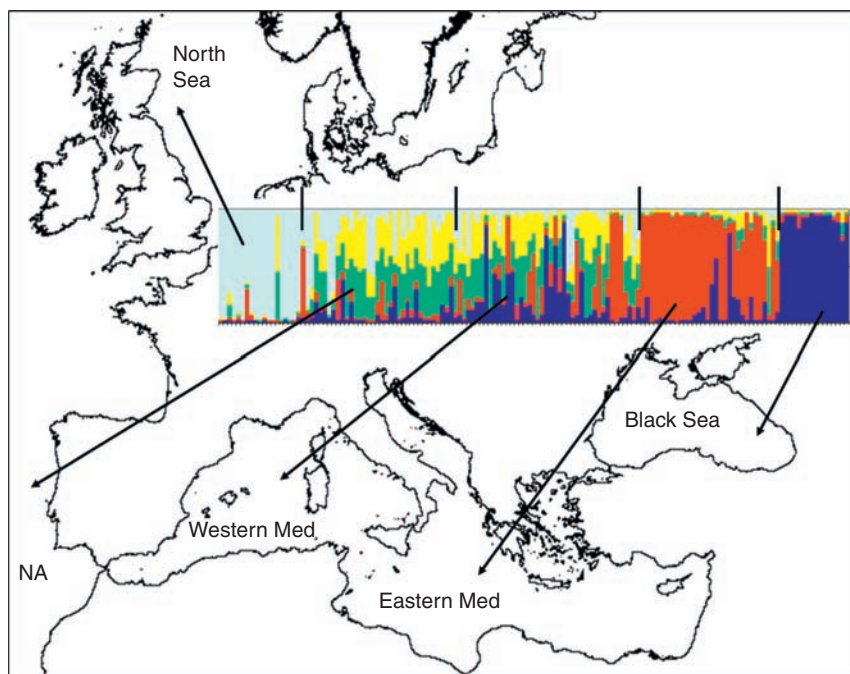

Figure 2 Assignments to clusters based on equilibrium expectations were generated using the program structure and are shown in the histogram. The colors reflect assignment probability to different putative populations, and the black lines divide sample sets of bottlenose dolphins from different regions. After Natoli *et al.* (2005).

Pacific) are genetically differentiated at both allozyme (Wada, 1991) and mtDNA loci (Goto and Pastene, 1996). Both studies found evidence of seasonal mixing on feeding grounds to the north in the Okhotsk Sea. In another example involving minke whales, a temporal mixing of two genetically differentiated populations from Antarctic management areas IV and V was described based on mtDNA variation (Pastene *et al.*, 1996).

IV. Beyond Populations

Sometimes even quite familiar marine mammal “species” become reclassified as multiple cryptic species when molecular genetic methods are employed. One important driver appears the same type of adaptation to different habitats that often defines populations within these species. For example, populations in nearshore and offshore habitat have in some cases been recognized as genetically distinct. For the genus *Tursiops* a nearshore form off China (an “aduncus” type that has a proportionally longer rostrum) was shown to occupy a separate phylogenetic lineage from the offshore form (Wang *et al.*, 1999). However, the coastal *Tursiops aduncus* in South Africa was as genetically differentiated from the coastal aduncus type in Asia as from the *T. truncatus* form, implying at least three species in the genus *Tursiops*, two of which are morphotypically very similar (Natoli *et al.*, 2004; Kurihara and Oda, 2007). As with intraspecific populations of the killer whale, it appears that both ecotype and geographic isolation are important mechanisms promoting differentiation and (in this case) eventual speciation. In the genus *Delphinus* there is also a “long-beaked” form typically found in nearshore habitat (recognized in this volume as *Delphinus capensis*), but only one of several long-beaked populations showed differentiation at a level expected among species (Natoli *et al.*, 2006). In *Sotalia*, another genus where

taxonomic classification has been problematic, a recent phylogenetic study (using mtDNA) proposed the division of *Sotalia fluviatilis* into two species, one adapted to riverine habitat, and the other to marine, coastal waters (Cunha *et al.*, 2005).

V. Summary

In general, the pattern and degree of genetic differentiation among populations is not easily predicted by geographic patterns for marine mammal species, and instead depends on a complex interaction between life history and habitat. Even for the highly mobile and pelagic species, such as the minke whale, there can be considerable genetic differentiation among regional populations, and for some species (such as the killer whale) among populations in sympatry. What we know of the molecular ecology of these species emphasizes the need for more data and a careful consideration of the mechanisms affecting patterns of diversity within and among populations.

monk seal, *M. tropicalis*, once widely distributed around the Caribbean and last seen in 1952.

Monk seals originated in the North Atlantic, with the Hawaiian species of probable Caribbean origin at least 15 million years ago across the Central American seaway (Repenning and Ray, 1977). Unique among pinnipeds in some primitive, unspecialized skeletal, and vascular anatomy, the Hawaiian monk seal is known as the most primitive of living seals.

Mediterranean monk seals are uniformly black at birth with a conspicuous white ventral patch unique to each individual and distinct in shape by sex (Samarach and González, 2000). Newly molted seals of all ages are silvery gray dorsally and lighter ventrally, with the ventral patch pattern persisting through life. Pups are completely molted at 70 days (range 40–108). Juveniles have a medium-to-dark gray pelage, similar to that of adult females but with less coloration disruptions caused by scarring. Pups at birth weigh 20 kg on average and measure between 0.80 and 0.90 m. Near the age of 4, adult males become almost uniformly black, with their white ventral patch; coloration in females is more variable, but not as dark as males dorsally and the ventral fur is also lighter. Adult males may also be slightly longer than females. Adult lengths are 2.3–2.8 m and weights are 240–300 kg, with a maximum recorded weight of 400 kg.

Hawaiian monk seals are also black at birth, with some showing small white patches at various sites. These seals are also silvery gray following molt, with the fur color changing in juveniles to a yellow-brown prior to the next molt and darkening through the year in adults. Hawaiian seals show no differences in fur coloration by sex. Adult females may attain a slightly larger size than males. Adult lengths are 2.1–2.4 m and weights are 170–240 kg. Pups at birth weigh 16–20 kg and measure between 0.80 and 1 m. Both the hair and the epidermis are sloughed and replaced during the annual molt in monk seals. This type of molt is similar to elephant seals, but unlike all other seals. In the Hawaiian monk seal the actual observed molting period is about 10 days, but based on an observed high proportion of time ashore before and after the hair-skin sloughing period, the entire physiological process is probably much longer.

Caribbean monk seals were similar to Hawaiian and Mediterranean monk seals, with uniformly dark brown coloration, lighter in the ventral area, and limited sexual dimorphism. Adult lengths were 2.3 m and weights lower than 200 kg. Pup length at birth was approximately 1 m and weight between 16 and 18 kg. Juveniles reached 1.5 m. The hair was short, about 1 cm in length, and uniformly dark or black in newborn pups. Vibrissae were dark in juveniles, up to 12-cm long, and lighter in adults and up to 10-cm long. The skull had large orbital areas and a smoother part behind these. Adult skull length was approximately 25 cm and similar between sexes. They had 32 teeth, with well-developed canines, like the other *Monachus* species. The other common name of the species is West Indian monk seal.

II. Distribution and Abundance

Historically, the Mediterranean monk seal inhabited the entire Mediterranean Basin and the southeastern North Atlantic, from the Azores Islands to near the equator (Aguilar, 1999). The current distribution is severely contracted and fragmented, with the largest population approximately 250–300 seals in the Eastern Mediterranean, on the islands in the Aegean and Ionian Seas, and along the coasts of Greece and Turkey. Only two breeding populations are known in the Atlantic, one at the Cap Blanc peninsula in the Western Sahara and Mauritania approximately 120 seals and a smaller group in the Desertas Islands at the Madeira Islands

Monk Seals

Monachus monachus, *M. tropicalis*, and *M. schauinslandi*

WILLIAM G. GILMARTIN AND
JAUME FORCADA

I. Characteristics and Taxonomy

Order Carnivora, family Phocidae (Gray 1825). The genus *Monachus* includes two endangered species that live in the world's tropical and subtropical seas of the Northern Hemisphere, the Mediterranean monk seal, *M. monachus*, and the Hawaiian monk seal, *M. schauinslandi*; and the extinct Caribbean

approximately 25 seals (Forcada *et al.*, 1999). Sightings are rare now in other areas within the historical range. Genetic variability is low, most likely as a consequence of severe bottlenecks following extensive sealing in the Atlantic and fisheries-related losses that continue today. Mediterranean monk seals have high site-fidelity and tend to occupy only a restricted part of the suitable habitat. The species only preserves colonial aggregations are in the Atlantic, whereas in the Mediterranean it is found in secluded caves, commonly with underwater entrance, and the distribution is greatly fragmented.

Hawaiian monk seals occur only in the Central Pacific in the mostly uninhabited Northwestern Hawaiian Islands (Ragen and Lavigne, 1999). A small breeding population also inhabits the main Hawaiian Islands, and monk seals have been reported on rare occasions south of the Hawaiian Archipelago at Johnston Atoll, Wake Island, and Palmyra Atoll. Hawaiian monk seals have a high fidelity to their island of birth; only 10–30% of seals born at any of the major breeding islands will move to another island during their life. Very low genetic diversity is also evident in this species, which now includes 1200–1300 individuals.

Caribbean monk seals lived in the Caribbean Sea, from the Florida Keys and northeastern Gulf of Mexico to the coast of Guyana. The preferred habitat were small islands, keys, and atolls, surrounded by reefs and shallow, protected waters. Suggested breeding grounds were in the Southern Gulf of Mexico and Bahamas, and Arrecifes Triángulos (Yucatán). Seals occurred at these locations throughout the year (Adam and García, 2003). Historical population numbers are unknown, but following discovery their numbers were reported in the thousands.

III. Ecology

Both extant monk seal species consume a highly diverse diet of diurnally and nocturnally active fish, octopus, squid, and lobster (Goodman-Lowe, 1999). Proportions of these prey species in the diet vary by location, season, and age of the seals. Although most of the prey species are benthic in the coral reef ecosystem, a few are pelagic. Hawaiian monk seals have a broad prey base of at least 40 species. They forage within their resident atolls and along the fringing reefs; and may, where a population is food stressed, also forage at reefs 60–200 km from their breeding islands and at sea mounts to depths near 500 m. Mediterranean monk seals are mostly benthic feeders, regularly reaching bottom depths in areas of wide continental shelf like the western Sahara. Caribbean monk seals probably preyed upon fish and crustaceans. Killer whales and sharks are probably the only predators of monk seals.

IV. Behavior, Physiology, and Life History

Both living monk seal species have protracted reproductive seasons, and copulation occurs in the water. Some female Mediterranean monk seals may be reproductively active at 3 years and Hawaiian monk seals at 4 years. However, in the Hawaiian seal, the mean is perhaps 6–7 years and maturity is as late as 10–11 years in females at sites where prey abundance is low, showing nutritional status is a critical factor in maturation. Mediterranean monk seals give birth year-round, but mostly in the summer through early winter months. Caribbean monk seals followed a similar seasonal pattern. Monk seal births in Hawaii usually occur from February to August, peaking in April–June, but births are known in all months. At birth, Mediterranean monk seal pups weigh between 15 and 26 kg and gain weight fast during a suckling time of up to 4 months, with

the females mixing feeding trips with pup attendance. Hawaiian monk seal pups are weaned at 6 weeks, after attaining weights of 50–100 kg, a broad range, reflecting the varying nutritional status of different populations. Hawaiian females do not forage during the lactation period. After weaning, pups of both species survive on their fat reserves while they acquire prey-catching skills. Kenyon and Rice (1959) discussed the life history of monk seals.

Females of both living species have four functional mammary glands, and while they can give birth to single pups in consecutive years, they will also skip some years. Hawaiian females exhibit an average 381-day interval between annual births; thus these females give birth later each year until a year in which they do not give birth, and then they cycle earlier the following year. Some females give birth on a more interrupted schedule. The breeding interval of the Mediterranean monk seal is approximately 1 year with a variability of 15 days and correlates with lactation duration.

When Hawaiian monk seal female–pup pairs are near each other, accidental exchanges of the pups between the females can occur. Serious consequences result when the exchanged pups have suckled for very different times and are of very different size. The mothers will still wean their foster nursing pups after about 6 weeks of lactation, leaving one pup larger than normal size and one smaller, with the latter's survival chances highly compromised. Mediterranean monk seal females may foster pups discarded by other mothers, and also simultaneously nurse two pups, including a pup from a different mother. Milk stealing by pups has also been reported.

A mating tactic of some nondominant male Hawaiian monk seals is an attack by a group of these males, a few to over 20, on an adult female or an immature seal on some occasions. The attention of the dominant male in consort with the female becomes distracted by one or more of the challengers in the group, allowing the others to then breed with the female during bouts that may last over 3 h in the water. The repeated and prolonged biting on the back of the female by males attempting copulation results in extensive trauma and tissue and fluid loss, often leading to her death. This detrimental behavior has occurred primarily at seal colonies where the adult sex ratio was skewed toward males.

V. Interactions with Humans

Both living species of monk seals have been impacted greatly by human activities, from direct killing to competition for prey with

Figure 1 Weaned Hawaiian monk seal female pup, showing lighter ventral pelage of younger seals. Photo credit: William G. Gilmartin.

fisheries and incidental disturbance of seals due to human presence on or near hauling and breeding beaches. Extinction of *M. tropicalis* in the 1950s and the international endangered status of the two remaining *Monachus* species result from this high sensitivity of the genus to direct and indirect human interactions.

The Mediterranean monk seal has been exploited since ancient times, and a significant decline in all of its range occurred in the second half of the twentieth century. The total population was thought to be between 600 and 1000 individuals in the 1970s but at present is estimated at 350–450. Hawaiian monk seals are estimated at 1200–1300 animals. Less than 10% of the population reside in the main Hawaiian Islands where size and survival of young suggest that these seals are doing well. The much larger population in the northwestern islands is currently experiencing very high juvenile losses, primarily due to starvation.

Pup mortality increases sharply for Mediterranean and Hawaiian monk seals when human beach-use of a preferred habitat forces females to give birth at unsuitable pup-rearing sites. Both monk seals also interact with fisheries—commercial bottomfish and longline hooks and hooks from shoreline recreational fisheries in the

main Hawaiian Islands have been observed in Hawaiian seals. Mediterranean seals have been entangled in active fishing gear and shot. Mediterranean monk seals also feed on fish farms which increases their risk of mortality. Entanglement in marine debris is a threat to both monk seals. Usually affecting pup and juveniles, the frequency of observations of entangled Hawaiian monk seals is increasing and, in many cases, where the debris is not removed, the seals are likely to be seriously injured or die.

Although the monk seal colony on the western Sahara coast had been considered the most viable population of the species and characterized by high adult survival rates, it also exhibited high pup mortality and very low recruitment. Then, during May–July 1997, the size of this colony was tragically reduced by two-thirds due to a large-scale mass mortality event. The most probable cause was a phytoplankton paralytic toxin, although a morbillivirus was also detected during the event. The age structure of the surviving population was severely altered because juvenile mortality was insignificant compared to that of adults. This high mortality event severely compromised the recovery potential of the species in the Atlantic.

Hawaiian monk seal numbers have also been reduced due to human activities. Currently, however, all of the major breeding islands of the Hawaiian monk seal occur within federal and state government refuges where access is controlled and the remaining bottomfish fishery is being phased out over 5 years, at which time the foraging habitat in the Northwestern Hawaiian Islands will be completely protected from direct fishery interactions. The Hawaiian monk seal has a well-organized research and recovery effort, with guidance provided by a “recovery team” of scientists. Recovery actions have included disentanglement of seals and two successful programs to enhance female survival. Underweight female pups were collected, rehabilitated, and then released back to the wild during the 1980s and early 1990s. In another effort, adult male seals that were killing females were captured and relocated to areas remote from the main breeding populations. Both projects contributed to population recovery in some colonies during the 1990s.

The remaining populations of both monk seal species are highly vulnerable to random catastrophic events such as die-offs due to introduced disease, biotoxin poisoning, effects of inbreeding depression, human disturbance, and competition with fisheries. The stability of the extant populations relies on high adult female survival rates. Fortunately, most of the Hawaiian monk seal population is now moderately buffered from anthropogenic pressures by the isolation and protected status of its major breeding habitat. The Mediterranean monk seal is not as fortunate. While a few protected areas have been established for the Mediterranean seal by Greece in the Aegean and by Portugal at the Desertas Islands in the Atlantic, only an immediate and significant reduction in anthropogenic pressures on the Mediterranean species and a range-wide coordinated recovery effort will avoid its extinction in the twenty-first century.

Musculature

J.G.M. THEWISSEN

The muscular system of mammals was designed on a single blueprint; there is a remarkable constancy of muscles and associated nerves from the most agile bat to the fastest antelope, and the largest whale. Details differ, and most of these differences reflect adaptations to specific demands of the environment. This article presents an outline of muscular anatomy of marine mammals, emphasizing how pinnipeds, cetaceans, and sirenians differ from terrestrial mammals. General summaries of cetacean muscles can be found in Slijper (1936, 1962), and of manatees in Domning (1978). Howell (1930) discussed locomotor morphology of all marine mammals.

I. Cranial Muscles

In the cranial muscles, marine mammals differ from terrestrial mammals in the arrangement of their eye muscles, facial muscles, their masticatory muscles, and the muscles of the palate, pharynx, larynx, and tongue.

The facial muscles in land mammals are attached to the skin of the face and moderate facial expressions. In all marine mammals, the facial muscles are involved in closing of the nose opening (or blowhole) to prevent the entry of water during diving. In sirenians, the most important of these muscles insert on the mobile snout and are involved in the manipulation of food. In cetaceans, the facial muscles are greatly rearranged and are positioned around the airsac system

on the forehead (Purves and Pilleri, 1983). As such, they are involved in the production of sound. In many mysticetes, facial muscles also extend between the two halves of the mandible where they assist in squeezing gulps of ingested water through the baleen.

One particular facial muscle, buccinator, is unusual in that it is not near the surface of the skin in land mammals. It forms the wall of the cheek and gives the cheek a rigid wall when suction is produced. As such it is critical for nursing young. In cetaceans, partly as a result of the long snout, this muscle does not give the cheek a rigid wall. Nursing females assist young in suckling by actively squirting milk into their mouths by the contraction of special skin muscles overlying the mammary gland.

The masticatory muscles of pinnipeds are similar to those of terrestrial carnivores, and sirenian masticatory muscles are not unlike those of herbivorous land mammals. In cetaceans, the temporal muscle is greatly reduced and the muscles used to close the jaws are the pterygoids and masseter. Unlike land mammals, in which these muscles direct lateral movements of the lower jaws, simple closing of the jaws is their main function in cetaceans.

The muscles of the throat of most marine mammals do not differ greatly from those of land mammals. The throat of odontocete cetaceans (Fig. 1) is more specialized than that of other marine mammals. The larynx of odontocetes is elongate and its epiglottis projects far anteriorly, reaching the back of the palate and extending into the nasopharyngeal duct. The walls of the nasopharyngeal duct, including the soft palate, consist of a strong annular muscle that encloses the epiglottis and seals the lumen of the larynx functionally from the pharynx.

Figure 1 Midline sections through the head of a horse (top) and common porpoise (*Phocoena phocoena*, bottom) showing the unique shape of the throat and larynx in odontocete cetaceans. Air in all mammals passes from the nasal cavity (nas) to the nasopharyngeal duct (naph), to the larynx, and to the trachea (tr). Food in all mammals passes from the oral cavity (or), to the pharynx (throat), and to the esophagus (eso). The laryngeal cartilages (colored black); form a spout in odontocetes that fits into the nasopharyngeal duct and can be closed tightly by means of annular muscles (ann). This closure causes a tight separation of the air and food passages. Modified after Slijper (1962).

The tongue of most mammals is very muscular, and its large size in baleen whales is remarkable. In blue whales (*Balaenoptera musculus*), the tongue is the size of an adult elephant and makes up 2.5% of the whale's entire weight. However, rorqual tongues are not very muscular, consisting mainly of fat and connective tissue.

A. Axial Muscles

The neck muscles in cetaceans are unremarkable because the neck is short. The neck is long in pinnipeds and may be very muscular. It functions in balancing the body during locomotion and intraspecific fighting.

Muscles extending along the back and tail are the main muscles of propulsion in cetaceans. Epaxial muscles extend along the dorsal side of the transverse processes of the vertebrae. These muscles contract and cause dorsal concavity of the back and tail, pulling the fluke up in the upstroke. These muscles, especially the multifidus and longissimus, are enormous (Fig. 2). The upstroke in cetaceans is powered mainly by the longissimus and extensor caudae lateralis (Pabst, 1993). The latter muscle inserts directly on the dorsal surface of the vertebrae of the fluke, but the longissimus exerts its power by attaching to a subdermal sheath of tendons (Fig. 2) which attaches on spinous and transverse processes along most of the back of the cetacean. It is through the connections of this sheath to the terminal tail vertebrae that the fluke is moved, allowing muscular force to be distributed evenly along the caudal peduncle. The multifidus does not insert on this sheath, instead attaching to the posterior thoracic vertebrae and the lumbar vertebrae. Its main function appears to be to stiffen the back, providing a stable platform of origin for longissimus. The longissimus is also large in sirenians and is probably important in their upstroke. Lumbar epaxial muscles are also important in powering the undulatory movements of *Enhydra lutris* (sea otter).

The downstroke of the fluke in cetaceans is mainly powered by muscles attaching to the ventral side of the thoracic and lumbar vertebrae and inserting, via a tendon sheet, to the ventral side of the caudal vertebrae and chevron bones (Pabst, 1983). These muscles are large and are commonly called hypaxialis lumborum. In sirenians, specialized tail muscles called sacrocaudalis ventralis lateralis and medialis produce depression of the tail.

Figure 2 Cross section through the lumbar region of a bottlenose dolphin (*Tursiops truncatus*). Note the large development muscles, which, at this level, are cross sectionally larger than the abdominal cavity (*abd*). Dorsal to the vertebra (stippled area) are epaxial muscles (*mul*, multifidus; *lon*, longissimus) and ventral to the vertebra are hypaxial (*hyp*) muscles. Muscles are closely associated to the subdermal connective tissue sheath (*sct*). Modified after Pabst (1993).

Epaxial and hypaxial muscles are large in phocids, where they are used to produce the side-to-side movements that propel the body in swimming. Among the larger of these muscles is the iliocostalis.

B. Muscles of Thorax, Abdomen, and Limbs

A large superficial skin muscle, the cutaneous trunci (also called panniculus carnosus), covers much of the thorax and abdomen in many mammals. In sirenians, this muscle is especially large and assists in the downstroke of the tail. In cetaceans, part of this muscle is specialized and overlies the mammary gland. It compresses the gland (Fig. 3) and squirts milk into the mouth of nursing young.

Unusual among mammals is the muscle system associated with the penis of cetaceans. Just like in most mammals, erection in cetaceans is not under muscular control. However, unlike most mammals, retraction of the penis into a pouch on the body of the cetacean is caused by contraction of the retractor penis muscles (see Male Reproductive System). These muscles also occur in artiodactyls but are absent in other mammals.

The forelimb of cetaceans (see Forelimb Anatomy) is mainly involved in steering and does not provide propulsive force during rectilinear swimming. Shoulder movements are mainly adduction and abduction; flexion and extension are limited. The shoulder of cetaceans allows less mobility than that of most terrestrial mammals. The clavicle is absent, and tight muscles anchor the scapula to the thorax. These muscles include pectoralis, rhomboids, serratus ventralis, and latissimus dorsi. A large additional muscle, the trapezius, occurs in most mammals but is absent in cetaceans. At the scapulo-humeral joint, the deltoid is a strong abductor, and the latissimus dorsi probably the main adductor, assisted by the subscapularis. The joint between scapula and humerus is a ball and socket joint in cetaceans, as in all mammals, but there are no flexible synovial joints below the cetacean shoulder. Ligaments at the elbow, wrist, and fingers allow for some elastic mobility. A few muscles in cetaceans (e.g., triceps) insert distal to the elbow, but there are no muscle bellies in the forearm and hand.

Just like cetaceans, the forelimb of phocid and odobenid pinnipeds does not provide much of the propulsive force when swimming. It is, however, important in land locomotion. In contrast, otariid pinnipeds use their forelimb as the main propulsor during swimming, and the forelimbs also have an important role in land locomotion.

All pinnipeds lack a functional clavicle, and the shoulder is loosely attached to the chest. Of the shoulder muscles, the pectoralis and latissimus dorsi are the largest and probably provide most propulsive force during swimming in otariids (Fig. 4). The forearm and wrist of otariids contain synovial joints, although mobility at the wrist is reduced. The flippers that form the hands of otariids lack extensive musculature.

The forearm and hand of phocids are relatively mobile, unlike those of otariids. In the northern phocids (phocines), the hands are used in terrestrial locomotion and have well-developed muscles.

Modern Sirenia do not use their forelimbs for propulsion but retain synovial joints at the shoulder, elbow, and wrist. The hands are used in manipulating food and retain many of the muscles that are present in land mammals. In the extinct *Hydrodamalis gigas* (Steller's sea cow), there were no wrist and hand bones and, consequently, no hand muscles.

There are no hind limb muscles in modern cetaceans (see Hind Limb Anatomy), although they were developed in Eocene forms. A rudiment of the pelvis and sometimes the femur and tibia occurs in modern cetaceans, but its main purpose is the attachment of retractor penis. Pelvic bones were also known in early sirenians, but

Figure 3 The cutaneous trunci muscle of finless porpoise (*Neophocaena phocaenoides*). Note the muscular tissue overlying the mammary gland on the ventral side near the tail. After Howell (1930).

Figure 4 Dorsal views of a partially dissected sea lion (*Zalophus*) and a harbor seal (*Phoca*) superficial muscles on left side of the animal, deeper muscles on the right. Modified after Howell (1930).

these bones and all of the hind limb musculature were lost in the extant forms.

Hind limbs are well developed in the pinnipeds. Phocidae and Odobenidae use their hind limbs in aquatic locomotion, making adduction and abduction movements with an inverted foot. Phocidae do not use their hind limbs to support the body while on land. Otariidae trail their hind limbs during swimming, but use them during locomotion on land. Odobenidae also support their body with their hind limbs while on land.

In the phocids, the hind limb flexors (e.g., the hamstrings) are reduced, whereas the extensors are supported by changed insertion of the adductors and obturator externus, which also serve in extension (Fig. 4). Muscles below the knee are present in all pinnipeds, but those crossing the heel are stronger in phocids than in otariids.

Museums and Collections

JOHN E. HEYNING AND JAMES G. MEAD

The integrative approach to studying biology is similar to constructing a jigsaw puzzle—each discipline and data set contribute in a meaningful way to understand the whole. Individual pieces may contribute more or less to the picture, but nonetheless all pieces are important. In biology, each discipline contributes its own unique set of pieces to the puzzle of life. Research in museums has historically focused on specimen-oriented disciplines and thus has contributed to these suites of puzzle pieces. Specimens are potential sources of data for the disciplines of systematics, paleontology, morphology, histology, genetics, pathology, life history, parasitology, toxicology, and biochemistry. In addition, museums serve as important forums of informal learning for the visitors that peruse the exhibits or engage in an educational program.

I. Biodiversity and Systematics

Perhaps the most fundamental among the specimen-oriented disciplines is the study of biodiversity, the defining of species and

populations within species. Most marine mammalogists working within museums in the nineteenth and early twentieth centuries spent their hours primarily describing new species from the vast array of specimens unloaded from some recent voyage of exploration so characteristic of that time. For instance, from the numerous marine mammal specimens collected by the Southern Hemisphere expeditions of the HMS *Erebus and Terror* during the years 1839–1843, John Gray of the British Museum (Natural History) described numerous new species, including the Ross seal (*Ommatophoca rossii*), the crabeater seal (*Lobodon carcinophaga*), the pygmy right whale (*Caperea marginata*), and the Chilean dolphin (*Cephalorhynchus eutropia*). While the heyday of prolific new species description peaked a century ago, the need for the ongoing study remains very relevant today. Several new species (or resurrected old species) have been defined within recent years, and most populations are just now being understood.

The classical approach of using morphology to define species continues to be relevant. However, analyses of molecular genetic data provide us with additional new tools to help define populations, species, and the relationship among species. Exemplary of this is the recent discovery of a new species of beaked whale. In the mid-1970s, several STRANDINGS occurred of a small species of beaked whale along a restricted section of southern California coastline. Because these specimens morphologically resembled the Southern Hemisphere species *Mesoplodon hectori*, scientists tentatively assigned these California animals to that taxon. A graduate student from New Zealand investigating beaked whale phylogeny sampled the DNA from these specimens along with many others held in museums. To her astonishment, these California specimens clustered nowhere near specimens of *M. hectori* from the Southern Hemisphere (Dalebout *et al.*, 1998), hence providing evidence that they represented a new species.

Determining the evolutionary relationships, or phylogeny, among this diversity of species, both living and extinct, is the study of systematics. Systematics provides an evolutionary framework that becomes the foundation for the comparable biological approach. Phylogenies can be constructed using a variety of data sets, morphological, molecular, and fossils—all of which reside primarily within museums. Hence, researchers today can infer past events from phylogenetic reconstructions of evolutionary relationships. Most modern systematists use a philosophical approach called cladistics. The basic tenets of cladistics are quite simple: organisms are deemed to be related based on shared derived characters called synapomorphies. Derived characters are defined as having arisen in the common ancestor of the taxa and subsequently passed onto their descendant taxa.

Museums have a long-term commitment to house specimens for research. Thus, material collected in the 1700s and 1800s is still available for scientific inquiry today. For many species, it is only through the accumulation of specimens and data over several decades, even over a century that we can obtain the sample sizes needed to begin to understand even the basic biology of these species. For systematic studies, it is crucial to examine a large series of specimens (Fig. 1). To define species or populations, one must first know the limits of variation—individual, ontogenetic, SEXUAL DIMORPHISM—to ascribe that the observed variation is due to limited genetic exchange.

II. Morphology

How can a blue whale engulf up to 70 tons of water? Why does not a narwhal break its tusk? How can a dolphin cool its testes so that spermatogenesis can occur? All these questions require the detailed examination of anatomical structures. This in turn requires that some

Figure 1 Museum workers collect a series of pilot whale specimens (*Globicephala macrorhynchus*). Series such as these allow biologists to define species and to understand populations within species. Defining these biological units is crucial to conservation biology among other disciplines.

specimens are readily available. Some studies are limited to hard parts and can be answered by examining osteological material. However, studies of soft anatomy require that these structures be preserved. For most organisms, storage of the whole beast can be accomplished easily by plunking the specimen into a jar of formalin and/or alcohol. Preservation for future study of a good-sized dolphin, let alone a whale, presents far more of a logistical challenge. As the immense specimens typically need to be dissected without preservation, the task can be demanding, as these large, oil-laden mammals produce a rich organic bouquet as they decompose. Fortunately, there is now a renaissance of morphological work requiring innovative ways of preserving and studying cetacean anatomy.

III. History of Museum Research

The first large collections of marine mammals had their genesis in the grand museums of Europe. Baron von Cuvier amassed and published on a very important collection in the early 1800s, which now resides in the Museum National d'Histoire Naturelle in Paris. By the mid-1800s, the British Museum of Natural History (now the Natural History Museum, London) had built major collections as the British Empire explored the world. Two of the preeminent marine mammalogists of this era, William Henry Flower and John Edward Gray, increased our knowledge considerably by studying the specimens within this venerable museum. Aside from the collections amassed from expeditions, museums in Britain had a distinct advantage for growing their collections. In 1324, stranded whales and dolphins were declared “Royal Fishe” and therefore property of the Crown. The original intent of this decree was to ensure that an economically valuable stranded fresh whale would enhance the coffers of the government. An unforeseen benefit was that the majority of strandings were of the economically non-valuable uneatable variety and therefore available for government supported museums. Hence the first stranding program began (Fraser, 1974). This original decree and subsequent museum-oriented mindset was passed along to the then

British colonies. These former colonies now have museums with major collections including those in Australia, New Zealand, South Africa, and the United States.

Marine mammals as museum specimens are difficult to acquire, store, and maintain. As a result, there are very few large collections for researchers to use. Of the largest collection of land mammals, well over one dozen have more than 100,000 specimens. The majority of specimens in these collections are the taxonomically diverse and numerically abundant rodents and bats. In striking contrast, less than a dozen or so museums have collections of marine mammals numbering over a mere 1000 or so. These include the National Museum of Natural History (Smithsonian), Washington DC, USA; Natural History Museum of Los Angeles County, California, USA; National Science Museum, Tokyo, Japan; The Natural History Museum, London, UK; National Museum of New Zealand (Te Papa), Wellington; American Museum of Natural History, New York, USA; California Academy of Sciences, San Francisco, California, USA; South Australian Museum, Adelaide; Museum National d'Histoire Naturelle, Paris, France; and South African Museum, Cape Town.

For a specimen to be of greatest utility for answering questions, it needs to have as much associated data with it as possible. Such archives provide context for the additional data collected by scientists. Originally, museum curators collected only skulls or skeletons along with occasional sketches of the living beast. Early in this century, following the lead set by the systematic collection of data from whaling stations, museum workers began documenting more data from each specimen. As the number of questions regarding marine mammal biology have increased concurrent with new analytical tools to address these questions, far more is being collected. Now it is not uncommon to collect the complete skeleton, frozen tissues, measurements, fluid-preserved tissues, photographs, and notes.

IV. Public Display

Over the past century and a half, museums have served an increasing role as important centers for the public to learn about the natural world. Accurately mounted exhibits can convey great biological detail and grand-scale presence that would be difficult for the public to ever experience in the wild.

Many museums have also capitalized on the immensity of whales to create exhibit icons, most notably the model of a living blue whale (*Balaenoptera musculus*). In 1907, a model created from a 74.4-foot blue whale went on display at the American Museum of Natural History. Subsequently, the British Museum of Natural History (now called the Natural History Museum, London) erected its own blue whale model measuring some 88 feet in length. In the early 1960s, the Smithsonian Institution (Washington, DC) unveiled their 92-foot model (Figure 2). Not to be outdone, the American Museum christened their new and anatomically more accurate 94-foot (28.7 m) model in 1969!

Museums hold collections in the public trust so that they are available to scholars in perpetuity. Thus they serve as guardians of the tangible evidence of time past and the archivists of our current natural heritage. In addition, museums serve as important centers at which the public can learn.

Mysticetes, Evolution

ANNALISA BERTA AND THOMAS A. DEMÉRÉ

I. Introduction

The fossil record of mysticete cetaceans is rapidly improving and the origin and diversification of this highly specialized mammalian group is coming into focus. Crown mysticetes (i.e., extant baleen whales of the families Balaenidae, Neobalaenidae, Balaenopteridae, and Eschrichtiidae) are edentulous as adults, but possess deciduous teeth that are resorbed prior to birth. This ontogenetic pattern reflects an ancestral ontogeny in which fully formed teeth were retained into adulthood. Archaic baleen whales include stem mysticetes, both toothed and toothless, that do not belong to extant families. Toothed mysticetes first evolved in the late Eocene or earliest Oligocene, diversified in the late Oligocene, and appear to have been extinct before the Miocene began. They do not constitute a monophyletic group. Stem edentulous mysticetes are first reported

from the late Oligocene coincident with the radiation of toothed forms, but are not diverse until the Miocene. Although contested, it is likely that most, if not all, archaic mysticetes possessed some form of baleen in the upper jaw. This key filter feeding innovation permitted exploitation of a new niche and heralded the evolution of modern baleen whales, the largest animals on Earth.

II. Toothed Mysticetes

As currently understood, toothed mysticetes are grouped into four families: Llanocetidae, Mammalodontidae, and Janjucetidae from the Southern Ocean and Aetiocetidae, from the North Pacific. To date no toothed mysticetes are known from the Atlantic region. The retention of an adult dentition in toothed mysticetes is the primitive condition seen in basilosaurid “archaeocetes” and stem odontocetes. The degree of telescoping of the skull is also primitive with little interdigitation of rostral and cranial elements. Consequently, there is a long intertemporal exposure of the frontal and parietal on the cranial vertex. In addition, the supraorbital processes of the frontals retain an elevated position on the cranium, and the external narial opening (“blowhole”) is only midway between the tip of the rostrum and the orbit. Derived features of toothed and later mysticetes include transverse expansion of the descending process of the maxilla to form an edentulous infraorbital plate, loss of a bony mandibular symphysis, and thin lateral margins of the maxillae.

The geologically oldest purported mysticete is *Llanocetus denticrenatus* from the late Eocene or early Oligocene of the Antarctic Peninsula. Although only a portion of the mandible and an endocranial cast have been described, the holotype also includes a nearly complete skull and partial skeleton under study by Ewan Fordyce. Despite its antiquity, *Llanocetus* was a large whale with a skull length

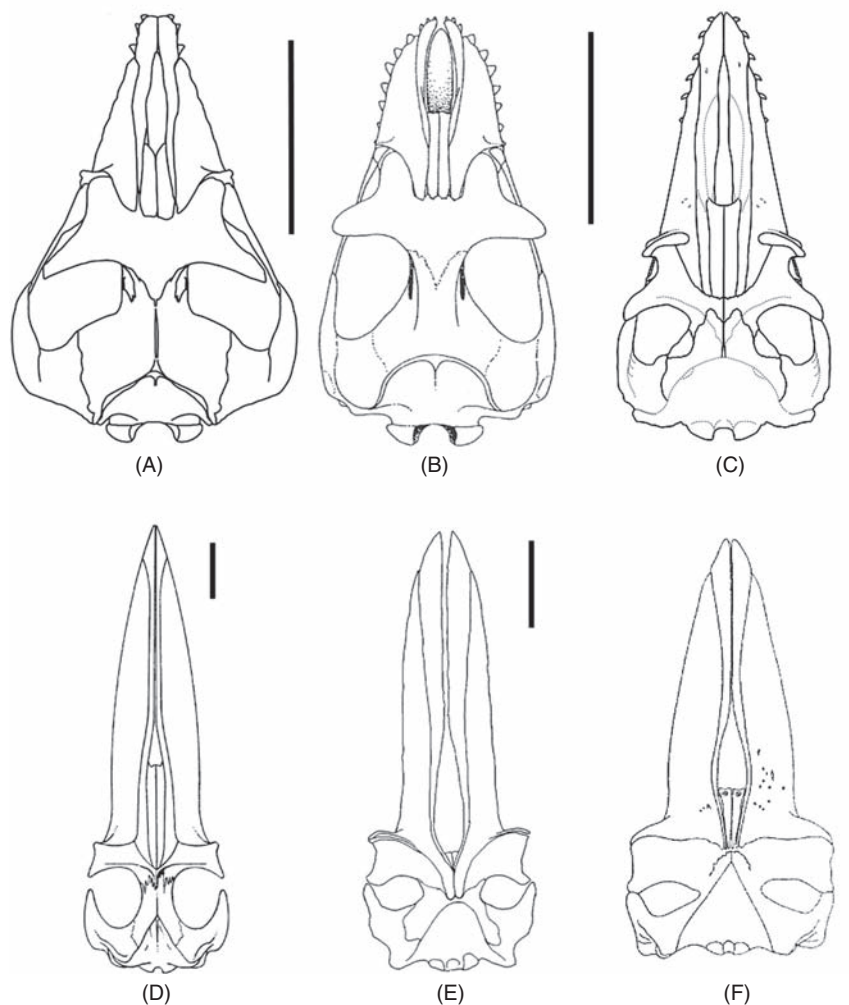

Figure 1 Archaic mysticete skulls: (A) *Janjucetus hunderi* (from Fitzgerald, 2006); (B) *Mammalodon collivieri* (from Fordyce and Muizon, 2001); (C) *Aetiocetus weltoni* (from Deméré and Berta, 2008); (D) *Eomysticetus whitmorei* (from Sanders and Barnes, 2002); (E) *Piscobalaena nana* (from Bouetel and Muizon, 2006); (F) *Aglaoctetus patulus* (from Kellogg, 1968). Scale bars equal 20 cm.

of about 2 m. The distinctly heterodont dentition of *Llanocetus* consisted of widely spaced molariform postcanine teeth with crowns characterized by roughened enamel and large, palmate denticles. Functional comparisons have been made with the palmate teeth of the modern filter-feeding crabeater seal, *Lobodon carcinophagus*.

Janjucetus hunderi and *Mammalodon collivieri* from the late Oligocene of Victoria, Australia (Fitzgerald, 2000), were smaller, short-faced toothed mysticetes with closely spaced, heterodont dentitions (Fig. 1). Crown morphology of the postcanine teeth is poorly known for *M. collivieri*, but for *J. hunderi* consists of roughened enamel and moderately sized, closely appressed denticles. The orbits of *J. hunderi* are large relative to skull length (~46 cm), suggesting acute vision. Although both taxa have been assigned to separate monotypic families, character support for this distinction is weak and they eventually may be shown to be sister taxa.

Aetiocetids represent the most diverse clade of toothed mysticetes and include seven nominal species grouped into 3–4 genera. *Aetiocetus* is the most speciose genus, followed by *Chonecetus* and *Morawanocetus*. Overall, aetiocetids were small-bodied cetaceans with skull lengths of about 60–70 cm and an estimated total body length of 2–3 m. Unlike species of *Mammalodon* and *Janjucetus*, aetiocetids had a relatively long rostrum (Fig. 1). Little is known of their postcranial skeleton except that they had elongated necks and relatively long arms with rigid elbow joints. The aetiocetid skull retained numerous primitive features inherited from their archaeocete ancestors (e.g., anteriorly positioned “blowhole,” elevated supraorbital processes of the frontals, long intertemporal constriction, large mandibular coronoid process, and large mandibular foramen). However, as mosaic stem mysticetes, aetiocetids also possessed important advanced features (e.g., broad rostrum, vascularized palate, and

Figure 2 Mysticete palates showing lateral foramina and sulci: (A) Toothed mysticete (*Aetiocetus weltoni* ~28–25 million years old; scale bar equals 10 cm); (B) Edentulous mysticete (*Balaenoptera acutorostrata*; scale bar equals 20 cm). From Deméré and Berta (2008) and Deméré et al (2008).

outwardly bowed mandible with prominent groove for the fibrocartilaginous symphysis) that portend the later diversification of fully edentulous baleen whales. Dental morphology varied within the group with *Morawanocetus* possessing a distinctly heterodont dentition and postcanine crowns with roughened enamel and moderately sized denticles. In contrast species of *Aetiocetus* had a more weakly heterodont dentition with postcanine crowns with lightly roughened enamel and diminutive denticles. The teeth were widely spaced and eastern North Pacific species (*A. cotylaveus* and *A. weltoni*) show a tendency toward polydonta, while one western North Pacific species (*A. polydentatus*) was distinctly polydont.

III. Origin of Baleen

Baleen is a unique mammalian structure consisting of keratinized tubules typically organized into transverse cornified plates suspended from epithelial tissues of the roof of the mouth. The frayed tubules on the medial margin of each plate overlap those of adjacent plates to produce a sieve that entraps prey within the oral cavity. The origin of baleen, although still poorly documented by fossils, appears to have been a stepwise transition from an ancestor with teeth only, to an intermediate state with functional teeth and baleen, to the derived condition with baleen only. Because baleen rarely fossilizes, morphologic evidence for its presence (or absence)

must rely on correlated osteological features. Extant mysticetes have a highly vascularized palate with distinct foramina and associated sulci concentrated along the medial portion of each maxilla (Fig. 2). The blood supply and innervation of the developing baleen apparatus pass through these openings. Thus, the presence of lateral palatal foramina and sulci in fossil mysticetes serves as indirect evidence for the presence of baleen (Figs. 2,3). Importantly, such structures have been reported in some toothed mysticetes.

IV. Edentulous Mysticetes

Archaic edentulous mysticetes are grouped into two families, Eomysticetidae and “Cetotheriidae.” Described eomysticetids include *Eomysticetus whitmorei* and *E. carolinensis* from the late Oligocene (30–28 Ma) of South Carolina, USA (Sanders and Barnes, 2002). These earliest edentulous baleen whales were of medium size (skull length ~1.5 m) and possessed a mosaic of primitive (e.g., elongated intertemporal region with long parietal and frontal exposures on the cranial vertex, anteriorly placed “blowholes,” elongated nasals, large mandibular coronoid processes, and large mandibular foramina) and derived (e.g., loss of adult dentition, flattened rostrum, and laterally bowed mandibles) features. Other probable eomysticetids include species of *Mauicetus* from the late Oligocene of New Zealand

Figure 3 Reconstruction of *Aetiocetus weltoni* by Carl Buell (Deméré et al., 2008).

Figure 4 Phylogeny of mysticetes based on Deméré et al., accepted. (2008).

and undescribed specimens from the late Oligocene of Japan; Baja California, Mexico; and California and Washington, USA.

“Cetotheriidae” is a large, diverse, nonmonophyletic assemblage of extinct small-to-medium-sized toothless mysticetes that traditionally

have been grouped together primarily based on their lack of synapomorphies of crown mysticetes. “Cetotheres” comprise the greatest taxonomic and morphologic diversity among fossil mysticetes with over 45 described species divided among more than 30 genera. Nominal “cetotheres” range in age from the late Oligocene to the late Pliocene of North and South America, Europe, Japan, Australia, and New Zealand. Monophyly of the “Cetotheriidae” has been questioned since at least the 1920s and the group currently is recognized as paraphyletic or possibly polyphyletic (Bouetel and Muizon, 2006). Several recent cladistic studies have utilized a small number of “cetotheres” to investigate mysticete phylogeny and in the process have recognized two alternative topologies: either “cetotheres” lie outside of crown mysticetes or they are positioned within crown Mysticeti (Fig. 4). With the current increased interest in mysticete paleontology and the description of critical new fossils, it is likely that greater phylogenetic resolution will emerge for “cetotheres.” It is also likely that this greater resolution will allow recognition of distinct groups of “cetotheres” that are implicated in the origin of specific crown mysticete clades.

N

Narwhal *Monodon monoceros*

M.P. HEIDE-JØRGENSEN

I. Characteristics and Taxonomy

In 1758, Linnaeus used the scientific name *Monodon monoceros* for the whale with one tooth and one horn. Together with the close relative the white whale or beluga, *Delphinapterus leucas*, the narwhal now forms the two-species family of Monodontidae.

Newborn narwhals are evenly gray or dark-brownish gray. While nursing for 1–2 years, the coloration changes gradually to a dark background color with white patches that give a mottled appearance. When adult, the animals are completely mottled on the upper side but with increasing white fields on the ventral side. Old adult males only maintain a narrow dark-spotted pattern on the top of the back, whereas the rest of the body is white. Unlike in other cetaceans, the tail flukes are concave in fully grown narwhals, and a low ridge replaces the dorsal fin.

The most conspicuous feature of the narwhal is the up to 3-m long spiraled tusk (Fig. 1). Six pairs of maxillary and two pairs of mandibular dental papillae are present in early narwhal embryos, but only two maxillary pairs persist and develop. Of these, the two anterior teeth

develop into an elongated tooth that is the start of the tusk. The other two teeth remain vestigial. In males, the left of the two elongated teeth grows and protrudes through the maxillary bones and skin of the rostrum of the whale. During growth the tusk spirals to the left.

In males the right elongated maxillary tooth and in females both maxillary teeth remain inside the skull, sometimes just protruding through an opening in the maxillary bone. Irregularities in the development of tusks are frequently seen; females sometimes attain a tusk, males occasionally have no tusk, and narwhals with two tusks, so-called “double tuskers”, are not rare. There are several records of anomalous narwhals with skull characteristics that suggest hybridization with belugas (Heide-Jørgensen and Reeves, 1993). Most of these observations are from Disko Bay in West Greenland where narwhals and belugas occur together during the mating season in late winter (Heide-Jørgensen and Laidre, 2006)

There is a great variability in the shape and the dimensions of the protruding tusk. Some tusks are fairly straight and others are corkscrew-like; some are thin and fragile, whereas others are short and thick. The largest tusk measured was 267-cm long, but a full-grown male usually carries a tusk of about 200 cm. Tusks are sometimes broken, and there are records of a fragment of tusk from another narwhal sitting inside the broken tip, suggesting a head-on collision. The purpose of the tusk has been much disputed, but because both females and males without tusks thrive, they do not seem critical for survival. The tusk is more likely a secondary sexual character that is related to the hierarchy of male narwhals. Displays and crossing of tusks are frequently seen on narwhal summering grounds, and it is likely that this activity determines dominance hierarchies. Narwhals have not been observed using their tusks for fighting or other aggressive behavior.

There are several records of narwhal fragments from Pleistocene deposits in England and Germany. Bones found along the Russian Arctic coasts—both on the mainland and on the Russian Arctic Islands—also suggest a different occurrence or form of narwhals before or during the most recent glaciation. In Canada, bone remains from early postglacial times have also been found both north (Ellesmere Island) and south (Gulf of Saint Lawrence) of present narwhal distribution.

The main reason the narwhal remained a legendary animal for so long may be because of its preference for remote and inaccessible

Figure 1 The narwhal, *Monodon monoceros*, occurs in the remote North Atlantic and Arctic Oceans and is conspicuous with a long tusk in males, usually formed from one tooth in the left upper jaw.

habitats, usually in areas over deep water that is covered with heavy pack ice during dark winter months. Europeans did not visit most of these areas until the nineteenth century, and even though Inuit hunters traded the tusks with whalers, precise descriptions were lacking.

II. Distribution and Abundance

The narwhal essentially inhabits the Atlantic sector of the Arctic Ocean with few records of stragglers from the Pacific sector (Fig. 2). During the last glaciation, narwhals were restricted to the North Atlantic, but with the retreating ice they inhabited the archipelago of the Canadian high Arctic, northern Hudson Bay, Davis Strait, Baffin Bay, the Greenland Sea, and the Arctic Ocean between Svalbard and Franz Josef Land.

Today, low numbers of narwhals are found offshore in deep-water areas of the Eurasian sector of the Arctic Ocean, where they are seen most frequently around Franz Josef Land and Svalbard. The northernmost recordings of narwhals are from the area between 84°N and 85°N northeast of Franz Josef Land at 70–80°E. In the Greenland Sea, narwhals are widely distributed in the pack ice but probably in low numbers. Along the coast of East Greenland, narwhals are found during the open-water season in fjords from 65°N to 81°N, with particularly large concentrations in Scoresby Sound and Kangerlussuaq. No complete abundance estimates are available from any of the Northeast Atlantic areas, but in 1983 a negatively biased estimate of 300 narwhals was derived from a visual aerial survey in Scoresby Sound (Dietz *et al.*, 1994).

In West Greenland, narwhals visit coastal areas in northwest Greenland (Inglefield Bredning and Melville Bay) during summer and central West Greenland during autumn (Uummannaq) and winter (Uummannaq and Disko Bay). The number of narwhals present at the surface is estimated by visual or photographic aerial surveys (Innes *et al.*, 2002; Heide-Jørgensen, 2004). This number is then corrected for the fraction of the whales that are submerged during passage of the survey plane. Up to 4000 narwhals have been counted in Inglefield Bredning in August and 3000 in Disko Bay in March. Offshore, narwhals are abundant in the heavy consolidated pack ice in northern Davis Strait and Baffin Bay from late November through May, and the number of narwhals wintering in this area has been estimated at 35,000 (NAMMCO, 2006).

Most of the narwhals that spend the winter in Baffin Bay summer in the Canadian high Arctic. During ice break-up, narwhals move from Baffin Bay into the Canadian high Arctic through Lancaster Sound and Pond Inlet. They visit the fjord systems of Eclipse Sound, Admiralty Inlet, Prince Regent Inlet, and Peel Sound during the open-water season from June through September. The abundance in Prince Regent Inlet was estimated at 45,000 in 1996 and in Admiralty Inlet and Eclipse Sound at 15,000 and 3000 narwhals, respectively, in 1984 (NAMMCO, 2006). Prior to the formation of fast ice in October, narwhals move east towards Baffin Bay and Davis Strait.

In northern Hudson Bay and Foxe Basin, a group of 1300 narwhals is found in the summer; they winter in Davis Strait at the eastern entrance to Hudson Strait.

Narwhals seem to follow relatively strict migration schedules and seem to use the same routes for their annual migrations. It is uncertain how much of the migration is affected by the development of sea ice. The whales arrive at their wintering ground long before pack ice is formed in these areas, and during winter they stay in very heavy consolidated pack ice, usually in leads or holes in areas with less than 3% open water. Before the pack ice breaks up in the spring,

the narwhals penetrate north through narrow leads and open-water channels.

Movements from summer through winter have been monitored by tracking of narwhals instrumented with satellite-linked radio transmitters attached to the dorsal ridge or the tusk of the whales. At summering grounds in West Greenland and Canada, narwhals move back and forth between glacier fronts, offshore areas, and neighboring fjords. Before the fast ice forms, the whales move out to deeper water, usually up to 1000 m in depth. In October the whales move southward toward the edge of the continental shelf where the water depth increases over a short distance from 1000 to 2000 m. This slope is also used as a wintering ground, and even though the whales seem stationary in this area, they still conduct shorter movements along this steep slope. Narwhals tracked from Canada and West Greenland were within a few kilometers from each other at these wintering grounds at the deep slope at the edge of the continental shelf in central Baffin Bay. Satellite tracking of a few whales has also confirmed that they return to the summering ground where they were instrumented the year before, and no exchange between summering grounds has so far been found. The mean swimming speed of traveling narwhals is about 60 km per day (Dietz *et al.*, 2001; Heide-Jørgensen *et al.*, 2002).

Studies of mitochondrial DNA have revealed a low level of nucleotide and haplotype diversity in narwhals. This is probably the result of a rapid expansion of the population from a small founding population after the last glaciation. Despite the low variation in narwhal mtDNA, there are still genetic differences between narwhals from different areas. Not so surprisingly, narwhals from East Greenland are different from those inhabiting Baffin Bay, but more surprising is the distinctness of narwhals at two summering grounds (Inglefield Bredning and Melville Bay) and one autumn ground (Uummannaq) in West Greenland (Palsbøll *et al.*, 1997). Apparently, narwhals have annual fidelity to certain summer and autumn feeding localities, but the extent of mixing on the wintering grounds is unknown. The complex stock structure and the apparent overlap in distribution of whales from different areas suggest that narwhals in Baffin Bay and adjacent areas have a metapopulation structure where small populations are connected through movement of at least a few individuals, even if most of the populations remain physically separate.

III. Ecology

Feeding activity and prey selection by narwhals have been studied by examining stomachs, collected from the Inuit harvest in Canada and Greenland. Stomach samples in the summer were mostly empty with little evidence of recent feeding. Stomachs collected in late fall and winter had considerable amounts of undigested material with evidence of recent feeding. In summer, remains from Arctic cod (*Arctogadus glacialis*) and polar cod (*Boreogadus saida*) were occasionally detected. Gonatus squid remains were found in all seasons and in all localities, positively identified as 100% *G. fabricii* in late fall and winter stomachs. Greenland halibut (*Reinhardtius hippoglossoides*) was a major part of the diet of narwhals in winter and was often the only prey item identified in a completely full stomach. On a caloric basis, Greenland halibut are lipid-rich and contain higher energy content than Arctic or polar cod. The benefit of making deep dives to the bottom to prey on Greenland halibut may be due to the energy gained from this lipid-rich source (Laidre and Heide-Jørgensen, 2005).

Killer whales and polar bears are the only predators on narwhals. Killer whales feed on narwhals during the summer open-water

Figure 2 Distribution of the narwhal.

season, when the whales are found in dense aggregations in bays and fjords. Polar bears kill narwhals when they can use the sea ice as a platform to pull the whales out of the water, therefore polar bear predation is limited to winter and spring.

IV. Behavior and Physiology

Narwhals are usually found in small groups of 5–10 whales, migrating together. Sometimes larger herds are formed that consist of several smaller groups, often all in directional movement along

a coastline or toward the head of a fjord. The narwhal groups are usually segregated, with adult males in separate groups and females with calves sometimes together with immature males. Mixed groups occur, especially in large herds, but single animals, particularly males, can also be seen.

Data on narwhal diving have been collected from whales instrumented with dive recorders and satellite transmitters in both Canada and Greenland. Narwhals change their diving habits when moving from coastal and relatively shallow summering grounds to deep offshore wintering grounds. During summer narwhals make few dives below 500 m. This changes gradually during the autumn migration, and by the time they are at the wintering grounds, they make between 5 and 25 dives/day to depths exceeding 800 m, probably in search of deep-water prey. With several dive records exceeding 1500 m, narwhals are among the deepest diving marine mammals, and with a maximum dive record of 1864 m they rival some of the other deep-diving whales (e.g., sperm whales and beaked whales). However, the dives are usually completed within 25 min, and only few dives exceed 30 min, so the whales only have a short time at the bottom as ascent–descent rates for deep dives are 2 and 1 m/sec for shallow dives (Laidre *et al.*, 2003). The accumulated time spent below 800 m can exceed 3 h during a 24-h period on the wintering grounds.

Narwhals make a variety of noises. Clicks that are believed to be used for echolocation have been measured to have their maximum amplitudes at 48 kHz with rates of 3–10 clicks/sec. Faster click rates of 110–150 clicks/sec had maximum amplitudes at 19 kHz. Whistles or pure tones in frequencies from 300 Hz to 18 kHz have also been recorded; they are suspected to serve as social signals among the whales (Ford and Fisher, 1978; Miller *et al.*, 1995).

V. Life History

Age estimation of narwhals has proven to be difficult. Both the protruding tusk and the embedded teeth contain distinctive growth layers in both dentine and cementum, but with increasing age the growth layers apparently collapse and become unreadable. Also, there has been no empirical way to determine how many growth layers are deposited annually. So far, narwhals have not been kept successfully in captivity.

It has recently been shown that age of narwhals can be estimated by measuring the racemization of l-aspartic acid into d-aspartic acid in the nucleus of the eye lens. Based on this method, it seems likely that female narwhals can attain a maximum age of 115 years and that females have a slightly higher survival rate than males (Garde *et al.*, 2007).

Length at birth is approximately 160 cm. The male tusk erupts at a body length of 260 cm and attains a length of 150 cm at sexual maturity (Fig. 3). Body length at sexual maturity is around 360 and 420 cm for females and males, respectively. Mean length and weight at physical maturity are around 400 cm and 1000 kg for females and 450 cm and 1600 kg for males. Based on age estimates from aspartic acid racemization, age at sexual maturity is likely around 6–7 years for females and 9 years for males (Garde *et al.*, 2007).

The gestation period of the narwhal is subject to some uncertainty, as mating probably occurs in inaccessible areas in April–May. Calving seems to occur in June–August in both Greenland and Canada, and with a mating season early in spring, this implies a gestation period of 13–16 months. Lactation lasts 1–2 years, and females are generally believed to calve every 3 years, but data supporting this seem inadequate.

Figure 3 Narwhals lift their tusks in male-dominance display.

VI. Interactions with Humans

The narwhal is the animal behind the legend about the mysterious unicorn: a horse-like creature with a spiraled horn protruding from the forehead. The horn was supposed to have healing abilities, and the wild and shy animal could only be captured with a virgin as bait. Based on narwhal tusks that were brought south from Arctic coasts, this was essentially how narwhals were perceived in western civilization until the seventeenth century when the first descriptions of a fish-like sea monster appeared.

Narwhals have never been a target for commercial whaling, probably because of their skittishness and the difficulties involved in catching them. Inuit hunters in Greenland and Canada hunt narwhals for their valuable tusks and the highly prized skin that is considered a delicacy throughout the Inuit communities. The annual harvest level was on average 535 and 433 during 2000–2004 in West Greenland and Canada, respectively; this is considered small relative to the population size in most areas. However, depending on the population structure, some subpopulations may be overexploited. Concern has been raised about the sustainability of the harvest in West Greenland, and quotas have been installed to reduce the harvest to the recommended level of 135 whales per year. The harvest in East Greenland was on average 100 narwhals per year during 2000–2004; there are no quotas and no assessment of the sustainability of this harvest (NAMMCO, 2006).

Narwhals have high levels of some organochlorines and heavy metals where at least the first are of anthropogenic origin. Possible effects of these contaminants have not been studied in narwhals.

Because of their prevalence for high-density pack ice, narwhals are susceptible to climatic changes that influence the water currents and thereby ice formation in the Arctic. Whether it is naturally occurring or human-induced climate changes, narwhals may become entrapped or lose access to important feeding areas if ice conditions change.

A peculiar feature of the natural history of narwhals is their susceptibility to being entrapped in ice. Because of their preference for heavy pack ice, large schools of narwhals are occasionally caught in ice that freezes rapidly during intense cold, thereby preventing the whales from being able to breathe. This happens particularly often in areas where unpredictable ice conditions persist due to the mixing of warm and cold water masses of variable strength, e.g., Disko Bay in West Greenland. Large numbers of narwhals may succumb during such an ice entrapment, and in January 1915, more than 1000 narwhals died in a well-known ice entrapment in Disko Bay. If the whales are discovered, Inuit hunters may also prey upon them, using the word “sassat” for the event (Siegstad and Heide-Jørgensen, 1994).

Narwhals are only hunted in the Canadian Arctic and in East and West Greenland. In Canada the management of the hunt is regulated by a co-management agreement between the Department of Fisheries and Oceans and the Nunavut Wildlife Management Board. In Greenland the hunt is managed by the Greenland Home Rule Government. Scientific and management advice on sustainable harvest levels is generated by the North Atlantic Marine Mammal Commission and the Canada–Greenland Joint Commission for the Conservation and Management of Narwhal and Beluga. Narwhal hunting in both Canada and Greenland is managed by quotas that are based on the latest scientific information on sustainable harvest levels.

International trade in narwhal tusks and other narwhal products is monitored by the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES). The narwhals are currently listed under Appendix II of CITES, which requires national permits for import and export of products. Greenland installed a ban on export of narwhal products in 2006 due to concern about the sustainability of the hunt.

Greenland maintains two sanctuaries (Melville Bay and Northeast Greenland) that protect local stocks of narwhals from hunting and disturbances. In Northwest Greenland narwhal hunting is only allowed from kayak, and it is required that the whales are harpooned before being shot.

Neoceti

R. EWAN FORDYCE

I. Introduction

Neoceti is the taxonomic group comprising the two living clades of Cetacea (Odontoceti and Mysticeti) but excluding the extinct Archaeoceti. The two living groups are quite disparate, each distinguished by a unique combination of anatomical and ecological features. The Odontoceti (toothed whales, dolphins, porpoises) are echolocating macro-predators, whereas Mysticeti (baleen whales) are filter-feeders. Ancient cetaceans from Oligocene times (25 to +30 Ma) show skull structures indicative of echolocation in odontocetes and of filter-feeding in mysticetes, emphasizing the early divergence of feeding habits. Apart from the feeding apparatus, however, basal odontocetes and mysticetes are much more similar to one another than are their modern descendants. Similarities include some evolutionary novelties (synapomorphies) of the skull which are not seen in archaeocetes. Thus, odontocetes and mysticetes are regarded as sister taxa, forming a clade termed crown Cetacea, or Neoceti, or Autoceta. Basal odontocetes and mysticetes also show marked similarities with archaic cetaceans (Archaeoceti), indicating an origin within the archaeocete family Basilosauridae (Fordyce and Muizon 2001; Gingerich 2005).

The qualifiers “crown” and “stem,” below, are important in discussing cetacean systematics. The terms ensure that anatomists, molecular biologists, and paleontologists actually discuss the same taxonomic entities.

Figure 1 W. H. Flower, an influential cetacean systematist from the later 1800s (from Cornish 1904).

II. Changing Concepts of Names

The name Cetacea was first used in a modern sense by Brisson in 1762 for genera and species of living whales, dolphins, and porpoises. Until the mid-1800s, high-level classification was based on superficial features, with no implication that patterns amongst living cetaceans had arisen by evolution. In the 1860s, W. H. Flower (Fig. 1), who was perhaps the first cetologist to use evolutionary principles, was instrumental in establishing formal names for the living cetaceans: Mysticeti and Odontoceti (Table I). Flower implied that these were real groups (in modern terms, clades). The discovery of fossils broadened the concept of Cetacea in the earlier 1800s. Initially, most fossils were recognized as related to living species, and modern generic names (e.g., *Delphinus* and *Balaena*) were often used for such material. The discovery of the archaic Eocene whale *Basilosaurus* in the 1830s eventually led Flower in 1883 to name another formal group of cetaceans, the extinct Archaeoceti. Thus, the concept of Cetacea was expanded to include three suborders, one extinct (Archaeoceti), and two living (Odontoceti and Mysticeti) (Fig. 2).

III. The Monophyly of Odontoceti

Odontocetes include 74–75 living species in the families Physteridae, Kogiidae, Ziphiidae, Platanistidae, Delphinidae,

TABLE I
History of First Records for Names of Higher Divisions of the Cetacea

Author (date)	Formal name	Status
Linnaeus (1758)	Cete	A forgotten or little-used name for Cetacea
Brisson (1762)	Cetacea	First formal use of name
Gray (1864)	Mysticete	Formal precursor to Mysticeti
Gray (1864)	Denticete	A forgotten or little-used name for Odontoceti
Flower (1865)	Odontocete	Formal precursor to Odontoceti
Haeckel (1866)	Autoceta	A forgotten or little-used name for Neoceti
Flower (1867)	Odontoceti	First formal use of name
Flower (1867)	Mystacoceti	A forgotten or little-used name for Mysticeti
Cope (1869)	Mysticeti	First formal use of name
Gill (1871)	Zeuglodontia	A forgotten or little-used name for Archaeoceti
Flower (1883)	Archaeoceti	First formal use of name
Fordyce and Muizon (2001)	Neoceti	Formalization of a name used by J.G. Mead in an oral paper delivered at North American Paleontological Convention, 1996, Washington, DC

Based partly on Rice (1998).

Phocoenidae, Monodontidae, Iniidae, Pontoporiidae, and Lipotidae. Phylogenetic analyses based on molecules, anatomy, and fossils indicate that the Odontoceti is monophyletic (Nikaido *et al.*, 2001; Geisler and Sanders, 2003). Strictly defined, the Odontoceti comprises the most-recent common ancestor of all living species, plus all the descendants of that ancestor. The oldest named odontocete is the early Oligocene *Simocetus rayi* (~32 million years), but older unnamed odontocetes are known. Odontocetes arose at the same time as their sister group, Mysticeti (Section IV), by 34.2 million years in late Eocene time. In practice, fossil and recent odontocetes are distinguished by osteological features (Fig. 3), particularly in the skull (Miller, 1923). For example, above the eye, a large supraorbital process in each maxilla rises posteriorly over frontal, forming a voluminous facial fossa in which open dorsal infraorbital foramina for nerves and blood vessels; in living species, this fossa forms the origin for the nasofacial muscles which manipulate diverticula or sacs in the soft nasal passages. In turn, the diverticula help to produce echolocation sounds. Where the rostrum passes into the facial fossa, a vertical antorbital notch transmits the facial nerve to the nasofrontal muscles. Anteriorly, in front of the bony nares, are premaxillary sac fossae, premaxillary foramina, and premaxillary sulci which, in living species, are implicated in sound generation in the nasal passages. Below the face, the infraorbital process is vestigial or absent, and the most posterior tooth lies far forward of the antorbital notch. In the ear region on the skull base, the periotic no longer contributes to the floor of the braincase. Finally, odontocetes have a middle sinus extending laterally from the ear near the jaw joint in the glenoid cavity.

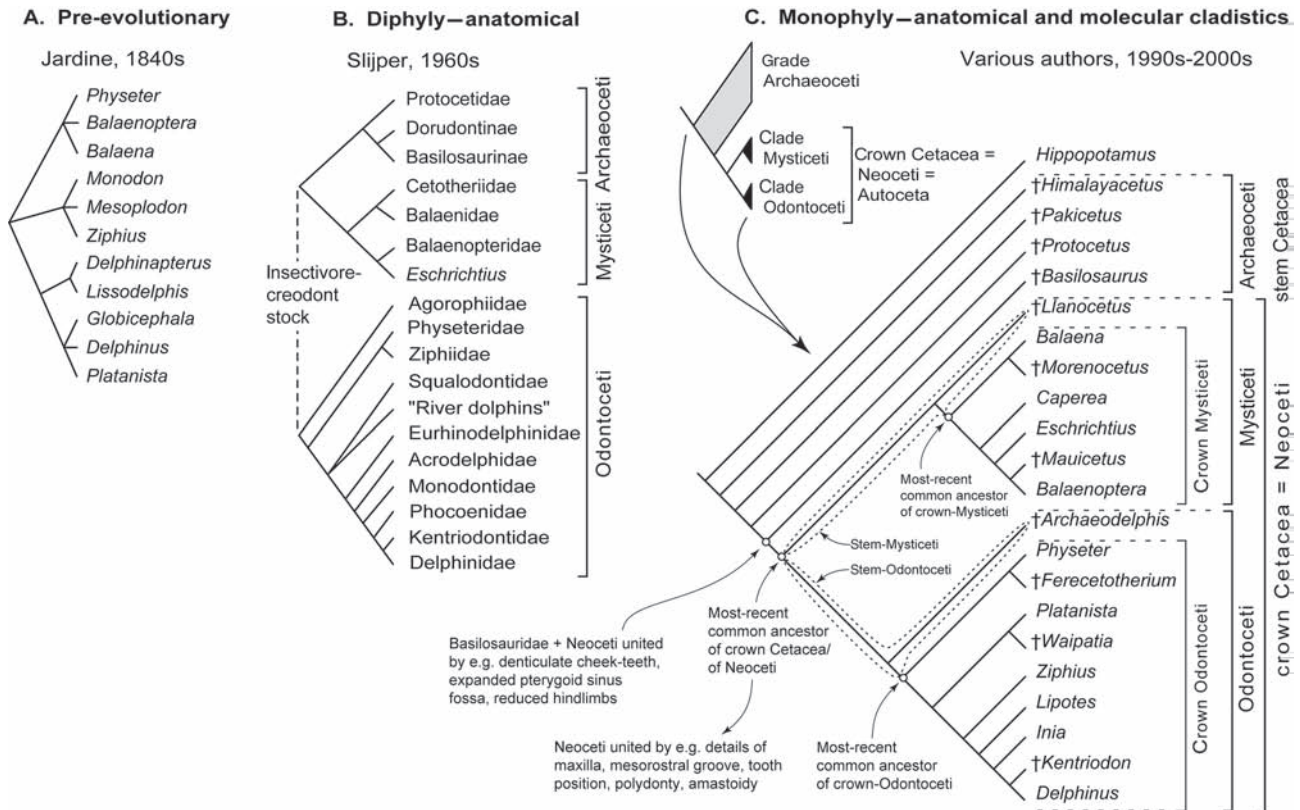

Figure 2 Changing concepts of the Cetacea. (A) Pre-evolutionary classification as used by Jardine and others, early to mid-1800s. Species are clustered on the basis of sometimes-superficial features. Genealogical relationships are not particularly implied. (B) Interpretation of cetacean diphyly, as used by Slijper (cladogram based on a phylogeny from Slijper 1979). (C) Composite simple cladogram showing current understanding of Cetacea. Crown-group Cetacea (Neoceti) has two sister taxa, Odontoceti and Mysticeti; included genera represent most of the recognized crown families; only a few fossil genera are included.

IV. The Monophyly of Mysticeti

Mysticetes include 13–14 living species in the families Balaenidae, Neobalaenidae, Balaenopteridae, and Eschrichtiidae. Phylogenetic analyses based on molecules, anatomy, and fossils indicate that the Mysticeti is monophyletic. Strictly, the Mysticeti comprises the most-recent common ancestor of all living species, plus all the descendants of that ancestor. The oldest named mysticete is the latest Eocene *Llanocetus denticrenatus* (about 34.2 million years); this fossil is also the oldest named species of Neoceti. Unlike living species, fossil mysticetes are not recognized by the presence of baleen for, though this probably occurred in most extinct species, it preserves rarely. Rather, osteological features (Fig. 3), particularly in the skull (Miller, 1923), distinguish the Mysticeti. The rostrum is relatively large, with thin edges and a smoothly concave and usually broad lower surface. The main bones in the rostrum (vomere, premaxilla, and maxilla) are generally sutured loosely with each other and, posteriorly, with the cranium. The lacrimal is also loosely sutured between the frontal and the preorbital part of the maxilla. Loose sutures between the feeding apparatus and cranium account for the common loss of the rostrum in fossil mysticetes; perhaps, such sutures function in skull kinesis during filter feeding. Ventrally, the toothless maxilla carries baleen; in some archaic forms, the maxilla may have teeth which lie well forward of the orbit. Posteriorly, the maxilla extends towards the orbit, forming a prominent infraorbital plate below the frontal. Finally, the mandibles are joined by ligaments at a short symphysis. Other

putative diagnostic features of the skull are seen in most, but not all, mysticetes, as noted below for archaic forms.

V. The Monophyly of Odontoceti and Mysticeti

In the later 1800s and indeed until the 1960s, the known archaeocetes and fossil mysticetes and odontocetes seemed rather divergent from one another. Slijper (1979) and other influential cetologists doubted a close relationship between the odontocetes and the other two groups, and were uncertain about mysticete origins amongst the archaeocetes. Thus, the two living groups of cetaceans were regarded as diphyetic, of different ancestry. They were sometimes classified as distinct orders.

From the 1970s to 1990s, several major advances overturned notions of diphyly and ultimately changed cetacean nomenclature. The fossil record of Eocene archaeocetes and of Oligocene odontocetes and mysticetes expanded markedly, helping bridge the structural and stratigraphic “gap” between the three groups. It became clear that evolution is not always slow and gradual, and that major structural change can occur in short geological intervals. Developments in deep ocean drilling led to much improved geological correlation, helping to date, and clarify, evolutionary sequences. Molecular and biochemical approaches to phylogeny indicated close relationship between odontocetes and mysticetes. The rise of cladistics (phylogenetic systematics) clarified many concepts of relationship and nomenclature.

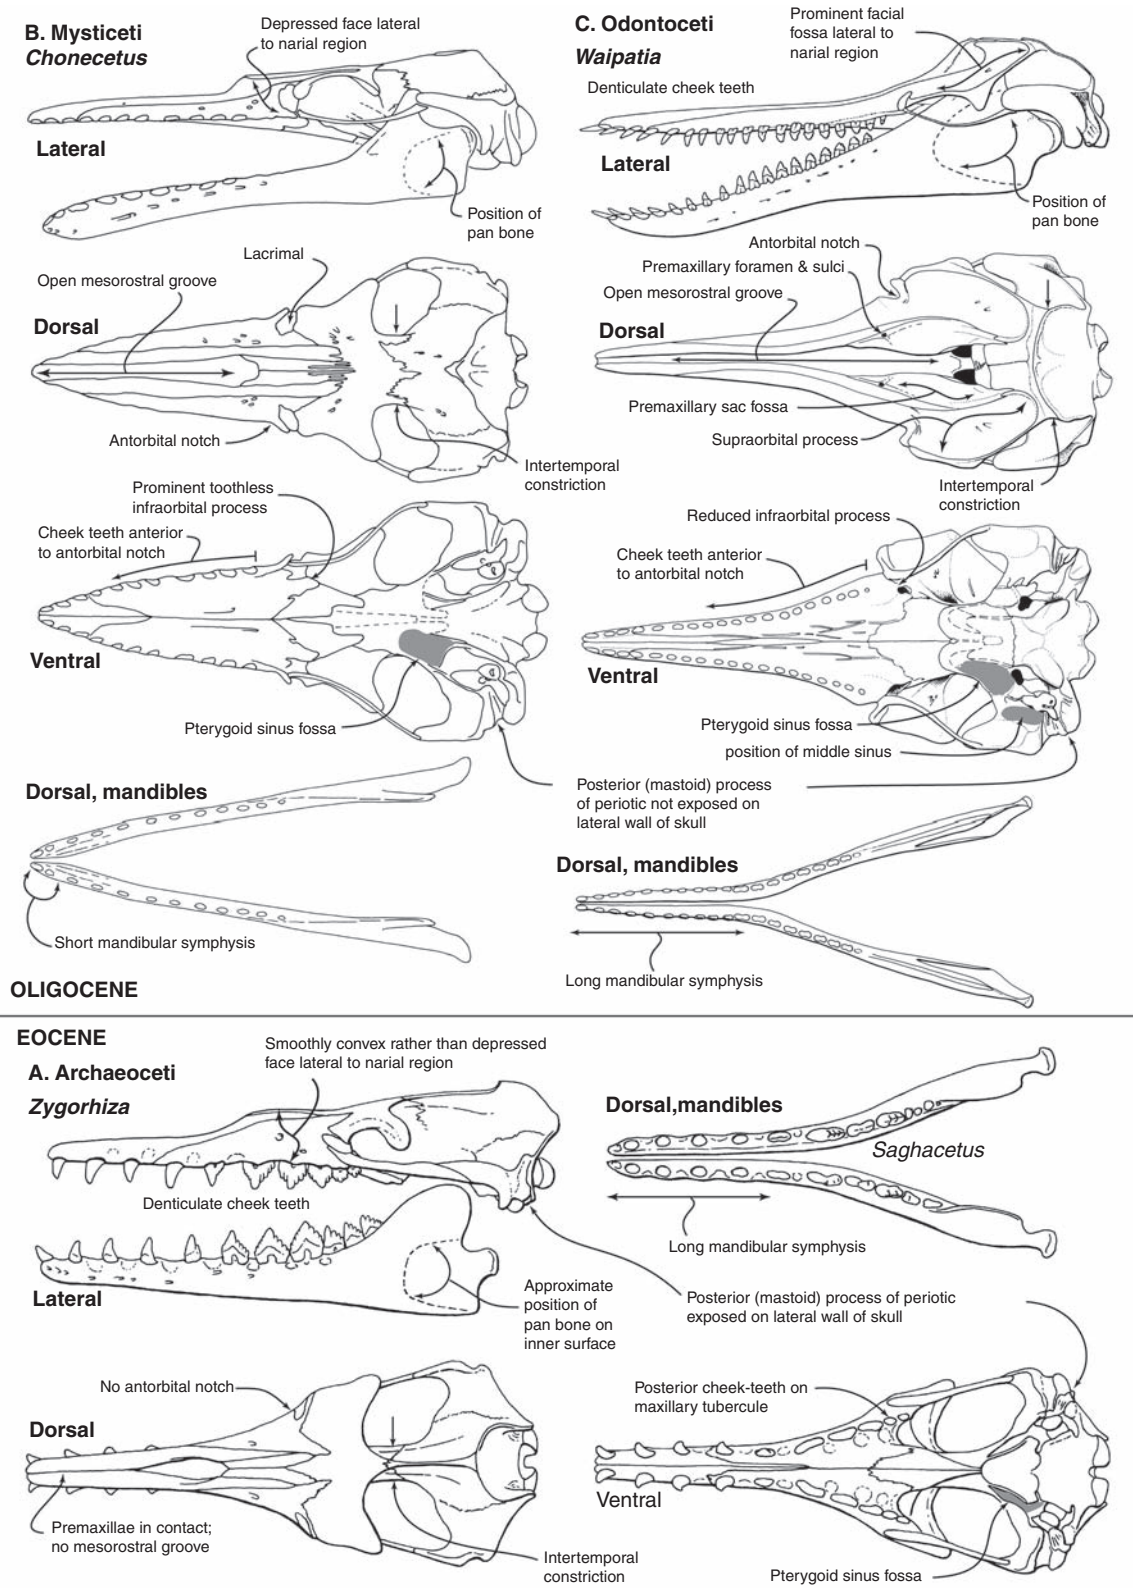

Figure 3 Morphological similarities and differences amongst later archaeocetes and basal odontocetes and mysticetes. Originally published as Figure 2, in *Neoceti*, R. E. Fordyce, *Encyclopedia of Marine Mammals*, W.F. Perrin et al. (eds), Copyright Elsevier 2002. (A) Archaeocete. Lateral, dorsal and ventral views of the archaeocete skull show the dorudontine *Zygorhiza kochii* (Basilosauridae: Dorudontinae; Priabonian, latest Eocene), based on Kellogg (1936). Dorsal view of the archaeocete mandibles shows the dorudontine *Saghacetus osiris* (Basilosauridae: Dorudontinae; Priabonian, latest Eocene), based on Stromer (1908). (B) Archaic mysticete. Lateral, dorsal and ventral views of skull, and dorsal view of mandibles show *Chonecetus goedertorum* (Mysticeti: Aetiocetidae; Chattian, Late Oligocene), based on Barnes et al. (1995). In life, the animal had teeth which were lost at burial. (C) Basal platanistoid odontocete. Lateral, dorsal and ventral views of skull, and dorsal view of mandibles show *Waipatia maerewhenua* (Odontoceti, Waipatiidae; Chattian, Late Oligocene), based on Fordyce (1994). Some teeth are in situ on the original fossil, but for simplicity are not shown in other than the lateral view.

The Odontoceti and Mysticeti are now widely regarded as forming a clade Neoceti, equivalent to the Cetacea in the sense of Brisson and, indeed, of many modern systematists. There is no support for the 1990s molecular diphyly concept of sperm-whales-as-mysticetes. Strictly, the Neoceti is the crown Cetacea; it includes all descendants, living and extinct, of the most-recent common ancestor of Odontoceti and Mysticeti.

Odontocetes and mysticetes do share bony features not seen in archaeocetes, supporting their sister-group relationship. In both, the posterior of the maxilla is at least slightly concave, rather than smoothly convex, and carries multiple dorsal infraorbital foramina that open dorsally rather than anteriorly. On the rostrum, an open mesorostral groove extends far anteriorly, so that the premaxillae have little or no contact in the midline. The posterior-most teeth in odontocetes and toothed mysticetes lie anterior to the antorbital notch. Most (not all) basal species are polydont, with more than the usual mammalian number of cheek-teeth, and a tooth succession is unknown. Compared with basilosaurid archaeocetes, the zygomatic process of squamosal is more robust and anteriorly produced, with a more-delicate jugal. Finally, odontocetes and mysticetes are amastoid, with the posterior (mastoid) process of the periotic not exposed laterally on the skull wall.

Odontocetes and mysticetes are often identified as having a “telescoped” skull, in which bone positions have moved dramatically relative to familiar mammalian landmarks such as the nose and the eye (Miller, 1923). However, “telescoping” is a wide-ranging term applied to at least four different functional shifts involving both the facial region and braincase. It should not be cited to support the monophyly of odontocetes and mysticetes.

VI. Primitive Features in Basal Odontocetes and Mysticetes

Some early fossil odontocetes and mysticetes have features similar or even identical to those seen in some basilosaurid archaeocetes (Fig. 3) (Fordyce and Muizon, 2001). Examples of such fossils include, amongst odontocetes, *Xenorophus* and *Archaeodelphis*, and amongst mysticetes, the Aetiocetidae, *Mammalodon*, *Janjucetus*, and *Llanocetus*. These examples are stem, rather than crown, members of Odontoceti and Mysticeti respectively. The most-obvious basilosaurid-like features of archaic odontocetes and mysticetes are the prominent intertemporal constriction, formed by elongate parietals dorsally on the braincase, and heterodont teeth. In all, the anterior teeth have single roots and simple crowns clearly distinct from two- or three-rooted cheek-teeth with complex denticulate crowns. Multiple denticles on the crown are an evolutionary novelty linking basilosaurids, odontocetes, and mysticetes. Further, the posterior mandibular cheek-teeth in archaic odontocetes have a distinctive anterior vertical groove, as in basilosaurids. (The loss of the last upper molar, M3, in basilosaurids, has been used to dismiss a basilosaurid origin for odontocetes and mysticetes. However, a widely variable tooth complement in the latter, and the likelihood that polydonta involved increase in the number of mid- to posterior cheek-teeth would allow a basilosaurid origin.)

Other parts of the feeding apparatus are revealing. In basilosaurids and basal odontocetes and mysticetes, the mandible has a large mandibular fossa (reduced in more-crownward mysticetes), and the temporal muscle has a distinct vertical origin on the frontal. (This origin changes dramatically in most odontocetes, becoming overridden by facial bones, and in mysticetes, migrating over the orbit.)

In all groups, the foramina in the orbit are not tightly clustered (as in living species) but are scattered anteroposteriorly. Ventrally,

in the skull base, an enlarged subspherical pterygoid sinus fossa is formed by alisphenoid and pterygoid. Such a fossa is absent in Protocetidae and more basal archaeocetes, and becomes more elaborate in more crownward Odontoceti and Mysticeti. Common features in the ear region include a lack of fusion between the periotic and the tympanic bulla (fusion occurs in later mysticetes), laterally compressed processes on the periotic (becoming more inflated in many later odontocetes), and a rather low squat tympanic bulla (becoming smoothly rounded in later mysticetes, but more elevated and delicate in later odontocetes). Other basilosaurid features in stem Neoceti include persistent postparietal foramina in the braincase, and prominent exoccipital condyles.

VII. The Paraphyly of Archaeocetes

Because odontocetes and mysticetes (=crown Cetacea) arose from amongst basilosaurid archaeocetes (Uhen, 2004; Gingerich, 2005), the suborder Archaeoceti is paraphyletic. Archaeocetes form an artificial cluster of cetaceans that lack the features of Odontoceti or Mysticeti. Many cladists would not recognize archaeocetes as a formal group and would use the term “stem Cetacea” as an alternative to Archaeoceti. To recognize archaeocetes as cetaceans expands the concept of Cetacea beyond the crown group, and indeed expands it beyond the concept used by Brisson. It is possible that some archaeocete species, in the traditional sense, might be closest to odontocetes, whereas others may be closer to mysticetes.

New Zealand Sea Lion

Phocarctos hookeri

NICHOLAS J. GALES

I. Characteristics and Taxonomy

Phocarctos hookeri (Gray, 1844) is named in honor of Sir James Hooker, who was the botanist with the British Antarctic expedition of 1839–1843. It is monotypic and is one of the world's seven extant sea lions.

New Zealand sea lions, like all otariids (eared seals), have marked sexual dimorphism; adult males are 240–350 cm long and weigh 320–450 kg and adult females are 180–200 cm long and weigh 90–165 kg. At birth, pups are 70–100 cm long and weigh 7–8 kg; the natal pelage is a thick coat of dark brown hair that becomes dark gray with cream markings on the top of the head, the nose, tail, and at the base of the flippers. Adult females' coats vary from buff to creamy gray with darker pigmentation around the muzzle and flippers. Adult males are blackish-brown with a well-developed black mane of coarse hair reaching the shoulders (Fig. 1).

II. Distribution and Abundance

The New Zealand sea lion is endemic to New Zealand and is one of the most regionally localized and rare of the world's pinnipeds. It is classified as a threatened species by the International Union for

the Conservation of Nature (IUCN). Prior to human arrival in New Zealand, *P. hookeri* was more widespread and probably more abundant than today. While the pristine breeding range of *P. hookeri* included almost all New Zealand coastal, island, and subantarctic territory, a combination of subsistence hunting by Maori and commercial sealing by Europeans have virtually reduced the current breeding range to two groups of subantarctic islands. Currently about 86% of New Zealand sea lion pups are born at three sites in the remote Auckland Islands; the remaining pups being born at nearby Campbell island (Fig. 2). Occasionally, single pups are born at regular sea lion haul-out sites on the South Island, the most regular of which is at the Otago Peninsula. Total annual pup production has been monitored intensively since 1994. Typically 2800–3000 pups are produced, but since 2004 this has reduced to about 2500, possibly through a combination of disease events and incidental mortality in an adjacent squid fishery (Gales and Fletcher, 1999; Chilvers *et al.*, 2007). Estimates of absolute abundance based on a pup production of 2800 are 12,500 (95% CI 11,100–14,000). Although recent variations in pup production have been recorded, the population appears to have been stable for the past few decades.

III. Ecology

New Zealand sea lions breed and haul out on a diverse range of terrestrial habitats, including sandy beaches, reef flats, grass and herb fields, dense bush and forests, and solid bedrock. Each site generally has easy access to relatively protected waters (Fig. 3). The sympatric New Zealand fur seal (*Arctocephalus forsteri*) selects rockier, more exposed sites, and the two species rarely interact on land. The marine habitats of New Zealand sea lions have only been described for lactating females from the Auckland Islands. Here they forage on primarily benthic and demersal habitats in the waters of the adjacent Auckland Island shelf. Other age and sex classes disperse more widely; in particular, adult and subadult males, tagged at the Auckland Islands, have been seen at Macquarie Island and around the southern parts of New Zealand.

Little is known of the normal disease status of New Zealand sea lions. The highly localized distribution of this species makes it particularly vulnerable to the effect of epizootic disease, and indeed in January 1998 an unusual mortality event occurred. At least 53% ($n = 1600$) of the pups of the year died, as well as many juveniles and adults. The principal cause is thought to be the bacteria *Klebsiella pneumoniae*, and several smaller scale outbreaks have been reported since (Wilkinson *et al.*, 2006). The sea lion population was also found to have been exposed previously to phocine distemper virus, a virus that has resulted in many marine mammal deaths worldwide. An undefined suite of environmental factors (including a strong ENSO event, or El Niño) that stressed the sea lion population and decreased its immunity may have influenced these events.

Sharks are likely to be the most significant predator of sea lions; with recent and healed bite wounds being a feature of many animals at the Auckland Islands. Occasional visitors such as leopard seals (*Hydrurga leptonyx*) have been observed to eat small sea lions, and the killer whale (*Orcinus orca*) may also be a predator.

Sea lions at the Auckland Islands forage on a wide variety of prey, with benthic and pelagic organisms being represented. Thirty-three taxa have been identified from analyses of identifiable remains in scats and regurgitations, with fish comprising 59%, cephalopods 22%, and crustaceans 15% of the remains found. The six most abundant prey items [in decreasing order of abundance: opalfish (*Hemerocoetes* sp.), octopus (*Enteroctopus zelandicus*), mumida (*Mumida gregaria*), hoki

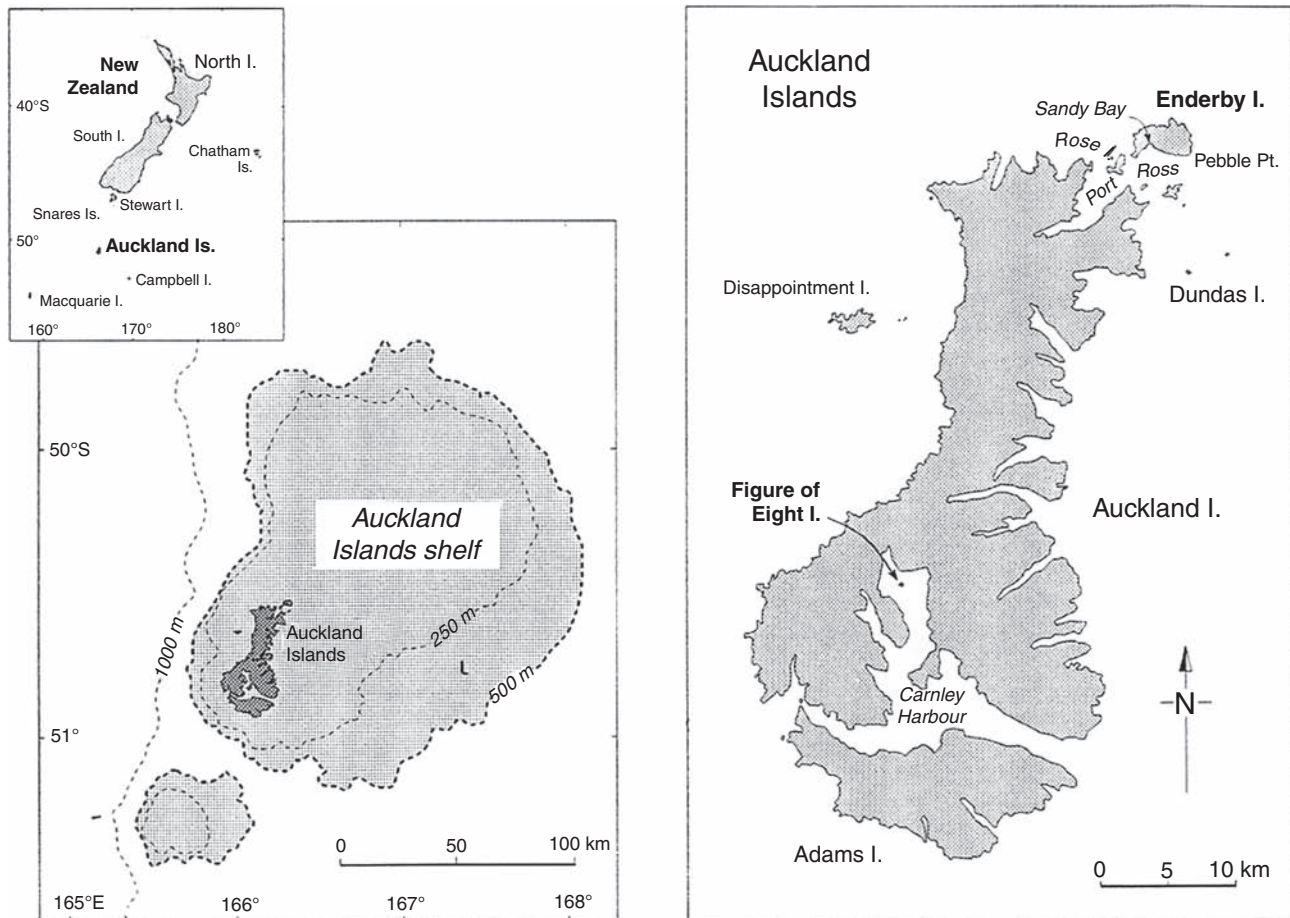

Figure 2 Distribution of the New Zealand sea lion.

Figure 3 New Zealand sea lion rookery at Enderby Island.

(*Macruonius novaezelandiae*), oblique-banded rattail (*Coelorhynchus aspercephalus*), and salps (*Pyrosoma* sp.)] accounted for 90% of the total prey items. The diet of male sea lions on the Otago Peninsula has been found to represent a similar range of prey. Given the problems of bias associated with quantifying diet from scat and regurgitate analysis, further work utilizing newer, more precise tools such as genetic and fatty acid analyses would be most instructive.

IV. Behavior and Physiology

New Zealand sea lions are among the deepest and longest diving of the otariids. At sea they dive at a mean rate of 7.5 dives/h and spend 45% of the time submerged. They undertake dives to a mean of 123 m (median 124 m, maximum >500 m) and spend an average of 3.9 min (median 4.33 min, maximum 11.3 min) on each dive more than 6 m. Almost half of the dives exceed the calculated *aerobic dive limit*, leading to a hypothesis that the dive behavior of *P. hookeri* reflects either successful physiological adaptation to exploiting benthic prey or a marginal foraging environment in which diving behavior is close to physiological limits (Gales and Mattlin, 1997). It has been shown subsequently that New Zealand sea lions have indeed equipped themselves physiologically for deep diving by having the largest blood volume of any otariid (Costa *et al.*, 1998). Behavioral adaptations, such as “burst and glide” diving, also appear to be used by this species to maximize the time available for foraging on the benthos, while still maintaining an effective energy budget. They have also been shown to be operating at what is likely to be close to their physiological maximum, as the gains in diving performance have been made with O₂ storage increase but not through a significant decrease at their at-sea metabolic rate (Costa and Gales, 2000). This degree of physiological and behavioral adaptation may well suggest a marginal habitat for this species (Chilvers *et al.*, 2006).

The breeding behavior of *P. hookeri* is typical of that of a polygynous otariid. Territorial males begin to assemble and defend physical

territories at breeding rookeries in late November. Pregnant females begin to arrive in early December and aggregate into harems of up to 25 animals attended by a single dominant bull. Challenges from peripheral males are regular and the tenure of territorial males is short. There are no published studies to elucidate the behavioral mechanisms by which female movement within and between the harems is determined. Females give birth soon after arrival; the pupping season lasting about 35 days. By mid-January most territorial bulls have departed, the harems break up, and females and pups disperse to occupy surrounding areas.

Postparturient females exhibit estrus 7–10 days after the birth of their pup and are mated by the territorial bull. Soon after, they depart on their first foraging trip. During the first few months of lactation trip durations average 1.7 days at sea, interspersed with an average of 1.2 days ashore feeding the pup. Unattended pups gather into groups during maternal absence. At least 10% of pups die during the pupping season. Although the causes of this early mortality have not been studied, it is thought to be caused principally by starvation, parasitism, trauma, and disease. Infanticide and cannibalism by bulls have been observed. A high frequency of cows simultaneously nursing more than one pup (6% of observations) has been reported for *P. hookeri* during the first few weeks of pup rearing. This fostering behavior may be associated with kin selection in small populations. Lactation lasts about 10 months (Gales, 1995).

V. Life History

Females are thought to become sexually mature at 3 years or older and produce their first pup a year later. The duration of an assumed embryonic diapause has not been measured. The mean reproductive rate of females is 0.67. Males are reported to be sexually mature at 5 years but do not hold territories for a further 3–5 years. Mean adult survival is 0.81 and females have been recorded living to 28 years. The average age of reproductive females is about 11 years. These data show that New Zealand sea lions are among the slowest growing, slowest reproducing, and longest lived sea lion species.

VI. Interactions with Humans

New Zealand sea lions are subject to incidental drowning in squid and other trawl fisheries that operate around the Auckland Islands. The number of sea lions killed in the squid fishery (estimated to range from 17 to 141 per year for the period 1988–2006) has been the cause of serious concern and has led to a number of management measures. These include the imposition of a 12 nautical-mile marine reserve around the Auckland islands in which commercial fishing is prohibited; the deployment of government observers on trawlers to record the incidence of marine mammal bycatch (7–32% of tows observed each year for 1988–2006; bycatch rate varied from 0.6% to 11.2% of tows during this period); a delay in the opening of the seasonal fishery until February 1 each year; a voluntary code of practice for the industry, which aims to reduce the chance of bycatch; and the imposition by the New Zealand government of a maximum number of sea lions that could be killed in any 1 year. Initially this was a maximum allowable level of fishing related mortality (MALFIRM), the reaching of which leads to the early closure of the fishery for that season. This MALFIRM (set at the beginning of each season on the basis of an approved model at about 60–80 sea lions) was exceeded each year between 1995 and 1998, and the fishery was closed early in the latter 3 years. In 2003 the MALFIRM was superseded by a Bayesian model; the Fisheries-Related Mortality Limit (FRML). This has allowed higher levels of sea lions deaths,

ranging from 97 to 150 each year and has not led to the closure of the fishery. This increase in allowable bycatch has coincided with a substantial decrease in pup production in the past few years. In efforts to mitigate the sea lion–fishery interaction, specially designed escape devices are also being tested and deployed.

Another identified danger to New Zealand sea lions is tourism (principally subantarctic, but also on the Otago Peninsula). These interactions are regulated via a limited-entry permit system on the subantarctic islands and by behavioral protocols for tourists here and elsewhere. Other impacts, such as pollution, entanglement, and direct killing, are not thought to be significant. There are no *P. hookeri* held in captivity. Under the auspices of a population management plan, the New Zealand government aims to monitor and research the sea lion population, mitigate threatening processes and remove the sea lion from its threatened status within 20 years (from 1999).

Noise, Effects of

BERND WÜRSIG AND W. JOHN RICHARDSON

When we humans submerge our heads, the ocean seems relatively silent. This misconception occurs because our ears are optimized to hear in air and have poor sensitivity in the much denser medium of water. In reality, the oceans are full of sounds. Natural sources of underwater sound include breaking waves and surf,

rain striking the sea surface, ice cracking and groaning in the higher latitudes, and the distant rumble of storms and earthquakes. Besides these physical sources, there is also a rich biological repertoire. There are sounds of snapping shrimp, grunting fishes, squeaking and popping sirenians, and the amazingly varied vocalizations of pinnipeds and cetaceans. Walrus (*Odobenus rosmarus*) display by knocks and mews; bearded seals (*Erignathus barbatus*) emit elaborate trills during their breeding season; toothed whales often whistle, send bursts of staccato-like click trains, and echolocate; and large whales moan, groan, and in some cases sing for group cohesion, sexual displays, and communication (Tyack, 2000). Some researchers suspect that strong low-frequency sounds of certain baleen whales may also function as

active sonar, helping them to navigate across wide open ocean spaces or around ice, or to locate silent conspecifics.

Unfortunately, the industrialized world has created other sources of noise underwater (Fig. 1). There is motorized shipping, underwater blasting, and offshore drilling, dredging, and construction. These activities produce underwater sounds incidentally, not purposefully. Several other types of underwater sounds are created purposefully: fathometers and sonars of many types operating at frequencies ranging from very high to low; air gun pulses for oil and gas exploration; pingers used to locate underwater equipment and to alert marine mammals to the presence of fishing nets; electronic acoustic harassment devices to keep marine mammals away

Figure 1 General types of natural and human-made sounds in the world's oceans. Adapted from Wenz (1962).

from mariculture facilities; and widely varying sounds used for ocean science measurements over short and long distances. Fish and marine mammals have evolved with the rich physical and biological cacophony of nature and are presumably well adapted to those sounds. However, most anthropogenic (human-generated) sounds first appeared in the past about 100 years, and in some parts of the world are increasing in intensity and geographical extent decade by decade (Gisiner *et al.*, 1999; Simmonds *et al.*, 2004; Jasny *et al.*, 2005).

Most marine mammals rely on underwater sound for communicating, finding prey, avoiding predators, and probably navigating. Other senses are available to them (sense organs, overview), but sound is the most important one at distances or in environments where the senses of touch, taste, and sight are not available. However, it is well known that pinnipeds (sea lions, fur seals, seals, and walruses), sirenians (manatees and dugong, *Dugong dugon*), and cetaceans (dolphins, porpoises, and whales) use sound both passively, when listening to the environment, and actively, when communicating. The toothed whales also echolocate to find prey, detect predators, and maneuver in the environment. It is unclear how much sea otters (*Enhydra lutris*) and polar bears (*Ursus maritimus*) rely on sounds underwater.

The acoustic frequencies that are most important vary with the type of marine mammal. See also the chapter on (sense organs, overview). Baleen whales tend to use lower frequencies of sound: predominantly below 1 kHz and reaching down into the infrasonic (below human hearing; <20 Hz) range in fin and blue whales, *Balaenoptera physalus* and *B. musculus*. Toothed whale communication is mainly above 1 kHz, and the echolocation sounds of most species are at very high frequencies, some as high as 150 kHz. The latter sounds are far above the frequency range audible to humans (“ultrasonic”). Pinnipeds and sirenians tend to be intermediate between baleen and toothed whales with respect to the frequencies of their calls (mainly at 0.5–10 kHz) and optimum hearing range. The optimum frequencies for pinnipeds and sirenians are similar to those for humans.

Although sounds of sirenians, some pinnipeds, and some small odontocetes are weak and audible only within a few tens of meters, most cetacean sounds are much stronger (Richardson *et al.*, 1995). Received sound levels and maximum detection distances depend not only on the strength of the sound at the source (“source level”), but also on the frequency, on physical properties of the environment through which the sound propagates, and on background noise levels. Nevertheless, smaller dolphins and porpoises can be heard to several hundred meters. Killer whale (*Orcinus orca*) “screams,” social sounds of pilot whales (*Globicephala* spp.) and the staccato click sounds of sperm whales (*Physeter macrocephalus*) reach to several kilometers. Communication sounds of many odontocetes and mysticetes have source levels of 160–180 dB re 1 μ Pa at 1 m distance (as “decibels relative to one micropascal at one meter distance”; see noise level descriptions). The clicks of bottlenose dolphins (*Tursiops* spp.) and sperm whales can have much higher peak levels, more than 220 dB in the same units (Au *et al.*, 2000; Møhl *et al.*, 2000). Echolocation clicks of some smaller odontocetes have lower peak levels (Würsig and Au, 2004), and all odontocete echolocation pulses are very brief and do not contain much energy despite the high peak levels sometimes achieved. In a few species of seals, e.g., bearded and Weddell seals (*Leptonychotes weddellii*), the males appear to use complicated tonal sounds as advertising displays to warn off other males (and possibly to attract females); these sounds can also be quite strong. These seals, which defend underwater territories (or “maritories”), are exceptional among the pinnipeds, however.

Anthropogenic sounds can result in a variety of effects whose consequences to marine mammals can range from nil to severe, depending on the type and received level of the sound:

Tolerance (no overt response). Mammals exposed to audible levels of human-made sounds often exhibit no obvious responses, continuing their normal activities without moving away. A marine mammal hearing a sound does not always react overtly to it. However, responses can be subtle so a detailed behavioral and physiological study is needed before it is legitimate to conclude that there is no overt response. Marine mammals sometimes tolerate noise in order to remain in a preferred location, such as a feeding area, even if the noise is strong enough to cause reactions when the same species is engaged in other activities.

Changes in behavior or activity. Alterations in behavior are common when marine mammals are exposed to human-made sounds. Sometimes the effects are subtle, discernible only by detailed observation and statistical analysis, e.g., changes in surfacing/respiration/dive cycles. More conspicuous effects include changes in activity, e.g., from resting or feeding to alert, facing toward the noise source, and so on.

Avoidance reactions. Upon exposure to strong man-made sounds, marine mammals engaged in feeding, social interactions, or other “normal” activities often interrupt those activities and swim away (or occasionally toward). When a noise source operates in the path of migrating whales, they typically deflect a few degrees off their “normal” course and swim to one side or the other side of the noise source.

Masking. Masking is the process whereby sounds of interest to a listener are obscured by interfering sounds. If those sounds are important to the listener (e.g., for breeding or predator avoidance), continuous, and prolonged, masking could have a serious effect (Richardson *et al.*, 1995). However, masking is likely to be a problem only if a human-made sound is persistent and at a similar frequency to the sound of interest to the animal, and then mainly if the two sounds are received from similar directions.

Hearing impairment. Animals (including humans) exposed to strong sounds can incur a reduction in their hearing sensitivity. This impairment is often temporary, provided the sound levels are not too high or too prolonged. However, repeated exposure to strong sounds, and even a single brief exposure to an extremely strong sound (e.g., nearby explosion), might cause permanent hearing impairment. Temporary threshold shift (TTS) has been demonstrated in captive odontocetes and pinnipeds exposed to strong sounds. Except for nearby explosions, there is as yet no demonstrated case of noise-induced permanent threshold shift (PTS) in a marine mammal.

Nonauditory physiological effects and stress. In humans, exposure to very strong underwater sounds can, under special circumstances, cause resonances in lung cavities and other types of nonauditory physiological effects. Chronic exposure to strong noise may also at times cause stress reactions. These phenomena are almost entirely unstudied in marine mammals.

Mortality of beaked whales. Several mass strandings and deaths of beaked whales have occurred in various regions upon exposure of these little-known animals to sounds from mid-frequency naval sonars. The involvement of sonar in causing mass strandings of beaked whales in the Mediterranean Sea, Canary Islands, Bahamas, etc., is generally agreed. However, the specific reason(s) for these deaths are controversial. Suggested mechanisms include panic reactions leading to stranding, a form of “the bends” when normal dive patterns are disrupted, resonance in body cavities, and auditory injury (Fernández *et al.*, 2005; Cox *et al.*, 2006).

The term “noise” indicates an unintentional or unwanted sound, possibly disagreeable or noxious. We tend to think of noise as sound we do not like, but this is a subjective impression; a sound that is noise to one person or animal may be an important signal (or music) to another. For example, the songs of humpback whales (*Megaptera novaeangliae*) are undoubtedly important to them. We do not know whether these strong and—in some areas—seasonally persistent sounds are regarded as “music” or as noise by pilot whales and bottlenose, spinner (*Stenella longirostris*), and spotted dolphins (*S. attenuata* and *S. frontalis*) that are attempting to communicate in the presence of this background of whale song. Singing baleen whales and listening/communicating toothed whales and dolphins have co-evolved, and depend primarily on sounds at different frequencies. We expect that neither group is overtly bothered by the sounds of the other. However, industrial sounds are likely to be perceived by marine mammals as noise, especially when the frequencies of those sounds overlap with frequencies used by the mammals. Nevertheless, some anthropogenic noises may themselves be important cues to mammals: a boat is approaching, take evasive action; a seismic vessel is active, do not get too close, etc. Thus, noise can have an important signaling function. In human terms, it is good that we hear an approaching truck or train if we are in its path.

Sound strength can be measured near the source or at some greater distance. By convention, source levels usually are reported for a standard distance of 1 m. The received sound level tends to diminish with increasing distance—often rapidly when close to the source, and then more gradually at longer distances. In interpreting quoted sound levels, it is essential to know whether the value is a source or received level and, for the latter, the distance from the source. The received levels 10, 100, and 1000 m from a source are often about 20, 40, and 50–70 dB, respectively, less than the corresponding source level. However, the initial decrease with distance (close to the source) will be less rapid if the source is large, like a ship or an array of many airguns. In that case, the source level is a somewhat artificial construct, and there is no location in the water—even immediately adjacent to the source—where the sound level is as high as the nominal source level. A further complication is that sound levels are measured in many different and sometimes difficult-to-convert units. Decibel (dB) values are meaningless unless the reference level is also specified. This is typically $1\ \mu\text{Pa}$ for underwater sound and $20\ \mu\text{Pa}$ for airborne sound, but other reference pressures are sometimes used, especially in the older literature. Even when the distance from source and the reference level are stated, other complications can make it difficult or impossible to compare acoustical measurements from different studies. In addition, simple comparisons of levels in water vs air are usually of doubtful validity given a variety of complications.

The levels quoted in this chapter concern underwater sound measured in dB re $1\ \mu\text{Pa}$ and, except for values shown in Fig. 1, are overall broadband levels (i.e., including sound components at a wide range of frequencies). In the case of source levels, the levels are standardized to a distance of 1 m, in which case the units are dB re $1\ \mu\text{Pa} \cdot \text{m}$.

One way of categorizing anthropogenic noises is whether they are transient or continuous. Sounds from explosions and most seismic surveys, sonars, and ocean acoustic studies are inherently transient. The source (and received) levels of some of these transient sources can be high (Richardson *et al.*, 1995). However, because these sounds are brief and intermittent, the average sound level over an extended period is lower than the peak level. Sounds from moving ships and aircraft are continuous, but from the perspective

of an individual animal, these sounds will normally be transient. Similarly, an animal traveling past a stationary source of continuous sound will also perceive that sound as a transient. Transient sounds are likely to have less effect on animal behavior and hearing as compared with truly continuous sounds having a similar received level.

The strongest transient sounds in the sea come from explosions, which produce shock waves as well as very strong (but brief) underwater sounds. The shock waves from explosions can injure, stun, and even kill nearby fishes, sea turtles, humans, and marine mammals. The distances within which death or injury will occur depend on the size and depth of the explosion, the type of animal, and other factors. Aside from explosions, some of the strongest sources of underwater sound are pulsed sounds from seismic surveys (typically using air gun arrays to produce noise pulses, mainly at low frequency), military search sonars operating at medium and low frequencies, and some types of pile-driving. Air gun arrays and sonars can produce transient sounds with effective source levels of 230 dB re $1\ \mu\text{Pa} \cdot \text{m}$ or more. Sounds received from these sources diminish rapidly with increasing distance, but often are detectable as much as 100 km away. Under special conditions, they can be detected at considerably greater distances, though whether the weak sounds detected far away from these sources have any biological effects is largely unknown. There are many other types of transient anthropogenic sounds with a wide variety of levels and characteristics.

Continuous sounds are caused by sources such as drillships, dredging, and vessels of all sizes underway, with the aforementioned caveat that sounds from a specific moving ship will be transient for a given mammal. Of these sound producers, large tankers, container ships, and icebreakers while working in ice are among the strongest sources. Their overall source levels (i.e., including all frequencies) are on the order of 200 dB or more. Although that level is not as high as for some transient sources, it is sustained without gaps. Much of this sound energy is at infrasonic frequencies (below 20 Hz), which are important to at least some of the baleen whales, but may be irrelevant to odontocetes that have little or no hearing sensitivity at those low frequencies. Shipping is concentrated along defined shipping lanes, where sound levels will wax and wane as individual ships pass. However, at least in the Northern Hemisphere, the overall din of vessels pervades not only the lanes themselves, but also the major parts of the ocean basins involved (Fig. 2).

The strongest components of sound from many of the major anthropogenic sources are below 1 kHz, in the same frequency band as is used by most of the baleen whales for their communication calls. For seismic surveys and large ships, most sound energy is below 200 Hz. A recently acknowledged source of strong low-frequency sound is the low-frequency active (LFA) sonar used to detect quiet submarines. The US Navy’s LFA projectors produce a beam of intense sound (source level up to about 240 dB re $1\ \mu\text{Pa} \cdot \text{m}$) at frequencies in the 100- to 500-Hz band. However, most of the strongest military sonars, some with source levels up to at least 235 dB, operate in the mid-frequency (a few kilohertz) range. Likewise, the sounds from outboard engines operating at high speed, snowmobiles traveling on ice, and acoustic harassment devices at mariculture facilities are in the low kilohertz range. Sounds at medium and especially at low frequencies tend to propagate for longer distances than sounds at high frequencies (e.g., $>10\ \text{kHz}$). At progressively higher frequencies, sound is absorbed more rapidly into seawater. Hence, high-frequency pinger and sonar sounds (including dolphin clicks) generally diminish to low or undetectable levels within 1 km or less and thus do not present potential problems except at close range.

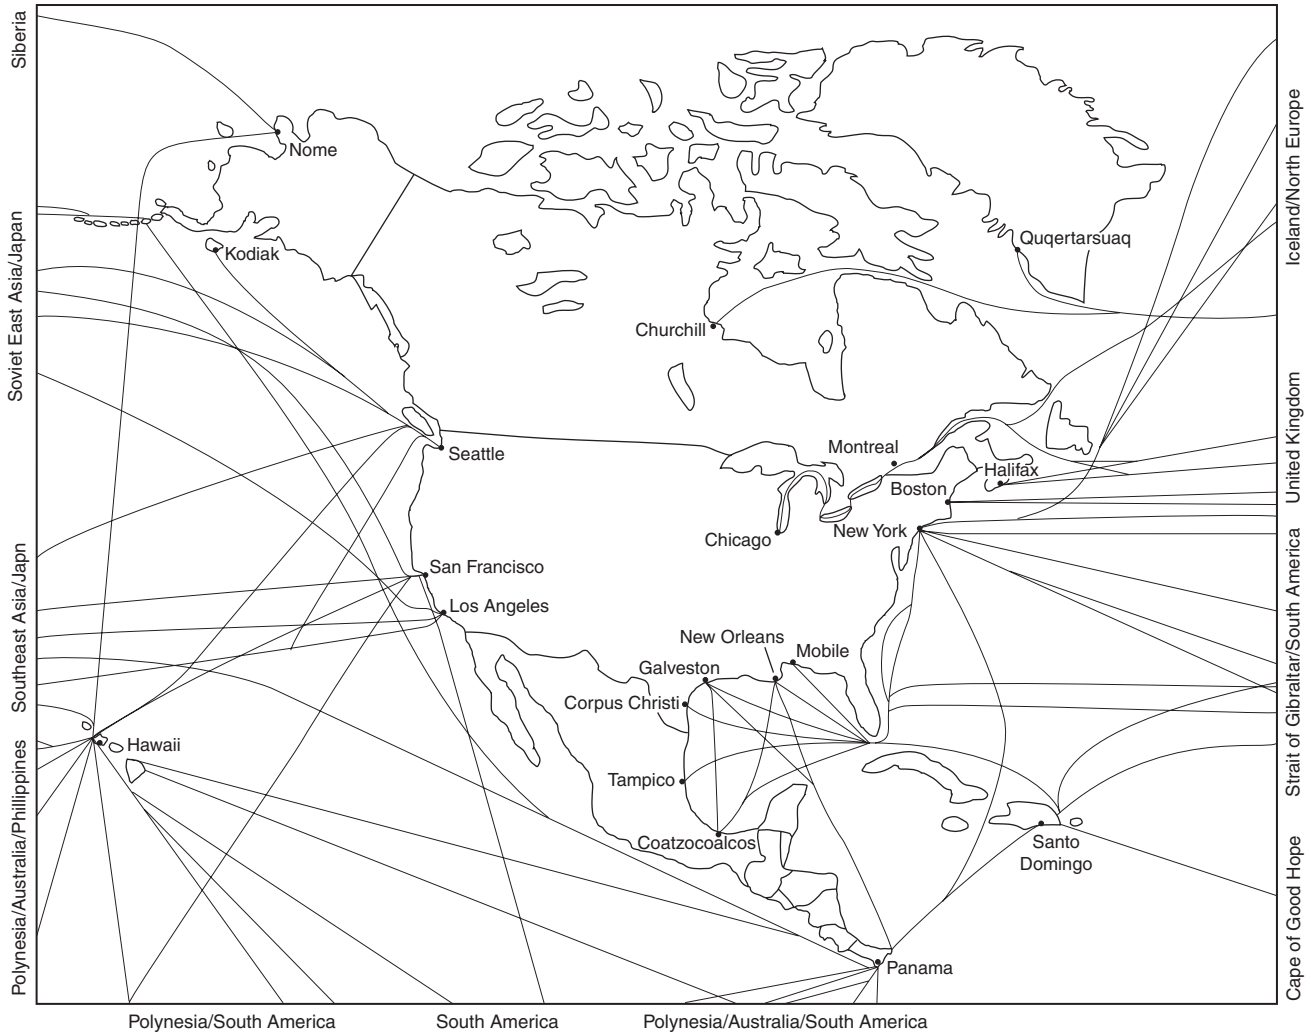

Figure 2 Major international shipping lanes in North American waters. From Jasny et al. (1999) and US Department of State.

Because most, if not all, marine mammals rely on underwater sound for various purposes, any strong anthropogenic sounds at relevant frequencies might have an effect. Animals attuned to different sound frequencies will be most affected by different types of sounds. Mid- and high-frequency sounds as produced by small vessels and mid- and high-frequency sonars are likely to affect dolphins, porpoises, pinnipeds, and sirenians. In contrast, large whales are more susceptible to lower frequency sounds such as those from large vessels, drilling operations, and sounds specifically designed to propagate long distances through the water and/or bottom, such as LFA sonar, marine seismic exploration, and large-scale ocean tomography studies.

Although it was once thought that nearshore animals are likely to be most vulnerable to acoustic effects because of the concentration of industrial activities in nearshore waters, this is no longer as clear. Marine mammals on the high seas can be affected as well, given the occurrence in deep water of shipping, military operations, acoustic oceanography projects, and (increasingly) oil industry operations. In general, it is probable that mammals of the southern oceans are still affected less often and less intensively by anthropogenic sounds as compared with those in the Northern Hemisphere, simply because of the preponderance of human occupation, industry, and shipping

in the north. However, anthropogenic underwater noise is now everywhere, at least some of the time, and has the potential to affect all animals that can hear it and that need to communicate through it.

Most, if not all, marine mammals have evolved special adaptations to hear well underwater (Au *et al.*, 2000). However, the adaptations that make their ears sensitive to pressure fluctuations in the water may also increase the risk of damage from exposure to strong waterborne sound and shock waves.

Sounds that are not strong enough to cause profound physical injury or outright death may nonetheless impair hearing, resulting in either temporary or permanent threshold shifts (TTS and PTS, respectively). TTS occurs in humans and animals subjected to intense sounds for short periods of time or to less intense sounds for longer times. The temporary loss of hearing acuity by humans listening to a rock concert is an example. Mild TTS has been demonstrated in common bottlenose dolphins (*Tursiops truncatus*) and beluga whales (*Delphinapterus leucas*) exposed to a single 1 sec pulse of strong sound (192–201 dB) and in dolphins and various pinnipeds exposed to lower sound levels for periods as long as 50 min (Kastak *et al.*, 2005; Finneran *et al.*, 2005). In most experiments, hearing thresholds returned to pre-exposure levels within about 12h, and none of these exposures caused long-term hearing impairment.

Temporary hearing impairment could be deleterious to animals that rely strongly on their abilities to detect sound. In addition, data on the sound levels and durations at which TTS begins are useful in identifying situations when there is concern about permanent hearing damage (PTS). However, for marine mammals it is not known how much additional exposure (higher levels and/or longer durations) would be necessary before PTS would occur. This is an important data gap. In general, permanent damage typically results from a loss of sensory hair cells within the inner ear. The loss is most pronounced in the part of the inner ear responsible for detecting sound at or near the frequency of the injurious stimulus. In terrestrial mammals, lost hair cells do not grow back, and this is likely the case for marine mammals as well. (Interestingly, at least partial regeneration occurs in birds and fishes.) Older bottlenose dolphins in captivity are known to have reduced hearing sensitivity (especially at the higher frequencies), presumably at least in part because of the cumulative effects of sound (Ridgway and Carder, 1997). This loss is similar to the progressive hearing loss in humans, or similar to presbycusis.

The initial TTS results from small odontocetes and pinnipeds confirm that sound levels necessary to cause TTS are correlated with the duration of exposure. More data are needed to better quantify this relationship and to determine the TTS thresholds for repeated pulsed sounds such as seismic and sonar pulses. Sound levels necessary to cause TTS in baleen whales and sirenians are entirely unknown. In addition, as discussed earlier, it is not known how much additional exposure (above levels causing onset of TTS) any marine mammal can tolerate before there is PTS, but recent work shows that 40 dB of shift is recoverable in dolphins.

Even less is known about potential effects of strong noises on non-hearing physiology than on hearing. Human and animal studies show that strong sounds can affect the vestibular system (and thus sense of balance), air sinuses and adjacent tissues, neural transmission (skin tingling in divers), and reproductive functions. Studies of some terrestrial animals exposed to strong noise have shown reduced sperm production, menstrual irregularities, abortions, and stillbirths. Most of these drastic effects come from intense low-frequency sounds and attendant physical vibrations of body tissues. It is not known whether there are circumstances in which low-frequency underwater sounds from LFA sonars, seismic exploration or ocean tomography studies could elicit similar effects in marine mammals. If this ever occurs, these effects would probably be limited to animals close to the sound source.

It has been suggested that strong and prolonged sound could cause bubbles to form in blood or tissues, and that animals might succumb to a lodging of these bubbles in the brain and elsewhere (Crum and Mao, 1996). This situation is analogous to bubble formation in human divers when they return too rapidly from depth—the condition known as the bends. It is questionable whether this phenomenon would occur under realistic conditions (Cox *et al.*, 2006). However, there has been recent speculation that a different phenomenon, alterations of surfacing-dive cycles of deep-diving species like beaked whales, might lead to accumulation of gas bubbles and cases of “the bends” (Cox *et al.*, 2006).

Stress is one possible outcome of exposure to sounds that are disturbing to animals. Stress could, in theory, inhibit normal social interactions, feeding, reproduction, longevity, and a host of other important functions (Curry, 1999). However, noise-induced stress is not well understood even in humans and terrestrial mammals, and there are few data on noise-induced stress in marine mammals. Research is needed.

Short-term behavioral and avoidance reactions to noise have received more study than damage to hearing and other physiological

effects, to the point that there are now at least some data on noise-induced disturbance in every group of marine mammals. For most marine mammals, it is relatively easy to observe some aspects of their distribution and behavior, as they need to come to the surface to breathe. Nevertheless, much of their time is spent below the waves, and our brief glimpses of them at the surface can present a biased view. Further, short-term reactions (or lack thereof) are not necessarily a good indicator of long-term effects, and the latter have rarely been studied directly. This section does not attempt to review the numerous studies on behavioral and distributional responses to underwater noise; for more details, see Richardson *et al.* (1995) and Southall *et al.* (in press).

Mammals often appear to become alert to novel sounds when they are received at low levels, but this alertness quickly wanes if there is no danger connected with the sound. Thus, the droning of ships or drilling platforms in the distance often appears to be ignored due to habituation or sensory adaptation. Some mammals may avoid the immediate area around the noise source, but remain within the area where the sounds are at least faintly audible. When sounds are tolerated, it is possible (though unproven) that they may elicit stress or other unseen physiological reactions.

Marine mammals often react more dramatically when received sound levels are high (indicative of a strong or nearby source) or when they are increasing (indicative of an approaching source). Bowhead whales (*Balaena mysticetus*) migrating toward a drillship or a marine seismic operation typically deflect their course so that their closest point of approach as they pass the noise source is at least 20 km away. At that distance, the received level of the strongest air gun pulses was near 130 dB, averaged over pulse duration. Migrating gray whales (*Eschrichtius robustus*) show similar deflections of their migration route as they approach a simulated seismic operation or LFA sonar, but they seem to tolerate higher sound levels than migrating bowheads. These deflections by migrating bowhead and gray whales are not a sudden fright reaction, but an edging away—analogous to a person walking along a sidewalk, seeing a disturbance ahead, and crossing to the sidewalk on the other side of the road. In addition, at least in bowheads, there is a decrease in durations of surfacings and dives, and number of breaths per surfacing. In other words, the whales cycle through their surfacing and dive repertoire more rapidly. There must be at least subtle commensurate changes in activities such as feeding, socializing, or rest.

Cetacean responses to noise are quite variable, depending on the circumstances of exposure and the activities of the animals at the time. For example, bowhead whales exposed to seismic survey sounds are one example; in contrast to the long-range responses of migrating bowheads, summering (feeding) bowheads tolerate much higher levels of airgun pulses from seismic vessels within a few kilometers (Miller *et al.*, 2005). The beluga whale is another example of a species whose responses to anthropogenic noise are highly variable. Belugas sometimes tolerate exposure to large fleets of fishing vessels, but in other circumstances flee when exposed to faint sounds from approaching ships 35–50 km away (Finley *et al.*, 1990). Belugas summering in the Beaufort Sea also show long-range avoidance of an operating seismic vessel (Miller *et al.*, 2005).

A noise that is associated with danger, such as a catcher boat of a whaling fleet or a purse-seine vessel that encircles dolphins to catch the tuna underneath, can trigger strong avoidance reactions at distances of 10 km or more. Reactions may become stronger upon repeated exposure to aversive stimuli; in this case, “sensitization” is said to occur. At least some dolphins seem to distinguish vessels based on their sounds and react differently to boats that habitually harass the

animals (such as aggressive tour operators or researchers who tag or collect biopsy samples) vs boats that approach slowly and carefully. In the latter case, the marine mammals may have learned that the vessel is not harmful—a case of behavioral adaptation.

In contrast to the extreme examples just cited, some marine mammals tolerate exposure to high levels of sound. Seals and sea lions attracted to locations where prey fish are concentrated often tolerate exposure to high levels of noise from acoustic harassment devices designed to disperse pinnipeds. Also, during the Heard Island study, hourglass dolphins (*Lagenorhynchus cruciger*) approached to within several hundred meters of a powerful source of low-frequency sound (57 Hz; source level 209–220 dB), whereas long-finned pilot (*Globicephala melas*), southern bottlenose (*Hyperoodon planifrons*), and minke whales (*Balaenoptera* spp.) were seen less often during sound transmissions than during silent periods (Bowles *et al.*, 1994). The hearing systems of the small hourglass dolphins probably were not very sensitive to low-frequency sounds; they may have been curious about but not discomfited by the noise. However, it is also noteworthy that, when visible near the surface, they would not have been exposed to levels much above 160 dB given the nature of the sound field around this particular sound source. It is possible that they exhibited a vertical avoidance response, staying near the surface simply because the noise was less strong there.

Marine mammals sometimes approach and tolerate a sound source for their own benefit. Bottlenose dolphins that feed on prey stirred up by shrimp fishers know the sounds of all aspects of the trawling and net-lifting operations; they move from vessel to vessel according to stage of trawling, even from several kilometers away. Killer and sperm whales and several pinniped species of the northeast Pacific similarly react to net lifting like the gong of a dinner bell. Many species of dolphins and some species of sea lions and fur seals approach vessels to bow ride or wake ride near the vessel, apparently “for fun.”

While this discussion centers mainly on underwater sounds, in-air noises can affect pinnipeds on land, occasionally with serious consequences. A low-flying aircraft, the sudden honk of an automobile horn, or the noisy approach of humans on foot can cause animals on land to stampede into the water. If this occurs on a birthing/nursing beach, adults may, on rare occasions, trample pups in their rush to escape the perceived danger; however, it is not always clear whether sound or sight (and, at times, substrate vibration) is more responsible for the stampede and loss of pups.

Because sound is such an important sensory modality for almost all marine mammals, it stands to reason that human-made noise has, at times, the potential to disrupt the efficiency of communication (and echolocation). Indeed, there is some evidence for this. Some animals fall silent when they perceive danger (or a novel sound). During the aforementioned Heard Island study, sperm and pilot whales were heard 24% and 8% (respectively) of 1137 min when there was no sound, but none was heard to vocalize during 2202 min with sound transmissions. Although these data suggest a strong effect of noise on communication, they are not yet sufficient to indicate at what received levels the whales became quiet (Bowles *et al.*, 1994).

Acoustic reactions to intense sounds vary among species and with the activity of the animals when they perceived the sound. Belugas are vocally active when they detect ship sounds, but narwhals (*Monodon monoceros*) fall silent. Dusky dolphins (*Lagenorhynchus obscurus*) resting in small groups fall silent when they perceive danger. However, those same dolphins will continue their social whistling and burst-pulse “chatter” when they are engaged in high-energy social and sexual activities. They seem less easily disturbed at these higher energy times. There is increasing evidence that both toothed

and baleen whales sometimes alter the frequencies or other characteristics of their calls.

Masking of sounds useful to animals by strong anthropogenic noise is another important phenomenon. We humans have the ability to converse with each other even at noisy parties, and can separate useful speech from an amazing background din (the well-known “cocktail party” phenomenon). Marine mammals can probably do likewise, for they have evolved in a world where physical and biological sounds other than their own abound. Nevertheless, studies of captive dolphins and pinnipeds have confirmed that, in marine as well as terrestrial mammals, strong human-made noise can physically “drown out” other sounds at similar frequencies, especially if the two sources are in similar directions. The noise reduces the maximum distance at which one animal can hear calls from another animal or some other environmental sound that may be important (Richardson *et al.*, 1995). There is increasing evidence, e.g., in gray and right (*Eubalaena* spp.) whales, killer whales, belugas, and bottlenose dolphins, that cetaceans sometimes shift the primary frequencies or increase the source levels of their sounds to reduce the effects of masking by background noise.

Marine mammals are generally very social. If noise disrupts social structure, and if the effect is sufficiently strong and long lasting, then it could be detrimental to the well-being and survival of individuals and perhaps ultimately populations. Noise disturbance can cause some degree of social disruption, but the consequences are largely unknown. When a supply ship comes within 2–4 km of a group of bowhead whales, the whales scatter in all directions. They are “socially disrupted” for as much as a few hours. However, we have no idea how important this disruption may be to the well-being and productivity of the whales. We can guess that they will be harmed if this kind of disruption happens day after day to animals that feed more efficiently when together than when apart. Social disruption also includes the accidental separation of a nursing mother from her pup or calf. When this happens, the probability of pup or calf survival may be reduced substantially.

We do not know to what extent the masking of communication sounds by noise can cause social disruption. Blue whales and fin whale calls can, at times, be detected over distances of several hundred kilometers. If there are important social interactions over those long distances (not proven), these interactions may be impeded by the masking effects of background noise, especially if that noise is continuous. For example, these whales may not be able to find each other as efficiently for feeding and mating purposes given the masking effect of the human-made noise. If whale societies are mediated in large part by acoustic contact, as we suspect (Wells *et al.*, 1999; Tyack, 2000), then background noise that diminishes the distances over which whales can communicate also diminishes the spatial scale of their societies.

Although short-term disruption of behavior by noise is known to occur, it is less clear how this may translate to overall use of habitat and to long-term disturbance. It was mentioned earlier that migrating bowhead whales “edge away” from seismic exploration and drillships, in most cases maintaining a minimum distance of about 20 km. It is unlikely that this results in any major harm to the animals. However, if there were a similar and prolonged displacement from a localized area of important feeding habitat, then the potential for harm would be great. At this point, we know that some whales move away from sources of strong noise, but we do not know whether this significantly reduces their yearly food intake or causes other important disruption. There is, however, building evidence that tourism based on motorized vessels going to dolphins can affect overall their

occurrence patterns and habitat use, with the best such information coming from bottlenose dolphins in western Australia (Bejder *et al.*, 2006) and southwestern New Zealand (Lusseau, 2003). It is not clear whether it is mainly the noise of the vessels, the physical interaction by the vessel, or both that are responsible. Another area of concern is long-term operation of acoustic harassment devices (AHDs) designed to keep pinnipeds away from aquaculture facilities. Though less than fully successful in deterring pinnipeds from feeding on the fish, AHDs can cause long-term displacement of non-target species such as porpoises and killer whales (Morton and Symonds, 2002).

Similarly, human disturbance of island spinner dolphins has affected their use of nearshore bays that appear to be important to them for daytime rest (after feeding in deep water at night). It is possible to argue that this reduced use of safe havens might affect their survivability as individuals and therefore as populations. However, to date, we have no information on such a population-wide effect.

The concept of habitat available vs habitat disturbed is an important one in conservation biology. The purist would argue that any habitat disrupted is too much, and compromises the natural world. The pragmatist argues that we humans are so overpoweringly disruptive that we must be content with keeping at least a minimum of area available for the animals in question to survive. In the case of marine mammals, that means keeping some critical habitats relatively free of strong noises that create unacceptable disruption in short-term behavior, long-term behavior, aspects of physiology, and hearing. The task is a difficult one and needs further research, monitoring, mitigation, and political enforcement to have a chance of success.

The first step in mitigation is to develop a better knowledge base. Detailed discussions of the research base and needs can be found in NRC (1994, 2000, 2003, 2005), Richardson *et al.* (1995), and Southall *et al.* (in press). We need better information on auditory sensitivity, especially of large whales, and the levels and frequencies of noises that cause TTS, PTS, and (to the extent they occur) nonauditory physiological disruptions in all marine mammals. Researchers have acquired the technical capability to study noise-induced stress and other aspects of physiology, with miniature data loggers and telemetry transmitters attached to animals under field conditions. This is a relatively new avenue of research for marine animals and is likely to grow in the near future. Studies of short-term behavioral disruptions are worthwhile, but it is the long-term behavioral, social, communication, and habitat disruption effects that are in greatest need of study (NRC, 2005). It is our challenge to study and monitor the health of marine mammals as related not only to anthropogenic sound pollution, but also to other aspects of habitat degradation.

Potential mitigation avenues are many. Naval vessels are already engineered to reduce sound emissions, e.g., by physical decoupling of rotating machinery from the hull, propeller design, and emission of screens of air bubbles. This knowledge needs to be taken into the private sector, which is responsible for the vast majority of shipping noise. Bubble screening has been shown to strongly decrease the noise from a stationary pile-driving activity in Hong Kong waters (Würsig *et al.*, 2000), and improved versions of this technique are increasingly being used to dampen some industrial sounds. A controversial technique that is often employed is “ramping up” of sounds in order to alert animals of impending strong noise, essentially to chase them away from the zone of most influence. This approach probably is effective for some species and situations (e.g., baleen whales vs airguns). However, in other situations it may attract curious marine mammals into a zone of danger. Further study is needed to determine the situations when ramping up is a useful mitigation technique.

In projects where sound is emitted purposefully, e.g., marine seismic exploration, ocean science studies, and navy LFA sonar, refinements in equipment and operational procedures may be possible that will reduce the exposure of marine mammals to noise. Some efforts have already been made to reduce source levels to the minimum that will be effective, and to improve beam forming to reduce sound radiation in unnecessary directions. Furthermore, these (and some other) noisy activities are amenable to regulation as to where and when they are used, especially as pertains to the seasonal migration and movement patterns of sensitive baleen whales. It is common for noisy projects to be restricted to certain times of year and/or to certain areas in order to reduce impacts on marine mammals.

It is up to scientists to help provide badly needed information on disturbance reactions and zones of potential influence, and up to politicians and regulators to write and enforce legislation to curb the uncontrolled proliferation of ocean noise. In the absence of adequate information on the levels and durations of sound exposure that cause problems for marine mammals, regulatory actions are often taken based on “best available” information, with or without allowance for the precautionary principle. More specific data are needed to provide adequate protection for marine mammals while avoiding unnecessary restrictions on worthwhile human activities.

North Atlantic Marine Mammals

GORDON T. WARING, DEBRA L. PALKA AND
PETER G.H. EVANS

Marine mammals are a diverse, widespread, and significant component of North Atlantic marine ecosystems. Four of the five commonly recognized marine mammal taxa reside in the North Atlantic: cetaceans (mysticetes, baleen whales; and odontocetes, toothed whales, dolphins, and porpoises), sirenians [manatees (*Trichechus* spp.)], pinnipeds, [seals and walrus (*Odobenus rosmarus*)], and polar bears (*Ursus maritimus*) (Rice, 1998; Reeves et al., 2002). A fifth taxon [marine (*Lontra felina*) and sea (*Enhydra lutris*) otters] and sea lions and fur seals (family Otariidae) have not inhabited the North Atlantic since at least the late Pleistocene.

The systematics of marine mammals is still being disputed (Rice, 1998). Marine mammals occupy all North Atlantic marine regimes, tropical to polar, although species-specific ranges exist and distribution patterns are not uniform (Tables I and II). The large-scale, nonrandom distribution of marine mammals is influenced by oceanographic features, whereas small-scale distributions are influenced by factors such as the animal's physiology, behavior, and ecology (Bowen and Siniff, 1999). Over geologic time scales, the diversity and ecology of North Atlantic marine mammals reflect adaptation to a dynamic aquatic environment. As elsewhere, North Atlantic marine mammal populations have been impacted significantly by human interactions (Sahrhage and Lundbek, 1992; Kinze, 1995; Gambell, 1999; Reeves et al., 2003). Some species have been, and continue to be, harvested for subsistence and commercial use and for their cultural value. Overexploitation has resulted in extinction [e.g., Caribbean monk seal (*Monachus tropicalis*), Atlantic gray whale (*Eschrichtius robustus*)] and significant population declines [e.g., North Atlantic right whale (*Eubalaena glacialis*)], and has also likely caused significant ecological "changes" (e.g., reduction of top predators and competitive interactions; Rice, 1998; Kraus and Rolland, 2007). Indirect mortality (e.g., fishery bycatch and pollution) has adversely affected numerous species [e.g., harbor porpoise (*Phocoena phocoena*), bottlenose dolphin (*Tursiops truncatus*), beluga whale (*Delphinapterus leucas*), and a ringed seal subspecies (*Phoca hispida botnica*)] (Kinze, 1995; Northridge and Hofman, 1999; O'Shea, 1999; Reijnders et al., 1999; Hall and Donovan, 2002). Climate change is also affecting marine mammal populations, especially species that live in close association with the Arctic ice and/or in the cold temperate to polar seas influenced by Arctic ice [e.g., polar bears and Arctic ringed seal (*Phoca hispida hispida*)] (Learmonth et al., 2006).

I Physical Environment

The physical characteristics of the North Atlantic ecosystem (Fig. 1) critically influence marine mammal distribution. Although the ocean basin provides marine mammals with an open pathway that extends from the equator northward to the Arctic and includes adjacent bodies of water (e.g., Gulf of Mexico, Caribbean Sea, North Sea, Norwegian Sea, and Bay of Biscay), the North Atlantic has many different ecosystems (Reid et al., 2003; Stenseth et al., 2004). Some adjacent seas, such as the Baltic and Mediterranean, are more isolated from the open ocean and form separate ecosystems. In the

NOTES: Countries: FO, Faroe Islands; IC, Iceland; NO, Norway; DK, Denmark; SE, Sweden; FI, Finland; RUS, Russia (both Barents Sea and Eastern Baltic); EBA, Eastern Baltic States (Latvia, Lithuania, and Estonia); PL, Poland; DE, Germany; NL, Netherlands; BE, Belgium; UK, United Kingdom; IE, Ireland; FR, (Atlantic) France; ES, (Atlantic) Spain (excl. Canaries); PT, (Atlantic) Portugal (excl. Azores & Madeira/Desertas); MAC, Macaronesia (Azores, Madeira/Desertas, Canaries, Cape Verdes); WAFR, West Africa from Morocco to the Equator Occurrence (based on records since 1980): VAG, Vagrant; RAR, Rare; REG, Regular (but Uncommon); COM, Common; EXT, Extinct; -, Not Recorded; *, Record(s) before 1980.

RAR in northern Norway only.

REG in Kattegat/Baltic.

But REG in Channel and Southern North Sea.

But COM in Southwest.

But annual, periodically.

But periodic, at other times RAR.

REG in Kattegat/Baltic.

RAR in Kattegat/Baltic.

REG only in arctic islands of Svalbard, Bornøya and Jan Mayen.

COM in N. France, rare further south in France.

But REG in parts of Norway; Includes isolated population in Svalbard.

But VAG in Canaries and Cape Verdes.

But RAR in Canaries.

But RAR in Canaries and Cape Verdes.

RAR in Madeira/Desertas and Canaries, VAG in Cape Verdes, absent from Azores.

RAR only in Morocco and Mauritania, VAG further south.

But RAR in Cape Verdes.

RAR in Canaries, but REG in Cape Verdes and absent from Azores and Madeira/Desertas.

Mainly around Frantz-Josef Land.

But VAG in eastern Baltic.

Records only from Belgium, Netherlands, Sweden, and the United Kingdom.

open ocean, water masses define tropical to polar ecosystems that are influenced by circulation patterns of the major ocean currents such as the Gulf Stream, Greenland current, and North Equatorial current. There are broad continental shelf ecosystems defined by basins, banks, channels, ice, submarine canyons, and volcanic islands. Sea mounts and the mid-Atlantic Ridge also define important ecosystems. These types of oceanographic features influence productivity which concentrate prey and create high-use marine mammal habitats (Reid *et al.*, 2003).

II. Distribution and Habits

Baleen whales are widely distributed in the North Atlantic, with individual species exhibiting preferences for certain ecosystems (Bowen and Siniff, 1999). Some preferences are temperature driven. For example, bowhead whales (*Balaena mysticetus*) occupy only polar waters, whereas Bryde's whales (*Balaenoptera edeni*) are found only in tropical waters. Other preferences are more topography driven. For example, right humpback (*Megaptera novaeangliae*), and minke (*Balaenoptera acutorostrata*) whales prefer continental shelf ecosystems, whereas blue (*B. musculus*), sei (*B. borealis*), and Bryde's whales are associated with shelf-edge and deeper oceanic water. While fin whale (*Balaenoptera physalus*) habitat preference differs geographically (i.e., shelf ecosystems in the northwest Atlantic and shelf-edge habitats off NW Europe). Large whales, however, are highly mobile and seasonally may occupy different habitats. Baleen whales, except bowhead and Bryde's whales, can undergo the most extensive seasonal migrations of all North Atlantic marine mammals, migrating between

warm low-latitude breeding grounds in winter and cold high-latitude feeding grounds in summer. North Atlantic humpback whales exemplify this migratory behavior (Bowen and Siniff, 1999). In summer, humpback whale stocks feed in Iceland, Greenland, Newfoundland, Gulf of St. Lawrence, and Gulf of Maine/Scotian Shelf and then spend winter on breeding grounds in the Caribbean Sea. A smaller eastern North Atlantic population summers between the Bay of Biscay and Norway, and spends the winter between the British Isles and Cape Verdes. Molecular genetic studies indicate that the feeding stocks are matrilineal groups of related individuals (Baker and Palumbi, 1997). There is little evidence of recent genetic exchange between North Atlantic and South Atlantic populations of baleen whales, due largely to seasonal differences in the migration paths of the two populations (Baker and Palumbi, 1997).

Odontocetes also occupy nearly all marine ecosystems in the North Atlantic, with individual species exhibiting preferences for particular ecosystems (Bowen and Siniff, 1999; Reeves *et al.*, 2002; Reid *et al.*, 2003; Macleod *et al.*, 2006). Continental shelf species found in cool temperate to subpolar waters are harbor porpoises, Atlantic white-sided and white-beaked dolphins (*Lagenorhynchus acutus* and *L. albirostris*), long-finned pilot whales (*Globicephala melas*), and two Arctic species, narwhal (*Monodon monoceros*) and beluga whales. Continental shelf break/pelagic species found in warm-temperate to cooler waters include bottlenose (offshore and coastal forms), short-beaked common (*Delphinus delphis*), Risso's (*Grampus griseus*), striped (*Stenella coeruleoalba*), and Atlantic spotted (*S. frontalis*; coastal form) dolphins, sperm (*Physeter macrocephalus*) and northern bottlenose (*Hyperoodon ampullatus*) whales, and Cuvier's (*Ziphius cavirostris*), Blainville's (*Mesoplodon densirostris*), Sowerby's (*M. bidens*), and True's (*M. mirus*) beaked whales. The range of northern bottlenose and Sowerby's beaked whales extends into subarctic waters. Continental shelf break/pelagic species found in warm-temperate to tropical waters are pantropical spotted (*Stenella attenuata*), Atlantic spotted (offshore form), spinner (*S. longirostris*), Clymene (*S. clymene*), rough-toothed (*Steno bredanensis*), Atlantic humpbacked (*Sousa teuszii*), and Fraser's (*Lagenodelphis hosei*) dolphins and melon-headed (*Peponocephala electra*), false killer (*Pseudorca crassidens*), pygmy killer (*Feresa attenuata*), short-finned pilot (*Globicephala macrorhynchus*), pygmy sperm (*Kogia breviceps*), dwarf sperm (*K. sima*), and Gervais' beaked (*Mesoplodon europaeus*) whales. Within warm temperate to tropical water mass habitats, bottom topography and frontal boundaries are important characteristics that define cetacean distribution. Unlike baleen whales, only a few odontocetes (e.g., sperm and long-finned pilot whales) are known to undergo long-range seasonal migrations (Bowen and Siniff, 1999). Stock structure is largely unknown, except for a few nearshore continental shelf species (e.g., harbor porpoise, beluga). Some oceanic odontocetes likely move between North and South Atlantic waters (e.g., pantropical spotted dolphin and Cuvier's beaked whale).

North Atlantic seals (phocids) include both Northern and Southern Hemisphere species (Tables I and II; Reeves *et al.*, 2002). Northern phocids [harbor (*Phoca vitulina*), and gray seals (*Halichoerus grypus*)] are widely distributed in boreal to polar waters (Bowen and Siniff, 1999). The ice seals [hooded (*Cystophora cristata*), bearded (*Erignathus barbatus*), harp (*Pagophilus groenlandicus*), and ringed (*Pusa hispida*) seals] pup on ice and have seasonal migrations that are strongly associated with seasonal ice fluctuations. Bearded, hooded, and harp seals also utilize pelagic habitats. Ranges change; for example, since the 1990s, the winter/spring distributions of hooded and harp seals extended southward into northeast US. coastal waters. Harbor seals are the most widely distributed species, occupying cool

temperate to Arctic North Atlantic waters. Gray seals have a discontinuous distribution in cold temperate to subarctic coastal waters. Southern phocids include the Mediterranean (*Monachus monachus*) and Caribbean (extinct) monk seals. The Mediterranean monk seal is primarily found in the Mediterranean, adjacent seas, and along northwestern Africa. The Caribbean monk seal previously inhabited the Caribbean Sea and southern portion of the Gulf of Mexico. Stock structure for North Atlantic seals is well defined.

Cetaceans and phocid seals constitute the largest component of North Atlantic marine mammal fauna (Bowen and Siniff, 1999; Reeves *et al.*, 2002). Additional species include walruses, polar bears, and West Indian manatees (*Trichechus manatus*). Walruses and polar bears have a circumpolar distribution. Both species are usually associated with ice habitats but also spend time on coastal land areas. The Florida (*Trichechus manatus latirostris*) and Antillean (*T. m. manatus*) manatees have a tropical to subtropical distribution. The Florida manatee is found in coastal waters of the Gulf of Mexico and southeastern United States. Seasonal extralimital movements northward have been recorded for the Florida manatee. The Antillean manatee is distributed from northern Mexico to central Brazil and throughout the islands of the Caribbean.

III. Feeding

The taxonomic division of cetaceans into Odontoceti and Mysticeti reflects their different feeding strategies (Rice, 1998; Bowen and Siniff, 1999; Reeves *et al.*, 2002). Baleen whales are strainers who largely feed on planktonic or micronektonic crustaceans and/or relatively small pelagic fish by using visual or passive acoustic techniques. Toothed whales are graspers who capture fish, squid, and other species by hunting using sight, sound, or active echolocation. Pinnipeds and polar bears are carnivores. Pinnipeds consume primarily fish and invertebrates, and some species occasionally eat seabirds, seals, or small whales. Polar bears prey primarily on seals and sometimes feed on fish and other small mammals. In contrast, manatees are herbivores, grazing in shallow waters on vegetation using primarily their sense of touch.

IV. Human Impact

Centuries of human activities have affected all North Atlantic marine mammal populations. Prehistoric people hunted coastal marine mammals for subsistence use, and in some areas (e.g., Canada, Greenland) aboriginal hunting still exists (Sahrhage and Lundbek, 1992; Kinze, 1995; Gambell, 1999; Heide-Jørgensen and Wiig, 2002; Kraus and Rolland, 2007). Early subsistence hunting, however, was likely insignificant compared to commercial whaling that began in Europe during the tenth century (Slijper, 1979; Sahrhage and Lundbek, 1992). By the beginning of the eighteenth century, European whalers had already depleted bowhead and right (*Eubalaena* spp.) whale stocks in the eastern North Atlantic, so then moved on to hunt these species in the western North Atlantic, from Greenland to the Gulf of St. Lawrence. American whalers also depleted right and humpback whale stocks in coastal waters off the American colonies. Depletion of these stocks initiated pelagic whaling for sperm and humpback whales. Modern whaling, as we know it today, began in the late nineteenth century when Norwegians invented the explosive harpoon and converted from sail to steam vessels. This allowed whaling to expand to the faster swimming blue, fin, and sei whales. By the 1920s, the stocks of North Atlantic large whales had all been over-exploited, and so whaling activities were

redirected into Antarctic waters. Commercial whaling depleted most of these stocks as well. In 1946 the International Convention for the Regulation of Whaling was signed to provide for the CONSERVATION of whale stocks (Gambell, 1999). However, North Atlantic whaling continued until the 1987 INTERNATIONAL WHALING COMMISSION moratorium was enacted. Following the moratorium, fin, minke and humpback whales are taken for subsistence in West Greenland, and humpback whales are taken in St. Vincent. Most recently, Norway has been taking minke whales and Iceland minke and fin whales, both commercially under objection to the moratorium. Despite the many years since whaling of most species has stopped, some of the North Atlantic large whales (in particular the North Atlantic right whale) have not yet recovered (Clapham *et al.*, 1999; Kraus and Rolland, 2007). This is probably due to slow growth, low reproductive rates, and other human interactions (Boyd *et al.*, 1999; Evans and Stirling, 2002).

Commercial exploitation of smaller cetaceans began in the fourteenth century when the Danes initiated organized hunts of Baltic Sea harbor porpoises (Kinze, 1995). Although these hunts ended in the mid-twentieth century, there are still very few harbor porpoises in the Baltic Sea. In the 1500s, the Faroese initiated a pilot whale (*Globicephala* spp.) drive fishery that continues to this day. Examples of hunts during the early to mid-1900s include Norwegian hunts of minke, killer (*Orcinus orca*), northern bottlenose, and pilot whales, American bounty hunts on harbor porpoises, and pilot whale drives in Shetland, Orkney, and Newfoundland. The Newfoundland fishery continued through the twentieth century but had to stop in 1971 due to local depletion (Mercer, 1975). In the Atlantic islands of the Azores and Madeira, subsistence hunting of sperm whales continued until as recently as the 1980s. Small-cetacean hunts occurring today are small-scale subsistence fisheries, such as for harbor porpoises in Greenland and belugas in Canada, Greenland, and Russia. It is unknown whether these stocks can sustain these removals. Now, even in the traditional whaling countries, whale and dolphin watching has largely replaced whaling as an economic activity (in the Canary Islands currently estimated to involve more than 1 million tourists a year; Urquiola and de Stephanis, 2000).

North Atlantic walrus populations were similarly exploited (Sahrhage and Lundbek, 1992). In the early 1600s, Britain initiated walrus hunting around Spitzbergen, Jan Mayen, and Norway. Russians, Europeans, and Canadians joined in to expand the hunts further northward. As a result, these walrus populations were severely depleted by the nineteenth century and have not yet recovered.

Seals were first commercially hunted for oil and blubber in Europe and Newfoundland (Sahrhage and Lundbek, 1992). In these areas, large-scale commercial hunts for seal skins started in the early eighteenth century, focusing on harp and hooded seals, although bearded, ring, gray, and harbor seals were also taken. By the late 1800s, hunting expanded to Greenland for harp, hooded, and ringed seals. During the World Wars, hunting slowed down, allowing some populations to recover. However, sealing resumed immediately afterwards. During the 1960s, killing methods raised public opinion against sealing, which then prompted management actions and quotas to reduce hunting. The largest reduction began in 1983, particularly in Canadian waters, when the European community enacted a ban on the importation of seal skins. However, since 1996, the level of Canadian harp sealing has resumed to pre-1970s levels because new markets for skins and meat have opened up (DFO, 2003).

Long-standing conflicts between humans and seals have occurred because seals impact economically valuable fishery resources. Impacts include seals preying on fish species, and seals, particularly

gray and harbor seals, infecting many North Atlantic fish species with seal (or cod) worm (*Pseudoterranova decipiens*). These issues have initiated seal bounty programs in Europe and North America, which resulted in regional extirpation (e.g., northeast United States, Baltic Sea), of some gray and harbor seal stocks. Although bounty and other seal removal programs have either ended or been greatly reduced, ecological and fishing gear interactions between seals and fisheries remain a management challenge in the North Atlantic.

Following World War II, technological improvements in fishing gear and vessels led not only to the expansion of coastal and high seas fisheries, but also to the incidental mortality of thousands of marine mammals and rapid depletion of fish resources (Northridge and Hofman, 1999; Hall and Donovan, 2002). By the 1970s, the elevated levels of marine mammal takes, particularly dolphins in the eastern tropical Pacific tuna purse seine fishery, instigated management and conservation measures that were aimed at reducing incidental takes of marine mammals in fisheries (e.g., US Marine Mammal Protection Act of 1972). Over the past two decades, national and international measures have aimed to improve fish stocks and to monitor and reduce fishery-related impacts on marine mammals [e.g., 1991 Agreement on the Conservation of Small Cetaceans of the Baltic and North Sea (ASCOBANS)]. Unfortunately, marine mammal mortality still occurring in many fisheries threatens some marine mammal populations in the North Atlantic, such as right whales, bottlenose and common dolphins (*Delphinus* spp.), harbor porpoises, and Mediterranean monk seals.

Environmental contaminants potentially pose a threat to the health of marine mammals (O'Shea, 1999; Reijnders *et al.*, 1999; Geraci and Lounsbury, 2002). Contaminant levels can become toxic in marine mammals because most feed at high trophic levels and so accumulate low levels of toxins from their contaminated prey. Numerous studies have documented the presence of organochlorine and heavy metals in tissues of marine mammals. The debate is: are these levels dangerous? Potential deleterious biological effects of these contaminants include immunosuppression, endocrine disruption, and reproductive and pathological disorders. Documented cases of deleterious effects include the reproductive failure that has been linked to organochlorine levels in seals from the Baltic and Wadden Seas and to beluga whales from the St. Lawrence Estuary. It has been suggested that some of the large-scale die-off events that have killed thousands of seals and dolphins in northern Europe, the Mediterranean, the US east coast, and Gulf of Mexico are due, at least in part, to high levels of organochlorines (e.g., PCBs; Domingo *et al.*, 2002) or toxic metals (e.g., cadmium, mercury; O'Shea, 1999). Epizootic events and toxic algal blooms have also caused large-scale die-offs (Geraci and Lounsbury, 2002; Härkönen *et al.*, 2006). For example, both the 1988 and the 2002 *Phocine distemper virus* epidemics in Europe killed approximately 56% and 45%, respectively of the European harbor seal populations. In winter 1987/1988, 14 humpback whales died in the vicinity of Cape Cod after consuming Atlantic mackerel (*Scomber scombrus*) containing a dinoflagellate saxitoxin. However, in nearly all cases, it has not been possible to demonstrate a direct link between death and contaminants. Other types of potentially dangerous environmental contaminants include oil spills and acoustic disturbances because these may cause behavioral modifications, prey displacement, or direct mortality. For example, several unusual mass strandings of beaked whales in North Atlantic marine environments (e.g., Bahamas, Canaries, Madeira) have been associated with military sonar activities (Evans and Miller, 2004; Cox *et al.*, 2006).

V. Status

The current status of North Atlantic marine mammal populations is tightly linked to the population's biological characteristics and their long history of interacting with human activities. Most populations are no longer commercially hunted, but some are still severely depleted (e.g., North Atlantic right whales; Gambell, 1999; Kraus and Rolland, 2007). Human activities, such as hunting, incidental fishing mortality, acoustic activities, vessel strikes, environmental contaminants and climate change continue to directly and indirectly adversely impact marine mammals. Further, human enhanced climate warming is predicted to be detrimental to most marine mammal populations, particularly species associated with Arctic ice (Learmonth *et al.*, 2006). Conservation and research programs, particularly for small cetaceans, are highly variable among countries. Because most marine mammal populations are mobile, the only way to assess the status of and conserve these populations is to ensure that scientific research and conservation programs are effective ocean wide.

North Pacific Marine Mammals

SERGIO ESCORZA-TREVIÑO

I. North Pacific Marine and Fresh Water Biomes

The vastness and diversity of the North Pacific Ocean is reflected in the richness of its marine mammal community. Sixteen of the world's 36 species of pinnipeds, 50 of the more than 80 species of cetaceans, and two of the 5 species of sirenians have been reported to occur in the North Pacific, in addition to the polar bear (*Ursus maritimus*) and the sea otter (*Enhydra lutris*). Most of these species are also found in other parts of the world, as is the case of most balenids and delphinids, many ziphiids, and some otariids, phocids, and phocoenids. However, a large proportion of the species found in the North Pacific are endemic to its marine or riverine ecosystems: nine pinnipeds, eleven cetaceans, one sirenian, and the sea otter.

The North Pacific Ocean ranges from about 80°W to 130°E, covering almost 60% of the earth's circumference, and from the Arctic Ocean to the Equator (Fig. 1). The North Pacific encompasses a great number of peripheral basins, as different as the highly evaporative and relatively small Gulf of California (also known as Sea of Cortés) in the east, the large and epicontinental Bering Sea in the north, or the complex region of small, semi-enclosed seas and shallow shelves around the Indo-Pacific Archipelago in the west, where the Pacific and the Indian oceans meet. In addition, there exist a number of large, complex river systems that extend thousands of kilometers upstream, as is the case of the Yangtze River in China.

The geographic distribution of mammal species in the ocean depends on a number of factors, among which temperature, depth, and productivity tend to be the most important. Rice (1998) presents a comprehensive review of the ranges for most species. Some, such as the killer whale (*Orcinus orca*) or the sperm whale (*Physeter macrocephalus*), are considered cosmopolitan. Others, like the vaquita (*Phocoena sinus*), or the now extinct Steller's sea cow (*Hydrodamalis gigas*), have very limited ranges. Many species are circumglobal, but limited to particular climatic zones. For example, some species are pantropical, inhabiting low latitude waters in all the world oceans, whereas others have antitropical (or bipolar) distributions. Species such as the ringed seal (*Pusa hispida*) and polar bear have been sighted as far north as the North Pole. Others can range hundreds of kilometers up the great rivers of both sides of the Pacific Ocean, either permanently or on a seasonal basis.

The North Pacific is dominated by a large subtropical gyre (Fig. 1). This North Pacific central gyre flows clockwise, bounded to the west by the Kuroshio Current, to the north by the North Pacific Current, to the east by the California Current, and along the south by the North Equatorial Current. To the north of the North Pacific central gyre, the cold Oyashio Current flows along the Kamchatka Peninsula and forms the western boundary of a counterclockwise subarctic gyre. The Alaska Current flows counterclockwise along the southeastern coast of Alaska and the Aleutian Peninsula. The convergence zone of these subarctic gyres and the central gyre, known as the Subarctic Boundary, crosses the western and central North Pacific at about 42°N, and marks the steepest change in the abundance of cold-water vs warm-water species. To the south of the central gyre, the equatorial current system

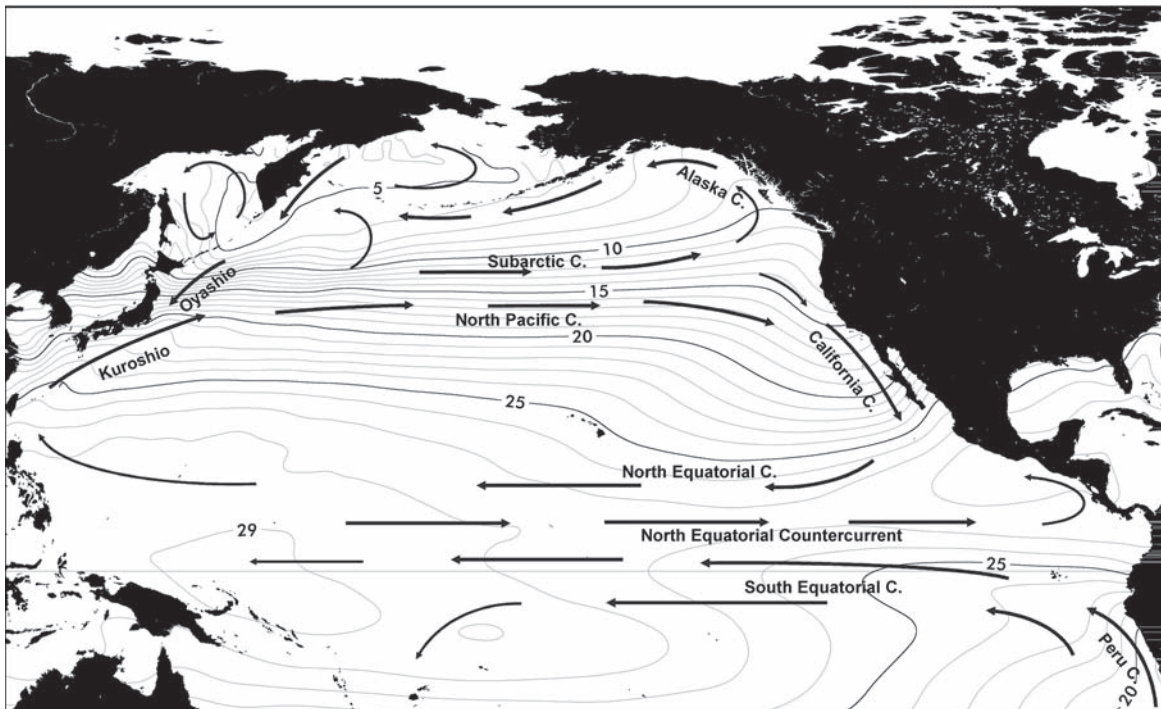

Figure 1 Annual mean surface temperatures and principal currents of the North Pacific Ocean (graphic by Paul Fiedler).

consists of the North Equatorial Countercurrent between the North and South Equatorial Currents.

An important differentiating characteristic between the Pacific and the other ocean basins is the strong effects of El Niño – Southern Oscillation (ENSO) events. Two distinct modes of Pacific circulation exist, depending on the variability of trade winds stress. When the trade winds weaken and are replaced by westerlies at low latitudes in the western Pacific (an ENSO event), the entire heat balance at low latitudes is perturbed, a situation that can last from a few months to 1 or 2 years. When this occurs, the major oceanographic features usually found in the Eastern Tropical Pacific can weaken or even disappear completely, resulting in an atypical distribution for many marine mammal species.

II. Marine Mammals of Cold Water Marine Ecosystems

Most of the endemic species of marine mammals in the North Pacific Ocean inhabit its cold temperate, subarctic, or arctic waters. Among the pinnipeds, in the family Otariidae, we can find several of these endemic species. In fact, of the seven species of otariids present in the North Pacific, five are endemic. The other two are also represented in the Southern Pacific, since they occur in the Galapagos archipelago. Arnason *et al.* (2006) hypothesize that pinnipeds originated in North America and that early speciation of otariids took place in the northeast Pacific. The Guadalupe fur seal (*Arctocephalus townsendi*) now breeds only on Guadalupe Island, off Baja California. The northern fur seal (*Callorhinus ursinus*) is a pelagic species that ranges from the Sea of Okhotsk and southern Bering Sea to the Sea of Japan and northern Baja California. The California sea lion (*Zalophus californianus*) includes two geographical divisions, one on the Pacific coast, and one in the Gulf of California (Fig. 2). Some animals have also been sighted on both sides of the Atlantic, but represent escapees

Figure 2 California sea lions (*Zalophus californianus*) occur along much of the coast of southwestern Canada, the western United States, and northern Mexico, as well as on islands nearby. These animals are from the midriff islands of the Mexican Sea of Cortez. Photo by Bernd Würsig.

from captive facilities. Along the western side of the Pacific, the Japanese sea lion (*Zalophus japonicus*) is, very probably, extinct. The last confirmed sighting took place over 50 years ago. The Steller sea lion (*Eumetopias jubatus*) inhabits the coastal and immediate offshore waters of the cool temperate North Pacific.

Of the eight species of phocids (seals) present in the North Pacific Ocean, four are endemic: the spotted seal (*Phoca largha*) (Fig. 3), the ribbon seal (*Histiophoca fasciata*), the Hawaiian monk seal (*Monachus schauinslandi*), and the northern elephant seal (*Mirounga angustirostris*) (Fig. 4). The former two inhabit the pack ice zone of

Figure 3 Spotted and Larga seals (*Phoca largha*) occur throughout the northern area, with this photo taken in the Sea of Okhotsk, far east Russia. Photo by Bernd Würsig.

Figure 5 Walrus (*Odobenus rosmarus*) off Round Island, Alaska. Photo by Bernd Würsig.

Figure 4 The highly sexually dimorphic elephant seals (*Mirounga angustirostris*) can be found on islands, shorelines even quite close to intensive human use, and in the deep sea. These animals are from Año Nuevo, California. Photo by Bernd Würsig.

the arctic North Pacific, although the ribbon seal becomes pelagic during the summer. The Hawaiian monk seal, which probably represents the most primitive of the living phocids, inhabits the Northwestern chain of the Hawaiian Islands, whereas the northern elephant seal, whose population numbers once dwindled down to a few tens, ranges throughout the northeastern Pacific, from the Aleutian Islands to the Gulf of California. Other seals present in the North Pacific are the bearded seal (*Erignathus barbatus*) and the ringed seal (*Pusa hispida*), which are both arctic species, the harbor seal (*Phoca vitulina*), whose range extends from the Bering Sea to Baja California, and the hooded seal (*Cystophora cristata*), present only as a rare vagrant into the Beaufort Sea, Bering Sea, and even southern California. The only living species of the family Odobenidae, the walrus (*Odobenus rosmarus*) also inhabits the arctic North Pacific (Fig. 5).

There are many cetacean species present in the higher latitudes of the North Pacific. Among the mysticeti, three families are found. The balaenids are represented by both the bowhead whale (*Balaena mysticetus*), which inhabits the pack ice zone of the Arctic, and the migrant and endemic North Pacific right whale (*Eubalaena japonica*), whose range extends from the Bering Sea to California in the East

Figure 6 A gray whale (*Eschrichtius robustus*) migrating south past Point Reyes, California. Photo by Bernd Würsig.

and Taiwan in the West. The single living representative of the family Eschrichtiidae, the gray whale (*Eschrichtius robustus*), occurs only in the North Pacific, as the North Atlantic populations are extinct (Fig. 6). At present, the western, or “Korean,” gray whale population is in very low numbers, whereas the eastern, or “California,” population is considered to have recovered from past exploitation and ranges from subarctic waters to Baja California. It is not clear whether this is a full recuperation or not, as suggested by Alter *et al.* (2007).

Five species of rorquals are found in the cold waters of the North Pacific. The humpback whale (*Megaptera novaeangliae*) inhabits all the oceans of the world, from high-latitude summer feeding grounds to tropical winter grounds. The sei whale (*Balaenoptera borealis*) also is present in all oceans, but in more temperate waters than other rorquals. The common minke whale (*B. acutorostrata*) can be found from the Chukchi Sea almost to the Equator. The blue whale (*B. musculus*) lives almost everywhere in the world, from the tropics to the arctic pack ice. And the fin whale (*B. physalus*), also almost worldwide in distribution, can be sighted in the North Pacific from the Okhotsk Sea, Bering Sea and Chukchi Sea to Taiwan, Hawaii, and Baja California (including the Gulf of California).

The cosmopolitan sperm whale is present from the Equator to the edges of the pack ice. The ranges of the two species of the family Kogiidae are somewhat smaller, but are present in temperate and tropical waters around the world. The pygmy sperm whale (*Kogia breviceps*) inhabits oceanic waters, whereas the dwarf sperm whale (*K. sima*) lives over the continental shelf and slopes.

The family Ziphiidae is well represented in the North Pacific. Cuvier's beaked whale (*Ziphius cavirostris*) lives in all temperate and tropical waters around the world, whereas the North Pacific bottlenose whale (*Berardius bairdii*) is an endemic species, present only in the temperate and subarctic North Pacific. Also endemic are Hubbs' beaked whale (*Mesoplodon carlhubbsi*), in temperate waters, and the saber-toothed whale (*M. stejnegeri*), which ranges from the subarctic waters to the cold temperate North Pacific. The pygmy beaked whale (*M. peruvianus*) is a recently discovered species, known only from the Gulf of California and Peru. Also newly discovered is the Perrin's beaked whale (*M. perrini*), so far endemic to the North Pacific. In their study, Dalebout *et al.* (2002) indicated that individuals stranded and sighted off southern California, previously considered to be Hector's beaked whales (*M. hectori*), are likely to be *M. perrini*, suggesting that the Hector's beaked whale is confined to the temperate waters of the Southern Hemisphere.

Both members of the family Monodontidae are also present in the North Pacific Ocean. The beluga (*Delphinapterus leucas*) inhabits the Arctic Sea and spreads into its adjacent seas, mainly in shallow shelf waters. The narwhal (*Monodon monoceros*) is present as a vagrant in the Chukchi Sea and Bering Sea.

Several delphinids that can be found in the cold North Pacific are widespread species that mainly inhabit warm waters and will be discussed in the next section. In addition, the cosmopolitan killer whale is present from equatorial regions to the polar pack ice. The long-finned pilot whale (*Globicephala melas*) represents a special case. This species is bipolar in temperate waters and, although common in the North Atlantic, there are no historical records of living animals in the North Pacific. However, skulls were recovered at two archeological sites in Japan, in areas now occupied by the short-finned pilot whale (*Globicephala macrorhynchus*). Two other species present in this area are endemic to the North Pacific: the northern right-whale dolphin (*Lissodelphis borealis*), in subarctic and temperate waters, and the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), also in cool temperate areas (Fig. 7). Other species of *Lagenorhynchus* occupy this same niche in the Southern Hemisphere. However, genetic studies by LeDuc *et al.* (1999) have indicated that the genus might be polyphyletic, and the Pacific white-sided dolphin might indeed represent a different genus. If this were indeed the case, the correct scientific name for the Pacific white-sided dolphin would be *Sagmatias obliquidens*.

Four species of porpoises are present in the North Pacific. The Dall's porpoise (*Phocoenoides dalli*) is endemic to the cold temperate waters of the North Pacific (Fig. 8). The recently discovered and critically endangered vaquita, with only few hundred individuals left, is endemic to the northern Gulf of California. Its closest relative (Burmeister's porpoise, *Phocoena spinipinnis*), curiously, does not live in the North Pacific, but in southern latitudes, indicating that the vaquita evolved independently in the Gulf of California when it became trapped there after crossing the Equator during the last cooling period. The other two species present in the North Pacific are the harbor porpoise (*Phocoena phocoena*), restricted to shallow coastal temperate waters, and the finless porpoise (*Neophocaena phocaenoides*), which inhabits coastal waters along the mainland of southern and southeastern Asia and Japan, as well as up the Yangtze river system, up to 1600 km inland.

Figure 8 Dall's porpoises (*Phocoenoides dalli*) "rooster tailing" in the southern Bering Sea during rapid surfacings, a very species characteristic behavior. Photo by Bernd Würsig.

A member of the order Sirenia, the only herbivorous marine mammals, used to be present in the cold waters of the North Pacific. The Steller's sea cow, endemic to shallow subarctic waters of this ocean, has been extinct since 1768. Hopes for the survival of the species went up briefly in 1962, but the alleged sighting has been discredited since.

There are two other marine mammals in the North Pacific that do not belong to the "traditional" marine mammal groups. One is the sea otter, which is endemic to the North Pacific and inhabits the cold temperate and subarctic zones (Fig. 9). This species dipped to near extinction at the end of the nineteenth century and beginnings of the twentieth century. The other is the polar bear, which inhabits the pack ice regions of the Arctic Ocean and contiguous seas and adjacent coastal areas.

III. Marine Mammals of Warm Water Marine Ecosystems

The marine mammals that inhabit these ecosystems tend to be also present south of the Equator, or even in other oceans. Among the otariids, two Pacific species occur only in tropical waters. The

Figure 9 A territorial male sea otter (*Enhydra lutris*) swims within his territory in Simpson Bay, Prince William Sound, Alaska. Sea otters are sexually segregated when not mating, with males and females separated by less than 150km. During the mating season, male sea otters enter female areas and establish resource-based territories to attract potential mates. Photo by Heidi Pearson.

Galapagos sea lion (*Zalophus wollebaeki*) was originally confined to this archipelago, but a small rookery exists now on La Plata Island (01°S), which is why the species cannot be considered endemic to the North Pacific. The Galapagos fur seal is also endemic to this equatorial archipelago.

Many of the cetaceans present in warm waters are widespread species, with wide latitudinal ranges, and have already been referred to in the previous section (Table I). This is the case of most rorquals, except for the Bryde's whale (*Balaenoptera brydei*), which prefers tropical and warm temperate waters, and the small type or pygmy Bryde's whale (*B. edeni*), which lives in coastal and shelf waters of the eastern Indian Ocean and the western Pacific. Among the ziphids, some are found exclusively in warm water. Such is the case of the ginkgo-toothed whale (*Mesoplodon ginkgodens*), which lives in tropical and warm temperate areas of the Indian and Pacific Oceans, and the Blainville's beaked whale (*Mesoplodon densirostris*), also with a tropical and warm temperate distribution, but around the world. Most beaked whales, specially the genus *Mesoplodon*, are rarely spotted at sea and, even when they are, their identification is extremely difficult. It is very probable that some species have not been described yet. Two such undescribed species of *Mesoplodon* have been sighted in the Eastern Tropical Pacific: *Mesoplodon sp. A*, also known as bandolero beaked whale, and *Mesoplodon sp. B*. It has been suggested that the former is in fact the pygmy beaked whale and the latter could possibly be the Bahamonde's beaked whale (*Mesoplodon traversii*). It is also possible that large unidentified "tropical bottlenose whales" seen in the tropical Indian and Pacific Oceans are indeed Longman's beaked whales (*Indopacetus pacificus*), although this will remain a mystery until specimens are collected.

In addition to the widespread delphinids mentioned in the previous section, several species typically found in warm waters can also range into temperate waters. Probably the most familiar is the bottlenose dolphin (*Tursiops truncatus*), which is present in temperate and tropical zones of all oceans. The species usually inhabits coastal areas and shallow offshore banks, although there are pelagic populations that live far offshore. The type specimen of the Indian Ocean bottlenose dolphin (*Tursiops aduncus*) comes from the Red Sea, but some *aduncus*-like *Tursiops* have been sighted throughout the North Pacific. The

striped dolphin (*Stenella coeruleoalba*) is also found worldwide in temperate and tropical waters, as are the Risso's dolphin (*Grampus griseus*) and the false killer whale (*Pseudorca crassidens*). Other species are characteristic of the tropical and warm temperate waters around the world and thus are also found in the North Pacific. Such is the case of the rough-toothed dolphin (*Steno bredanensis*), the pantropical spotted dolphin (*Stenella attenuata*), the spinner dolphin (*Stenella longirostris*), Fraser's dolphin (*Lagenodelphis hosei*), the melon-headed whale (*Peponocephala electra*), the pygmy killer whale (*Feresa attenuata*), and the short-finned pilot whale. Both the short-beaked common dolphin (*Delphinus delphis*) and the long-beaked common dolphin (*D. capensis*) inhabit tropical and warm temperate waters worldwide. The former occupies both offshore and coastal habitats. However, the latter shows a disjunct distribution in near-shore waters, which might be due to the fact that these populations had evolved from independent events. The Indo-Pacific humpback dolphin (*Sousa chinensis*) is discontinuously distributed in coastal waters of the western Pacific, as well as river basins. It is also present in the southern Pacific and Indian Ocean.

The dugong (*Dugong dugon*), the only sirenian found in warm North Pacific waters, has a widespread but discontinuous range along the continental coasts among the islands of the Indian and western Pacific oceans.

IV. Aquatic Mammals of River Ecosystems

The river basins, systems, and their mouths in southeastern Asia provide a unique habitat for several cetacean species. The most important hydrographic system for marine mammals is the Yangtze River, and several species can be found here. The baiji (*Lipotes vexillifer*) lives exclusively in fresh water, and is endemic to this basin, from its estuary upstream for 1600km. Unfortunately, it might very well be already extinct. The Indo-Pacific humpback dolphin can ascend as far as 1200km up this river system as well. The finless porpoise inhabits the coastal waters along the mainland of southern and southeastern Asia and Japan, and also ranges into the middle and lower reaches of the Yangtze River and its tributaries. Finally, the Irrawaddy dolphin (*Orcaella brevirostris*) is discontinuously distributed in shallow and murky waters at the mouth of rivers around the Asian mainland and Australasia, as well as in river systems such as the Mekong.

V. Conservation Issues

The problems faced by North Pacific marine mammals are common to marine mammals in other areas of the world: pollution, habitat degradation, fishery interactions, directed takes, climatic shifts and lack of sufficient resources for successful protection and management. Although the hunting of marine mammals for oil, meat, or fur has been largely reduced by international agreement, some species are still targeted. The active harpoon fishery for the North Pacific endemic Dall's porpoise, for example, causes the largest fishery-related mortality for any cetacean species in the world. A large number of animals from several species are taken incidentally each year by net entanglements, fishery by-catch, or boat strikes. Two North Pacific marine mammal species have been driven to extinction by humans in the recent past: the Japanese sea lion and Steller's sea cow. A third one, the baiji, is very probably the latest addition to this list, as no authenticated sightings have taken place since 2002, including a dedicated expedition in 2006 by Turvey *et al.* (2007). Several other North Pacific species are dangerously close to following in their wake, as is the case for the vaquita, the western population

Endemic species are shown in bold.

of the gray whale and the North Pacific right whale. Sea otters and some pinnipeds, especially some populations of Steller sea lions, have experienced a dramatic decrease in the last few decades whose causing factors are not entirely understood, as demonstrated by the different explanations put forward by Springer *et al.* (2003) or DeMaster *et al.* (2006). However, the recovery of other North Pacific species gives us reason for hope. The northern elephant seal, driven down to a few tens of individuals by hunting in the early 1900s, now numbers in the tens of thousands. The eastern gray whale, whose population size was once dangerously low, has recovered significantly (there exists debate whether to its pre-exploitation stock size) and was taken off the endangered species list in 1995. With continued protection, two species that once faced extinction are now showing positive signs of recovery, the sea otter and the Guadalupe fur seal. Because of their mobility and vast geographic ranges, the distributions of most marine mammal species extend across borders and international waters. For these reasons, effective management and conservation strategies depend greatly on international agreements that coordinate objectives, resources, and efforts.

Figure 1 Adult male and female northern fur seals and newborn pups. Photo by C.W. Fowler, AFSC, Seattle, WA.

When the Fur Seal Treaty was resumed after World War II, one of the first decisions was to intentionally reduce the size of the herd. About 331,000 adult females were killed at the Pribilof Islands and at sea between 1956 and 1968 in the belief that pelt production would increase. From that point onward, the different breeding populations followed different trends. The Commander Islands population increased from 1958 to the mid-1970s, decreased slightly, then remained stable from the mid 1990s to 2005 at about 60,000 pups annually. The Kurile Islands population increased rapidly from 1962 to 1977, decreased slightly until 1988, and increased rapidly again until 2006 to about 30,000 pups annually. Robben Island declined until the mid-1990s, and increased until 2003 at 30,000 pups annually. From 1968 to 1974 the Pribilof Island herd recovered to about 1.25 million animals, declined rapidly (8% per year) until the mid-1980s, stabilized until 1996, then declined rapidly (5.8% per year) to 2004 (Towell *et al.*, 2006). Bogoslof Island began as a new colony in 1980 and increased to 12,600 pups annually by 2005. San Miguel Island, California began as a breeding colony in 1968 and peaked at over 3000 pups 1996. Twice (1982 and 1996) the San Miguel population was driven down by severe El Niño Southern Oscillation events that reduced fur seal food (Angliss and Outlaw, 2007). Overall the species is doing well except the Pribilof Islands seals, which are still declining and producing fewer than half the pups born there in 1968.

Northern Fur Seal

Callorhinus ursinus

ROGER L. GENTRY

I. Characteristics and Taxonomy

C*allorhinus* is the oldest living genus of the family Otariidae, with origins 2–5 million years ago. *Callorhinus* means "beautiful nose" and *ursinus* means "bear-like." Sea Bear was a former common name. This species has a short nose, and lacks the dog-like profile of the other fur seal genus, *Arctocephalus*. Females are small (45 kg) and gray-brown with a light underbelly; males are larger (200–250 kg) and vary from black to reddish (Fig. 1). The young (pups) are generally black with a light belly.

II. Distribution and Abundance

The northern fur seal inhabits the North Pacific Ocean and Bering Sea (Fig. 2). About 91% of the northern fur seal population breeds at the Pribilof Islands of Alaska (74%) or at the Commander Islands of Russia (17%). The remainder breeds at the Kurile Islands (Kammenye Lovushki and Sredney Rocks in Fig. 2) and Robben Island (Russia), Bogoslof Island (Alaska), and the Farallone and San Miguel Islands (California). The species predates some of the islands on which it now breeds, so some past population redistribution has occurred. For example, bones of pups and adult males in kitchen middens show that breeding colonies once occurred at several mainland sites in the United States. The northern fur seal is primarily a sub-polar species whose adaptations do not preclude breeding at lower latitudes (for general reading about pinniped biology, see Riedman (1990)).

III. Ecology

Ecologically the species is a high-level consumer, taking a variety of fish, cephalopods, crustaceans, and an occasional bird. Seventy-five different prey species have been identified in northern fur seal stomachs. Juvenile walleye pollock, Atka mackerel, capelin, eulachon, herring, and several species of squid predominate. The seals take these prey items at relatively shallow depths (100–200 m for females, <400 m for males) compared to other species of marine mammals that can dive to more than a thousand meters. Northern fur seals feed mostly at night on prey that migrate vertically. A major component of their diet is lantern fish (myctophids) which live in deep water. Northern fur seals are preyed upon by large sharks, killer whales, and (for young only) Steller sea lions (*Eumetopias jubatus*).

This species is not under intense competition for breeding space by other species of eared seals (otariids). California sea lions (*Zalophus californianus*) compete with them for space only at San Miguel. Steller

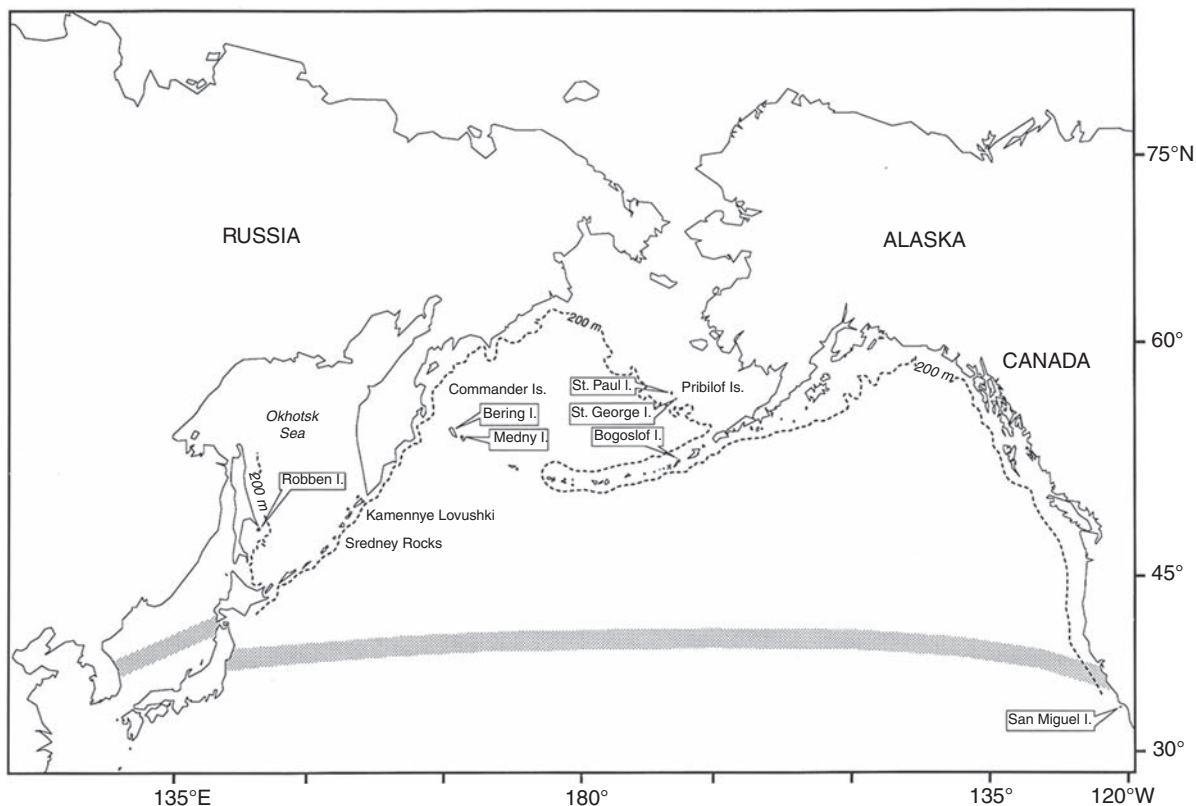

Figure 2 Distribution of the northern fur seal (Shaded line is southern limit of pelagic range).

sea lions may rest among northern fur seals (and sometimes eat their young at sea) but do not usually mate on the same sites. Guadalupe fur seals (*Arctocephalus townsendi*) are seen on and occasionally pup there, but do not compete with them for space. Furthermore, northern fur seals do not often compete with other otariids for food. They take small fish and squid over deep water, whereas sea lions tend to feed mostly on the continental shelves on larger fish. An exception is that northern fur seals and Steller sea lions in the Bering Sea both take juvenile walleye pollock. Guadalupe fur seals probably prey on small fish and squid like the northern fur seal, but the Oyashio/Kuroshio transition zone effectively separates the two fur seal species at sea.

Like other fur seals and sea lions, northern fur seal females must feed themselves while raising their pups. They are so-called “income” foragers as opposed to “capitol” foragers like true seals, which nurse their young from fat stores laid down well before birth. The need to alternate feeding with nursing means that fur seals can only raise pups where nearby food supplies are abundant. But how they forage and what they eat depend largely on the local environment. The Commander Islands in Russia have a narrow continental shelf that lacks a good fish population. There, females cross the shelf quickly and forage in nearby deep water where small squid rise to the surface at night. The Pribilof Islands have a wide shelf that supports a good fish population. Females there catch fish near the bottom as they cross this shelf going to and returning from more distant deep waters where they feed like the Commander Islands females on deep-water squid at night. The length of time females are away from their pups, the depth of their dives, number of dives per day, and the food they eat all differ among islands, and they change seasonally as the energy needs of the pups increase.

IV. Behavior and Physiology

Males partition the birthing areas used by females into spaces called territories. They defend the boundaries of these territories (not the females therein) using mainly calls and postural threats, sometimes by fighting. Males arrive on territory about 1 month before the females, and spend their time maintaining boundaries and fasting. Fasts last on average 38–42 days for the population, but uninterrupted fasts of 80 days have been recorded for individuals. Throughout the main breeding season (July) males spend most of their time interacting with females and mating. Each male has exclusive access to all females in his territory. They abandon their territory in late July, and are replaced by large sub-adult males, which perform perhaps 20% of the year’s copulations, including with all the virgin females which arrive after pupping has ended. Males are highly specific in the area they will defend, maintaining at least some of the same boundaries from year to year. Very few defend a territory that is more than 10 m distance from the previous year’s territory. Males will persist in defending a territory from year to year even if it contains few females.

Females arrive usually one day before giving birth, select a birth site without regard to the male that defends that site, and usually gives birth at night. Females remain with the pup in that location and defend it from other females until mating occurs. Then they leave to feed for a few days before returning to nurse their pup. Returning mothers locate their young by their calls and probably by smell. They will not suckle any pup but their own. Orphans and starlings sneak suckle but are often bitten and many die of wounds and infection.

Females use the same birthing site from year to year if the population remains the same size. But, if a population declines the females will abandon favored birth sites and move closer to the water

to avoid being alone in a territory with an adult male. Males bite and herd females to control their movements. So, by giving birth near other females a mother can reduce being injured by males.

Despite seeking the close company of others, females are quite aggressive toward near neighbors. They bite and frequently threaten all other females, do not allow them to lie in full body contact (like sea lions do), and show no sign of social bonds with other females. That is, females are gregarious but not social. This combination allows each animal to enter and leave the aggregation without loss of social status. The largest females win contests over resting sites, but there is no evidence that individuals form a stable social hierarchy.

Active female mate choice is not apparent. Females mate at nearly the same site for many years whereas the male defending that site as part of his territory changes on average every 1.5 seasons. That is, females do not move around trying to find the highest ranking, most fit male. In captivity, sexually receptive females do not discriminate between high- and low-ranking males, or even between fur seals and humans. Females mate with highly fit males in the population, but by a more indirect means than individual choice. By arriving predictably at a given time and place, receptive females become a resource over which males compete. Males that win this competition remain on shore as potential mates. Females thus indirectly acquire as potential mates the class of males that is highest ranking, but they accomplish this without making a choice among individual males. This appears to explain why females are uniformly receptive to all males when they are in estrus. Individuals show strong preferences for using specific land sites at particular times of year. Despite having many square kilometers of suitable land available for giving birth, individual females bear their young within 8–10 m of the same site in successive years. Males will defend only one territorial location for their reproductive lifetime. This tie to specific sites may be an extreme form of philopatry (mating on the site of their own birth). Furthermore, females and males tend to arrive on a date that is specific to them as individuals despite the fact that births and mating in the population occur over a 6-week period. On the beach, tens of thousands of breeding animals appear to form one large, amorphous mass. However, in reality it is composed of individuals each with fairly specific preferences for breeding at a given location and time of year (Gentry, 1998).

These space and time preferences of individuals create breeding aggregations that are highly predictable in timing and location. Thirty-two breeding sites, or “rookeries,” now exist. One in Russia has been occupied yearly since at least 1742. These sites do not change much in size or shape from year to year if the population is stable, mainly because of site fidelity in individual females. The onset and duration of the birth/mating season are quite stable and change little in response to weather or climatic conditions.

The young from all islands except San Miguel leave land at 4 months of age with modest fat reserves and little foraging experience. At sea, they must immediately learn to find and capture solid food alone while migrating in the appropriate direction. This is apparently difficult because some 60% or more of the pups born per year fail to live to age 2 years when their age mates first return to land. Despite this seemingly low survival rate, the species is evolutionarily quite successful; it numbered approximately 2.5 million animals at its peak in the mid-1950s.

The migratory pathways, distribution, diet, and behavior of weaned pups at sea are largely unknown because they are small and difficult to instrument and recapture. It is known that Pribilof pups migrate through the Aleutian passes into the North Pacific Ocean in November of their birth year, and that some of them are seen on the coasts of Washington, British Columbia and Japan by the following

January. Pups return to land during the summer of their second or third year, usually to the island of their birth. Juvenile females usually land on the breeding grounds but juvenile males are excluded from these areas by adult males and instead come ashore on all-male landing areas that old sealers called “hauling grounds.” Juvenile males stay around the breeding island for 80 days or so, making periodic feeding trips to sea, visiting different hauling grounds, and playing with other males as they perfect the movements they will later use in fighting. Many juvenile males make brief incursions onto the breeding grounds where they visit sites that some of them will later defend as territories, which suggests philopatry. The hauling grounds are where sealers used to capture and kill animals for pelts. Despite the fact that killing occurred on some of these sites weekly during the breeding seasons for over two centuries, fur seals persist in using them.

Physiology drives some aspects of foraging behavior such as the duration of the deepest dives and the recovery times from these dives neither of which change seasonally. The deepest dives are about 200 m, last about 5 min, and require 20 min of recovery. These are made by large females that are foraging near the bottom. Females that feed in deep water change their dive depths in a way that suggests the prey are deep during the day, rise to the surface at dusk, and remain there all night before migrating to deeper water again at dawn. This pattern fits the behavior of the Deep Scattering Layer, a layer of fish and other animals that forms in deep waters almost globally.

The northern fur seal keeps from losing body heat to cold ocean waters by means of dense underfur that traps small air bubbles. This fur is so dense it stays dry even when submerged. While at sea, and especially after deep dives, fur seals spend long periods grooming the fur and restoring its air content. They lose heat through their naked rear flippers, which are the longest and thinnest of any pinniped. To reduce heat loss while sleeping they often extend one front flipper into the air and hold it between both rear flippers, thereby creating an arch that sealers used to call a “jug handle.” To increase heat loss on land in warm weather they fan their rear flippers, keep them damp, or pant. The fur is such an effective insulator that snow falling on sleeping animals does not melt or make the animals shiver.

Oxygen management is as important to fur seals as to any diving mammal. They are apneustic breathers, meaning they take in a breath and hold it as they would during a dive. Even sleeping animals breathe this way. During a dive, they shut off blood circulation to inessential organs and greatly reduce their heart rate to help conserve oxygen stores. While swimming at high speed northern fur seals often leap free of the water to breathe in a “porpoising” motion.

Both vision and hearing are highly effective in both air and under water. In bright light, their pupil closes to a small pinhole showing a brown iris. In dim light, the pupil opens wide to gather more light. An open pupil and a reflective layer in the retina contribute to good vision in dim light where most feeding occurs. The reflective layer is visible as an “eye shine” if a light is trained on animals at night. Their best hearing is between 2 and 29 kHz. The highest frequency they can hear is about 40 kHz (compared to 20 kHz for humans). These modest hearing abilities are related to the fact that fur seals do not find food by echolocation, as dolphins do.

V. Life History

The species is sexually dimorphic; males are at maximum 4.5 times larger than females. A size difference exists as early in embryonic growth as the sexes can be identified, and it accelerates at sexual maturity, about age 3–5 years of age. Females mate almost immediately after becoming sexually mature, and begin to produce one young per year.

Males do not become socially mature (large enough to gain a territory among females) until they are 8- to 9-years old. Like other otariids, the sex ratio at birth of northern fur seals is nearly 1:1, but due to greater age-specific mortality rates in males than in females, and delayed mating in males, mating is polygynous. The average adult sex ratio is about nine females per male, but it once reached 60:1 when males were being killed for pelts.

Females have the highest pregnancy rates between ages 8 and 13 years, the rates sometimes exceeding 93% of an age class. Females can produce offspring yearly to about age 22 years, although few survive to that age. Older, larger females do not preferentially give birth to male pups, but larger mothers give birth to larger pups. Twinning is rare. For unknown reasons, females in the Commander Islands population have their first pup on average a year younger than females in the Pribilof population (Wickens and York, 1997).

Females usually enter estrus (heat) and mate about 5.3 days after giving birth. About 85% of the females mate only once during estrus; the other 15% mate no more than twice. The reason for this low number of copulations is that the physical act of mating terminates receptivity. Males can cause females to come into estrus by interacting with them (called the Whitten effect). However, if no male is present, females enter estrus spontaneously and become non-receptive again after about 36h if they fail to copulate. No second estrus occurs that year (Gentry, 1998).

Sexually receptive females mate indiscriminately with any male that approaches them. When no adult males are present (as in captivity) females will mate with a male of any size or age. They will arch their backs in a sexually receptive posture when touched on the pelvic area by other females, their own pups, or even a human. Adult males do most of the mating because adults drive juvenile males off the breeding areas, not because females reject juvenile males. Males may mate 115 times or more per year, depending on their size and the location of their territory relative to females. The reproductive life span of males averages 1.5 seasons, but one unusual male held a territory for 10 consecutive seasons.

As in other pinnipeds, the young of northern fur seals are precocial. They can swim on the day of birth but do not voluntarily do so until they are a month old. While their mothers are away foraging, pups withdraw to unoccupied parts of the breeding grounds to avoid being bitten by adult females. There they join other pups in dense “pods” and sleep and play until their mothers return. Males actively avoid trampling pups so these pods are places of relative safety for pups. Intentional infanticide by adult males is unknown in this species. Some of the behavior of pups appears to be instinctual. For example, a 6-day old male pup can mount a female correctly and make coordinated mating motions without ever having observed mating behavior in adult males.

Male pups are on average 0.6kg heavier than females at birth, and remain larger until weaning. Suckling pups grow slower (1.1–1.3% of maternal mass per day) than in true seals because they fast each time their mothers are away foraging, and most of them face cold wind and rain that requires high metabolic rates to survive. About 10% of pups die on shore before weaning. Starvation, trauma, hookworm, and several infectious diseases account for most of the deaths. Pups are weaned at about 40% of adult female mass. Most pups wean themselves and depart from land before their mothers.

VI. Human Interactions

Northern fur seals have been studied longer than most other marine mammals. George Wilhelm Steller first described the species in 1749 after he returned from Vitus Bering’s 1742 expedition that discovered the Commander Islands, Russia. Heavy exploitation of

this colony (for pelts to be made into garments) began almost immediately after its discovery. Killing for pelts expanded considerably in 1786 when the Pribilof population was discovered. To protect the populations from over exploitation the Russians prohibited the killing of females, which was one of the first known wildlife management actions. Despite this protection, the species declined three times after 1742, each time in association with killing for pelts or other management actions. After the biggest decline (1911), the North Pacific Fur Seal Treaty was enacted (Fur Seal Treaty, 1911) which involved Japan, Russia, United States, and Britain (for Canada). Under treaty protection the herd recovered at 8.6% per year from 1912 to 1924. The treaty remained in effect until 1985, except during World War II. Part of the treaty involved a vigorous international research program that made the northern fur seal one of the best known marine mammal species. It produced many of the study methods that are used in modern marine mammal research such as the study of foraging ecology using dive instruments (Gentry and Kooyman, 1986).

The Pribilof Islands herd was declared legally “depleted” in 1988. The stock still contains an estimated 888,120 animals, but the population trend is a major concern because the cause of the ongoing, massive decline is still not known. It may be related to declines in some stocks of harbor seals, sea lions, and sea otters over the past 30 years. The reasons that have been suggested for all these declines include predation by killer whales (Springer *et al.*, 2003), climate change, interaction with fisheries, and combinations of these factors that vary by region (Wade *et al.*, 2007). For more information, consult the chapters on killer whales, ecological effects of marine mammals, and sea otters.

The Ocean Environment

PAUL C. FIEDLER

Marine mammals live, feed, and reproduce in a vast, three-dimensional fluid environment—the ocean. Air-breathing necessitates frequent attendance to the sea surface for all marine mammals, whereas pinnipeds cannot reproduce in the water and have thus retained a close tie to land or ice. Despite these ties to the boundaries of the ocean environment, oceanography is an important part of the study of marine mammals. Habitat and distribution of marine mammals are affected by the physical and chemical properties of the water through which they swim and communicate, the topography of the ocean bottom where they feed, the physical state of the ocean surface where they breathe and haul out, and numerous factors influencing the distribution of food organisms.

I. Surface Temperature, Salinity

Temperature at the earth and ocean surface generally decreases from the equator to the poles (Fig. 1), but local processes complicate this simple pattern. Upwelling brings cold water to the surface along the equator and along eastern boundaries between oceans

and continents. Ocean currents move cold water equatorward along these eastern boundaries, and warm water poleward along western boundaries.

Salinity of the surface waters of the open ocean varies between 32 practical salinity units (psu) in the subarctic Pacific and 37 psu in subtropical gyres. This variation affects the density of seawater and thus the distribution of mass and the resulting thermohaline circulation. Salinity variations over this range have little or no physiological effect on marine mammals, but can influence availability of food organisms through effects on stratification and circulation. At the coastal and polar limits of the ocean and in marginal seas, processes such as local precipitation and evaporation, river runoff, and ice formation can result in salinities less than 10 and greater than 40 psu. Marine mammals have adapted to tolerate even these extremes.

II. Surface Currents, Winds

Surface waters of the ocean are constantly in motion due to waves, tides, and currents. Currents move water across ocean basins and thus alter the distribution of temperature, salinity and, indirectly, food organisms. Ocean currents are driven by energy from the sun, both by changes in the distribution of mass due to heating and cooling, and by wind forcing at the surface. The distribution of solar radiation and rotation of the earth set up a basic pattern of winds consisting of (1) easterly trade winds over low latitudes, (2) westerlies over mid-latitudes, and (3) polar easterlies. Heating and cooling of land masses and the seasonal cycle of solar energy input alter this basic pattern.

The surface circulation of most of the area of the world's oceans consists of subtropical gyres which move cyclonically (Fig. 2). Equatorial currents move from east to west, western boundary currents (Gulf Stream, Kuroshio) move warm water from near the equator toward the poles, eastward currents (Antarctic Circumpolar, North Pacific) move water back across the oceans on the poleward side of the gyres, and eastern boundary currents (California, Peru, Canary, Benguela) move cold water towards the equator.

The strength of these currents varies seasonally. Eastern and western boundary currents spin off eddies, on the order of 100 km in diameter, which move both water and prey organisms and alter

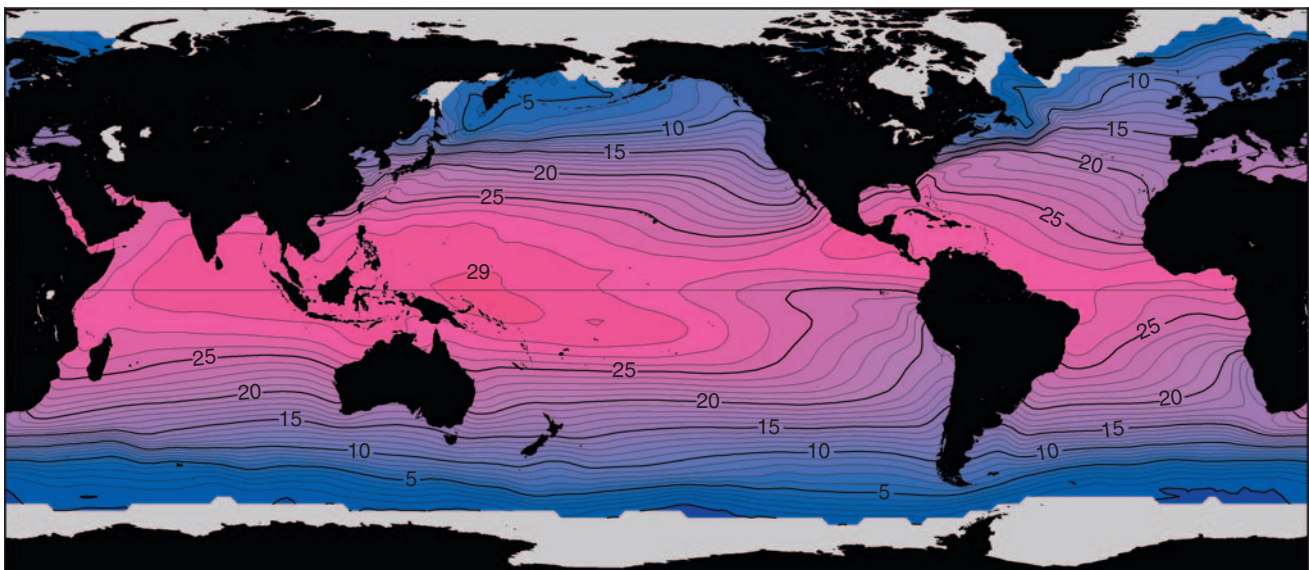

Figure 1 Mean sea surface temperature ($^{\circ}\text{C}$, data from Shea et al., 1992).

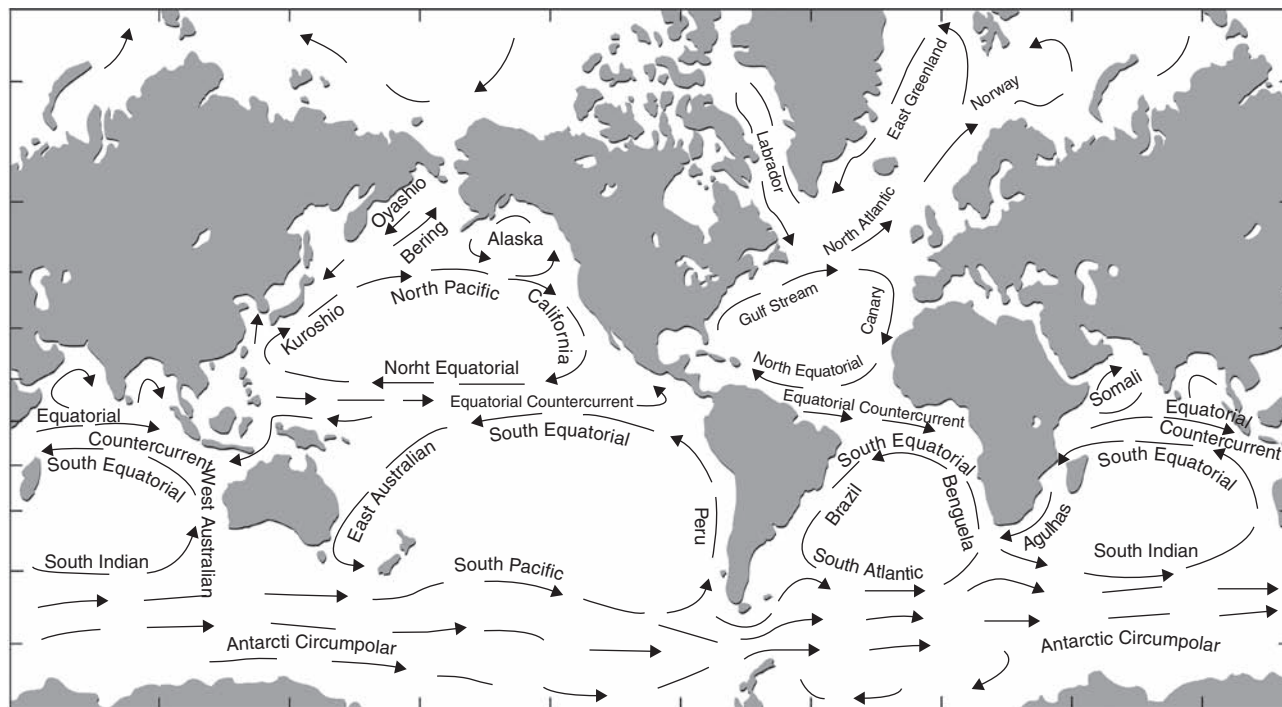

Figure 2 Surface currents of the world oceans.

the distribution of favorable habitat for marine mammals. Eastern boundary currents are sites of seasonal coastal upwelling, when equatorward winds move surface water offshore, and deeper nutrient-rich water is brought to the surface. Westward equatorial currents are also sites of upwelling, due to divergence of surface water caused by the rotation of the earth.

III. Vertical Structure

Physical (and biological) variability in the ocean environment is generally much greater in the vertical than in the horizontal dimension. Water temperature may be nearly constant for a few meters or tens of meters below the surface in the mixed layer, but then decreases rapidly with depth in the thermocline. Vertical changes in salinity may contribute to this stratification, especially in polar seas. Stratification influences productivity because deeper colder water has higher nutrient concentrations than the warmer water near the surface. Stratification also influences the distribution of food organisms.

IV. Productivity

Biological productivity is the rate of production of living matter; oceanographers often speak of “production”, which is the variable standing stock of living organisms and is closely linked to productivity (Fig. 3). Primary productivity in the ocean is the rate of production of plants (phytoplankton), and is often limited by light and nutrient availability, both of which are controlled by physical oceanographic processes. Light intensity at the sea surface varies with latitude and time of year, as well as time of day. Thus, photosynthesis occurs in polar seas only during summer. Light intensity decreases rapidly with depth, so that photosynthesis is possible within only a few meters or tens of meters of the sea surface.

Plant growth also requires nutrients (nitrate, phosphate and, for some phytoplankton, silicate). The importance of micronutrients, notably iron, in some regions of the open ocean, such as the Southern Ocean around Antarctica where many baleen whales feed, has been recognized in recent years. Nutrient availability is affected by oceanographic processes including stratification, wind and tidal mixing, circulation, and upwelling.

Marine mammals consume zooplankton, fish, squid, and even other marine mammals. Therefore, distribution and foraging are not directly determined by primary production. Food chains involving marine mammals are as short as diatoms–krill–baleen whales. Sperm whales (*Physeter macrocephalus*), however, consume large deep-living squid and are at least four steps removed from primary production at the sea surface.

V. Ice

Ice is an important component of the habitat of migratory and endemic marine mammals in both the Arctic and the Southern Ocean. Ice cover varies seasonally with temperature and is also subject to the influence of winds and currents. There must be some open water in any ice-covered habitat utilized by marine mammals to allow access to both air and food. Ice on the sea surface is found in a variety of types (pack ice, icebergs, shore ice, fast ice, drift ice, new ice) and forms (small floes, brash ice, pancake ice, etc.).

Sea ice in the Arctic is tightly packed except at the ice edge. Much of the Arctic Ocean is permanently ice covered, although summer ice cover has been decreasing due to global warming (IPCC, 2007). The Antarctic has a broad zone of looser pack ice with many internal leads. Most of this ice melts during summer. Polynyas are areas within the pack ice that are almost always clear of ice. Providing both

Figure 3 Mean chlorophyll concentration from SeaWiFS satellite data, 1998–2006, increasing from violet and blue to red, black is land and gray is permanent ice (data from Ocean Color Web, SeaWiFS Reprocessing 5, NASA Goddard Space Flight Center, <http://oceancolor.gsfc.nasa.gov/>).

access to the water and locally enhanced productivity, they are relatively more important in the Arctic than in the Antarctic.

VI. Temporal Variability

The ocean environment varies seasonally, especially at higher latitudes where ice closes accessibility to most species during winter. Seasonal variability in wind-driven upwelling causes significant changes during the year, even in the tropics. The ocean environment varies between years as well. The cycle in the ocean–atmosphere system known as the El Niño–Southern Oscillation, or simply “El Niño”, causes major changes in the tropics every 3 to 5 years. Both seasonal and interannual variability occur in all marine mammal habitats. However, the relative magnitude of variability at each scale varies (Fig. 4).

Climate variability over periods of decades has been documented in the ocean environment. For example, the Pacific Decadal Oscillation, driven by changes in the strength of the Aleutian Low pressure system results in changes in winds, temperature, and circulation in the North Pacific (Hare and Mantua, 2000). Ecological regime shifts are fundamental changes in the structure and function of ecosystems forced by climate change, fishery mortality or habitat modification, and exhibiting nonlinearities such as irreversibility (Bakun, 2004). Seal and sea lion declines in Alaska have been linked to a major oceanic regime shift that occurred in the late 1970s (Trites *et al.*, 2007).

Marine mammals have experienced climate change—variations in the ocean environment over periods of hundreds to thousands of years—throughout their evolutionary history. Concern is now focused on the possible effects of rapid global warming caused by mankind’s input of excess carbon dioxide and other greenhouse gases into the atmosphere. Scientists generally, although not universally, agree that by 2100 global average temperature will increase by 1.8°C to 4.0°C, sea level will rise by several tens of centimeters, and sea ice coverage will be reduced (IPCC, 2007). Changes in environmental variability on shorter time scales, such as the frequency or magnitude of El Niño events, the amplitude of seasonal cycles, or the frequency or intensity of storms are possible. Regional changes

in precipitation, circulation and upwelling, wind speed, wave conditions, acidity (pH), and UV-B (ultraviolet) radiation are expected.

VII. Effects on Life History and Function

Temperature can be a critical factor in the energy budget of warm-blooded mammals. However, marine mammals live and breed in the polar ice and even small young harp seals are able to tolerate freezing temperatures. Some baleen whale species tend to be slightly larger in the cold Southern Ocean than in the warmer North Pacific. Adaptations including an insulating blubber layer and an ability to reduce blood circulation to peripheral parts of the body have reduced the direct influence of temperature on distribution.

It has long been believed that large whales migrate from summer polar feeding grounds to warmer tropical breeding grounds because of adverse effects of low temperature on growth and survival of neonates. However, this hypothesis is no longer supported by considerations of energy intake, insulation by blubber, and heat loss. Even though the energy cost of migration may be very low for large whales, adult whales do not optimize their energy budget by migrating to warm tropical or temperate waters.

Cetaceans use underwater sound in several ways. Odontocetes use high-frequency sound to locate prey individuals and patches over short distances. Mysticetes use low-frequency signals for navigation and communication. Although the effects of temperature, salinity, and pressure on the propagation of sound in water are well known, it is not known whether oceanographic variability can affect the use of sound by marine mammals. If blue (*Balaenoptera musculus*) and fin (*B. physalus*) whales use the low-frequency sound channel of the deep ocean to acoustically “visualize” their environment, variations in water properties very likely distort or obscure the image they can obtain.

VIII. Effects on Feeding

Marine mammals are generally apex predators, or at the top of the food chain, although some are preyed upon by killer whales (*Orcinus orca*) and leopard seals (*Hydrurga leptonyx*). They are

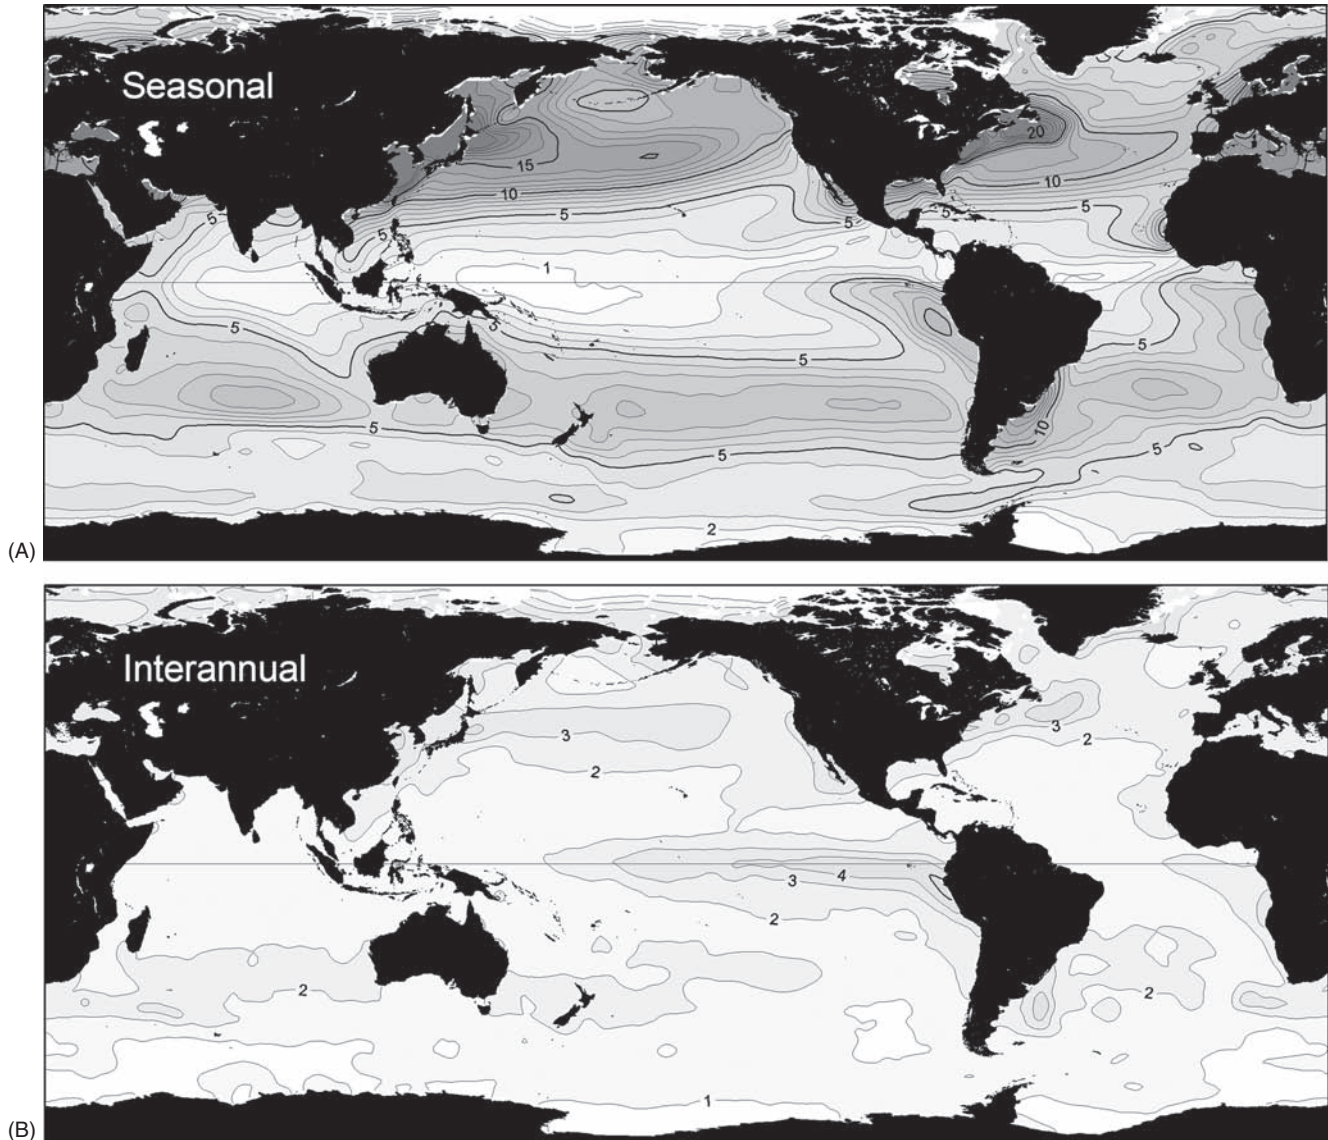

Figure 4 Approximate seasonal (A) and interannual (B) ranges of sea surface temperature (UK Meteorological Office HadISST 1.1 global monthly SST, 1950–2004).

motile, social, and intelligent, so that they are able to take advantage of prey in locally dense patches. Like all aquatic and terrestrial predators, marine mammals cannot forage efficiently on average concentrations of prey. It has been shown that right whales (*Eubalaena* spp.) and humpback whales (*Megaptera novaeangliae*) require concentrations of prey that are more dense than the maximum densities observed by net sampling. This is an indication of the limitations of oceanographic sampling, as well as the paucity of prey in the ocean environment. Sampling by acoustic backscattering from echo sounders and by photography with tethered cameras has now revealed small patches of prey of the required densities.

Prey consumed by marine mammals include crustaceans (copepods, euphausiids or krill, amphipods, shrimp), cephalopods (squid), and schooling fish [herring (*Clupea* spp.), capelin (*Mallotus villosus*), cod, mackerel, myctophids or lanternfish, and others]. Availability of these prey in dense patches has been linked to oceanographic features including bathymetry, fronts, eddies, and primary productivity.

Except for bathymetry, these features or characteristics of the ocean environment vary over time.

Baleen whales feed on dense patches of zooplankton. Distribution of feeding North Atlantic right whales (*Eubalaena glacialis*) can be predicted by surface temperature and bathymetric variables including depth and slope. These are the simplest oceanographic variables to measure, but they explain the distribution of whales only indirectly through effects on prey. Zooplankton patches are available in productive coastal waters, where upwelling and wind mixing results in high primary production, and in polar seas, where high primary productivity results from summer solar effects and enhanced phytoplankton growth at the melting ice edge and even under the ice. The patches are often located at bathymetric features like the shelf edge, islands, and seamounts, because bathymetry affects circulation and production and serves as a cue for aggregation of krill and fish. Blue whales feed on krill at the ice edge in the Antarctic, but also at the shelf edge off California (Croll *et al.*, 2005).

Along the northeast United States continental shelf, cetaceans tend to frequent distinct regions based on food preferences (Kenney and Winn, 1986). Piscivores—humpback, fin, and minke whales (*Balaenoptera acutorostrata*); and bottlenose (*Tursiops* spp.), Atlantic white-sided (*Lagenorhynchus acutus*), and common dolphins (*Delphinus* spp.)—are most abundant over shallow banks in the western Gulf of Maine and mid-shelf east of Chesapeake Bay. Planktivores—right, blue and sei (*Balaenoptera borealis*) whales—are most abundant in the western Gulf of Maine and over the western and southern portions of Georges Bank. Teuthivores (squid eaters)—sperm and pilot (*Globicephala* spp.) whales and Risso's dolphins (*Grampus griseus*)—are most abundant at the shelf edge. Most of these patterns can be related to availability of specific prey. Right whales feed on dense patches of copepods in the vicinity of the Great South Channel. Humpbacks and fin whales feed on a small schooling fish, the American sand lance (*Ammodytes americanus*), which is very abundant on Stellwagen Bank and Jeffreys Ledge in the Gulf of Maine, and is also abundant off Chesapeake Bay.

Cetaceans are distributed over distinct depth ranges along the continental slope in the northwestern Gulf of Mexico (Davis *et al.*, 2002). Deep-diving teuthivores, such as Risso's dolphins, sperm whales and beaked whales, are found near temperature fronts in deep water, where their squid prey may aggregate. Sperm whales are more abundant in regions of high zooplankton biomass and steep topography in the Pacific Ocean, where deep-living squid are aggregated. Most of the nineteenth-century sperm whaling grounds in the Pacific were in regions of coastal or oceanic upwelling where primary production is high (Jaquet *et al.*, 1996).

In the Antarctic, both Antarctic fur seals (*Arctocephalus gazella*) and minke whales are found in the marginal ice zone, where primary productivity and, presumably, prey availability are enhanced (Ribic *et al.*, 1991). Winter pack ice extends out beyond the narrow Antarctic continental shelf and over the deep ocean. Minke whales, beaked whales and several species of seals live in this ice and feed on krill (the euphausiid *Euphausia superba*), myctophid fishes, and squid. As the pack ice retreats in summer, many of these winter residents and other predators including large baleen whales, male sperm whales, and killer whales, follow the ice edge to feed on abundant plankton and nekton. Right whales, feeding on smaller copepods not concentrated at the ice edge, remain in open waters north of the retreating ice.

Ice is an important habitat component for breeding and shelter of pinnipeds. Antarctic ice floes in the marginal ice zone are a refuge for fur seals from predation by killer whales. Crabeater seals (*Lobodon carcinophaga*), in contrast, are found in the interior of the pack ice where larger, more stable floes provide breeding sites.

In the Arctic, gray (*Eschrichtius robustus*), bowhead (*Balaena mysticetus*), and beluga (*Delphinapterus leucas*) whales migrate into the Chukchi and Beaufort Sea north of Alaska to feed in summer and fall (Moore and DeMaster, 1998). Bottom-feeding gray whales feed in shallow, ice-free waters, piscivorous belugas feed in deep water near the ice edge, whereas planktivorous bowhead whales feed closer to the coast where ice cover is less. These distribution differences are clearly related to prey availability. River plumes formed by summer runoff into the Arctic have been shown to limit the distribution of prey and thus determine the distribution of foraging whales.

IX. Effects on Distribution and Migration

Distribution of baleen whales on summer feeding grounds and movement on these feeding grounds are associated with oceanographic features, including fronts between water masses, eddies along these fronts, eddies caused by circulation around islands and capes, and oceanic

and coastal upwelling. Prey availability is enhanced by nutrient input and enhanced primary production, or by convergence and aggregation of plankton. Japanese whalers have exploited concentrations of (1) sei whales off Japan where the warm Kuroshio Current meets the cold Oyashio, (2) fin whales in a cold cyclonic eddy and in a mixing zone between cold coastal waters and warmer Bering Sea waters in the western subarctic Pacific, (3) fin whales at shelf edge fronts and upwelling zones off islands in the eastern Bering Sea, (4) blue and fin whales at the Polar Front north of the Antarctic pack ice (Nasu, 1966). Both resident and migrant cetaceans utilize prey aggregations associated with summer upwelling along the California coast (Tynan *et al.*, 2005).

Relatively little is known about migration routes of most baleen whales between summer feeding grounds and winter breeding grounds. Gray whales migrating south along the California coast remain near the coast and apparently use bottom topography for navigation. Humpback whales have been tagged off Hawaii and observed to linger at seamounts in the middle of the North Pacific on the way to summer feeding grounds in the Gulf of Alaska (Mate *et al.*, 2007). Seamounts are known to be sites of aggregation of fishes. These whales may be feeding, regrouping, or simply navigating.

X. Effects of Climate Change

Direct effects of temperature increase are unlikely for most marine mammals, because of their mobility and thermoregulatory ability. However, direct effects could occur for populations at the limits of their range or with physical limits to migration that preclude distribution shifts to track environmental changes. For example, the Gulf of California harbor porpoise, or vaquita, is a rare species trapped at the warm northern end of the Gulf of California. Other species, such as the beluga whale, with low skin pigmentation and living in a polar region subject to atmospheric ozone depletion, may suffer direct effects of increased UV-B radiation.

Indirect effects on marine mammal populations might include changes in distribution, timing and range of migration, abundance of competitors and/or predators, prey availability, timing of breeding, and reproductive success (Learmonth *et al.*, 2006). Global warming is predicted to be greatest at high latitudes in the Northern Hemisphere. The resulting reduction of ice cover in the Arctic will affect ice-associated species through changes in the distribution of critical habitat such as ice-free areas, polynyas, and the ice edge. Seasonal and geographical shifts in prey availability in both the Arctic and Antarctic may have a variety of indirect effects on nutritional status and reproductive success, geographic range, and timing or patterns of migration. Bowhead whales and narwhals (*Monodon monoceros*), and especially beluga whales, that feed close to the ice edge, will be affected by reduced ice extent in the Arctic. Warming could also reduce the extent of pack ice in the Antarctic and thus affect the distribution and abundance of krill. Declining krill abundance in the region of the Antarctic Peninsula during the early 1990s has been linked to low winter sea ice extent.

Global warming is expected to be less intense at lower latitudes. However, reduction in wind-driven coastal and equatorial upwelling is possible and may reduce prey availability for marine mammals. A decline in zooplankton biomass off California since 1951 has been linked to warming of surface waters, increased stratification, and reduced mixing and upwelling of nutrients. Odontocetes that depend on squid, such as sperm whales, may be more adversely affected because cephalopod populations are known to be highly variable. Rising sea level will change the lagoons and shelf areas where gray whales and humpbacks breed, but past changes in these breeding sites are known to have occurred over longer periods of geologic time.

Odobenocetops is a startling example of convergence with the walrus in its cranial morphology and inferred feeding habits (Muizon, 1993; Muizon et al., 2002a, b). *Odobenocetops* is known from two species, both from the Pliocene Pisco Formation of Peru.

I. Descriptive Anatomy

Odobenocetops (Figs 1 and 2) has lost the elongated rostrum of the other cetaceans. Instead, the rostrum is short, rounded, and blunt and formed by the premaxillae, which are greatly enlarged. It has large, asymmetrical ventral alveolar sheaths holding sexually dimorphic tusks. The right tusk of the male is large and can reach 1 m or more in length. The left tusk is ca. 25-cm long, of which a few centimeters only were erupted. Both tusks are straight. In the female both tusks approach the size of the left tusk of the male, although the right tusk is slightly larger than the left. Premaxillary sheath and tusks are oriented posteroventrally. The bony nares are displaced anteriorly (when compared to other odontocetes). The palate is very deep and arched, and its anterior border is U- to V-shaped. It bears no maxillary teeth. The orbits face anterolaterally and dorsally. The portion of the frontal and maxillae which cover the temporal fossae in other odontocetes have been reduced and narrowed in such a way that the temporal fossae are opened dorsally. The periotic and tympanic have the characteristic morphology observed in the other delphinoid cetaceans. The mandible is not known, and there are few postcranial bones. The length of the body could have ranged from 3 to 4 m.

II. Relationships

In spite of its extremely modified morphology, several characters of the skull indicate that *Odobenocetops* is a delphinoid cetacean. Cetacean characters of *Odobenocetops* are the presence of large air sinuses in the auditory region connected to well-developed pterygoid sinuses, thickened and pachyostotic tympanic bulla, and dorsal opening of the narial fossae. Odontocete affinities of *Odobenocetops* are attested by the maxillae covering the supraorbital processes of the frontals (Muizon, 1994), dorsoventral expansion of the pterygoid sinuses, presence of large premaxillary foramina (in *O. peruvianus* only), and asymmetry of the premaxillae and maxillae in the facial region. The sigmoid morphology of dorsomedial view of the involucrum and the presence of a medial maxilla-premaxilla suture at the anterolateral edge of each narial fossa are delphinoid characters (Muizon, 1988). Several characters of the pterygoid, alisphenoid, and temporal fossa, indicate close affinities of *Odobenocetops* and the Monodontidae (Muizon, 1993; Muizon et al., 2002a). The exceptional specializations of *Odobenocetops* merit that it is referred to a new odontocete family, the *Odobenocetopsidae*, regarded as the sister group of the Monodontidae.

The occurrence of tusks in *Odobenocetops* is a convergence with *Monodon* as in the latter genus the large tusk of the male is implanted in the left maxilla, whereas in *Odobenocetops* it is implanted in the right premaxilla. Consequently, the tusks of *Monodon* and *Odobenocetops* are not homologous.

III. Functional Anatomy

Odobenocetops and the living walrus are convergent in the large and deep palate; the strong development of a wide, the blunt snout which is highly vascularized and has strong muscular insertions, suggesting

Odobenocetops

CHRISTIAN DE MUIZON

One of the most unusual fossil cetaceans is a tropical tusked whale related to narwhals—*Odobenocetopsidae*, *Odobenocetops*—from the early Pliocene beds of the Pisco Formation of Peru (Muizon, 1993; Muizon et al., 2002a, b). As its name indicates, this marine mammal presents several similarities with the living walrus, *Odobenus rosmarus*, in spite of being a cetacean.

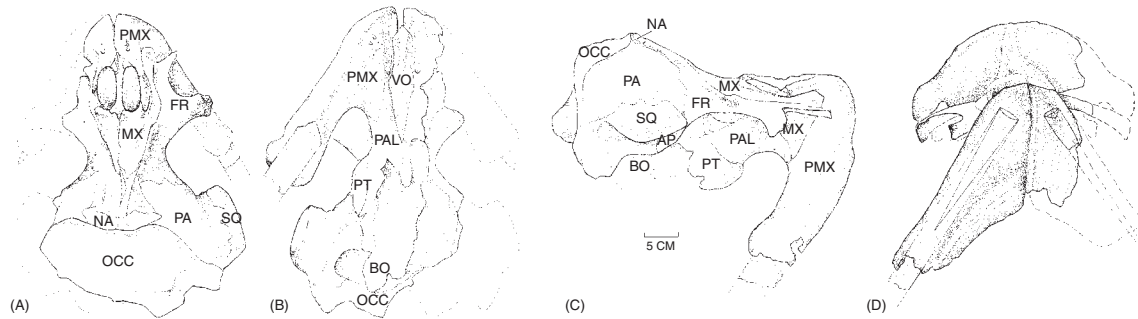

Figure 1 Skull of *Odobenocetops peruvianus* in dorsal (A), ventral (B) lateral (C) and rostral (D) view. AP, ali-sphenoid; BQ, basioccipital; FR, frontal; MX, maxilla; NA, nasal; OCC, occipital; PA, parietal; PAL, palatine; PMX, premaxilla; PT, pterygoid; SQ, squamosal; VO, vomer. Modified from Muizon (1993), reprinted with permission from Nature (365, 745–748, 1993).

Figure 2 *Odobenocetops leptodon*: skull of a male in left ventrolateral (A), anteroventral (B), dorsal (C), and left lateral (D) views. Scale bar: 20 cm (A, B); 10 cm (C, D) from Muizon et al. (1999). Reprinted by permission from the Comptes Rendus de l'Académie des Sciences, Série IIA, 329, 449–455. Copyright (1999) Elsevier.

the presence of a powerful tactile upper lip; the presence of tusks, and reduction of the maxillary dentition. The living walrus feeds mainly on benthic invertebrates (Fay, 1982) sucking out the siphon and foot of bivalves or gastropods shells, using the tongue as a piston powered by the very large lingual retractors and depressors. Given the anatomy of its palate, it is likely that *Odobenocetops* used a similar feeding strategy. *Odobenocetops* was, therefore, probably feeding upon benthic invertebrates (bivalves and gastropod mollusks and/or crustaceans), which are abundant in the Pisco Formation. Because of the great vascularization of the inferred upper lip it is possible that, as in the walrus, *Odobenocetops* had vibrissae, which would have had an important tactile role in the search for food. When feeding on the sea floor, the body of *Odobenocetops* was probably held in an oblique position as is observed in the living walrus (Fig. 3).

The visual and the echolocation system of the two species of *Odobenocetops* differed. *O. peruvianus* probably had greatly reduced premaxillary air sacs and melon of most odontocetes, as a result of the extreme shortening of the rostrum and the very short space between the premaxillary foramina and the nares. In contrast, in *O. leptodon* fossae for premaxillary sacs are present and left a clear scar on the premaxillae, and a small melon was probably located anterior to the nares. Thus, *O. peruvianus* probably did not echolocate but *O. leptodon* did.

The anterodorsal edge of the orbit (i.e., the anterior border of the supraorbital process of the frontal) in *O. peruvianus* is deeply notched, allowing overlapping visual fields and binocular vision. In contrast, this region of the frontal in *O. leptodon* is only slightly concave, which probably prevented (or at least reduced) binocular vision.

Therefore, in *O. peruvianus*, the probable lack of echolocation ability was probably compensated for by a good anterodorsal binocular vision. As in the walrus, the latter was especially useful when the animal was searching for food on the sea floor with the body in an oblique position (Kastelein et al., 1993).

The posteroventrally oriented tusks are certainly one of the most unusual characteristics of *Odobenocetops*. Because of its great length and slenderness the right tusk of the male was probably very fragile and it is unlikely that the animal was swimming with the tusk held at a 45° angle with the axis of the body. Comparison of the occipital condyles to the anterior articular facets of the atlas indicates that, when swimming, the dorsal plane of the skull was oriented anterodorsally and the tusk was approximately parallel to the axis of the body. When feeding, the large tusk was dragged on the sea floor, and because of the oblique position of the body, the tusk was at an angle

Figure 3 Reconstruction of three male *Odobenocetops leptodon* in swimming and feeding position. From Muizon et al. (1999), reprinted with permission. Painting by Mary Parrish.

of 20° to 40° with the axis of the body (Fig. 3). In other respects, the convexity of the occipital condyles of *Odobenocetops* indicates that its neck was extremely mobile, allowing amplitude of the head movement approaching 90° or more.

In narwhals, the tusk is mainly used in intraspecific behaviors, and the same is probably true for *Odobenocetops*. The tooth was fragile and sexually dimorphic and is unlikely to have been used to exert forces (in digging or fighting), and was probably used in intraspecific displays (Muizon et al., 2002a, b). It is also possible that tusks of walrus and the premaxillary tusks and sheaths of *Odobenocetops* played a role in bottom feeding, as orientation guides to keep the mouth and any vibrissae in stable position relative to the substrate.

Omura's Whale

Balaenoptera omurai

TADASU K. YAMADA

I. Characteristics and Taxonomy

Omura's whale (Fig. 1) is a medium-sized baleen whale found in lower latitude Indo-Pacific waters of both the hemispheres. Although the species was described quite recently, it has been sighted at sea and a number of specimens have been collected and placed in museums, some only recently identified.

The body length of the species is about 10–12 m. The smallest newborn known was 3.2 m in length. External proportions of the body are similar to those of the Bryde's whales (*B. edeni/brydei* complex) and sei whale (*B. borealis*). Absence of lateral ridges on the dorsal surface of the head is the most diagnostic characteristic for distinguishing it from the Bryde's whales. The lateral contour of the upper jaw is convex as in the blue whale (*B. musculus*). The ventral pleats extend as far as around the umbilicus, separating it from the sei whale. Omura's whale is distinctly counter-shaded, basically black above and off-white below. The dark portion of the color pattern is lighter than in the fin whale (*B. physalus*). The ventral surface of the flukes is off-white with dark irregular margins. Young animals may be lighter in color than adults. The lower jaw area is asymmetrically pigmented, black on the left side and white on the right. The dorsal fin is relatively small, low, and strongly falcate. The number of baleen plates (about 200 on each side) is less than that known for any other species in the genus *Balaenoptera*. The anterior one-third of the baleen plates are yellowish white, more so on the right side. The posterior one-fifth of the plates are all black, whereas the intermediate plates are bi-colored (dark brownish-gray outside and pale inside). The base of a baleen plate is wide relative to the length. The bristles are not coarse but thicker than those in the sei whale.

Figure 1 Omura's whale. Illustration by Watanabe Yoshimi.

Figure 2 Skull of Omura's whale.

There is no record of an anatomical examination of a fresh specimen. Data are available only for the skull and the skeleton (Fig. 2). The most specific feature of the skull is the convex contour of the lateral border in both maxillae. The configuration of the vertex is also unique; the posterior end of the ascending process of the maxilla widens and becomes squarish and the posterior end of the premaxilla becomes thin and sinks between the nasal and the maxilla. A narrow area of the frontal is exposed between the nasals and the occipital shield. There are one or two foramina in the suture line between the parietal and the squamosal on the posterior wall of the temporal fossa, which is unique to this species. In older individuals, however, these foramina are barely discernible. A groove exists in the posterosuperior edge of the orbital process of the frontal. The lateral border of the parietal spreads widely and is visible in dorsal view. The vertebral formula is $C7 + Th13 + L12 + Ca21 = 53$. The anterior four ribs have both head and tuberculum, whereas the posterior nine are without head. The head of the first rib is not bifurcated (not composed of two fused ribs). The flippers are relatively longer than those of Bryde's whales; the phalangeal formula of the type specimen is I-5, II-7, IV-6, V-3, excluding the metacarpals. The one pair of pelvic bones available for examination have a peculiar spatulate shape, which could be a pathological condition.

Among the species of the genus *Balaenoptera*, *B. omurai* was first considered close to the Bryde's whales. This was only because of the similarity in their size. The morphological characteristics of mainly the skull of *B. omurai* are very different and distinct from those in the Bryde's whales. Sasaki *et al.* (2006) in their molecular work based

on complete mtDNA sequences and short interspersed repetitive element (SINE) insertion patterns suggested that *B. omurai* evolved as an ancient independent lineage that diverged much earlier than the Bryde's whales and sei whale.

The species was first called "small-form Bryde's whale" by Wada and Numachi (1991). "Pygmy Bryde's whale" was also used by several authors. Considering the morphological and molecular differences from the Bryde's whales, common names based on that species or species complex should be avoided. The scientific name, *Balaenoptera omurai*, honors the late Dr. Hideo Omura, who first recognized the significance of the Bryde's whale in global whale fisheries. The Japanese name is related to the type locality Tsunoshima Island in western Japan.

II. Distribution and Abundance

Current knowledge of the distribution of this whale is very limited and remains tentative (Fig. 3); it is based on sporadic and accidentally collected records. However, the species probably ranges throughout less oceanic waters of tropical/subtropical lower latitudes of the Indo-Pacific region, including the Solomon Sea, Java Sea, Andaman Sea, Gulf of Thailand, Philippines, South China Sea, East China sea, and the western edge of the North Pacific including the seas around Taiwan and southwest Japan. The type locality in the Sea of Japan ($34^{\circ}21'N$) and the South Australian record ($34^{\circ}37'S$) may be at the northern and southern extremes of the range, respectively. The known longitudinal range is between $90^{\circ}E$ and $160^{\circ}E$. There

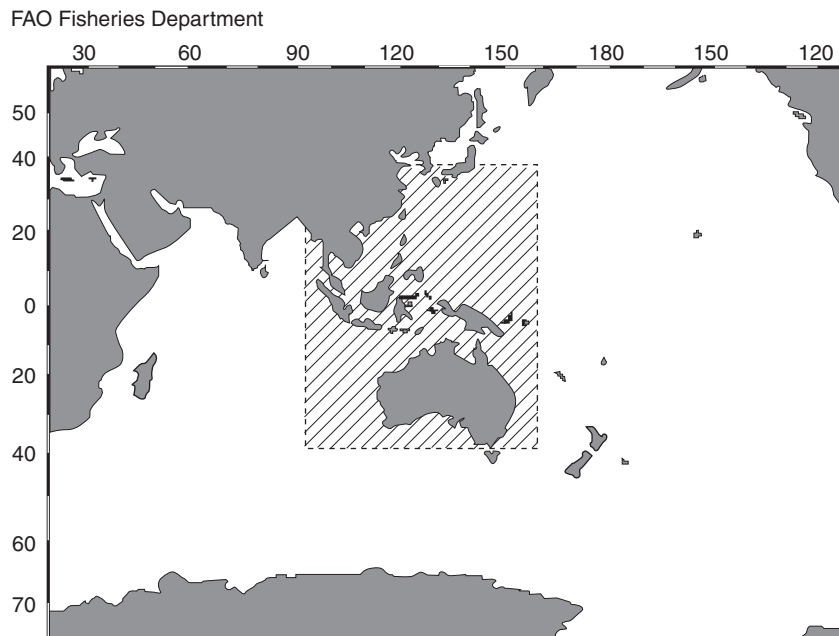

Figure 3 Approximate probable range of Omura's whale.

is no estimate of population size. Strandings have all been of single animals.

III. Ecology

There is a sighting report of what was possibly a group of Omura's whales chasing tuna (possibly longtail tuna, skipjack tuna, or eastern little tuna) in the Andaman Sea.

IV. Behavior and Physiology

Nothing is known of the behavior and physiology of this whale.

V. Life History

Among the six individuals captured in the Solomon Sea, the largest female was 11.5 m and male 9.6 m long. Maximum age among them, based on earplug laminations, was 38 years for a 9.6 m male. The greatest age for a female was 29; she was 11.5 m long. A newborn with fetal folds and folded dorsal fin and flukes was collected off southern Japan on August 30, 2005.

VI. Interactions with Humans

Apart from the inadvertent take under scientific permit by Japan near the Solomon Islands and Java, there is no record of the species being hunted. Recently, two individuals were incidentally caught in set nets in Japan. In the Philippines sporadic captures by an artisanal land-based fishery in the Bohol Sea existed in the past.

Osmoregulation

DANIEL P. COSTA

I. Introduction

An organism can be thought of as a large volume of fluid surrounded by the body wall. Mammals must maintain both the concentration and volume of this internal fluid within a very narrow range, and can only tolerate minor deviations. Even though most marine mammals live in an aquatic medium, the animals' internal fluid composition differs from the ambient environment and therefore requires active processes to maintain it. Osmoregulation describes the way in which the internal water and electrolyte concentration of this internal environment is maintained. When animals feed, they take in both water and electrolytes that must be excreted. While they gain water from metabolizing food, they lose water through evaporation when they breathe to obtain the oxygen necessary for metabolism. Maintenance of a constant internal environment requires that whatever comes into the animal must equal what goes out. The easiest way to understand osmoregulation is to account for the ways water and electrolytes enter and leave the organism (Fig. 1). For example, if a dolphin consumes a large volume of water and electrolytes, it must have the capability to excrete an

equivalently large volume in the feces and urine, through breathing and in milk during lactation. Conversely, if a seal on the beach does not have access to food or water, it must be able to survive on the water produced from metabolism and have mechanisms in place to reduce water loss. Following the relative rates of water and electrolyte input and output helps us to understand the mechanisms that marine mammals use for osmoregulation.

II. Water and Electrolyte Ingestion

Water and electrolytes enter the animal through the ingestion of food and water. Water that is consumed in food or actively drunk is called preformed water. Compared to terrestrial mammals, marine mammals consume a water rich diet of fish and marine invertebrates (70–80% water). Prey contains electrolytes and nitrogen that requires water for excretion by the kidney. Ingestion of invertebrate prey (i.e., squid, krill, clams), results in the intake of more electrolytes than vertebrate prey (fish). The internal fluid concentration of invertebrates is essentially the same as seawater, whereas vertebrates contain about one-third the electrolyte content. Thus, a dolphin eating squid will get almost 3 times as much electrolyte than if it consumed fish. Furthermore, an animal like a manatee, *Trichechus* spp., with access to freshwater can drink freshwater to flush electrolytes, whereas an oceanic dolphin can only drink seawater. Water is also produced as a byproduct of metabolism; this is called metabolic

water production (MWP). The amount of MWP varies with the chemical composition of the diet; therefore, different diets produce varying amounts of metabolic water. For example, 1.07 g of water is generated for every gram of fat oxidized, 0.56 g H₂O/g of carbohydrate, and only 0.39 g H₂O/g of protein.

III. Water and Electrolyte Output

Both water and electrolytes are excreted in the urine and feces, whereas only water is lost through evaporation. Water is lost via evaporation both across the skin, cutaneous water loss, and through the lungs, respiratory evaporative water loss. Since marine mammals do not sweat there is no loss of salt across the skin (Whittow *et al.*, 1972). Unlike sea birds and marine reptiles, marine mammals lack specialized glands to excrete salts. All salt excretion is through the kidney, and marine mammals have developed a specialized kidney to handle the large volume of electrolytes and water they process (Ortiz, 2001).

IV. Do Marine Mammals Drink Seawater?

In most cases, marine mammals can derive sufficient water from their diet so that they do not need to ingest seawater. Measurements of the water, electrolyte and nitrogen intake, coupled with measurements of evaporative, urinary and fecal water loss suggest that a feeding seal can get all of the water it needs from its prey (through both preformed and metabolic water) (Pilson, 1970; Depocas *et al.*, 1971; Tarasoff and Toews, 1972; Ortiz, 2001). This is due to the high water content of the prey coupled with the low evaporative water loss of an animal living in a marine environment.

Do animals drink seawater when they become osmotically stressed in environments where the evaporative water loss is high? To determine whether a marine mammal can gain freshwater by drinking seawater we need to know whether the animal can excrete urine that is more concentrated than seawater. The more concentrated the urine, the greater the amount of “freshwater” that can be derived from ingestion of seawater. A simple calculation can show how much water is gained or lost relative to the concentrating ability of the kidney (Table I). For example, if a humpback whale, *Megaptera novaeangliae*, consumed 1000 ml of seawater and its kidney had the ability to excrete urine with a chloride concentration of 820 mmol/l, it could gain 350 ml of freshwater. Whereas humans, who cannot produce urine as concentrated as seawater, would lose 350 ml of freshwater for every liter of seawater they consumed. The maximum urine concentrating ability of marine and terrestrial mammals is presented in Table II.

So, do marine mammals drink seawater? Many species of marine mammals have the capacity to drink seawater, but they do not always

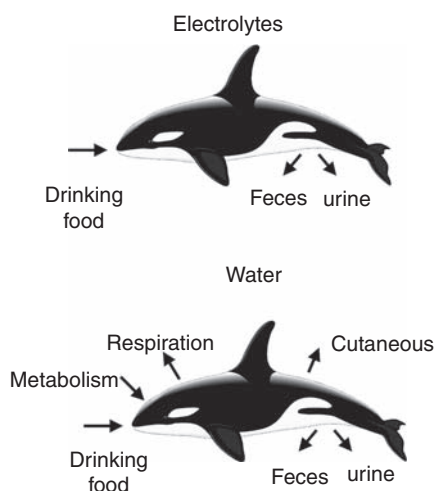

Figure 1 Schematic of ways water and electrolytes enter and leave a marine mammal. Excretion of electrolyte and water as milk only occurs when females are lactating.

TABLE I
Differences in the urine concentrating ability of a humpback whale, and a human given to show a gain or loss of body water after the ingestion of a liter of seawater

	Seawater consumed volume (ml)	Cl ⁻ concentration (mmol/l)	Maximum urine concentration (mmol/l)	Urine volume produced (ml)	Water balance gain or loss (ml)
Whale	1000	535	820	650	+350
Human	1000	535	400	1350	-350

TABLE II

do so. Isotopically labeled water and/or electrolytes have been used to quantify seawater drinking in a variety of marine mammals (Table III). In these studies, the amount of water and/or electrolytes consumed in the food was added to that produced by metabolism and compared to the total amount of water and/or electrolytes that passed through the animal as measured by isotopic tracers. Using these methods, investigators found that sea otters (*Enhydra lutris*), common bottlenose dolphins (*Tursiops truncatus*), hooded seals (*Cystophora cristata*), and harp seals (*Phoca groenlandica*) that were feeding; and Galapagos fur seals (*Arctocephalus galapagoensis*), short-beaked common dolphins (*Delphinus delphis*), and short-finned pilot whales (*Globicephala macrorhynchus*), that were fasting, consumed seawater (Telfer *et al.*, 1970; Hui, 1981; Costa, 1982; Costa and Trillmich, 1988; Skjalstad and Nordoy, 2000; Storeheier and Nordoy, 2001). In contrast, feeding and fasting harbor seals (*Phoca vitulina*), feeding northern fur seals (*Callorhinus ursinus*), and fasting Antarctic fur seals (*Arctocephalus gazella*), all had negligible amounts of seawater ingestion (Depocas *et al.*, 1971; Ortiz *et al.*, 1978; Costa, 1987; Costa and Trillmich, 1988). Weaned northern elephant seal pups (*Mirounga angustirostris*) fast for up to 3 months without any measurable ingestion of seawater (Ortiz *et al.*, 1978). The need to drink seawater varies with climate and habitat. For example, fur seals in warm environments tended to drink seawater whereas those in colder climates did not (Gentry, 1981; Costa and Trillmich, 1988).

TABLE III
The rate of seawater ingestion measured, using isotopic tracer techniques, in marine mammals

	Body mass (kg)	Rate of seawater consumption		
		ml/kg/day	ml/day	Proportion of total water influx (%)

V. Relative Reductions in Water Loss

As described earlier, many marine mammals do not need to drink seawater because they have reduced their evaporative water loss. Amazingly, northern elephant seals can fast for months without access to food or water (Fig. 2). The only water available to fasting seals is MWP from the oxidation of fat and protein in their tissue (Ortiz *et al.*, 1978). Remember that positive water balance requires that water input equals water output. This requires that water lost in the urine, feces, and from evaporation be equal to or less than MWP. How then do elephant seals, and probably other seals and sea lions, reduce their water loss?

A. Cutaneous Water Loss

Given their aquatic life style, marine mammals have very low evaporative cutaneous (skin) water loss. In water, there would be no evaporative water loss, and on land, as pinnipeds apparently do not sweat, their cutaneous evaporative loss is quite low (Whittow *et al.*, 1972). However, common dolphins (*Delphinus* spp.) and harbor porpoise (*Phocoena phocoena*) appear to lose a substantial amount of water across their skin surface (Hui, 1981; Andersen and

Figure 2 A male northern elephant seal (*Mirounga angustirostris*) fasting on the beach without access to water. Elephant seals undergo fasts of up to 3 months without access to water. Photo by Dan Costa.

Nielsen, 1983). Common dolphins lose as much as 41 H₂O/day, or 70% of their total water intake. It may be that seawater ingestion is necessary to make up for the water lost across the skin.

B. Respiratory Evaporative Water Loss

Endotherms lose water through respiration by the simple physics of warming and saturating the air they breathe. Ambient air is inhaled, warmed, and humidified to core body temperature. For example, air fully saturated (100% relative humidity) with water at 10°C contains 10 ml H₂O/l of air, whereas fully saturated air in the lungs at 37°C contains 40 ml H₂O/l of air. Unless there is a mechanism to recover water, a seal would lose 30 ml of H₂O for every liter of 10°C air it inhaled.

Marine mammals employ a few tricks to reduce the water lost through respiration (Lester and Costa, 2006). The first is to breathe periodically; i.e., to inhale, hold their breath and then exhale. This is called apneustic breathing. Apneustic breathing increases the amount of oxygen extracted per liter of air inhaled. While terrestrial animals typically extract 4% oxygen per breath, marine mammals can extract as much as 8% per breath. This allows marine mammals to breathe less frequently and thereby lose less water because they make fewer respirations to obtain an equivalent amount of oxygen. Pinnipeds, sea otters and polar bears (*Ursus maritimus*), further reduce their respiratory evaporative water loss by employing a nasal countercurrent heat exchanger.

1. Nasal Countercurrent Heat exchanger Marine mammals, rodents and desert ungulates have small passageways in their nasal passages that allows them to recover water vapor and heat that was added to the air at inhalation (Huntley *et al.*, 1984; Folkow and Blix, 1987). The nasal turbinates are composed of very small passageways that allow intimate contact between the inhaled air and the nasal membranes (Fig. 3). As the cold air passes across the small nasal passage, it is warmed and water evaporates. Heat and moisture is transferred from the nasal passage to the air so that by the time it leaves the nasal turbinate it is warmed and humidified to body temperature. In the process of warming the inhaled air, the membranes lining the nasal passages have cooled. On the following exhalation the warm moisture laden air is cooled as it passes over the cool membranes. As the air temperature declines, water vapor condenses and is recovered in the nasal passage (Fig. 4).

Figure 3 (A) Sagittal section of a weanling elephant seal skull showing the nasal turbinates. (B) Cross-section through one half of the skull at line "X" in A. With permission The Company of Zoologists.

C. Fecal Water Loss

Although there are no direct measurements, fecal water loss of feeding cetaceans is probably quite high. Fecal water loss in pinnipeds feeding on fish is comparable to that of terrestrial carnivores. However, it is not clear how marine mammals that ingest seawater avoid the laxative effect of $MgSO_4$. Fasting animals have negligible fecal water loss, as their fecal production is quite low.

Figure 4 Temperature at 1-cm intervals within the nasal passage of a weanling elephant seals where the ambient air temperature was 15°C (open symbols) and 5°C (closed symbols). With permission The Company of Zoologists.

D. Urinary Water Loss

The rate and amount of water lost in the urine is directly related to both the urine concentrating ability of the kidney and the hydration state of the animal. The kidney ultimately regulates the water and electrolyte state of the animal. When there is a surplus

Figure 5 A sagittal section of a kidney from a California sea lion (*Zalophus californianus*), showing the two halves. Notice the individual lobules or reniculi that together make up the kidney. Each lobule acts like an individual kidney. Cetaceans, pinnipeds and the sea otter have kidneys constructed this way. Photo by Dave Casper.

Figure 6 A female northern elephant seal and her suckling pup. Over the entire 28 day lactation interval the mother does not eat or drink. All the water and energy contained in the milk provided to the pup must come from the mother. Milk is also the only source of water for the pup. After the pup is weaned it will fast on the beach between 2 and 3 months. During this fasting period the pups does not drink measurable amounts of sea water.

TABLE IV
Water, lipid and protein content of marine mammal milk compared to human and cow milk

	% water	% lipid	% protein
Blue whale, <i>Balaenoptera musculus</i>	45.4	41.5	11.9

Cow, <i>Bos Taurus</i>	87.3	3.7	3.3

of water, the kidney produces dilute urine, whereas during periods of water stress, the kidney excretes concentrated urine. The kidney must be able to excrete metabolic end products in the form of urea and all excess electrolytes with the water that remains after cutaneous, respiratory, and fecal water loss. While at sea, marine mammals either get all of their water from their prey or they drink seawater. This requires the processing of large urine volumes at moderate to high urine concentrations, and most marine mammals (cetaceans, pinnipeds, sea otters) have a specialized lobulate or reniculate kidney that enables them to do this (Vardy and Bryden, 1981; Costa, 1982; Ortiz, 2001) (Fig. 5; see kidney section).

However, pinnipeds, such as the northern elephant seal, undergo prolonged fasts on land without access to water. These animals are able to stay in water balance by a combination of low rates of evaporative water loss, coupled with low rates of urine production (Adams and Costa, 1993; Lester and Costa, 2006). Elephant seals, *Mirounga* spp., utilize fat almost entirely (96–98%) for their metabolism while fasting. Fat oxidation produces only CO₂ and H₂O, whereas oxidation of protein results in CO₂, H₂O, and urea. Urea is the end product de-amination of amino acids and requires water to be excreted by the kidney. Therefore, fat is not only an efficient way to store energy, it is also economical with respect to water balance (see pinniped physiology section).

VI. Water Balance During Reproduction

Many female pinnipeds do not have access to water while they suckle their young, and thus could become dehydrated during lactation (Fig. 6). However, marine mammal milk is high in lipid and low in water compared to terrestrial mammals (Table IV). This has the advantage of providing the young with the maximum amount of energy with minimal loss of water from the mother. This is likely an advantageous byproduct of the energetics of marine mammal

lactation and not a derived adaptation for water balance (see marine mammal energetics section). Pups also do not have access to water, and therefore must be capable of maintaining water balance entirely from the water provided in the milk.

Otters, Marine

J.A. ESTES, J.L. BODKIN, AND M. BEN-DAVID

The otters (Mustelidae; Lutrinae) provide an exceptional perspective into the evolution of marine living by mammals. Most extant marine mammals (e.g., the cetaceans, pinnipeds and sirenians) have been so highly modified by long periods of selection for life in the sea that they bear little resemblance to their terrestrial ancestors. Marine otters, in contrast, are more recent expatriates from freshwater habitats and some species still live in both environments. Contrasts among species within the otters, and among the otters, terrestrial mammals, and the more highly adapted pinnipeds and cetaceans provide powerful insights into mammalian adaptations to life in the sea (Estes, 1989). Among the marine mammals, sea otters (*Enhydra lutris*, Fig. 1) provide the clearest understanding of consumer-induced effects on ecosystem function. This is due in part to opportunities provided by history and in part to the relative ease with which shallow coastal systems where sea otters live can be observed and studied. Although more difficult to study than sea otters, other otter species reveal the connectivity among the marine, freshwater, and terrestrial systems. These three qualities of the otters—their comparative biology, their role as predators, and their role as agents of ecosystem connectivity—are what make them most interesting to marine mammalogy.

The following account provides a broad overview of the comparative biology and ecology of the otters, with particular emphasis on those species or populations that live in the sea. Sea otters are featured prominently, in part because they are comparatively well known and in part because they live exclusively in the sea whereas other otters have obligate associations with freshwater and terrestrial environments (Kenyon, 1969; Riedman and Estes, 1990).

I. Evolution and Phylogeny

Mustelids arose from primitive arctoid carnivores at the Eocene/Oligocene border. Early lutrine phylogenies were based on the morphology of fossil and extant species, from which the otters were viewed as a monophyletic group that diversified into three clades: the fish-eating otters (*Lutra*, *Lontra*, and *Pteronura*), crab-eating otters (*Aonyx*), and the sea otter (*Enhydra*). However, the otters probably have been under strong selection for parallel or convergent evolution, thereby confounding efforts to understand phylogenetic relationships based on morphology. Distinctive features of the three purported clades might thus have resulted from differences among their common ancestors or selective divergence resulting from different prey (fishes vs invertebrates) or habitats (the ocean vs freshwater). Patterns of brain form and function in the otters exemplifies this problem. Sensory and motor function in the mammalian brain maps medially along the prefrontal gyrus. Architectural and functional differences among otter brains correlate with their principal-foraging modes—invertebrate vs fish feeding. The fish-eating otters, which require precise sensory/motor function of the mouth and facial area, have well-developed proximal regions of the prefrontal gyrus. The invertebrate-feeding otters (*Enhydra* and *Aonyx*), which require precise sensory/motor function of their forelimbs for prey capture, have more highly developed lateral regions of the prefrontal gyrus. But are these features primitive or derived? If primitive, then they might accurately reflect phylogeny; otherwise, they surely do not.

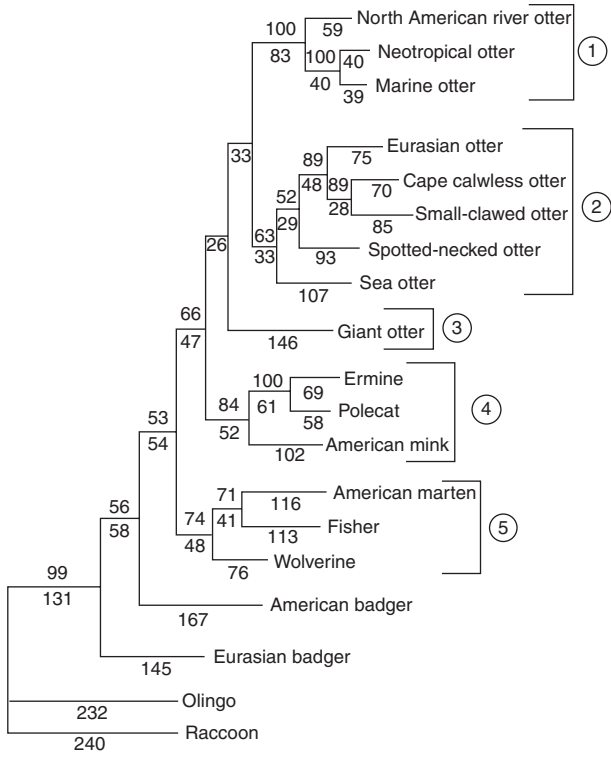

Figure 1 Sea otter (*Enhydra lutris*). Photograph courtesy of Randall Davis and students (taken under USFWS permit No. MA078744-2).

Nucleotide sequence analysis of the mitochondrial cytochrome b gene (Koepfli and Wayne, 1998) has been used to disassociate the confounding effects of adaptation in constructing a lutrine phylogeny for 9 of the 13 extant species (Fig. 2). These data demonstrate that earlier phylogenies based solely on morphology were grossly inaccurate. The molecular analysis indicates three primary clades including the (1) North American otter (*Lontra canadensis*), neotropical otter (*L. longicaudus*), and chungungo (*L. felina*); (2) sea otter (*Enhydra lutris*), Eurasian otter (*Lutra lutra*), spotted-necked otter (*Hydriectis maculicollis*), cape clawless otter (*Aonyx capensis*), and small-clawed otter (*A. cinerea*); and (3) giant otter (*Pteronura brasiliensis*). Fundamental life history differences (e.g., seasonal vs aseasonal reproduction; direct vs delayed implantation) between Eurasian and North American otters, species once thought to have diverged from a common ancestor only after late Pleistocene isolation of Asia and North America, make much more sense based on the molecular phylogeny. The pattern of long terminal branches and short internal branches in the phylogenetic tree further suggests rapid radiation of the otters.

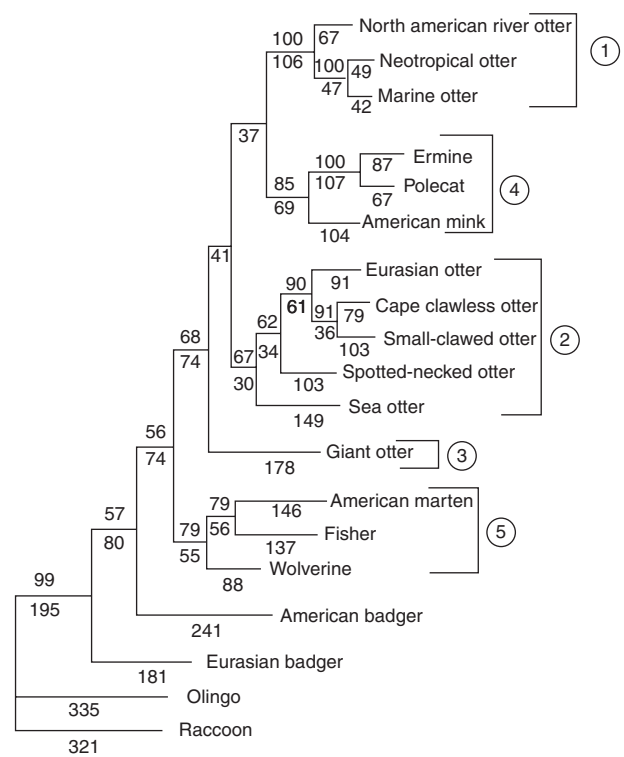

Estimates of divergence time indicate that the clades containing *Pteronura* and *Lontra* had separated by the late Miocene. This phylogeny also suggests that sea otters, the only fully marine otter and the most distinctive of all otter species in terms of morphology, physiology and behavior, diverged recently but have taken on these different characters because of strong selection imposed by life in the sea.

II. Marine Otters

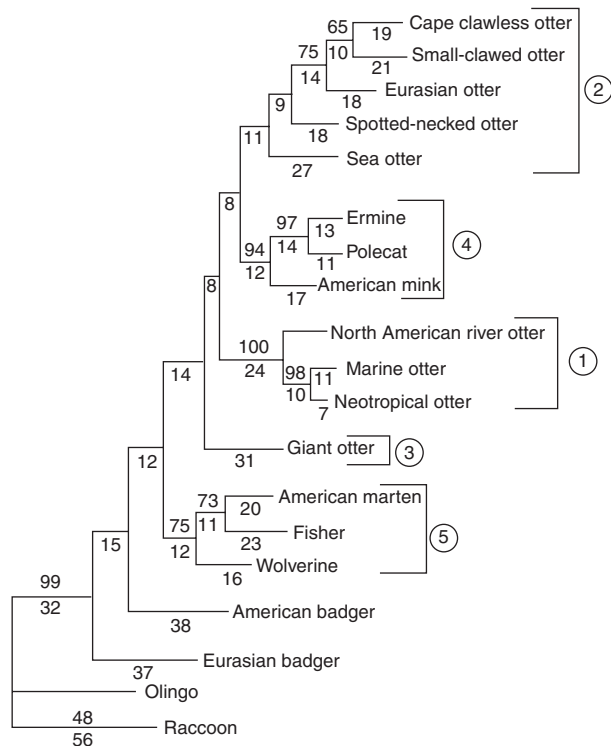

At least 6 of the 13 extant otter species are fully or partially marine living (Fig. 3). All of the marine-living species or populations occur at high latitudes. Sea otters (North Pacific Ocean, genus *Enhydra*) are the only fully aquatic otter species, with no obligate associations with terrestrial habitats for any life history function. The other otters can be considered semi-aquatic, retaining ties to terrestrial habitats for most behaviors other than hunting. Sea otters and chungungos (*Lontra felina*) are the only lutrines that feed exclusively in the sea. Sea otters range from the northern Japanese archipelago, across the rim of the Pacific to about central Baja California, Mexico. Chungungos range along the west coast of South America from Peru to southern Chile and only spend about 20% of their time feeding in the sea. Chungungos often take their prey ashore to be eaten, and rest, give birth, and rear their young in dens formed in rocky areas just above high water. Sea otters occupy a broad range of habitats, from protected bays to exposed

Figure 3 The geographical distributions of marine-living otters.

outer shores while chungungos occur only along exposed shorelines. Marine-living populations of *Lontra provocax* (southern river otter) occur in the protected inner waters of coastal Chile and southern Argentina. Marine-living populations of North American otters occur northward from about San Francisco in the Pacific and Martha's Vineyard in the Atlantic, although there is anecdotal evidence of marine foraging by river otters in Florida. Marine-living populations of Eurasian otters have a roughly similar latitudinal distribution (from about Portugal northward to northern Scotland and Scandinavia in the North Atlantic; from Japan into Russia in the North Pacific). Marine-living populations of cape clawless otters occur in the southernmost regions of South Africa. Tropical lutrines, in contrast, rarely enter the sea.

While marine-living species or populations of otters occur only at high latitudes, otters inhabiting freshwater habitats occur over a much broader latitudinal range—from the most poleward ice-free environments to the tropics in the northern and southern hemispheres of both the Old and New worlds. These distributional differences between marine- and freshwater-living otters probably relate to latitudinal differences in production between freshwater and coastal marine habitats, and the fact that otters have secondarily entered the sea from freshwater environments. At low latitudes, freshwater production exceeds that of the coastal ocean whereas at high latitudes the pattern is reversed. This production gradient may have drawn the primitively freshwater-living otters into the sea at high latitudes. The most compelling evidence for this proposal is provided by Hans Kruuk's comparative study of freshwater and marine-living populations of river otters in northern Scotland (Kruuk, 2006). Kruuk found that marine-living populations are able to meet their energy requirements by 2–3 h of fishing per day whereas those living in freshwater must double to triple the time investment in foraging to meet their energy requirements. Remarkably different population densities of marine and freshwater-living otters further indicates that production and food availability are superior in coastal marine habitats. Reported densities for Eurasian and North American otters in rivers and streams at high latitudes range between about 1 and 5

individuals per 10 km whereas densities of these same species living in marine habitats are about 5-fold greater. These data indicate that otters at high latitudes maintain higher population densities in the sea than they do in freshwater, and that most low latitude freshwater habitats may not be productive enough to support high otter densities. Some exceptions to this rule are giant otters that live in fairly large family groups in the productive waters of the Amazon and its tributaries, the Asian small-clawed otters (*Aonyx cinerea*) of south-east Asia that forage in productive mangrove forests, and the spotted-necked otters (*Hydrictis maculicollis*) that form large groups and inhabit productive lakes of central Africa.

Different population densities of otters in freshwater and marine environments appear to have influenced the evolution of social behavior. Low-density freshwater environments afford little or no opportunity for males to compete for females; consequently, most freshwater-living otters appear to have monogamous or promiscuous mating systems. The elevated marine production and high female densities may have driven the strongly polygynous mating system of sea otters wherein dominant males defend small territories against other males and attempt to sequester receptive females within their territories. In contrast, female North American otters in coastal marine environments of northwestern North America are usually solitary whereas most males form large groups. Again this discrepancy is likely a result of food availability. While social male otters forage cooperatively on abundant schooling fishes in the nearshore environment, nonsocial females and their cubs forage on the less abundant and spatially dispersed intertidal/demersal fishes.

III. Status and Trends

Aboriginal maritime hunters developed sophisticated methods to hunt sea otters and may have caused local depletions, as evidenced from faunal remains in Aleut kitchen middens. The species subsequently was hunted to near-extinction in the Pacific maritime fur trade. About a dozen remnant colonies, in total containing no more

than a thousand or so individuals, survived into the early twentieth century. Following protection in 1911, these colonies increased with some regaining historical levels by the mid-twentieth century. Reintroductions were undertaken in the 1960s and 1970s to reestablish sea otters in southeast Alaska, British Columbia, Washington and Oregon, and sea otters were relocated to San Nicolas Island (southern California) in 1987. Most of these translocated populations increased at rates of 17–20% per year, about the theoretical maximum (r_{\max}) for sea otters. All or most of the sea otter's range in Asia is now reoccupied. Several populations in the Kuril and Commander islands had recovered to historical levels by the 1970s or 1980s.

In apparent response to increased killer whale predation, sea otter populations in southwest Alaska declined sharply during the 1990s. This decline ranges from west of the Kodiak archipelago along the Alaska Peninsula and through the Aleutian archipelago. Reintroduced sea otter populations in British Columbia and Washington continue to increase in numbers and range. The introduced population to southeast Alaska appears to have ceased growing in recent years although localized increases are evident in the protected waters of Glacier Bay National Park and Preserve. The California sea otter population, which increased slowly throughout most of the twentieth century, has not changed measurably since the mid-1990s. The reintroduced population at San Nicolas Island, after declining sharply because of emigration, remained roughly stable at 15–25 through the late 1990s but since has increased to more than 40 individuals.

Compared to the sea otter, there is little current information on the status and trends of other marine-living otter populations. The chungungo, listed in IUCN's Red Data Book, is believed by some authorities to be threatened with extinction. Illegal harvesting for fur, habitat destruction in the form of deforestation, mining and pollution, and competition with fisheries are thought to be the species' main threats. Chungungos are rare from Peru southward through central Chile, but there are conflicting reports on their abundance from Chiloe Island southward to Cape Horn (Medina-Vogel *et al.*, 2006).

North American otters (*Lontra canadensis*) are common to abundant along much of the west coast of North America. Their abundance along the Atlantic coast of North America is uncertain and information on population trends is lacking for both areas. Eurasian otters (*Lutra lutra*) are common in marine habitats of Europe and Russia, especially from Norway to Scotland in the eastern North Atlantic. However, as for marine-living river otters in North America, information on the status and trends of these populations is lacking. Coastal populations in Asia are practically unknown. The status and trends of marine-living populations of southern river otters and cape clawless otters are unknown or unreported.

IV. History

The otter lineage dates back to the early Miocene (approximately 20 million years ago) as indicated by fossils of the genus *Mionictis*. Divergence of this monophyletic group during the Miocene ("11–14" million years ago) was rapid and resulted in the three main lineages described above. Species resembling modern sea otters (based on body size and dentition) had arisen by the Miocene (Berta and Morgan, 1986). There are two recognized lineages, one of which led to the extinct *Enhydriodon* and the other of which led to *Enhydritherium* and presumably to modern sea otters, *Enhydra* spp. Members of both lineages possessed large flattened molars for crushing the exoskeletons of their invertebrate prey. Fossil remains of these early sea otters are known from North America, Eurasia, and Africa. The distribution of modern sea otters, which apparently arose during the late Pliocene

or early Pleistocene, was restricted to the North Pacific Ocean. One extinct species, *E. macrodonta*, is described from the late Pleistocene of California.

Based on the fossil record it appears that both *Lutra* and *Lontra* groups originated in Southeast Asia from which they expanded into Europe (*Lutra*) and the Americas (*Lontra*). The earliest *Lutra* fossil in Europe is dated to the Pliocene. *Lontra* colonized North America as recently as the Pleistocene, approximately 1.7 million years ago. The relationship between *Lontra* and *Petronura* (giant otters) is unclear but fossil evidence suggest that giant otters evolved from an Asian lineage (*Satherium*) that, as with the ancestors of *Lontra*, emigrated to North America and then spread south.

V. Morphology and Physiology

Compared with the diversity of size and form in other extant marine mammals, the otters are relatively small and generally similar in overall body plan. Body mass ranges from <5 kg in chungungos to more than 50 kg in sea otters. Their shortened limbs, lengthened and often stout tails, and slim, elongated head, neck and body, and loosely articulated axial skeleton combine to create an almost serpentine appearance. All otter species have dense fur for insulation against heat loss and interdigital webbing of the fore and/or hind limbs to assist in aquatic propulsion. Like pinnipeds, the sea otter's clavicle has been lost or greatly reduced, apparently in response to the reduced need for skeletal support on land and the increased need for flexibility in the water.

The internal morphology of otters is generally unremarkable, except for the sea otter's comparative large lung and blood volumes (which facilitate flotation and oxygen storage), and a large lobular kidney (which facilitates osmoregulation).

Except for sea otters, none of the other marine-living otter species are fully aquatic. Because of their relatively smaller body size and less efficient insulation, these other species or populations are probably incapable of long-term thermal maintenance in high latitude oceans. As the smallest fully aquatic marine mammal, sea otters face an especially severe thermal challenge because they spend all or most of their lives immersed in cold water. This challenge has been met by increasing heat production or reducing heat loss. Like other mustelids, the basal metabolic rate of sea otters is well above that predicted by the Kleiber curve and sea otters gain additional heat from the specific dynamic activity (SDA) of digestion. Sea otters lack the blubber layer that insulates cetaceans and pinnipeds, instead depending upon their dense fur. Although fur is a superior insulator to blubber in air, it has three disadvantages in water: high maintenance costs, the inability to regulate heat flow, and compressibility at depth.

In order to maintain the fur's insulation, sea otters must groom almost continuously, an activity that consumes up to 10% of their time. Because fur (in contrast to blubber) is an inflexible insulator, sea otters require some means of facilitating heat loss during exercise. This apparently is accomplished mainly through the enlarged rear flippers, which are sparsely furred and highly vascularized. The compressibility of fur causes it to loose volume, and hence insulation, with increased depth.

Water conservation also presents a challenge to sea otters because they feed primarily on marine invertebrates, which are isotonic to seawater. They meet this challenge in part with a large and efficient kidney.

Marine-living North American and Eurasian otters also rely on fur for insulation. Unlike sea otters these semi-aquatic otters require rinsing in freshwater to restore the insulative capacity of their coats.

For example, Eurasian otters that were unable to rinse their coats in freshwater spent about 30% longer grooming than animals that washed in freshwater. In general Eurasian otters spend up to 6% of their time grooming. Also, because North American and Eurasian otters have less dense coats than sea otters, they spend much less time in the water. For example, Eurasian otters spend on average only 14.5 ± 10.7 min in the water during any given foraging bout.

Like nearly all aquatic mammals, otters must dive to feed. The semi-aquatic otter species usually dive in shallow waters. Eurasian otters may forage as deeply as 15 m but the vast majority of dives occur in depths of 8 m or less. North American otters in Prince William Sound, Alaska, have been observed to dive as deep as 30 m, but again these dives are relatively rare. Although sea otters do not dive to such extreme depths as many other marine mammals, they are considerably better divers than other otter species, attaining depths in excess of 100 m. The respiratory system is appropriately modified for deep diving. For instance, the tracheal length–width ratio is less in sea otters than river otters, thus permitting more rapid and complete air exchange before and after a dive. Like the pinnipeds, sea otters have cartilaginous airways that empty directly into their alveoli, thus insuring patency until alveolar compression collapse during deep dives. Sea otters also have comparatively large lungs that provide both oxygen storage and increased buoyancy. Although the sea otter's blood hemoglobin concentration is similar to that of most terrestrial mammals and less than that of most phocid seals, oxygen–hemoglobin affinity in the sea otter is relatively high, thus increasing their blood-oxygen storage capacity.

VI. Locomotion

Compared with fully terrestrial or fully aquatic mammals, locomotor efficiency in otters is reduced on both land and in water (Williams, 1999). The otters have retained the general structure of their limbs but all possess webbing between their toes. Among the lutrines, sea otters possess the most extreme modifications for aquatic propulsion. These include enlarged, flipper-like hind limbs; a loosely articulated skeleton that permits increased flexibility, reduced forelimb length, and an increased tendency toward body movement and away from paddling in swimming.

In all otters, two types of terrestrial locomotion—walking and bounding—follow the typical pattern of terrestrial carnivores. Running, described in Eurasian otters as a rapid forward movement in the same pattern as walking, has apparently been lost in the sea otter. In North American otters, stride frequency increases linearly with speed until the animal shifts to bounding. No pattern between speed and bounding strides has been observed. A maximum velocity on land of about 5 m/sec can be achieved in short bursts (Williams *et al.*, 2002).

There are three forms of aquatic locomotion by the sea otter. One involves a sweeping motion of the tail and is used for slow movement while feeding, grooming, and to maintain position while resting. The second is paddling—vertical thrusts and recovery of the hind limbs while in either a supine or prone position. This type of movement is typically used during long-distance travel and may be interspersed with submerged travel, grooming, or foraging. Paddling velocities range from about 0.5 to 1.0 m/sec. The third means of aquatic locomotion in sea otters is accomplished by craniocaudal thrusts of the pelvic limbs, often including bending of the lumbar, sacral and caudal regions for increased sustained speed up to about 2 m/sec. This method of locomotion is used in foraging dives and rapid surface movement. Other otter species also have flexible spines and use undulation in diving. Many species have laterally flattened tails which assist in controlling the direction and velocity under water. This is especially

pronounced in giant otters. Unlike sea otters, other species of otters do frequently paddle and only Eurasian otters and sea otters float on their back for extended periods of time.

VII. Diving

In all otter species, diving can occur during traveling and foraging. Because locomotion is more efficient underwater than on the surface, otters frequently make relatively long, shallow dives while traveling. Foraging dives are generally deeper and longer in duration compared to travel dives and include time searching for and capturing prey. Because sea otters forage almost exclusively on benthic prey that are brought to the surface for consumption, classification of dive function is often possible. Visual observations and data from archival time-depth recorders (TDRs) in sea otters indicate substantial individual and sex-related variation in forage dive behavior that is consistent with individual dietary variation. Mean (maximum) forage dive depths ranged from about 5 to 35 m (35–100 m) and dive durations from 57 to 135 sec (162–422 sec) among 31 sea otters that were studied in Alaska (Bodkin *et al.*, 2004). Females generally dive to shallower depths than males, although individuals of both sexes can exhibit strong bimodal forage depth distributions with peaks near 15 and 50 m. Dive times and their interceding surface intervals correlate with water depth although the deepest dives are not necessarily associated with maximum dive times. Surface intervals are highly correlated with prey size and type, with the longest intervals allied with the largest prey, thus reflecting associated increases in handling and consumption times.

Most information on diving in North American and Eurasian otters is derived from captive experiments. These observations were corroborated in the field from telemetry data and direct observations. In general, dive durations of both species are limited to 20–23 sec. The longest voluntary dive in a North American otter was clocked at 3 min. In both North American and Eurasian otters, there is a strong correlation between length of dive and time spent on the surface following the dive.

VIII. Feeding Ecology

Marine otters feed on a wide array of fish and invertebrate species. With some exceptions, the semi-aquatic otters specialize on fish whereas the fully aquatic sea otter specializes on benthic marine invertebrates. The chungungo, unlike other *Lontra* species feeds extensively on crustaceans, mollusks, and echinoderms and makes relatively low use of fishes (occurrence in about 20% of feces; Medina-Vogel *et al.*, 2004). Cape clawless otters also feed largely on invertebrates. Crabs (*Plagusia chabrus* and *Cyclograpsus punctatus*), and lobster (*Jasus lalandii*) comprise most of the diet of these otters around Cape Town, South Africa. Similarly, the sea otter, typically a predator on benthic invertebrates, occasionally consumes fish in large quantities.

Sea otters feed mainly on echinoderms, mollusks, and arthropods. The enlarged molariform teeth are used to crush the exoskeletons of these invertebrate prey. Tool use has developed in both the sea otter and Cape clawless otter as a further aid to foraging. This is accomplished by using rocks or other hard objects to break open unusually large or well armored invertebrates.

While sea otters are known to consume more than 150 prey species, only a few of these predominate in any particular place, depending on location, habitat type, season and length of occupation. Increasing dietary diversity through time as sea otter populations recolonize new habitats and grow toward resource limitation has been chronicled in the Aleutian Islands, Prince William Sound, and California (Estes

et al., 1981). These changes are probably the consequence of otters reducing the abundance of their preferred prey.

Studies of marked sea otters in California reveal extreme individual variation in diet and foraging behavior. Most individuals specialize on 1 to 3 prey types. This individual variation does not appear to be directly influenced by access to prey as different individuals often consume different prey at the same time and place. Individual dietary patterns, which appear to be matrilineally inherited, are known to persist for years and may be lifelong characters of individuals. Dietary individuality may develop in response to resource limitation.

Sea otters may also take advantage of episodically abundant prey. Examples include squid (*Loligo* sp.) and pelagic red crabs (*Pleuroncodes planipes*) in California and smooth lumpstickers (*Aptocyclus ventricosus*) in the Aleutian Islands. Pelagic red crabs appear in coastal waters of southern and central California during strong El Niño events and vast numbers of lumpstickers appear episodically in coastal waters of the western and central Aleutian Islands to spawn. Sea otters attack and consume various species of sea birds on occasion.

Marine-foraging Eurasian otters usually hunt alone and largely consume benthic fishes such as eelpout (*Zoarces viviparus*), rocklings (*Ciliata mustela*), and sea scorpion (*Taurulus bubalis*). Invertebrates are rarely consumed. Also, there is little difference in the diet of males and females. In contrast, marine-living North American otters consume bivalves and crabs (up to 13% of diet). In addition, diets of males and females differ greatly during the summer. While most females forage alone on benthic fishes, male otters form large groups and cooperatively forage on schooling fishes such as Pacific herring (*Clupea pallasii*), Pacific sand lance (*Ammodytes hexapterus*), capelin (*Mallotus villosus*), and Pacific salmon (*Oncorhynchus* spp.).

IX. Community Ecology

The ecology of sea otters at the community and ecosystem level has been studied extensively whereas the other otter species are poorly known in this regard. Therefore, this section focuses mostly on the interactions between sea otters and coastal marine ecosystems.

A. Food Web Effects

The sea otter's role in kelp ecosystem preservation, by keeping kelp-eating sea urchin populations in check, was discovered by contrasting otherwise similar areas at which the species was fortuitously present or absent because of exploitation and recovery from the Pacific maritime fur trade. Shallow reef habitats with abundant sea otters supported few sea urchins and well-developed kelp forests whereas abundant sea urchins had destroyed the kelp forests at islands lacking sea otters (Fig. 4). The explanation for this pattern is a straightforward consequence of what has since come to be known as a "trophic cascade". That is, sea urchin populations are regulated by sea otter predation, in turn allowing the kelp forest to flourish in the absence of significant herbivory. When otters were removed, sea urchins increased to such levels that deforestation occurred. These relationships have been documented in Russia, the Aleutian Islands, southeast Alaska, British Columbia, Washington, and California (Estes and Duggins, 1995).

Because sea otters influence the distribution and abundance of kelp forests, they also affect numerous other species via three general ecosystem-level processes: production, habitat modification, and altered flow. Total primary production and the growth rates of filter-feeding invertebrates are significantly greater in otter-dominated compared with otter-free ecosystems (Duggins *et al.*, 1989). Various other indirect effects of sea otter predation are known or suspected.

Figure 4 Alternate community states in areas with (kelp forests; Top) and without (sea urchin barrens) sea otters. Photographs were taken of reef habitats at about 10m depths in the western Aleutian Islands.

For instance, a reduction in disturbance from herbivory enhances the strength of competitive interactions among kelp species. The sea otter's influence on kelp forest abundance and distribution has strong effects on the abundance and species composition of kelp

Figure 5 Fretwell's (1987) model of alternating plant-herbivore interaction strength with increasing food chain length.

forest fishes. Rock greenling (*Hexagrammos lagocephalus*) exist at roughly 10-fold higher densities where sea otters are abundant in the Aleutian Islands. Sea otters therefore may facilitate the abundance of solitary river otters as they feed on greenling. If so, trophic cascades in the nearshore environment may have rippling effects onto the adjacent shoreline. Conversely, common eiders (*Somateria mollissima*), which feed mainly on sea urchins, mollusks, and other benthic invertebrates, occur at higher densities where sea otters are rare or absent than where they are abundant. The indirect effects of sea otters also influence the diet and foraging behavior of Glaucous winged gulls (*Larus glaucescens*), which are mainly piscivorous when sea otters are present and invertebrate-feeders when they are absent. Bald eagles (*Haliaeetus leucocephalus*) in the Aleutian Islands consume fewer kelp forest fishes and marine mammals and more sea birds when sea otters are lost from the system. Sea otters also influence predator-prey interactions between sea stars and mussels in the Aleutian archipelago.

The top-down influences of apex predators through trophic cascades have been incorporated into a conceptual model relating the strength of plant-herbivore interactions to trophic complexity (Fig. 5). The model predicts that plant-herbivore interactions should be strong in food chains with an even number of trophic levels (e.g., 2, 4, etc.) and relatively weak for odd-numbered food chains (e.g., 1, 3, 5, etc., Fretwell, 1987). The accumulated evidence from three decades of research on sea otters and kelp forests provides empirical evidence for this conceptual model.

B. Evolutionary Forces

Strong species interactions maintained over sufficiently large scales of space and time should lead to selective responses in the interacting species. This expectation, coupled with predicted differences in the strength of plant-herbivore interactions between odd- vs even-numbered food webs, suggests that kelp forests in the North Pacific Ocean evolved in the absence of intense herbivory whereas Australasian kelp forests evolved in the absence of an apex predator of comparable influence. Striking differences between the two regions in the spatial association between fleshy marine algae and marine invertebrates, the intensity of herbivory, concentrations of

plant secondary metabolites that act as deterrents against herbivory, and the resistance of herbivores to these secondary metabolites have been documented. These patterns are consistent with the hypothesis that intense predation from sea otters and their immediate ancestors decoupled a co-evolutionary arms race between plants and their herbivores in the North Pacific Ocean, perhaps helping to explain why North Pacific kelps are so poorly defended against herbivores and thus why the system changes so markedly in response to the presence or absence of sea otters.

Evolutionary interactions among sea otters, sea urchins, and kelp have also been evoked to explain other seemingly serendipitous patterns in other species of obligate or facultative kelp forest associates. For example, the abundance and high food quality of North Pacific kelps may help explain why Steller's sea cows (*Hydrodamalis gigas*) radiated from the tropics into the North Pacific Ocean, and why body size in North Pacific abalones (genus *Haliotis*) is the largest in the world.

C. Nutrient Transport

Semi-aquatic otters link aquatic and terrestrial systems by transporting nutrients from sea to land. Most otters use scent marking with feces, urine, and anal gland secretion for social and territorial communication. Otters select specific features of the landscape for establishing communication/latrine sites and these differ among species. For example, North American otters select for high canopy cover of mature trees, large intertidal rocks, and extensive kelp beds of *Laminaria*. There is also high variation among otter species and between the sexes within a species in the use of latrines. For example, in coastal Alaska, social males use latrines for intra-group communication whereas non-social otters likely signal mutual avoidance. Females appear to use latrines to defend their territories. Social otters use fewer sites with greater intensity, whereas nonsocial otters use more sites with lower intensity, resulting in high variability in inputs of marine-derived nutrients to different latrine sites (Ben-David *et al.*, 2005). While some sites may receive 2.7 g/m² year nitrogen (N) and 0.4 g/m² year phosphorus (P), others may be fertilized with up to 47.6 g/m² year N and 6.7 g/m² year P. Preliminary studies suggest that these nutrient inputs change the microbial community and increase plant growth and change plant diversity. Although little information on the effects of other otter species exists, it is likely that similar processes occur along all coastlines where otter densities are high and scent marking occurs.

X. Population Biology

A. Genetics

A reasonably well-known history of decline, a recovery period that includes multiple reintroductions, and the relatively sedentary behavior of sea otters combine to provide unique opportunities for the study of population and conservation genetics. Both morphological and genetic study of sea otters indicate some level of population structuring prior to the eighteenth and nineteenth century fur harvests. Isolation and local extinctions caused by Pleistocene ice-sheets extending over large coastal areas probably resulted during glacial extension, whereas levels of gene flow likely increased during periods of glacial retreat. Extensive human harvest reduced and fragmented sea otters into a small number of isolated colonies by 1900, from which all current populations are derived. Additionally, translocations have established viable populations in Washington, British Columbia, and southeast Alaska. The sea otter's dependency on shallow benthic

habitats and limited diving capacity restricts their distribution to coastal environments where relatively small home ranges (generally <20 km of coast) constrain gene flow over large distances.

Sea otter skull size declines from Russia, across Alaska and into California and variation in skull morphology forms the basis for the three currently designated sub-species—Russia, *E. l. lutris*; Alaska, *E. l. kenyoni*; and California, *E. l. nereis*. Mitochondrial DNA (mtDNA) haplotype frequencies identify at least four distinct groupings of sea otters, including California, Prince William Sound, the Kodiak/Aleutian/Commander Islands, and the Kuril Islands. The magnitude of difference in current mtDNA haplotype frequencies suggests at least some genetic differentiation existed among these groups prior to the population declines and isolation that occurred between 1750 and 1900. The extant California population probably represents a monophyletic mtDNA lineage that contains two unique mtDNA haplotypes.

The extent to which long-term evolutionary processes and recent human exploitation have contributed to genetic differences among and within modern sea otter sub-species is unknown. The degree of difference in mtDNA haplotypes suggests that there has been little gene flow across the range of the species from California to the Kuril Islands. However, low levels of mtDNA sequence divergence in sea otters across their present range also suggests that major phylogenetic breaks or long-term barriers to gene flow have not persisted.

There is concern over the potential loss of genetic diversity stemming from severe population bottlenecks experienced by sea otter populations over the past two centuries. Theoretical analyses suggest that perhaps 23% of the original genetic variation was lost from the California population because of this bottleneck effect. Recent research comparing DNA extracted from pre-fur harvest sea otter bones to contemporary samples suggest significant losses of microsatellite alleles and heterozygosity as a consequence of the fur trade-induced population bottlenecks (Larson *et al.*, 2002). A similar reduction in mtDNA alleles and haplotype diversity was not detected.

Geographic isolation of reintroduced and remnant sea otter populations provide the opportunity to study the effects of the duration and magnitude of bottlenecks on genetic diversity and population growth rates. Genetic diversity was greater in translocated populations that were derived from two source stocks compared with those derived from a single source stock. Haplotype frequencies in populations with estimated founding sizes of 4 and 28 animals (Washington and British Columbia) differed from the source population, probably signaling the effect of genetic drift. This interpretation is supported by the fact that haplotype frequencies from sea otters in southeast Alaska, a translocated population with an estimated founding size of 150 individuals, did not differ from its two source populations. The mtDNA haplotype diversity was inversely correlated with both minimum population size and the number of years a population remained at that minimum size. And although translocated populations demonstrated significantly higher annual growth rates ($\lambda = 1.18\text{--}1.24$) than remnant populations ($\lambda = 1.06\text{--}1.09$), no relation was detected between genetic diversity and population growth rates (Bodkin *et al.*, 1999).

As sea otters continue to reoccupy former habitat, and currently isolated populations become contiguous we may be afforded the opportunity to view the process of genetic exchange across the species' range. Genetic differences currently observed among geographically isolated populations may diminish, reducing current levels of genetic population structure.

In contrast with the wealth of genetic information for sea otters, little is known about other marine-living otter species. Several

studies in Britain and western Europe indicate that Eurasian otters have relatively high genetic diversity despite large population reductions in most countries. Also, genetic data suggest that the recolonization of extirpated areas in Europe occurred from populations in eastern Europe, and in Britain from remnant populations in Wales and Scotland. In Prince William Sound, North American otters exhibit isolation by distance mainly where dispersal requires the crossing of large bodies of water (Blundell *et al.*, 2002). Recent reintroductions and population supplementations along the Atlantic seaboard resulted in mixing of genetic stocks that previously were distinct.

B. Demography

Age- and sex-specific rates of reproduction and survival vary markedly among the different otter species. Life history patterns in sea otters are more similar to those of the pinnipeds (with whom they share the ocean as a common environment) than they are to the other lutrines (with whom they share a more recent common ancestor). Perhaps the most remarkable life history feature of sea otters is that they almost invariably conceive and give birth to a single young, a character shared with other marine mammals. Other otter species invariably have multiple young litters, typically varying in size up to five cubs.

Female sea otters become sexually mature at 3 years, occasionally earlier. The reproductive cycle is normally 1 year, with roughly 6 months from conception to birth and another 6 months from birth to weaning. Primiparous females often fail to successfully wean their pups. Adult females apparently enter estrous within several days after mother/pup separation (either from weaning or death). The majority of pre-weaning deaths occur shortly after birth. Thus, in many areas there is a biannual peak in births, the primary peak occurring in spring or early summer and the secondary peak (by females who failed in their previous cycle) in fall or early winter. Females continue to reproduce throughout life, with little evidence for either reproductive senescence or adjustments of fertility rate to environmental variation.

Population regulation in sea otters occurs largely or exclusively through variation in age- and sex-specific mortality rates. The high rates of population growth that have been observed in parts of Alaska, Canada, and Washington (17–20% per year, near r_{\max}) could only be realized if there were little or no mortality from birth to senescence. As growing populations become limited by resource availability, mortality in young otters increases greatly. Data from the Aleutian Islands and central California indicate that about half of the births fail to reach weaning age, compared to Kodiak where the population was not food limited and pup survival was more than 90%. The probability of mortality during the next 6 months, measured in the Prince William Sound, Alaska population was higher in males (56%) than females (36%) and lower in individuals that were in better condition. Mortality rates from about 1 year of age to physiological senescence (10–15 years) are low, even in food-limited populations. Thus, the principal mechanism of population regulation in sea otters appears to be pup abandonment and starvation-induced mortality early in life.

In Eurasian otters both males and females reach sexual maturity at 2 years of age. Data on age-specific birth rates are few but it is assumed that in coastal areas most females produce young in their third year. Number of cubs is highly correlated with prey abundance. Unlike Eurasian otters, North American otters have delayed implantation and thus while they reach maturity at age 2 they do

not have their first litter until age 3. In coastal areas, 55–61% of 3 year olds are pregnant and up to 91% of all adults. Recruitment of Eurasian otters in Shetland, was estimated at 34 2-year-old females per 100 adults. No such information is available for other otter species.

Most semi-aquatic otters die young. In Shetland more than 50% of otters die before they are 3.5 years old. Similarly, the average age of North American otters captured in Prince William Sound, Alaska was 3.5 years. Annual mortality of adults was less than 20% suggesting that animals mostly perish in the first 2 years of life. Causes of mortality vary and in most cases are difficult to document. In Shetland and Alaska, where otters live far from humans, mortality is largely caused by low food availability and less so by predation. Closer to human habitations, other causes are trapping, persecution by owners of fish farms, car collisions, diseases transmitted by pets and livestock, and pollution. Because of their position at the top of the food chain, otters readily accumulate metal and organic pollutants which may lead to reduced survivorship and reproduction (Gaydos *et al.*, 2007).

XI. Behavior

The behavioral ecology of marine otters strongly reflects life in the sea (Blundell *et al.*, 2002a). Vigorous grooming in sea otters is the species' behavioral hallmark. Sea otters probably spend more time and energy grooming their fur than any other mammal. This is accomplished by rubbing, rolling, blowing, and splashing. Grooming is necessary for cleaning and replenishing air to the under fur.

Sea otters are unusual among both the carnivores and marine mammals in the generally small size of their home ranges, which typically includes no more than 20km of shoreline. Both males and females occasionally move longer distances for uncertain reasons. Extralimital sightings in central Baja California and near Wrangel Island in the Chuchi Sea demonstrate that, on occasion, individual sea otters can move hundreds of miles.

Adult male sea otters maintain territories that in California average about 0.4km². Adult females apparently move freely among these territories but the territory holder aggressively excludes other males. Adult males harass females with large pups in an apparent effort to force separation, thus inducing the female to enter estrous and conceive the male's offspring. Copulation occurs repeatedly during brief consorts, after which the pair separates. A male grasps the female's nose in his mouth and rolls vigorously on the surface of the ocean to achieve intromission. Distinctive nose scars in adult females often result from this behavior. In severe cases, trauma to the nose and facial region may result in death to the female. Some males seem especially prone to such brutality. Upon killing their mates, these males usually continue to copulate with the corpses, sometimes for days. Adult male sea otters on occasion will copulate with and kill young harbor seals. These last two behaviors have not been observed outside California.

The sea otter's polygynous mating system (and the resulting high male libido) likely evolved in response to their unusually high population density, thus promoting male competition for females as the limiting resource in sexual reproduction. Polygynous mating systems are typical of all otariids and some phocids in temperate latitude systems but apparently are rare or absent in other species of otters (Blundell *et al.*, 2002a). As is true for other polygynous species, male sea otters provide no parental care.

Mating behavior of other otter species is similar in that the male forcibly holds the female by her nape. Copulation is vigorous, likely

because otters are induced ovulators. Male paternal care is absent from most species except for giant otters and possibly the social small-clawed otters. Allo-grooming is common in all social species, likely serving to reinforce social connections.

XII. Conservation and Management

The recovery and growth of sea otter populations has been heralded as one of conservation's great success stories. However, concerns are now growing over the sea otter's long-term welfare. Several thousand sea otters were killed by the *Exxon Valdez* oil spill in 1989, and while the overall impact of this event on the population is unclear, chronic detrimental effects appear to have persisted for at least 17 years (Ballachey *et al.*, 2003). North American otter populations in Prince William Sound were also negatively affected by the *Exxon Valdez* oil spill. Unlike sea otters, however, North American otters had recovered from the effects of the spill by the end of the 1990s (Ben-David *et al.*, 2002; Bowyer *et al.*, 2003).

Alaska natives are permitted to harvest sea otters for traditional purposes. There are no restrictions on take and large numbers of otters are currently being removed from some populations. Sustainable harvest levels and take quotas need to be developed from life table data and the spatial ecology of individual otters. Quotas also should take into account the status and genetic structure of populations, and the availability of food and space. Population declines in southwest Alaska continue but the ultimate reason for this large-scale collapse remains uncertain and controversial.

As sea otters in British Columbia continue to grow and expand in range, conflicts with various shellfisheries are the primary concern of resource managers. Others believe that the population is still precariously small. Sea otter harvests have been proposed but at present are not permitted under either Canadian national or provincial law. The growing sea otter population in Washington State has spread around Cape Flattery eastward through the Straits of Juan de Fuca. These animals now occupy tribal waters of the Makah Indians and are rapidly depleting red urchin populations, which until recently supported a tribal fishery.

California sea otters have long been the subject of debate and controversy. Fisheries interests have maligned sea otters because they compete with humans for various commercial and recreational resources while conservationists remain concerned over the small size and slow growth rate of the population. The California sea otter's range has recently expanded southeastward around Pt. Conception into the "no-otter zone" established by US PL 625. Shellfishery interests would like these otters removed while conservation groups encourage continued range expansion. Increased trafficking of oil tankers and outer continental shelf oil development along the California coast have heightened concern that a spill might reduce or even extinguish the California sea otter population. Concern has recently developed over land-based effluents and the high frequency of death from various parasites, diseases and biotoxins seen in beach-cast carcasses.

Currently only giant otters (*Pteronura*) are protected internationally through the Convention on International Trade in Endangered Species (CITES). Similarly most populations of Eurasian otters are protected through the European Union, although culling of nuisance otters is allowed in several countries. Of the other otter species, several enjoy local protection although many are still exploited for fur.

XIII. Concluding Remarks

After having been hunted to the brink of extinction, sea otters recovered dramatically. Whereas the status of other marine-living otters is less certain, these animals appear better off than their freshwater-living counterparts, many of which are imperiled because of human exploitation and of habitat destruction. The relative well-being of marine otters is thought to result from lower levels of habitat destruction in the sea than on land. Although that may be true, coastal marine environments increasingly are the recipients of terrestrial pollution and are being more extensively exploited by numerous fisheries. Furthermore, scientists are beginning to understand that the coastal zone is linked in important and complex ways with both the open sea on its one side and land on the other. The fact that people live in disproportionately high densities along the land-sea margin is a direct threat to coastal marine ecosystems and many of the species that depend on these systems. All of this does not bode well for the future of marine-living otters. Overall, sea otters are far more abundant today than they were 50 years ago. However, the recent and ongoing declines of otter populations in Alaska and failure of the California population to increase in recent years may be among the first signs from these animals that coastal oceans are in peril.

In the process of recovery, expanding otter populations have come into conflict with fishery interests that developed during their absence. Similar conflicts surround other carnivores, but in few cases is the effect so apparent as it is with sea otters and shellfisheries. Numerous other species and ecosystem-level processes are also influenced by the indirect effects of sea otter predation. These examples contributed significantly to the growing realization that apex predators often play complex but important roles in the maintenance of biodiversity, and thus that effective strategies for biodiversity conservation must include viable populations of apex predators.

P

Pacific White-Sided Dolphin

Lagenorhynchus obliquidens

NANCY A. BLACK

I. Characteristics and Taxonomy

The Pacific white-sided dolphin is a North Pacific endemic and one of six species of the genus *Lagenorhynchus*. It most closely resembles the dusky dolphin (*L. obscurus*) from the southern hemisphere. Theodore Gill originally described this species in 1865 based on three skulls collected by W. P. Trowbridge off San Francisco, California. Adults range from 1.7 to 2.5 m, and weigh 75–198 kg, with males slightly larger than females. They have an average of 30 teeth in each side of the upper and lower jaw (Walker *et al.*, 1986).

These dolphins are boldly marked (Fig. 1) with a dark gray or black dorsal surface, light gray sides with light gray “suspender stripes” originating near the melon and angling toward the blowhole across each side into the light gray flank patch. The beak is dark with a narrow stripe extending to the bicolored flipper. The dorsal fin has a darker leading edge with light gray covering two-thirds of the posterior portion. The flukes are all dark. The white belly is separated from the body by a thin black line. Anomalous or predominately white individuals with small areas of black pigmentation on their sides, heads, and

Figure 1 The Pacific white-sided dolphin is a highly acrobatic endemic to the North Pacific Ocean. Photo by Nancy A. Black.

fins or ones with an unusual white stripe extending up from their flank and widening over each eye are occasionally sighted. Several of these anomalous dolphins have been identified in Monterey Bay, California and Hokkaido, Japan and have been successfully used as “herd markers” (Black, 1994; Tsutsui *et al.*, 2001).

The dorsal fin ranges from falcate to lobate with a more rounded tip. In most cases the shape appears related to age, as both sexes have variable fins. Some dolphins in coastal Japan appear to have a strongly hooked dorsal fin compared to those observed off California. Extremely falcate-finned dolphins also sighted in small subgroups off inland waters of British Columbia may be all males (Morton, 2000).

II. Distribution and Abundance

The Pacific white-sided dolphin is one of the most abundant pelagic species of dolphin found in the cold-temperate North Pacific. In the western Pacific it occurs coastally from Taiwan to the Sea of Japan and off the Pacific coast of Japan northward to the Kuril and Commander Islands. In the eastern Pacific it occurs as far west as Amchitka in the Aleutian Islands through the Gulf of Alaska and down the west coast to 20°N, just south of Baja, California, and into the southwestern Gulf of California. It occurs continuously across the North Pacific in a band from 38 to 47°N off California; Pacific white-sided dolphins inhabit productive continental shelf and slope waters generally within 185 km of shore.

Although they do not migrate, there are seasonal shifts in distribution found both off Japan and the eastern Pacific that are related to oceanographic conditions, primarily water temperature but also fronts, intensity and location of upwelling regions, currents, and thermocline depths. Changes in distribution are likely prey-related with such changes noted seasonally and interannually depending on warm or cold water years, as evident by increased abundance in Monterey Bay, California, inland waters of British Columbia, and Southeast Alaska in warmer-water years. These dolphins frequent some areas with complex bathymetry such as Monterey Bay, California, an area where a deep submarine canyon approaches shore (Black, 1994; Dahlheim and Towell, 1994; Morton, 2000).

Based on genetic, skull, and body size differences, three populations that are not completely isolated from each other occur in the eastern North Pacific: off Baja California; California to Oregon; and off British Columbia. Additionally these appear separate from dolphins found in offshore waters of the North Pacific. Another two populations occur in coastal Japan, also separate from offshore animals (Walker *et al.*, 1986; Lux *et al.*, 1997; Miyazaki and Shikano, 1997; Hayano *et al.*, 2004).

Accurate population estimates are difficult to ascertain for the entire range, but close to 1,000,000 are estimated for the North Pacific (Buckland *et al.*, 1993; Miyashita, 1993) and 10,000–41,000 for the California Current ecosystem from California to Washington, with the number varying by season and year as animals move into and out of the region (Barlow and Forney, 2007).

III. Ecology

Killer whales (*Orcinus orca*) appear to be a significant predator, as these dolphins exhibit a strong flight response when killer whales are near, and several direct observations have been made of predation (Fig. 2).

Dominant prey type varies by region. They feed opportunistically on abundant species of fishes (60 species) and cephalopods (20 species) both day and night: schooling epipelagic (0–200 m) fishes and

Figure 2 A killer whale attacks a Pacific white-sided dolphin in Monterey Bay, California. The killer whale is their main predator. Photo by Lori Mazzuca.

cephalopods in California (northern anchovy, Pacific whiting, and squid), Washington (salmon and squid), and British Columbia (herring, salmon, sardine, cod, shrimp, capelin, and squid) (Stroud *et al.*, 1981; Walker *et al.*, 1986; Black, 1994; Heise, 1997a; Morton, 2000); a large variety of primarily mesopelagic (200–1000 m) species in offshore waters (Walker and Jones, 1993); and predominantly myctophids in the western Pacific (Miyazaki *et al.*, 1991).

IV. Behavior and Physiology

These highly social dolphins are avid bow riders that commonly occur in groups of less than a hundred but can form herds containing several thousands of individuals. They often associate with northern right whale dolphins (*Lissodelphis borealis*), Risso's dolphins (*Grampus griseus*), and short-beaked common dolphins (*Delphinus delphis*). They occasionally feed in association with humpback whales (*Megaptera novaeangliae*), California sea lions (*Zalophus californianus*), and seabirds in mixed-species aggregations. The cohesiveness of dolphin groups differs according to behavior, with dolphins generally in more dispersed subgroups while milling, socializing, and feeding and usually more tightly grouped while traveling and resting. They often cooperate as a group while herding and feeding on small schooling fish. They are highly acrobatic, often exhibiting percussive repetitive leaps while traveling and single leaps most while feeding and engaged in social behavior. They exhibit a variety of leap types, such as somersaults, dorsal fin slaps, and belly slaps.

Three dolphins radiotracked in Monterey Bay for 2 days exhibited a mean respiration rate of 2.5/min, a mean dive duration of 24 sec, and a maximum dive time of 6.2 min, which is exceptionally long. Dives of around 3 min are more commonly considered long dives (Black, 1994).

V. Life History

Calving occurs from May to September, corresponding to a mid-to-late summer breeding season. In addition, males exhibit an extreme enlargement in testis size from mid-to-late summer (Ridgway and Green, 1967). Age and length at maturation vary by area, with females becoming sexually mature at 8–11 years and 175–186 cm with a 4 to 5-year calving interval, and males at 9–12 years and 170–180 cm. The

mean neonatal length is 94 cm with a gestation of 11–12 months. Males may live to 42 years and females 46 years (Heise, 1997b).

VI. Interactions with Humans

Until 1992 when large-scale pelagic drift net fishing was banned, a minimum of 4000–8000 of these dolphins were killed each year. Today, dolphins are still taken in Japan by harpoon for human consumption. The drive fishery at Taiji, the last left in Japan, does not generally catch Pacific white-sided dolphins. The long-term effect of the exploitation on the western population has not been evaluated. Dolphins continue to be caught as well to a lesser extent as bycatch in coastal fisheries throughout their range. Pacific white-sided dolphins are found in aquariums in the United States, Canada, and Japan, but generally survival rates are low.

Pantropical Spotted Dolphin

Stenella attenuata

WILLIAM F. PERRIN

I. Characteristics and Taxonomy

This dolphin can be identified externally by its long beak sharply demarcated from the melon, slender body, strongly falcate dorsal fin, and (in adults) spots (Fig. 1). The newborn calf is unspotted. Dark spots begin to appear ventrally in large juveniles. Near-adult animals and some young adults have large discrete or overlapping spots both above (light) and below (dark). In adults, the ventral spots fuse and fade to a medium gray, and the dorsal light spots intensify, sometimes to the point of making the animal appear nearly white above. The light spots sweep up behind the dorsal fin. The underlying pattern (observable in calves and juveniles) consists of a dark cape sweeping over the eye to maximum depth below the dorsal fin, a very light to dark gray lateral/ventral field, a narrow well-defined eye stripe to the apex of the melon, a dark band of varying definition extending from the lower corner of the mouth to the flipper, and dorsoventral division of the peduncle into darker upper and lower lighter halves. The last can also be seen in adults. The tip of the beak is white in adults. Details of coloration vary regionally. The large coastal spotted dolphin of the eastern tropical Pacific, *S. g. graffmani*, is extremely heavily spotted, whereas animals around Hawaii tend to be lightly spotted (Perrin and Hohn, 1994; Perrin, 2001).

Sexually mature adults examined range from 166 to 257 cm ($n > 1650$) and weigh up to 119 kg (a 257-cm male from Panama Bay) with a wide GEOGRAPHIC VARIATION. Males are on the average slightly larger than females in body size and most skull characters.

This species may be confused in the tropical Atlantic with the endemic Atlantic spotted dolphin, *S. frontalis*, which is of similar size and may be seen in the same area. A distinguishing characteristic of *S. frontalis* is a light spinal blaze that sweeps up through the cape toward the dorsal fin, but this may be almost absent in some individuals. The dorsoventral division of the peduncle present in *S. attenuata* is absent in *S. frontalis*. The ground pattern is three-part, with a distinct cape, lateral field, and ventral field, as opposed

to the two-part pattern in *S. attenuata*. Adults may have dark ventral spots on a very light ground; this is not seen in adults of *S. attenuata* (ventral spots are medium gray and obscured by fusion).

The skull (35.6–46.0 cm long in 183 adults) overlaps with that of *S. frontalis* in tooth counts and all measurements; some specimens can be identified to species only through multivariate analysis (Perrin *et al.*, 1987). The skull in both species has a long narrow rostrum with no palatal grooves, about 35–50 teeth in each row, medium-sized rounded temporal fossae, convergent premaxillae, and arcuate mandibles. However, vertebral counts determined to date have been nonoverlapping: 74–84 ($n = 75$) vs 67–72 ($n = 52$) in *S. frontalis*.

The pantropical dolphin is a member of the delphinid subfamily Delphininae *sensu stricto* (LeDuc *et al.*, 1999). In a cladistic phylogenetic analysis based on cytochrome *b* mtDNA, it shares a strongly supported polytomic clade with *S. clymene* and *S. coeruleoalba* (sister species), *S. frontalis*, *Delphinus* spp., and *Tursiops aduncus* (to the exclusion of *T. truncatus*). In skull characters it is similar to *S. frontalis*, *T. truncatus*, and *T. aduncus* vs another coherent series of species composed of *S. longirostris*, *S. clymene*, and *S. coeruleoalba*. However, these latter groupings are not supported by results of the molecular studies to date. Some of the similarities may be synplesiomorphies, similarities due to the retention of primitive character states.

II. Distribution and Abundance

Distribution is worldwide in tropical and some subtropical waters, from roughly 30–40°N to 20–40°S (Jefferson *et al.*, 2007). It ranks first in abundance among cetaceans (second only to bottlenose dolphins, *Tursiops truncatus*); in the deeper waters of the Gulf of Mexico (Würsig *et al.*, 2000), second in the eastern tropical Pacific and the Sulu Sea, but only sixth in the tropical Indian Ocean (Ballance and Pitman, 1998; Dolar *et al.*, 2006). The coastal subspecies *S. a. graffmani* occurs only in a narrow coastal band along the Pacific coasts of southern Mexico and south Peru; it may consist of a number of subpopulations (Escorza-Treviño *et al.*, 2005).

An estimated 640,000 northeastern offshore spotted dolphins exist currently in the eastern tropical Pacific, down roughly 80% from original abundance before the tuna purse-seine fishery began killing them in fishing operations (see Section VI below). Other populations of the species in the eastern Pacific have not been as heavily impacted. Estimates of abundance exist for several other regions (IUCN, 2008): Hawaii, about 9000; Japan, about 438,000 in early+1990s; northern Gulf of Mexico, about 34,000; east coast of US,

about 4400; eastern Sulu Sea, about 15,000; Tañon Strait between Negros and Cebu (Philippines), 640.

III. Ecology

In the eastern Pacific, the offshore form, *S. a. attenuata*, inhabits the tropical, equatorial, and southern subtropical water masses, being most abundant in waters underlain by a sharp thermocline at depths of 50 m or less, a surface temperature over 25°C, and salinities less than 34 parts per thousand. In these areas, pantropical spotted dolphins commonly occur in large multispecies aggregations, including spinner dolphins (*S. longirostris*) and yellowfin tuna (*Thunnus albacares*) (Perrin and Hohn, 1994; Ballance *et al.*, 2006). A large coastal subspecies, *S. a. graffmani*, occurs in the eastern tropical Pacific from Mexico to northern Peru; this form is replaced ecologically in the Atlantic by a large coastal form (unnamed) of the endemic Atlantic spotted dolphin, *S. frontalis* (Perrin and Hohn, 1994). In the Southwest Atlantic, the species occurs beyond the continental shelf break in waters of >850 m (Moreno *et al.*, 2005). In the Gulf of Mexico it occurs over the lower continental slope and deeper waters (>1000 m) (Baumgartner *et al.*, 2001). In the Philippines it inhabits both shallow and deep waters (Dolar *et al.*, 2006).

Prey of the offshore form include mainly small epipelagic fishes, squids, and crustaceans (Robertson and Chivers, 1997; Wang *et al.*, 2003). Flying fish are a major diet item in some regions. In Hawaii, recorded diving behavior indicates that the dolphins feed primarily at night on organisms associated with the deep-scattering layer as it rises toward the surface (Baird *et al.*, 2001). The diet in the eastern Pacific overlaps greatly with that of the yellowfin tuna, *T. albacares*. Diet of the large coastal form is unknown but may include larger and tougher benthic fishes. Predators include the killer whale, *Orcinus orca* (Pitman *et al.*, 2003) and sharks (Maldini, 2003), probably the pygmy killer whale (*Feresa attenuata*), and possibly the false killer whale (*Pseudorca crassidens*) and the short-finned pilot whale (*Globicephala macrorhynchus*). Parasites may cause direct or indirect mortality.

IV. Behavior and Physiology

Spotted dolphins exhibit a wide variety of aerial behavior (but not spinning); juveniles (identifiable as such by their lack of spots) make especially high vertical leaps. In areas where they are not harpooned or pursued by purse seiners, they readily come to vessels to ride the bow wave and sometimes can be observed closely for long periods. Burst swimming speed exceeds 12 knt (about 22 km/h), and dives of up to 3.4 min have been observed.

School size may range from a few individuals to several thousand and may be segregated by age or sex or both (Perrin, 2001). Mean school size in the eastern tropical Pacific is about 120, in the western tropical Indian Ocean about 170, in the Philippines about 90, and in the Gulf of Mexico about 70 (Dolar *et al.*, 2006).

Why spotted dolphins associate closely with tuna in the eastern Pacific is unknown, although it is suspected to be related to foraging efficiency at some level (Perrin and Hohn, 1994). Other suggested reasons for the association involve physiological efficiency or protection from predators. Immature and subadult males and females tend to form smaller schools or join larger spinner dolphin schools not associated with tuna.

Physiological and behavioral development of young calves may not be sufficiently advanced to allow them to cope successfully with being chased and captured by tuna purse seiners (Edwards, 2005; Noren and Edwards, 2007). Dolphins have learned to attempt to evade purse seiners (Lennert-Cody and Scott, 2005).

V. Life History

The breeding system is unknown but may be promiscuous as in the spinner dolphin. Gestation is 11.2–11.5 months (Perrin and Hohn, 1994). Length at birth is 80–85 cm. Females reach sexual maturity at 9–11 years and males at 12–15 years. The calving interval is about 2–3 years but varies with population status. The average age and length at weaning are approximately 9 months and 122 cm, but nursing can continue up to 2 years of age (Archer and Robertson, 2004). Breeding is diffusely seasonal, with multiple peaks in some regions.

VI. Interactions with Humans

Direct and incidental catches have been substantial. Japanese drive and harpoon fisheries take spotted dolphins for human consumption; the catch in 1 year (1982) was 3799 (Perrin and Hohn, 1994); between 1995 and 2004, the average annual catch was 129 (Kasuya, 2007). Tuna fishermen seek out aggregations of spotted dolphins and tuna in the eastern tropical Pacific and set their nets on them to capture the tuna. Abundance of the northeastern stock of the offshore form has been reduced to a fraction of its original size by incidental kill in tuna purse seines since the early 1960s. While kill in the fishery has been reduced to the low 100s annually for a number of years, the population has not grown toward recovery as rapidly as expected; the continued chase and capture in the fishery may have an indirect effect on fecundity or survival, or there may have been a change in carrying capacity of the ecosystem for this species (Archer *et al.*, 2004; Gerrodette and Forcada, 2005; Wade *et al.*, 2007; Cramer *et al.*, in press). Directed fisheries (legal or illegal) also exist or have existed in the Philippines, Laccadive Islands in the Indian Ocean, Solomon Islands, Indonesia, Taiwan, the Philippines, and St. Helena in the South Atlantic (Perrin and Hohn, 1994), and bycatches also occur in fishing nets of various types in the Philippines, India, Australasia, western North Pacific, Central America, coastal Peru and Ecuador, and Taiwan (Perrin *et al.*, 1994; IUCN, 2008). The impacts of most of these takes on the populations have not been assessed.

Pantropical spotted dolphins have been implicated in depredation on or interference with hook-and-line fisheries for squid and fish in Japan, and 538 were culled during the period 1976–1982 (IUCN, 2008).

The species has not been kept successfully in captivity.

Parasites

J. ANTONIO RAGA, MERCEDES FERNÁNDEZ,
JUAN A. BALBUENA AND F. JAVIER AZNAR

Beyond their sanitary or economic importance, parasites are an integral part of the biosphere. They are so diverse and pervasive that they virtually infect every free-living organism, potentially influencing, among other things, host health, behavior and population size, food web dynamics, and community structure. These effects are usually undesirable when human health or economy are at stake but confer parasites a paramount importance in nature that should not be neglected.

This entry provides an overview of the diversity of marine mammal parasites. Its aim is to explain concisely what they are and how they have become associated with their hosts. Other aspects, such as the impact of parasites on marine mammal populations, are covered only briefly as they have been dealt with extensively elsewhere (Aznar *et al.*, 2001). Under the term “parasite,” we will only consider the protozoans and metazoans (helminths and arthropods) that have adopted this life history strategy. Some representative parasites of marine mammals are shown in Fig. 1.

I. Parasite Diversity

Protozoan parasites have been reported rarely in marine mammals. Most species have been described only recently thanks to an increasing interest in these organisms and the use of new techniques with fresh samples. So our knowledge of protozoan diversity in marine mammals is likely to increase substantially in the coming years (Raga and Gulland, 2008). As for metazoan parasites, differences in sampling effort are considerable depending on the host group. In particular, beaked whales (Ziphiidae) and fur seals (Otariidae) are speciose taxa for which parasite studies are still very scarce, and therefore diversity is likely to be higher than currently perceived.

Another fundamental factor affecting current diversity estimates is the existence of sibling species. This phenomenon is relatively frequent among marine invertebrates and has been documented extensively in parasitic nematodes of cetaceans and pinnipeds (family Anisakidae). Accordingly, the actual diversity of many other parasite taxa might have been underestimated because of our inability to tell species apart based on morphology. We suspect that many parasites infecting marine mammals that are currently considered as cosmopolitan or widespread may actually represent complexes of sibling or pseudosibling species.

A. Cetaceans

Four types of coccidians occur in cetaceans: *Cystoisospora delphini* in common bottlenose dolphins (*Tursiops truncatus*) causing enteritis; *Toxoplasma gondii* (or *Toxoplasma* spp.) in four dolphin species, associated with toxoplasmosis; *Sarcocystis* spp. in toothed whales, usually with little or no obvious pathologic effect—fatal hepatic sarcocystosis has been reported only in one striped dolphin (*Stenella coeruleoalba*); and *Neospora caninum* in bottlenose dolphins although its pathological effect is currently unknown (Dailey, 2005). The life cycles of these coccidians have not been elucidated in the aquatic environment, although there are reports of congenital and transplacental transmission of *Toxoplasma* spp. in dolphins. Flagellates have been rarely

found in cetaceans. *Jarrellia atramenti* was described in the blowhole mucus of a pygmy sperm whale (*Kogia breviceps*), but whether or not this protozoon is a parasite is still unclear. *Giardia* spp. is found regularly in feces from North Atlantic right whales (*Eubalaena glacialis*) and bowhead whales (*Balaena mysticetus*). In addition, the sarcodinan *Entamoeba* spp. has been recorded in the contents of the colon of the bowhead whale. Parasitic ciliates have been reported in both baleen and toothed whales. *Haematophagus megapterae* feeds on blood cells and attaches to the baleen plates of humpback whales (*Megaptera novaeangliae*), fin whales (*Balaenoptera physalus*), and blue whales (*B. musculus*). *Kyaroikeus cetarius*, *Planilamina ovata*, and *P. magna* (family Kyaroikeidae) occur in the blowhole and lungs of many species of toothed whales. These ciliates are thought to have direct life cycles, requiring perhaps repeated exposure to be successfully transmitted (Dailey, 2005).

Four families of flukes occur typically in cetaceans: species of Brachycladiidae (formerly Campulidae) occur in whales and dolphins; species of Pholeteridae and Brauninidae occur in dolphins, and species of Notocotyliidae in whales. In terms of diversity and geographic range, the family Brachycladiidae is the most important. It comprises some 41 species, 35 of which are distributed among the most families of cetaceans. Species of *Campula*, *Oschmarinella*, and *Brachycladium* (formerly *Zalophotrema*) inhabit the hepatic and pancreatic ducts of TOOTHED WHALES; *Hadwenius*, the intestine; *Nasitrema*, the air sinuses; and *Hunterotrema*, the lungs. Baleen whales harbor species of *Brachycladium* (formerly *Lecithodesmus*) in the bile ducts. The life cycles of the brachycladiids are not known, although their widespread occurrence in fish and squid species eaten by cetaceans suggests that these prey act as second intermediate or transport hosts. *Pholeter gastrophilus* (Pholeteridae) parasitizes many toothed whales (mainly

delphinids) throughout the world. These flukes bore into the wall of the glandular part of the stomach, and the duodenum, sometimes generating extensive fibrosis. Their distribution among digestive chambers seems to be driven by the diet and digestive physiology of each host species (Aznar *et al.*, 2006). *Braunina cordiformis* (Brauninidae) has a peculiar ovoid morphology and attaches to the stomach and the duodenal ampulla of small toothed whales. Several species of *Ogmogaster* (Notocotyliidae) have been found in the large intestine of baleen whales from the Antarctic, Pacific, Atlantic, and Mediterranean. The life cycle is unknown, but information derived from other notocotyliids suggests that the cercaria (larvae) might not need a second intermediate host, encysting directly on crustaceans that are preyed upon by whales.

Cetaceans are infected with both adult and larval tapeworms. The adult forms belong to two families, Tetrabothriidae (16 species of 23 in marine mammals) and Diphyllobothriidae (11 of 48 in marine mammals). Their body sizes range from small (a few millimeters) to very large (several meters) and they dwell in the intestine, from the duodenum (e.g., *Tetrabothrius forsteri*) to the terminal colon and rectum (e.g., *Strobilocephalus triangularis*). The Tetrabothriidae have diversified morphologically in cetaceans (represented by the genera *Trigonocotyle*, *Strobilocephalus*, *Priapocephalus*, and *Tetrabothrius*; only the latter two have representatives in baleen whales). The diphyllobothriids belong to the genera *Diphyllobothrium* (infecting toothed whales, more rarely baleen whales), *Diplogonoporus* (in baleen whales and the sperm whale, *Physeter macrocephalus*), *Hexagonoporus* (in the sperm whale), and *Plicobothrium* (typical from pilot whales, *Globicephala* spp., rarely in other dolphins). In general, tapeworms of marine homeotherms use zooplanktonic crustaceans as first intermediate hosts. In some tetrabothriids, euphasiids (the krill) act as intermediate hosts and fish as transport hosts. In contrast, the known cycles of members of the Diphyllobothriidae involve copepods and fish as intermediate hosts. Cetaceans and some pinnipeds also harbor larvae (plerocercoids and merocercoids) of the family Phyllobothriidae worldwide. Recent studies have revealed two types of plerocercoid (termed as “small” and “large”) in the digestive tract. Likewise two types of merocercoid, classically designated as *Phyllobothrium delphini* and *Monorygma grimaldii*, occur in the blubber and mesenteries, respectively. A detailed study of these larvae in cetaceans from the Mediterranean, based on morphological, molecular, and ecological data, suggests that “large” plerocercoids, *P. delphini* and *M. grimaldii* represent different species, whereas the “small” plerocercoid is a previous stage of *M. grimaldii*. The adult stage of these tapeworms is not known but all these larvae are closely related to phyllobothriids infecting large sharks that feed on cetaceans. Apparently, cetaceans are intermediate hosts of these tapeworms, raising interesting questions about the evolution of the life cycles of tetraphyllideans (Aznar *et al.*, 2007).

Among the nematodes, the family Anisakidae is probably the most successful in terms of potential for colonizing hosts in many environments. Different studies have revealed the existence of several complexes of sibling species. The anisakids occurring in cetaceans belong to the genera *Pseudoterranova*, *Contracaecum* and *Anisakis*, although only species of the latter are found mainly in cetaceans, hence their vernacular name of “whaleworm.” Eight species of *Anisakis* have been reported in at least 35 species of marine cetaceans. Whaleworms occur in the stomach, mainly in the forestomach. The larvae can attach to the stomach walls in aggregates and provoke ulcers. The life cycle is well documented. The eggs, shed in the feces, hatch and release the free-living larvae that are subsequently ingested by planktonic crustaceans. Apparently, the parasite is then ready to infect cetaceans (e.g., mysticetes). However, the larvae are usually transmitted to fish and

squid feeding on infected crustaceans, and most cetaceans become eventually infected by consuming these prey. The worms molt to the adult stage and mate in the stomach of cetaceans, where the cycle is closed when the female nematodes release the fertilized eggs (Dailey, 2005). The large histozoic nematodes of Crassicaudidae (about 11 species exclusive of cetaceans) occur in the kidneys and urogenital organs, placenta, mammary glands, muscles, and pterygoid sinuses, sometimes causing extensive damage. Species of *Crassicauda* infect both whales and dolphins, whereas the up to 9-m-long *Placentonema gigantissima* dwells in the placenta of sperm whales (Geraci and St. Aubin, 1987). Life cycles are largely unknown. It has been speculated that *C. boopis* might infect fin whale calves either by ingestion of larvae shed in their mothers’ urine or by transplacental transmission (Dailey, 2005). Pseudaliids (about 17 species exclusive to toothed whales) are distributed among the genera *Pseudostenurus*, *Pharurus*, *Torynurus*, *Stenurus*, *Halocercus*, *Pseudalius*, and *Skrybinalius*. They occur mainly in the lungs, air sinuses, and heart of phocoenids and monodontids, secondarily delphinids. Prenatal transmission of *Halocercus* in common bottlenose dolphins has been suggested. However, indirect transmission through the food web is probably the main route of infection for most species (Dailey, 2005).

Only species from two genera of acanthocephalans (family Polymorphidae) reproduce in the intestine and occasionally in the stomach of marine mammals. These worms are closely allied to forms infecting aquatic birds. Whales and dolphins are the typical hosts for *Bolbosoma* (some nine species). Pelagic euphasiids and copepods are thought to act as intermediate hosts, and fish as transport hosts (Raga and Gulland, in press). A few members of *Corynosoma* have speciated in cetaceans, but the bulk of diversity in this genus is found in pinnipeds (see later).

Cetaceans harbor a specific and rather diverse fauna of parasitic and nonparasitic crustaceans; interestingly, such associations are rare in sirenians, and do not occur on pinnipeds. Whale lice (Cyamidae, about 26 species) have diversified extensively among dolphins and whales, becoming one of the few groups of parasitic amphipods. Whale lice attach to the skin (especially on natural openings, wounds, and scars), feeding mostly on epidermal tissue. The life cycle takes place completely on the hosts and transmission is by bodily contact (Raga, 1997). Copepods of the genus *Pennella* (family Pennellidae) are primarily parasites of fish. However, about six species have successfully colonized cetaceans. Their life cycle is complex: after two free-swimming stages, they develop, mate, and attain sexual maturity on squid and then females seek a suitable definitive host, e.g., cetaceans, where they burrow on the host’s body (mainly on the back and belly) to get their head anchored, and subsequently feed on blood and body fluids.

B. Sirenians

Four species of Coccidia have been reported in sirenians: *Eimeria manatus*, *E. nodulosa*, and *T. gondii* in the West Indian manatee (*Trichechus manatus*) and *E. trichechi* in the Amazonian manatee (*T. inunguis*). The species of *Eimeria* have been detected as oocysts in feces. Nothing is known about their life cycles, but the oocyst of *E. nodulosa* bears peculiar nodules that are thought to serve for attachment to aquatic vegetation. Thus the cycle might be direct (Raga and Gulland, in press).

The fauna of metazoan parasites in manatees and dugongs is restricted to digeneans and nematodes, but it is fairly diversified relative to the number of extant host species, and very specific. Except *Nudacotyle undicola*, which belongs to a genus typical from land mammals, all species and genera recorded so far (3 species

of nematodes belonging to 2 genera; 22 species of digeneans in 16 genera) are exclusive to sirenians (three out of six families also are). Interestingly, the dugong (*Dugong dugon*) exhibits a distinct and richer helminth fauna than the manatees (17 vs 7 species). This difference might simply result from corresponding differences in research effort. However, dugongs inhabit the Tropical Pacific, whose richer marine fauna may offer a larger selection of intermediate hosts and, perhaps more importantly, dugongs have remained longer in the marine habitat of ancestral sirenians. In contrast, the manatees moved and adapted to freshwater habitats, which probably resulted in the loss of some ancestral marine parasites (Beck and Forrester, 1988; Dailey, 2001).

The parasites of sirenians occur in a variety of sites within the host. The roundworms *Paradujardinia halicoris* and *Heterocheilus* spp. inhabit the stomach, more rarely the small intestine. Flukes exhibit a notable morphological diversity, e.g., *Taprobanella bicaudata*, and are found in diverse locations. Species of Paramphistomidae (4), Rhabdiopoeidae (4), and Nudacotylidae (1) and most of the Opisthotrematidae (6) occur in different sites in the digestive system, including the stomach, pyloric ceca, duodenum, ileum, colon, pancreas, and liver. In some cases they form cysts, e.g., *Faredifex clavata* (Rhabdiopoeidae) or *Lankatrema mannarensis* (Opisthotrematidae). In contrast, species of *Opisthotrema* (2), *Cochleotrema* (2), and *Pulmonicola* (1) dwell in the ear system or the lungs, whereas *Labicola elongata* (Labicolidae) occurs in the upper lip of dugongs (Lauckner, 1985a; Dailey, 2001). The life cycles have not been determined for any of these parasites. Some authors have suggested that the nematodes of sirenians use crustaceans as intermediate hosts that would be consumed incidentally while feeding on vegetation. Other propose that the eggs might be ingested directly when the hosts feed on contaminated vegetation. Similar conjectures have been advanced for digeneans. *Chiorchis fabaceus* is thought to infect manatees through the incidental ingestion of snails containing metacercariae (larvae), whereas the cercariae of *Lankatrematoides gardneri* use a mollusk as an intermediate host, and perhaps then the larvae escape and encyst on aquatic vegetation, where they wait to infect dugongs (Beck and Forrester, 1988).

C. Pinnipeds

The most common protozoans found in pinnipeds are coccidians. Species of *Eimeria* have been detected in the intestine of seals, sometimes causing severe disorders. *Eimeria phocae* is typical from harbor seals (*Phoca vitulina*) in the northwestern Atlantic. Although its life cycle is still unclear, experimental evidence shows that oocysts sporulate in feces if incubated in air but not if suspended in seawater, suggesting that transmission occurs on land. Another six species of *Eimeria* occur in Weddell seals (*Leptonychotes weddelli*) and crabeater seals (*Lobodon carcinophagus*). Species of *Sarcocystis* have been reported in harbor seals in California, northern fur seals (*Callorhinus ursinus*) in Alaska, Hawaiian monk seals (*Monachus schauinslandi*), and leopard seals (*Hydrurga leptonyx*) in Antarctica. *Isospora miroungae* and *Cystoisospora israeli* have been described in young Antarctic southern elephant seals (*Mirounga leonina*) and South African fur seals (*Arctocephalus pusillus*), respectively. Toxoplasmosis due to *T. gondii* has been observed in harbor seals, California sea lions (*Zalophus californianus*), ringed seals (*Pusa hispida*), spotted seals (*Phoca largha*), and walruses (*Odobenus rosmarus*) (Raga and Gulland, in press). Experimental infections in gray seals (*Halichoerus grypus*) have demonstrated that oocysts of this parasite can establish viable infection in seals, and that oocysts are probably acquired in surface water runoffs and sewer discharges (see also below). Likewise,

harbor seals, ringed seals, spotted seals, and walruses have been found to be seropositive to *N. caninum* (Dubey *et al.*, 2003). In addition to coccidians, flagellates of *Giardia* spp. have been detected in feces from ringed seals, harp seals (*Pagophilus groenlandicus*), gray seals, and a harbor seal from the arctic, subarctic, and eastern coasts of Canada, and in California sea lions in northern California. It has been suggested that seals and sea lions could serve as reservoirs for *Giardia* spp. but little is known about the transmission of this parasite in the sea (Dailey, 2005).

Flukes are represented by eight families. Within the Brachycladiidae (formerly Campulidae) four species of the genus *Orthosplanchnus* infect arctic and subarctic phocids, and walruses, whereas *O. antarcticus* occurs in Antarctic seals. *Zalophotrema hepaticum* is associated with California sea lions in the northeastern Pacific. Brachycladiids of pinnipeds live in the bile ducts, gall bladder, and rarely, the intestine. The family Heterophyidae is widespread in pinnipeds, particularly in the Northern Hemisphere. About 12 intestinal species have been recorded so far, belonging to *Cryptocotyle*, *Phagicola*, *Rossicotrema*, *Galactosomum*, *Mesostphanus*, *Heterophyopsis*, *Pricetrema*, and *Phocitrema*. Species of the two latter genera are associated more specifically with pinnipeds (in the Pacific region). Nothing is known of the life cycles of these heterophyids. Inferences made from other species strongly suggest that a gastropod would function as first and various species of fish as second intermediate hosts. Five species of opistorchiids from the genera *Opistorchis*, *Metorchis*, and *Pseudamphistomum* inhabit the bile ducts of seals from the Northern Hemisphere. Their life cycles are unknown, but, from other opistorchiids, it might be inferred that fish act as second intermediate hosts. Microphallids (three species) from the genera *Microphallus* and *Maritrema* are intestinal flukes. *Microphallus orientalis* has been reported in immense numbers in walruses and bearded seals (*Erignathus barbatus*) from the Barents Sea. The majority of microphallid larvae encyst in benthic crustaceans, which may explain their occurrence in seals that feed on bottom invertebrates. Finally, *Ogmogaster antarcticus* (Notocotylidae) is known from Weddell and crabeater seals (Lauckner, 1985b). These hosts likely become infected when feeding on benthic invertebrates (see earlier discussion).

The tapeworm fauna of pinnipeds is rich. The majority of species belong to the family Diphyllbothriidae (37 species out of 48 in marine mammals). Of these species, those of *Diphyllbothrium* form the major component, being distributed in pinnipeds worldwide (Lauckner, 1985b). In contrast, species of *Baylisia*, *Baylisiella*, and *Glandicephalus* are exclusive to Antarctic seals, and those of *Diplogonoporus* to boreal pinnipeds. Insights of the life cycles of diphyllbothriids have already been discussed above. One genus of Tetrabothriidae, *Anophryyocephalus* (seven species) is associated with arctic and subarctic pinnipeds. Euphasiids and fish appear to be intermediate and transport hosts, respectively, in the life cycle (Lauckner, 1985b).

Pinnipeds harbor a diverse nematode fauna that comprises six families: Ancylostomatidae (2 species), Dipetalonematidae (2), Trichinellidae (1–2), Filaroididae (4), Crenosomatidae (1), and Anisakidae (14). To a great extent, this parasite fauna is related to taxa found in land carnivores. Thus, the cycle of some groups is land-dependent and resembles that of their terrestrial counterparts. For instance, the eggs and the first three larval stages of *Uncinaria* spp. (Ancylostomatidae) develop on the soil of otariid rookeries. Third-stage larvae infect adult hosts by boring the skin (especially in the flippers) and migrate to host tissues, particularly the ventral blubber and mammary glands. Larvae use the milk of adult female seals to infect the pups, where worms become adults in the intestine. Transmission occurs only during the breeding period; infective

larvae overwinter on the rookery until the arrival of the hosts (Raga and Gulland, in press). The heartworm, *Acanthocheilonema* (= *Dipetalonema*) *spirocauda* (Dipetalonematidae), likely requires an arthropod vector (a louse) to trigger development and to transmit the microfilaria to North Atlantic seals, although this mode of transmission has yet to be proven. Transplacental or transmammary transmission to pups has been also suggested to occur. Species of *Trichinella* (Trichinellidae) are typical tissue parasites of terrestrial mammals. However, as discussed in the next section, a natural cycle of trichinosis involving pinnipeds seems to exist in the Arctic (Raga and Gulland, in press). With regard to nematodes with aquatic cycles, experiments have demonstrated that the lungworm *Parafilaroides decorus* (Filaroididae) infects fish that consume excrements of Californian sea lions contaminated with the larvae. These fish are, in turn, preyed upon by the sea lions. Recent experimental studies of the lungworm *Otostrongylus circumlitus* (Crenosomatidae), a species infecting boreal seals, have shown that fish seem to act as intermediate hosts (Dailey, 2005). By far the most widespread nematode group in seals is the Anisakidae, dwelling in the stomach and duodenum. Pinnipeds are primary hosts for species of *Pseudoterranova* and *Phocascaris*, whereas species of *Contracaecum* appear primarily in aquatic birds, although some species occur in phocids and otariids. In addition, *Anisakis simplex* may occasionally mature in some phocids, particularly in the gray seal. The life cycle of the sealworm, *Pseudoterranova decipiens*, is the best known. Experiments have shown that the sealworm can infect a wide variety of invertebrates. Under natural conditions, however, it utilizes only benthic and epibenthic organisms as intermediate and transport hosts. The free-living larva emerging from the egg has negative buoyancy and adheres to the substrate by its tail. This behavior favors ingestion by benthic copepods, which, in turn, are consumed by benthic macroinvertebrates. At this point, the larvae have molted twice and are ready to infect seals, but benthophagous fish, or their demersal predators, can be used as transport hosts, enhancing transmission (Aznar *et al.*, 2001).

Acanthocephalans of the genus *Corynosoma* (Polymorphidae), some 20 species in pinnipeds) exhibit a protracted history of association with pinnipeds. They have a cosmopolitan distribution, appearing in the intestine of most species of seals and sea lions, and the walrus. The complete life cycle for *C. strumosum* and *C. pseudohammanni* has been inferred from field collections. Nearshore amphipods acquire the cystacanth larvae, which, following ingestion, encyst in the body cavity of several fish species and await seals to prey on these fish. Species of *Bolbosoma* have also been reported incidentally in Arctic seals (Lauckner, 1985b).

Two main arthropod groups are associated with pinnipeds: sucking lice (Echinophthiriidae) and mites (Halarachnidae). The entire life cycle of sucking lice is spent on the seals and, therefore, they rely on bodily contact for transmission. Echinophthiriids (four genera, nine species) are associated with all major pinniped groups (otariids, odobenids, phocids) worldwide. They are physiologically adapted to the particular hosts' amphibious conditions and are transmitted on land (Lauckner, 1985b). Mites (six species) inhabit the respiratory tract and belong to two genera: *Halarachne* (in phocids) and *Orthohalarachne* (in otariids and odobenids). The life cycle takes place in the same individual host and comprises four stages: a larva, two nymphal stages, and the adult. Transmission occurs on land when active larvae are transferred by nose contact or are sneezed from the nostrils of infested animals. Acari also have some representatives in pinnipeds. *Dermacentor rosmari* (Ixodidae) appears between the fingers of walruses, especially in the hind legs, in the Arctic waters of Russia; nymphal stages are not known. *Demodex zalophi* (Demodicidae) occurs in the hair follicles

of the flippers and genital region of California sea lions. Each follicle usually contains one female and four males. All stages of development take place in the hair follicle, usually in the distal portion of the duct of the sebaceous gland (Lauckner, 1985b).

D. Sea Otter

Three protozoan species have been reported in the sea otter (*Enhydra lutris*): *T. gondii*, *N. caninum*, and *Sarcocystis neurona*. These species are terrestrial and thus their occurrence in the sea otter and other marine mammals (see above) is intriguing. Recent studies reveal that between 40 and 70% of sea otters analyzed in the North American Pacific coast are seropositive to *T. gondii*. Apparently, oocysts in cat feces are washed into the sea through freshwater runoff. It is assumed that otters are infected either by feeding on filter-feeding invertebrates that retain the oocysts or by direct ingestion in sea water (see above). Interestingly, the most common strain of *T. gondii* infecting sea otters, and some pinnipeds, has not been described in terrestrial hosts. Concerning *S. neurona*, experimental studies have shown that sea otters can support the development of mature sporocysts that are infectious to competent definitive hosts (Miller *et al.*, 2002; Dubey *et al.*, 2003; Kreuder *et al.*, 2003).

Some 20 metazoan parasite species have been reported from sea otters throughout their range. Most are acquired directly from sympatric pinnipeds, for instance, *Orthosplanchnus fraterculus*, *Pricetrema zalophi*, *Phocitrema fusiforme*, *Diplogonoporus* sp., *Diphyllobothrium phocarum*, *Pseudoterranova decipiens*, *P. azarasi*, *Corynosoma strumosum*, *C. villosum*, and *Halarachne miroungae* or from cetaceans (*Anisakis* sp. larvae). Other parasites appear to derive from seabirds, such as the microphallid digeneans *Microphallus pirum*, *M. nicolli*, and *Plenosoma minimum*, and three acanthocephalan species of *Proflicollis* (Polymorphidae) occurring as immature. Apparently, the only parasite specific to the sea otter is *Corynosoma enhydri*, the largest species in this genus (Lauckner, 1985c; Margolis *et al.*, 1997; Mayer *et al.*, 2003).

E. Polar Bear

Polar bears (*Ursus maritimus*) have been relatively little analyzed for parasites. In wild animals, *Trichinella* spp. (Trichinellidae) represent the most frequent records. Three cestode species, *D. latum*, *Bothriocephalus* sp., and *Taenia ursi-maritimus* have also been reported (Dailey, 2001).

II. Patterns and Processes in Host–Parasite Associations

To understand how marine mammals and their parasites have become associated, we have to first discuss the principles that regulate the outcomes of host–parasite interactions. The evolutionary fate of every parasite species depends on that of its hosts. If parasites are able to track their hosts' evolution, host and parasite phylogenies will match exactly, resulting in a perfect cospeciation pattern. However, if parasites speciate or go extinct whereas their hosts do not, or if hosts speciate but parasites do not, incongruences between both phylogenies will occur. Another fundamental reason for incongruence is host switching (also called "host capture"), i.e., parasites colonize new hosts through ecological mechanisms. Host switching deserves more detailed comments because of its importance for the development of parasite faunas in marine mammals (Fig. 2) (Aznar *et al.*, 2001).

In order to successfully colonize a new host, the parasite has to encounter the host and be compatible with it. Encounters depend

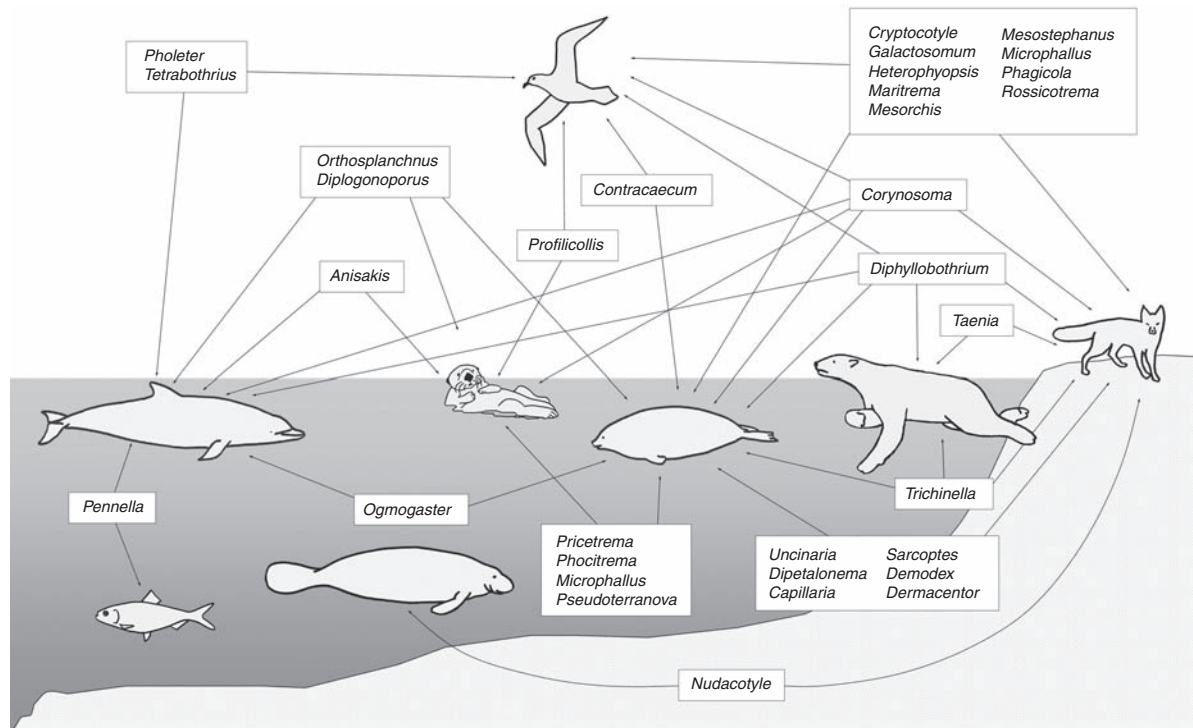

Figure 2 Genera of parasitic helminths and arthropods that are shared between marine mammals and between marine mammals and other hosts, i.e., terrestrial mammals (represented by a fox) and seabirds (represented by a gull). Complex patterns of putative colonization involving terrestrial mammals, pinnipeds, fish-eating seabirds, and the sea otter occur in the coastal realm. Pinnipeds also share arthropods and nematodes of terrestrial origin with other mammals. Cetaceans share a smaller number of genera apparently because of the lack of coevolutionary elements of terrestrial origin and their pelagic habits, which would hamper colonization events. Sirenians are isolated from other marine mammals because of their herbivorous diet. Fish are phylogenetically too apart for most parasite exchanges between them and mammals to be successful (see the text for details).

on behavioral, ecological, or biogeographical factors. For instance, the transmission of digeneans of sirenians appears to be linked to either sea vegetation or the organisms associated to it. Therefore, the chances of transmission to fish-eating marine mammals will be small indeed. If contact occurs, the new host can be “right” or “wrong” depending on compatibility, i.e., those morphological, physiological, or immunological factors that either allow or preclude that a given parasite becomes established, matures, or reproduces in/on the newly contacted host. Since most parasites of marine mammals use food webs for transmission, they cannot exert strong selection on host compatibility, thus ending in both “right” and “wrong” hosts. For instance, species of *Corynosoma* are mainly associated with pinnipeds worldwide, but their larvae frequently end up in sympatric seabirds or cetaceans. However, for unknown physiological and/or immunological reasons, these larvae rarely mature in these nonpinniped hosts.

When encounters with “wrong” hosts are fortuitous, their ecological and evolutionary significance is minimal. For example, sea otters from California seldom acquire larvae of *Polymorphus* spp. from aquatic birds. However, if encounters repeat predictably throughout time, true accommodation or SPECIATION of parasites in initially “wrong” hosts can be promoted, providing that parasites are eventually able to overcome the compatibility filter. This is obviously easier as the target host is phylogenetically closer to the original host. However, the probability of encounter is always of paramount importance. This explains why, for instance, carnivorous marine mammals have more parasitic taxa in common with fish-eating seabirds than with sirenians (Fig. 2).

A typical case of accommodation is that of the ecological facultative hosts, i.e., suitable hosts for a parasite species that originated elsewhere (Hoberg and Adams, 2000). For example, the tapeworm *Anoplyrocephalus ochotensis* originated in the Steller sea lion (*Eumetopias jubatus*) due to colonization of seals by *Anoplyrocephalus* spp. However, *A. ochotensis* also infects and reproduces now in sympatric northern fur seals (Hoberg, 1995). Facultative hosts are particularly important when they sustain a significant portion of a parasite population.

A. General Hypothesis on the Origin of Associations

Based on the above concepts, we can elaborate a general hypothesis on the origin of host–parasite associations. Let us consider the terrestrial ancestors of each marine mammal group (cetaceans, sirenians, pinnipeds, the sea otter, and the polar bear). These ancestors certainly harbored parasites in a variable number, but the subsequent host transitions from land to sea likely posed a barrier for these terrestrial parasites to track their hosts. In other words, parasites were compelled to either precisely adjust their life cycle and/or physiology to the new environment or face extinction. There are beautiful examples of such biological adjustment (e.g., the life cycle of *U. lucasi* explained above), but many parasite extinctions should have occurred, particularly in the two marine mammal groups (cetaceans and sirenians) that eventually severed their ties with land (Aznar *et al.*, 2001; see also Hoberg and Adams, 2000; Hoberg and Klassen, 2002).

When the ancestors of sea mammals made it to the sea, they became literally immersed in an ocean of infective stages of marine parasites. Then the mechanisms favoring host switching began to work. Some host captures involved marine mammals and parasites from nonmammalian hosts. However, due to compatibility limitations, these episodes should have been rare as compared to the parasite exchange between marine mammals themselves. An example can illustrate the intricacies of colonization events. The Brachycladiidae, a family of digeneans occurring in marine mammals worldwide, are the putative sister group of flukes using fish as definitive hosts. Apparently, the brachycladiid ancestors amplified a cycle that formerly ended up in these fish by adding a new step where fish predators (some unknown ancestor of toothed whales) became the new definitive hosts. This initial host switch opened the possibility for brachycladiids of subsequent coevolution (host tracking) of toothed whales and, of course, of new host-switching events. Not surprisingly, the latter involved other marine mammals. Baleen whales and pinnipeds apparently acquired brachycladiids from toothed whales, and sea otters from pinnipeds (Aznar *et al.*, 2001).

It is therefore likely that most parasite taxa infecting cetaceans have a marine origin, whereas coevolved products from land have remained in hosts with a permanent or close contact with this realm. The evidence available indicates that the arthropods and intestinal helminths of cetaceans probably rose from marine ancestors, whereas a sizeable part of parasites of pinnipeds has a clear terrestrial affiliation. To test this prediction thoroughly, we need robust phylogenetic hypotheses dealing with all parasite taxa.

B. Parasite Exchange in Ecological Scenarios

We have learned from the above discussion that the distribution of parasites in marine mammals can be largely understood from patterns of exchange, either past or present day, within communities of marine vertebrates. This section analyzes with more detail some major features of these patterns within each specific ecosystem.

1. Terrestrial Ecosystem According to the previous discussion, we would expect that most monoxenous parasites disappeared when the terrestrial ancestors of cetaceans entered the aquatic environment. Whale lice, coming from free-living amphipods, are among the few aquatic forms that rely exclusively on direct transmission. However, some parasites of pinnipeds, sea otters, and polar bears, derived putatively from terrestrial counterparts, have cycles constrained to develop on land (Aznar *et al.*, 2001). Most of these land parasites have monoxenous life cycles and many are host specific. For instance, echinophthirid lice and halarachnid mites likely coevolved with the ancestor(s) of pinnipeds and are largely restricted to these hosts today. In this context, the occurrence of *Halarachne miroungae* in sea otters should be regarded as fortuitous. Another interesting example is that of *Trichinella* spp. These extremely generalist parasites occur worldwide in terrestrial CARNIVORES and other mammals. Bearded and ringed seals, walruses, and polar bears are known to serve as hosts of these nematodes in the Arctic. The infections can evidently be traced to a terrestrial origin, but patterns of transmission are intricate and have not been proven definitively. Crustaceans and birds have been suggested to acquire *Trichinella* spp. larvae when feeding on mammal carcasses. Then, seals would be infected by direct ingestion of these crustaceans or while feeding on grounds contaminated with bird feces (Lauckner, 1985b). The nematode might then be transmitted to polar bears and some walruses that feed on seals. Polar bears could also acquire *Trichinella* independently by consuming carrion of other mammals. Perhaps, no other example of terrestrial infections in

marine mammals is as intriguing as that of coccidians. For *T. gondii*, runoff water contaminated with cat excrements has been proposed as the most likely route of transmission, given that felids are the only known hosts that can excrete environmentally resistant oocysts and in high numbers (Miller *et al.*, 2002; Dubey *et al.*, 2003). By contrast, the routes of infection of *N. caninum* and *Sarcocystis* spp. in the marine realm are still largely unknown (Dubey *et al.*, 2003).

2. Freshwater Ecosystems River dolphins, Baikal seals (*Pusa sibirica*), and manatees (*Trichechus* spp.) have a comparatively poor and specific helminth fauna. Since these hosts have secondarily colonized freshwater habitats, an interesting question is what kind of parasite fauna they are expected to harbor. Parasites may have followed these hosts from the marine realm or may have colonized them in freshwater habitats. The species of *Hunterotrema* and *Peritrachelius* (= *Anisakis*) *insignis* infecting the Amazonian river dolphin (*Inia geoffrensis*) seem to exemplify ancestral associations of marine origin. In contrast, many other parasites should have been acquired after freshwater colonization. For instance, the congeners of the fluke *Nudacotyle undicola* from West Indian manatees infect freshwater and terrestrial mammals. Likewise, Baikal seals are infected with *Diphyllobothrium dendriticum*, a typical freshwater tapeworm occurring in aquatic birds and land mammals. *Ruffetrema indirae* in the Indian river dolphin (*Platanista gangetica*) provides another example, given that relatives of this fluke infect terrestrial birds and mammals. In this instance, however, infections seem accidental because worms are apparently unable to produce viable eggs, although it might well represent a case of incipient colonization of a new host.

Some other parasites have an uncertain origin. The digenean *Chiorchis fabaceae* and nematodes of the genus *Heterocheilus* are common to species of manatees from both freshwater and coastal habitats, but the origin of these associations is currently unknown. Likewise, the nematode *Contraecum lobulatum* is exclusive to Indian river dolphins, and species of *Contraecum* are typical of fish-eating aquatic birds, pinnipeds, and cetaceans. Where might *C. lobulatum* have come from, a marine or a freshwater habitat?

3. Coastal Ecosystems Coasts constitute probably the most important realm in terms of historical and current parasite exchange between carnivorous marine mammals, and between these hosts and other vertebrates (Hoberg and Adams, 2000; Hoberg and Klassen, 2002). Perhaps the best example of rich parasite exchange in coastal waters is provided by the parasite fauna of sea otters, which is almost entirely made up of parasites from either sympatric pinnipeds or seabirds (Margolis *et al.*, 1997). The influx of parasites through coastal food webs puts many parasites in contact with incidental hosts, in which, depending on the compatibility filter, parasites are able or not to reproduce at ecological time. Examples of apparent failure are, e.g., *P. decipiens* in sea otters, *A. simplex* in many seals, or most *Corynosoma* spp. in nonpinniped hosts. In contrast, some parasites are notoriously unspecific with respect to the choice of their final hosts: heterophyid, opisthorchiid, and microphallid digeneans found typically in terrestrial mammals or aquatic birds infect and reproduce in pinnipeds and the sea otter (rarely coastal cetaceans) in neritic and littoral waters (Lauckner, 1985b). Most of these records are occasional, but in the Caspian seal (*Pusa caspica*) they represent an important portion of the helminth fauna: many species occur also in sympatric aquatic birds or terrestrial carnivores.

There are also many examples of recent accommodation or speciation of parasites in new hosts (although, in most cases, we are not certain of which were the donor and the target hosts). For instance, the brachycladiid *Orthosplanchnus fraterculus* infects and reproduces readily in

walrus, bearded seals, and sea otters, which share a similar diet on benthic invertebrates (sea otters probably acquired this fluke from pinnipeds) (Margolis *et al.*, 1997). Likewise, diet similarity seems to be responsible for the occurrence of *Ogmogaster antarcticus* in fin whales, blue whales, Weddell seals, and crabeater seals in Antarctic waters. There are also many examples of apparent parasite speciation associated with recent colonization in the coastal environment. Species of *Corynosoma* in cetaceans (e.g., *C. cetaceum* in dolphins from the Southern Hemisphere), otters (*C. enhydri* in sea otters), and seabirds (*C. shackletoni* in the Gentoo penguin, *Pygoscelis papua*) appear to constitute independent host-switching events from *Corynosoma* of pinnipeds.

Finally, some cases represent more archaic colonization events followed by secondary diversification within the new association. It is postulated that the genera *Anophryocephalus* (Tetrabothriidae) and *Orthosplanchnus* (Brachycladiidae), typical from pinnipeds of the arctic and subarctic waters, arose during the Quaternary from ancestors infecting toothed whales (Hoberg and Adams, 2000; Aznar *et al.*, 2001). After the initial host capture, a complex history of parasite diversification apparently occurred associated to pinnipeds themselves. One of the most striking examples is that of *Contracecum* spp. in pinnipeds: there is phylogenetic evidence that boreal seals and austral otariids acquired species of *Contracecum* from seabirds independently.

4. Pelagic Ecosystems Despite the appearance of continuity between coastal and oceanic domains, the parasitic fauna of pelagic marine mammals is distinctive and comparatively poorer than that of coastal hosts. Several factors appear to contribute to this singularity. First, some parasitic groups are underrepresented. The diversity of digeneans is probably constrained because they almost exclusively require gastropods or bivalves as first intermediate hosts, which are abundant in coastal but not in pelagic waters. Indeed the Brachycladiidae are among the few flukes with representatives in pelagic marine mammals. Second, the probability of parasite exchange is decreased (e.g., there is little chance for terrestrial influence). Third, infective stages are much more “diluted” in the pelagic environment (Hoberg and Adams, 2000; Hoberg and Klassen, 2002). Transmission rates are thus lowered, also reducing the likelihood of host captures.

Some parasitic groups infecting marine mammals are predominantly pelagic and probably originated in this ecosystem. Except for species of the genus *Anophryocephalus*, most tetrabothriid cestodes occur in pelagic birds and cetaceans (Hoberg, 1995). Seabirds have been considered as initial hosts for ancestral tetrabothriids, from which these tapeworms would have switched to cetaceans (seabirds, dolphins, and whales share the genus *Tetrabothrius*). There are two other interesting cases of host switching. First, pelagic cetaceans seem to have acquired species of *Pennella* from oceanic fish. Even, there are records of the same species, *P. crassicornis*, parasitizing both cetaceans and fishes. However, females of *Pennella* can actively select their definitive hosts, in contrast to the majority of examples discussed thus far. How did this host switch to cetaceans happen? Second, some species of *Phyllobothrium* and *Monorygma* (Cestoda) appear to use cetaceans (mostly pelagic) as intermediate hosts (Aznar *et al.*, 2007). Evidently, a shift in the ancestral life cycle of these tapeworms had to occur as other relatives within the class Tetraphyllidea use only invertebrates and fish.

III. Effects and Applications

A. Parasitosis

The severity of the parasite-induced damage is related to the type of parasite, its abundance, the host's health status, and the

concurrency of other pathogenic agents. The effects of parasites usually have little relevance on host health, such as local reactions produced by, for instance, the proboscis of *Bolbosoma* or *Corynosoma*. Sometimes, the lesions can be more important, such as ulcers and hemorrhages caused by species of *Anisakis* and *Pseudoterranova*, and on occasion, parasites can compromise the health of its host and even lead to its death. For instance, *Nasitrema* spp. can cause neuropathies that have been related to both single and mass strandings. Likewise, lungworms of cetaceans and pinnipeds cause bronchitis and pneumonia that may result in death, particularly among the youngest individuals. Sometimes, the direct action of the parasite might not be severe, but propitiates more serious viral, bacterial, and other parasite infections, e.g., sucking lice may transmit heartworms while feeding on their hosts (Dailey, 2005; Raga and Gulland, in press).

Sometimes, parasites represent a major cause of mortality in marine mammal populations. For instance, encephalitis by *T. gondii* and intestinal perforation caused by *Proflicollis* spp. accounts for about 38% of the total mortality of southern sea otters off California (Kreuder *et al.*, 2003). Indeed, parasites might contribute significantly to marine mammal POPULATION DYNAMICS by affecting either host reproduction or survival. For instance, many females in a herd of Atlantic white-sided dolphins (*Lagenorhynchus acutus*) suffered from mastitis caused by *Crassicauda* nematodes. The parasites damaged the secretory tissue, affecting the quality and quantity of the milk, which would ultimately compromise the survival of the calves and the reproductive output of the herd (Geraci and St. Aubin, 1987). In other instances, parasites can lead to direct mortality. *Crassicauda* spp. causes cranial damage in pantropical spotted dolphins (*Stenella attenuata*) from the eastern Tropical Pacific. A study of dolphins caught in a tuna purse-seine fishery showed an increase of lesions among individuals up to 5 years old. In contrast, in animals older than 8 years, lesions diminished by 12.3% annually. Assuming that the lesions were irreversible, that there were no reinfections, and that dolphins with lesions had the same probability of being caught as those without, the mortality rate attributable to the parasite was estimated as 1.1%. Since the annual natural mortality rate for the Pacific spotted dolphin population is 10–13%, the study suggests that *Crassicauda* spp. accounts for 11–14% of that rate.

In some cases, parasites might actually regulate marine mammal populations. A density-dependent relationship between parasite-induced mortality and population size has been shown for the hookworm *U. lucasi* in northern fur seals from the North Pacific. These nematodes constitute the most important mortality factor among newborns by causing diarrhea, anemia, and intense intestinal hemorrhages. The population size of pups born in St. Paul Island (Alaska) peaked around 1940 and declined more or less steadily until the present. Data of hookworm mortality from previous surveys showed a decrease in pup numbers, which means that recent mortality is less than in the past. These data suggest a density-dependent relationship and, therefore, a possible regulatory effect.

B. Economic and Public Health Importance

The parasites of marine mammals can infect valuable animals in aquaria, causing lesions and diseases. For this reason, expensive prophylactic measures must be used routinely. The most important economic impact, however, is due to anisakid nematodes whose larvae occur in commercial fish and squid. These larvae also have public health repercussions (see Box 1) but, from an economic perspective, the problem is cosmetic, rendering the fish unappealing to consumers.

Box 1 Main parasitic zoonoses

Trichinosis occurs mainly among people from the Arctic due to the consumption of raw or undercooked meat, particularly of polar bear, walrus, and some seals. Larvae of *Trichinella* species are found in the striate muscle of many mammals, encapsulated inside individual nurse cells. When the muscles are ingested by another mammal, the larvae are released into the small intestine, where they penetrate the mucosa and develop to adult stage. The females give birth to numerous larvae, which migrate through the circulatory system to the skeletal muscles. The damage to the host is due to both penetration of adult females in the mucosa, migration of juveniles, and penetration in the muscle and nurse cell formation. Infections in humans can be fatal. Traditional arctic dishes based on seal meat, such as igunaq, nikku, raw frozen sausage, and poorly cooked sausage represent a potential source of infection for people (Raga and Gulland, in press).

Diphyllobothriosis is caused by tapeworms of the genera *Diphyllobothrium* and *Diplogonoporus*. Human infections occur by ingestion of plerocercoids (larval stages) encysted in fish muscles. These larvae can develop into the adult stage in the human intestine. Usually the infections are not severe, but sometimes can lead to pernicious anemia due to B12 vitamin deficit. Cases of marine transmitted diphyllobothriosis are particularly common in Japan and Peru due to the ingestion of raw fish dishes such as ceviche (Lauckner, 1985b; Oshima and Kliks, 1987).

Anisakidosis is produced by anisakid nematodes, particularly those of the genus *Anisakis*. Infections in humans occur when the larvae are eaten with either raw or lightly cooked fish or squid. The larvae cannot develop to the adult stage in the digestive tract of humans, but can make considerable damage to the gastric or intestinal wall. They may produce ulcers and eventually peritonitis and other severe pathologies. Although anisakidosis has been traditionally common in Asian countries, especially in Japan, the popularity of raw fish dishes, as sushi, has spread human infections worldwide (Oshima and Kliks, 1987; Smith, 1999). Allergic reactions due to antigens released by the worms in the fish have been reported both among consumers and workers in fish processing plants. This places the problem of anisakidosis under a whole new light because some of the antigens are thermostable (Moneo *et al.*, 1997). Thus, common prophylactic methods, such as cooking or freezing that kill the larvae and prevent infections are not useful to avoid allergies.

In 1982, the losses caused by *P. decipiens* in eastern Canada were valued \$20 million, only in processing of cod fillets (Aznar *et al.*, 2001).

The parasites with repercussions on public health are those that can infect humans with food (Box 1), when animals consume meat from marine mammals or, more frequently, raw fish or squid containing living infective stages.

C. Natural Tags

Many parasites are useful natural markers of biological and environmental phenomena because their transmission is linked intimately

to features of the host and the ecosystem. Despite some limitations, marine mammal parasites have proven themselves as biological indicators of phylogeny, local migration, distribution, disease, stock identity, and social behavior of their hosts.

Regarding host behavior, differences in the occurrence of two whale lice (Cyamidae) species on sperm whales were interpreted as evidence of spatial segregation between the bulls and the rest of the population off South Africa. Assuming that males leave their natal herd at attainment of sexual maturity, parasite information suggested that this should occur at 12 m of length. This prediction was validated later on by analyses of gonadal tissue. Another example is the comparison of intestinal helminth abundance between pods of long-finned pilot whales (*Globicephala melas*) in the North Atlantic. Monte Carlo simulations revealed that adult males were more difficult to allocate into their pods than other individuals. This suggests male exchanges between pods, a conclusion that agrees with genetic studies that adult males do not breed within their natal pods (Balbuena *et al.*, 1995).

Parasites transmitted through the food web have also provided information on past and present host feeding grounds. This has served to reveal geographical differences between areas for Antarctic whales, spotted seal, populations on both sides of the North Pacific, inshore and offshore forms of bottlenose dolphins in both the east coast of the United States and Peru, and geographical segregation of franciscana (*Pontoporia blainvillei*) south and north of the La Plata River Estuary, between Argentina and Uruguay (Aznar *et al.*, 2001).

Finally, marine mammals can be used to evaluate the risk of human infections of protozoan pathogens. In particular, since sea otters are nearshore predators that share the same environment and some food items with humans, the ongoing studies of transmission and spatial dynamics of *T. gondii* in this species may prove useful to tackle toxoplasmosis of marine origin in humans (Miller *et al.*, 2002; Dubey *et al.*, 2003).

Parental Behavior

JANET MANN

Parental behavior in pinnipeds, sirenia, sea otters (*Enhydra lutris*), polar bears (*Ursus maritimus*), and cetaceans shares several features: paternal care is virtually absent, gestation and lactation periods are typically long, females give birth to and nurse one offspring at a time (polar bears excepted), and many marine mammals fast during the early stages of lactation. In sum, marine mammal mothers invest extensively and exclusively in single offspring; this article reviews the diversity and nature of that investment.

Marine mammal maternal strategies vary in important respects. Polar bears, sea otters, and all three families of pinnipeds—Odobenidae (walrus, *Odobenus rosmarus*), Phocidae (earless or "true seals"), and Otariidae (eared seals, sea lions, fur seals)—give birth on land or ice. Twenty-three species of pinnipeds breed on land and 13 breed on ice. Cetacean and sirenian females give birth in the water; this pattern favors precocial swimming and diving. Among many pinnipeds, maternal care is largely restricted to milk transfer, whereas the prolonged association characteristic of many cetaceans, sirenians, otters, polar bears, and some pinnipeds also involves protection and potentially extensive information transfer.

I. Feeding, Lactation, and Patterns of Association

Lactation strategies in marine mammals generally depend on trade-offs among foraging, predation risk, and reproduction. This trade-off is exemplified by many marine mammal species that fast during the early stages of lactation. That females forgo feeding by breeding on land (i.e., pinnipeds) or in warm coastal waters (i.e., baleen whales) suggests that benefits, such as reduced predation risk and rapid energy transfer from mother to offspring, outweigh the costs of fasting. Larger bodied mammals can withstand fasting for longer periods than smaller, thus able to afford longer fasting periods devoted to offspring care. Fasting and lactation coincide in many marine mammal species and only rarely in terrestrial mammals. Early-weaning marine mammals tend to have milk that is high in fat, investing heavily in offspring for a shorter period. Late-weaning marine mammals tend to have lower fat milk (although still much higher than for terrestrial mammals). This pattern is generally true for comparisons between phocids and otariids, or toothed and baleen whales (Oftedal, 1997; Table I). Other factors, such as the development of pup or calf foraging skills, also contribute to late weaning ages and prolonged association (see Section IV).

Phocids tend to fast and remain near the ROOKERY until their pup is weaned; they rely on fat stores to nurse offspring. Phocid maternal strategies are generally characterized as fasting. A few phocids feed during lactation, notably the harp (*Pagophilus groenlandicus*), harbor (*Phoca vitulina*), ringed (*Pusa hispida*), and Weddell (*Leptonychotes weddellii*) seals. Most remarkable is the hooded seal (*Cystophora cristata*), which breeds on pack ice and nurses her pup for only 4 days, transferring approximately 748,000 J or 178,657 kcal to the pup in that time (Oftedal et al., 1993).

Predator and prey distributions are likely to influence breeding habitat (i.e., pack ice, fast ice, beach, cave, and water) and lactation length. The relationship between breeding habitat and lactation length has been difficult to test using the comparative method because species breeding in similar habitats tend to be close phylogenetically.

TABLE I
Parameters Related to Maternal Care in Marine Mammals

Taxon	Birth location (land, ice, water)	Sexual dimorphism (high/moderate vs low)	Mother fasts during lactation	Milk fat (%)	Duration of lactation (months)	Association postweaning?
Pinnipedia						
Otariidae	L	H	Yes	25–53	4–30	No
Phocidae	L, I	H, L	Yes	47–61	<3	No
Odobenidae	L, I	H	No	25–32	>24	Yes
Sirenia	W	L	No	13	12–36	No?
Ursidae (polar bears)	L	L	Yes	17–25	18–42	No
Mustelidae (sea otters)	L	L	No	21–26	6–12	Yes
Cetacea						
Platanistoidae	W	L	No	13	<12	Yes
Delphinoidae	W	H, L	No	22–30	12–48+	Yes
Ziphioidae	W	H	No	18–24	–	–
Physeteroidae	W	L	No	24	>12	Yes
Balaenidae	W	L	Yes	22	<10	No
Neobalaenidae	W	L	Yes	–	<6	No
Eschrichtiidae	W	L	Yes	53	<6	No
Balaenopteridae	W	L	Yes	24–40	<10	No

However a recent analysis using independent contrasts does suggest that breeding substrate selects for lactation length (Schulz and Bowen, 2005). Those breeding on unstable substrates (pack or floe ice) wean early relative to those breeding on land, but other selective pressures (metabolic rate, foraging strategies, predation risk) are likely to be involved (Schulz and Bowen, 2005). Some species with protective lairs or caves [arctic Baikal seal (*Pusa sibirica*), and Mediterranean monk seal (*Monachus monachus*)] wean late for phocids, at 2–3 months. Phocid females tend to be larger than otariid females and can thus fast longer. Since phocid pups are generally more vulnerable to terrestrial predation than otariids, they are adapted to briefer lactation periods.

Otariid mothers leave their young after the first week to hunt for 1–14 days before returning to nurse their pups. When the mother is hunting, the pup is typically fasting. She returns for 1–3 days and fasts while she feeds her pup. The duration of her absence is correlated positively with the milk she provides per pup visit. If food is abundant, then mothers make shorter foraging trips than when food is scarce and feed their young more often. Thus, prey abundance is correlated positively with maternal body condition and pup growth rate. Some otariids, such as sea lions, nurse their pups for 6–11 months. The Galapagos fur seal (*Arctocephalus galapagoensis*) nurses her pup for as long as 3 years.

As pups grow, otariid mothers may spend three-fourths of their time at sea, but each foraging trip tends to vary in duration. Phocids are adapted to store energy and fast for the entire lactation period, whereas otariids must supplement stores with some food. Thus otariid mothers must find breeding breaches that are also near productive feeding grounds. Beach breeding can provide safety to pups, but also constrains how far and how often females can venture to hunt. Otariid pups grow more slowly than phocid pups, but tend to be weaned at

larger weights, 40% of maternal mass compared with 30% in phocids. Recent analyses suggest that weaning and maternal mass are isometric for pinnipeds overall (Schulz and Bowen, 2005). When food abundance is high, otariid mothers can transfer more milk to their offspring than when food is scarce. Phocid females concentrate on feeding offspring rather than expend energy traveling to and from feeding areas. Notably, otariids are the only mammals capable of continuing to lactate despite long periods (occasionally >3 weeks; Georges and Guinet, 2000) of separation from offspring. Molecular data suggest a mutation of the α -LA gene in otariids is involved in the delay of mammary involution (Reich and Arnould, 2007). In sum, most otariids wean their young within the year, but later than most phocids.

Of all pinnipeds, walrus appear to have the longest average period of maternal care, nursing their young for up to 3 years. It is not known whether walrus mothers fast during the initial stage of lactation. They give birth on ice, but the mother nurses her pup in the water. Known for their sociability, females and pups spend most of their time in female herds. Daughters stay in their mothers' herd. Sons leave the herd when 2–3 years old and join all-male herds. Some evidence suggests that adult males return to their natal group after several years (Stewart *et al.*, 2003).

There are few studies of maternal care in Sirenia. Manatees (*Trichechus* spp.) and dugongs (*Dugong dugon*) are thought to have similar gestation lengths (12–13 months), but differ when it comes to other life history traits. Manatees give birth as early as their fourth year, and have interbirth intervals less than 2 years (Koelsch, 2001), whereas dugongs do not breed until age 10, and typically have 3-year intervals (Marsh *et al.*, 1984). Based on tooth wear in dead specimens, Sirenia calves feed on seagrass within months after birth.

Polar bears begin reproduction at 5–6 years of age and nurse their cubs for 2–3 years. Females birth and fast in dens on coastal shores

or on multiyear pack-ice up to 300 km offshore (Stirling, 2002). Unlike all marine mammals, polar bear females have the challenge of hunting [mostly ringed and bearded (*Erignathus barbatus*) seals] with two dependent offspring in tow. A long period of dependency is probably essential for cubs to both build body mass, gain protection from aggressive adult male polar bears, and learn hunting and denning skills before they begin breeding themselves.

Similar to the fast vs feed pattern that distinguishes lactating phocids and otariids, the larger baleen whales fast for long periods and toothed whales little or not at all. Baleen whales have higher fat milk and nurse for shorter periods than toothed whales. Mysticete mothers, who typically migrate to warmer waters to birth and rear young, can devote their time and energy almost exclusively to milk transfer, much like phocid mothers. Like pinnipeds, baleen whales are characterized by annual breeding and feeding cycles, including cases of postpartum estrus. Among baleen whales and pinnipeds, females are often attractive to males soon after giving birth. Thus, intense competition between males over access to females could interfere with maternal care, but detailed behavioral studies are needed.

Little is known about the nature of the baleen whale mother–calf relationship. Humpback (*Megaptera novaeangliae*) and right whales (*Eubalaena* spp.) are the best-studied baleen whales, likely due to their tendency to visit protected coastal areas to breed. Interactions between more than one mother–calf pair are infrequent, especially between humpback mother–calf pairs, which appear to actively avoid each other during the initial stage of lactation. The explanation for avoidance is unclear. Association between mother–calf pairs may disrupt the development of maternal or calf recognition. Similar to some of the large ungulate species, mothers may avoid unrelated calves to avoid milk theft. Anecdotal reports of Southern right whale (*E. australis*) behavior indicate that calves occasionally attempt to nurse from other females. With such a tremendous energetic output, milk transfer may be difficult to inhibit if the “wrong” calf attempts to nurse. Additionally, fasting in warm water likely reduces the metabolic demands on the mother. (Warm water would also reduce metabolic demands on the calf.) Fasting terrestrial mammals convert body fat to fatty milk more easily than mammals that eat during lactation, and this pattern is likely to favor fasting in baleen whales that invest in rapid growth of a large calf. Consistent with this, fasting mammals (terrestrial and marine), including baleen whales, have milk low in carbohydrate, protein, and water, but very high in fat. The baleen whale mother can thus fatten in the feeding grounds, transfer that energy efficiently to her calf in the warmer breeding grounds, and assure a safer migration to higher latitudes. Larger calf body size would likely reduce predation risk and other somatic costs (e.g., metabolic). Four balaenopterids [blue (*Balaenoptera musculus*), fin (*B. physalus*), minke (*B. acutorostrata* and *B. bonaerensis*), and sei (*B. borealis*) whales] tend to wean early, before or soon after reaching the feeding grounds (at 6–7 months). Humpback, right, bowhead (*Balaena mysticetus*) and gray (*Eschrichtius robustus*) whales continue to nurse offspring to older ages and are typically feeding during the latter stage of lactation. Although bowhead whales migrate, they do not migrate to warmer waters to calve and apparently do not fast. Given this pattern, bowhead whales are predicted to have milk lower in fat, nurse offspring for longer periods, and have slower growth rates compared to other baleen whales. Existing data on bowhead whales support this, with late age of sexual maturity (20 years) and 4–7 interbirth intervals, but data are still too limited to make explicit comparisons (George *et al.*, 1999).

Little is known about mother–calf behavior during migration, but available data suggest that mothers and calves do remain

together during the first migration between the breeding and feeding grounds. Observations of Pacific humpback whales off the coasts of Australia and of gray whales off the coasts of North America indicate that adult males often accompany mothers and calves during the migration. This may reduce killer whale (*Orcinus orca*) predation risk, although the males are likely there to mate with the female, not protect the calf. Several studies have indicated that up to one-third of humpback whale calves bear killer whale tooth marks by the time they reach the feeding grounds with their mothers. Killer whale attacks on gray and humpback whale calves have been observed, but there is no evidence to suggest that males aid calves during such attacks. A recent analysis suggests that killer whale attacks are likely to occur during the baleen whale calf’s first migration, but are rare after that (Mehta *et al.*, 2007).

Odontocete life history patterns are slow relative to baleen whales. The baleen whale usually reaches reproductive maturity in 4 or 5 years, but the typical odontocete takes 10 years or more, despite a much smaller body size. A notable exception appears to be the bowhead whale, which reaches sexual maturity much later and may live for 200 years. Only the smallest odontocetes, such as porpoises, tend to reach reproductive maturity by age 5. With a relatively long period of immaturity and calf vulnerability, odontocetes may benefit more by stable patterns of group living compared to mysticetes.

Odontocetes do tend to have stable groups and patterns of association compared to mysticetes. In contrast to the baleen pattern, odontocete mother–calf pairs tend to associate with each other and stable associations with female kin are common. Adult male associations with mothers and young calves are more variable. For example, adult male killer whales consistently associate with female kin and their offspring. Female sperm whales (*Physeter macrocephalus*) and young spend most of their time with female kin and rarely associate with adult males. Shark Bay bottlenose dolphin (*Tursiops* spp.) females and calves appear to avoid juvenile and adult males (Mann and Smuts, 1999; Gibson and Mann, in press).

Close mother–calf association is characteristic of many toothed whales and dolphins, particularly in the delphinid family. Delphinid calves typically swim alongside the mother for the first few weeks in what is known as “echelon position.” Within a few months, they begin to swim under the mother regularly in what is known as “infant position.” In contrast, humpback and right whale calves tend to swim alongside the mother throughout development and separations are not common during lactation. Bowhead calves occasionally ride on the backs of their mothers during migrations. Odontocete mothers are presented with particular challenges that baleen mothers do not face. Because they feed throughout lactation and hunt single prey, the mother must accelerate or dive deeply to hunt, often leaving her calf alone at the surface. Young calves are not very proficient divers, and they breathe more often, thus they sometimes “wait” at the surface while the mother forages below. This is especially pronounced in deep-diving species such as sperm whales. Mothers may dive for as long as between 30 and 50 min. The calf, often alone at the surface, has a tendency to swim toward any whale that comes up first. Some form of communal care in this deep-diving species may be an important selective force favoring matrilineal sperm whale units. A lone sperm whale mother would be at a distinct disadvantage if she had to abandon her vulnerable calf at the surface for long periods as she hunted for squid at depth. Among pantropical spotted dolphins (*Stenella attenuata*), lactating females feed on flying fish rather than squid (preferred by nonlactating females), which necessitates diving and separation from their calf. In bottlenose dolphins, most mother–calf separations occur during the mother’s foraging.

When foraging, bowhead mothers and calves may separate 1–2 km for 30 min or more.

II. Protection and Predation

Otariids tend to breed on predator-free islands. Phocid pups can be vulnerable on fast ice, where polar bears and killer whales may feed on them. In the North Pacific, killer whales frequently catch harbor seal pups on their first forays into the ocean. South American sea lion (*Otaria flavescens*) pups are picked off beaches by killer whales. Great white sharks (*Carcharodon carcharias*) are common predators of elephant seal pups (*Mirounga* spp.) and a variety of other pinniped prey. Mammal-eating killer whales will also prey on most pinniped species they encounter, including the largest species, Steller sea lions (*Eumetopias jubatus*). Maternal protection of pups from predation is not well documented. Adult male and female pinnipeds sometimes pursue predators, such as killer whales and sharks, but nothing about this behavior suggests that they are protecting offspring *per se*.

Mothers and other female whales and dolphins do protect offspring from predatory attacks. Sperm whale females may form a ring “marguerite formation” around a calf and sometimes they place their heads to the center and use their powerful tails to deter a predator. At other times they will face out in a circle, with their tails facing the calf. Indian Ocean bottlenose dolphin mothers and close associates have also defended calves from predation attempts by tiger sharks (*Galeocerdo cuvieri*) (Mann and Barnett, 1999). Gray whale mothers have been observed placing themselves between killer whales and their calves (Black *et al.*, 1999).

Bottlenose dolphin infanticide has been documented from retrieved carcasses at two Atlantic Ocean sites: the Moray Firth in Scotland and Virginia, United States. The perpetrators of calf killing are not known. If the pattern is similar to that found widely in felids, ursids, primates, and rodents, then it is likely that unrelated adult males are the perpetrators and might gain a reproductive advantage by monopolizing and mating with the mother of the victim. Polar bear mothers, like other ursid females, are known for their protectiveness and fierce defense of cubs from infanticidal males.

Among land-breeding SEXUALLY DIMORPHIC pinnipeds, offspring are occasionally killed incidentally by large patrolling males (e.g., elephant seals and sea lions). These killings appear to be by accident, e.g., when the male is preoccupied with defending the breeding beach. However, males also abduct and force matings on pups, sometimes resulting in the pup's death. Among ice-breeding pinnipeds, or when mating occurs in the water, pups are less vulnerable to patrolling males. In these species, sexual dimorphism is also less pronounced and the risk of being squashed is lower than for land-breeding species.

III. Mother–Offspring Recognition

Mutual vocal and olfactory recognition is common in a number of pinniped species, especially among otariids. This might be expected given that otariid mothers and pups often separate during the mother's foraging trips and the reunion depends on mutual recognition through repeated calling. Otariid pups are also fairly mobile, so the previous location of her pup would not be a reliable cue. In addition, otariids breed colonially, complicating the task of finding the pup or mother among hundreds. Phocid mothers would not necessarily need a recognition system if they remain close to their offspring, but some species that separate during lactation (e.g., harbor seals) exhibit vocal recognition. After feeding trips, it is common for mothers to inspect several pups before finding her own.

Sea otter vocalizations have been compared to pinnipeds in structure and complexity. There is some evidence for short range COMMUNICATION and vocal recognition between mothers and pups. Olfactory cues may also play a role.

Cetaceans have little or no sense of smell (absent in odontocetes; rudimentary in mysticetes), but likely use vocal communication for individual identification. Little is known about mysticete mother–calf recognition and only slightly more is known in odontocetes. Delphinids produce a diverse array of sounds, including echolocation clicks, burst-pulse sounds, and whistles. Dolphin calves are born able to whistle and will whistle often during the first days of life. Bottlenose dolphins and potentially other delphinids exhibit signature whistles, individually distinctive whistles in the first years of life. In bottlenose dolphins, simple whistles are present at birth, but the calf develops a more distinctive contour with age (although the calf may continue to produce simple whistles as well). Mechanisms influencing the development of SIGNATURE WHISTLE contours are not known. Although the calf's signature whistle is not present at birth, the young calf may learn to identify his or her mother's signature whistle soon after birth and mothers may be able to recognize the calf's simple whistle. Field studies suggest that whistles mediate natural separations and reunions between mothers and calves. Calves tend to whistle more than mothers, perhaps indicating the calf's greater motivation to reunite with the mother than vice versa. Experimental work with captive and temporarily captured animals suggests that dolphins can recognize the whistles of others. In the marine environment, depth (water pressure) and other habitat features may alter sound enough to make voice recognition difficult; thus, selection may favor individually distinctive whistle contours in an environment where individuals join and leave each other and frequently lose visual contact. Few studies have sufficiently examined cetacean mother–calf communication in captive or wild settings to elaborate further.

IV. Maternal Influence on Offspring Behavioral Development

Mothers influence offspring behavioral development by the experiences they provide, including migration and navigation, communication, social interactions, and foraging. To secure the transition from dependence to independence, marine mammal offspring must acquire necessary survival skills. Although data are limited, maternal influence on the development of foraging skills has received the most attention (Mann and Sargeant, 2003).

Some types of marine mammal foraging may not require learning, but other foraging skills clearly require experience. Marine mammal young may develop foraging skills by independent (nonsocial) learning or by social learning, including stimulus or local enhancement (e.g., exposure to foraging areas with the mother), observation of maternal foraging or prey caught, and rarely pedagogy. Teaching requires that the “teacher” modifies his or her behavior in the presence of a naive observer (pupil) at some cost or without benefit to the “teacher,” which results in or facilitates acquisition of some skill or knowledge by the “pupil” (Caro and Hauser, 1992). As such, a pup or calf can “learn” from another animal, without teaching occurring. There are good examples of extensive social and nonsocial learning in Cetacea, but only a few possible examples of teaching. There are no examples of teaching in pinnipeds and little evidence for learning from the mother. In sea otters, learning by observing from the mother appears to be important, but teaching probably does not occur (Estes *et al.*, 2003).

Pinniped pups theoretically could learn some foraging skills by following and observing the mother. However, there is little evidence to suggest this. Phocid mothers fast for most of lactation and leave the rookery before their pups do. Otariid pups could accompany their mothers on foraging trips, but most studies find little evidence of this. Pup absence from the rookery often coincides with maternal absence (a pup does not leave the rookery while the mother is present), but mother and pup travel and forage independently at sea. Otariid pups have more opportunities to develop swimming, diving, and hunting skills while relying principally on their mothers nutritionally. In the late-weaning Galapagos fur seal, pups catch their own prey for a year or longer before weaning. Some phocid pups gain considerable diving and swimming experience independently before weaning (e.g., bearded and ringed seals). Some harbor seals change haul-out sites during lactation. The pup, then, may follow the mother 30 km or more. Although research with captive pinnipeds indicates that they are adept learners, including vocal learners, there is little to suggest that learning in the context of the mother–pup relationship is particularly important except for mother–pup recognition. Walrus are likely to be an exception among pinnipeds, given their prolonged mother–offspring association and sociability at sea.

Several studies clearly document that otter pups [Eurasian river (*Lutra lutra*) and sea] learn from their mothers. Mothers take their pups on foraging trips and the pup watches the mother as she dives and retrieves prey. Mothers share their catch with pups, and in sea otters, pups even develop the specific tool-using strategy of the mother (use of rocks, soft-drink bottles, or other objects) to open shellfish or other prey (Lyons and Estes, 1989; Estes *et al.*, 2003). It takes time for pups to develop adequate diving and foraging skills, which may help explain the long dependence period in this small marine mammal. Other MUSTELIDS typically wean offspring at much younger ages (i.e., 2–3 months).

To become independent, cetacean calves must be able to forage successfully on their own. They must also catch their first prey on their own. Unlike other hunting species (e.g., felids, canids), cetacean mothers generally do not share prey with young. One exception is the killer whale, where prey sharing between mother and offspring has been well documented. Despite many thousands of hours of observation on bottlenose dolphin calves in Shark Bay by the author, prey sharing has not been observed. Delphinids exhibit a diverse range of foraging strategies and there is some evidence that these are learned. Whether calves learn foraging skills by simple trial and error, social learning, i.e., observing the mother and other conspecifics, or other mechanisms is generally not known. Shark Bay bottlenose dolphin calves begin capturing prey within 4–6 months, even though they continue nursing 3 years or more. Female bottlenose dolphin calves in Shark Bay, Australia, adopt the sponge-foraging tactic of their mother, and those without sponging mothers do not develop the trait. This unusual form of tool use, which is adopted by only a small subset of the population, may be transmitted socially (and culturally) from mother to offspring. Humpback whale juveniles in the North Atlantic have learned new foraging strategies, likely due to shifts in prey density and distribution. These tactics spread rapidly through the population, although data suggest that older animals generally did not adopt the behavior. The humpback example may provide evidence for learning (horizontal transmission), but not from the mother (vertical transmission).

The diversity of foraging strategies that humpback whales exhibit (e.g., bubble-net, cooperative lunge feeding) may help explain their relatively longer nursing period compared to other mysticetes; i.e., the duration of lactation may, in part, be determined by the ability of

young animals to forage independently. This might also help explain the longer nursing periods of odontocetes relative to mysticetes. The odontocete's task of capturing single, elusive, and specialized prey is likely to require greater foraging skill than the gulp-feeding techniques characteristic of mysticetes.

Killer whales may provide the only reasonable cetacean example of teaching, but more observations are needed. Experienced beach-feeding whales (who beach to capture pinnipeds) actively help younger animals develop this risky technique by nudging them to shore, partially wounding prey for young to manipulate, and assisting their departure from the beach.

V. Parity

For many mammals, parity (number of pregnancies/live births experienced) is correlated negatively with offspring mortality. For example, sea otter pups born to older, more experienced mothers tend to have lower mortality than pups born to younger mothers. First-time (primiparous) elephant seal mothers have lower weaning success than experienced multiparous mothers. However, a number of factors may contribute to this difference, including maternal mass (young mothers are smaller than old mothers), experience, dominance, and placement of pups in the rookery. Young, subordinate females relegated to the peripheral area of a breeding beach may have more difficulty relocating their pup and their pup may be more vulnerable to harassment and death.

First-born dolphin calves in captivity have higher mortality than later-born calves, but the cause(s) for the difference is not known. Both maternal experience and body size may be factors. Patterns of first-born mortality in wild populations are not sufficiently documented to draw conclusions, but in Sarasota, Florida, high mortality of first-born offspring might be related to maternal transfer “offloading” of perfluoroalkyl compounds (PFCs) through milk. Later-born offspring receive fewer PFCs from their mothers (Houde *et al.*, 2006).

VI. Sex-Biased Investment

Several pinniped studies have investigated whether, consistent with the predictions of Trivers and Willard (1973), mothers in good condition preferentially invest in sons over daughters. According to the Trivers–Willard model, in polygynous species, maternal investment is likely to have marginally greater genetic payoff in terms of grand-offspring if the mother can influence offspring quality and thus produce a “super-son” compared to a “super-daughter” because males have greater variance in reproductive success than females. This depends on whether mothers can confer benefits, such as increased body size, to their offspring. Biased investment generally takes two forms: sex ratio and differential investment or maternal care.

Data on biased maternal care or sex ratios are equivocal for both phocids and otariids. The sex ratio does not covary with maternal mass, a good indicator of maternal condition. For example, Northern elephant seal (*M. angustirostris*) males are born heavier than females and young mothers are less likely to successfully wean sons compared to daughters; however, there is little evidence that mothers differentially invest in sons compared to daughters. Males gain most of their size during the 3- to 5-year growth spurt, long after weaning. Maternal expenditure may not contribute significantly to male reproductive success. Gray seal (*Halichoerus grypus*) data are similarly equivocal. Otariid males are born slightly heavier and appear to grow faster than female pups, but none of the pinniped data provides clear evidence that sons exact greater reproductive costs on mothers than daughters.

In cetaceans, much less is known about biases in either sex ratio or maternal care. However, one study found that humpback whales were more likely to give birth to sons than daughters following the close of a long (3-year) birth interval compared to a short (1- to 2-year) one, although they hypothesized that as the mothers were in better condition after a 3-year interval, they were thus more likely to give birth to sons. However, the actual condition of mothers is unknown. Notably, adult female baleen whales are slightly larger than adult males. It thus remains unclear what benefit mothers in good condition might gain by biasing the sex ratio toward sons if larger body size relative to females or other males is unlikely to give them an advantage. Available growth data suggest that weanling males are slightly smaller than weanling females. Other potential cases supporting Trivers and Willard are findings suggesting that male teenage sperm and short-finned pilot whales (*Globicephala macrorhynchus*) are occasionally still nursing, but female offspring nurse no later than age 7. Because both species are markedly sexually dimorphic, these examples may be more likely to fit the Trivers–Willard model.

VII. Mother–Offspring Conflict and Weaning

In a number of pinnipeds, weaning can be initiated by either mother or pup. Otariid pups may leave the rookery while their mother continues to return from foraging trips. Phocid pups are typically weaned by the mother. She leaves the rookery permanently. Likely, the proximate cue for both the mother's and the pup's departure from land or ice is hunger. The mother leaves when her fat stores are depleted. The pup leaves when it is no longer receiving enough milk to sustain itself. Among some otariids, such as the Galapagos fur seal, the older sibling (1–2 years) may compete with the newborn for milk, providing one of the few examples of clear sibling competition among marine mammals. The size of the older sibling appears to influence the degree of competition with the younger sibling.

Little is known about the weaning process in whales or dolphins. Weaning may be fairly sudden in some baleen whales that separate feeding and breeding. Some baleen species wean during the migration to higher latitudes or soon after, but other species wean toward the end of the first year. Weaning in toothed whales is likely more gradual than in mysticetes. Evidence for mother–calf conflict comes from studies of Indian Ocean bottlenose dolphins in Shark Bay and southern right whales in Patagonia. At both sites, mothers are less responsible for maintaining proximity to their calves as they age and mothers appear to use the sea floor to prevent calves from nursing. A right whale mother may also roll belly up to prevent her calf from nursing.

VIII. Association Postweaning

Like humans and a few other mammals, mother and offspring may continue to associate postweaning and sometimes for life. Evidence for strong mother–offspring association in pinnipeds is weak. Phocids wean abruptly and separate. Among otariids, some postweaning association is possible but difficult to study. Many otariid and walrus females stay in or return to the same breeding areas, and thus may well recognize each other and interact. Walrus males are known to return to their natal area in adulthood and might encounter maternal relatives.

However, among cetaceans, high group stability and patterns of preferential mother–daughter association in fission–fusion societies (fluid patterns of group association, often with some underlying stability) indicate that strong bonds may persist. For example, resident

killer whale male and female offspring remain with their mothers for life, a pattern unique to this species. Pilot whale (*Globicephala* spp.) daughters remain with their mothers postweaning, but sons may disperse temporarily or permanently. Sperm whale daughters remain in their matrilineal unit for life, much like elephants. Bottlenose dolphin daughters associate with mothers more postweaning than sons. In contrast, few daughter or son associations postweaning persist in mysticete whales. Among delphinids, the significance of such long-term kin associations is not known, but given the diversity of prey, the complexity of some delphinid social relationships, and other selective pressures on odontocetes, continued association is likely to offer the benefits of group living. Such benefits include protection from predators or conspecifics and sharing of information and/or tasks, such as calf care.

Pathology

DANIEL F. COWAN

I. Introduction

This article focuses on naturally occurring diseases of marine mammals, and how their behavioral, physiologic, and anatomical adaptations to life spent mainly or entirely in the water influence those disease processes. Pathology is the study of diseases, including their mechanisms, manifestations, and diagnosis. One of the fundamental principles of pathology is that *every disease is a reaction to injury*. This means that an organism responds to an injury within its anatomical and physiological capacity, and that the way the organism responds, that is, the way the disease process shows itself, will be determined or at least influenced by the organism’s adaptation to its environment. Thus, a fish can develop an infectious disease of the gills, but cannot get pneumonia, a disease of the lungs. This seems obvious enough, but it may easily be forgotten when making assumptions about marine mammals. For example, the presence or absence of a thick coat of hair makes a difference in the way mercury is handled by an animal. In hairy species, a large portion

of the mercury burden accumulated in the diet is eliminated by binding to hair, which is later shed. Cetaceans, however, which may be exposed to at least as much environmental mercury as their hairy fellow marine mammals, the pinnipeds, otters and polar bears, have no hair to bind mercury, and they must find some other way of dealing with it. Their protective mechanism appears to be to combine it with selenium, rendering it insoluble and inert, and tucking it away in storage sites. This seems to serve the cetacean well, but it can be totally misleading to the researcher who finds large tissue burdens, even “lethal levels” of mercury in a healthy dolphin, and immediately casts about for a polluter to blame.

“Injury” is understood broadly to mean any noxious influence, which may include physical trauma; action of physical agents such as heat and cold; infection; intoxication; metabolic disease; nutritional deficiency; genetic disorders and developmental malformations. To this list some would add “stress,” the often (but not always) injurious effects of the attempts of an organism to adapt to environmental influences not directly injurious to themselves. This idea allows us to think of concepts of, for example, deleterious effects of excess population density (crowding), even in the presence of an adequate food supply. We can also think of an animal living at the margin of its nutritional support, with enough food available to support day-to-day functions, but unable to respond to an event, such as pregnancy, exposure to unaccustomed cold, and exposure to toxins, among many others, that places an increased energy demand on it. In such circumstances, the factors that comprise immune resistance may be too feeble to prevent heavy parasitic infestation or infection. With this perspective, we can readily understand that the environment in which an organism lives has a profound, if not determining influence on the things that make the organism ill, or cause it to die. By studying the specific diseases and patterns of occurrences of diseases in a group of animals we can gain insight not only into the hazards of the environment, but also the basic physiology of the organism. We also have to consider that animals differ even within species, and that they may differ in their reactions because of experience, so that two animals that seem nearly identical might exhibit wide differences in their response to apparently identical environmental situations or stressors.

Since environments vary, it may be expected that patterns of disease might vary among populations of a single species of animal living in different places, and since physiology and anatomy vary, patterns of disease may also vary among different species living in the same environment. Indeed, this phenomenon is well known in the world of experience. Human populations living in temperate climates and industrialized societies have very different patterns of disease than do people living in tropical agricultural societies, even though both populations would be susceptible to the same noxious agents if only they were exposed to them. Conversely, dogs, cats, and humans all living in the same house will have their own separate infectious diseases, and only rarely do they infect each other.

From the foregoing, it can be seen that study of the diseases of wild marine mammals can offer insights into anatomy, physiology, and environment that might be gained in no other way. Disease represents an interaction between an individual animal and its environment, which demands an understanding of complex, often intricate processes involving several different organisms. For example, it is not enough to simply measure the level of a toxin in water to gauge its effects on animals living in the water, since the toxin itself can be changed not only by the presence of other chemicals in the water, or by bacterial action, but also by sequential processing through metabolic systems of different organisms, and ultimately by the physiology and chemistry of the marine mammal itself. Observations

indicate, for example, that adaptation to environmental mercury over millennia makes it possible for dolphins to tolerate tissue burdens of mercury that would be fatal to cattle (Turnbull *et al.*, 1998). Animals with high tissue mercury burdens may show no sign of the tissue lesions associated with mercury toxicity in land animals (Siebert *et al.*, 1999). Diseases may appear as a secondary effect of some primary phenomenon; for example, a population with inadequate food supplies may become debilitated, with lowered resistance, and so be overwhelmed by parasites that ordinarily are held in check. In this instance, the load of parasites is obvious, the lowered resistance to parasitism may be inferred, and the lack of appropriate nutrition recognized by other factors, such as body condition, serum protein levels, and measurements of specific nutrients in body fluids.

It is remarkable that until relatively recent times, almost nothing was known about the diseases of free-ranging marine mammals, and even today not much is known about the diseases of sea otters, polar bears, manatees, and walrus in the wild. Even though many tens of thousands of large whales were taken in the whaling industry, only a few reports of pathology resulted. Simpson and Gardner (1972) compiled a detailed discussion of the histology and histopathology of marine mammals, based mainly on their own experience and an appraisal of the scattered reports then available in the literature. This work remained the standard resource and reference for two decades and is still very valuable. For practical purposes, systematic study of the pathology of marine mammals in the wild is limited to pinnipeds and dolphins, and to a lesser degree manatees, and did not begin until the middle 1960s. The current literature contains many reports of findings in single animals, or small groups of animals, but relatively few investigations resulting from long term, detailed studies. The state of the art and science of pathology of marine mammals is such that new and important observations may still be made using dissection and light microscopy, techniques developed and applied to many species in the nineteenth century, supported by the latest developments in molecular biology and molecular diagnostics.

II. Sources of information

All marine mammals are protected by law in most advanced countries with notable exceptions being Canada and Japan, which allow commercial hunting of some species. In countries with protective laws, access to marine mammals is carefully limited, and experimentation, with rare exceptions is prohibited. This means that apart from animals maintained in marine aquaria and under the care of specialized veterinarians, all information is derived from animals that strand on beaches, are accidentally killed as by-catch in the fishing industry, or taken by approved subsistence hunters, who may make arrangements with researchers for access. Not much scientific use is made of animals in commercial hunting operations. Apart from the occasional stranding near a population center, or accidental death associated with fishing, it is rare for an animal to be found in an undecomposed condition by a trained observer with appropriate equipment and supplies. Therefore, what we know is based mainly on case reports, often incomplete, and a few studies involving at most a few dozen animals, often of several different species. Stranding and rehabilitation centers are the main source of information. These obviously can describe only what they see, which is mainly coastal species and the occasional pelagic animal that is cast up on the beach.

Despite these limitations, observations made in stranding centers may be the source of powerful insights into the state of the free-ranging, otherwise unaccessible wild populations. Phocine distemper virus (PDV), a morbillivirus responsible for the deaths of at

least 18,000 harbor seals in Europe in 1988 was first isolated from stranded seals in that year. Phocine herpesvirus (PhHV1) was identified in 1985. The highly toxic domoic acid, a product of the diatom *Pseudo-nitzschia australis*, was recognized as a cause of death in over 400 California sea lions (*Zalophus californianus*) examined in a rehabilitation center in 1998.

It is not clear just how representative beach-stranded animals are of the population at large, but for the time being this issue is of lesser importance than simply building a reliable database of descriptions of pathological findings, and relating these to age, sex, reproductive status, incidence and type of trauma sustained, identification of infectious diseases, toxin and parasite burdens, etc. Continuing, detailed pathological studies of stranded dolphins are currently taking place in a number of areas, most notably on the North Sea coast of Germany, the St. Lawrence River and estuary in Quebec, coastal New Zealand, the United Kingdom, Italy, Peru, the Canary Islands, and the Texas and Florida coasts of the Gulf of Mexico, among other locations. Pinnipeds are studied in central California, and manatees in Florida. Important but noncontinuing studies of strandings have been done in southern California, in which the focus was solitary strandings, and in the eastern United States, involving mass strandings. Mortality events in which unusually large numbers of deaths of marine mammals, sometimes accompanied by substantial mortality of fish, sea birds and turtles, occur over a period of days to months, are under a special program conducted by the US National Marine Fisheries Service.

III. Differences between Pathology of Strandings and By-Caught Animals

Spontaneous strandings of single animals are believed to be caused by sickness or some other impairment, such as injury, and are therefore a selected and perhaps nonrepresentative element of the population from which they come, while by-catch animals are snatched from their daily lives, and may be presumed to be healthy, or at least representative of the general condition of the population. Diseases seen in these may be a better indicator of the disease status of the population, or, of disease in an early stage, while strandings might represent a late stage. This is mostly a presumption, based on logic rather than observation, although accumulating experience suggests it is true.

“By-catch” is the term used to refer to animals that are caught by accident during the course of trying to catch something else. In the case of marine mammals, it usually means entanglement of the animal in fishing nets. Commonly this involves one or a few animals, but in the early days of the purse-seine tuna fishery in the eastern tropical Pacific Ocean, it might mean hundreds or even thousands of animals. At least two episodic studies of pathology have been conducted on this group of animals, and a continuing study of by-catch is taking place in northern Germany.

IV. Mass Strandings vs Mortality Events and Solitary Strandings

Mass strandings, the more or less sudden appearance on the beach of large numbers of whales or dolphins remains a problem to explain. Various theories have been put forth, such as bad luck of animals swimming inshore, in being caught by an ebbing tide. This presupposes several things; complex bottom topography, a gently sloping bottom, a rapidly moving tide, failure of echolocation in shallow water, interference in echolocation by extraneous noise, and

perhaps distraction of attention by feeding. Other theories implicate an impaired leader who misjudges the tide and leads the herd into a strand, or more likely, fails to lead them away from the beach at the right time. One or two observers even see similarities to lemming migrations, and postulate a mass suicide. All of these theories lack supporting experimental evidence. What is known from the few pathological studies of mass stranded animals is that substantial disease is found, mainly parasitism, which would have been present for some time. Some of this may have been severe, but most is of a tolerable level. If the disease causing the strand was present yesterday or the day before, why did they strand today?

Geraci and St. Aubin (1977) examined the naturally occurring diseases in 41 of a herd of approximately 150 stranded Atlantic white-sided dolphins, *Lagenorhynchus obliquidens acutus*. The most prevalent lesions were associated with parasites; mastitis associated with the nematode *Crassicauda grampicola*, and biliary and pancreatic fibrosis associated with biliary flukes *Oschmarinella laevicaecum*. In these conditions, the parasite enters the duct system and provokes inflammation and scarring. Other parasites commonly found were *Phyllobothrium delphini* and *Monorygma grimaldi* cysts in the blubber and abdomen, *Crassicauda* sp in the fascia, all of which were encysted, and long-term infestations. A roundworm, *Stenurus globicephalae* was present in the cranial air sinuses and lungs, where it caused minor inflammation, and the tapeworm *Tetrabothrius forsteri* was found in the duodenum. These findings are all typical of wild dolphins in the North Atlantic, and cannot be invoked to explain the stranding. This is generally the story of mass strandings; many clues, but little definitive evidence.

“Unusual mortality event” is the term applied to excess deaths (over that known to occur in an average period of time) in a relatively limited geographic area. The difference between a mass stranding and a mass mortality is the time scale and circumstances. The mass stranding is an event of a day or so, while the mass mortality evolves slowly over days, weeks, or months. In contrast to mass strandings, the animals involved in a mortality event are very likely to suffer from infectious disease (Schulman *et al.*, 1997) affecting some segment of the local population, or a toxic event such as the brevetoxicosis associated with red tide (Bossart *et al.*, 1998), or domoic acid toxicity associated with bloom of a particular diatom (Scholin *et al.*, 2000). One obvious difference between an infection and an environmental toxicosis is that the infection, typically viral, tends to be limited to one kind of animal, while the toxicosis may affect mammals, birds, fish, and turtles alike. Epizootic infection can occur among terrestrial animals as well, but an environmental bio-toxicosis is a uniquely aquatic event.

Solitary strandings of dolphins, which may be taken as representative of coastal marine mammal strandings, reflect a variety of causes, from trauma (boat strikes, intra-specific and inter-specific aggression, accidents, and a wide variety of disease causes (Haubold *et al.*, 1999)). This tends to apply more to juvenile and adult animals, while young calves seem to strand more for social reasons, such as separation from the mother, and although debilitated, are less likely to be sick. This observation does not apply to pinniped pups, however, which tend to be suffering from infection, septicemia, dehydration, starvation, or trauma when found stranded.

V. Parasitism

Infestation by parasites is nearly universal in wild animals, and marine mammals are no exception. Indeed, the parasites found in pinnipeds and cetaceans are so widespread, and bear such a consistent

relationship to their hosts and their environments that they have been used as “tags” to study specific mammal populations (Dailey and Otto, 1982). Parasitism is probably the best recognized disease factor in free-ranging marine mammals, and the variety of lesions caused may be illustrated by a few examples.

Parasitism is by far the leading cause of pathology associated with stranding in wild pinnipeds and cetaceans, affecting the brain and lungs as well as the gastrointestinal tract, liver, and pancreas. Large (baleen) whales may suffer kidney damage from *Crassicauda*, and seals may carry heavy, often fatal burdens of heartworm. While parasites occur in other sites, such as in the blubber and under the peritoneal membranes, they are not usually of any particular significance, and apparently are not an important mortality factor.

The great majority of small cetaceans, approaching 100%, have nematode lung worms. These seem to be relatively innocuous as long as they remain in the airways, but provoke an inflammatory reaction on entering the alveolar spaces, the distal sites of air exchange. These delicate tissues lack the defenses of the airways, which are covered by a cell layer adapted to a passageway, and have a thin coat of protective mucin. The parasite in the alveolus, perhaps associated with bacteria, provokes the formation of small abscesses, which rarely may rupture into the pleural space, but typically subside into fibrous nodules (granulomas), which may mineralize. At this stage, they are inert, and probably of no further consequence, except as a marker of past events. In some delphinids, notably the harbor porpoise, *Phocoena phocoena*, in the North Sea, the airways may be filled to occlusion by large nematodes of several species (Siebert *et al.*, 1995).

The effect of parasites in the lungs illustrates very well the influence of adaptation of the lung to diving on the disease process. The cetacean lung differs from the lung of a typical land mammal in that the diving mammal has structural adaptations designed to keep air in the gas exchange spaces, the alveoli, while also tending to eliminate or reduce “dead space.” Dead space is the functional compartment of the lung in which gas exchange does not take place; for practical purposes, the airways. In diving, compression of the animal by surrounding water, which increases with depth, forces incompressible blood into any compressible space. This is familiar to human divers as the “squeeze effect.” In the lung, the alveoli can be collapsed by compression of the chest wall, but the airways are held rigidly open by cartilage bars. It appears that reduction of airway dead space, and prevention of forcing of alveolar air back into airways is accomplished by the action of a series of muscular valves or sphincters within the airway. All of this extra tissue (compared with the lung of a terrestrial mammal) makes the cetacean lung dense and heavy. When an agent such as a lungworm, bacteria, or aspirated contaminated water reaches the distal airways and provokes an inflammatory reaction, it appears that the muscular sphincters go into spasm, preventing movement of air, and evacuation of secretions.

The effect of the peculiar anatomy of the cetacean lung is to cause nearly all infections to form abscesses with focal destruction of tissue. The density of the lung tissues in general prevent spread of the inflammation beyond the local focus. In contrast, bacterial infections of the terrestrial mammalian lung may resolve without destruction of tissue, but may spread in an unconfined fashion to involve large regions of the lung.

Delphinids of many species harbor flukes of the genus *Nasitrema* in the pterygoid air sinuses of the skull. These sinuses connect with the external environment by way of the nasal passages, and by way of the eustachian tubes, with the specialized structures of the ear, the ossicles or acoustic bullae. The bullae are connected to the brain

by the statico-acoustic nerve, concerned with both balance and hearing, which passes into the skull within a dense fibrous sheath. Characteristics of the anatomy of the air sinus, the acoustic bullae, and the statico-acoustic nerve permit invasion by the worm into the subarachnoid space of the brain, in which the spinal fluid circulates. Taking advantage of this space, they migrate over the surface of the brain, until they reach a point of penetration, at which they burrow through the cortex or gray matter deep into the white matter, laying large numbers of eggs (ova). This migration produces destructive tracts or galleries in the white matter, with hemorrhage and necrosis. It is not clear what induces the migration of the parasite into the brain, as it is a dead-end for the worm as well as damaging to the host. It is a complex problem, seen mainly in beach-stranded dolphins in both the Atlantic and the Pacific Oceans. Dolphins of the same species caught as by-catch in the eastern tropical Pacific tuna fishery also have infestations of the same fluke in the air sinuses, but apparently without invasion of the nervous system (Walker and Cowan, 1981). Why this difference should occur is not known. It is possible that a third factor is involved, such as some agent in the in-shore water that influences the worm; that is, makes it “sick” and disoriented. There is clearly a differential species susceptibility among dolphins, as the air sinus infestation occurs with great frequency in stranded Atlantic bottlenose dolphins, *Tursiops truncatus*, but without nervous system invasion.

Flukes of several species (*Campula rochebruni*, *C. oblongata*, among others) infest the bile duct and pancreatic duct of dolphins and porpoises. The effect may be a relatively low-grade irritation or inflammatory reaction ranging up to chronic active inflammation with fibrosis and occlusion of the duct. This results in inflammation and fibrosis of the affected organs, a form of hepatitis (cholangitis) and pancreatitis. Serious disease is relatively uncommon, but may be life-threatening when it occurs.

The stomach and intestine of marine mammals are the frequent site of infestation with nematodes, trematodes, and cestodes. A light infestation may be relatively innocuous, but occasionally the stomach or intestine may be perforated by parasites, resulting in peritonitis. In some geographic areas, gastric ulcers associated with the nematode *Anisakis simplex* are common in stranded cetaceans (Abollo *et al.*, 1998). Sea lions may carry heavy burdens of hookworm.

Massive infestation of the heart and great vessels of elephant seals by nematodes (*Otostrongylus circumlitus*) is described from strandings on the central California coast (Gulland *et al.*, 1997). Heavy burdens in the right atrium, right ventricle, and pulmonary artery were associated with pulmonary thromboembolism (blood clots in the lungs) and pulmonary arteritis, an important cause of mortality. Death of infested juvenile elephant seals before the parasite reaches maturity suggests that the host–parasite association is relatively recent. Similar heartworm infestation occurs in seals in the Atlantic Ocean. This disease is very much like the heartworm infestation of dogs seen in parts of the United States.

VI. Neoplasia

“Neoplasia” is the process of the formation of autonomous new growths in a tissue. The mass of tissue formed is called a tumor. Some of these are benign, meaning limited in capacity to harm, and some are malignant—cancer—having the ability to invade adjacent tissues, and to set up colonies in remote organs and tissues. Some tumors have been shown to be caused by viruses, some by chemicals, and a rare few are associated with parasitic infestation. For most, a definitive “cause” is not known; we can only speak of “associations.”

Once thought to be rare in marine mammals, neoplasms were found to occur at an incidence of 2.5% in a large surveyed population of marine mammals (Howard *et al.*, 1983b). As of 1987, there were probably only 41 confirmable reports of tumors in cetaceans. Then, in 1994, 21 additional tumors, some benign and some malignant, were reported in 12 of 24 animals from the small, isolated, and highly contaminated population of beluga whales (*Delphinapterus leucas*) in the St. Lawrence River, in Quebec (De Guise *et al.*, 1994). Seven of these animals had more than one tumor; one had as many as three tumors, two malignant. One was as young as 1.5 years, another 3.5 years. The ages ranged up to over 29 years. This particular environment, the estuary of the St. Lawrence River, suffers heavy industrial pollution, with the waters containing polycyclic aromatic hydrocarbons (PAH). High concentrations of organochlorines, heavy metals, and benzo-*a*-pyrene were found in the tissues of the belugas. Thirty-seven percent of all tumors reported from cetaceans to that time were found in this small population of belugas, suggesting the direct carcinogenic effect of the pollutants, or an impairment of resistance to the development of tumors.

Gulland *et al.* (1996) reported an incidence of 66 transitional cell carcinomas in a population of 370 (18%) California sea lions examined over a 15-year period. Transitional cell carcinomas are a particular type of cancer that arise from the lining epithelium or membrane of part of the urogenital tract. The original site and cause of this extraordinary incidence of a particular tumor type was a mystery for a number of years, owing to the advanced state of the disease when recognized. Typically, it had spread to involve most of the lower abdominal lymph nodes and viscera, and the primary site could not be determined. Environmental pollution with a variety of industrial chemicals was speculated to be the cause. Recently, using a variety of modern analytical techniques, strong evidence has been found that the cause of the malignancy is infection with a gamma herpesvirus, and not chemical pollution (Lipscomb *et al.*, 1999). This virus is implicated in the etiology of several animal cancers.

These two studies are very instructive, in that they emphasize that a presumed low incidence of tumors in wild populations may be merely an artifact of not looking. When populations of wild animals are studied carefully over a long time clusters of disease may be revealed. They also illustrate the value of modern technology in evaluating cause. In the case of the transitional cell carcinomas, the cause, a herpesvirus, is demonstrated as well as it can be, while the tumors in Belugas are associated with pollution on epidemiological grounds, but have not been conclusively proven to be caused by pollution.

VII. Infectious Disease

In their life in the oceans, marine mammals are exposed to a very great array of infectious agents, including dozens, if not hundreds of species of bacteria, viruses, fungi, and protozoa. These are not randomly distributed, and so actual infection will vary with features such as location, water temperature, contamination from terrestrial sources, river effluents, food species, and exposure to other marine mammals. Most organisms are successfully resisted, and a state of more or less peaceful coexistence maintained. Occasionally, however, an individual's defenses are so weakened or breached that one of these microorganisms can gain effective entry and set up a disease state. Sometimes an otherwise perfectly healthy animal comes into contact with a particularly virulent strain of organism, or simply a novel one to which there is no natural or acquired immunity conferred by previous exposure. Under these circumstances, the organism can sweep through a

population, causing epizootic disease with high death rates. Some isolated, small populations may be seriously threatened with extinction by new infections.

Bacterial, viral, and mycotic (fungal) infections are important morbidity and mortality factors in marine mammals, often appearing in outbreaks, such as one that occurred in the endangered New Zealand sea lion (*Phocarctos hookeri*), involving both adults and pups (Gales *et al.*, 1999). At least 53% of the pups born during the 1998 breeding season (total number was not known) had died within the first 2 months of life, with acute necrotizing inflammation of the blood vessels of the skin and lungs in adults, and pneumonia and abscesses in the pups. The causative agent was determined to be a pleomorphic gram negative bacterium, most likely *Campylobacter* sp., an organism not previously associated with this kind of mortality.

Several viral diseases are well known among pinnipeds, including seal pox virus, and the San Miguel calcivirus, which produce contagious crusted lesions on the skin and oral mucosa. These are serious but not fatal diseases, much like human chicken pox. Seals, sea lions, and dolphins are known to be infected with herpesviruses, and dolphins are susceptible to a pox virus, which produces transient "pin hole" lesions of the skin. Rabies virus is uncommon, but has been observed in ringed seals. Herpesvirus is familiar to most people in the context of the infections known as shingles and cold sores. This virus occurs in many types and strains, some relatively innocuous, others capable of producing severe disease of many organs, including the brain, lungs, liver, and heart as well as the skin. Several outbreaks of herpes infection have been recognized among marine mammals, usually producing skin lesions and sometimes pneumonia, as well as the spectacular incidence of cancer in California pinnipeds.

Morbilliviruses, which comprise a large group of viruses that cause measles in humans, and distempers in dogs and many other species also produce respiratory disease, immune deficiency, and neurological injury in seals, dolphins, porpoises, and a wide range of other cetaceans.

Marine mammals are quite susceptible to infection with morbillivirus. Morbillivirus infections, which were not documented in aquatic mammals until 1988, have caused at least five epizootics in these species in recent years (Kennedy, 1998). Disease has been recognized in seals from Europe and Siberia, dolphins in the Mediterranean Sea, the northern Atlantic Ocean, and the Gulf of Mexico, and seropositivity, indicating previous exposure to the virus, has been found in many species of seal, dolphin, porpoise, and whale, from the Antarctic to the Arctic circle, in Florida manatees, and in polar bears in Russia and Canada. The disease in marine mammals is much like distemper in dogs, with destructive and inflammatory lesions in the brain, gastrointestinal tract, lungs, and lymph nodes, with immune suppression, and frequently superinfection of immune impaired animals with fungi. Lung lesions include broncho-interstitial pneumonia, with filling of alveolar spaces by exudates, hyaline membranes formed by protein exudate covering gas exchange surfaces, and hemorrhage. Brain lesions are typically in the form of nonsuppurative encephalitis (nonpus forming inflammation of the brain), with neuronal and glial necrosis, microgliosis (the brain equivalent of scar), and focal demyelination, or loss of the insulating covering of nerve processes. Necrosis of the cerebral cortex is also sometimes found (Kennedy, 1998).

It is not entirely clear whether the observed increase in cases of the morbillivirus distempers is due to actual spread of the infection, or improved case-finding permitted by clear descriptions of the lesions in the literature, accompanied by the development of advanced methods of laboratory diagnosis.

Many bacterial species are found in marine waters and may be recovered from marine mammals, either as primary pathogens, or as part of a complex normal flora. Bacterial infection is thought to be the main cause of disease and death in marine mammals, especially in captivity (Howard *et al.*, 1983a). Certain marine organisms are known to produce severe or fatal infections. These include the halophilic or salt-water *Vibrios* of which there are many species, and *Edwardsiella tarda*. These organisms are common in the marine environment, and are frequently encountered in cetaceans, and less often in pinnipeds. The exact means by which these organisms are acquired by marine mammals is not known, but experience with humans indicates that they can be directly inoculated, infect wounds, and be ingested with food items, such as shellfish. It is reasonable to assume these routes of entry in marine mammals as well.

The *Clostridia* are obligate anaerobic bacilli, ubiquitous in the environment in soil, sewage, marine sediments, decaying animals and plant products, and the intestinal tracts of many animals. More than 80 species are known. Some species are potent toxin producers, causing botulism and gas gangrene. Many species of *Clostridia* have been cultured from blood, lesions and intestinal tract of stranded dolphins in the Gulf of Mexico, but are less common in California pinnipeds. Some *Clostridia* may be merely part of the normal intestinal flora, while some species have been recovered from lungs in cases of pneumonia.

Many species of bacteria have been recovered from cultures of respiratory tract, kidney, and intestinal tract as well as lesions of captive and stranded marine mammals. The majority of these species are known to be pathogenic or potentially pathogenic. There may be a differential distribution of bacteria in different kinds of marine mammals, as in cetaceans *Vibrio*, *Clostridia*, *Pseudomonas*, and *Edwardsiella* tend to predominate, while in pinnipeds from the California coast, for example, the major pathogens encountered in sea lions, elephant seals, and harbor seals are organisms usually associated with the intestine, mainly *Escherichia coli*, *Klebsiella pneumoniae*, *K. oxytoca*, *Proteus spp.*, *Pseudomonas spp.*, *Enterococcus spp.*, and *Salmonella*. Leptospirosis occurs in harbor seals, California sea lions, and northern fur seals.

Brucella infection of the placenta with abortion has been reported in dolphins. The organism, *Brucella delphini*, appears to be readily transmissible among dolphins and has also been cultured from the lung of a bottlenose dolphin at necropsy. *Brucella* meningoencephalitis with hydrocephalus also has been recognized. Brucella infection occurs in other cetaceans and seals. A substantial percentage of marine mammal serum samples (about 30%) react positively on tests used to detect antibody to *Brucella spp.*, and a number of *Brucella* isolates have been obtained from marine mammals. However, only the one first designated *Brucella delphinus* has been associated with reproductive failure. Exactly how many species of marine Brucella exist is under investigation.

The mycobacteria include the organisms that cause tuberculosis and leprosy. They are hardy organisms, and may produce infection across a wide array of warm and cold blooded animals. *Mycobacterium marinum*, originally described from fish, was first recognized as a human pathogen in 1951. *M. marinum* infection has been transmitted to a handler by a dolphin bite. The lesions, when localized resemble abscesses, but are very slow to heal. Infection of deeper tissues and organs, such as heart valves, brain, eye, and joints are very serious. *Mycobacterium bovis*, the agent of bovine tuberculosis, was transmitted from seals to their trainer. It caused similar lesions in both. Six cases of tuberculosis were observed over a 4-year period in stranded sea lions and fur seals from the coast of Argentina

(Bernardelli *et al.*, 1996). Disease was widespread, involving lungs, lymph nodes, liver, spleen, pleura, and peritoneum. The lesions were typical granulomatous inflammation, from which organisms belonging to the *Mycobacterium tuberculosis* complex were isolated. This organism complex was similar to both *M. bovis*, the agent of bovine tuberculosis, and *M. tuberculosis*, the agent of human tuberculosis, but with enough molecular differences to be judged different from both. This suggests that the seals and sea lions did not acquire their infection from contact with humans or cattle. The organisms associated with the pinniped cases all had similar genetic features, suggesting that seal tuberculosis in that geographic area is caused by organisms belonging to a distinct grouping within the *M. tuberculosis* complex. An instance of disseminated *Mycobacterium chelonae* infection in a manatee (*Trichechus inunguis*) has been reported, and cases of cutaneous mycobacteriosis in a manatee and its handler have been attributed to *M. chelonae*. This organism was first identified in a reptile.

Marine mammals are subject to infection with a wide variety of fungi and filamentous bacteria (*actinomyces*, *nocardia*, *dermatophilus*, which produce lesions similar to those caused by fungi) (Migaki and Jones, 1983; Reidarson *et al.*, 1999). Some of these are opportunistic, meaning that they occur in the context of debility or other disease, and some are primary pathogens capable of initiating disease in healthy hosts. Both opportunists and pathogens are species that are familiar in human and veterinary medicine, and are not peculiar to the marine environment.

Animals suffering immune suppression from morbillivirus disease may suffer severe, disseminated fungal infection, frequently from molds such as *Aspergillus spp.*, as a terminal event. These organisms may produce disease in one of the two patterns: superficial infections of skin which cause mild disease, or indolent, very chronic processes; and the deep or systemic mycoses, which produce severe pyogranulomatous lesions. A pyogranulomatous lesion is a mixture of granulomatous inflammation, which is produced by persistent infection, with a pus-forming acute inflammation, indicative of a more active injury. Deep infections may involve any organ, especially the lungs and respiratory tract, and the brain. They may produce bulky lesions, which displace normal tissues ("mass lesion") as well as destroy tissues. Some organisms tend to permeate tissues, and invade and block blood vessels.

Dermatophytoses, ringworm-like lesions, occur in manatees and pinnipeds, caused by the same organisms that cause ringworms in land animals and humans. Since infection with fungi requires spores from the environment, rather than the vegetative stages found in marine mammals, direct transmission from animal to animal seems unlikely. Lobo's disease, caused by a fungus *Loboa lobo* (syn. *Lacazia lobo*), is a very unusual disease recognized only in dolphins and humans, and no other species. One instance of transmission from dolphin to human has been reported. Lobo's disease (once called keloidal blastomycosis) is a skin infection producing chronic, treatment-resistant, thick nodular swellings of the superficial dermis and epidermis, occasionally with ulceration. While the lesions in man and dolphin are quite similar, there are subtle morphological differences in the organisms in the lesions, which may represent separate species (Haubold *et al.*, 2000). In man, Lobo's disease is a disease of the Central and South American tropics, while in dolphins it ranges from the Gulf of Mexico, mainly Florida, to South America.

A number of protozoal infections, similar to those seen in land animals are known to occur in marine mammals. These include toxoplasmosis, infection with *Toxoplasma gondii*, found in a West Indian manatee, pinnipeds, stranded Atlantic bottlenose dolphins, *Tursiops*

truncatus, a Pacific spinner dolphin, *Stenella longirostris*, Beluga whales, *Delphinapterus leucas*, and a killer whale, *Orcinus orca*. The animals were found both in Atlantic and Pacific Oceans, were captive and free-ranging, and the lesions ranged from incidental to disseminated and fatal. The mode of transmission in these animals is not known. *Cryptosporidium* morphologically, immunologically, and genetically indistinguishable from those obtained from infected calves have been recovered from feces of California sea lions (*Zalophus californianus*) suggesting that the sea lion could serve as a reservoir for environmental transmission of this organism. Giardia have been isolated from fecal material from harp seals (*Phoca groenlandica*), gray seals (*Halichoerus gryphus*), and harbor seals (*Phoca vitulina*) in eastern Canada waters and ringed seals (*Phoca hispida*) from western arctic Canada, and from California sea lions in northern coastal California. The widespread occurrence of these organisms in both terrestrial and marine mammals suggests transmission via rivers and streams, and perhaps carrier species taken as food.

VIII. Chronic Diseases of Undetermined Cause

Several chronic diseases of unknown cause have been recognized in dolphins and small whales stranding along the Texas coast of the Gulf of Mexico. These are arthritis, pulmonary angiomas, and amyloidosis.

A high incidence of arthritis of the synovial joints (neck and flipper joints) was found in several cetacean species, including 10 of 49 (20%) bottlenose dolphins (*T. truncatus*), 1 of 2 (50%) striped dolphins (*Stenella attenuata*), one Fraser's dolphin (*Lagenodelphis hosei*), and one pygmy sperm whale (*Kogia breviceps*) (Turnbull and Cowan, 1999a). Some of these cases were associated with infection of the joint, while others showed features typical of degenerative or osteoarthritis, commonly thought of as a disease of aging. Two such cases however, were in immature animals. The severity of disease ranged from relatively minor loss of articular cartilage, to complete destruction and fusion of the joint.

Angiomas, a newly recognized and bizarre disease, initially found only in bottlenose dolphins from the Texas coast (Turnbull and Cowan, 1999b), has now been seen in dolphins of other species from the coast of Florida and southern California. This disease was first recognized in 1991 in a minor form, but over the following 9 years increased in incidence and severity to involve all adult bottlenose dolphins stranding on the Texas coast. It is characterized by the proliferation of small blood vessels in the lungs to form small clusters. It involves all parts of both lungs equally and to the same degree, and is not associated with inflammation. These vascular clusters progressively enlarge and fuse. In advanced stages of the disease, the walls of the new vessels thicken and lumens are reduced. Proliferation of vessels in the bronchial lining mucosa erodes the bronchial cartilages and severely constricts airway diameter. The normally very thin and pliable pleura is similarly involved, and becomes thick, stiff, and opaque, reaching a thickness of 3 mm. The effect on respiratory physiology has not been measured, but the gross and microscopic appearance suggests marked impairment of lung ventilation and restriction of circulation. One animal with advanced disease had massive thickening of the right ventricle of the heart, suggesting marked increase in pulmonary artery blood pressure (pulmonary hypertension). Lymph nodes associated with the lungs, in advanced cases may also show a pronounced vascular proliferation, and hemangiomas (tumors of blood vessels) are a common finding in the lymph nodes and an occasional one in the lungs. The cause of this disease is not known.

Amyloidosis, a disease characterized by a deposition of a dense amorphous waxy proteinaceous material in the interstitial tissues of various organs occurs in bottlenose dolphins stranding along the Texas coast of the Gulf of Mexico at an incidence of about 20%, a remarkable figure considering that the disease had not been reported from any other cetacean species (Cowan, 1995). It has since been found in beaked whales in Japan. Amyloid deposition occurs consistently in the kidneys, but also in small arteries in the spleen, heart, and lungs, and around the acini of the thyroid gland and the palatal salivary gland. In the amounts present, the amyloidosis likely did not result in death, but experience in man and other animals is that it can progress to organ failure. Several causes and associations are known for amyloidosis in man and other animals, including chronic infection and disorders of the lymphoreticular system, but the cause of dolphin amyloidosis remains obscure.

IX. Stress

Similar recurring patterns of changes in organs and tissues have been observed in many species of beach stranded, net-caught, and captive dolphins at necropsy. They occur across species and appear to be generalizable in cetaceans. The changes are consistent with injury caused by massive release of endogenous catecholamines (adrenalin, noradrenalin) or by spasm of small cardiac arteries, with ischemia and reperfusion. This recurring pattern of pathology includes a particular pattern of necrosis of cardiac and smooth muscle; ischemic injury to the intestinal mucosa, especially the mucosa of the small intestine; and acute necrosis of the proximal tubules of the kidney. The pattern appears to result from a stereotypic stress response, independent of the nature of the provoking stimulus. It may explain the propensity of otherwise hardy animals to die in an otherwise nondamaging stressful situation.

This pattern of injury appears to be rooted in the physiologic adaptations of cetaceans that are associated with a fully aquatic life. In a voluntary dive, these are reflective of exercise, including a reflexive breath holding (apnea), with voluntary override, minimal cardiovascular adjustments, and a general maintenance of aerobic metabolism, the *dive response*. A dolphin in an *involuntary* dive situation undergoes a "dive reflex," better termed as an *alarm reaction*. This includes not only the reflexive apnea, but also decreased heart rate (diving bradycardia), reduction of cardiac output, vasoconstriction with markedly decreased perfusion of gut, liver, kidneys, and skeletal muscle. The clear implication of the distinctive reactions to voluntary and involuntary diving is that the dolphin is responding to the environment *as it is perceived*; the triggering of the alarm reaction is a reaction to a situation interpreted by the dolphin as a dire threat, and is responded to by a marked autonomic reaction. Since the major threats to an aquatic, air breathing mammal are drowning and predation, the alarm reaction is an accentuation of the physiologic dive and escape responses.

Histopathologic findings suggest that the reflexive response of a dolphin to any major perceived threat, the alarm reaction, is to activate all the physiologic adaptations to diving or escape to an extreme or pathological level, resulting, if greatly prolonged, in widespread ischemic injury to tissues. A dolphin in extreme physical or psychological distress will exhibit an extreme, protracted alarm reaction. These observations may explain the mechanism whereby "sensitive" species die abruptly from handling or transportation, why the mortality of highly stressed beach stranded animals is very high.

X. Conclusions

There is much to be learned from the study of the pathology of marine mammals. Work by many observers over the past 30 years

has done much to reveal the causes of sickness and death among these heretofore mysterious animals. We are coming to understand how similar the diseases of marine mammals can be to those of terrestrial mammals, and how different they can be. This is well illustrated by the evolution of inflammatory processes in the lung, which are strongly influenced by the special anatomy of the diving lung, and by the phenomenon of cerebral parasitism, which appears to depend not only on the special anatomy of the nasal passages, air sinuses, the specialized inner ear and their relations to the brain, but also exposure to a very specific parasite.

Recognition of similarities in tissue structure and diseases can be treacherous if we approach the study of the diseases of marine mammals as if they are just like land animals, only wet. What we see, or think we see may mean something very different than it would mean if we saw it in a land animal.

A great deal has been learned about the anatomy and physiology of pinnipeds and cetaceans in particular, and especially about cetaceans, who have taken typical mammalian systems, inherited from what many believe to be terrestrial forbears, back into the water and made them work there. The adaptive changes in the anatomy of the lungs in particular, which influence the development of disease processes in that organ are plain and obvious. These are the adaptations we can see and are relatively easy to puzzle out. We are only now gaining insight into the unseen adaptations, such as the metabolic management of mercury, a protoplasmic poison. The vast majority of mercury (and most other toxic metals) in the environment is from natural, not industrial sources, and comes from rocks and the soil. They are leached out by rain and reach streams, rivers, and ultimately the oceans. These metals have always been present in the environment, perhaps not in the levels now recognized in some geographic regions. However, the adaptive experience of animals who spend their entire lives in the water, and whose food consists of other organisms that spend their entire lives in the water has endowed them with startling abilities. These natural toxins cannot be avoided; they must be dealt with within the metabolic capacities of the animal who is inevitably exposed to them. Who could have predicted that a dolphin can carry a burden of mercury in its tissues sufficient to kill a cow four times over, and still be healthy? The next task is to understand better these unseen adaptations, so that we do not misread or misunderstand the message that Nature is sending us about the state of our oceans, written in the tissues of marine mammals.

Peale's Dolphin

Lagenorhynchus australis

R. NATALIE P. GOODALL

I. Characteristics and Taxonomy

Peale's dolphin (*Lagenorhynchus australis*) is common in inshore waters of southernmost South America, but because it seldom strands, its natural history is not well known. Nearly

a century passed before the first descriptions of its pigmentation and a museum skull were discovered to be of the same species. It is the most coastal of the three species of *Lagenorhynchus* inhabiting the Southern Hemisphere.

This species was first described as *Phocaena australis* Peale, 1848 and *Sagmatias amblodon* Cope, 1866. Although lumped with *Delphinus obscurus* and *L. cruciger* at different times, the present combination *Lagenorhynchus australis* was proposed by Kellogg in 1941. *Tursio chiloensis* is a synonym. A review of the early specimens and the history of classification of this species are given by Goodall *et al.* (1997a, b). New work with DNA shows that the genus *Lagenorhynchus* needs revision and that the genus name of one Northern Hemisphere species and the three Southern Hemisphere SPECIES should revert to *Sagmatias*. Although there have been several common names in English, Peale's dolphin is now standard. *Delfin austral* (southern dolphin) is the common name in Argentina and Chile, although *llampa* is sometimes used in the latter.

Peale's dolphins are dark gray or black on the dorsal surface, with two areas of lighter pigmentation on the sides (Fig. 1). A curved white-to-gray flank patch angles forward from the vent, narrowing to a single line ending below or in front of the dorsal fin. The posterior curves of the flank patch almost meet above the tail stock. The larger thoracic patch is light-to-medium gray, outlined with a narrow dark line on its lower surface. Both patches may be flecked with darker gray. A double black eye ring extends forward onto the snout, which is inconspicuous. The black chin or throat patch varies individually in the shape of its posterior border, usually extending backward on the sides to leave a forward-pointing white area in the middle. The white flipper patch is also delineated with gray and may extend onto the ventral part of the flipper. The flippers and dorsal fin are dark with lighter posterior edges. Flippers in older animals may have a series of small knobs on the leading edge. The ventral surface behind the throat patch is white, with a few dark streaks in the genital area. Young animals are lighter gray than adults and have less definition between thoracic and flank patches. Variations in pigmentation have been illustrated by Goodall *et al.* (1997b).

Peale's dolphins can be confused with dusky dolphins, *L. obscurus*, throughout much of their range. The latter are usually a lighter gray and have white on the sides of the face and two light lines running forward from the flank patch, while the Peale's dolphin has a dark chin and only one line running forward along the back.

This is a stocky dolphin with the barest indication of a beak. Total length for 35 specimens ranged from 98 to 218 cm. Females ($n = 20$)

Figure 1 Peale's dolphin, *Lagenorhynchus australis* (C. Brett Jarrett).

measured 130–210 cm, males ($n = 9$) from 138 to 218 cm, and animals of unknown sex ($n = 5$) from 172 to 213 cm. The collections to date probably do not represent the total size range for the species. The heaviest animal ($n = 5$), a sexually mature female, weighed 115 kg.

The number of teeth is variable, with up to 37 upper and 34 lower teeth in each jaw. The mouth is unusual in having a wide lip outside the tooth line, which may be useful in capturing small squid and octopus (Goodall *et al.*, 1997b).

The condylobasal lengths of 27 skulls ranged from 352 to 359 mm. The vertebral count is CV7 with the first two fused, T14, L13–16, Ca 31–34 for a total of 66–70, normally 67–68. The Peale's dolphin is larger and more robust than the other two southern *Lagenorhynchus*, *L. obscurus*, and *L. cruciger*, with larger, more massive vertebrae. The phalangeal number is I = 2–3, II = 6–9, III = 5–6, IV = 2–4, V = 0–2.

II. Distribution and Abundance

Peale's dolphin is a southern South American species commonly found from 59°S (the Drake Passage south of Cape Horn) northward to Valdivia, Chile (about 38°S) on the west coast and Golfo San Jorge, Argentina (44°S) on the east, including the Falkland Islands (Islas Malvinas), with exceptional records to 33°S in the southeastern South Pacific and 38°S in the southwestern South Atlantic (Fig. 2). Sightings of animals similar to *L. australis* in 1988 near the Cook Islands, in tropical waters thousands of miles from its normal distribution, have been considered an anomalous occurrence by some authors or perhaps a new species by others (Leatherword *et al.*, 1991).

III. Ecology

Peale's dolphins occupy two major habitats: (a) open coasts over the shallow continental shelf of the eastern coast of Patagonia and Tierra del Fuego and Chile north of Chiloé and (b) the deep, protected bays, and intricate channels of southern Chile. In the channels, this is an “entrance animal” found in tide rips at the entrance to fjords. They will join a vessel entering a fjord and accompany it to its anchorage; later the dolphins appear when engines are started and accompany the vessel to the mouth of the fjord, where they turn back.

Peale's dolphins are strongly associated with kelp (*Macrocystis pyrifera*) beds. Observed from the coast, they often swim inside, through channels, or on the border of kelp beds. When traveling, they swim outside the kelp. Although their distributions overlap, Peale's dolphins are usually coast hugging, while the similarly pigmented dusky dolphin is mainly found a few miles seaward. There is no information on abundance, stocks, or population size.

Habitat preferences have been studied in the waters of the Chiloé Archipelago (42–43°S), where Chilean dolphins (*Cephalorhynchus eutropia*) select shallow coastal waters (up to 500 m from shore and 20 m in depth) near rivers in southern Chiloé while Peale's dolphins prefer similar areas over shallow shoals in central and southern Chiloé, an area densely occupied by extensive salmon and shellfish (mussel) farms (Heinrich *et al.*, 2008).

Peale's dolphins are noted for feeding in the kelp, where divers collecting sea urchins have observed them picking small octopus from the kelp fronds, probably assisted by their wide, flat lips. They also feed in open waters beyond the kelp on fish, often using the “sunburst” formation for herding. Few stomachs have been examined ($n = 16$) and those only from the southwestern South Atlantic. About 20 prey taxa have been identified, mainly demersal and bottom fish,

octopus, and squid species common over the continental shelf or in kelp beds. The most important prey were bottom fish: hagfish (*Myxine australis*), southern cod (*Salilota australis* and Patagonian grenadier (*Macruronus magellanicus*), followed by red octopus (*Enteroctopus megalocyathus*) and Patagonian squid (*Loligo gahi*). Two very young animals from the eastern Beagle Channel had salps as well as milk in their stomachs (Schiavini *et al.*, 1997).

Peale's dolphins associate closely with other dolphins, especially Commerson's dolphins (*C. commersonii*). We have watched a Peale's dolphin swim with several of these dolphins near shore, moving southward along the Páramo Península for several miles. In Chilean waters, they share shallow bays with Chilean dolphins, occupying areas just slightly seaward of these coastal dolphins.

No predators but humans are known, although killer whales, leopard seals, and sharks are possibilities. In a study of the food of 22 broadnosed seven-gill sharks (*Notorynchus cepedianus*), 30% of the stomach contents were of marine mammals: three species of pinnipeds and two of cetaceans, although no actual attacks on living animals were observed. Parts of three cetaceans were found in three stomachs; one of these may have been the tail of a Peale's dolphin (Crespi-Abril *et al.*, 2003).

IV. Behavior and Physiology

Peale's dolphins are most often seen swimming slowly in or near the kelp. Dive times range from 3 to 157 sec, with an average of 28 sec ($n = 723$), with three short dives followed by a longer one. They commonly BOW RIDE, with much head movement, rolling, BREACHING, spy hopping, and spinning. They produce a wide splash when surface swimming, earning the name “plough-share” dolphins.

Group size is usually small, from 2 to 5 animals, but aggregations of up to 100 have been seen. Their behavior still needs to be investigated.

Near Isla Chiloé and in the Strait of Magellan, resident groups have been noted throughout the year, although more animals were present during summer. In southern Tierra del Fuego, animals also seem to move inshore during summer, possibly following fish migrations, and are seldom seen in winter. It is not known whether the dolphins in different parts of the range belong to different populations or stocks.

Pulsed sounds were recorded in the Chilean channel region, revealing broadband clicks at 5–12 kHz and narrowband clicks at 1–2 kHz bandwidths. Whistle-like squeals were not recorded, but may have been above the limits of the recording equipment used.

V. Life History

There is little information on reproduction. A female of 185 cm was sexually immature, one of 193 cm was pubescent, and one of 210 cm was mature. There is no information on sexual maturity in males. Calves have been reported from spring through fall, October to April. Physical maturity, on the basis of epiphyseal fusion, has been recorded for 24 specimens. Neonates measured 98–130 cm, juveniles 138–176 cm, subadults 142–210 cm, and adults over 190 cm. The oldest animal was a physically mature female with 13 growth layer groups (GLGs) in the teeth.

VI. Interactions with Humans

As far as we know, no Peale's dolphins have been kept in CAPTIVITY.

Peale's (and possibly Commerson's) dolphins are credited with coming to the rescue of Indonesian seamen who jumped overboard

Figure 2 The distribution of Peale's dolphin, based on sightings and strandings from 1839 to 2007.

from their fishing vessel near Port Stanley in the Falkland Islands (Islas Malvinas) in February 2007. The seamen were nudged upward from below by dolphins until they could be picked up by boats. Two seamen drowned, but eight were saved (Anonymous, 2007).

One specimen had a piece of fishing net balled in its first stomach and impacted with food items.

Prehistorically, Peale's dolphins were exploited for food by the canoe people of the channels of southernmost South America; remains have been found in kitchen middens dated at 2500 and 6000 years before present. More recently, a few dolphins were taken for scientific research.

Peale's dolphins have been heavily exploited for crab (*centolla*, *Lithodes santolla*) bait in the Magellan region of southern Chile since at least the early 1970s, with highest exploitation in the 1980s (Lescrauwaet and Gibbons, 1994). Overfishing, resulting in greatly reduced populations of crabs, has led fishermen to concentrate on other types of fishing that do not need bait, such as scallops and sea urchins. In addition, crabbing companies now supply bait to their fishermen, so there is less illegal take of dolphins. The full extent of the exploitation of dolphins for crab bait at present in Chile is unknown, but is thought to be much less than formerly. A few Peale's dolphins were taken for crab bait in eastern Beagle Channel in Argentina in the late 1970s and early 1980s, but this has not continued. However, these dolphins have not recolonized the areas of the Beagle Channel with denser human population, but are seen to the east, far west, and southern areas near Cape Horn.

Although common, Peale's dolphins are rarely taken incidentally in nets in the northern part of their range between Valdivia and San Antonio in Chile. A few dolphins have been caught in anti-pinniped nets near the salmon pens in the Isla Chiloé area. A small incidental take occurs in shore-set gill nets off Tierra del Fuego in Argentina, but fishermen claim that Peale's dolphins are usually strong enough to fight and release themselves from the net (Goodall *et al.*, 1994). Likewise, a few Peale's dolphins die in offshore fishing activities south of Golfo San Jorge, but not as many as other species. The extent of this exploitation is unknown; it represents a potential danger that should be monitored.

Kelp forests seem to be a fundamental habitat for Peale's dolphins in coastal ecosystems and their protection may be crucial for the conservation of this species (Viddi and Lescrauwaet, 2005). The coastal habitat preferred by this species is compromised in certain areas of their distribution by extensive salmon and mussel farming activities (Heinrich *et al.*, 2008).

Pilot Whales

Globicephala melas and *G. macrorhynchus*

PAULA A. OLSON

I. Characteristics and Taxonomy

Two species are recognized: *Globicephala melas* (long-finned pilot whale) and *G. macrorhynchus* (short-finned pilot whale).

Adult pilot whales reach an average length of approximately 6 m. Males are larger than females. Most pilot whales appear black or dark gray in color. The body is robust with a thick tailstock. The melon is exaggerated and bulbous, and there is either no beak

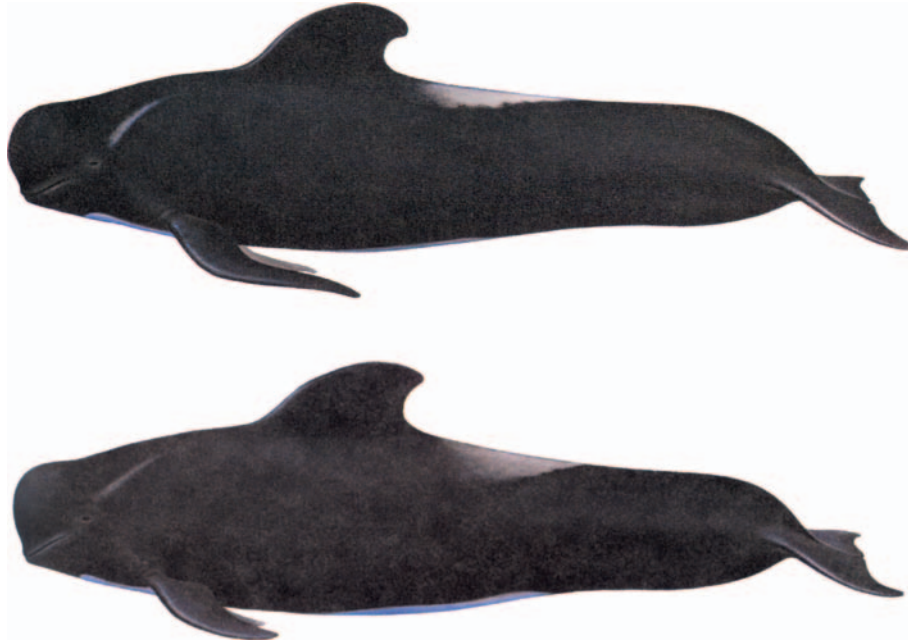

Figure 1 Full-body view of the long-finned pilot whale (top) and the short-finned pilot whale (bottom). Drawings courtesy of P. Folkens.

Figure 2 A group of male and female pilot whales. Males are larger than females and develop exaggeratedly wide dorsal fins. Photo by P. Olson.

Figure 3 This group of long-finned pilot whales with a calf exhibit the external features common to both species including a bulbous melon and a broad-based dorsal fin. Photo by P. Olson.

or a barely discernible one. A wide, broad-based falcate dorsal fin is set well forward on the body. The flippers are long, slender, and sickle shaped. A faint gray “saddle” patch may be visible behind the dorsal fin as well as a faint postorbital blaze (Fig. 1). On the ventrum, a gray midline extends anteriorly into an anchor-shaped chest patch and widens posteriorly into a genital patch. Calves are paler than adults.

Pilot whales exhibit striking sexual dimorphism in size, similar to that observed in sperm whales (*Physeter macrocephalus*) and killer whales (*Orcinus orca*). Adult males are longer than females, develop a more pronounced melon, and have a much larger dorsal fin (Fig. 2). The function of sexual dimorphism in pilot whales is unknown, although several have been hypothesized. The males’ enlarged features may be used for display to other males or females or for increased agility when maneuvering for mate access or for herding

females. The males’ large size may aid in defense of their school from attacks by killer whales or sharks.

Long-finned and short-finned pilot whales are difficult to distinguish at sea (Fig. 3). The morphological differences between the two species are subtle: length of flippers, differences in skull shape, and number of teeth (Bernard and Reilly, 1999). On average the pectoral flippers of long-finned pilot whales are one-fifth the body length, whereas on short-finned whales they are one-sixth the body length.

Figure 4 (A) Dorsal view of the skull of a long-finned pilot whale (*G. melas*). (B) Dorsal view of the skull of a short-finned pilot whale (*G. macrorhynchus*). Note the differences in the shape and length of the rostrums and the degree to which the maxillae are covered by the premaxillae. Illustration courtesy of Uko Gorter.

However, overlap exists between the two species. Long-finned flippers exhibit a noticeable “elbow” whereas short-finned pectorals have a more curved appearance.

Because most size, shape, and color pattern distinctions between the two species are so variable, the shape of the skull is the only definitive characteristic for identification to species. The long-finned pilot whale has a narrower skull, with the premaxillae leaving uncovered 1 cm of the lateral borders of the maxillae (Fig. 4A). There are 9–12 teeth in each row. The skull of the short-finned pilot whale is shorter and broader, and the premaxillae cover the maxillae (Fig. 4B). There are seven to nine teeth in each row. Pilot whales have notably fewer teeth than most other delphiniids. This is similar to the evolutionary reduction of teeth found in Risso’s dolphins (*Grampus griseus*) and sperm whales, two other heavy squid consumers.

The extant delphinid groups (to which *Globicephala* belongs) appeared in the Middle to Late Miocene Epoch. Fossils of the genus *Globicephala* dating from the Pleistocene Epoch have been uncovered in Florida (*G. baerreckei*). Odontocete remains from the Pliocene Epoch uncovered in Tuscany, Italy, have been designated as *Globicephala? eturia*.

The name “pilot whale” originated with an early theory that a school is piloted by a leader. Other common names for these whales

include pothead (after the whales’ bulbous melon) and blackfish (a term also used for melon-headed whales, pygmy killer whales, and false killer whales). The genus name, *Globicephala*, is derived from the Latin word *globus*, meaning round ball or globe, and the Greek word *kephale*, meaning head. *Melas* is a Greek word for black. The trivial name *macrorhynchus* is likewise derived from Greek words: *macro*, meaning enlarged and *rhynchus*, meaning snout or beak. For many decades, *malaena* was used as the trivial name for the long-finned pilot whale. However, in 1986 the name was revised to *melas*.

II. Distribution and Abundance

Pilot whales are wide ranging and abundant (Fig. 5). Generally, short-finned pilot whales have a tropical and subtropical distribution, and long-finned pilot whales are distributed antitropically. There is little overlap in the range of the two species. Areas of marginal overlap include the temperate waters of the North and South Atlantic, in the Pacific off the coast of Peru, and off South Africa. Pilot whales are found in both nearshore and pelagic environments.

Long-finned pilot whales inhabit the cold temperate waters of both the North Atlantic and the Southern Ocean. Whales in the two hemispheres are isolated and are accorded subspecies status: *G. melas melas* in the North Atlantic and *G. melas edwardii* in the Southern Hemisphere. There are slight morphological differences between the subspecies. In the North Atlantic, the range of *G. melas melas* includes the waters of Greenland (Denmark), Iceland, and the Barents Sea south to the Tropic of Cancer. The species is present in the western Mediterranean Sea. *G. melas edwardii* is circumglobal in the Southern Hemisphere, with records as far north as 14°S in the Pacific and farther south than the Antarctic Convergence. Although the long-finned pilot whale does not currently inhabit the North Pacific, skulls dated to the eighth to twelfth centuries have been recovered in Japan. Short-finned pilot whales now inhabit those waters.

Short-finned pilot whales are found worldwide in tropical, subtropical, and warm temperate waters. Their northern range in the Atlantic extends to the mid-coast area of the United States and to France. Short-finned pilot whales are not found in the Mediterranean. Latitude 25°S marks the southernmost record for the Atlantic and the Pacific coasts of South America. Elsewhere in the Pacific, the range of the short-finned pilot whale continues north to Japan and to the west coast of the United States.

Pacific short-finned pilot whales in higher latitudes are generally larger than those in lower latitudes. Two distinct populations of short-finned pilot whales are found off northern and southern Japan. These populations exhibit morphological differences in external and cranial features. The populations are segregated geographically and genetically. However, their exact taxonomic status is undetermined and currently they are both classified as *G. macrorhynchus*.

Estimates of abundance for pilot whales have generally been undertaken in response to management issues. Survey areas are typically determined by management goals rather than natural population boundaries. Most of the quantitatively derived estimates of abundance are for nearshore populations. Estimates using line-transect methods have been made for the eastern US and Canada, Newfoundland/Labrador (Canada), the northeast Atlantic, northern and southern Japan, Hawaiian Islands, the US west coast, the eastern tropical Pacific, the US Gulf of Mexico, and the Antarctic (Table I).

III. Ecology

Pilot whales are generally nomadic, but resident populations have been documented in a few locations such as coastal California and

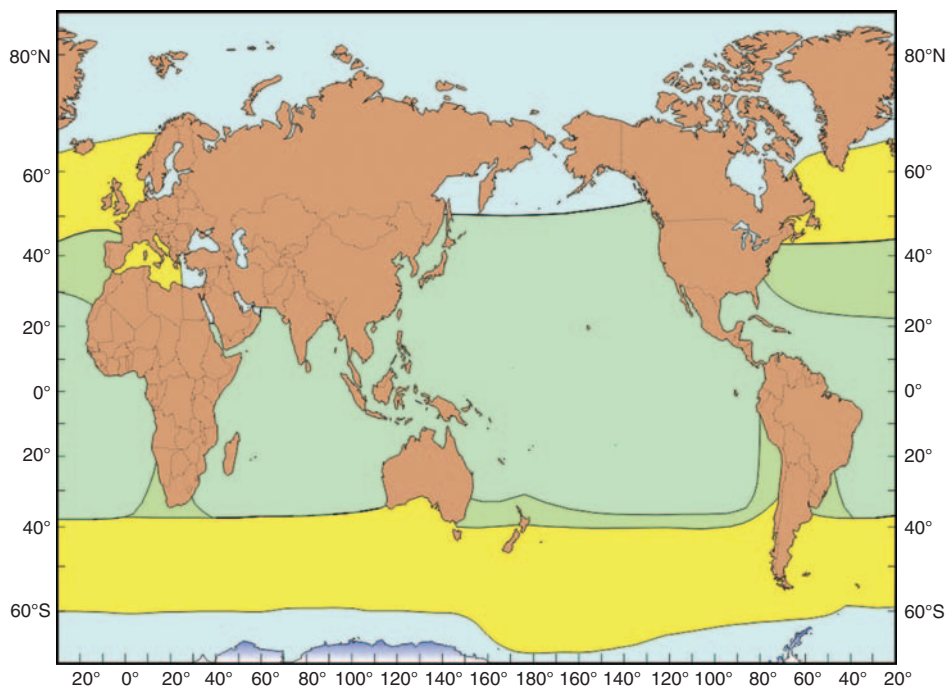

Figure 5 Worldwide distribution of pilot whales. The distribution of long-finned pilot whales is indicated by yellow and the distribution of short-finned pilot whales by light green. Dark green indicates areas where the species overlap.

^aEstimates of abundance for this area vary between years, likely the result of whales moving in and out of the area in response to oceanographic conditions.

Hawaii. Common habitats are the continental shelf break, slope waters, and areas of high topographic relief. Seasonal inshore/offshore movements of pilot whales are related to the distribution of squid, their favorite prey. Studies in Newfoundland and California correlated the seasonal abundance of pilot whales with spawning squid. Individual whales have been recorded moving distances up to 2400km/month.

The pilot whale diet consists primarily of squid, with lesser amounts of fish. Fish prey in the northwest Atlantic include Atlantic cod (*Gadus morhua*), Greenland turbot (*Rheinhardtius hippoglossoides*), Atlantic mackerel (*Scomber scombris*), Atlantic herring (*Clupea harengus*), hake (*Urophycis* spp.), silver hake (*Merluccius*

bilinearis), and spiny dogfish (*Squalus acanthias*). Pilot whales in the northeast Atlantic have been known to take Atlantic Argentine (*Argentina silus*) and blue whiting (*Micromesistius poutassou*).

The ecosystem changes brought about by a strong El Niño event in 1982–1983 affected the distribution of pilot whales off southern California dramatically. With the influx of warm water during the El Niño, squid did not spawn as usual in the area. Pilot whales were virtually absent from the region that year and remained so for another 9 years. It is not known where the whales went during that time or whether the whales sighted there now are returning or are new individuals.

Pilot whales are often observed in mixed species aggregations. They are most commonly sighted in association with common bottlenose dolphins (*Tursiops truncatus*) but have also been seen with short-beaked common dolphins (*Delphinus delphis*) Atlantic white-sided dolphins (*Lagenorhynchus acutus*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), striped dolphins (*Stenella coeruleoalba*), Fraser's dolphins (*Lagenodelphis hosei*), melon-headed whales (*Peponocephala electra*), killer whales, fin whales (*Balaenoptera physalus*), sperm whales, and gray whales (*Eschrichtius robustus*). There are accounts of pilot whales behaving aggressively toward humpbacks (*Megaptera novaeangliae*), sperm whales, common dolphins, and dolphins of the genus *Stenella*. Pilot whales have also been reported carrying the carcasses of dead California sea lions (*Zalophus californianus*) and towing a human diver.

Pilot whales in the Atlantic have been affected by the morbilliviruses that have plagued other marine mammals in recent decades (Duignan *et al.*, 1995). Although to date no large-scale outbreak of disease has been reported in pilot whales, high percentages of both species sampled during the 1980s and 1990s carried virus-neutralizing antibodies. It appears that most individuals are immune. Due to their wide-ranging movements and their propensity to mix with other species, it is considered likely that pilot whales act as a vector for morbilliviruses in other cetaceans, such as bottlenose dolphins.

IV. Behavior and Physiology

Pilot whales are highly social and are usually found in schools, or pods, averaging 20–90 individuals. A variety of group behaviors have been documented. Commonly reported are traveling or foraging in a loose chorus-line formation or collective logging at the surface. The social structure of pilot whale pods is similar to that of killer whales. Pilot whales form stable pods composed of individuals with close matrilineal associations (Amos *et al.*, 1993). All age and sex classes are included, although there is a female bias in adults. The groups are stable; pilot whales grow to maturity in their natal group and most remain there for life. Genetic evidence supports the theory that males breed outside their family group.

Pilot whales are polygynous. Huge aggregations of pilot whales are occasionally reported and it is believed that males move between family groups to mate during these temporary aggregations. This type of social structure where adult males stay with their female kin and mate elsewhere is unusual among mammals.

Pilot whales are one of the most frequently reported cetaceans in mass strandings. Strandings are dramatic events because they usually involve groups of animals and because live whales that are assisted back into the ocean often return to the beach. Pilot whales strand singly as well as in groups; often single animals are diseased.

Curiously, most of the whales in a group event do not show any pathology. It is not understood why apparently healthy animals strand, although there are a variety of hypotheses. The whales may become confused or trapped in shallow areas; geomagnetic anomalies may disorient whales if they are using the earth's magnetic field for navigation; or if an ill animal strands it may be followed by members of its pod. The strong social bonds within a pilot whale pod are likely to play a role in stranding events, whatever the other underlying reasons may be.

Pilot whales are known to make shallower dives (1–16 m) during the day and perform deeper dives (>100 m) at night, presumably foraging. It has been theorized that pilot whales use deeper dives to track the rise of the deep scattering layer (DSL) at night. The deepest dives recorded for pilot whales are over 600 m.

Pilot whales echolocate with a precision similar to that of bottlenose dolphins. Pilot whales also vocalize, the primary purpose probably being to maintain contact among school members. Vocalizations are more complex with active behavior and simpler with less active behavior.

Significant differences have been found between the calls of long-finned and short-finned pilot whales (Rendell *et al.*, 1999). The calls of long-finned pilot whales are of a lower frequency and a narrower frequency range than those of short-finned pilot whales. The mean frequency for long-finned pilot whales is 4480 Hz, for short-finned pilot whales the mean frequency is 7870. Short-finned pilot whales were also found to have distinct group-specific call repertoires, as would be expected for a species with stable matrilineal kinship groups.

V. Life History

Pilot whales share several features of life history with other large odontocetes: long life span, delayed maturity, different rates of maturation for males and females, seasonal mating, and the production of a single calf in multiyear intervals.

Short-finned pilot whales have a slower growth rate than long-finned pilot whales and reach a shorter body length. The pattern of growth for both species is similar. Rapid neonatal growth is followed by a less rapid but continual growth phase during the juvenile years. Growth slows even further after the attainment of sexual maturity and ceases some years later. Short-finned females become sexually mature at 9 years, males at age 13–16. Long-finned females reach sexual maturity at 8 years, males at about 12. Males become socially mature, e.g., mate successfully, several years after reaching sexual maturity.

In the Northern Hemisphere, mating generally occurs in spring or early summer and parturition in summer or early autumn. An exception to this is the population of pilot whales off northern Japan. Their peak breeding season is autumn with parturition in winter. Gestation is estimated to be 12 months for long-finned pilot whales and 15–16 months for short-finned whales.

The birth interval in pilot whales is one of the longest of all the cetaceans. Lactation lasts for at least 3 years, often longer. Such an extended lactation period probably serves a social rather than nutritional purpose in later years. The capability of a short-finned female to lactate years past final ovulation has been reported. This supports the theory that females may invest more in present offspring as their likelihood to bear more offspring diminishes. Sizable numbers of post-reproductive females have been found in populations of both species.

Estimates of natural mortality for pilot whales are based on data from the directed fisheries in the Faeroe Islands (Denmark) and Japan. These data indicate that male pilot whales have a higher mortality rate at all ages than those of females. Females are known to be long-lived. Females live past 60 years; males reach 35–45 years.

VI. Interactions with Humans

Pilot whales are subject to several types of human interactions, including direct exploitation, bycatch in fisheries, and exposure to chemical contaminants (Donovan *et al.*, 1993). The IUCN designates both species as Data Deficient (DD). More research is needed to determine their status.

Because of their cohesive social structure, pilot whales are susceptible to herding by humans. Meat, blubber, and oil are the desired products. Historically, there have been a number of directed fisheries for pilot whales. In the North Atlantic, drive fisheries for long-finned pilot whales were conducted in Newfoundland, Cape Cod, Norway,

Iceland, Orkney Islands (Scotland), Hebrides Islands (Scotland), Greenland, and the Faeroe Islands. The intensive drive fishery in Newfoundland (1947–1971) is estimated to have taken 54,000 animals and to have reduced the local population substantially. The population may be recovering, but more information is needed. Fisheries for short-finned pilot whales have operated in the Caribbean, Indonesia, and in Japan. The drive fisheries in the Faeroe Islands and in Japan continue today. These fisheries have been in existence for several hundred years. In 2006, the catch of long-finned pilot whales in the Faeroes was 856 animals; in 2004, Japan reported a catch of 63 short-finned pilot whales. The Faeroe fishery is considered sustainable.

The incidental bycatch of cetaceans in fisheries is a worldwide phenomenon. Most bycatch goes unreported because this information is not recorded in many countries. Pilot whales are particularly susceptible to entanglement in driftnets. The effect of such mortality on pilot whale populations is unknown.

Bycatch records are kept in the United States. In northeast US waters, pilot whales have been taken incidentally in a variety of fisheries including pelagic drift gill nets, pelagic long lines, pelagic pair trawls, and trawls for mackerel, herring, and squid. Most takes occurred along the shelf break. Some of these fisheries are now closed. None of the current fisheries exceed the allowable annual take for pilot whales under US law.

Pilot whales off California are taken incidental to driftnet fisheries targeting swordfish and sharks. A take reduction plan was implemented in 1997 and currently the incidental take is lower than the allowable annual limit. Prior to the El Niño of 1982–1983, pilot whales were taken incidentally in the Californian squid purse-seine fishery. Pilot whale redistribution in response to El Niño is the likely reason no mortality was reported for this fishery during the following years. Currently the squid fishery is not monitored, but there have been anecdotal reports of pilot whales seen near squid fishing operations in recent years. Driftnet fisheries similar to those in California operate out of Mexico; any pilot whale takes there are likely from the same population of short-finned pilot whales that occurs off California.

A minimal number of pilot whales have been reported taken incidental to the long-line fisheries based in Hawaii. The mortality and injury sustained by pilot whales interacting with the fishery occurred outside the 200 nmi Exclusive Economic Zone (EEZ) of Hawaii. Less is known about pilot whale populations away from the nearshore areas of Hawaii, so the impact of the takes on these whales is also not known.

Long-finned pilot whales from both sides of the north Atlantic carry high levels of organochlorine contaminants (pesticides such as DDT and PCB) in their tissues. Concentrated organochlorines may impair reproduction or increase susceptibility to disease. Studies are continuing on the effects these compounds have on marine mammals. Accumulations of cadmium and mercury are also present in the tissues of long-finned pilot whales from the Faeroe Islands. As top predators, pilot whales are a repository of these heavy metals accumulating through the marine food chain. Pilot whales seem unusually tolerant to elevated levels of these metals, as studies have not yet revealed a major toxicity problem in these species.

Pinniped Ecology

W.D. BOWEN, C.A. BECK, AND D.A. AUSTIN

Ecology is the study of the interactions between individuals and their environment. In this context, environment is taken broadly to include other organisms and the physical characteristics of habitat. These interactions take place at various spatial and temporal scales, and influence both the abundance and distribution of individuals. However, ecology is also a historical science in that the patterns we see today reflect past events and phylogenetic relationships. Thus, processes acting on both evolutionary and ecological time-scales have undoubtedly influenced many of the characteristics of pinniped ecology we see today. Pinnipeds are large, long-lived, aquatic mammals exhibiting delayed sexual maturity and reduced litter size; a single precocial offspring is the norm. As such, they share many of the demographic features of other large mammals. Population numbers do not change dramatically from year to year, and numbers are most sensitive to changes in adult survival, followed by juvenile survival and fecundity (Eberhardt and Siniff, 1977). We assume that these characteristics are under selection and that variability in foraging success affects survival probability and reproductive performance of individuals. Inevitably, discussions of pinniped ecology and other aspects of pinniped biology will overlap. Here we focus on five aspects of pinniped ecology: abundance, distribution, reproduction, foraging, and the ecological roles of pinnipeds in aquatic ecosystems.

I. Abundance

Despite the interest in the ecology of pinnipeds, the abundance of many species is poorly known. The abundance of commercially harvested species (e.g., past-northern fur seals [*Callorhinus ursinus*])

or present-harp seals [*Pagophilus groenlandicus*] is generally better known than for those species that have not been exploited. The accuracy and precision attached to the estimates of abundance varies greatly, owing to the difficulty in carrying out surveys or to the lack of effort to obtain good estimates. Good estimates of abundance are important because abundance and trends in abundance are perhaps the most useful indicators of population status.

Commercial exploitation decimated many pinniped species, in some cases to levels nearing extinction (e.g., northern elephant seals [*Mirounga angustirostris*]). Over the past several decades or more, some species have recovered or are continuing to recover. Thus, the present abundance of heavily exploited species may not be a good measure of their preexploitation numbers. Pinniped species range over four orders of magnitude in abundance, from the crabeater seals (*Lobodon carcinophaga*) at about 12 million (probably the most abundant marine mammal in the world) to the Mediterranean monk seal (*Monachus monachus*) at probably fewer than several hundred individuals (Reijnders *et al.*, 1993). Phocid species are generally more abundant than otariids, with 15 of 18 phocid species numbering greater than 100,000 individuals compared with only 8 of 14 otariid species (Bowen and Siniff, 1999). The reasons for this difference are not entirely clear. Over the past 100 years, both families have been commercially exploited and subjected to other human factors that might have influenced abundance. More likely, the greater abundance of phocids is the result of their greater use of high-productivity areas in temperate and polar waters than is the case in most otariid species. The three most abundant otariids, the northern fur seal, Antarctic fur seal (*Arctocephalus gazella*), and South African fur seal (*A. pusillus pusillus*), all forage in seasonally productive, high-latitude ecosystems, a characteristic shared with the most abundant phocid species (i.e., the ringed seal [*Pusa hispida*], the harp seal, and the crabeater seal).

Abundance is determined by the movement of individuals in and out of the population, and by births and deaths. These processes are influenced by ecological factors such as predation, food supply, breeding habitat, disease, competition with other species, and environmental variability, and by both direct and indirect human activities. In the absence of human effects, combinations of these ecological factors determine abundance and some of which, operating in a density-dependent way, will regulate population size about a level known as carrying capacity. With the recovery of populations from earlier periods of exploitation, there is increasing evidence that a number of species have reached or are approaching the current carrying capacity of their environments (e.g., Weddell seal [*Leptonychotes weddellii*], gray seals [*Halichoerus grypus*], harbor seals [*Phoca vitulina*], harp seals). During periods of recovery, species such as Antarctic fur seal, Northern fur seal, gray seal, and harbor seal increased at rates in excess of 12% per year over several decades or more. At Sable Island, Canada, the number of gray seal pups born each year has increased exponentially, with a doubling time of about 6 years, for more than 40 years. Although they can increase rapidly, pinniped populations may decline even more rapidly as a result of epizootics, such as the phocine distemper virus that killed large numbers of harbor seals in the North Sea, and during short-term extreme changes in ocean climate, such as El Niño (see below).

II. Distribution

Fundamentally, pinniped distributions reflect the need to give birth on solid substrate of land or ice, and to feed at sea. Within these broad constraints, the distribution of pinnipeds is affected by physical (e.g., ice cover, location of remote islands) and biological

(e.g., productivity, abundance of predators) characteristics of habitat, demographic factors (e.g., population size, age, sex, and reproductive status), morphological and physiological constraints and human actions (e.g., disturbance). Although each of these factors may influence distribution, combinations of factors are generally responsible for the distribution patterns we observe. Pinniped distribution is also three-dimensional, where the third dimension is water depth and the underlying bathymetry. Although a complete understanding of pinniped distribution must consider this three-dimensional world, this aspect of pinniped behavior is discussed in sections on Energetics, Telemetry, and Diving Behavior.

Pinniped species have a restricted and generally patchy distribution in most aquatic environments: estuaries and continental shelves (e.g., gray seals), tropical seas (e.g., monk seals [*Monachus* spp.], Galapagos fur seals [*Arctocephalus galapagoensis*]), the deep ocean (e.g., elephant seals [*Mirounga* spp.]), Arctic (e.g., ringed seals) and Antarctic polar seas (e.g., crabeater seals, Antarctic fur seals), and freshwater lakes (e.g., Baikal seals [*Pusa sibirica*]) (King, 1983). However, our understanding of the distribution of most species is based primarily on the location of breeding colonies. We know considerably less about where most species forage at sea, and our view of overall distribution is therefore incomplete. For example, based on the location of breeding colonies, northern elephant seals range from Baja California to central California. However, satellite telemetry studies show that this species forages over broad areas of the North Pacific Ocean for much of the year. This new information has dramatically changed our understanding of the ecology of this and a growing number of species (e.g., gray seal, harbor seals, and southern elephant seals [*Mirounga leonina*]).

The distributions of pinniped breeding colonies seem to reflect the evolutionary history of pinnipeds and the distribution of resources. At large scales, both sea lion and fur seal distributions reflect their origins in the Pacific Ocean. Northern fur seals and Steller sea lions (*Eumetopias jubatus*) are widely distributed along both sides of the North Pacific Ocean. The four other species of sea lions occupy colonies along the west coast of South America, southern Australia, and New Zealand. With the exception of the northern fur seal and Guadalupe fur seal, the other six species of fur seals occur in tropical or subtropical southern waters, but also extend into the cool, nutrient-rich waters of the South Atlantic and Indian Oceans. Sea lion and fur seal breeding colonies are usually located on remote islands near areas of high biological productivity (e.g., northern fur seals, Antarctic fur seals), which provide both protection from mainland predators and nearby food sources. These conditions are particularly important for lactating females.

Species of the Family Phocidae are widely distributed in biologically productive temperate and polar seas. Although most abundant in the North Atlantic and Antarctic Oceans, a reflection of their evolutionary origins in the Atlantic basin during the middle Miocene, phocid species have circumpolar distributions in both the Arctic Ocean (e.g., ringed seal, bearded seal [*Erignathus barbatus*]) and Antarctic Ocean (e.g., Weddell seal, crabeater seal), as well as a broad distribution in the North Pacific Ocean (e.g., harbor seal, largha seal [*Phoca largha*], ribbon seal [*Histiophoca fasciata*]). Several endangered species also occur in tropical waters (Hawaiian [*Monachus schauinslandi*] and Mediterranean monk seals).

Pinnipeds must return to a solid substrate (land or ice) to give birth, rear their offspring, and in many species to molt. For most species, these requirements result in seasonal changes in distribution. In the case of species that breed on pack ice, such as harp and hooded (*Cystophora cristata*) seals and the walrus (*Odobenus rosmarus*),

seasonal changes in ice cover virtually guarantee changes in distribution. This may partly explain why 7 of 13 (54%) species of pinnipeds that give birth on ice (i.e., most phocid seals and the walrus) are migratory, compared to only 4 of 20 (20%) species that give birth on land (2 of 6 phocids, 2 of 14 otariids; Bowen and Siniff, 1999). However, this difference also may be partly explained by the variable quality of data on the at-sea distribution of pinnipeds.

Migration appears to be a common feature of the ice-breeding phocid species, but this behavior is perhaps best documented in the northern elephant seal. This land-breeding species shows extreme sexual size-dimorphism, with males being about five times heavier than females. Northern elephant seals undertake the longest known migration and some of the deepest dives reported for a mammal (Stewart and DeLong, 1993). Individual elephant seals make two long-distance migrations of 18,000–21,000 km between breeding and molting sites in California and pelagic foraging areas in the North Pacific. Using the California Current as a corridor to areas further north, northern elephant seals leave the breeding beaches in southern California for northern offshore foraging areas. The first migration occurs following the breeding season, in which adult male and female elephant seals travel an average of 11,967 and 6289 km respectively, and remain at sea for an average of 124 and 73 days. After the molt, the seals depart on a second migration; females are at sea for approximately twice as long as males and cover an average distance of 12,264 km compared to an average of 9608 km by males. Males migrate farther north than females, with most males traveling as far as the northern Gulf of Alaska and the eastern Aleutian Islands. These sex differences in foraging distribution, and presumably diet, may have evolved to reduce competition between females and males.

III. Reproductive Ecology

The reproductive ecology of pinniped species share features that reflect their common ancestry as terrestrial carnivores, and their subsequent adaptation to a predominately aquatic lifestyle. As noted previously, a conserved trait of their terrestrial ancestry is the requirement for all pinniped species to give birth to their offspring on a solid substrate (land or ice). However, pinnipeds must feed at sea, often some distance from the breeding grounds. This spatial and temporal separation of parturition from aquatic foraging is thought to have played a large role in shaping the mating and lactation strategies of pinnipeds. Three general strategies have evolved to deal with the conflict between at-sea foraging and terrestrial parturition (see below); however, the requirement for terrestrial parturition has likely contributed to some common features of pinniped reproduction, such as birth synchrony.

In most pinniped species, reproduction is seasonal and highly synchronous (e.g., harp seals). The evolution of reproductive synchrony is often associated with seasonal resource availability. In ice-breeding species (e.g., harp and hooded seals), the timing of reproduction is linked to the seasonal availability of sea ice. Seasonal changes in prey abundance and environmental conditions can also influence the timing of parturition and mating. The Hawaiian monk seal displays only weak synchrony in reproduction. In this species, births extend over a 6-month period. Given the less variable tropical habitat of this species, reproductive synchrony may not have been under strong selection relative to species in more variable temperate and polar environments. Subtropical populations of California sea lions (*Zalophus californianus californianus*) and Galapagos fur seals also show slightly less temporal synchrony of reproduction relative to more temperate populations (Boness, 1991).

Departures from the annual cycle of reproduction are found in several species. The Australian sea lion (*Neophoca cinerea*) has a cycle lasting 18 months, resulting in a seasonal pattern of births. Similarly, the walrus has a reproductive cycle of 2 years, including a 15-month gestation period, in which the period of births remains seasonal.

Other common features of pinniped reproduction include postpartum mating and delayed implantation. These two characteristics of pinniped reproduction also appear to reflect the terrestrial ancestry of the taxa, with both features occurring in many modern terrestrial carnivores (see Female Reproductive Systems). However, selection for postpartum mating may have continued as pinnipeds adapted to their aquatic environment. Given the wide-ranging and dispersed distribution of pinniped species during the at-sea foraging season, the aggregation of individuals at pupping colonies may have offered one of the few predictable opportunities for males and females to mate.

Another common feature of pinniped reproduction is the production of a single, precocious offspring; litters of two are rare. Offspring are born with their eyes open and begin to vocalize within minutes of birth. Neonates are also able to move short distances to their mother and begin suckling shortly after birth. Harbor seal females produce extremely precocial offspring that are capable of swimming and diving with their mothers within an hour after birth (Bowen, 1991).

A. Mating Systems

Within the order Pinnipedia, mating systems range from extreme polygyny (e.g., northern fur seals) to sequential defense by males of individual females. Mating systems are closely associated with the dimensionality and stability of the habitat used, and distribution of females at parturition. Broadly speaking, species can be grouped as land-breeding and aquatic-breeding species.

1. Land-Breeding Species Land-breeding pinniped species include all fur seals and sea lions, northern and southern elephant seals, and the gray seal. These species colonize oceanic islands and coastal areas to give birth and mate. The aggregation of individuals during the breeding season has been attributed to the fact that oceanic islands are relatively rare and unevenly dispersed, such that the availability of suitable pupping sites may limit the distribution of females (Boness, 1991). Predation may also select for female clustering, with females being less vulnerable to terrestrial predators and/or harassment by conspecific males when in large groups (dilution effect). Aggregation of females within a stable, two-dimensional habitat has led to the evolution of polygyny in these species, with males defending either resources needed by females (e.g., birth and thermoregulatory sites in otariid species) or the females themselves (e.g., elephant seals and gray seals). By competing with and limiting the access of other males to females, successful males mate with multiple females, thus increasing their reproductive success. The degree of polygyny in land-breeding pinniped species ranges from extreme in the northern fur seal and elephant seals where one male may mate with 16–100 females, to moderate (6–15 females) in gray seals, Hooker sea lions (*Phocartos hookeri*) and the Galapagos fur seal (Le Boeuf, 1991).

As in other polygynous species, land-breeding pinniped species are sexually size-dimorphic. Males in these species can be much larger than females and often show other secondary sex characteristics. These dimorphic characteristics are the result of sexual selection for traits that increase an individual's ability to monopolize and defend resources needed by females or females themselves. Large body size, and concomitant body energy stores in the form of subcutaneous blubber, permits dominant males to fast and thus remain ashore

during the period when females become receptive. The most extreme example of sexual size dimorphism in pinnipeds occurs in elephant seals, where males are 5–6 times heavier than females in the northern species and up to 10 times heavier than females in the southern species.

2. Aquatic-Breeding Species Walruses and all other phocid seals (Weddell, Ross [*Ommatophoca rossii*], crabeater, leopard (*Hydrurga leptonyx*), bearded, hooded, ringed, Baikal, Caspian (*Pusa caspica*), spotted, harp and ribbon) give birth on pack ice or fast ice and mate in the water. Although Hawaiian monk seals and harbor seals give birth to their offspring on land, they too mate in the water. In species where pups are born on ice, females tend to be more widely distributed, although access to breathing holes in the ice may promote clumping in some species (e.g., walrus and Weddell seals). This broader distribution of females, on an unstable habitat, limits the number of females a male can monopolize at any given time, and as a result these species typically show reduced levels of polygyny (e.g., harbor seals; Coltman *et al.*, 1999). The fact that mating occurs in the water, a fluid three-dimensional environment, also may limit the ability of males to monopolize females resulting in reduced levels of polygyny.

Wells *et al.* (1999) classified the mating strategies used by ice-breeding species as: scrambling-males search for receptive females and move on to the next, sequential defense-males sequentially defend single females through mating, and lekking-males aggregate and attract females using displays. At present, there is insufficient information on the breeding behavior of most aquatic breeding species to draw firm conclusions about the type of mating system used. Until recently, data on the mating behavior of these species is limited to that which can be observed on ice prior to copulation. For example, observational data suggest that hooded seals use a sequential defense mating system whereby males compete with one another to defend a single female and her pup on the ice. The dominant male remains with the pair until the pup is weaned and then enters the water with the female, presumably to mate. However, the application of newer methods, including genetic paternity assessment, animal-borne video, and positional analysis of vocalizations have clarified the mating systems of harbor seals (Boness *et al.*, 2006) and bearded seals (Van Parijs and Clark, 2006).

In species that mate aquatically, there may be less selective advantage for males to be larger than females because of the limited ability of males to monopolize females in this environment. As a consequence, in most of these species, males and females are of similar size and in some cases females are larger than males. For example, male Weddell seals are slightly smaller than females and it has been suggested that smaller size makes the male more agile during underwater mating activities (Le Boeuf, 1991). Underwater vocalizations also appear to be an important component of the mating behavior in aquatically mating pinniped species. For example, in Pacific walruses, which exhibit a lekking mating system, males perform complex underwater visual and vocal displays in small groups next to female haul-out sites to attract females. Male Weddell, harbor, harp, hooded, and bearded seals also produce a range of underwater vocalizations during the breeding season that may be used to attract females or to establish underwater territories or display areas.

B. Lactation Strategies

Male pinnipeds do not participate in the care of the offspring. Thus, parental care is the exclusive responsibility of the female. Female care involves the transfer of energy-rich milk to the pup, and protection from conspecifics and terrestrial predators (Bowen, 1991).

In some species (e.g., the walrus), females may also teach their young to forage, as young accompany mothers on foraging trips during the lactation period. Female pinnipeds have dealt with the temporal and spatial separation of energy acquisition (aquatic foraging) from high levels of energy expenditure (terrestrial lactation) in different ways, resulting in the three basic lactation strategies: long lactation length and foraging cycle, short lactation length and fasting, and long lactation length and aquatic nursing. Although maternal body size has long been thought to have been an important trait in the evolution of these strategies, on the basis of a comparative analysis of 12 life-history and ecological traits, Schulz and Bowen (2005) concluded that there is little evidence for the influence of body size on lactation length. The patterns we see today appear to reflect an early divergence in body size between otariids and phocids, which influenced their foraging strategies and metabolic rates and subsequently influenced lactation strategies. Abbreviated lactation seems to represent an adaptation for minimizing the relative milk energy expended over lactation, but may also have been selected to reduce terrestrial predation and the uncertainty of breeding on unpredictable pack ice.

1. Foraging Cycle All otariids and some of the smaller phocid species (e.g., harbor seals) exhibit this lactation strategy. Females come ashore for parturition with a moderate level of stored body energy. After giving birth, females remain onshore and fast while attending and nursing their young for a perinatal period ranging from a few days to a week. After this initial provisioning period, females leave their pups and return to sea to feed. These trips range from less than 1 day in some species to as long as 23 days in others, depending on the distance to the foraging location and prey abundance. Females then return to land to nurse their pup, after which they repeat the cycle until the pup is weaned. The lactation period in otariid species is quite long, ranging from 4 months to 3 years (Bowen, 1991). Females of these species are considered income breeders, relying on current food intake to support both their own metabolic needs and the energetic cost of milk production. The milk produced by female otariids is relatively energy-dense (24–40% fat) compared to terrestrial mammalian species. Pup growth rates are rather low, ranging from 0.06 kg/day in Galapagos fur seals to 0.38 kg/day in Steller sea lions (Boness and Bowen, 1996).

Harbor seals, a phocid species, also exhibit a form of this lactation strategy—alternating short foraging trips to sea (7–10 h) with terrestrial nursing. The harbor seal is a relatively small phocid species, with females weighing approximately 84 kg at parturition. Given the small quantity of body energy that these females are able to store, female harbor seals are forced to make regular foraging trips to acquire sufficient energy to successfully wean their pups. Compared to otariid species, the length of the lactation period in harbor seals is much shorter (24 days) and the milk produced by females has a relatively higher fat content (50%). Consequently, pup growth rate is higher in harbor seals relative to otariid species (0.6 kg/day). Foraging cycles during lactation also may occur in ringed seals, and other relatively small phocid species. There is evidence that the females of two medium size phocids, the Weddell seal and the harp seal, may also forage during the lactation period. However, as noted above, the intensity of foraging and the degree to which successful weaning of offspring relies on these foraging trips is not clearly understood. Although small body size of some phocid species may limit females to a lactation strategy similar to otariids, difference in mammary gland structure between otariids and phocids may constrain the ability of phocid females from evolving a full-fledged foraging cycle (Schulz and Bowen, 2005).

2. *Fasting Strategy* In the larger-bodied phocid species, females fast during lactation. Females arrive at the breeding site with large energy stores in the form of adipose tissue (i.e., blubber). In the western Atlantic, for example, gray seal females arrive at Sable Island weighing an average of 210 kg. Of this body mass, 32% or 67 kg is fat. After parturition, females fast for the entire lactation period (e.g., 16 days in the case of gray seals), using their stored energy to support the energetic cost of milk production and their own maintenance metabolism. For this reason, female phocids are considered capital breeders—having stored energy often months before it is needed. The lactation period in phocids is much shorter than in otariid species ranging from 4 days in hooded seals to 60 days in Weddell seals. Another characteristic feature of the phocid fasting strategy is the production of extremely high fat milk, ranging from 47% fat in southern elephant seals to 61% fat in hooded seals. This energy-dense milk results in a high rate of offspring growth, ranging from 1.4 kg/day in the Hawaiian monk seal to 7.1 kg/day in the hooded seal (Bowen, 1991). Weaning occurs abruptly when mothers return to sea to feed. Pups often fast for weeks following weaning, living off their accumulated fat stores before entering the water and beginning to forage independently. Unstable breeding habitat, reduction in the fraction of energy expenditure devoted to maternal vs offspring requirements, and increased efficiency of milk energy transfer to offspring leading to higher growth rates all appear to have favored the evolution of the fasting strategy (Schulz and Bowen, 2005).

3. *Aquatic Nursing* The walrus is the only pinniped species that exhibits aquatic nursing. Just prior to parturition, pregnant females separate from the herd and give birth to their offspring alone on pack ice. New mothers remain on the ice, fasting for the first few days postpartum, and relying on stored body energy accumulated prior to parturition. Subsequently, females and their young return to the herd to forage. Walrus pups suckle in the water for between 2 and 3 years on relatively low-fat milk (24.1%). As with otariids, weaning is gradual. Young walruses begin to feed on benthic organisms as early as 5 months of age and likely gain valuable foraging experience from their mothers over the remainder of lactation. At weaning, female offspring are assimilated into the mother's herd, whereas male offspring join other male groups.

Lactation strategies are often viewed from the female's perspective. This seems reasonable, but in long-lived species such as pinnipeds, females may trade-off investment in current offspring against investment in future offspring. This may lead to conflicts between females and their offspring over the level of investment received. The transition from nursing pup to nutritionally independent juvenile usually occurs without parental supervision in pinnipeds. This transition is arguably the most important period of a pinniped's young life. As offspring size affects subsequent survival, we should expect that offspring would attempt to obtain as much milk as they can during lactation. Thus, the nutritional requirements and physiological abilities of individual offspring also must play a role in shaping lactation strategies. For example, the fasting ability of offspring constrains the duration of foraging trips by female fur seals and sea lions.

IV. Foraging

Successful foraging is essential for survival and reproduction, and is therefore a critical determinant of fitness. Pinnipeds are among the largest vertebrate carnivores in marine ecosystems, and yet the foraging behavior of these upper-trophic level predators is generally poorly understood. As noted earlier, pinnipeds inhabit diverse habitats;

consequently they forage over highly variable spatial and temporal scales, and in doing so they exploit a wide range of prey.

A. Methods

As pinnipeds generally feed under water at remote locations, ecologists rely upon indirect methods to gain insight into their foraging behavior and diets. Very high frequency (VHF) radio tags have been used to study the at-sea locations of coastal species such as harbor seals. Acoustic tags have been used to track the underwater movements of gray seals. More recently, microprocessor-based, time-depth recorders (TDRs) have been used to collect information on dive duration, depth, frequency, and temporal distribution and to calculate the at-sea locations of pinnipeds using solar navigation equations. However, the use of TDRs is often limited by the need to recover the instrument to retrieve the stored information and therefore only those species which can be reliably recaptured are used in TDR studies. In contrast, satellite-linked, time-depth recorders (SLTDRs) transmit collected data on diving parameters and surface positions to polar-orbiting satellites operated by Service Argos. This technology has broadened the range of species that have been studied, but the expense of using satellite-linked tags often places limits on the number of individuals studied. A new generation of tags, using fastloc GPS, is providing more accurate locations to permit finer scale studies of foraging behavior and habitat use.

Although we have learned a great deal from the use of location telemetry and dive recorders, these studies have provided little insight into the feeding success rate of pinnipeds. Recent work has demonstrated that estimates of feeding success can be determined using stomach-temperature telemetry and animal-borne video. The body temperature of marine prey is often considerably lower than that of its pinniped predator, thus the stomach temperature of the predator should drop following prey ingestion. This approach has been used successfully on free-living gray seals (Austin *et al.*, 2006a) and several other species. When combined with information on the diving behavior and movement patterns in the same individual, stomach telemetry can provide new insights into the spatial and temporal patterns of foraging success relative to foraging effort (Austin *et al.*, 2006b). Animal-borne video technology has taken our understanding of foraging behavior and diet one step further by providing direct observations of the way in which pinnipeds search for and capture prey, and how foraging behavior changes as a function of prey type (Bowen *et al.*, 2002).

Determining the diet of marine mammals also requires the use of indirect methods. The most common methods rely on the recovery and identification of hard prey structures that are resistant to digestion from the stomach, intestine, or feces of individual animals. Sagittal otoliths, cephalopod beaks, bones, scales, invertebrate exoskeletons, and shells can be used to determine the species consumed, and in some cases, to estimate the size and age of the prey. Fecal samples are increasingly being used for this purpose because they are less expensive to collect; a high proportion of samples contain identifiable prey, and estimates of diet are less affected by differential rates of digestion than are estimates from stomach samples (Bowen and Siniff, 1999). Although the use of hard parts to estimate the diet of pinnipeds is common, this method is subject to a number of biases, which may limit the value of results. Firstly, stomach and fecal contents only provide an estimate of the diet near the point of collection, and as a result, offshore diets cannot easily be sampled. This may seriously bias the diet of wide-ranging species such as elephant seals, harp seals, northern fur seals, and Juan Fernandez fur

seals (*Arctocephalus philippii*). Secondly, hard parts are often eroded during digestion or are completely digested, such that prey size may be seriously underestimated and prey identification may not be possible. Finally, dietary analysis based on hard parts is strongly biased against soft-bodied or small prey with fragile structures.

Inevitably, our understanding of the diets of pinnipeds is tied to the development of new methods. One such method is fatty acid signature analysis and its quantitative formulation, called quantitative fatty acid signature analysis (QFASA) (Iverson *et al.*, 2004). Lipids in marine ecosystems are diverse and characterized by long-chain polyunsaturated fatty acids that originate in unicellular phytoplankton. In carnivores such as pinnipeds, ingested fatty acids with a carbon chain length greater than 14 are deposited in body tissues in a predictable way. As a result, the fatty acid composition or signature of the predator reflects (but will never be the same as) the fatty acid composition of the prey species consumed (Iverson *et al.*, 2004, also see Blubber, this volume). By comparing the reference signature of various prey species to the fatty acid signature of the predator, obtained from blubber tissue or milk, diet composition can be estimated. The use of fatty acid signature analysis eliminates the dependence on recovery of hard parts and integrates the diet over a period of weeks to months, such that the location of sampling becomes less important. Nevertheless, QFASA depends on having determined the fatty acid composition of potential prey species; there is always the possibility that some prey species may not be reliably distinguish on the basis of fatty acids, leading to false positive identification of prey consumed.

Stable isotope ratios of carbon and nitrogen found in the muscle, skin, vibrissae, or blood of pinnipeds and other predators are also being used to investigate diet. These ratios reflect a composite of prey species eaten over a broad time scale. By examining the levels of $^{15}\text{N}/^{14}\text{N}$ found in body tissues, researchers can determine the trophic level at which the pinnipeds fed. The carbon isotope ratio ($^{13}\text{C}/^{12}\text{C}$) has been found to vary geographically, and thus the level of carbon isotope in the predator's tissues provides insight into foraging location. While this technique is useful in determining trophic level and foraging location, it does not permit the diet composition of individuals to be estimated, except when only a few prey species are consumed.

Finally, recent studies have indicated that the identification of prey species' DNA recovered from pinniped feces can provide qualitative information on prey consumed, and may eventually also yield quantitative diet estimates (Deagle and Tollit, 2007).

B. Diet

A large number of prey species have been identified in the diet of pinniped species, leading to the view that pinnipeds are generalist predators. This is consistent with the expectation that large wide-ranging predators consume more types of prey as their environment becomes patchier. However, in most cases, a relatively small number of species account for the majority of food eaten (Bowen and Siniff, 1999). For example, gray seals on the Scotian Shelf, Canada, consumed 24 different taxa, but only 2–4 species accounted for over 80% of the energy consumed, depending on the time of the year.

Fish and cephalopod species are the main prey types eaten by pinnipeds (Table I). However, crustaceans also appear to account for a substantial portion of prey consumed by some species. Crustaceans are a major prey of harp seals in the North Atlantic, and of ringed seals and bearded seals in the Bering Sea. In three Antarctic species, Antarctic fur seals, crabeater seals, and leopard seals, krill accounts for up to 50% of the diet. Unlike most pinnipeds, which generally

feed on mobile prey (e.g., fishes, cephalopod molluscs, and crustaceans) in pelagic and benthic habitats, the walrus feed almost exclusively on sessile benthic invertebrates in soft-bottom sediments.

Several pinniped species are also known to feed on other pinnipeds (Bowen and Siniff, 1999). There is evidence that adult male South American fur seals (*Arctocephalus australis*) commonly feed on conspecific young. Steller sea lions are known to prey on a variety of pinniped species including harbor seals, ringed seals, bearded seals, young northern fur seals, and spotted seals. Walrus prey on spotted seals, ringed seals, and young bearded seals.

The diet and foraging behavior of pinnipeds are influenced by a number of factors. The ecology and behavior of prey species clearly play a role in shaping the foraging tactics of pinnipeds. Research on the foraging behavior of adult male harbor seals at Sable Island, Canada, using animal-borne video, showed that prey behavior affected both capture technique and profitability of different prey types. Other studies have shown that between-year differences in diet composition of harbor seals were correlated with differences in the distribution and abundance of herring (*Clupea* spp.) and sprat, two important prey species in Scotland.

Intrinsic factors such as age and sex may also play a role in the diet composition of individuals within pinniped species. Given that pinnipeds are long-lived predators, their individual foraging tactics and behavior may change over time to reflect increased physiological capabilities and learning. For example, harbor seal pups feed on pelagic prey such as herring and squid, whereas the diet of adults is dominated by benthic species. Similarly, the contribution of benthic prey (e.g., crabs, clams, and sculpins) to the diet of bearded seals increases with age. Age-specific differences in diet composition have also been found in southern elephant seals and harp seals.

In pinniped species that exhibit sexual body-size dimorphism, the diets of adult males and females may differ due to the relationship between energy requirements and body mass, whereby larger individuals require more total energy per unit time than do smaller individuals. Oxygen storage capacity also increases with body mass due to the larger blood pool in which to store oxygen and the larger muscle (myoglobin) mass. In addition, larger animals have a slower mass-specific metabolic rate, such that they utilize their larger oxygen stores at a slower rate relative to smaller individuals. Thus, larger individuals are capable of longer and deeper foraging dives. These physiological attributes may allow, or require, males (the larger sex) to pursue different prey types (potentially higher quality prey) than females. Males and females may also consume different prey to reduce the effects of intraspecific competition for food, and as a reflection of differences in the timing of reproductive costs. Gray seals are a good example of these effects acting on males and females to produce seasonal differences in both the energy density and diversity of the diet (Beck *et al.*, 2007).

C. Foraging and Diving Behavior

The foraging ecology of pinnipeds and other air-breathing vertebrates is constrained by the need to surface for oxygen. Dive duration is constrained by the interplay between the amount of oxygen that can be stored and the rate at which the diver expends oxygen. Thus, it is inevitable that the distribution of foraging in time and space will be influenced by the physiological constraints. Other factors, such as prey characteristics, presence of competitors, and predators also play an important role in how pinnipeds forage within these physiological constraints.

Foraging pinnipeds dive repeatedly with relatively short surface intervals between dives; this cluster of dives is called a dive bout. In

TABLE I
Major Prey of Selected Pinnipeds

Species	Location	Main prey
Gray seal (<i>Halichoerus grypus</i>)	Eastern Canada United Kingdom	Sandlance, redfish Sandlance
Harbor seal (<i>Phoca vitulina</i>)	Eastern Canada Western Canada	Herring, Atlantic cod (<i>Gadus morhua</i>), pollock (<i>Pollachius</i> spp.), squid Pacific hake (<i>Merluccius productus</i>), Pacific herring (<i>Clupea pallasii</i>)
Harp seal (<i>Pagophilus groenlandicus</i>)	Sweden Northwest Atlantic	Atlantic cod, sole, herring, sandlance Arctic cod (<i>Arctogadus glacialis</i>), herring, capelin (<i>Mallotus villosus</i>)
Hooded seal (<i>Cystophora cristata</i>)	White Sea/East ice Greenland	Capelin, sandlance, herring Greenland halibut (<i>Reinhardtius hippoglossoides</i>), redfish, Gadidae
Ringed seal (<i>Pusa hispida</i>)	Bering Sea	Saffron cod (<i>Eleginus gracilis</i>), Arctic cod, shrimps
Ribbon seal (<i>Histiophoca fasciata</i>)	Bering Sea	Pollock, eelpout, Saffron cod
Bearded seal (<i>Erignathus barbatus</i>)	Bering Sea	Shrimp, crab, clam
S. elephant seal (<i>Mirounga leonina</i>)	Heard/Macquarie Island Heard Island	Squids, pelagic and benthic fishes Squids, pelagic fishes
N. elephant seal (<i>M. angustirostris</i>)	California	Cephalopods, Pacific whiting (hake)
Leopard seal (<i>Hydrurga leptonyx</i>)	Southern Ocean	Krill, cephalopods, penguins, seals
Northern fur seal (<i>Callorhinus ursinus</i>)	North Pacific Bering Sea	Anchovy, herring, capelin, sandlance Pollock, capelin, herring, squids
South African fur seal (<i>Arctocephalus pusillus pusillus</i>)	Benquela Current	Anchovy, hakes, squid
Antarctic fur seal (<i>Arctocephalus gazella</i>)	South Georgia	Krill, cephalopods, fish
Sub-Antarctic fur seal (<i>A. tropicalis</i>)	Gough Island	Squids
Australian fur seal (<i>A. pusillus doriferus</i>)	Tasmania	Squids
South American fur seal (<i>A. australis</i>)	Peru	Sardine, southern anchovy, jack mackerel (<i>Trachurus</i> spp.)
Juan Fernández fur seal (<i>A. philippii</i>)	Alejandro Selkirk Island	Myctophid fishes, squid
New Zealand fur seal (<i>A. forsteri</i>)	New Zealand	Octopus, squid, barracuda
Steller sea lion (<i>Eumetopias jubatus</i>)	Gulf of Alaska	Pollock, herring, squids
California sea lion (<i>Zalophus californianus</i>)	California	Northern anchovy, Pacific whiting, squid

general, dive bouts are thought to indicate foraging within a prey patch, particularly in otariid species. Theoretically, divers should organize their behavior for optimal use of prey. To organize their behavior in this way, divers should optimize both the time budget of the dive cycle (dive duration and surface interval) and the number of dive cycles to repeat. Both of these factors will influence the amount of prey caught and the energy and time consumed during the dive bout. However, there may be a trade-off between prey depth and profitability, such that prey items that might be exploited when closer to the surface are less likely to be exploited as the depth of that prey increases.

Empirical tests of optimal foraging theory and optimal patch use in diving pinnipeds are uncommon, largely due to the difficulty and expense of studying these wide-ranging predators and their prey. However, it appears that some otariids feed near the surface on vertically migrating prey, such as krill, to maximize energetic efficiency.

Phocids are generally better suited for deep diving and for longer periods of time than are their otariid and odobenid counterparts. This is largely because phocids have a larger blood volume and larger myoglobin content in the muscles and thus store more oxygen

per unit of body mass. Phocids also dive in continuous bouts and are known to spend up to 90% of their time in the water submerged. Thus, unlike otariids and odobenids, phocid seals live at depth, periodically returning to the surface to breathe. Although diving behavior is often considered to be synonymous with foraging in otariids, dive shape analysis in phocids demonstrates that diving may also be used for travel, predator avoidance, and sleep (Wells *et al.*, 1999).

D. Factors Affecting Foraging Ecology

Pinnipeds are no doubt important consumers of marine species; however, for most species relatively little is still known about the ecological factors affecting diet or foraging success. Knowledge of the at-sea movements of pinnipeds is important because spatial patterns can fundamentally affect the nature and dynamics of species interactions. These interactions largely determine the distribution of foraging. Within the ocean, food is distributed in patches and this distribution can be strongly influenced by the physical properties, such as water temperature and the availability of nutrients. For example, the distribution and migratory patterns of northern

elephant seals correspond with the location of three dominant water masses of the North Pacific. The localized biological productivity in these water masses and associated fronts result in a high abundance of cephalopods, an important food of this species.

Seasonal changes in prey distribution and abundance can also influence pinniped foraging patterns. Reduced prey availability leads to changes in foraging behavior that include increased trip duration, trip distance, and increased foraging effort. For example, Antarctic fur seals increase their times at sea, northern fur seals increase diving effort, and California sea lions use both tactics during periods of limited prey resources.

E. Spatial and Temporal Scales of Foraging

The relative mobility, range, and body size of an animal affects the resolution at which it recognizes environmental heterogeneity. For example, a relatively small-bodied, central place forager, such as a lactating harbor seal, would identify resource patches at a smaller mesoscale than would a highly mobile animal, such as a gray seal. To understand the relationship of an organism to its environment, one must understand the interactions between the intrinsic scales of heterogeneity within the environment and the scales at which the organism can respond to this heterogeneity. Scale issues are critical for effective conservation and management of pinnipeds because of shifts in habitat use and dispersal over ontogeny and a relatively long lifespan.

Large body size and the capacity for storing large amounts of fat in the form of blubber enables some species of pinnipeds to feed irregularly, and thus to exploit distant foraging locations and patchy resources. Austin *et al.* (2006b) found that in adult gray seals, trip duration and total time spent at depth during diving were the best predictors of the number of feeding events per day. However, the predictors differed at different temporal scales. At the 3-h scale, mean bottom time and distance traveled were the best predictors; but at longer scales, only distance traveled predicted the number of feeding events. In contrast, smaller pinnipeds, such as Antarctic fur seals, perceive environmental heterogeneity at a more local scale. For example, fur seals forage at two spatial distributions: (1) fine-scale, represented by short (<5 min) travel durations between patches, and (2) mesoscale, represented by longer periods of travel (>5 min) (Boyd, 1996). Similarly, based on fatty acid signature analysis, harbor seals appear to demonstrate mesoscale partitioning of foraging habitat in Prince William Sound, Alaska. Fatty acid signatures obtained from harbor seal blubber biopsies differed within the Sound at a spatial scale of about 40–50 km, and at a smaller scale of 9–25 km, reflecting fine-scale differences in diet between haul-out sites (Iverson *et al.*, 1997).

Although the patch structure of an environment is expressed in both space and time, temporal variation in predator behavior is likely to provide an insight into the spatial distribution of a highly dynamic prey source that may be difficult to track in other ways. For example, in the Antarctic Ocean, krill is patchily distributed and is the major prey resource of lactating Antarctic fur seals. By using the diving behavior of females obtained from TDR records, it is possible to track the way in which fur seals respond to within-season and inter-annual variation in prey patchiness and abundance. Over a 5-year period, changes in the distribution of travel durations between diving bouts suggested that the spatial distribution of krill swarms varied between years. Although their foraging behavior did not indicate that there was a reduction in the number of krill patches, reduced pup growth rates suggested that patches were of poorer quality, and thus the females had difficulty meeting lactation needs. To compensate,

females spent a greater amount of time at each patch, thereby maximizing their average rate of energy intake (Boyd, 1996).

To maximize fitness during years of reduced prey abundance, pinnipeds must be sufficiently plastic in their foraging strategies to compensate for added foraging costs. To determine the temporal scales at which predators make these behavioral decisions, Boyd and colleagues simulated increased foraging costs in Antarctic fur seals by adding an extra drag to lactating females, thereby increasing energy expenditure. At the scales of individual dives, the treatment group made shorter and shallower dives than did the control (no extra drag added) seals. It appeared that diving behavior was adjusted to maximize the proportion of time spent at the bottom of dives. At the scale of diving bouts, there was no variation between the two groups in bout frequency and duration, or the time spent diving. However, at the scale of complete foraging cycles, the time spent at sea was significantly longer in the treatment group, yet there was no difference in pup growth rate between control and treatment groups.

In contrast to otariids, most phocid seals are able to fast throughout much of the breeding season, owing to their large body size and corresponding energy stores. As a result, behavioral responses of phocids to changes in food availability between years may be more flexible, resulting in less severe effects on their population dynamics. Nevertheless, a change to less profitable prey or increased foraging effort may have energetic consequences that result in impacts at the population level. In the Moray Firth, Scotland, clupeid fishes are the dominant prey of harbor seals. In years when clupeids are absent from inshore waters, seals travel further to feed and use alternative prey. As a consequence, the seals showed evidence of reduced body condition, suggesting that there were energetic consequences to this change in diet. Between-year differences in survival rates suggest that temporal variation in prey abundance and resulting diets also have consequences for the dynamics of phocid populations (Thompson *et al.*, 1996).

IV. Role of Pinnipeds in Aquatic Ecosystems

Although pinnipeds are one of the more visible components of the marine ecosystems, our understanding of their ecological roles is surprisingly limited. Still, there is some evidence that pinnipeds may have important effects on the structure and functioning of some ecosystems (Bowen, 1997). Given that pinnipeds are large, long-lived animals that are often present in considerable numbers, we might expect some species to exert top-down control on ecosystems. However, conclusive studies are lacking, largely owing to the difficulty of conducting manipulative experiments in the ocean, the fact that interactions occur at quite different spatial and temporal scales, and the inherent indeterminacy in the behavior of complex marine systems.

Ecosystem structure and functioning are influenced by both top-down (i.e., consumer driven) and bottom-up (i.e., producer driven) processes. Pinnipeds likely exert top-down control on some ecosystems through predation and are affected by changes in food available brought about by changes in primary and secondary productivity. An example of a top-down ecosystem perturbation affecting pinniped abundance occurred in the Southern Ocean in the early 1900s. The overexploitation of some species of seals and whales led to an enormous uncontrolled “experiment” in this cold-water ecosystem. A high biomass of Antarctic krill is the cornerstone of the Southern Ocean food web, accounting for half of total zooplankton biomass. Of the six species of pinniped which inhabit the Southern Ocean, crabeater seals, Antarctic fur seals, and leopard seals feed mainly on krill, while southern elephant seals and Ross seals consume mainly

cephalopods, and Weddell seals eat primarily fish. Krill is also the main food resource for the resident large baleen whales (blue [*Balaenoptera musculus*], sei [*B. borealis*], minke [*B. acutorostrata*], humpback [*Megaptera novaeangliae*], fin [*B. physalus*], and southern right [*Eubalaena australis*]). As the cetacean biomass declined from exploitation by more than 50% between 1904 and 1973, an estimated 150 million tons of krill were released annually to the remaining predators (Laws, 1985). The abundance of krill-eating species of pinniped, such as the crabeater seal and the Antarctic fur seal, increased substantially following the massive cetacean exploitation.

Bottom-up effects on top predators such as pinnipeds also can occur rapidly over the course of months. Perhaps the most dramatic example of this occurs during El Niño. El Niño events occur approximately every 4 years in the eastern tropical Pacific, resulting in reduced upwelling and a decrease in primary and secondary productivity. During a severe El Niño, the effects of reduced food availability on seabirds and marine mammals can be quite pronounced. Galapagos fur seals have an unusually long lactation period of approximately 2 years that is thought to have evolved to buffer young against minor El Niño events. However, during the severe El Niño event between August 1982 and July 1983, pup production of Galapagos fur seals was only 11% of previous years, and no pups survived past the first 5 months. Adult females responded by increasing foraging trip length, while most adult males did not appear on the breeding site and were unable to hold territories during the breeding season (Trillmich and Ono, 1991).

Top-down and bottom-up processes usually act simultaneously to influence the abundance of pinnipeds, although it may be difficult to determine their relative strengths. One example of this is illustrated by the dramatic declines in western population of Steller sea lion numbers in the Bering Sea, Aleutian Islands, and Gulf of Alaska beginning in the 1970s and continuing through the late 1990s. Both top-down (lethal takes by humans, killer whale [*Orcinus orca*] predation) and bottom-up (regime shift in ocean climate effects on food, commercial fishing effects on food) effects have been advanced to account for the observed declines. Although, specific causes remain uncertain, an important feature of the dynamics of the western population is that both declines and the recent increases in numbers were not spread uniformly throughout the population. This indicates that multiple factors have driven changes in Steller sea lion dynamics, but that both the nature and magnitude of those factors have differed over time and space.

One example of top-down control exerted by a pinniped species comes from a study of lakes in northern Quebec. Lower Seal Lake has a population of landlocked harbor seals, and compared to nine neighboring lakes without seals, supports a different fish community. The relative abundance of lake trout (*Salvelinus fontinalis*) was greater in the nine lakes without seals, whereas brook trout (*S. namaycush*) was the dominant species in Lower Seal Lake. Compared to lake trout in neighboring lakes, those in Lower Seal Lake were on average smaller, younger, grew more rapidly, and matured earlier, all of which represent life history characteristics that are associated with heavy exploitation. Although based on strong inference rather than direct empirical evidence, it appears that seal predation was responsible for both the changes in community structure and life history traits of fish species in Lower Seal Lake (reviewed in Bowen, 1997).

Pinnipeds may also play a role in structuring benthic communities. Walrus disturb bottom sediments during feeding. By selectively feeding on older individuals of a few species of bivalve molluscs, walrus may be responsible for structuring the benthic fauna. Ingestion and defecation by walrus may result in substantial

redistribution of bottom sediments, which may favor colonization of some species. In addition, during the process of feeding, walrus produce many pits and furrows in the soft sediments. Thus, walrus feeding appears to affect community structure in three ways: by (1) providing food for scavengers such as sea stars and brittle stars, (2) providing habitat under discarded bivalve shells, and (3) reducing the abundance of macroinvertebrates in feeding pits compared to surrounding sediments. Nonetheless, the effects of walrus feeding behavior on macrobenthic assemblages over periods greater than a few months and at larger spatial scales remain unknown.

V. Conclusions

Our understanding of the ecology of pinnipeds has increased dramatically over the past several decades, but advances have been rather uneven. For example, the mating systems of terrestrial species and lactation strategies of pinnipeds are reasonably well understood, as are both diving and ranging behavior of many species, but other aspects of foraging ecology, diet, and the ecological role of pinnipeds in aquatic ecosystems remain difficult to study. As in all areas of science, our ability to measure the system under study profoundly influences the rate of progress. New types of data-loggers, telemetry, and methods to estimate the diet of free-ranging pinnipeds have played an important part in recent advances in current understanding. As well, we should not underestimate the importance of collaborative research involving ecologists, oceanographers, and population and ecosystem modelers.

The earliest pinnipeds were aquatic carnivores with well-developed paddle shaped limbs and feet. A North Pacific origin for pinnipeds has been hypothesized; the group subsequently diversified throughout the world's oceans.

I. Pinniped Ancestry: Origin and Affinities

There has long been a debate about the relationship of pinnipeds to one another and to other mammals. The traditional view, also referred to as diphyly, proposes that pinnipeds originated from two carnivore lineages, an odobenid (walrus) plus otariids (fur seals and sea lions) grouping affiliated with ursids (bears) and phocids (seals) being related to mustelids (weasels, skunks, otters, and kin) (Fig. 1a). The current view overwhelmingly supported by both morphologic and molecular data confirms pinnipeds as monophyletic (having a single origin). Although the hypothesis presented here positions ursids as the closest relatives of pinnipeds, it is acknowledged that there is difficulty separating the various lineages of arctoid carnivores (mustelids, procyonids, and ursids) at their point of divergence (Fig. 1b). An alternative hypothesis supports pinnipeds as having an ursid-mustelid ancestry (see PINNIPEDIA). With regard to relationships among pinnipeds most current data robustly supports a link between odobenids and otariids.

II. Divergence of Major Lineages

The broad pattern of evolution within pinnipeds shows divergence of five major lineages. These include the three extant lineages: Otariidae, Phocidae, and Odobenidae and two extinct groups, the Desmatophocidae and a basal lineage *Enaliarctos* (Fig. 2). At times the Odobenidae have been included in the Otariidae, although current studies consistently support these as distinct monophyletic groups that share a sister group relationship.

Within Pinnipedimorpha (living pinnipeds plus their fossil allies) are included archaic pinnipeds *Enaliarctos* and *Pteronarctos* + pinnipeds (Fig. 2). Unequivocal synapomorphies include: large infraorbital foramen, anterior palatine foramina anterior of maxillary-palatine suture, upper molars reduced in size, lower first molar metaconid reduced or absent, humerus short and robust, deltopectoral crest on the humerus strongly developed, digit I on the manus and digit I and V on the pes emphasized. The basal taxon *Enaliarctos* from the late Oligocene and early Miocene (27–18 Ma; Fig. 3) of California is known by five species, one represented by a nearly complete skeleton (Fig. 4). *Enaliarctos* was a small, fully aquatic pinnipedimorph with shearing teeth (as is typical of most terrestrial carnivorans), flexible spine, and fore and hindlimbs modified as flippers. Several features of the hindlimb suggest that *Enaliarctos* was capable of maneuvering on land although probably spent more time near the shore than extant pinnipeds. *Enaliarctos* shows features that are consistent with both fore- and hindlimb swimming, but seems slightly more specialized for forelimb swimming (Berta and Adam, 2001). A later diverging lineage more closely allied with pinnipeds than with *Enaliarctos* is *Pteronarctos* from the late Miocene (19–15 Ma) of coastal Oregon. *Pteronarctos* is recognized as the earliest pinniped to have evolved the unique maxilla diagnostic of modern pinnipeds. The maxilla of pinnipeds makes a significant contribution to the orbital wall. This differs from the condition in terrestrial carnivores in which the maxilla is limited in its posterior extent by contact of several facial bones (jugal, palatine, and/or lacrimal). Ecologically, the earliest pinnipedimorphs were coastal dwellers that evolved a pierce feeding strategy and likely fed on fish and other aquatic prey (Adam and Berta, 2002).

The fur seals and sea lions (eared seals), the Otariidae, are diagnosed by frontals that extend anteriorly between the nasals, large and

Pinniped Evolution

ANNALISA BERTA

The name Pinnipedia was first proposed for fin-footed carnivores more than a century ago. Pinnipeds—fur seals and sea lions, walruses and seals—are one of three major clades of modern marine mammals, having a fossil record going back at least to the late Oligocene (27–25 Ma—millions of years before present).

Figure 1 Alternative hypotheses for relationships among pinnipeds (A) Monophyly with ursids as the closest pinniped relatives. (B) Diphily in which phocids and mustelids are united as sister taxa as are otariids, odobenids, and ursids. (From Berta et al., 2006.)

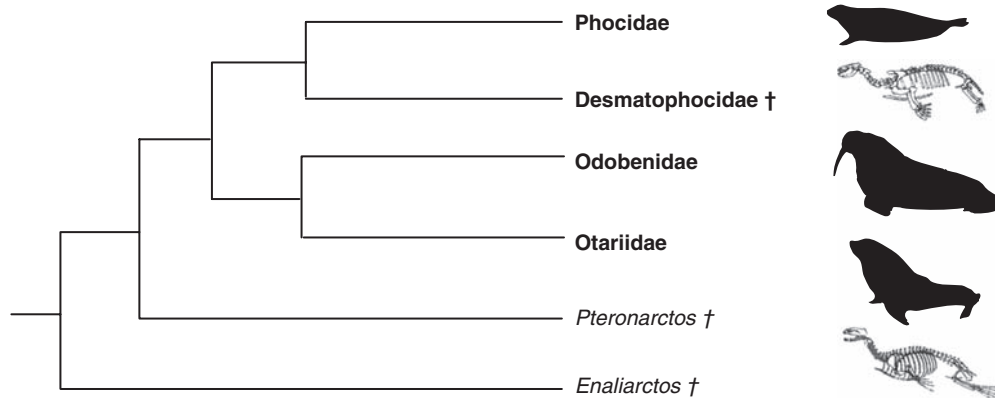

Figure 2 A cladogram depicting the relationships of the major clades of pinnipeds. (Modified from Berta et al., 2006.)

shelf-like supraorbital process of the frontal, secondary spine dividing the supraspinous fossa of the scapula, uniformly spaced pelage units, and by the presence of a trachea with an anterior bifurcation of the bronchi (Fig. 5). Although otariids are often divided into two subfamilies, the Otariinae (sea lions) and the Arctocephaline (fur seals), both groups have been shown to be paraphyletic on the basis of molecular data. The otariids are the earliest diverging pinniped lineage originating approximately 11–12 Ma (Fig. 3) and including the poorly known *Pithanotaria* from the late Miocene of California and three species of *Thalassoleon* described from the late Miocene and early Pliocene of California, Mexico and Japan (Deméré and

Berta, 2005; Fig. 6). An extinct species of the Northern fur seal, *Callorhinus* has been described from the late Pliocene of southern California, Mexico, and Japan. *Hydrarctos* is an extinct fur seal from the Pleistocene of Peru. Several extant species of *Arctocephalus* have a fossil record extending to the Pleistocene in South Africa and North America (California). The fossil record of modern sea lions is poorly known. The following taxa are reported from the Pleistocene: *Neophoca* (New Zealand), *Eumetopias* and *Zalophus* (Japan), and *Otaria* (Brazil).

The basal split between otariids and odobenids based on molecular data is close to the age of the oldest enaliarctid fossils and much

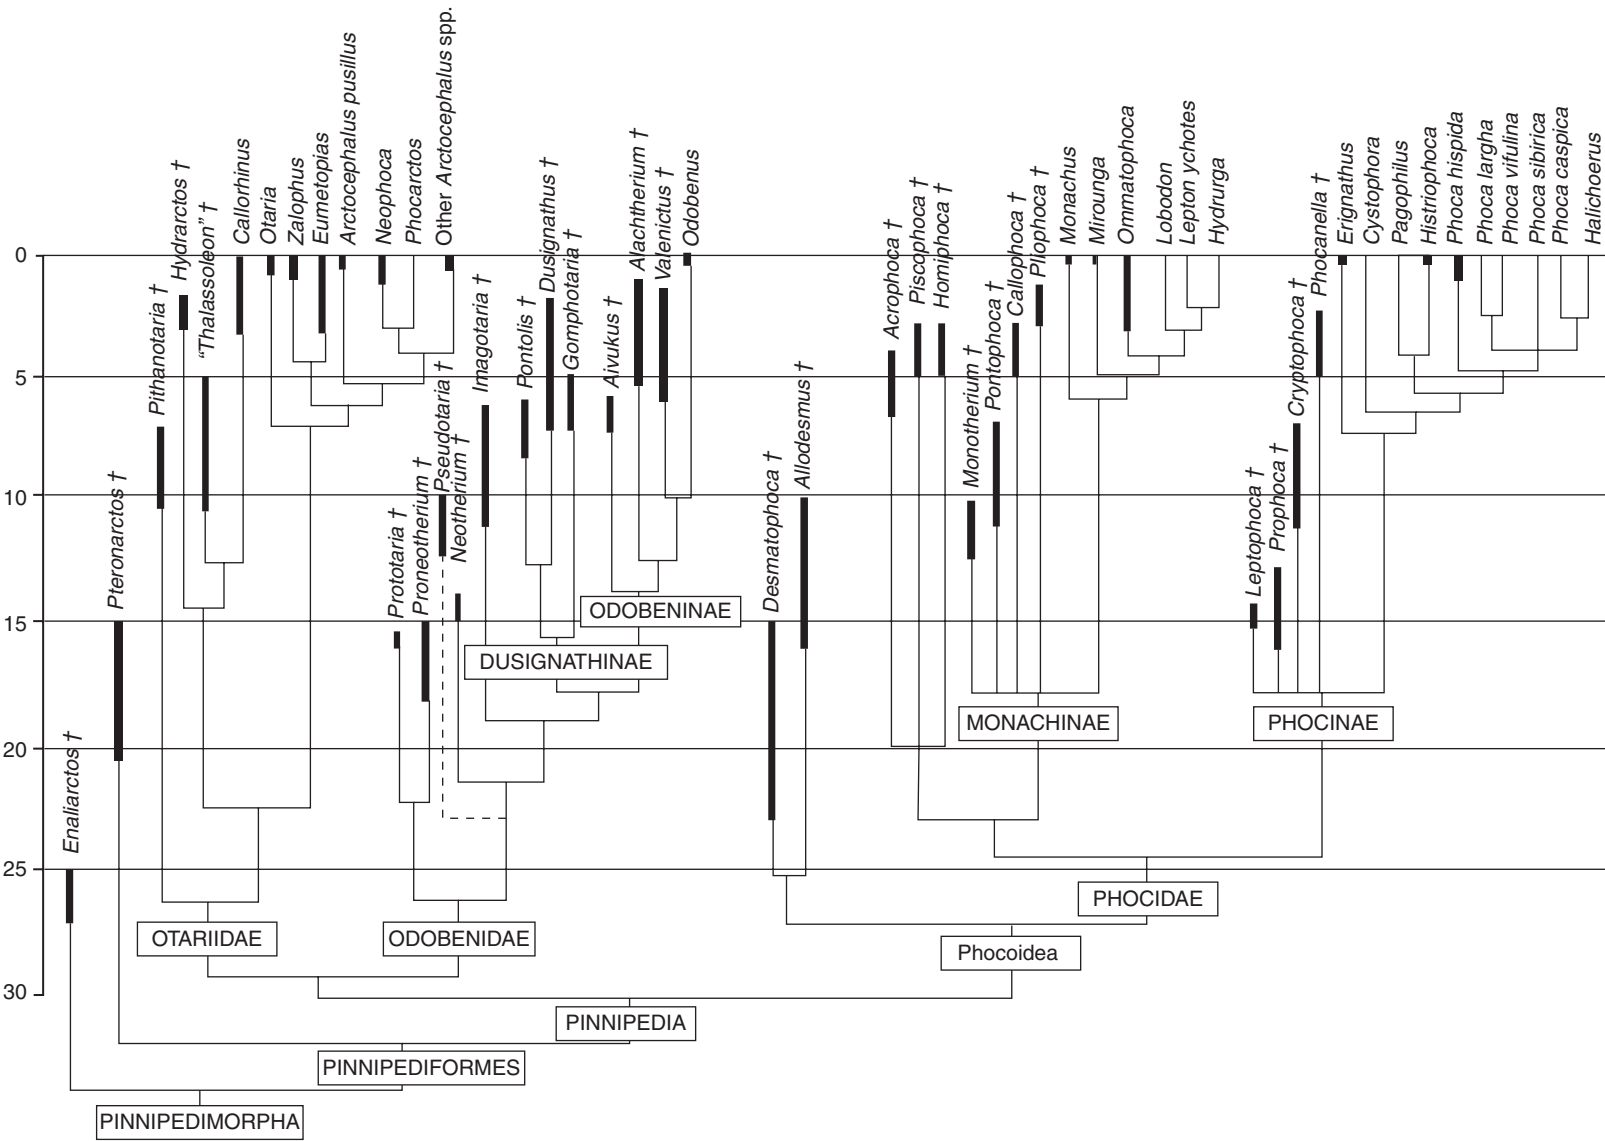

Figure 3 Chronologic ranges of major lineages and genera of extinct and living pinnipeds. Time scale in millions of years. Thick lines show stratigraphic ranges of taxa and thin lines indicate their phylogenetic relationships (otariid and phocid phylogeny based on Arnason et al., 2006). Position of fossil walrus *Pseudotaria* indicated by dashed line is based on Kohno (2006). Branching points are not necessarily correlated with the time scale. (Modified from Deméré et al., 2003.)

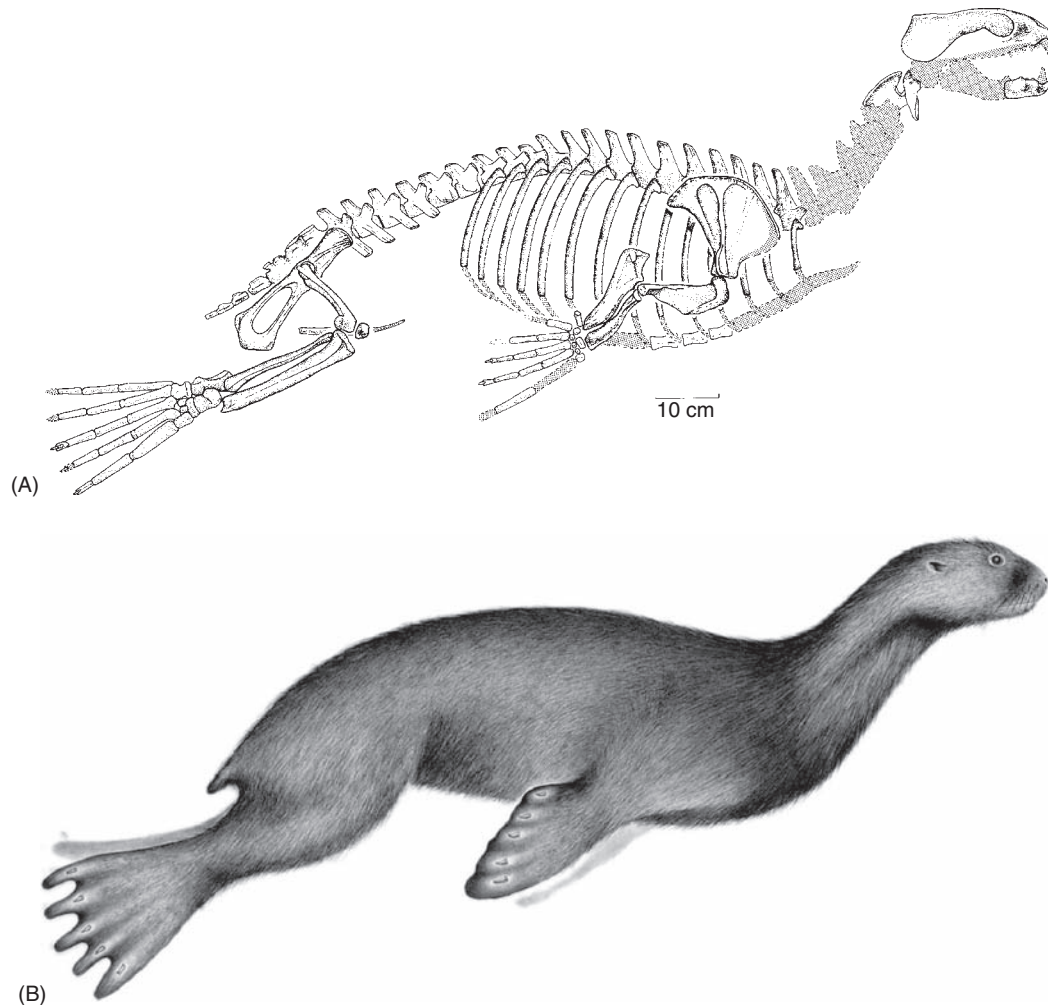

Figure 4 The pinnipedimorph *Enaliarctos mealsi* showing pinnipedimorph synapomorphies described in text. (From Berta and Ray, 1990.)

older than the earliest recognized fossils of these lineages (Arnason *et al.*, 2006). Otariids appear to have originated in the North Pacific (Fig. 7). The basal split between *Callorhinus* and other otariids dated to 16mya is older than the oldest otariid fossil *Pithanotaria* from 11 mya rocks in California. The subsequent divergence of *Otaria*, *Zalophus* + *Eumetopias* from other otariids likely took place in the North Pacific with *Otaria* dispersing along the west coast of South America and later along the Atlantic coast. The diversification of remaining otariids took place in the southern hemisphere with the exception of *Arctocephalus townsendi* which remained in the North Pacific.

The walruses or Odobenidae are diagnosed as a monophyletic group by the presence of a broad, thick pterygoid strut, fourth upper premolar with a strong posterolingually placed protocone shelf, lower first molar with the talonid heel absent, and a calcaneum with a prominent medial tuberosity (Deméré and Berta, 2001 but see also Kohno, 2006; Fig. 6). Morphologic study of the evolutionary relationships among walruses has identified the following taxa: *Prototaria*, *Pseudotaria*, *Proneotherium*, *Neotherium*, *Imagotaria*, dusignathines and odobenines, the latter includes the modern walrus (see PINNIPEDIA).

Fossil walruses first appear in the early Miocene (16–18 Ma; Fig. 3) fossil record with *Prototaria* in Japan and *Proneotherium* in North America (Oregon). These archaic walruses are characterized by unenlarged canines and narrow, multiple rooted premolars with a trend toward molarization (Fig. 8), adaptations suggesting retention of the fish diet hypothesized for archaic pinnipeds rather than evolution of the specialized mollusc diet for the modern walrus. Portions of the axial and hindlimb skeleton of *Proneotherium* preserve evidence of a number of aquatic adaptations including a laterally flexible spine, a broad, shortened femur, and a paddle-shaped foot (Deméré and Berta, 2001). In addition to *Proneotherium*, *Prototaria*, and the recently described *Pseudotaria* (Kohno, 2006) a monophyletic clade of walruses comprised of *Neotherium*, *Imagotaria*, and Dusignathinae and Odobeninae diversified in the middle and late Miocene (Fig. 3). Dusignathine walruses which include *Dusignathus*, *Pontolis*, and *Gomphotaria* developed enlarged upper and lower canines. *Gomphotaria pugnax* the most completely known dusignathine is distinct cranially and dentally in its possession of large, procumbent upper lateral incisors and canines; the latter with deeply fluted roots and a small orbit. Odobenines which include *Aivukus*, *Ontocetus* (= *Alachtherium* fide Kohno, 2006), *Valenictus*

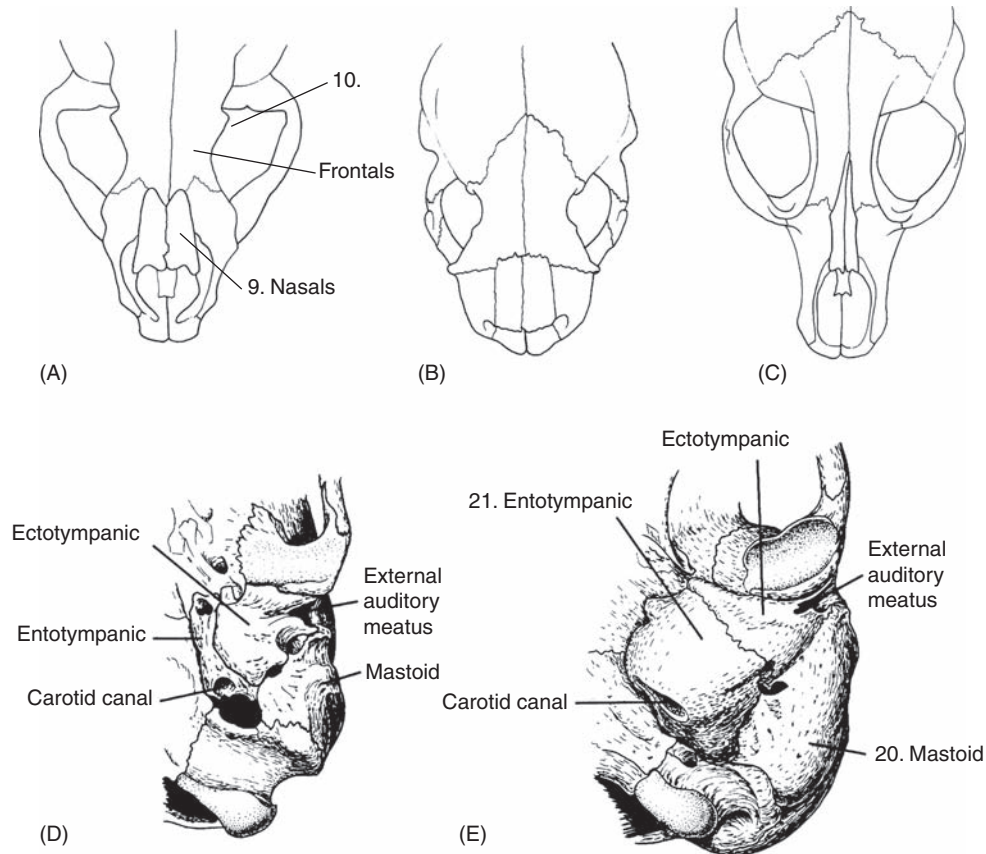

Figure 5 Skulls/ventral view of ear regions of (A, D) otariid, (B) walrus, (C, E) phocid illustrating otariid synapomorphies: frontals extend anteriorly between nasals (contact between these bones in transverse, walrus, or V-shaped, phocids and phocid synapomorphies: pachyostotic mastoid bone (not seen in other pinnipeds) and greatly inflated ectotympanic bone. (From Berta et al., 2006.)

and *Odobenus* evolved the enlarged upper tusks seen in the modern walrus. Unique among pinnipeds is the toothlessness of *Valenictus chulavistensis* from the late Pliocene of California, presumably an adaptation for suction feeding.

It has been proposed that the modern walrus lineage (odobenine walruses) entered the Caribbean from the Pacific via the Central American Seaway (between 5 and 8 Ma) and dispersed northward into the North Atlantic (Fig. 7). Less than 1 Ma the living genus *Odobenus* returned to the North Pacific through the Arctic Ocean. Alternatively, on the basis of a new, earlier record of the modern walrus lineage from Japan it has been suggested that this lineage may have evolved in the North Pacific and dispersed instead to the North Atlantic through the Arctic during the Pleistocene.

The earless seals, the Phocidae, are diagnosed as a monophyletic group by pachyostotic mastoid region, greatly inflated entotympanic bone, complete absence of the supraorbital process of the frontal, strongly everted ilia and lack of an ability to draw the hindlimbs forward under the body due to a massively developed astragalar process, and greatly reduced calcaneal tuber (Fig. 5). Although phocids have traditionally been divided into two or four major subgroups, recent molecular studies consistently support monophyly of Monachinae and Phocinae (see also PINNIPEDIA).

Figure 7 Reconstruction of continents, ocean basins, and paleocoastlines in the (A) early Miocene (20 Ma) (1: 5 early records of archaic pinnipeds, odobenids, and desmatophocids) and (B) middle Miocene (12 Ma) (1: 5 early well documented phocids, 2: 5 dispersal of “monachines” and odobenids to Atlantic, 3: 5 dispersal of phocines to South Pacific, 4: 5 isolation of phocines in remnants of Paratethys Sea and in North Atlantic). Figure 9 Skeleton of an archaic phocid, *Acrophoca longistrostris* from the Miocene of Peru. (From Muizon, 1981.)

Although an earlier less well documented record of phocids from the late Oligocene of South Carolina exists, there is undisputed evidence for both monachine and phocine seal lineages from the middle Miocene (approximately 15Ma) on both sides of the North Atlantic. Molecular estimates place monachine and phocine divergence at approximately 22mya (Arnason *et al.*, 2006). The earliest phocine *Leptophoca* and the earliest monachine *Monotherium* (Fig. 3) are known from the southeastern North America. Despite the fact that a number of fossil monachines have been described not all are known by comparable elements. In addition to *Monotherium* among the better known taxa from eastern Europe are *Pontophoca* from the middle Miocene and *Callophoca* from the early Pliocene (Koretsky, 2001). Several archaic seals (i.e., *Acrophoca* and *Piscophoca*) represented by complete skeletons are known from the late Miocene and/or early Pliocene of South America (Peru and Chile; Walsh and Naish, 2002) and *Homiphoca* from South Africa (Fig. 3). *Acrophoca* is unique among phocids with its long, slender skull, flexible neck, and elongated body (Fig. 9). Although these fossil monachines have been referred to the lobodontines (see also PINNIPEDIA), new discoveries as well as restudy of material previously referred to these taxa suggests that they may in fact be phocines. The fossil record of extant monachines is poorly known and includes only *Monachus* and *Mirounga* from the late Pleistocene and the lobodontine *Ommatophoca* from the late Pliocene (Fig. 3). With regard to fossil phocines among the best known taxa are *Prophoca* (middle Miocene) in the eastern North Atlantic, *Cryptophoca* (late Miocene) in the Black Sea region, and *Phocanella* (early Pliocene) in both the eastern the western North Atlantic (Fig. 3). Extant phocine genera with a fossil record include *Phoca* from the late Pliocene and *Erignathus* and *Histriophoca* from the late Pleistocene (Fig. 3).

The purported first appearance of phocids in the North Atlantic suggests that the common ancestor of phocids had migrated to the North Atlantic, either northward through the Arctic Basin or southward through the Central American Seaway (Fig. 7). Support for a southern route is based on the hypothesized close relationship of phocids and the extinct desmatophocids, the latter occurring as far south as Mexico, and the fact that the Bering land bridge blocked access to the Arctic through much of the late Oligocene and early Miocene. Fyler *et al.* (2005) confirmed an earlier proposal by Muizon (1982) that monk seals originated in the Mediterranean (*Monachus monachus*) with dispersal first to the Caribbean (*M. tropicalis*) and later to the central North Pacific (Hawaiian monk seal, *M. schauinslandi*). The 4mya molecular divergence of northern and southern elephant seals (*Mirounga*) may be the result of vicariance following emergence of the Panamanian isthmus (Arnason *et al.*, 2006).

The biogeographic pattern for phocine seals is no less complicated given the different phylogenetic hypotheses proposed. Although it was suggested earlier that phocines were a northern hemisphere radiation, a considerable diversity of phocine seals is known from

the southern hemisphere during the late Miocene and/or early Pliocene (assuming that *Acrophoca*, *Homiphoca*, and *Piscophoca* are phocines rather than lobodontines). In addition other phocine lineages appear to have been isolated in the Paratethys Sea (northern arm of the Tethys Sea stretching across the area now occupied by the Black, Caspian, and Aral Seas of Asia) and the North Atlantic during the late Miocene and Pliocene. Several dispersal routes for phocines seem likely. The deepest phocine split, that between the bearded (*Erignathus*) and hooded seals (*Cystophora*) was dated to 17mya based on molecular data (Arnason *et al.*, 2006). This suggests an eastward and northward migration of phocines in the North Atlantic. The hooded seal occurs at high latitudes of the Atlantic basin and apparently never successfully dispersed to the Pacific. The bearded seal is presently confined to the Arctic and subarctic around the North Atlantic but Pleistocene records extend as far south as Portugal. A subsequent dispersal route for phocines involved initial migration from Paratethys Sea into the Arctic Basin, followed by an eastward migration to give rise to modern *Phoca/Pusa*. In this scenario the landlocked Baikal seal (*Pusa sibirica*) gained access to Lake Baikal from the Arctic via large lakes at the southern margin of the Siberian ice sheet. A second landlocked species, the Caspian seal (*Pusa caspica*) remained in the Caspian Sea an isolated remnant of Paratethys as judged by the presence of fossils similar to living Caspian seals in this location. Another hypothesis argues for a North Atlantic origin for all phocines with glacial events causing speciation. For example, cyclical fluctuations in glacial maxima (with concomitant variations in sea level) through the Pleistocene mediated range expansions of *Phoca* spp. ultimately leading to isolation of populations in refugial centers (i.e., Arctic, Okhotsk, Aleutian) and divergence of populations (e.g., ribbon seal, *Histriophoca fasciata*, ringed seal, *Pusa hispida*, largha seal, *Phoca largha*, harbor seal, *Phoca vitulina*, harp seal, *Pagophilus groenlandica*).

An extinct family of archaic pinnipeds, the desmatophocids are characterized by elongate skulls, relatively large eyes, mortised contact between two cheekbones, and bulbous cheek teeth (Fig. 10). Cladistic analysis has identified the Desmatophocidae which includes two genera, *Desmatophoca* and *Allodesmus* as the common ancestors of phocid pinnipeds. This clade, phocids + *Allodesmus* and *Desmatophoca*, termed the Phocoidea, is supported by four synapomorphies including: premaxilla–nasal contact reduced, squamosal–jugal contact mortised, marginal process below ascending ramus well-developed (Deméré and Berta, 2002; Fig. 2). This interpretation differs from previous work that recognized desmatophocids as otarioid pinnipeds (a paraphyletic group that includes walruses but excludes phocids). Desmatophocids are known from the early and middle Miocene (23–10Ma) of western US and Japan (Fig. 3). Newly reported occurrences of *Desmatophoca* confirm the presence of sexual dimorphism and large body size in these pinnipeds (Deméré and Berta, 2002). *Allodesmus* is a diverse taxon (as many

Figure 10 Skeleton of the desmatophocid, *Allodesmus kernensis* from the Miocene of western North America. Original 2.2 m long. (From Mitchell, 1975.)

as six species have named) with taxa informally divided into “broad headed” and “long headed” subgroups. The previous suggestion that *Allodesmus* retained a mobile proboscis, much like the modern elephant seal seems unlikely on anatomical grounds. *Allodesmus*, known by several complete skeletons, retains several features consistent with forelimb propulsion but also displays adaptations for hindlimb swimming (Berta and Adam, 2001).

Pinniped Life History

IAN L. BOYD

The life history of an individual is the pattern of allocation of resources to maintenance, growth, and reproduction throughout its lifetime. Life history analysis attempts to explain the scheduling of the allocation process throughout an organism’s life. It assumes implicitly that it is appropriate to classify individuals by age because this is a major component of the independent variable representing time that is used to examine variation in resource allocation. However, we know that other properties of an individual, such as its body condition or foraging skill, are also important variables that affect reproduction and ultimately fitness.

Most life history studies involving pinnipeds have assumed that age is the main force in pinniped life histories when, in fact, age *per se* may have relatively little to do with influencing fitness. It is a paradox of life history studies that they are, by definition, time-based approaches to examining variation in the fitness between individuals when time itself probably has less biological importance than other factors. One such factor in pinnipeds is body size, long recognized as a determinant of sexual maturity in pinnipeds. Age at sexual maturity in pinnipeds can be expressed as a decreasing function of growth rate. Expressed at the level of populations, this is interpreted to mean that individuals within pinniped populations that are at a level well below the environmental carrying capacity would experience higher growth rates and would, therefore, become sexually mature at an earlier age (Bengston and Laws, 1985). This was an implicit acknowledgment that age was not the operant factor in pinniped life histories and was at best secondary to the size of the energy reserves of an individual. Nevertheless, despite the considerably greater difficulties that exist with measuring age in pinnipeds than there are with measuring body size (e.g., mass or some other suite of morphometrics), age has continued to be used as the primary independent variable in life history studies.

I. Characteristics of Pinniped Life Histories

Pinniped life histories are characterized by three main features: (1) by mammalian standards, pinnipeds have high annual survival rates, giving potential longevities in the order of two to four decades; (2) the average age at sexual maturity is delayed by 2–6 years depending on the species (Table I); and (3) each adult female normally produces a maximum of one offspring per reproductive cycle. Variations on this theme at the level of individuals and species can provide insight into the evolution of life histories in pinnipeds.

Pinniped life histories are assumed to have evolved to maximize the genetic fitness of individuals. This occurs in pinnipeds within the constraints of a semiaquatic existence and has most probably led to the relatively narrow range of life histories we observe within the taxon. All pinnipeds rely to some degree on ice or land for reproduction, particularly the processes of birth and lactation. Many interacting variables have led to the evolution of pinniped life histories, including the joint and sometimes conflicting needs to avoid predation, to forage with maximum efficiency, and to choose a mate of high quality.

By mammalian standards, pinnipeds are animals with a large body size. However, in terms of their demography and their investment in reproduction, pinnipeds do not appear to differ greatly from other mammals after body size has been taken into consideration. There are also no obvious relationships between body size and life history variables at the species level within the pinnipeds (Table I), although, as we shall see, this is not the case for variation between individuals within species.

Large body size has a cost in that relatively large amounts of resources are invested in tissue growth and maintenance and it takes a relatively long time to reach a body size capable of supporting reproduction. There is also a need to produce precocial young that can defend themselves against predation from an early age or that can forage independently of their mothers within days to weeks of birth. This necessitates greater investment in individual offspring and limits the number of young that can be produced at a single reproductive attempt. It also means that the rate of reproduction (number of young born per unit time) is relatively low. The combination of high investment in growth, causing a delay in sexual maturity, and low reproductive rates, even when sexually mature, means that pinnipeds must have relatively high longevities (low rates of mortality). Without this combination of demographic variables individuals could not, on average, replace themselves during their lifetimes.

II. Methods for Examining Life Histories

Life histories are represented most concisely by demographic models based on empirical measurements of survival and fecundity rates. Demographic variables for pinnipeds are summarized in Table I. Among the 36 species of pinnipeds, some form of demographic information is available for most species, but as seen from Table I, there are very few for which there could be said to be complete information, and, in almost all of these, information is mainly available for females. Very little is known about the life histories of male pinnipeds. It is also perhaps a little misleading to represent these demographic variables in terms of species, as many vary as much between different populations of the same species as they do between the species themselves. Averaging across populations also has the disadvantage that it obscures the variation in life histories between individuals. Therefore, while life histories may, in practice, often be examined at the level of populations using demographic parameters, it is an important tenet of life history analysis that it is

based on the demography of individuals. This distinguishes life history analysis from the study of population dynamics, which normally deals with individuals as if they are all identical.

The most complete information about life histories for any population of pinnipeds comes from Weddell seals (*Leptonychotes weddellii*) at McMurdo Sound, Antarctic (Hastings and Testa, 1998), and northern elephant seals (*Mirounga angustirostris*) from Año Nuevo or the Farallon Islands, California (Reiter *et al.*, 1981; Sydeman *et al.*, 1991). These studies were based on the long-term mark-recapture of individuals. Similar studies have been carried out on Antarctic fur seals species (*Arctocephalus gazella*) (Boyd *et al.*, 1995) and gray seals (*Halichoerus grypus*) (Pomeroy *et al.*, 1999). Mark-recapture is probably the only way to examine life histories in pinnipeds to provide the quality of data necessary to understand the complex interactions between factors that influence fitness. However, such studies can only be undertaken in special circumstances where there is particularly easy access to the study population. In most cases, information about population life histories has been derived from cross-sectional samples of populations based on one-off or sequential culls that were often part of a commercial harvest (Bowen *et al.*, 1981; Fowler, 1990). Although some of the disadvantages of this method may be offset by the advantages of a large sample size, it has the potential to lead to misinterpretation of the pattern of life history. Some of these problems are discussed.

III. Constraints on Life Histories

Pinniped life histories have evolved under a combination of factors that are broadly based around the need for animals to balance their energy budgets. These include the constraints involved with (1) being homeothermic in water that is 25 times more conductive than air and (2) the high temporal and spatial variability in the distribution of resources within the marine environment. Phylogeny may also be seen as a constraint in that the ancestors of pinnipeds may not have possessed an ideal range of characteristics (physiological, anatomical, social, or distributional) for exploiting the marine environment. Therefore, current pinniped life histories may be constrained by difficulties with inherent mechanisms.

An example of such a constraint is the apparent necessity for a terrestrial (or pagophilic) phase during the reproductive cycle. This may be a consequence of the occupancy by ancestral pinnipeds mainly of temperate and polar marine habitats in which small neotates may have difficulty with thermoregulating in cold water, thereby necessitating terrestrial living for young neonates. Pinnipeds may have been locked into this form of reproductive cycle from an early stage in their evolution.

The constraint of the terrestrial phase in reproduction has brought with it other social and life history consequences. The necessity for mothers to find suitable terrestrial habitat (including ice) for parturition has more or less isolated, both spatially and temporally, the reproductive process from the feeding grounds. Species that exploit distant, unpredictable food sources require larger body mass than those that exploit food that is present at relatively close range to the pupping location. This is because there will be a critical duration over which a pup can be left without feeding and with low risk of starvation. If mothers cannot forage profitably during lactation within this critical duration, it is necessary for mothers to carry with them at parturition most of the food reserves required to raise their pup to independence (Boyd, 1998).

The extreme seasonality of food availability in higher latitudes has also led to extreme seasonality of reproduction, resulting in

^dJuvenile survival rates fall within the same range.

^eJuvenile survival >1 year old ~0.70.

^fSurvival in first year.

^gValues for juvenile males aged 4 months–2 years are 0.20–0.50; those for males aged 2–5 years are 0.75–0.90.

^hProbably negatively biased because of the inclusion of juveniles.

spatially and temporally synchronized reproduction. It is possible that both sexes have used this to affect greater mate choice, which has produced polygynous, highly competitive mating systems. These combined factors have led, in most species to an annual cycle of reproduction.

IV. Costs vs Benefits of Reproduction

Even though individuals may have the option to reproduce annually, longitudinal studies show that they do not always exercise this option. Even when individuals do reproduce, they may adjust the amount of resources they supply to their offspring. The reasons for this are centered on the decision that individuals must make during their life times in order to maximize their fitness, often measured in terms of number of offspring produced across their whole lifetime and not just one reproductive cycle.

There are obvious fitness gains from reproduction, but there are also costs involved. For example, in Antarctic fur seals (*Arctocephalus gazella*), reproduction in any year carries with it a 40% greater chance of dying in the following year. It also carries a similar cost in terms of reduced probability of breeding in the following year (Boyd *et al.*, 1995). In northern elephant seals (*Mirounga angustirostris*), mothers that reproduce for the first time at age 3 incur greater costs, in terms of reduced survival, than those that breed first at age 4 (Reiter and Le Boeuf, 1991). Female gray seals (*Halichoerus grypus*) that expend more on their offspring in 1 year also have reduced reproductive success in the following year (Pomeroy *et al.*, 1999). Thus, female pinnipeds must find a solution of how best to allocate energy between growth/maintenance and reproduction that optimizes the balance between fitness costs and benefits of reproduction. Male and female pups have different survival rates as a result of maternal investment (Hall *et al.*, 2001). Those individuals that achieve the optimum balance will have greatest lifetime fitness. How pinnipeds make investment decisions in order to optimize this balance is the focus of much recent research (Schulz and Bowen, 2004). In reality, few individuals may actually achieve the optimum, especially in variable environments, but natural selection favors those individuals that make investment decisions that approach the optimum most closely.

V. Age at First Reproduction

All pinnipeds experience a delay of several years in the time taken to reach sexual maturity (Table I). Several studies have shown that the age at first reproduction is not constant. In harp seals (*Pagophilus groenlandicus*) it is negatively related to population size (Bowen *et al.*, 1981), implying that the age at which individuals mature is density dependent (Trites and York, 1993). Further evidence for a shift in age at sexual maturity with population size exists for crabeater seals (*Lobodon carcinophaga*) (Bengston and Laws, 1985). The speed with which the change occurs shows that this is not an effect mediated by natural selection for individuals with different life history patterns, rather it is almost certainly driven by changes in the growth rates of individuals as population density and, by implication, per capita food availability changes. Consequently, the mean age at sexual maturity in a population may simply be a reflection of the mean growth rate.

Among northern elephant seals, females tend to begin breeding at age 3 or 4. The fitness of individuals that begin to breed at age 4 is greater than those that begin at age 3 because there is a cost, in terms of reduced survivorship, for those that begin breeding at age 3 (Reiter and Le Boeuf, 1991). In Antarctic fur seals there is a similar disadvantage to breeding at an earlier age (Lunn *et al.*, 1994), although, for those individuals that survive, there is no subsequent effect on reproduction through the remainder of life.

These results suggest how age at sexual maturity can be determined by natural selection. In northern elephant seals and Antarctic fur seals there appears to be a trade-off between the fitness costs of breeding early in life and the fitness gains from early reproduction. Although, on average, individuals that begin breeding at age 3 have lower survival, it is possible that those that breed at age 3 and survive have increased fitness mainly because they have, on average, one more reproductive attempt than those that begin breeding at age 4. Animals may opt to take a greater risk by breeding first at age 3 but with the prospect of greater ultimate lifetime fitness. For the trade-off between breeding first at age 3 or 4 to operate and be evolutionarily stable, both strategies must have equal median lifetime fitness.

VI. Variations in Measures of Fitness

Strictly speaking, fitness should be measured in terms of the number of grandchildren that are produced by an individual. However, no study of pinnipeds has been able to do this, so a variety of fitness indices are used. The simplest and least informative of these is fertility rate, followed by weaning rate, proportion of offspring surviving their first year, and proportion of offspring surviving to reproductive age. There are specific examples of each of these measures from studies of pinnipeds.

Fertility rates in pinnipeds are normally in excess of 0.8 (Table I) and, given other vital rates in pinniped demography, they normally have to be of this order for populations to have the potential to grow. Longitudinal studies of individual pinnipeds show that most females experience fallow reproductive cycles in their lifetimes (Lunn *et al.*, 1994). It remains unclear if the observation of declining fertility with increasing age in cross-sectional samples of pinniped populations reflects senescence of individuals. The observation could equally be caused by greater survival rate, and therefore greater representation in older age classes, of individuals with intrinsically low reproductive rates.

Like age at sexual maturity, fertility is probably linked to the attainment of a critical minimum body condition at a specific stage of the reproductive cycle. In fact, physiologically, there may be virtually no difference between the process of puberty and the seasonal recrudescence of the reproductive system, so the two processes could be considered to be controlled by a common mechanism.

Fertility rates are influenced by previous experience of reproduction. In northern elephant seals, it appears that most females that miss a breeding attempt compensate for this by having a higher probability of weaning a pup in the following year, although, early in the reproductive life span, the opposite effect has been observed, i.e., individuals that miss a reproductive cycle have low success in the following year. Therefore, offspring quality may be affected by previous reproductive experience. Antarctic fur seals are significantly less likely to reproduce in a year following a reproductive attempt.

Weaning rates are affected by both age and previous experience of reproduction in northern elephant seals. It appears that although weaning rates increase initially with experience, these begin to decline later in life. This may represent a cumulative cost of reproduction that is manifest as senescence. However, it is still uncertain if this effect is an artifact of sampling caused by greater longevity in individuals that tend to skip reproduction more frequently or invest a smaller proportion of their energy reserves in their offspring.

Weddell seal (*Leptonychotes weddellii*) offspring survival to age 1 and reproductive age both increase with maternal age and experience and, for male offspring, in relation to maternal body length (Hastings and Testa, 1998). Again, this suggests that those individuals that were able to invest more resources in their offspring, by virtue

of their larger size and greater experience (perhaps reflecting the occupancy of better habitat), had enhanced fitness.

VII. Comparing Males and Females

Because females are the limiting sex and because it is much more difficult to study reproductive success in males, more attention has been focused on female than on male pinnipeds. Nevertheless, males may invest large amounts of their energy reserves in reproduction. In general, males have shorter life expectancies than females (shown by lower annual survival rates in Table I), but it is not clear how this is influenced by the investment in reproductive effort. Investment theory would suggest that the shorter life expectancy of males is because of their preparedness to take greater risks with their survival. The potential gains from reproduction, in terms of offspring, in males that are successful competitors because they make a large investment are greater than for females that are restricted to producing a single offspring per season.

There is also confusion in the literature about when males become sexually mature. The age at physiological maturity in males is probably similar to that of females, but many authors make a distinction between physiological and social maturity, which is defined by the age at which individuals are capable of competing for matings. Recent genetic evidence (Amos *et al.*, 1993) is casting doubt on some of the former interpretations of what social maturity actually means because the pattern of mating success in males often does not follow the pattern suggested by the observed social structure. In the near future, we may have to revise our views of the life history patterns of male pinnipeds.

VIII. Optimal Life Histories: Modeling the Way Forward

Life history analysis in pinnipeds is fraught with difficulties. Longitudinal studies in which individuals are studied throughout their lifetimes can only be carried out on a narrow range of accessible populations and they are expensive and logistically complex to maintain over the time periods (usually decades) required to achieve useful results. Cross-sectional studies are extremely limited in what they can tell us about the dynamics of life histories, and commercial harvests, the usual source of these data, are a thing of the past. We have to find a new way forward.

To date, almost all studies of pinniped life histories have been empirically based and, as pointed out in this description, they have highlighted the interactive nature of parameters such as longevity and reproductive rate. A modeling framework is required in order to allow these interactions to be investigated, to make better use of the data sets that already exist, and to identify critical gaps in the empirical data.

If a pinniped is to maximize its lifetime fitness F , then it must choose the optimal allocation of resources to reproduction through its lifetime. Thus, $F = f_1 + f_2 + f_3 \dots f_n$, where f_a is the fitness contribution from year a in the life of the pinniped, which lasts n years. We know that there are certain functional relationships between maternal size or condition and the probability that mothers will reproduce or survive. If we assume that the relationship between offspring condition and its ultimate fitness is asymptotic, then, up to a certain level, the more energy that a female delivers to her offspring the greater will be her fitness. If the energy delivered to an offspring (ea) is a proportion p of the energy available to the mother, then from what we know of the growth patterns and the energetic efficiencies of pinnipeds, it is possible to estimate the energy available for reproduction throughout

the life span of an average individual. By setting rules that an individual will only reproduce if it has a sufficient excess of energy above that required for maintenance, we may be able to investigate the life history patterns in different environments as well as the effects of stochastic variability in food availability on life histories.

Many of the dynamic relationships described here should become explicit in the results of such an energy-based life history model. Similarly, such a model could help the interpretation of some of the cross-sectional population data in the context of dynamic life history processes. This type of approach seems to be essential if progress is to be made in pinniped life history analysis and for the full implications of life history analysis to be realized. Because the mechanism underlying population trajectories is the sum of individual life histories, understanding the environmental factors that affect life histories is fundamental to understanding population and species viabilities.

Pinniped Physiology

DANIEL E. CROCKER AND DANIEL P. COSTA

I. Introduction

Pinnipeds are unique among mammals because they feed in the marine environment and reproduce on land or ice, requiring a spatial and temporal separation of feeding from lactation (Costa, 1993). Seals stay at sea for weeks and often months at a time, yet they must spend considerable amounts of time on land. The amphibious nature of pinniped life has necessitated a wide range of physiological adaptations to life in water and on land. Pinnipeds must

meet the physiological challenges of marine existence using specialized adaptations that still facilitate existence on land. This life history requires a remarkable plasticity of physiology. Broad categories of physiological adaptation include: (1) aquatic locomotion, (2) apnea and diving physiology, (3) sensory physiology, (4) osmoregulation, (5) thermoregulation, (6) fasting physiology, and (7) lactation physiology.

Pinnipeds have had to overcome numerous problems associated with moving efficiently in the dense aquatic medium and this adaptation has reduced their ability to move about on land. Otariids have hindflippers that can be turned under the body for terrestrial locomotion, whereas phocid seals cannot turn their hindflippers under the body and instead use lunging movements to get around on land.

Perhaps the most complex suite of adaptations required for making a living in the ocean is the physiology associated with breath-hold diving to foraging depths. In addition to adaptations for dealing with great pressures, pinnipeds exhibit physiological adaptation for apnea, increased oxygen storage, bradycardia, hypoperfusion, hypometabolism, and neuronal and hormonal control of cardiac and spleen function.

The sensory systems of pinnipeds enable them to successfully navigate, forage, and communicate in a variety of environments. Seals hear and see relatively well both in the air and underwater. Since the behavior of sound and light in water is markedly different than that in air, this again requires plasticity in their sensory physiology. Ultimately, sensory physiology must provide the appropriate visual and auditory information to facilitate social interactions on land, while allowing detection and capture of prey and detection and avoidance of predators at sea. Adaptations include well-developed underwater directional hearing and visual sensitivity at low light levels.

Living in salt water poses osmoregulatory problems for pinnipeds. In addition pinnipeds must stay in water balance during periods onshore during which they may fast completely from food or water. Since animals also lose water for evaporative cooling, osmoregulatory strategies are linked to thermoregulation.

Pinnipeds are exposed to a remarkably variable range of environmental temperatures. They are able to tolerate frigid ocean temperatures at depth as well as high amounts of thermal radiation encountered when hauled-out on land. Adaptations that help pinnipeds retain heat in the ocean environment, such as thick blubber or dense fur, may also promote overheating on land. Adaptations that may play a role in thermoregulation include large body size, blubber or dense fur, countercurrent heat exchange systems and possibly, high metabolic rates.

II. Fasting Physiology

A. Lipid Utilization and Protein Sparing

Many pinnipeds fast for extended periods during their breeding season or during molting (Table I). Mating, giving birth, nursing pups, and for some species, molting all require long periods of time on land. This is particularly true of phocid seals, which undergo voluntary periods of prolonged fasting twice a year. Adult male pinnipeds may abstain from food or water for as long as 3 months while maintaining a territory or competing for dominance rank on the breeding rookery (Costa and Williams, 2000). In many phocid species females fast completely from food and water for over a month, while delivering tremendous amounts of energy to their pups as milk. Offspring are weaned abruptly and in many species the pup then undergoes an extended postweaning fast before departing to sea and initiating foraging. This postweaning fast may be an important developmental time relative to the diving physiology of the offspring.

TABLE I
Duration of Natural Fasts for Pinnipeds Exhibiting Extended Fasts during Breeding

Females	Duration	Males	Duration
Crabeater seal	~4 weeks	Crabeater seal	~4 weeks
Gray seal	2.5–3 weeks	Gray seal	3–8 weeks
Hawaiian monk seal	5–6 weeks	Hooded seal	~4 weeks
Hooded seal	1.5–2 weeks	Leopard seal	Unknown
Leopard seal	Unknown	Northern elephant seal	2–3 months
Northern elephant seal	5 weeks	Ross seal	Unknown
Ross seal	Unknown	Southern elephant seal	2–3 months
Southern elephant seal	4 weeks	All fur seals	~2.5 months
Weddell seal ^a	6–7 weeks ^a	All sea lions ^b	~2.5 months

^aWeddell seal females enter the water frequently and some may feed.

^bCalifornia sea lion males periodically enter the water to feed. Fasting duration in the species is ~2 weeks.

Figure 1 An adult female northern elephant seal early and late in the lactation period. Northern elephant seal females lose between 35 and 45% of the body mass during breeding.

In most cases, these extended fasts are associated with behaviors or processes resulting in considerable energy expenditure (e.g., combat, mating, lactation, molting). Adult animals may lose as much as 35–57% of stored body reserves during these periods (Fig. 1).

The lengths of these voluntary fasts may vary considerably. Fasts can last as long as 3 months in breeding males of both otariids and phocids. Otariid females alternate short on-shore periods with foraging trips. These fasts can last from several days to 1–2 weeks postpartum. In the phocid seals that fast throughout lactation, fasting duration can be as short as 3–5 days in hooded seals, while northern elephant seals nurse a pup for 23–30 days after an additional 1–2 weeks fasting before parturition. Lactating Weddell seals may fast for up to 7 weeks, although there is a growing body of evidence that some females feed during lactation. Unlike most other groups of animals that undergo natural fasts, activity levels remain high. Males expend energy in territorial interaction, dominance interactions, and mating behaviors. Females expend energy in agonistic encounters for breeding space, interaction with males, and for milk synthesis. Pups are also active during their fasts, making daily movements into the

Figure 2 Changes in daily urinary nitrogen excretion in fasting elephant seal pups. Letters denote significant differences between periods ($P < 0.05$). Sample sizes are in parentheses. (From Adams and Costa, 1993.)

water and often exhibiting high movement rates. In addition pups of many species undergo significant development during fasting including increases on blood volume and synthesis of respiratory pigments.

Despite these high levels of energy expenditure, seals are able to minimize the depletion of lean body mass, with the bulk of energy reserves coming from adipose tissue (Castellini and Rea, 1992). Within the first weeks of the fast, rates of mass loss in nonlactating animals decrease markedly and then remain relatively stable and low for the remainder of the fast. This is accomplished primarily through a reduction in metabolic rate during the fast. This decline is evident in some species on a whole body basis as well as when corrected for changing body size and composition. The key adaptation for extended fasting appears to be the ability to spare protein while fasting and thereby reduce vital organ damage. This stage of fasting, sometimes called Stage II fasting, is characterized by substantial decreases in blood urea nitrogen levels and urinary excretion of nitrogenous wastes. These characteristics are evident throughout the fasts of phocid seals (Fig. 2). This decreased protein degradation is reflected in reduced absolute and proportional declines in the use of protein reserves. Protein contributes as little as 1–6% of total energy utilization by the end of the fast. For example, at the beginning of the postweaning fast, northern elephant seals, *Mirounga angustirostris*, meet around 4% of their energy needs through protein catabolism. By the end of the postweaning fast this value has declined to around 1% (Adams and Costa, 1993).

Nonesterified fatty acids (NEFA) provide the majority of the animal's energy needs during long-term fasts. Increases in both turnover and plasma concentrations of NEFA have been demonstrated in several species. Reported NEFA values are greater than those reported for any other animal (as high as 3.2 mM) and increase over the fast in some species (Houser *et al.*, 2007). Plasma glycerol levels show similar increases and are available as a substrate for gluconeogenesis. There is some evidence that seals can selectively utilize reserves from different parts of the body (such as blubber reserves vs core

Figure 3 Changes in maternal mass and body composition over the lactation period in female northern elephant seals. On average females lose 27% of total body protein stores during lactation.

tissues) during different phases of the fast. Ketone bodies (HBA) accumulate somewhat during the fast in weaned elephant seals and gray seals, *Halichoerus grypus*, and Weddell seals, *Leptonychotes weddelli*, and subsequently decline rapidly as the end of the fast is approached (Castellini and Costa, 1990). This suggests that ketone bodies may contribute to energy metabolism during long-term fasting, although levels are significantly lower than nonfasting adapted species and never reach levels affecting acid-base balance or causing ketosis. Particularly striking in this regard are data from lactating female and breeding adult male northern elephant seals, who, despite the aforementioned high and increasing NEFA levels over the fast, exhibit consistently low HBA values across the breeding fast (<0.80 mM; Champagne *et al.*, 2006). It is also important to note that increasing HBA levels were only demonstrated in juvenile animals of relatively small body size.

Stage III fasting or terminal starvation occurs when 30–50% of total body protein has been used. In nonfasting adapted species this is associated with a decrease in lipid utilization and a decline in circulating ketone bodies. Evidence for entrance into Stage III fasting in seals has been equivocal. The increase and subsequent decline in ketone bodies at the end of the fast in some fasting pups would suggest entry into Stage III (Nordoy *et al.*, 1992; Houser and Costa, 2003). However, only two studies have demonstrated increases in protein catabolism following the period of effective protein sparing. When considering the protein utilization by lactating females it is important to include the loss of body protein for milk synthesis. One study on northern elephant seals demonstrated reductions in protein sparing with the depletion of lipid reserves (Crocker *et al.*, 1998) that together with the nutrient demands of milk synthesis moved females close to the 30% value of body protein loss considered extreme in humans (Fig. 3). It may be that in normal, voluntary fasts, Stage III fasting is never reached, with seals departing to sea before this point. Blubber reserves also play an important role in thermoregulation and blubber depletion for energy needs is limited by the need to thermoregulate (Worthy, 1991).

B. Glucose Metabolism

The primary constraint on the extended fasting durations exhibited by pinnipeds is the need to provide carbohydrate to glucose-dependent tissues that include the central nervous system,

Figure 4 Allometric comparison of rates of glucose production in fasting and nonfasting species. Each point represents a mean value for a species or age class from a wide variety of studies on domestic and wild animals. Closed circles represent postabsorptive animals. Open circles represent animals undergoing at least a 48h fast. Note the suppression of glucose production with fasting. Open triangles represent fasting values from several species, sexes, and age classes of phocid seals. Note that fasting phocids exhibit rates of glucose production consistent with nonfasting individuals of other species.

erythrocytes, renal medulla, and testes. Due to the limited ability to store carbohydrate in the body, fasting pinnipeds are dependent on gluconeogenesis, the production of sugar by the liver and kidney, to provide fuel for these tissues. The general model for fasting species is that protein is spared most effectively by reducing glucose utilization by nondependent tissues and using glycerol mobilized for fats to produce glucose instead of amino acids liberated from muscle. In most species of animals, fasting is associated with a suppression of endogenous glucose production (Fig. 4). In contrast, studies on elephant seals, harbor seals, *Phoca vitulina*, and gray seals, suggest that glucose turnover rates are typical of nonfasting mammals and that there is little or no suppression of glucose production during fasting (Davis, 1983; Nordøy and Blix, 1991; Champagne *et al.*, 2005, 2006). Despite this, the direct contribution of glucose to the total metabolic rate is less than 1% in seals during extended fasts (Keith and Ortiz, 1989). Furthermore, recent studies on the contribution of glycerol to gluconeogenesis in elephant seals suggest that it accounts for less than 3% of the glucose produced while fasting, leaving the primary gluconeogenic substrate as yet unidentified (Houser *et al.*, 2007). These findings suggest high levels of futile cycle activity that may play an important role in regulating fasting metabolism and that recycling of protein and glucose carbon may serve as an important shuttle mechanism for carbon (e.g., synthesis of nonessential amino acids).

As tracer methodologies have been used to examine metabolite flux in fasting pinnipeds, particularly in elephant seals, it has become clear that static values of metabolites in blood samples reflect complex relationships between synthesis, mobilization, and utilization of nutrients and should be interpreted cautiously. For example, dramatic increases in plasma levels of NEFA can occur despite decreases in overall rates of lipolysis, increased protein catabolism can be associated with decreases blood urea levels due to changes in renal filtration, increases in plasma glucose levels can occur despite static levels of glucose production due to impaired glucose clearance, and plasma ketone levels may not reflect levels of lipid mobilization and utilization. Thus the

traditional methods of examining metabolite flux through blood chemistries may lead to erroneous interpretations.

C. Hormonal and Fuel Regulation

Studies on hormonal and fuel regulation during fasting have suggested that seals may exhibit the protein conservation and high lipid utilization of Stage II fasting throughout their lives. Fat is an important energy source throughout development and life, including high fat milk, high fat fish, and body fat stores. Studies of the role of insulin in glucose regulation in suckling pups have suggested that seals may be preadapted for fasting (Kirby and Ortiz, 1994). Low insulin concentrations, impaired glucose clearance, and low insulin to glucagon ratios exhibited in both feeding and fasting pups contribute to the mobilization of lipids from body stores. In general, fasting pups are hyperglycemic and hypoinsulemic. Glucose tolerance tests in fasting pups and adults have suggested impaired insulin response and glucose clearance. Most strikingly, lactating females appear to functionally reduce insulin response as lactation progresses. Similarly, hormone challenge studies have suggested deviations from the standard mammalian push-pull model of glucose regulation and important developmental and reproductive impacts on receptor populations for hormones. For example, fasting elephant seal pups exhibit no gluconeogenic response to a pharmacological dose of glucagon. In contrast lactating and molting adult females exhibit a delayed but significant increase in blood glucose levels in response to the same challenge.

In general, studies on fasting pinnipeds have reported significant increases in growth hormone and cortisol associated with fasting (Ortiz *et al.*, 2001; Champagne *et al.*, 2005). However, tracer studies have also suggested an uncoupling between important metabolic regulatory hormones and the processes which they regulate in typical mammals, particularly with respect to carbohydrate metabolism, and a potentially increased importance of cycle activity in regulating metabolite flux. Currently our understanding of the fasting physiology of pinnipeds is biased toward studies on juvenile animals, especially the postweaning fast. Recent investigations have demonstrated dramatic differences in fasting physiology between lactating and molting females as well as fasting pups. The pressures of nutrient delivery for milk synthesis may have significant impacts on the metabolic strategies used by females during extended fasts. Less is known about fasting in adult males, who potentially have some of the highest metabolic rates while fasting. Future studies can benefit from interspecific comparisons of fasting physiology relative to natural fasting durations. Even more instructive may be intraspecific comparisons among sexes and age classes during development, lactation, molting, and breeding. These comparisons will help to demonstrate how the fasting biochemistry of animals responds to the varying energy and nutrient demands of breeding and lactation.

D. Renal Physiology during Fasting

Water balance during fasting is maintained by input of metabolic derived water from lipid catabolism. Significant reductions in urinary water loss contribute to maintenance of water balance (Adams and Costa, 1993; Fig. 5). The low rate of protein oxidation and an efficient urinary concentrating mechanism in pinnipeds reduces urinary water loss during fasting. Early work on harbor seals demonstrated reductions in glomerular filtration rates (GFR) associated with fasting and hyperfiltration after feeding (Hiatt and Hiatt, 1942). Subsequent investigations have been equivocal, leaving it unclear whether the mechanism underlying reduced urine flow is decreased glomerular filtration or increased tubular resorption (Pernia *et al.*,

Figure 5 The decline in daily urine production of elephant seal pups progressing through the postweaning fast. Letters denote significant differences between the periods ($P < 0.05$). Sample sizes are in parentheses. (From Adams and Costa, 1993.)

1989; Houser *et al.*, 2001). Investigations on weaned northern elephant seal pups have revealed no correlation between plasma levels of vasopressin and urinary concentrating ability but suggest that vasopressin may have important effects on solute excretion (Ortiz *et al.*, 2003). Similar investigations have demonstrated increases in aldosterone and angiotensin II during long-term fasts in seals suggesting an important role for aldosterone in regulating urine concentration by its action on sodium resorption in the collecting duct (Ortiz *et al.*, 2006).

Investigations on lactating adult northern elephant seals have demonstrated dramatic increases in GFR across the fast and suggest that these elevated rates could be an adaptation to increasing the efficiency of urea excretion during reduced urine flow (Crocker *et al.*, 1998). This mechanism reduces residency time and passive resorption of urea in the collecting tubules. The efficiency of urea excretion in lactating females declined from 49 to 38% over lactation, suggesting that with a declining urine flow and stable plasma urea concentration, increased GFR is necessary to increase urea excretion as protein catabolism increases.

E. Lactation Physiology

The physiology of lactation in pinnipeds is significantly impacted by constraints resulting from the temporal separation of foraging and parental investment. Pinnipeds have evolved two general lactation strategies to manage pup provisioning within these constraints (Costa, 1993). For a more detailed discussion of the energetics of lactation, see the section on “Energetics,” this volume. After a short perinatal fast, otariids alternate foraging trips with suckling bouts. Initial milk production is synthesized from maternal reserves while subsequent milk nutrients are derived from resources acquired while foraging. Phocids, particularly the larger species, fast during a brief but energy-intensive lactation during which nutrients for milk synthesis are derived exclusively from maternal tissues. Some smaller phocid seals, like harbor seals or ring seals, *Phoca hispida*, forage during lactation. Pinnipeds consistently produce lipid-rich milk, independent of lipid content of the diet (Costa, 1993). Even more amazing is that lactation, an energetically expensive period, occurs while the female is fasting. Long-term fasting is characterized by protein sparing, reductions in metabolic rate, and reductions in water loss for urea nitrogen

excretion. Studies on nonlactating fasting phocids have shown that protein stores are spared with the bulk of energy demands being supplied by the oxidation of fatty acids. In contrast, lactation is characterized by dramatic increases in metabolism and significant transfer of nutrients and water to the mammary gland for the synthesis and secretion of milk. The general metabolism of the lactating female is reorganized in a way that ensures the appropriate nutrients are partitioned to the mammary gland. In nonfasting animals, lactation is accompanied by increased levels of food consumption and digestion, with accompanying increases in the absorptive capacity of the gastrointestinal tract. In fasting phocids, regulatory mechanisms override protein and energy sparing mechanisms to make the nutrients necessary for milk synthesis available at the expense of body nutrient reserves. The high demands of lactation coupled with complete abstinence from food and water presents a complex regulatory problem. A recent investigation in northern elephant seals suggested that changes in the energy demands of milk synthesis across lactation may impact fasting physiology and ultimately limit the period of parental investment (Crocker *et al.*, 2001). From this perspective lactating phocid females may be one of the best examples of homeorhesis, “orchestrated changes for the priorities of a physiological state,” found in nature.

Studies have suggested changes in milk composition and the nutrient requirements of milk synthesis across lactation in pinnipeds. These patterns are controlled by hormonal and biochemical changes. Of these changes, those that impact mobilization of adipose tissue stores, metabolism of lipids, and utilization of lipids by the mammary gland are the most significant. These changes are also important as pinnipeds transition from periods of nutrient deposition and mobilization for milk synthesis. Decreased insulin levels remove the strong antilipolytic effects of this hormone. Cortisol and other glucocorticoids influence lipid metabolism directly and indirectly. Cortisol stimulates hormone sensitive lipase in adipose tissue and antagonizes the actions of insulin. Hormone sensitive lipase activity increases lipid mobilization from adipose tissue. Lipoprotein lipase (LPL) is the primary enzyme involved in directing triglycerides mobilized from tissue stores to tissues for utilization. LPL is bound to tissues and facilitates the hydrolyzation of triglycerides, allowing uptake of fatty acids by the tissue. Under normal conditions of insulin release, LPL activity in tissues increases and triglyceride is cleared from the blood. During fasting, LPL activity in adipose tissue decreases, while hormone sensitive lipase activity in adipocytes increases. The general pattern found in lactation is a decrease in adipocyte LPL activity before parturition and an increase in mammary gland LPL activity. The hormone prolactin is believed to be primarily responsible for LPL regulation in lactation. Recent investigations on harbor seals and gray seals have suggested a similar pattern. General activity levels of LPL increased 10-fold over lactation in these species and were significantly higher than levels found in humans. The dramatic increase in milk lipid content early in lactation in some phocid seals may in part be explained by a significant increase in mammary gland LPL activity (Iverson *et al.*, 1995).

Very little work has been done on the physiology underlying milk secretion in pinnipeds. The release of milk fat globules occurs by apocrine secretion, in which the apical portion of the cell membrane is sloughed off. The high fat contents of pinniped milk suggest significant increases in the amount of membrane and its turnover. Pinnipeds may partially reduce this requirement by utilizing larger fat globules that require smaller amounts of membrane loss per unit lipid secreted (Tedman, 1983). Data on mammary gland size in phocids has been equivocal, suggesting increased size relative to body mass in some species but not others (Tedman and Bryden, 1981). In any case, phocid seals appear to be particularly efficient at mobilizing and transporting

nutrients to the mammary gland, perhaps by reducing the levels of *de novo* synthesis of milk lipids occurring at the mammary gland (Mellish *et al.*, 1999). This efficiency must in turn be matched by rapid and efficient digestion and assimilation of milk lipids by the offspring.

It is apparent that the regulatory processes involved in the initiation and termination of lactation are quite complex. In most mammals the initiation and eventual termination of lactation is a long complex process. However, all otariids and some phocids are able to intermittently turn milk production on and off. Milk production is downregulated or turned off, while the mother is at sea foraging, but within hours of arriving ashore she can suckle her pup and within hours milk production is in full gear. This ability has received considerable attention by the lactation physiology community and may provide insight into general processes of lactation physiology (Lang *et al.*, 2005; Sharp *et al.*, 2006, 2007).

Pinnipeds comprise slightly more than one-fourth (26%) of the species diversity of marine mammals (approximately 128 species currently recognized). Thirty-three living species of pinnipeds are distributed throughout the world: 18 phocids, 14 otariids, and the walrus. One additional species of phocid (Caribbean monk seal) and one subspecies of otariid (Japanese sea lion) are reported extinct in historical time.

I. Systematics and Distribution

A. Otariidae: Fur Seals and Sea Lions

Of the two groups of seals, the otariids are characterized by the presence of external ear flaps or pinnae, and for this reason they are often called “eared” seals (Fig. 1). Otariids (and the walrus) can turn their hindflippers forward and use them to walk (discussed further under Adaptations). The Otariidae traditionally are divided into two subfamilies Otariinae (sea lions) and Arctocephalinae (fur seals) although recent molecular studies have revealed that neither fur seals nor sea lions are monophyletic. Five living genera and species of sea lions are recognized, occurring in both the northern and southern hemispheres: *Eumetopias jubata* (northern or Steller’s sea lion), *Neophoca cinerea* (Australian sea lion), *Otaria byronia* (Southern sea lion), *Zalophus californianus* (*Z. c. californianus* California sea lion, *Z. c. japonicus* Japanese sea lion, and *Z. c. wollebacki* Galapagos sea lion), and *Phocarctos hookeri* (New Zealand sea lion; Fig. 2). The fur seals, named for their thick, dense fur, include two genera, the monotypic Northern fur seal (*Callorhinus ursinus*) and the southern fur seals (*Arctocephalus*), consisting of eight species: *A. australis* (South American fur seal), *A. forsteri* (New Zealand fur seal), *A. gazella* (Antarctic fur seal), *A. galapagoensis* (Galapagos fur seal), *A. philippii* (Juan Fernandez fur seal), *A. pusillus* (*A. p. pusillus* South African fur seal and *A. p. doriferus* Australian fur seal), *A. townsendi* (Guadalupe fur seal), and *A. tropicalis* (Subantarctic fur seal). All of the fur seals except the northern and Guadalupe fur seals are found in the southern hemisphere. The northern fur seal is found in subarctic waters of the North Pacific, with the exception of a small population on San Miguel Island off California (Fig. 3).

Otariid monophyly is well supported based on a both morphologic as well as molecular data. Morphologic and molecular studies consistently position *Callorhinus* as the earliest diverging extant otariid (Fig. 4). Extinct otariids *Pithanotaria*, *Thalassoleon*, and *Hydractos* are sequential sister taxa to *Callorhinus*. Molecular results strongly support a branch containing the Guadalupe, South American, and New Zealand fur seals and the Australian and New Zealand sea lion. Good support was also found for South African fur seals as sister to this clade. The relationship between Northern + California sea lions, Southern sea lion and remaining sea lions and *Arctocephalus* species is not conclusively resolved. In support of fur seal and sea lion paraphyly is evidence for hybridization of various sympatric species (e.g., *Arctocephalus gazella*/*A. tropicalis*/*A. forsteri*, *Zalophus californianus*/*Otaria byronia*). Additionally, the violent sexual behavior by male sea lions toward females of different species may have resulted in more hybridization and introgression than has been typically recognized for the evolutionary history of otariids.

B. Odobenidae: Walruses

Although tusks are arguably the most characteristic feature of the modern walrus a rapidly improving fossil record indicates that these unique structures evolved in a single lineage of walruses and “tusks do not a walrus make” (Repenning and Tedford, 1977). The living walrus is the sole survivor of what was once a diverse radiation of at least 11

Pinnipedia, Overview

ANNALISA BERTA

Pinnipeds have always been understood to represent a group distinct from other aquatic mammals. They are recognized as members of the mammalian order Carnivora and include three monophyletic lineages, Otariidae (fur seals and sea lions), Odobenidae (walruses), and Phocidae (true or earless seals).

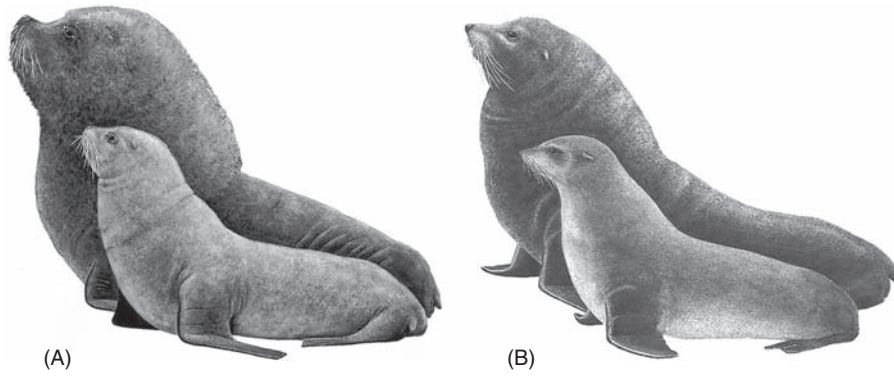

Figure 1 Representative otariids (A) southern sea lion, *Otaria byronia* and (B) South African fur seal, *Arctocephalus pusillus*, illustrating pinna. Note also the thick, dense fur characteristic of fur seals. Illustrations by P. Folkens. (From Berta et al., 2006.)

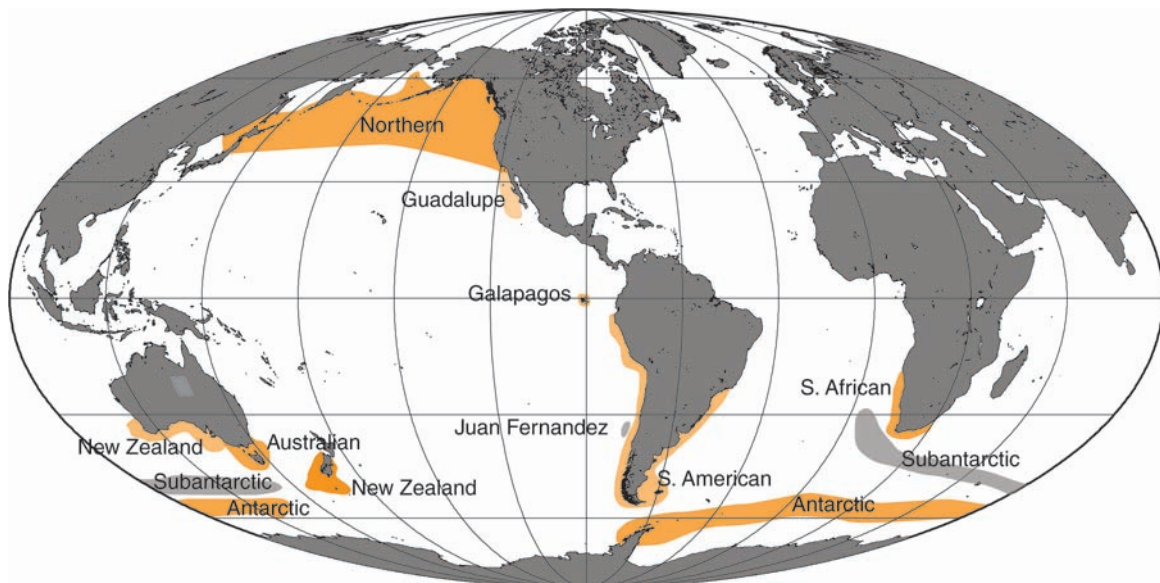

Figure 3 Distribution of fur seals. Based on Riedman (1990). (From Berta et al., 2006.)

genera and 14 species of walruses that lived from the early Miocene to the end of the Pliocene (see also PINNIPED EVOLUTION). Two subspecies of the modern walrus *Odobenus rosmarus* are usually recognized: *O. r. rosmarus* (Atlantic walrus) and *O. rosmarus divergens* (Pacific walrus) although a population from the Laptev Sea has been described as a third subspecies *O. rosmarus. lapteevi* but this has not been substantiated. Pacific walruses are more abundant, are larger, and have longer tusks than Atlantic walruses (Fay, 1981). Walruses inhabit the northern hemisphere in areas with pack ice over shallow water of the continental shelf (Fig. 5). Like phocids, walruses lack external ear flaps. A unique feature of members of the modern walrus lineage are enlarged upper canine tusks that function primarily in breeding and social contexts. Walrus locomotion combines elements of phocid and otariid locomotion (discussed further under Adaptations).

Monophyly of the walrus family is strongly supported although controversy continues regarding whether walruses are more closely related to otariids or to phocids. Although there is morphologic evidence to ally walruses and phocids recent total evidence and

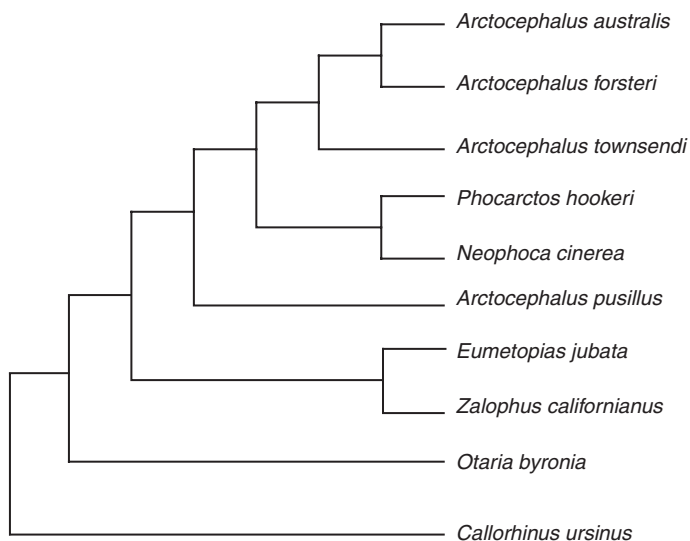

Figure 4 Phylogeny of the Otariidae based on molecular data. (From Arnason et al., 2006.)

molecular studies provide consistent, robust support for an alternative alliance between otariids and odobenids. A survey of genetic variation among Atlantic and Pacific populations of the walrus suggests separation of the subspecies about 500,000–750,000 years ago, supporting the suggestion that *Odobenus* evolved in the Pacific and reached the North Atlantic early in Pleistocene time (Cronin et al., 1994).

C. Phocidae: Seals

The second major grouping of seals, the phocids, often are referred to as the “true” or “earless” seals for their lack of visible ear pinnae, a characteristic which readily distinguishes them from otariids as well as the walrus (Fig. 6). Among the most distinguishing phocid

Figure 5 Distribution of modern walrus subspecies, *Odobenus rosmarus divergens* (Pacific walrus) and *Odobenus rosmarus rosmarus* (Atlantic walrus).

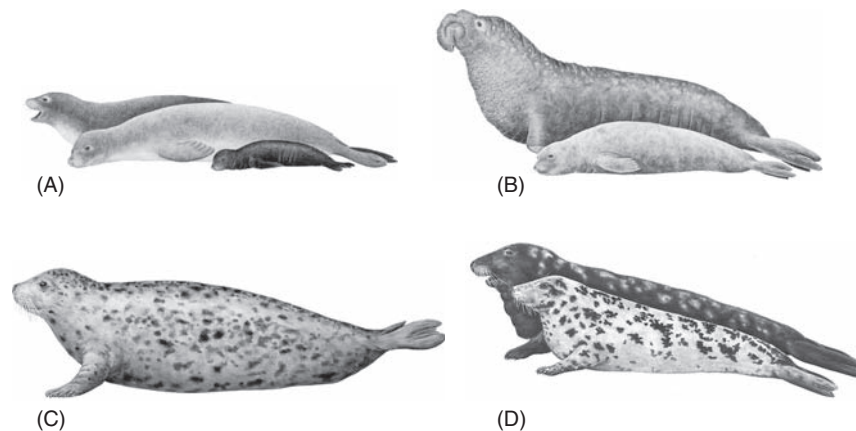

Figure 6 Representative monachines (A) Hawaiian monk seal, *Monachus schauinslandi* and (B) northern elephant seal, *Mirounga angustirostris* and phocines (C) Harbor seal, *Phoca vitulina*, and (D) gray seal, *Halichoerus grypus*. Males are shown behind smaller females. Illustrations by P. Folkens. (From Berta et al., 2006.)

characteristics is their inability to turn the hindlimbs forward to support the body, resulting in a peculiar crawling locomotion on land (discussed further under Adaptations). Phocids inhabit both northern and southern hemispheres, although they are largely restricted to polar and subpolar regions (Fig. 7). Among pinnipeds, phocids are unique in their ability to survive in estuarine and freshwater habitats (e.g., Caspian and Baikal seals inhabiting landlocked lakes).

Traditionally phocids have been divided into two to four major subgroups (including the Monachinae, Lobodontinae, Cystophorinae, and Phocinae). Recent molecular studies strongly support monophyly of both the Monachinae and Phocinae (Davis *et al.*, 2004; Arnason *et al.*, 2006; Fig. 8).

The Monachinae clade of “southern seals” includes Monachini (monk seals), Miroungini (elephant seals), and the Lobodontini

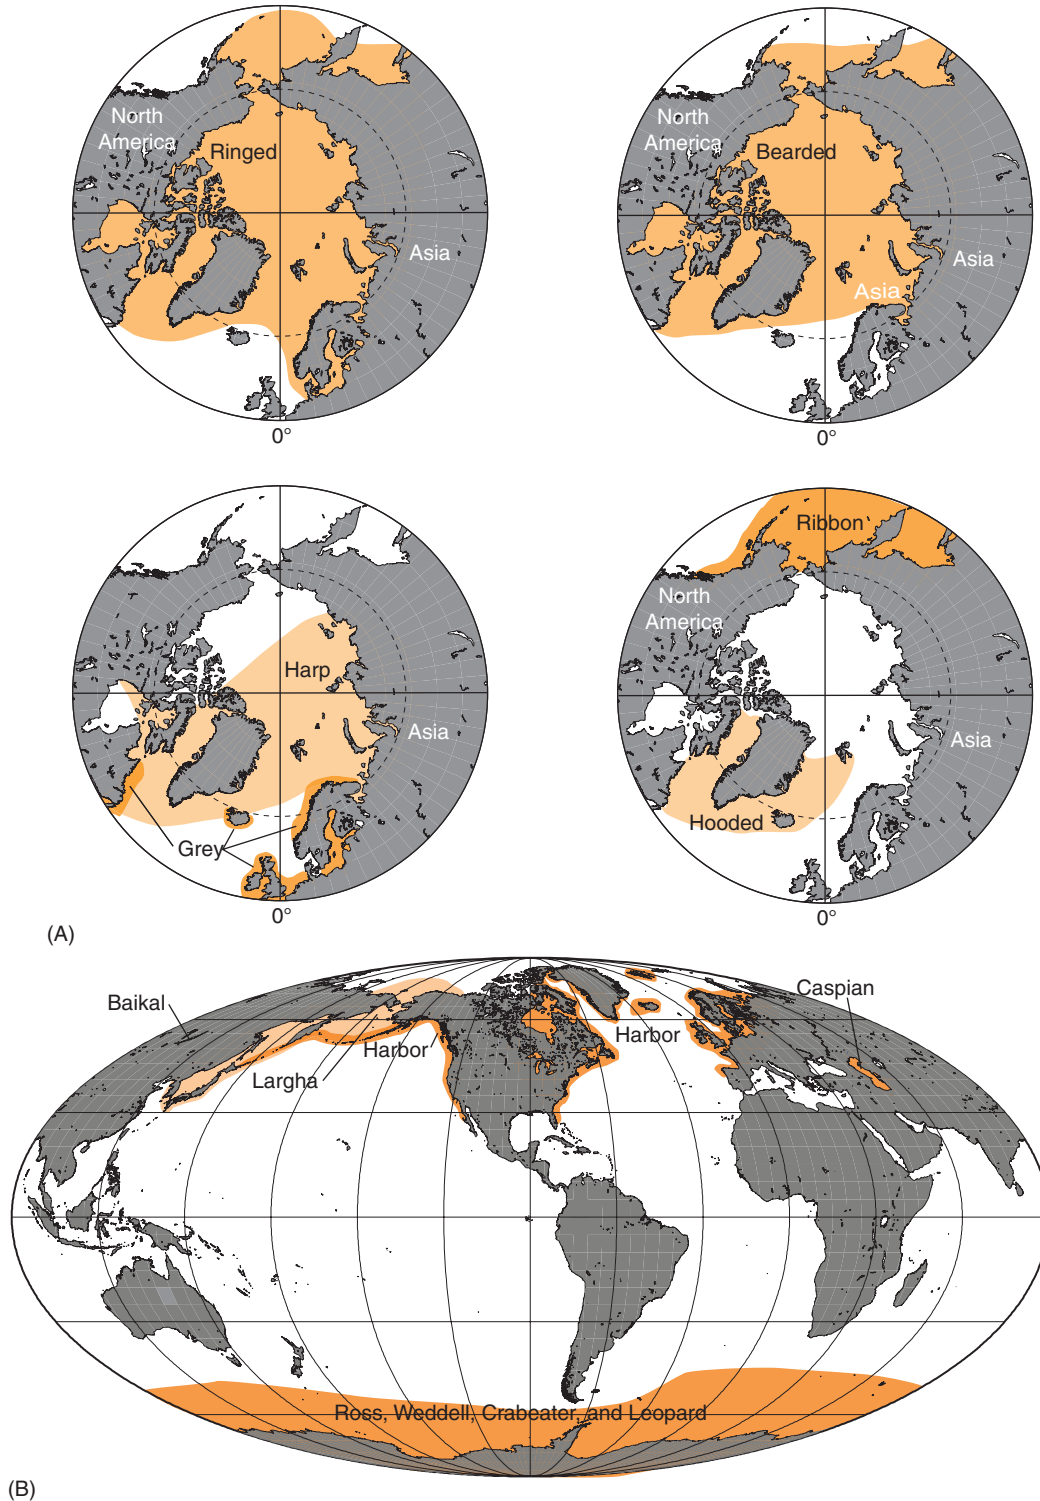

Figure 7 Distribution of some phocine seals (A), Antarctic phocine seals (B), and monachines (Facing page). Based on Riedman (1990). (From Berta *et al.*, 2006.)

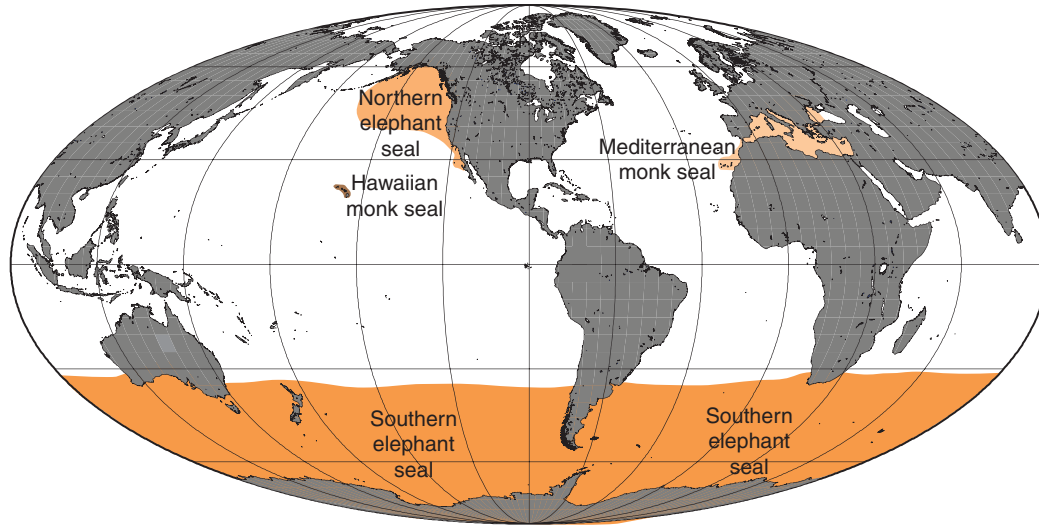

Figure 7 (continued)

Figure 8 Phylogeny of the Phocidae based on molecular data (Arnason et al., 2006).

(Antarctic seals). Within the Monachinae there is strong support for a split between Monachini, the deepest branching lineage and Miroungini and Lobobontini. Three species of *Monachus* have been described, *M. schauinslandi* (Hawaiian monk seal), *M. monachus* (Mediterranean monk seal), and the recently extinct *M. tropicalis* (Caribbean monk seal). Molecular sequence data for extant species of *Monachus* supports a sister group relationship between the Hawaiian and Mediterranean monk seals (Davis et al., 2004; Fyler et al., 2005). Elephant seals, named for their enlarged proboscis, are represented by two species, *Mirounga angustirostris* (northern elephant seal) and *Mirounga leonina* (southern elephant seal).

The Lobodontini which include *Leptonychotes weddelli* (Weddell seal), *Lobodon carcinophagus* (Crabeater seal), *Hydrurga leptonyx* (Leopard seal), and *Ommatophoca rossi* (Ross seal). Molecular studies consistently position the Ross seal as sister to the other three Antarctic seals.

The Phocinae clade of “northern seals” includes *Erignathus barbatus* (bearded seal), *Cystophora cristata* (hooded seal), *Halichoerus grypus* (gray seal), *Phoca* (including others harbor and spotted seal), *Pusa hispida* (ringed seal), *Histiophoca fasciata* (ribbon seal), and *Pagophilus groenlandica* (harp seal). A basal divergence between the bearded seal and the hooded seal + Phocini (*Pusa*, *Histiophoca*, *Pagophilus*, *Halichoerus*, and *Phoca*) is strongly supported by molecular studies (cited above). Disagreement about relationships among the Phocini, attributed to their rapid radiation, have resulted in taxonomic uncertainty regarding their classification. There is general agreement that the Phocini are divided into an earlier diverging lineage of spotted + harbor seals and remaining seals. It is acknowledged that relationships among the latter group are poorly resolved.

The harbor seal (*Phoca vitulina*) has the most extensive geographic distribution of any seal, with a range spanning over 16,000 km from the east Baltic, west across the Atlantic and Pacific Ocean to southern Japan. The population structure of the harbor seal studied by Stanley et al. (1996) revealed that populations in the Pacific and Atlantic Oceans are highly differentiated. The mitochondrial data are consistent with ancient isolation of populations in both oceans coincident with the development of continental glaciers and extensive sea ice. In the Atlantic and Pacific Oceans populations appear to have been established from west to east, with the European populations showing the most recent common ancestry.

II. Anatomy and Physiology

Pinniped aquatic specializations include their streamlined shape, reduced external ear pinnae, paddle-like limbs and feet, small tail, and genital organs and mammary glands that are retracted beneath the skin. In comparison to most terrestrial carnivores, pinnipeds are large which helps to conserve warmth. Pinnipeds, particularly phocids show tremendous diversity in size ranging from the smallest pinniped, the Baikal seal reaching a length of just over a meter and a weight of 45 kg to the largest pinniped, the elephant seals nearly 5 m

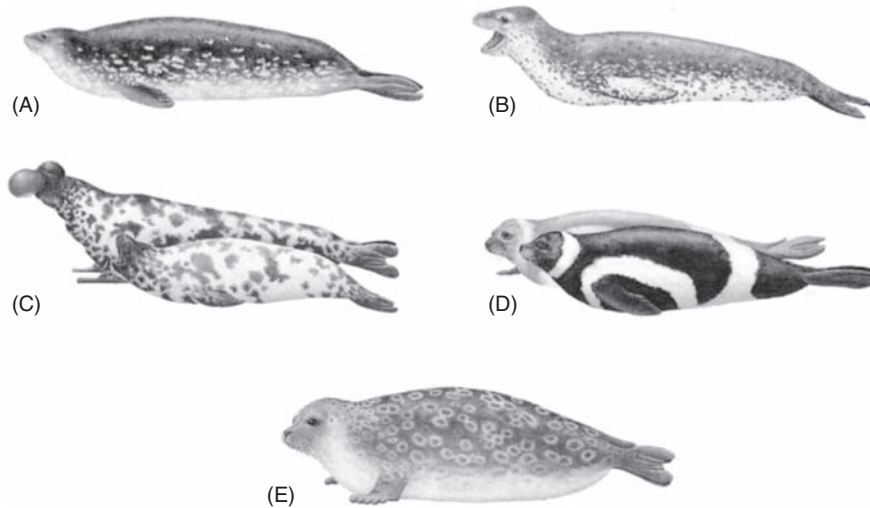

Figure 9 Examples of phocid pelage patterns (A) Weddell seal, *Leptonychotes weddellii*, (B) leopard seal, *Hydrurga leptonyx*, (C) hooded seal, *Cystophora cristata*, (D) ribbon seal *Histiophoca fasciata*, and (E) ringed seal, *Phoca hispida*. (Illustrations by P. Folkens, in Berta and Sumich, 1999.)

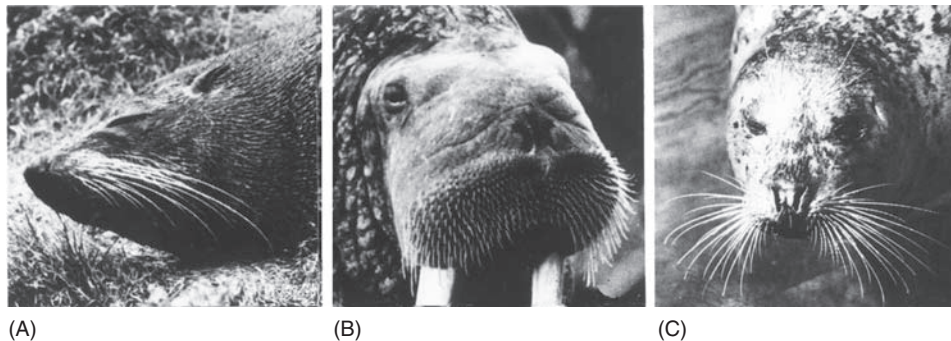

Figure 10 Heads of various pinnipeds showing facial vibrissae (A) New Zealand fur seal, *Arctocephalus forsteri*, (B) Walrus, *Odobenus rosmarus*, and (C) Pacific harbor seal, *Phoca vitulina richardsi*. (From Ling, 1977 in Berta *et al.*, 2006.)

in length (adult males) and up to 3200 kg (Bonner, 1990). Pinnipeds are ecologically diverse with habitats ranging from shelf to surface waters in tropical and polar seas, with some species living in fresh water lakes, while others freely move between rivers and the ocean.

Phocids and the walrus have lost much of their hair (fur) and are characterized by thick layers of blubber under the skin. Otariids, especially the fur seals, have retained a thick fur coat. Color patterns in the pelage of pinnipeds occur almost exclusively among phocids. Ice breeding seals (e.g., ribbon seal, harp seal, hooded seal, ringed seal, crabeater seal, Weddell seal, and leopard seal) show contrasting dark and light or disruptive color patterns (Fig. 9). The uniform coloration of some pinnipeds (e.g., white harp seal pups) allows them to readily blend into their arctic environment. Pinnipeds come ashore for birthing and molting. All phocid seals undergo an annual molt. Fur seals and sea lions instead renew their pelt gradually all year.

Vibrissae, or whiskers, are stiff hairs that occur on the face. Most prominent are the mystacial whiskers which range in size from the short stiff bristles of the walrus to the very long, fine bristles of fur seals (Fig. 10). Vibrissae function as sensitive touch receptors. Research on the Baltic ringed seal has shown that they have exceptionally well-developed

vibrissae which help them find their way in the dark and often cloudy water beneath the ice. A single vibrissae of the Baltic ringed seal contains more than 10 times the number of nerve fibers typically found in that of a land mammal. Experimental data has also shown that blind-folded harbor seals used vibrations detected by their vibrissae to follow prey (i.e., fish “trails”) in the water (Denhardt *et al.*, 2001). Evidence of heat conduction in the vibrissae of harbor seals indicates that they also play a role in thermoregulation (Mauck *et al.*, 2000).

Pinnipeds, like other marine mammals, have evolved ways to accommodate the immense heat loss that occurs in the water. Among these solutions are a spherical body and a resultant decreased surface to volume ratio and increased insulation (thick blubber or fur). In addition, heat exchange systems occurring in the flippers, fins, and reproductive tracts of pinnipeds conserves body heat (see THERMOREGULATION).

Among modern pinnipeds aquatic and terrestrial locomotion are achieved differently (see LOCOMOTION). Three distinct patterns of swimming are recognized: (1) pectoral oscillation (forelimb swimming) seen in otariids where the forelimbs are used in a “flapping” manner to produce thrust, (2) pelvic oscillation (hindlimb swimming)

seen in phocids where the hindlimbs are the major propulsors, and (3) a variant of pelvic oscillation exhibited by the walrus where the hindlimbs are the dominant propulsive force and the forelimbs are used as rudders or paddles. There is a major difference in locomotion on land between phocids on the one hand and otariids and walruses on the other. The inability of phocids to turn the hindlimbs forward results in forward progression by vertical undulations of the trunk which do not involve the hindlimbs. In walruses, as in otariids, the hindlimbs can be rotated forward in terrestrial locomotion.

Pinnipeds are carnivores, most are generalists feeding predominantly on fish and squid (see also DIET). Several pinnipeds, notably crabeater and leopard seals have highly modified cheek teeth with complex cusps to trap and strain krill. Leopard seals also possess well-developed canines for preying on birds and other pinnipeds. Walruses are specialists feeding almost exclusively on clams using a suction feeding strategy in which the muscular tongue acts as a piston creating low pressure in the mouth cavity. Some pinnipeds, for example elephant seals, rival gray whales in the distances traveled in migration (18,000–21,000 km) to forage offshore between breeding seasons. The advent of microprocessor-based geographic location time and depth recorders (GLTDRs), satellite telemetry, and crittercams has enabled documentation of details of the foraging behavior of these deep diving seals.

Among pinnipeds are found the most extraordinary of marine mammal divers (see DIVING BEHAVIOR and DIVING PHYSIOLOGY). Average dives of small species such as the Ross seal are just under 10 min in duration increasing to over 1 h for the northern elephant seal and the Weddell seal. Maximum depths vary from less than 100 m in the Guadalupe fur seal to more than 1500 m in northern elephant seal males. Some seals (in addition to sperm whales, sea turtles, and some penguins) are “incredible diving machines” with unique ways of budgeting their oxygen supply and responding to pressure.

Sounds produced by pinnipeds include both airborne and underwater vocalizations (see SOUND PRODUCTION). Airborne sounds vary from grunts, snorts, or barks identified as either mother–pup calls or threat calls among seals to the distinctive bell-like sounds produced by male walruses striking throat pouches with their flippers as part of a courting display during the breeding season. Pinnipeds produce a variety of underwater sounds that appear most often related to breeding activities and social interactions. Among these are the whistles, trills, chirps, and buzzes of Weddell seals that are used in territorial defense. These contrast with the soft, lyrical calls of leopard seals that may be related to their solitary social system. In contrast to toothed whales, pinnipeds have not been found to use echolocation in their natural surroundings.

The pinniped eye is adapted for vision both above and under water. The spherical lens, thick retina, and the well-developed tapetum lucidum increase light sensitivity. With the exception of the walrus which has small eyes, seals and sea lions have large eyes in relation to body size. The question of whether pinnipeds have color vision is still debated although behavioral experiments and the presence of both rods and cones in the retina have been documented in some species (e.g., California sea lion, spotted seal, walrus) (see VISION).

III. Behavior

Unlike other marine mammals, pinnipeds differ in their need to return to land (or to ice) to give birth. Many pinnipeds (e.g., elephant seal) are extremely polygynous, with successful males mating with dozens of females in a single breeding season (see BREEDING SYSTEMS). Species that are polygynous tend to breed in large colonies

on land where males compete for breeding territories (in otariids) or establish dominance hierarchies (in elephant seals). Because these males must compete for access to females associated with extreme polygyny is the strong sexual dimorphism seen in elephant seals including large body size (adult males as much as five times as large as females), elongated proboscis, enlarged canine teeth, and thick skin on the neck. Other phocids (e.g., Weddell seal, harp, ringed, ribbon, bearded, hooded) mate in the water or on ice and show a reduced level of polygyny, that is explained in part by the difficulty in gaining access to females in unstable environments such as pack ice.

Pinnipeds are characterized by sexual bimaturity with females reaching sexual maturity before males. In polygynous species males require several years of physical maturation following sexual maturity before they successfully compete for access to females. Gestation in most species of pinnipeds averages between 10 and 12 months; walruses have the longest gestation period of 16 months. Most species regulate their reproductive cycle (see REPRODUCTIVE BEHAVIORS) by delayed implantation (from 1.5 to 5 months). Delayed implantation prolongs birth until conditions are more favorable for offspring survival. Pinniped females of all species give birth to a single pup. In most species, pupping occurs in spring or summer when food availability is highest.

The maternal behaviors and lactation strategies of pinnipeds are influenced by their breeding habitat whether on ice or land. Most phocids exhibit a fasting strategy where females fast completely and remain out of water for the duration of a relatively short lactation, ranging from less than 1 week in hooded seals to almost 8 weeks in the Weddell seal. It has been suggested that the unstable nature of pack ice has selected for the extremely short lactation periods of some ice breeding phocid seals. To compensate for the brevity of lactation, the milk produced by these species is energy dense, with a fat content up to 60% in some species (i.e., hooded and harp seals). Rapid pup growth is ensured by the richness of the milk. In the foraging cycle strategy of most otariids, mothers fast for only a few days following the birth of pups. Then the mothers begin foraging trips at sea leaving their pups for a few days at a time. The lactation periods of otariids are longer, ranging from several months to more than 1 year, and milk is generally less energy dense than in phocids (e.g., milk fat content averaging between 24 and 40%). Walruses exhibit a variant of the otariid strategy, termed the aquatic nursing strategy, in which walrus pups accompany their mothers on foraging trips into the water. The length of lactation in walruses is the longest among pinnipeds, lasting 2–3 years.

Among generalizations that can be made about pinniped longevity is that females, especially those of polygynous species, tend to live longer than males. In many cases males do not survive even to the delayed age of sexual maturity. Seals have been known to pup successfully at 24–25 years and live as long as 40 years or more. Significant factors implicated in the natural mortality of pinnipeds include disease (especially morbilliviruses), predation (e.g., white sharks, killer whales), starvation, and parasites.

Playful Behavior

BERND WÜRSIG

Play consists of actions performed for no other apparent purpose than their own enjoyment. However, it is recognized that play occurs in young animals to learn motor and social skills needed to survive. Play as "enjoyment" may have evolved simply because something enjoyable will be sought after, and if needed actions of learning are enjoyable, they will be done. Tussling sibling brown bears, rolling and cuffing each other, are obviously playing. But it has long been a truism that such play in the proximal sense is vital in learning self-defense and in establishing rules of association. Play tends to decrease in frequency as mammals become older and does not often occur in adults. Obvious exceptions are some primates (including humans!) and cetaceans, although as behavioral studies gather details, researchers are learning that play in adults of other species is actually more common than described previously. Play may also be an attempt to relieve boredom, and we would expect play to be especially well developed in the larger brained, behaviorally flexible, mammals (Goodall, 1990; Marino *et al.*, 2007).

I. Motor Imitations

Many marine mammals seem to be especially good at imitating the actions of their conspecifics or of individuals of other species.

Thus, untrained dolphins in oceanaria have been described as performing a colleagues' trained repertoire essentially flawlessly when called upon to do so. Apparently, the dolphins learned the motor actions simply by observation (Pryor, 1995). While this by itself is not play, the capability of imitation is often expressed as play: dolphins have imitated a diver's movements of cleaning the pool; as well as the grooming and swimming movements of seals and other pool inhabitants. The dolphins would generally approach the object of imitation, slow their own travel to approximate that of the slower coinhabitant, and then move their body in exaggerated imitation of movements of the other individual. The human diver, alternately bending and straightening at the waist as he or she cleaned the aquarium tank with a rubber scraper, was imitated by the dolphin bobbing its head and neck up and down in rapid and jerky fashion. At the same time, the dolphin released clouds of bubbles from its blowhole in synchrony with the bubbles of the diver's air regulator and made a squeaking sound in an apparent attempt to reproduce the squeaks of the rubber on glass. The author has seen similar behavior in nature, with a bottlenose dolphin (*Tursiops truncatus*) adult in the Bahamas imitating a particularly clumsy tourist who had difficulty in descending below the water as she propelled herself with her skin dive flippers and by rotating her arms. The dolphin matched her speed, alternately bobbed at the surface and descended in unison with the woman, jerked its peduncle and tail back and forth in unnatural fashion, while at the same time rotating its short front flippers as if they were flailing arms. The effect looked highly hilarious, and it would be difficult to rationalize the behavior as anything but a bit of malicious fun, or play.

II. Vocal Imitation

While motor or physical imitation seems to be mainly in the purview of TOOTHED WHALES, other marine mammals also practice vocal imitation. This imitation may be an outgrowth of learning one's own species-specific (and perhaps group or pod-specific, as in killer whales, *Orcinus orca*) vocalizations, but the capability can then become a method of play. In the 1970s, a captive male harbor seal (*Phoca vitulina*), named Hoover by his caretakers, was capable of imitating the voice of a human worker who frequented his area, complete with a New England accent and a bit of a drunk-sounding slur (Ralls *et al.*, 1985). Beluga whales (*Delphinapterus leucas*) can also imitate human sound and will at times use these imitations in apparent mischievous play. While dolphins cannot imitate human sounds very precisely (they seem to lack the vocal capability, not the intelligence, to do so), they will easily imitate clicks, whistles, barks, scrapes, and squeaks (as the forementioned window-washing sounds) that can occur in an aquarium with other animals. A particularly readable account of imitation, innovation, intelligence, and cognition can be found in Tyack (1999).

III. Examples of Play

When we meet marine mammals underwater, we are apt to be subjects of intense curiosity. Sea lions, fur seals, and harbor seals will dash around us, pirouette in front of us, and gaze at us. Interestingly, these same animals ignore us or become wary if we approach too close to them when they are hauled out onshore. When in their watery milieu, however, fear is gone. Manatees (*Trichechus* spp.) and dugongs (*Dugong dugon*) are similarly attracted to humans underwater, except in those places where they are hunted. This curiosity can turn to play. Just about every researcher who dives with marine

mammals has tales of sea lions tugging on his or her flippers; manatees and dugongs mouthing an arm or leg in apparent playfulness; and dolphins playing “the leaf game,” where they present the human with a bit of flotsam and wait or return until it is given back to them (Johnson and Norris, 1994).

However, although many people prefer to think that dolphins and humans have an especially play-prone bond, dolphins (and pinnipeds) are known to interact in playful fashion with many other animate and inanimate objects in their environment. Thus, they may “tease” a sea turtle by mouthing and pulling on its tail or legs or they may swim beside a like-sized shark, imitating every movement that the shark makes. Some species of dolphins are also known for adroitly balancing pieces of flotsam on their jaws, flippers, dorsal fin, or tail, or carrying a piece of algae, plastic, or other pliable object in a manner to keep it balanced on an appendage simply by force of the forward movement of the body (Silva *et al.*, 2005). This activity tends to take place when the group of animals is being highly social, usually with much sexual activity as well. The dolphin playing with the inanimate object, however, tends to be alone, apparently transferring its sense of socializing to playing with the object (Fig. 1).

While apparent play is often clouded by the possibilities of curiosity or learning, the author has witnessed several clear-cut examples of play in nature, detailed in the next three sections.

A. The Mischievous Dusky Dolphin

When dusky dolphins (*Lagenorhynchus obscurus*) of Peninsula Valdés, Argentina, have fed and socialized, they are in a very playful mood. They race toward a boat from kilometers away, attempting to ride the bow wave of the vessel. They leap in acrobatic somersaults and flips that appear to show sheer exuberance and orient toward, bite at gently, and otherwise manipulate objects in their environment. There is much social/sexual interaction and apparent play, often in twos and threes, but lone animals carry pieces of kelp on their rostrum or melon and anterior edges of flippers, dorsal fin, or fluke. Most of these behaviors could be interpreted as being a part of learning or honing skills, but the author has repeatedly seen non-equivocal play, as follows.

After dusky dolphins have fed on schooling anchovy near the surface, marine birds who took advantage of the aggregated fish ball sit on the water, digesting. These are of a variety of species, but in

Figure 1 A dusky dolphin (*Lagenorhynchus obscurus*) playing with kelp in Patagonia, Argentina. Photo by Bernd Würsig.

Argentina almost always include kelp gulls (*Larus dominicanus*) and brown-hooded gulls (*L. maculipennis*), yellow or red legs, respectively, dangling below a round white rump. The sight seems almost irresistible for some dolphins, who slowly circle one of these birds, approach it at an angle and from the rear, very gently open their jaws around one or both dangling appendages, and then rapidly but not totally close the mouth and surge forward and down. This action drags the bird below water by about 30–60 cm before the mouth is reopened and the bird literally pops back to the surface. The bird frantically flutters and preens before it flies off. The dolphin meanwhile slowly swims off, at times to attempt the same “trick” with another hapless gull. At all times (this has been seen about two dozen times to date), the bird is unharmed, suggesting particular finesse as the dolphin closes its pointy-toothed jaws and surges forward. The intent appears to be to surprise, certainly not to harm, perhaps like a child sneaking up behind a person to pop a balloon (Würsig, 2000). The same attempts have been seen with dolphins orienting toward the dark feet of Magellanic penguins (*Spheniscus magellanicus*) bobbing at the surface, but the penguins, ever aware of their environment below, simply paddle rapidly ahead or dive before the dolphin can complete its action.

B. Creating a Bow Wave

Dolphins ride or surf on oceanic waves (Fig. 2) and those created by ships. They also ride on the fleeting bow waves created by rapidly surging large whales, and the dolphins appear to “work” particularly hard to get the whales to surge forward. A (generally small) group of dolphins will swim rapidly to the sides and front of the head of a baleen or sperm whale (*Physeter macrocephalus*), close to the eyes. When the whale surges forward abruptly in an apparent attempt to evade the dolphins, the dolphins surf the steep white-water wave so created during that surge. It is believed that the activity is not pleasing to the whale, as the whale exhales forcefully during the surge, with a sonorous “snort” that indicates aggression or anger in other contexts. In right whales (*Eubalaena* spp.), the loud in-air “dolphin blow” of a snorting, surging, whale alerts researchers that *Lagenorhynchus* spp. or bottlenose dolphins are playing with the leviathans. The snort is so loud that on a calm sea it can be heard for a distance of several kilometers. One whale is “good for” anywhere from 5 to 10 surges. It then tires or decides to give up evading the dolphins, and the sport is over for the time or needs to be reinitiated with another whale nearby.

Figure 2 A mom and calf common bottlenose dolphin (*Tursiops truncatus*) surf and leap on an oceanic wave off Maui, Hawaii. Photo by Bernd Würsig.

C. Balancing Bowhead Whales (*Balaena mysticetus*)

Baleen whales engage in the surface activities of breaching, tail lobbing, flipper slapping, and holding the tail above the surface of the water. While much of this is certainly play, at least at times, the percussive nature of these activities possibly aids in communication and may also represent outgrowths of anger or frustration. Holding the tail out of the water for many minutes at a time, a habit of some right and bowhead whales, may feel good as a stiff breeze touches the skin and may even be a form of recreational “sailing” with the tail (as suggested by Payne, 1995).

Adult bowhead whales (approximately 18 m long) have been seen interacting with tree trunks, or logs, up to 10 m long on summer–fall feeding grounds in the Beaufort Sea. They nudge and propel the large log, handle it with their flippers and tail, and attempt to push it under water. Several of these activities seem similar to surface social interactions during sexual activity, and it could be argued that log handling is play useful to developing physical social skills. However, the most dramatic part of log handling is balancing the object, quite adroitly, on the back or belly. The author has seen log balancing (by an adult female) wherein the whale rolled gently sideways to compensate for the action of large oceanic swells rolling past the whale’s body. The whale was so adept at this balancing that she could briefly keep both ends of the huge log suspended in air, a feat perhaps not unlike a trained sea lion balancing a ball on its snout. It is difficult to imagine how this activity could be anything but play or an “artistic” attempt at perfecting a difficult task (Würsig *et al.*, 1989; Wells *et al.*, 1999) (Fig. 3).

Figure 3 A bowhead whale (*Balaena mysticetus*) playing with a log in the Beaufort Sea in summertime. Photo by Bernd Würsig.

D. The Darker Side of Play

While apparent mischievous behavior of pulling on gull or turtle legs or of inciting whales to become aggravated could be potentially AGGRESSIVE or harmful play, it probably is not. Killer whales may use play as a form of learning (and possibly teaching, as well) of youngsters to efficiently hunt (Guinet and Bouvier, 1995; Pitman *et al.*, 2003). However, some interspecies behaviors are definitely harmful and it is unclear whether they represent play or merely aggression. Short-finned pilot whales (*Globicephala macrorhynchus*) have been described aggressively and for almost 2 hr swimming around and into a pod of obviously frightened sperm whales (Weller *et al.*, 1996). Because pilot whales are not known to feed on the much larger sperm whales, it is possible that this action occurred only “for the fun of it,” although other explanations, such as perhaps attempting to get whales to regurgitate squid gathered at depth, cannot be ruled out. A large male pilot whale in Hawaii carried a human diver into depth and held onto her with his mouth for tens of seconds. While he could easily have bit into her and killed her, his holding her was relatively gentle (but firm), and play appears to have been the reason (Shane *et al.*, 1993). The woman survived only because she was an expert swimmer and diver and did not panic.

Bottlenose dolphins, the staple of show dolphins in over 100 aquaria worldwide, are known for at times aggressive play. In Scotland, a group of bottlenose dolphins is known to attack and fling about harbor porpoises (*Phocoena phocoena*), not for food and possibly simply for the sport of it. Bottlenose dolphins and harbor porpoises of the area also do not appear to compete with each other for space or food, but it is unknown whether more than a few (“rogue”) dolphins are involved in this particularly gruesome sport that killed over one dozen harbor porpoises while being observed by researchers.

Polar Bear

Ursus maritimus

IAN STIRLING

I. Characteristics and Taxonomy

The polar bear (*Ursus maritimus* Phipps, 1774) is, on average, the largest of the eight species of bears found worldwide and is completely white. Ecologically, it is the only marine bear. Typically, the body is stocky, lacks a shoulder hump, and has a longer neck in relation to the rest of the body than other ursids. Other English common names for the species are white bear, ice bear, and Nanuk. The taxonomy is order Carnivora, family Ursidae, genus *Ursus*, and species *U. maritimus*. There are no subspecies (Fig. 1).

Polar bears are thought to have originated from brown bears (*Ursus arctos*, also called Grizzly Bear), 1.3 million years ago (Yu *et al.*, 2007). Polar bears and brown bears are capable of interbreeding in zoos and the young are fertile. Although, in the wild, there is little overlap in the habitats during the breeding season, there has been one confirmed

Figure 1 *Ursus maritimus*, the polar bear, is aptly named, as the species is often observed miles from the nearest land on polar pack ice and swimming between ice floes where they hunt ringed seals and sometimes bearded seals. Photo by François Gohier.

case of a hybrid, in which the mother was a polar bear and the father was a grizzly. The molars and premolars of polar bears are more jagged and sharper than those of other bears, reflecting their rapid evolutionary shift toward carnivory from the flatter grinding teeth of their more omnivorous relatives. The oldest known fossil is from London, England, and is less than 100,000 years old.

Adult males typically measure 200–250 cm in length from the tip of the nose to the tip of the tail and weigh 400–600 kg, although some individuals may reach about 800 kg. The total length of adult females is 180–200 cm and they normally weigh 200–350 kg while pregnant females may occasionally exceed 500 kg. There is some geographic variation in size and growth rates of bears in different populations. Polar bears are plantigrade and have five toes on each foot, with nonretractable claws. The forepaws are large and oar-like, as an adaptation for swimming and walking on thin ice. The hind legs are not used while swimming. The skin is black. Females normally have four functional mammae, although supernumerary nipples have also been reported. The dental formula is I 3/3, C 1/1, P 2–2–4, M 2/3. The vitamin A content of the liver is about 15,000 units per gram and is toxic to humans.

II. Distribution and Abundance

Polar bears are distributed in ice-covered waters throughout the circumpolar Arctic. Nineteen individual populations are currently recognized, varying in size from a few hundred to a few thousand bears in each, with a world population estimate in 2005 of 20,000–25,000 (Aars *et al.*, 2006). The southern limit of their distribution in winter varies with the extent of seasonal pack ice in the Bering, Labrador, and Barents seas. In areas where the ice melts completely in summer, such as Hudson Bay or southeastern Baffin Island in Canada, polar bears spend several months onshore fasting on their stored fat reserves until freeze-up in the fall.

III. Ecology

Although small numbers of animals may be found in the permanent multiyear pack ice of the central arctic basin, their preferred habitat is the annual ice over continental shelves of the continents and islands around the coastline of the Arctic Ocean where overall biological productivity and densities of ringed seals (*Phoca hispida*), their primary prey, are greatest.

Regional concentrations and seasonal movement patterns of polar bears are influenced primarily by the type and distribution of sea ice and by the density and distribution of seals. From freeze-up in the fall until breakup in the spring, polar bears prefer coastal areas and interisland channels lying over the continental shelf, especially active ice areas associated with shore leads or the floe edge. The size of home ranges of bears living within the Canadian Arctic Archipelago may be less than 20,000 km² or in excess of 250,000 km² in open ocean areas such as the Chukchi Sea (Amstrup, 2003). In general, polar bears are less abundant in areas of extensive multiyear ice and in the immediate vicinity of polynyas with overwintering walrus (*Odobenus rosmarus*) populations, probably because the density of ringed seals is lower there.

IV. Behavior and Physiology

Polar bears that have continuous access to sea ice continue to hunt throughout the year. Their hunting methods and rates of success change with the seasons and vary in different areas. The most common method of hunting is to lie beside a breathing hole waiting for a seal

to surface and breathe. Contrary to popular myth, they do not cover their noses with a paw when stalking a seal, although when stalking, they do keep their heads low while walking slowly and steadily toward potential prey. The largest proportion of a polar bear's annual caloric intake for the year occurs in spring and early summer, at which time newly weaned ringed seal pups are 50% fat by wet weight (Stirling and Øritsland, 1995). The specific sea ice habitats most hunted by polar bears in spring are stable shore-fast ice with deep snowdrifts along pressure ridges, which are suitable for ringed seal birth lairs and breathing holes; the floe edge where leads are wide, and areas of moving ice with seven-eighths or more of ice cover. After breakup of the annual ice in late spring to early summer, hunting success is reduced and, in areas where open water prevails from late summer through autumn, polar bears seek onshore retreats where they simply fast on their stored fat reserves until freeze-up (Stirling and Parkinson, 2006).

The principal prey species of polar bears are ringed seals and, to a lesser degree, bearded seals (*Erignathus barbatus*). Ringed seals maintain their breathing holes from freeze-up in the fall to breakup in the spring by abrading the ice with the heavy claws on their fore-flippers. Many winter breathing holes are located on the last cracks to close over in the fall and bears are able to locate them by smell, even under a meter or more of compacted wind-blown snow. In areas where wind, water currents, or tidal action causes the ice to continually crack and subsequently refreeze, seals are apparently more accessible to polar bears and the bears are able to hunt them there more successfully. In places where the snow cover in the fiords is deep in spring, large numbers of ringed seals give birth to their pups in sub-nivean lairs where they are hunted by polar bears of all ages and sex classes, but especially females with newborn cubs. Bearded seals concentrate where natural cracks and polynyas form through the winter because it is easier to breathe there. Polar bears are also known to prey on harp seals (*Pagophilus groenlandicus*), hooded seals (*Cystophora cristata*) where they are available and occasionally on walrus, belugas (*Dephinapterus leucas*), narwhals (*Monodon monoceros*), harp seals, waterfowl, and seabirds (Stirling, 1988).

Polar bears have a remarkable ability to store large amounts of fat during periods when prey, mainly seals, are available and then fast for protracted periods when food is not available. In Hudson Bay, where the annual ice melts completely by mid-July and does not reform until mid-November, all bears in the population must fast for at least 4 months on their stored fat, whereas pregnant females do not feed for 8 months, during which period they must support themselves as well as nurse their young so the cubs can grow large enough to withstand the rigors of the arctic environment (Ramsay and Stirling, 1988). Only pregnant females go into dens for the winter while bears of all other age and sex classes remain on the ice and hunt throughout the winter, except for brief periods of up to a few weeks during the coldest or most inclement periods when they may occupy temporary dens in the snow. Whenever food is unavailable, the metabolism of a polar bear automatically slows to a hibernation-like physiological state, in which energy is consumed at a lower rate. This change occurs after about 7–10 days of not eating and can occur at any season of the year, rather than only in the autumn prior to winter denning, like other species of bears. Because the digestibility of fat by a polar bear is about 98%, it has the ability to store large amounts of fat quickly when food is available and then switch to a more efficient metabolic state for as long as necessary when food is unavailable. This is probably the polar bear's single most important adaptation (Derocher *et al.*, 1990).

V. Life History

Breeding occurs from late March to early June. Ovulation is induced so male–female pairs remain together interacting and eventually mating over a period of a week or longer. Dominant adult males try to restrict the movements of adult females and keep them secluded away from areas where competitors are most likely to be until mating is finished. Females have delayed implantation and implant from mid-September to mid-October, probably varying with latitude. The altricial young are born 2 months later at a weight of about 0.6 kg, with fine hair, and closed eyes (Ramsay and Dunbrack, 1986). The family leaves the maternity den to return to the sea ice by late March to mid-April by which time the cubs weigh about 8–10 kg. A litter size of two is most common, followed by singletons and occasionally triplets. One litter of four has been recorded in the wild as it was departing its maternity den.

Most maternity denning takes place in snowdrifts on coastal areas. In western Hudson and James bays, however, pregnant females must enter maternity dens prior to when suitable snowdrifts form in most years. Thus, they dig dens in frozen peat in small banks along the edges of lakes or streams (Ramsay and Stirling, 1988). Individual females show fidelity to denning areas, although not to individual den sites. In the western Beaufort Sea north of Alaska, a large proportion of the adult females den 200 km or more offshore in the multi-year ice of the Beaufort Sea. However, as the climate has warmed and the ice is becoming less stable, the proportion of bears that den on the sea ice in that area has declined (Fischbach *et al.*, 2007).

VI. Interactions with Humans

Polar bears are important to the culture and economy of aboriginal people in Alaska, Canada, Greenland, and Siberia, who harvest 8–900 bears annually. Offshore development and production of hydrocarbons has the potential to impact negatively on polar bears (Stirling, 1990).

Many anthropogenic contaminants in the Arctic marine ecosystem are lipophilic and bioaccumulate as they move up in the food chain. Because polar bears are at the top of the ecological pyramid, and live predominantly on fat, they are capable of achieving high levels of contaminant loading in some areas. It is not yet known whether these contaminants are high enough to interfere with reproductive functions or the immune system (Norstrom *et al.*, 1998).

In recent years, ecotourism to view polar bears, especially at Churchill, Manitoba, has increased markedly with positive local economic benefits and a significant increase in the worldwide appreciation of the bears themselves. Tourist viewing of polar bears at Churchill in the fall and by ship in various areas of the High Arctic in summer, has not been associated with negative effects on the bears.

Conservation of polar bears and their habitats are mandated by a unique Agreement, signed by the five countries with polar bears [Canada, Denmark (for Greenland), Norway, USA, and USSR], signed in 1973 (Prestrud and Stirling, 1994). Population research continues in many areas to try to ensure that populations are harvested at sustainable levels. Thus, the survival of polar bears is not currently threatened by legal hunting, but this must still be regulated carefully because they have a low reproductive capability and would require 20 or more years to recover from an overharvest (Aars *et al.*, 2006).

In some areas, such as western Hudson Bay and the southern Beaufort Sea, long-term studies have demonstrated that climatic warming is causing the ice to break up earlier, or lie offshore of the continental shelf for extended periods respectively, which correlates with decreasing condition, reproductive rates, and declining population

size in both areas. Based on models of the steadily increasing temperatures in the Arctic, as a consequence of increasing concentrations of greenhouse gases, current observations from satellite data and climatic projection models confirm and predict a continuing and significant decline in the total amount of sea ice and an increase in open water in the foreseeable future. This loss of their critical sea ice habitat will likely have a devastating effect on the total population size of polar bears within the next few decades. The IUCN Polar Bear Specialist Group, at their most recent meeting in 2005, voted unanimously to upgrade the classification of polar bears from “species of special concern” to “vulnerable” because of the negative effects of climate warming on their sea ice habitat (Aars *et al.*, 2006).

Pollution and Marine Mammals

PETER J.H. REIJNDERS, ALEX AGUILAR
AND ASUNCION BORRELL

Awareness of the threat of environmental contaminants to marine mammals is widespread. High concentration of certain compounds in the tissues of these animals has been associated with organ anomalies, impaired reproduction and immune function, and as a consequence of the latter, with the occurrence of large die-offs among seal and cetacean species. This has prompted alertness about the impact of pollution and stimulated research into the relationship between observed effects and pollutants. However, a clear cause and effect relationship between residue levels of contaminants and the observed effects has been demonstrated in only a few studies. This might elicit a serious backlash, because in the absence of evidence, concerns expressed are easily interpreted as fear-mongering. This could lead to inertia in taking appropriate management measures, which is undesirable from a conservation as well as environmental management perspective.

The main reasons for the lack of proof of the impact of pollution on marine mammals are the difficulty or impossibility of experimenting in laboratory conditions with these animals, and the frequent occurrence of confounding factors that hamper the establishment of cause–effect relationships. Examples of these factors are the fact that pollution always occurs as a mixture of a large number of chemical compounds, the lack of data on biological variables influencing tissue levels, quality of samples usually analyzed, the limited information on pathology and occurrence of disease in the specimens studied, the absence of reliable population data, and the lack of information on the influence of other detrimental factors such as the impact of fisheries and of other human-related sources of disturbance.

I. Substances of Concern

In general, the concept of pollution incorporates many different substances to which marine mammals are exposed and might adversely affect their health. These include chemical compounds, oil-pollution derived substances, marine debris, sewage-related pathogens, excessive amounts of nutrients causing environmental changes, and radionuclides. The influence of oil and petroleum-derived compounds such as the polycyclic aromatic compounds, of marine debris, of sewage-related pathogens and of nutrient-related changes such as the occurrence of biotoxins, has not been the subject of focused research in marine mammalogy. As a consequence, data on these pollutants, either as concentrations in tissue of the affected marine mammals or as effects on them, are extremely limited. This chapter will therefore only address pollution caused by chemical substances.

Traditionally, most laboratories tended to routinely analyze organohalogenated compounds such as DDT, DDE, DDD, polychlorinated biphenyls (PCBs), lindane, dieldrin, endrin, hexachlorobenzene (HCB), heptachloro-epoxide (HEPOX), and mirex, and trace elements such as mercury, lead, selenium, and cadmium. Some laboratories, able to use more sophisticated equipment, have also analyzed polychlorinated dibenzo-dioxins (PCDDs) and polychlorinated dibenzofuranes (PCDFs). Such narrow approach brings the risk of overlooking the impact of other, poorly known compounds. However, the monitoring of all the known synthetic organic chemicals and their metabolites currently in use, would require analysis of about 300,000 compounds. Therefore, criteria have to be developed to identify priority compounds on which to focus monitoring. Criteria for the identification of these compounds should include level of production and release into the environment, bioaccumulation potential, and toxicity. Examples of “novel” compounds that fall into the category of priority compounds are the organotins, polybrominated biphenyls (PBBs), polybrominated diphenyl ethers (PBDEs), and polychlorinated naphthalenes (PCNs).

Because research funds are limited, another issue to be addressed is the choice between monitoring pollutants concentrations or investigating their effects. The latter option is in our view clearly preferable. If an effect is observed, more focused research for the responsible compounds can follow.

Taking into account the two elements discussed above, and without ignoring the potential impact of other compounds, it is currently accepted that a list of compounds of highest priority should include all organohalogens usually referred to as persistent organic pollutants (POPs), particularly including PCBs, DDTs, PCDDs, HCB, HCHs (hexachlorocyclohexanes), dieldrin, endrin, mirex, PCDFs, PBBs, PBDEs, PCNs, polycyclic-aromatic hydrocarbons (PAHs), phenols, and the metals, very particularly including their organic forms such as methyl-mercury and organotins.

II. Pollution from an Environmental Perspective

Pollution is only one of the many environmental factors that influence the health status of marine mammals. The assessment of the impact of pollution on marine mammals has therefore to be undertaken on a holistic perspective, considering also the potential of pollutants to interfere with their ability to recuperate from stress caused by other environmental forces. As an example, PCBs could cause immune-suppression in a given seal population without directly leading to an increased mortality. However, if such a population is exposed to an introduced virus, the extent of a resulting epidemic is likely to be much aggravated (Aguilar and Borrell, 1994).

Marine ecosystems are complex and environmental forces operating over populations are often multifactorial and produce synergistic or cumulative effects. Therefore, it will be complicated to attribute a given effect to a single factor. To illustrate the complexity of unraveling the impact of pollution, we discuss here some of the environmental factors, natural or anthropogenic, that influence the resilience of marine mammals to pollution.

A. Prey Depletion

Natural environmental variations such as redistribution of planktonic organisms may bring changes in distribution, abundance, or recruitment of the species that constitute the food of marine mammals. However, depletion of prey may often also be caused by

overfishing by commercial fisheries. Depending on the extent of the depletion, marine mammals may respond to the reduced supply of prey either by switching to other species, or by temporarily moving to another area. But frequently, they undergo an impoverishment of their body condition and their recruitment rates become lower. The resilience of animals in such populations/stocks is negatively affected, potentially increasing the detrimental impact of pollutants.

B. Habitat Disturbance

Habitat may be disturbed by a wide range of human activities, including recreation, construction works, and many others. For pinnipeds, sea otters (*Enhydra lutris*), and some coastal cetaceans, the physical alteration of the littoral, including the mere presence of humans and their associated infrastructures, may be a significant detrimental factor. Noise pollution is a particular source of concern because many marine mammals rely on sound emission and detection for finding their prey, communication, and navigation. Activities producing noise-related disturbance include shipping, boating, military maneuvers, seismic testing, and oil and gas drilling.

C. Disease

Natural factors influence incidence of disease. For example, a shift in distribution of prey species may lead to an increased parasite infestation rate likely to affect the resilience of populations to pollutants. Although in general terms the incidence of infectious disease in marine mammals is poorly known, *Morbillivirus* epizootics that have recently affected pinnipeds as well as cetaceans, have elicited extensive research on the effects of viral diseases on marine mammal populations.

Deadly bacterial diseases are generally considered to be secondary to other conditions such as viral disease, parasitic infection, or trauma. However, like some pollutants, bacteria can also interfere with reproduction, as was demonstrated by the finding of *Brucella* organisms in porpoises and dolphins.

In marine mammals, similarly to other better studied groups of vertebrates, disease and the toxic effect of pollutants are often interrelated. This relationship will be discussed in more detail in the next section in this chapter, although we should mention here that diseases can affect metabolic systems and, consequently, alter physiological functions. Chronically diseased females, for example, usually have a poor reproductive performance, as do females affected by some pollutants.

D. Overall Environmental Changes: Global Warming, Ozone Depletion

Albeit the potential effect of global changes on marine mammals has been very little investigated and its consequences are considered less imminent than those caused by other factors, this matter certainly deserves concern. It is predicted that global rise in temperature will alter marine communities and their productivity, sea level rise, reduce ice cover, and modify rainfall and water current systems. The consequences for marine mammals are unclear but undoubtedly those alterations will affect their behavior and distribution. Increased incidence of epizootics among pinnipeds is also postulated, as higher densities as a result of increased haul-out behavior, shall result in a higher transmission rate of infectious agents.

Despite the long-term character of these threats, changes in distribution and behavior of marine mammals caused by climate variation should be monitored to detect potential relationships at an early stage.

The examples mentioned above show clearly that studying the impact of pollution on marine mammals requires a multidisciplinary approach. Therefore we advocate assessing pollution impact not in an isolated way, but always in relation to other environmental factors.

III. Factors to be Taken into Account in Assessing Pollution Impact

Two sources of information may alert that pollution might affect a given population: high tissue pollutant concentrations in the members of that population, and changes in the population's biological parameters such as physiological condition and changes in reproductive or mortality rates. The latter are often derived from population monitoring and/or pathological investigations. However, a number of biological factors and inconsistencies in the sampling and analytical procedures seriously hamper the establishment of such relationships, sometimes even leading to spurious interpretations of environmental data (Krahn *et al.*, 2003).

A. Biological Factors Affecting Variability in Pollutant Levels

Some persistent chemicals are bioaccumulative and their concentrations in living organisms undergo a progressive amplification through food chains, a process called biomagnification. However, the increase at each trophic level is usually considerably higher than the 10-fold increase predicted by ecological models. Biomagnification, defined as the ratio of concentrations of a compound in the predator to its prey, can be significantly altered—and often much increased—by a number of variables such as the route of exposure, the physical and chemical properties of the compound, the metabolic capacity of the predator and its physiological constitution (Aguilar *et al.*, 1999).

B. Diet

Diet composition is a key factor determining resultant tissue concentrations. Because baleen whales feed on planktonic crustaceans, and are thus situated lower in the food web, their tissue organochlorines (OCs) concentrations are almost invariably lower than those in the top-predator toothed whales living in the same ecosystem.

Within a population of the same species, OC levels can also differ because of variations in diet. For example, juvenile pinnipeds often exploit different food resources than adults, and in many species of cetaceans and pinnipeds, adult males prey on different species than adult females. In some marine mammals, differences may even be associated to reproductive status: the diet of lactating females of some dolphin species is different from pregnant or resting females. Also, the geographical region where food is consumed is critical: during most of the year sperm whales (*Physeter macrocephalus*) occupy different geographical regions than females and, as a consequence, their pollutant profiles are quite dissimilar. Differences in diet are also assumed to have an influence on the tissue concentrations of PAHs in marine mammals. Levels of these compounds in marine mammals are generally low, although they tend to be higher in cephalopods-eating marine mammals than in those relying on fish. The explanation appears to be that the ability of fish to metabolize PAHs is better than that of cephalopods.

Tissue levels of metals also appear to be related to the feeding habits and region of exposure. Cadmium, copper, and zinc levels are higher in cetaceans that feed primarily on squid, than in those feeding on fish. This is attributed to the ability of squid to selectively

retain these elements. Intraspecific differences in tissue metal concentrations have also been linked to segregation in feeding areas; the levels of lead in kidney and muscle tissue of pilot whales and white beaked dolphins occurring during summer in the same areas, are much different because they segregate geographically—and feed—during the winter.

C. Age and Sex

The tissue concentration of a pollutant in a marine mammal is a function of the difference between the intake rate and the metabolization and excretion rates. OCs have been found to correlate positively with age; levels are relative low in young animals, increase until a certain age, and then either continue to increase or reach a plateau level or decrease. The leveling-off or decreasing phase is different for males and females, as is addressed further on. Factors that influence the age-related pattern of accumulation of organochlorines are the detoxification ability and the feeding rate. The capacity for detoxification is low in young animals and improves with age; thus, the initial increase during the juvenile stage is slowed down by improved metabolization and excretion rates. The resulting leveling-off of tissue concentrations is further enhanced by reduced feeding rates in adults.

Superimposed on these is the effect of reproduction in females. OCs, as most lipophilic compounds, cross the placenta and reach the fetus, although not all chemicals do it at equal rates. For example, the lower chlorine-substituted (lower weight) congeners of PCBs are more easily transported than the higher chlorinated ones. In addition to placental transport, OCs are also transferred from mother to offspring through milk. Higher chlorinated OCs are less efficiently transferred from the lipid tissue of the mother to her milk and hence to the suckling calf or pup. This process obviously does not start until the females reach sexual maturity and become pregnant for the first time. Therefore, the first pregnancy marks the start of the leveling-off or decrease phase in females. There are differences among species and compounds. But this reproductive discharge in females is not uniform and depends on the characteristics of the reproductive cycle of the species and the physical-chemical properties of the compound. The transfer during lactation is much higher than that occurring through deposition in the tissues of the calf or pup during pregnancy. In cetaceans, discharge of PCBs, expressed as percent transferred in relation to maternal tissue load, ranges from 5 to 96% during lactation and 4–6% during pregnancy. In pinnipeds, the ranges are 23–81% and 1–10%, respectively. Not surprisingly, the length of the lactation period significantly influences the proportion of the OCs' load transferred to the offspring. It has been estimated that this proportion ranged from 3 to 27% in fin whales (*Balaenoptera physalus*), with a lactation period of around 7–8 months, whereas it was around 80% in bottlenose dolphins (*Tursiops* spp.), and 72–91% in striped dolphins (*Stenella coeruleoalba*), two species in which lactation lasts about 14 months. Irrespective of the amount transferred, the reproductive discharge results in lower levels of lipophilic pollutants in reproductively active females as compared to males of the same age. However, there are some exceptions to the general rule. In southern hemisphere minke (*Balaenoptera acutorostrata*) whales, levels of PCBs and DDT were found to be higher in immature males than in mature males, as a result of a shift in diet caused by adult migration to less polluted areas. In the North Atlantic, adult female sperm whales are more polluted than males of comparable age because they feed on more polluted species and distribute year-round in regions where pollutant loads are higher.

Age-related variation in tissue concentrations of trace elements is less homogeneous. Mercury, cadmium, selenium, and lead increase

with age, somewhat more steeply in females compared to males. There is no clear leveling-off for any element except for lead, in which a slower increase has been observed at older age. As these elements are not lipophilic, reproductive transfer does not affect their loads in females. It has been suggested that the higher levels of those elements found in females compared to males may be related to differences in metabolic pathways linked to hormone cycles.

Information on other trace elements is scarce. Copper and zinc show no increase with age. In fact, concentrations in newborns are higher than in adults, which are attributed to an age-related decrease in absorption and retention of these essential elements.

D. Nutritive Condition

Nutritive condition affects the volume of fat in the body and its lipid composition. In some cetaceans and pinnipeds, blubber lipid richness may decrease from 90% in a female near term to 30–35% in females just having weaned their offspring. Though less impressive, males also show changes in blubber layer thickness during the reproductive season. Apart from this reproduction-related change, seasonal variation may also be significant. Variation in blubber layer thickness is lower in toothed whales compared to baleen whales. In some pinnipeds, independently of the reproduction-related changes, blubber layer thickness can vary by as much as 50% (taking the maximum thickness as a reference). This variation has implications for the dynamics of lipophilic contaminants. Because lipids are more readily mobilized from the blubber than lipophilic pollutants, lipid metabolism typically results in an increase in the residue levels. However, it has been found that the increase is less than a kinetic concentrative model would predict. It has been suggested that the more polar fraction of the pollutants is more readily mobilized through the enhanced metabolism and excretory capacity stimulated by a rise in tissue pollutant concentrations subsequent to the lipid metabolism.

It is unclear to what extent changes in nutritive condition affect tissue concentrations of nonlipophilic compounds. Changes in mass and composition of tissues where chemicals (e.g., heavy metals in liver and kidney) are likely to influence the dynamics of these pollutants, but data on these processes in marine mammals is lacking.

Body growth in young animals also influences tissue levels of pollutants. In both pinnipeds and cetaceans it has been found that dilution of contaminants occurs in the early stages of growth due to the rapid deposition of blubber and the amassing of liver and kidney tissue. Calculations of tissue concentrations on a lipid basis instead of a fresh weight basis can partially account for such variation, but it does not account for variation in the qualitative composition of the lipid fraction, which is also likely to affect the retention ability of the tissue.

E. Body Size

The influence of body size on variation in the accumulation pattern of pollutants is somewhat complex. Generally, elimination rates of xenobiotic compounds per unit of bodyweight are inversely related to bodyweight, a trend that also holds for the activity of detoxifying enzymes. Both would tend to favor accumulation of higher pollutant levels in larger animals. Contrary to that effect, metabolic rate is inversely correlated to body size. Because metabolic rate is correlated with pollutant intake, a higher pollutant accumulation can be expected in smaller species. The influence of metabolic rate has been found to outweigh the counter-effect of elimination and detoxifying activities. The concentration factor in a marine mammal is largely dependent of its daily rate of food consumption—inversely related to body size—and the mean concentration of pollutant in its

prey. Small animals therefore carry generally higher loads of pollutants relative to their bodyweight than do larger animals.

Variation in body size is more dramatic in cetaceans than in pinnipeds. Some dolphin and porpoise species weigh, when adult, about 30–40 kg, while the larger whales can weigh more than 150,000 kg. The range in adult pinnipeds varies from 50 to 4000 kg. An example of variation in pollutant levels between two species of different size is that of two krill eating baleen whale Atlantic species, in which differences in tissue pollutant levels were explained by differences in body mass. It has been proposed that, in species sharing the same waters, the effect of body mass on tissue concentration outweighs that of the small differences in diet or other biological traits.

F. Body Composition

The distribution pattern of pollutants in the body of an animal depends largely on the physical and chemical properties of the substances involved. For example, much work has been carried out to investigate the influence of the position of H-atoms on the biphenyl ring in all PCBs, which largely determines the possibilities for their metabolism by marine mammals.

Lipophilic pollutants accumulate in fatty tissue, so about 70–95% of lipophilic pollutants end up in the blubber, which in marine mammals is the largest fat compartment. The chemical composition of the blubber also influences pollutant concentrations. In species with thick blubber, pollutants are stratified in the different layers and significant differences may be found between the inner and outer strata. Therefore, the whole blubber layer must be sampled to obtain a representative picture of the individual's load.

Mercury, cadmium, zinc, and other heavy metals accumulate mostly in the liver and kidney, and lead predominantly in bone tissue.

G. Analysis and Sampling

One of the major handicaps in assessing temporal and spatial trends of contaminants in marine mammals is the poor comparability of data. This holds partly for heavy metals, but it is definitely critical for analyses of OCs. The analytical techniques used, and their accuracy, have changed considerably over time and also vary between different laboratories. This greatly hinders comparison between studies undertaken by different laboratories or time periods. Significant improvement in standardizing procedures has been achieved in the last decade through intercalibration exercises. Quality assurance and quality control are of utmost importance, but this holds also for the sampling procedures. To avoid contamination by the packaging material, clean glass or aluminum foil should be used to preserve samples for OCs analyses, and plastic bags to preserve samples for heavy metal analyses. Each sample should be accompanied by the appropriate biological data, and if possible, also with a detailed pathological examination, to reveal, e.g., incidence of alterations in reproductive biology, early development, and occurrence of diseases.

Detailed field and laboratory protocols taking into account these considerations have to be developed before embarking in any ecotoxicological study.

IV. Impacts of Pollution on Marine Mammals

Numerous studies have suggested that exposure to pollutants has an impact on marine mammal populations, mainly on reproduction and mortality. However, in most of these studies, the existence of confounding factors prevents reaching conclusive results and only

a few have actually succeeded in demonstrating such relationship (O'Shea, 1999; Reijnders *et al.*, 1999).

The effects of pollution, either observed or suggested, can be conveniently grouped under three categories: impaired reproduction, indirect mortality, and direct mortality.

A. Impaired Reproduction

OCs, particularly PCBs, have been demonstrated to be responsible for impaired reproduction in the harbor seal *Phoca vitulina*. This conclusion was reached by means of a feeding experiment in which 12 female harbor seals were fed diets low in OCs and 12 females received a diet high in OCs, particularly PCBs and DDE. The conclusion was that reproductive success was significantly lower in the more polluted diet group: 4 pups were born instead of 10 born in the control group. The latter figure is similar to what is normally found in free-ranging harbor seals. In addition, the analysis for oestradiol-17 β and progesterone in blood samples from these seals revealed that the reproductive failure occurred at the implantation stage, since such failure was accompanied by low levels of oestradiol-17 β (Reijnders, 1986). A plausible explanation of this effect is that PCBs enhanced the enzymatic metabolism lowering in this way the circulating levels of estradiol, which in turn led to imperfect endometrial receptivity and prevented successful implementation of the blastocyst.

Elevated OCs concentrations have been associated with reproductive impairment in gray seals, *Halichoerus grypus*, and ringed seals, *Pusa hispida* in the Baltic, and in California sea lions, *Zalophus californianus*. Female Baltic gray and ringed seals exhibited uterine occlusions and stenosis, leading to partial or complete sterility; concentrations of OCs were higher in the affected animals than in normally reproducing females. It has been proposed that pregnancy was interrupted by PCBs (or PCB-metabolites), followed by development of pathological disorders. The epidemiological studies on the involved populations strongly support the hypothesis that PCBs or their metabolites, i.e., methyl-sulfones, are responsible for the observed reproductive impairment. This has been apparently confirmed by the fact that the incidence of pathological conditions in younger but mature age-classes decreased, and OCs levels in seals as well as other Baltic biota, sharply declined between 1970 and 1980 (Olsson *et al.*, 1994). However, unequivocal evidence for a cause-effect relationship has not been provided, although this stage of proof is probably as far as one can get with the constraints of this type of field research.

The case of the California sea lion is even more complex. Initially stillbirths and premature pupping were attributed to high OCs (PCBs and DDE) concentrations. Later studies demonstrated that pathogenic disease agents could also have been responsible of the process. These confounding factors prevented reaching a clear cut conclusion on the causative role of pollution.

The proof for reproductive disorders in cetaceans caused by specific pollutants is weaker than for pinnipeds. There is a risk assessment study indicating a high likelihood of severe reproductive impairment in bottlenose dolphins from the southeast United States coast, caused by chronic exposure to PCBs. Impaired reproductive performance caused by PCBs has been suggested in beluga whales (*Delphinapterus leucas*) in the St. Lawrence River. In 2 out of 120 examined belugas, hermaphroditism was observed. However, the pathological studies were not conclusive, and the lack of sound population data with which to compare the observed findings, made it impossible to conclude on the actual role of pollutants on such abnormalities.

Low levels of testosterone were associated with high levels of PCBs and DDE in Dall's porpoises (*Phocoenoides dalli*). However, the biological significance and underlying mechanism are unclear since both variables are age-related, and further studies are needed to clarify the potential involvement of pollutants.

Abnormal testes, i.e., transformed epididymal and testicular tissue, were observed in North Pacific minke whales. A possible relation with high levels of OCs has been suggested, but not proved.

B. Disease

A suite of pathological disorders including skull lesions (paradentitis, osteoporosis, exostosis), cortical adenomas, hyperkeratosis, nail malformations, uterine stenosis and occlusions, uterine tumors (leiomyomas), and colonic ulcers, have been observed in Baltic gray and ringed seals and, to a lesser extent, in harbor seals. Pathological and epidemiological investigations revealed that the symptoms observed were part of a disease complex called hyperadrenocorticism, a disease syndrome associated with high levels of PCBs and DDT and their metabolites. Contrary to reproductive impairment, it is not possible to conclusively evaluate which of these substances elicit a response in seals, because of crossed or synergistic effects. Like in the case of the reproductive disorders, the prevalence of uterine lesions, adrenocortical hyperplasia, and skull-bone lesions was found to decrease following a decline of DDT and PCBs in Baltic biota. Conversely, however, the incidence of uterine leiomyoma in Baltic seals has not changed to date. Of even more concern is the increasing incidence during relative recent years of colonic ulcers in young Baltic gray seals, indicating an increasingly compromised immune system in these animals. DDT tissue levels in these animals have decreased strongly between 1969 and 1997, annually by 11–12%, but PCB levels decreased during the same period at a much lower pace, only 2–4% annually. This may suggest a role of PCBs and/or their metabolites in the observed pathologies, although the potential effect of novel, unknown compounds cannot be excluded.

Some studies have shown direct evidence of the immunotoxicity of OCs. Reduced immune responses were correlated with high levels of PCBs and DDT in *in vitro* immune function assays with peripheral blood lymphocytes from free-ranging common bottlenose dolphins, *Tursiops truncatus*. In an experiment with captive harbor seals, *in vitro* and *in vivo* immune function tests showed lower immune function related to higher dietary concentrations of OCs (Swart *et al.*, 1994). While these two studies show that OCs adversely interfere with immune function, the toxicological and biological significance remains unfortunately unclear. An indication for an increased risk of infection from PCBs on harbor porpoises has been reported.

It has been suggested that lowered immuno-competence induced by contaminants aggravated the die-offs of bottlenose dolphins in the Gulf of Mexico (1990, 1991, 1993) and in the east coast of the USA (1987–1988), striped dolphins in the Mediterranean Sea (1990–1992), harbor seals in the North Sea (1988), Baikal seals, *Phoca sibirica*, in Lake Baikal (1987–1988), and Caspian seals, *Phoca caspica*, in the Caspian Sea (2000). In most cases the mortalities were ultimately caused by a *Morbillivirus* infection, but exposure to high levels of OCs was proposed to have played a key role by facilitating viral transmission and increasing susceptibility of individuals to the disease. However, it has been difficult to conclude on the etiology of these mortalities. Different studies have tried to establish links between die-offs and pollution. In the case of the striped dolphin *Morbillivirus* epizootic, animals killed by the disease carried significantly

higher PCB concentrations than survivors. This finding could be explained by: (1) immune suppression caused by PCBs leading to higher mortality of the more polluted individuals, (2) mobilization of pollutants stored in depot tissues thinned by the disease, or (3) changes in physiological functions of the affected individuals, leading to increased PCB concentrations.

In two other studies levels of organochlorines were related to mortality. In one study, OCs levels in seals that died during the *Morbillivirus* outbreak were compared with those in surviving seals. In the other study, OCs concentrations in harbor porpoises, *Phocoena phocoena* that died from physical trauma were compared with animals known to have succumbed to an infectious disease. Both studies were inconclusive in establishment of a direct cause–effect relationship between pollutants and susceptibility to disease, because of the existence of confounding factors such as heterogeneous body condition between the groups compared. A recent follow-up study on harbor porpoises from England and Wales has been more conclusive (Jepson *et al.*, 2005). In this study, PCB concentrations in blubber from animals that died due to physical trauma (e.g., bycatch) were compared with those from animals that died because of an infectious disease. A significant association was demonstrated between blubber PCB concentrations and mortality due to infectious disease, suggesting a causal relationship with chronic PCB exposure. Again here, the possibility of additive or synergistic effects of other contaminants must be considered.

Other ecotoxicological studies point toward other effects of pollutants on marine mammals. It has been proposed that OCs produce thyroid hormone and vitamin A deficiency in at least harbor seals. Thyroid hormones are important in the structural and functional development of sex organs and the brain, both intrauterine and postnatal. Vitamin A deficiency may lead to increased susceptibility to microbial infections and retarded growth, as appeared to be indicated by the significant lower birthweights of pups born in the higher contaminated dietary group of the captive harbor seal study discussed earlier.

Another noteworthy example of impaired health status possibly caused by pollution is the case of the St. Lawrence beluga population (Martineau *et al.*, 1994). A range of pathological conditions have been documented in this population, particularly high prevalence of tumors, digestive tract and mammary gland lesions. High tissue levels of OCs, lead, and mercury have been found in these animals. The establishment of a cause–effect relationship between contaminants and the observed effects in this population is hampered by the possible adverse role of other environmental factors such as previous over-hunting, high levels of noise pollution, and overall habitat destruction. Any of these factors has a potential for causing most of the observed conditions and the population's small size and slow recovery.

C. Direct Mortality

There is no clearly documented record of any acute chemical poisoning event affecting marine mammals, apart from one case that affected harbor seals; a small colony had been acutely poisoned by an accidental discharge of mercury-contaminated agricultural disinfectant and several deaths occurred.

D. Endocrine Disrupting Chemicals

In the last decade, increasing concern has been expressed on xenobiotic-induced endocrine disruption in wildlife and humans. Adverse effects of contaminants on mammalian wildlife through modulation of endocrine systems are predominantly documented in fish-eating (aquatic) mammals. Indeed a large number of xenobiotics with

endocrine disrupting properties, like OCs, have been detected in marine mammal tissue. In previous sections, reproductive and non-reproductive effects, including possible links with the functioning of the immune system, have been discussed in relation to these pollutants. Except for the reproductive toxicity in harbor seals and Baltic seals, the evidence of a causal link between endocrine disruption and observed effects is weak or nonexistent. Most often neither a positive proof nor a dismissal, or simply a negative endocrine-like effect, could be provided. The reasons for lack of proof are the unavailability of reliable population data, the potential interaction between the many pollutants present, the role of disease agents and other environmental factors, the lack of biomarkers to assess endocrine effects, and the little research on early development in marine mammals.

V. Species Vulnerability

The impact of pollution on marine mammals can occur throughout the entire chain from exposure, uptake, metabolism to excretion. Concentration in prey is a determining factor. Generally, coastal species are exposed to higher environmental levels than more pelagic species, and species occurring in industrialized (including intensive agricultural) areas usually have higher pollutant levels compared to animals in less developed regions. Among marine mammals, coastal seals and dolphins usually carry the highest tissue residue levels. Superimposed to that is the preferred trophic level of feeding. In the same water mass, species feeding at lower trophic levels are exposed to lower levels of pollutants, compared to species feeding higher in the food chain. This is why pollutant levels are almost always lower in baleen whales than in toothed whales. Exceptions to this pattern have been discussed earlier, e.g., for metals in species feeding on squid rather than on fish. However, even species (harbor seals and gray seals from the east coast of Scotland) sharing the same environment, are differentially susceptible to OCs. Immune functions in harbor seals were more affected than in gray seals, the underlying mechanisms are still unclear (Hammond *et al.*, 2005)

As mentioned before, females get rid of pollutants through reproduction. Species that reach sexual maturity at a younger age are in an advantage as compared to those that start reproducing at an older age. Early reproduction is also positive for the offspring. The amount of pollutants descendants receive is lower if mothers initiate reproduction activities early, because they have not yet built up high tissue concentrations. Similarly, an earlier onset of sexual senescence is a disadvantage in this respect, because it halts the discharging process. A protracted lactation period is clearly beneficial for reproductive females, because the amount of lipophilic pollutants that they transfer is high. This latter obviously depends on the time they start to feed again, because then the pollutant uptake will counterbalance the discharge. However, the protracted lactation period may bear adverse effects to the offspring, because often milk is more polluted than the food that descendants will consume once weaned. It is unclear how this resolves at the population level; this is, whether the benefit for the reproductive female is higher or lower than the costs for the offspring.

A factor likely to lead to differential vulnerability between species is body size. Small species have generally higher levels of pollutants relative to their bodyweight, than those of larger body mass.

Metabolization is another operative factor in this context. The P450-enzyme system is the main physiological tool for metabolizing OCs. For example, this system can be induced by PCBs, mediated by the arylhydrocarbon (Ah) receptor, which is found in mammals and birds. But the metabolic ability is not uniform between marine mammals. Overall, cetaceans have a lower metabolization capacity,

as measured by Phenobarbital (PB) and methylcholantrene (MC) types of activity. Initially all cetaceans were thought to lack the Phenobarbital (PB)-type of enzyme. However, recent research has shown that several dolphin species possess at least some microsomal PB-type of enzyme. Still, their PB- and MC-type of metabolic activity is usually lower than that of pinnipeds and terrestrial species. At a more specific level, ringed seals and harbor porpoises seem to have metabolic capacities intermediate between those of other seals and cetaceans. In conclusion, apart from the more apparent cetacean-pinniped difference in metabolic capacity, sharp differences exist also among species within any given taxa (Boon *et al.*, 1992).

The critical question in this respect is, however, whether a low activity of, e.g., PB-type and/or MC-type enzymes renders cetaceans more vulnerable to pollution, as has been repeatedly suggested. This may not automatically be the case. For example, PCBs can potentially elicit toxicity in at least two ways: as parent compounds (persistent congeners) and as metabolized congeners. The persistent compounds show a PB- and mixed PB- and MC-type of toxicity associated with liver-hyperproliferation, lowered levels of thyroxin and vitamin A, and a dioxin-type of toxicity (MC) resulting in thymic atrophy, dermal disorders, and liver necrosis. Metabolization of parent compounds can result in at least two contrasting effects: a decreased level of dioxin type of toxicity and an increased metabolic specific toxicity such as immunotoxicity. The resultant effect of a lower metabolization capacity therefore depends on the relative contribution of the mitigating influence of a decreased dioxin type of toxicity vs a continued PB and mixed PB/MC induction and the effect of reactive intermediates.

In this respect, attention should be drawn to the often misused concept of toxic equivalency. This concept is based on the structure-activity relationships of contaminants with receptors. Tetrachlorodibenzo-dioxins (TCDD) and PCBs have a structure that fits the Ah-receptor. The degree of induction by TCDD has been correlated with their toxic effects observed in laboratory animals. Given the similarity in structure of PCB congeners, the ability of these latter compounds to induce the Ah-receptor mediated response is expressed as a ratio to the induction by TCDD. This is called the toxic equivalency factor (TEF), which has been extensively used to assess the toxicity of PCB congeners and their mixtures with, e.g., DDT and PCDD. That toxicity is calculated by multiplying the TEF of each compound by its concentration and the sum of the resulting values are considered to be the total toxic equivalent (TEQ) for the mixture of compounds found in the sample.

However, it needs to be stressed that TEFs are based on laboratory animal models. Therefore, the TEQ for a given marine mammal sample only means the effect that the mixture of compounds found in that sample would have on a laboratory animal. Because (1) large differences between species exist in induction of P450-based enzymes, (2) the toxicities of PCB-metabolites are not incorporated into the calculations, and (3) toxicity of modes other than that of a dioxin-type are disregarded, the application of TEQ to assess the toxicological risk to which a particular species is subject to, is not necessarily reliable. The same holds for extrapolating TEQ between species. We would therefore emphasize that the frequently used practice of assessing whether the toxic significance of a certain value of TEQ found in a marine mammal is lower/higher than a TEQ value found in a species where effects were observed, is unfounded and scientifically unsound.

Another issue that remains to be clarified is the occurrence of high levels of some heavy metals, such as mercury, lead, and cadmium, particularly observed in species in the northern-arctic regions (Muir *et al.*, 1999). They apparently possess the ability to tolerate

high levels of those compounds. It is known that marine mammals are able to detoxify these metallic compounds by, e.g., de-methylating the highly toxic form of organic mercury into the less dangerous inorganic mercury, by the binding of metals to metallothioneins, or by the binding of selenium to mercury where inactive salts are produced. It is tempting to speculate whether the animals in those areas have evolved responses to mitigate the effects caused by the naturally occurring contaminants.

VI. Developments in Spatial and Temporal Trends of Pollutants

Data on levels of pollutants in marine mammals are more numerous for western Europe, North America, Canada, and Japan. Limited data are available for many other countries and regions (e.g., Africa, New Zealand, India), and very little information is available for the southern hemisphere. As mentioned in an earlier section, the fish-eating marine mammals from the mid-latitudes (industrialized and intense agricultural use) of Europe, North America, and Japan have the highest loads (Fig. 1). Residue tissue concentrations are lowest in the upper north polar region and the Antarctic. Nearly all of the

Figure 1 Latitudinal Σ PCB concentrations ($\mu\text{g}\cdot\text{g}^{-1}$ wet weight) in blubber tissue of various marine mammals from the western Pacific and the eastern Atlantic.)

OCs contamination in marine mammals in the Arctic and Antarctic has reached these areas via atmospheric transport. The levels of the more volatile OCs are higher compared to PCBs and DDT and more homogeneously distributed. This pattern of distribution of residue concentrations in marine mammals, however, is gradually changing. Levels of OCs are declining in the mid-latitude areas, whereas they are increasing in regions distant from pollution sources. Particularly the transfer of OCs released in (sub)tropical countries to the atmosphere, causes global redistribution that were predicted to end up in the mid-term future into the Arctic. However, recent studies show that concentrations of most highly persistent OCs (PCBs, DDT, etc.) significantly declined in Canadian Arctic biota from the 1970s to the late 1990s, and today are generally less than half the levels of the 1970s, particularly in ringed seals.

Chlorobenzenes and endosulfan were among the few OCs to show increases during this period while tHCH remained relatively constant in most species. A suite of new-use chemicals previously unreported in Arctic biota (e.g., polybrominated diphenyl ethers (PBDEs), short chain chlorinated paraffins (SCCPs), polychlorinated naphthalenes (PCNs), perfluoro-octane sulfonic acid (PFOS), and perfluorocarboxylic acids (PFCAs) has recently been found. But information to assess the spatial and temporal patterns thereof, is still insufficient (Braune *et al.*, 2005).

For the most widely spread OCs, particularly PCBs and DDT, and the heavy metals mercury, lead, and cadmium, information on temporal trends is increasing. In most heavily industrialized and agricultural regions, the production and use of DDT and PCBs was halted in the early 1970s. From the mid-1970s onwards, levels of DDT and PCBs in marine mammal tissues decreased (Borrell and Reijnders, 1999). The decline in DDT levels was stronger than that of PCBs. In pinnipeds the decline was 80–90% for DDTs and 60% for PCBs. The difference is most likely due to less stringent control measures for PCBs; large quantities of these compounds have remained in use in many applications. The overall time trend for PCBs and DDT levels in marine mammals is that concentrations have decreased since the mid-1970s. The decrease in DDT levels has continued thereafter. However, PCB levels in some areas leveled off at the end of the 1970s/early 1980s, but are now declining.

Figure 2 shows the distribution over different compartments of all the globally produced (1.325.810 tons) PCBs by the industry. In the higher production scenario, 55.4% have been permanently lost through degradation, burial in landfills, or destroyed following various combustion processes; 12% has been emitted into the atmosphere. As a result, only 2.4% of all the PCBs produced has been deposited in soils, 14% is accumulated in dump sites and 15% is still

Figure 2 Global budget of produced PCBs.

in use (Breivik *et al.*, 2007). It is expected that the observed leveling-off of the decrease in marine mammals will be followed by a strong reduction in the near future.

Trends for heavy metal pollution are less apparent. In general, it is accepted that in the mid-1990s in ringed seals and beluga from the Canadian Arctic and Greenland, the levels of mercury were higher compared to the mid-1970s, whereas for cadmium there was no clear trend (Muir *et al.*, 1999; Breivik *et al.*, 2007). On the contrary, levels of mercury and lead in pinnipeds from the Wadden Sea have considerably decreased.

VII. A Fundamental Approach to Address Pollution Impact on Marine Mammals

It is clear that a considerable amount of fundamental research is needed before it will be possible to adequately address the impact of pollutants on marine mammals. Realizing this situation, the International Whaling Commission (IWC), through its Scientific Committee, developed recently a comprehensive program to investigate pollutant cause–effect relationships in cetaceans: “Pollution 2000+” (Reijnders *et al.*, 1999). The ultimate objective of pollution studies as related to marine mammal management is to determine a predictive model to link tissue pollutant levels with effects at the population level. This is obviously a longer term goal. It is realized that if any progress is to be made within a reasonable time frame, a multidisciplinary, multinational focused program of research is required, that concentrates on species and areas where there is most chance of success.

Pollution 2000+ focused on PCBs, because these chemicals can be used as model compounds for OCs pollution. Moreover, PCBs are found at extremely high tissue levels in cetaceans, their effects upon mammals are well known and substantial information is available on their patterns of variation, geographical distribution, and tissue kinetics. The focal species in the IWC program are bottlenose dolphin and harbor porpoise, because both species occur in waters extending over a gradient of pollution and are likely to provide reasonable sample sizes.

Because the ultimate aim of the program is to look at potential effects of pollutants at the population level, it was considered necessary to test and develop techniques to feasibly collect data from large numbers of free living animals. Since biopsy techniques allow such type of sampling, an initial step in the project has been to calibrate information obtained from biopsy sampling with that collected from dead animals. It was also considered similarly important to ascertain the influence of postmortem time on levels of contaminants and on indicators of exposure and effect. This calibration is needed to ensure that collected samples are representative of actual pollutant loads.

Phase I of this program is just finalized and a number of significant results were obtained (Reijnders *et al.*, 2007). These results provide a valuable scientific framework for this type of ecotoxicological studies. Worth mentioning publications include a study on pollutant effects at the population level showing that PCB accumulation in Sarasota bottlenose dolphins might be depressing the potential annual growth rate by some 3.6% (Hall *et al.*, 2005), studies in bottlenose dolphins on the effect of OCs and individual biological traits on blubber retinoids, a biomarker of OCs exposure (Tornero *et al.*, 2006b), research on dermal endothelial Cytochrome P450 1A1 expression in biopsies from the same bottlenose dolphin population related to blubber Σ PCB concentration (Wilson *et al.*, 2007), and a study on the postmortem stability of retinol, PCBs, and dioxin-like compounds in by-caught harbor porpoises (Tornero *et al.*, 2005b; Borrell *et al.*, 2007). It is clear that Pollution 2000+ is a core-program to address some fundamental questions. It does not imply that other research on pollutants and marine

mammals is less important. On the contrary, its value is enhanced by cooperation with existing studies and as a context for the development of new programs.

Popular Culture and Literature

PAUL H. FORESTELL

I. Introduction

A review of current human behavior and popular media highlights a contradiction in modern cultural perceptions of marine mammals. On the one hand, it would seem by almost any indicator that human interest in marine mammals is at a fever pitch (Fig. 1). Excursions to view marine mammals in the wild draw countless participants from many cultures and age groups (Hoyt, 2001). Attendance at marine parks and display facilities is at an all time high. The past two decades has seen an explosion in books and videos about marine mammals. The sale of marine mammal “themed” merchandise includes thousands of products worldwide. Campaigns to protect marine mammals and their habitat exist on every continent, and the number of local and national governments involved in legislative

Figure 1 Human interest in marine mammals: Part of the solution or part of the problem? Photo courtesy of Paul Forestell.

agendas related to marine mammals is growing (Carlson, 2004). In the past 20 years, there has been a strong increase in the number of marine mammal research projects, many involving direct public participation, and the population of marine mammal researchers is growing steadily.

On the other hand, there are at least five species of marine mammal [Chinese river dolphin, or Baiji (*Lipotes vexillifer*), Gulf of California harbor porpoise (*Phocoena sinus*), North Atlantic right whale (*Eubalaena glacialis*), North Pacific right whale (*E. japonica*), and Mediterranean monk seal (*Monachus monachus*)] in danger of becoming extinct because of human activities. Indeed, the Baiji has been deemed to be extinct as of this writing. Attempts to interact with dolphins in the wild may disturb the dolphins and endanger humans (Marsh *et al.*, 2003). Efforts to eliminate the killing of marine mammal fisheries-related by catch are not succeeding. Sealing continues, and efforts to cull seal populations to protect fisheries are on the rise. Commercial whaling (under the guise of “scientific” whaling”) has increased dramatically over the past two decades. The oceans are being poisoned: 3 million pounds of trash were cleaned from beaches in the United States in 1999, and that amount must be assumed to represent only a fraction of material floating in the world’s oceans.

Lavigne *et al.* (1999) studied North American attitudes toward marine mammals since the early 1960s by reviewing patterns of consumptive exploitation, tourism, media attention, legislation, non-governmental organization initiatives, and scientific research. They summarized their findings by noting that “With few exceptions... North American attitudes toward marine mammals have shifted from a focus on their killing and material utilization to a more aesthetic interest in observing these creatures in the wild, in captivity, and in various media forms” (Lavigne *et al.*, 1999). The most notable exception to the shift in focus is a general willingness to grant special status to aboriginal groups to hunt marine mammals. The authors further concluded that the change in attitudes has resulted primarily from a rapid urbanization of the human population, increased knowledge of marine mammals through new research and extensive media exposure, and a shift in ethical values.

It seems unarguable that North American attitudes (and those of many nations referred to as “industrialized”) have changed from a focus on killing. However, a qualitative analysis of available behavioral evidence (i.e., what people actually do, rather than what they express as a value or attitude in surveys) suggests that humans everywhere still basically regard marine mammals as a commodity. A consideration of how marine mammals are represented in current literature and the popular media; the types of marine mammal issues that win public attention; the types of activities that humans engage in around marine mammals; and the role that government plays in managing such activities, suggest that rather than a shift from material utilization to aesthetic interest, the shift has simply been from one sort of utilization (or exploitation) to another. In brief, while the general trend has been to an increasing effort to protect and conserve, the motivational basis for the change remains highly anthropocentric.

II. Background: Shaping Cultural Perceptions Prior to the 1950s

The recorded history of human interaction with marine mammals began with small-scale direct exploitation in pursuit of vital resources. From opportunistic scavenging of stranded animals to organized hunting of locally available species, subsistence efforts were focused on obtaining food and by-products needed by the hunters themselves for survival. Subsistence hunting has extended, relatively unchanged, over a considerable period of time in human history. Norwegian petroglyphs (rock drawings) believed to be nearly 4000 years old, show men in boats along with seals, dolphins, and whales. Handheld harpoons, nets, and stranding drives have been employed by indigenous hunters in many parts of the world, including Japan, North America, the South Pacific, and Europe, even into modern times (Fig. 2).

Subsistence hunting of marine mammals until the twelfth century primarily involved hunting for the immediate needs of the community; for food, clothing, and other products of domestic utility. In almost all cases, the traditions of subsistence hunters incorporate

Figure 2 Subsistence hunting was conducted for centuries with essentially unchanged techniques. Photo courtesy of the estate of Bill Daubin.

myths, chants, and rituals honoring the quarry and the skills needed to overcome it. This is an important consideration in understanding current cultural perspectives on marine mammals: a representation of the development of current attitudes as a linear evolution from utilitarian to aesthetic (as presented by Lavigne *et al.*, 1999) is incomplete on two counts. Ancient subsistence attitudes were far more complex than the utilitarian characterization would imply, and current perspectives are far less aesthetic than use of that term would prescribe. In fact, current perspectives on marine mammals probably represent a relatively recent reoccurrence of the same devolution of attitudes from holistic to exploitative that occurred during the transition from subsistence whaling, to commercial whaling, to industrialized whaling. In the present day there has been a parallel transition from “subsistence whale watching,” to “commercial whale watching,” to “industrialized whale watching” (Forestell and Kaufman, 1996).

The Basques of Spain apparently developed and implemented the first truly “commercial” hunt during the 11th and 12th centuries, initiating a fundamental change in attitude that would sow the seeds of “industrialized” whaling some 600 years later. The Basques probably learned whaling techniques from the Normans, Norwegian settlers who populated the Bay of Biscay during the ninth century. The Basques, tenacious settlers on a critical trade route to the Iberian Peninsula (and onward to Africa), were not subsistence whalers. Originally pastoralists who tended flocks in the mountains, they eventually founded the kingdom of Navarre, which included a number of tiny fishing villages along the Biscayan coast. There they found the North Atlantic right whale, which migrated into the Bay of Biscay each year from autumn through spring. Poised between a vast, untapped resource on the ocean side and a steady flow of traders to the world’s centers of commerce on the other, they found a ready market for almost the entire carcass of the whales they brought ashore: oil for lamps and lubricants; baleen for corsets, buggy whips, fishing poles, and brushes; bones for fence posts and portals; skin for footwear; and meat, blubber, and tongue for food. For 300 years Basque whalers pursued the right whale; first across the Bay of Biscay and then to the far side of the Atlantic. So good were they

Figure 3 By the middle of the twentieth century whales had become an oddity rather than a direct part of one’s survival. Drawing ©Larry Foster, used by permission.

at their craft that, as the need for whale oil grew in Europe, they became teachers of those who would take commercial whaling to the furthest reaches of the world’s oceans.

Preindustrial commercial whaling involved the application of subsistence techniques for the realization of profit rather than direct consumables. As the theater of endeavor moved from the Biscayan coast to North America, Spitsbergen, and the open seas of the Atlantic and Pacific, the method of catching and killing whales changed little, although the processing of whales was carried out variously either onshore or onboard the whaling ship itself. Without benefit of modern machinery, commercial whalers using sailing ships, whale boats, and handheld harpoons successfully pursued right whales, bowhead whales (*Balaena mysticetus*), and gray whales (*Eschrichtius robustus*) to near extinction, and decimated known sperm whale (*Physeter macrocephalus*) populations. A similar fate was visited upon elephant seals (*Mirounga spp.*), walrus (*Odobenus rosmarus*), and sea otters (*Enhydra lutris*), while the Steller sea cow (*Hydrodamalis gigas*) was completely extirpated.

An important change that accompanied commercial hunting was that animals were hunted and killed by humans who were not otherwise connected to the ecosystem or the animals targeted by the enterprise. Strangers came from faraway places for the sole purpose of obtaining as much of the resource as could be most quickly taken away for sale in distant markets. By the middle of the nineteenth century, the cost of whale oil climbed as stocks of whales declined. Alternative products derived from turpentine, cottonseed, and linseed replaced whale oil in a number of uses. And then distillation of petroleum hastened the decline of commercial whaling as practiced by the sailing ships of the American whaling fleets by the end of the nineteenth century.

Industrialized whaling began in 1863 when Svend Føyn, a Norwegian sealer, made his first successful kill of a blue whale (*Balaenoptera musculus*) using a cannon mounted on the bow of a 90-foot steamship. The cannon fired a 100-lb. harpoon fitted with an exploding tip. The combination of cannon, exploding harpoon, and steamship meant that large fast whales could be dispatched with relative speed and efficiency. Readily accessible populations of blue, fin (*B. physalus*), and humpback whales (*Megaptera novaeangliae*), unprofitable targets for sailing ships, gave new life to commercial whaling. For 40 years Norwegian-style whaling spread around the

Figure 4 By the 1950s commercial whaling was a highly sophisticated and industrialized operation. Photo courtesy of The New Bedford Whaling Museum.

world. At the turn of the twentieth century, processes were developed to rid whale oil of its inherently strong taste and odor, and convert it into solid fat. Whale oil once again became a commodity of worldwide importance, particularly for making margarine and soap.

Rapid developments in technology soon made it possible to hunt and kill whales more efficiently and in greater numbers. The hand-held harpoon was replaced with Svend Føyn's cannon, and try-pots gave way to huge pressure cookers. Gigantic hydraulic tail-grabbers dragged entire blue whales out of the ocean, through stern slipways, and onto the flensing decks of pelagic factory ships. Spotter planes, catcher boats, and factory ships coordinated their efforts by radio to increase the extent and efficiency of the catch (Fig. 3). In 1950, a 65-foot whale weighing 80 tons could be hauled up the slipway and turned into oil, frozen meat, and ground-up fertilizer in just over 1 h. Nearly every major nation of the world participated in the decimation of whale stocks—some 30,000–50,000 whales per year were taken in the Antarctic alone between 1930 and 1960.

By the 1950s it could well be said that the human attitude toward marine mammals had become a strictly utilitarian one (Fig. 4). The industrialization of slaughter occurred on a grand scale with regard to whales. At the same time, commercial hunting of elephant seals for oil and sea otters, fur seals, and harp seals (*Pagophilus groenlandicus*) for their coats, had disastrous results on pinniped populations throughout the world and sea otter populations throughout their range. The hunt for sirenians never progressed to anything near an industrialized effort. A combination of subsistence and small-scale commercial hunting has generally been sufficient to reduce known populations to extinction (in the case of Steller's sea cow) or near extinction [in the case of manatees (*Trichechus* spp.) and dugongs

(*Dugong dugon*)]. Hunting of small cetaceans throughout the world has also been marked by the shortsighted exploitation of pilot whales (*Globicephala* spp.), killer whales (*Orcinus orca*), bottlenose whales (*Hyperoodon* spp.), spinner dolphins (*Stenella longirostris*), spotted dolphins [pantropical (*S. attenuata*) and Atlantic (*S. frontalis*)], and common dolphins (*Delphinus* spp.).

What is unique to the history of human interaction with dolphins, compared with our exploitation of other marine mammals, is the massive destruction of pelagic species associated with modern drift-nets and purse seining. Industrialized fishing techniques have killed more dolphins in the last 50 years than were killed in the entire prior history of humankind. The late David Gaskin (1982) succinctly described the attitude underlying the industrialization of whaling and fishing as an ethical failure:

We could have conserved many other resources than just the stocks of large baleen whales, if the dead-end philosophy of the economic industrial growth ethic could be circumvented, and if the aces in the deck of cards with which we play were not invariably short-term economic gain and political expediency. (p. 387)

Little information about marine mammals was available to the public prior to the early nineteenth century. Dewhurst (1834) provides a fairly comprehensive review of scientific information on cetaceans up to that point. He cites 28 writers, beginning with Aristotle (third century BC) and Pliny (first century AD), and gives special praise to the work of Rondèlet (fifteenth century), Sibbald (seventeenth century), La Cépède, and Scoresby (both nineteenth century). A more complete review can be found in Matthews (1978),

who incidentally refers to Dewhurst as "...a self-advertising medical quack" (p. 18). Virtually none of the material described by either Dewhurst or Matthews was readily available for public consumption. In 1821 Sir Walter Scott's three volume novel "The Pirate" initiated popular fictional accounts of marine-mammal related literature—followed by James Fenimore Cooper's story "The Pilot" in 1823 and Melville's "Moby Dick" in 1851. The ensuing popular literature of the nineteenth and early twentieth centuries was more about whalers and whaling than it was about whales. Between 1800 and 1950 there were close to 100 published texts focusing on marine mammals. With limited exceptions, they all dealt with popularized accounts of whaling.

III. The 1950s: Out with the Old

Beginning in the 1950s, there was growing scientific evidence of the complexity of marine mammal behavior. Stimulated by the work of John Lilly in the United States, researchers in other American laboratories, Europe, and Japan conducted neuroanatomical and electrophysiological studies of cetacean brains. This work identified a number of unique characteristics in cortical architecture, structural morphology, degree of lateralization, and brain wave patterns. Philosopher, anthropologist, and ecologist Gregory Bateson explored the intricacies of dolphin social behavior by studying a group of spinner and pantropical spotted dolphins at Sea Life Park in Hawaii. William Schevill and colleagues (including his wife Barbara Lawrence) began collecting acoustic recordings that would eventually document the underwater sounds of nearly three dozen species of marine mammals, including odontocetes, mysticetes, and pinnipeds. David and Melba Caldwell explored the acoustic and social behaviors of whales and dolphins in captivity and the wild.

These researchers heralded an important shift in scientific focus that accompanied the end of the grand age of whaling during the 1950s and the beginnings of "modern" marine mammal studies in the 1960s. Earlier studies of marine mammals had been carried out, for the most part, on the flensing decks of whaling ships, on the slipways of coastal whaling stations, or on the rocky shores of pinniped haul-out and rookery sites. Information gleaned from such studies was applied to quantitative determinations of the size of harvestable stocks and the development of new commercial applications for whale products. Robertson's (1954) account of life aboard an Antarctic factory whaling ship describes such an approach. In one chapter, the author notes some of the questions entertained by the chemist/biologist on board the ship:

Why has no female sperm whale ever been sighted or killed in the Southern Ocean, though many thousands of old males are killed there every year... At what rate would whale tendon from the flukes be absorbed by the human body if it were put on the market in huge quantities of twenty-foot strands to replace the rare and expensive kangaroo tendon presently used as surgical sutures to repair hernias... What is the nutritive value of a properly cooked fin whale steak... How could one make the whale—as it should be—the world's main supply of the valuable new pituitary and adrenal hormones? (pp. 240–241)

Interest in the management of a commercial harvest prompted a group of American biologists to investigate the life history of gray whales by studying dead ones during the 1960s. From 1959 to 1969, special permits were issued to the Del Monte and Golden Gate Fishing Companies in Richmond, California, by the federally run Marine Mammal Biological Laboratory in Seattle, Washington. The

permits allowed the collection of 316 gray whales as they traveled along the west coast of the United States during their annual north-south migration between Mexico and the Bering, Chuckchi, and western Beaufort seas. The description of the whales' life history was based on shipboard and aerial observations of their migration numbers and timing, and documentation of a series of body measurements from the 316 whale carcasses. Data included overall length and weight; width of fluke and length of flippers; thickness of blubber; number and size of baleen plates; degree of vertebral fusion; condition of mammary glands, size of ovaries, and diameter of uterine horns in females; length of penis and weight of testes in males; number of wax ear plug growth layers; number and type of external body scars; number and type of endo- and ectoparasites; and stomach contents. Data were used to determine numbers and migratory patterns of different age/sex classes; prey species; reproductive patterns; and susceptibility to parasites and predators (other than humans). Rice and Wolman (1971) reported the results of the study. The expressed purpose of the work was to provide sound biological knowledge to ensure a wise management program if commercial exploitation, ended by international agreement in 1946, should resume.

Compare the questions of Robertson's chemist/biologist and the Marine Mammal Biological Laboratory's biologists with those posed by the legendary Kenneth Norris (Fig. 5), who began studying wild dolphins in California and Hawaii during the 1960s. In "The Porpoise Watcher" (1974), Norris describes his early musings about the intricacies of social organization in Hawaiian spinner dolphins:

... most of the subgroups we see in active schools have no clear function. Are they family groups, play groups, are they divided by sex or age... What is it that regulates porpoise school numbers? Why don't their schools grow and grow until every scrap of natural resource is used, as humans are busy doing? What racial wisdom, somehow lost by humans as they adopted civilization, keeps them in balance? (pp. 199–200)

Figure 5 Biologist Ken Norris was a pioneer in the study of marine mammals and their behavior in the wild. Photo courtesy of Bernd Würsig.

Norris' approach to the study of live animals represented a significant change in marine mammal science and ultimately helped reshape public perception of marine mammals in many parts of the world.

IV. The 1960s and 1970s: In with the New

It would be simplistic to point to one central mechanism behind the groundswell of interest in marine mammals (more specifically, cetaceans) that occurred during the second half of the twentieth century. The exotic undersea portraits and exciting escapades of Jacques Cousteau; the new age writings of John Lilly; the increasing exposure to whales and dolphins in zoos, parks, and oceanaria; the growing awareness of conservation issues due to books by (among others) Aldo Leopold (1949), Rachel Carson (1962), and Victor B. Scheffer (1969); and the “protest” mind-set of the 1960s and 1970s all played pivotal roles. The combined effect of these influences was to generate an entirely new look at marine mammals. Four predominant themes emerged quickly and simultaneously throughout North America, the United Kingdom, Europe, and Australia/New Zealand during the 1960s and 1970s: dolphins (and whales) exemplify cognitive capabilities rivaling human capacity; the opportunity to watch dolphins and whales is exciting and entertaining; the worldwide slaughter of whales is unethical and biologically disastrous; and marine mammals demonstrate a number of adaptations to the marine environment that may have important applications to human technology. These have remained the four corners of the box in which humans continue to contain marine mammals: intelligent, entertaining, endangered, and valuable to humans.

The widespread perception of cetaceans as highly intelligent animals was largely due to the writings of Lilly (Fig. 6), beginning with his book “Man and Dolphin” (Doubleday, 1961). Lilly was not the first scientist to note the possibility of complex cognitive capability in cetaceans—Arthur McBride, the first curator of Marine Studios, and Canadian psychologist Donald Hebb published detailed observations of bottlenose dolphin social behavior that served as a landmark reference for more than 20 years (McBride and Hebb, 1948). Lilly used his position as an acclaimed neurophysiologist with the National Institutes of Health to foster an enduring and widespread public perception of whales and dolphins as near-mythical species

Figure 6 Dr. John Lilly, neuro-physiologist (shown here with the author in 1994) had a profound influence on public perception of whales and dolphins. Photo courtesy of Paul Forestell.

with mental capacities rivaling or surpassing those of *Homo sapiens*. His succession of books for the popular press generated a hostile reaction from the scientific community, which disputed the validity of his claims. Overall, however, his characterization of cetaceans as socially and cognitively complex animals with rich emotional lives guided by a code of ethics resonated with the public. Paraphrasing one of his lectures, Lilly (1967) wrote:

I wish to tell you something of what we have learned of a group of uninhibited nudists who have never worn clothes. They have never walked on their own two feet. They have no property. They cannot write their own names. They have no commerce or stores. They have no radio, no TV. They have no fireplaces, nor furnaces, or any fire at all. They have no atomic or nuclear bombs, or power plants. They have no written or printed records. They have no libraries or paintings. In spite of all these handicaps, they are successful. They have big brains and have readily available food supplies. They have the sense to go south in the winter and to go north in summer. They have the ability to out-think, outmaneuver and fight successfully against their enemies. Finally, they think enough of us to save each of us when they find us in trouble. (p. 291)

Sexually liberated, antimaterialistic, antiwar, self-sufficient, intelligent, and altruistic. What suite of characteristics could have more poignantly caught the attention of an up-and-coming generation of “baby boomers” protesting post-World War II materialism, the Vietnam War, restrictive social mores, and cutthroat international capitalism? Lilly’s message is clear: cetaceans live a life of sun, surf, and sex—with big brains, and no guilt. Could it get any better?

Lilly’s writings and public lectures generated a backdrop against which a new-age philosophy of dolphin as genius, healer, therapist, and spiritual advisor flourished. Although Lilly’s interpretations of his findings were frequently based upon gratuitous explanations, he was instrumental in a number of critical discoveries concerning the peculiarities of dolphin acoustic behavior.

One can hardly discuss the work of the new brand of marine mammal scientist that emerged in the 1960s without noting the importance of marine mammal display facilities, beginning with Marine Studios (later called Marineland, Florida). Records of marine mammals in captivity for public amusement date back to ancient times. By far, pinnipeds comprise the majority of display animals. They are relatively easy to take from the wild, adapt well to captivity, and in many cases are trained easily to amuse human spectators. Cetaceans require a degree of knowledge, resources, and commitments that few display facilities are able to meet. Limited, unsuccessful attempts to maintain marine mammals in captivity occurred in the 1800s. However, beginning in 1938, Marine Studios was the first facility to successfully maintain bottlenose dolphins (*Tursiops truncatus*) in captivity for an extended period, in its role as an “oceanarium” rather than aquarium or zoo. Once Marine Studios established that dolphins could be placed successfully on display, the postwar climate fostered the rapid growth of similar facilities, first in the United States and then throughout the world.

From the beginning, those responsible for cetaceans at oceanaria encouraged outside scientists to explore the biology and behavior of the animals at their facilities. Arthur McBride, and later Forrest Wood at Marine Studios; Kenneth Norris, the first curator at Marineland of the Pacific (the west coast “sister” institution of Marine Studios); his graduate students William Evans at Hubbs-Sea World Research Institute and John Prescott at the New England Aquarium; Tap and Karen Pryor at Sea Life Park in Hawaii; and Murray Newman at the Vancouver Public Aquarium all opened their

doors to biologists, neuroscientists, anthropologists, physiologists, psychologists, acoustical engineers, and an ever-widening range of other professionals with an interest in studying live animals. At a time when television and Jacques Cousteau were flooding into American homes, the collaboration between science and the entertainment industry had a tremendous impact on the public perception of marine mammals. Scientists were not used to dealing directly with the public, but those who ran the oceanaria were. As scientists began to discover more and more about the hidden world of whales and dolphins, the oceanaria incorporated much of that knowledge in decisions about what animals to capture, improvements to husbandry programs, and, most importantly, in the subject matter of their shows.

One indication of the “coming of age” of dolphins as a significant cultural phenomenon in the United States was the 1960s production of two movies and a television series based on the adventures of “Flipper,” a bottlenose dolphin, and Sandy Ricks, the young son of a fisherman (later changed to a park ranger). The original movie, released in 1963, hinted of the ancient stories of the relationship between a boy and a dolphin, such as described in Iassos, Greece, and the Roman town of Hippo in Africa. In the movie, a dolphin met a young boy and they developed a friendship that led to a bonding that surpassed species distinctions and spawned a sequel. The mythical proportions of the story did not survive long, however, and the subsequent television series seemed to quickly develop into a marine version of “Lassie, Come Home.”

While the 1960s initiated a true Renaissance in the portrayal of marine mammals, oceanaria helped emphasize a conceptual “divide” that continues to the present. With limited exceptions, modern public attitudes about marine mammals are strongly predisposed toward whales and dolphins. In reviewing the status of marine mammals in popular literature and culture, it is important to bear the following caveat in mind. The typical representation of “marine mammal” does not reflect the diversity and extent of actual species. Marine mammals include over 120 species, divided into four general categories [whales, dolphins, and porpoises; seals, sea lions, and walrus; manatees and dugongs; sea otters and polar bears (*Ursus maritimus*)]. However, the preponderance of available information on nature excursions, visits to display facilities, and the sales of books, videos, and other merchandise suggest that the prototypical representative of the category “marine mammal” is one of a small set of relatively well-known cetacean species (e.g., bottlenose dolphin, killer whale, humpback whale, sperm whale).

Although occasional interest in other marine mammals has developed with respect to specific issues [e.g., the killing of neonatal harp seals for their white fur coats in Canada; the decimation of Caribbean manatee (*Trichechus manatus latirostris*) populations from boat collisions in Florida; competition between sea otters and abalone (*Haliotis* spp.) fishermen in California], it remains clear that cetaceans have drawn public attention in a way that far outdistances the attention generally paid to pinnipeds, sirenians, sea otters, or polar bears. This difference is despite the fact that about two-thirds of the marine mammals held in captivity since 1973 in North America are either California sea lions (*Zalophus californianus*) or harbor seals (*Phoca vitulina*). The most commonly displayed cetacean is the ubiquitous bottlenose dolphin (Fig. 7), which generally makes up about 20% of the total number of animals on display. Killer whales, although small in number, have generated a huge marketing success for their keepers. Much of the attraction of cetaceans appears to be related to a fascination with the size, beauty, strength, and perceived intelligence of these two most frequently seen examples. While sea lions balance balls on the end of their nose and make hilarious barking sounds on

Figure 7 The bottlenose dolphin (*Tursiops truncatus*) is the prototypical marine mammal for most humans. Photo courtesy Pacific Whale Foundation/Paul Forestell.

cue in oceanaria and marine parks, captive whales and dolphins cooperate in the development of spectacular water shows that train audiences to see them as powerful, beautiful, fun-loving, and intelligent.

An important influence in the perception of marine mammals by the public during the 1970s was a rapid growth in underwater images of whales and dolphins. Although television had introduced the world to the accomplishments of Jacques Cousteau and the crew of the *Calypso*, their exploits seemed far out of reach for the average individual. Cousteau’s books and television programs emphasized the dramatic nature of exploring beneath the surface of the ocean in remote and dangerous settings. Using SCUBA, sophisticated oceanographic equipment, and sheer nerve, Cousteau and his men peeled back the layers of the ocean in a fashion few members of the public thought possible. Until the late 1970s, a sense of the mystique of marine mammals was based on the accounts of explorers, whalers, sealers, and fishers. As late as 1975, an article in Audubon magazine on marine mammals had no photographs, but was illustrated with artwork. National Geographic magazine featured articles on killer whales in 1966, gray whales in 1971, and right whales in 1972 and 1974. The photographs and accompanying stories leave one with the clear impression that such experiences were the prerogative of a highly specialized breed of underwater adventurer/pioneer photographers such as Howard Hall, William Curtsinger, Charles (Chuck) Nicklin, Jen and Des Bartlett, Stan Waterman, and Al Giddings—generally working in the company of field scientists in exotic places.

Then the situation changed, and James Hudnall, a freelance photographer and self-styled whale researcher, helped lead the way. In a 1977 Audubon article, Hudnall wrote of venturing into the winter home of the North Pacific humpback whale offshore of Maui, Hawaii, beginning in 1974. Diving from a small inflatable boat, often by himself, with no more equipment than a mask, snorkel (sometimes a SCUBA tank), fins, and underwater camera, Hudnall revealed the first protracted look at living whales. He described the huge animals as “gentle, clever, passive, and rational beings,” and he provided spectacular images to prove it (Hudnall, 1977). By the end of the 1970s the public was sensitized to a perception of marine mammals, especially the great whales, as objects of wonder and mystery; to be held in awe rather than fear; and to be protected rather than hunted. A popular video for National Geographic in 1978 (“The Great Whales”; written, produced, and directed by Nicholas Noxon) represented the changing

view rather well. Included in the video was actual footage of modern whaling operations—and it was poignantly contrasted with footage of killer, blue, humpback, and gray whales that mirrored the message in Hudnall's article for Audubon magazine.

Just as Hudnall's photographs softened the public's perception of whales, additional discoveries about the sounds that whales make reinforced the idea that whales and dolphins engage in complex communication behaviors. Sounds made by humpback whales had been documented as early as 1952 by US Navy personnel using deepwater eavesdropping systems developed to detect submarines. In 1971 Roger Payne and Scott McVay reported the first detailed characterization of the sounds in the journal *Science*. Because of their complex structure and orderly sequence, Payne and McVay (1971) referred to the acoustic displays as songs. Subsequently Payne, his wife Katy, and a number of their students showed that the songs, produced only by males during the breeding season, changed slowly over successive years. In any given season, however, all males within a breeding group appeared to sing the same song. It was shown ultimately that song characteristics could be used to identify separate stocks of whales. The impact of the song on the public was dramatic. Musicians like Paul Winter incorporated the sounds into their recordings. Payne, a creative and charismatic individual, even managed (with Carl Sagan's help) to get a recording of humpback song included in the materials placed aboard the Voyager I spacecraft to provide potential "other intelligences" in the galaxy with artifacts of earth. In January of 1979 a plastic 45-rpm recording of humpback whale song was included as an insert accompanying an article in *National Geographic* on Payne's work. The hauntingly beautiful sounds of the humpback whale constituted one more piece of evidence that marine mammals demonstrate a high level of cognitive capability.

Lavigne *et al.* (1999) noted that during the 1970s the rate of marine mammal scientific publications increased from fewer than 10 titles per year to more than 20. As suggested earlier, there was also change in the nature of books published. Mowat's "A Whale for the Killing" (Atlantic Monthly Press, 1972) emphasized the clash between old values and new sensitivities in his fictionalized account of a true incident in Newfoundland, in which locals used a stranded fin whale for target practice. The growing perception that cetaceans are uniquely worthy of our attention because of their intelligence is evident in "Mind in the Waters," edited by McIntyre (Scribners, 1974). The book is an attractive compendium of art, editorial, history, science, and philosophy regarding human association with marine mammals. Scientist Ken Norris (1974) wrote eloquently about the day-to-day lives of dolphins and whales. One of the first "inside" views of a display facility occurred in "Lads Before the Wind" (Harper and Row, 1975) by Karen Pryor, head trainer and cofounder of Sea Life Park in Hawaii. Other books for the popular press included resource texts such as Mathews' "The Natural History of the Whale" (Columbia University Press, 1978) and the fictionalized natural history account of "The Last Blue Whale" (Harper and Row, 1979) by Smith. Fictional writings with marine mammals as central characters were few and largely forgettable.

Television productions featuring marine mammals were few in number, and the most notable movie representation was "The Day of the Dolphin," starring George C. Scott and directed by Mike Nichols (Avco Embassy Pictures, 1973). This box office hit helped solidify public attitudes about the intelligence of dolphins and raised questions about the training of dolphins by the military for a variety of warfare applications.

One of the effects of the exposure to whales and dolphins in oceanaria and in limited television coverage during the 1970s was the realization among the public that at least some species of marine

Figure 8 *The Save-the-Whales movement was a mediagenic and culturally diverse phenomenon of the 1980s. Photo courtesy of John Perry.*

mammals were very accessible in the wild. Whale watching became a rapidly growing industry. Whale watching first began in California and Mexico in 1955 (gray whales). In the 1970s it developed off the New England coast [humpback, fin, minke (*B. acutorostrata*), and right whales] and in Hawaii (humpback whales). It soon spread to other areas in North America [e.g., killer whale and gray whale watching in the Pacific Northwest; humpbacks in Alaska; blue whales and beluga whales (*Delphinapterus leucas*) in the St. Lawrence River, Canada].

The increased display of marine mammals in oceanaria and the growing opportunity to view them in their own world accelerated the idea that industrialized whaling had become a desecration of nature. The insistence of some nations on continuing to hunt in the face of collapsing populations of whales was viewed by many as an outrage, and efforts to thwart commercial whaling grew increasingly strident. A broad, international coalition of objectors joined forces in launching what later was termed "The Whale War" (Day, 1987). The war was fought on many fronts, and the participants acted more often in independent assaults, but the overall effect was to galvanize the public into a growing chant of "save the whales" (Fig. 8).

The "save the whales" movement was one of the most mediagenic and culturally diverse platforms for environmental activism during the twentieth century. Confrontation between catcher boats and rubber inflatables on the high seas provided a dramatic backdrop to land-based efforts to convince whaling nations to cease the hunt. Saving whales constituted a natural complement to the changing perception of marine mammals generated by oceanaria, whale watching excursions, and media attention.

It was also during the 1970s that the United States incorporated changing public opinion in revised federal legislation. Both the Marine Mammal Protection Act of 1972 and the Endangered Species Act of 1973 became international models of marine mammal protection by

Figure 9 Whale watching grew into a worldwide industry worth hundreds of millions of dollars a year during the 1980s and 1990s. Photo courtesy of Pacific Whale Foundation/Greg Kaufman.

affording broad powers to federal agencies to prevent not only the killing of marine mammals, but even their disturbance or harassment. These acts were broadly developed to ensure protection of species considered to be of special interest to the public, in part through ecosystem protection, but in general as single species efforts. Both acts provided wide latitude for research and international cooperation in fulfilling conservation agendas. Although revised many times since the original enactment, both these legislative initiatives have received considerable attention around the world as mechanisms for increasing marine mammal protection.

V. The 1980s and 1990s: Loving Marine Mammals Becomes an Industry

The most significant demonstration of the cultural importance of marine mammals in modern times is the explosion of interest in excursions to view marine mammals in the wild that has taken place over the past three decades (Fig. 9). The growth of the whale and dolphin watching industry has been detailed in a number of places, but the sheer speed and dimension of the changes that took place during the 1980s and 1990s warrant mention here. A detailed report on worldwide trends in whale watching by Erich Hoyt (2001) documents the dramatic growth of whale and dolphin watching from the 1950s. The numbers of people, venues, operators, and targeted species increased exponentially. The number of countries with marine mammal excursions has tripled since 1990 alone, while the number of passengers has more than doubled to some 10 million people each year. Direct revenues from marine mammal watching excursions now exceed 1 billion US dollars a year. If one considers the “multiplier” effect of the other expenditures associated with whale watching (travel, accommodations, food, and souvenirs), the economic impact must be seen as quite substantial.

The media focus on whale and dolphin research, the “taming” of cetaceans at oceanaria, and public access to marine mammals through commercial whale watching trips during the 1980s were accompanied by a unique phenomenon: the use of laypeople as marine mammal research assistants in return for financial support of the research project. One of the first instances of such a program took place aboard the R/V *Regina Maris*, a three-masted schooner that operated out of Gloucester, Massachusetts, under the direction

of Dr. George Nichols and the nonprofit Ocean Research Expedition Society. This was soon followed by the Center for Field Research in Massachusetts (Earthwatch); the School for Field Studies, also in Massachusetts; the Pacific Whale Foundation in Hawaii; Oceanic Society Expeditions in California; and ultimately a host of organizations throughout the world. Such efforts allowed members of the general public, without experience in conducting whale or dolphin research, the opportunity to participate in field studies of marine mammals. The benefit to the researchers was the financial support of their field work provided by the participants.

Throughout the 1980s, the “discovery” of marine mammals as objects of wonder allowed those with artistic and entrepreneurial abilities the opportunity to develop a wide variety of commercial ventures. Availability of marine mammal books, magazine articles, visual art works, decorated clothing, jewelry, videos, souvenirs and trinkets, marine expeditions, and captive displays increased dramatically. Artistic visual representations of marine mammals benefited enormously from the artists’ exposure to live animals (or, perhaps, photographs of live animals). At least two major styles of visual art emerged during the 1980s: one incorporated attention to detail based on biological and morphological data and the second attempted to represent the artist’s interpretation of the animal in its world. Prominent examples of attention to detail include the paintings of Larry Foster (Fig. 4), Pieter Folkens, Janet Biondi (all of California), and Richard Ellis (New York). Realism also characterized the work of sculptors John Perry, Randy Puckett, and Steve Aikenhead. More fanciful interpretations of the whale in its world were represented prominently in the works of Robert Lyn Nelson (Fig. 10), Wyland, and Christian Riese Lassen, who reached their pinnacle of commercial success from the island of Maui in Hawaii during the 1990s.

The marketing of marine mammal images grew through the 1980s and 1990s into a multimillion dollar enterprise, driven largely by art galleries catering to wealthy tourists in places like Lahaina Hawaii, Monterey, California, and Provincetown, Massachusetts. New techniques were developed to produce prints, posters, lithographs, and other facsimiles of original works that made art available to everyone. Additional products include T-shirts, coffee mugs, note cards, coffee table books, shopping bags, and stickers. Media attention to public relations extravaganzas such as the air brushing of “Whaling Walls” by Wyland in high-visibility settings in major cities throughout the world helped generate a public perception of marine mammals as beautiful, powerful, friendly, and intelligent. Jewelry, sculptures, and a wide variety of trinkets and other memorabilia were produced in mass quantities for the increasing population of whale watchers and marine mammal lovers with money to spend. A major outlet for such products became the retail centers associated with display facilities. Virtually every aquarium or oceanarium in the world has a retail center strategically located so visitors must move past or through it on the way to the exit. Artifacts related to marine mammals constitute a huge source of related income.

As the market for watching marine mammals in the wild and the purchase of memorabilia grew, the increase in publication of books and videos continued. It is possible to identify three major trends in modern published materials for adult readers: new-age, science fiction, and naturalist accounts. The dolphin as a mystic, healer, ancient communicator shows up in books by Horace Dobbs (British), Patricia St. John (American), Olivia de Bergerac (French), Frank Robinson (New Zealand), and a host of like-minded writers. The popularity of new-age musings on the significance of marine mammals is based on the use of personal transformation stories that foster an emotional response on the part of the reader. In most cases, the new-age perspective on marine mammals emphasizes what they

Figure 10 Marine artist Robert Lyn Nelson is a preeminent figure in the marine art world. Image ©Robert Lyn Nelson, used by permission.

(most often cetaceans) can do for humans: as teachers, healers, models of a better social order, and indicators of human mistreatment of the oceans.

A second type of modern adult literature provides science-fiction accounts of marine mammals. These works incorporate extensions of scientific studies of communication and other cognitive capabilities of marine mammals into stories based on themes such as military abuse of power, destruction of the environment by corporate greed, mistreatment of marine mammals by egotistical scientists, or cataclysmic events of nature. “Into the Deep” by Grimwood (William Morrow and Co., New York, 1995) weaves a complex plot that has dolphins communicating with humans to warn of impending natural disaster; representatives of each species eventually combine talents to use telepathic communication to prevent massive destruction of both humans and dolphins. “The Secret Oceans” by Ballentine (Bantam Books, New York, 1994) tells of a group of scientists who become captive subjects in a study of humans conducted deep in the ocean by a form of cetacean more intelligent than humans. “Sounding” by Searls (Ballantine Books, New York, 1982) uses two main characters (an aged bull sperm whale and a sonar officer on a Russian submarine) to explore cetacean behavior and the possibilities of interspecies communication.

The third, and largest, category of books includes nonfiction, naturalist accounts of a wide variety of species, including books on all the orders of marine mammals. These books bring together interpretations of scientific findings, stunning art or photography, and personal accounts of fieldwork by accomplished researchers. Two of the earliest are the “Book of Whales” (Alfred A. Knopf, 1980) and “Dolphins and Porpoises” (Alfred A. Knopf, 1982), both by naturalist, painter, and writer Richard Ellis. In “Hawaii’s Hump-back Whales” by Kaufman and Forestell (Island Heritage Press, 1986) the authors describe the biology and behavior of humpback whales, based largely on their observations and field studies in Hawaii and Australia. The writing style is meant to model the authors’ experiences narrating whale watches and provides a lively, but science-based interpretation of the life of one species. A photographic example of equivalent style is the Japanese photographer Mitsugi Iwago’s “Whales” (Chronicle Books, San Francisco, 1994), which documents his year-long journey to observe humpback whales in Hawaii, Alaska, and the Ogasawara Islands of Japan. Attractive, informative, and entertaining treatments of many species of marine mammals are now available. The National Geographic production of “Whales, Dolphins and Porpoises” (National Geographic Society, Washington, DC, 1995) featuring

photographs by Flip Nicklin (son of pioneering underwater photographer Chuck Nicklin) and written by several prominent scientists (Darling *et al.*, 1995) is an unsurpassed synthesis of prominent research findings from around the world. Bruemmer's "Seals in the Wild" (Laurel Glen Publishing, San Diego, 1998) offers an elegant collection of facts and photographs about pinnipeds. Sleeper and Foott team up to present an excellent description of the much overlooked manatee in their book "In the Company of Manatees" (Three Rivers Press, New York, 2000). Ken Norris, Roger Payne, Hal Whitehead, Peter Beamish, Jim Darling, and Carol Howard have written intriguing personal accounts of careers spent investigating marine mammals. A number of field guides for whale watchers in many settings throughout the world are also currently available. These books not only provide a great deal of current information on marine mammals, but serve as important vehicles for conservation efforts.

Certainly not all books published during the 1980s and 1990s can be categorized according to the three styles just described. Two books that deserve mention in this regard are Heathcote Williams' "Whale Nation" (Harmony Books, New York, 1988) and "The Delicate Art of Whale Watching" (Sierra Club Books, San Francisco, 1982) by Joana Varawa (formerly Joan McIntyre). "Whale Nation" is a celebration of the history of whale/human interactions through a book-length poem and a collection of whale-related excerpts from other sources. Following its publication, the author did a world tour of highly acclaimed public readings. Varawa's book is a deceptively small but powerful series of meditations on being in the presence of the sea and its creatures.

More than 300 videos and movies on marine mammals have been produced in the last two decades. Most of these are documentaries, generally based on describing the research of one or a few scientists. In some cases, researchers are simply followed in their work while the significance and findings of their efforts are detailed. In other cases, celebrities such as Robin Williams or Christopher Reeves accompany scientists to get a first-hand look at their work. A number of television programs have dealt with controversial issues such as dolphins in captivity ("A Whale of a Business," PBS Frontline, 1997); scientific whaling ("Whale Fever," BBC News and Current Affairs, 1993); captive-dolphin swim programs ("Dying to Please," Biosphere Films, 1990); and bycatch of dolphins by the tuna fishery ("If Dolphins Could Talk," PBS Video, 1990). The invention of a large-format (70-mm) camera by IMAX in the early 1970s has resulted in three big-screen movies that are based on marine mammals. The first was "Nomads of the Deep," featuring humpback whales, released in 1979 by IMAX. In 1996, Destination Cinema produced "Whales," a popular big-screen documentary covering a variety of whale species. In 2000, McGillivray Freeman Films released "Dolphins," a documentary on dolphin communication and behavior that featured the work of Bernd Würsig's students Kathleen Dudzinski and Alejandro Acevedo-Gutiérrez, as well as established researchers Louis Herman and others. It and the artistic and science teams were nominated for an Academy Award.

There have been a handful of feature movies with marine mammals as central characters. A bottlenose dolphin named Snowflake appeared in the comedy "Ace Ventura, Pet Detective" (starring Jim Carrey, 1994). Humpback whales were brought back to the future in the science fiction adventure "Star Trek IV: The Voyage Home" (William Shatner and Leonard Nimoy, 1987). A dog and a dolphin learned to communicate with each other and sparked a romance between the dog's owner and the scientist studying the dolphin in "Zeus and Roxanne" (Steven Guttenberg and Kathleen Quinlan, 1997). "The Secret of Roan Inish" (Jeni Courtney, 1994) was based on a Celtic myth about selkies (seals) and a young girl's search for

her lost brother. None of these movies achieved much success on the basis of their representation of marine mammals, however. In 1993 the movie "Free Willy" became a worldwide sensation and was ultimately followed by two sequels. The series chronicled a friendship between a 12-year-old boy (Jesse) and an adult male killer whale (Willy). When they met in the first movie, the whale was held captive in a small enclosure in a seaside marina. Willy refused to perform for audiences and the owner threatened dire consequences. Jesse arranged for the whale's dramatic release. In the second movie, Jesse and Willy ran into each other in the wild and discovered they must work together to avoid the perils of an offshore oil spill. In the third and final movie, the whale was threatened by an illegal whaling operation, but the whaler's son helped Jesse (who had grown into a 17-year-old whale researcher) save Willy and his family.

The Free Willy movies brought the question of captivity to the forefront of public consciousness, and resulted in a long and expensive campaign to return the killer whale that was used in the first movie to the ocean. That animal, Keiko, had been kept in rather miserable circumstances in a substandard facility in Mexico. With money raised through a publicity campaign sponsored by the movies' producers (Richard Donner and Lauren Shuler-Donner), Keiko went through a reorientation program in an Oregon facility and was then moved to Iceland, where he was reintroduced to the wild. Shortly thereafter the whale died of unknown causes. The public response to Free Willy was indicative of an increase in public questioning throughout the 1990s about the appropriateness of keeping marine mammals in captivity for public display. With increasing access to information about marine mammals in the wild (through excursions, books, and videos), it became clear that life in a captive facility was a poor substitute for nature. In response, the display industry made significant strides in upgrading facilities, improving husbandry, and refocusing shows to emphasize education and the display of animals' natural behaviors. The debate continues on many fronts about the pros and cons of maintaining marine mammals in captivity.

The removal of animals from the wild decreased significantly during the 1990s. Improved health of captive animals and an increase in the number born in captivity provided an ongoing supply of display animals that had no experience in the wild and would be unlikely to survive if released. Some facilities (e.g., the Vancouver Public Aquarium) chose not to replace whales or dolphins that died, and others (Maui Ocean Center; Monterey Bay Aquarium) decided from the outset not to hold cetaceans. In a graphic display of the continuing debate about animals in captivity, the producers of the Free Willy movies threatened a Hollywood-sponsored boycott of film-making on the Island of Maui if a proposal to put dolphins on display at a planned "theme park" on Maui was carried out. County legislators ultimately enacted a ban against keeping cetaceans in captivity anywhere in Maui County.

VI. Marine Mammals in the Twenty-First Century: The Domestic Dolphin and Urban Whale

The commoditization of marine mammals is now reaching a fever pitch with attempts to resume commercial whaling, continued growth in whale watching, increased competition for ocean resources, space-age technological advances in military and corporate attempts to control the oceans, continued destruction of ocean habitat, and the dire threat of global warming. Each of these concerns has generated an agenda that pits scientists, politicians, environmentalists, and business interests against each other.

Recovery of large whale populations from the depredations of industrial whaling has given whaling interests new-found energy in

challenging the two-decade old IWC moratorium. In defending his country's scientific whaling program, a Japanese official referred to minke whales as "cockroaches of the sea." Even while Australian government officials are working to create a sanctuary for whales across the entire South Pacific, one Australian scientist noted that humpback whales are "breeding like rabbits," while others suggest the public's infatuation with whales is the result of gullible susceptibility to "animal protectionists (who) mobilize concerned, yet uninformed citizens to clamour for an end to any animal use" (Marsh *et al.*, 2003). Echoing the claims of prowhaling nations that recovering marine mammal populations are consuming resources needed to feed humans, Corkeron (2004) characterized the "whales as icons" perspective as problematic because it interferes with a rational ability to address such current questions as "... how much of the reduced productivity of the oceans and coasts should remain available to whales" (Corkeron, 2004, p. 848). It may be time, he suggested, to "spread new messages" to whale watchers that "whale populations will fare better under an internationally controlled regime of sustainable hunting rather than under culls instigated by individual nations" (Corkeron, 2004, p. 848). Advocates for an end to the whaling moratorium generally emphasize that "culling" recovered populations may be a necessary antidote to the diminishing availability of the world's fish stocks.

Popular perceptions of marine mammals in the twenty-first century are being shaped by such powerful forces as increased human competition for diminishing resources and the unpredictable impacts of global warming. In the interests of protecting national security and ensuring ready access to world markets, military and commercial interests lobby for exemptions from national and international regulations that protect wildlife and the environment. Despite evidence that military use of powerful underwater acoustic signals harms marine animals, and that ship strikes have been a major factor in the impending demise of the North Atlantic right whale, attempts to curtail the military or redraw shipping lanes have led to several court challenges. As we attempt to engineer the ever-more difficult struggle for survival, human needs trump those of other species. In a recent court case pitting environmental groups against the US Navy over the use of high power SONAR, the court ruled 2-1 in favor of the Navy. Writing for the majority, Appeals Judge Andrew Kleinfeld noted that:

The public does indeed have a very considerable interest in preserving our natural environment and especially relatively scarce whales. But it also has an interest in national defense... The safety of the whales must be weighed, and so must the safety of our warriors. And of our country. (Honolulu Star Bulletin, 2007)

A review of cultural values and literature suggests that our current relationship with marine mammals may best be described as one of "domestication." Oceanaria, whale and dolphin watching operations, and ocean cruise lines provide a wide segment of the world's population the opportunity to interact with groups of a relatively small number of species at close range. Marine mammals are maintained in captivity to entertain, educate and provide "therapy" for the public. Dolphin Swim Programs now offered by most captive display facilities have become a major force in the domestication of bottlenose dolphins, and generate millions of dollars of revenue. Prospective customers are told that captive dolphins are actually better off than those in the wild, as in this statement from the Dolphin Discovery website (http://www.dolphindiscovery.com/teens/info_how-dolphin-learn.asp, retrieved August 22, 2007):

(The dolphins) live in an area protected by fences... where they are safe from predators such as sharks and where they can be

with people in a completely safe environment. During the day they play with people several times and they also have free time so they can be alone, play among themselves or do whatever they want. When one of them does not feel well it changes its attitude, it keeps away from the others or does not eat, this is when the veterinarians check them up and give them the right medicine so they can feel better.

These sentiments are echoed on the Dolphin Quest website (<http://www.dolphinquest.org/getthefacts/welfare/>, retrieved August 22, 2007):

The dolphins and whales in marine life parks, aquariums, oceanaria, and zoos consume consistently high quality nutritional food, receive excellent medical attention, and are kept free of debilitating parasites. This is in stark contrast to the predators, disease, pollution, well-documented commercial fishing and recreational boating dangers, and other stresses they face at sea, resulting in thousands of deaths each year.

In addition to captive swim programs, opportunities to swim with whales and dolphins in the wild may be found in countless locations around the globe—a Google search for "swim with dolphins" will return nearly 2,000,000 hits. The increasing popularity of swim programs may in part be the result of television exposure. The recent advent of High Definition format has resulted in a growing number of truly spectacular and visually pleasing documentaries that include stunning videography of marine mammals. The Discovery Channel and Animal Planet, National Geographic, and BBC have produced a range of programs devoted in whole or in part to marine mammals. BBC's "Blue Planet" is a prime example of the quality and beauty of such efforts.

Books about marine mammals since 2000 reflect a continuing interest in whales and dolphins, and run the gamut of topics. Excellent scientific texts on marine mammal biology and behavior include "Marine Mammal Biology: An Evolutionary Approach" edited by Hoelzel (Blackwell, 2002), and Berta, Sumich, and Kovacs' "Marine Mammals: Evolutionary Biology" (Academic Press, 2006). In-depth accounts of individual species have been written by Whitehead ("Sperm Whales," University of Chicago, 2003), Chadwick ("The Grandest of Whales," Sierra Club, 2006), and Krauss and Rolland ("The Urban Whale," Harvard University, 2007). Impacts of fisheries, tourism and management decisions on marine mammal species is considered in "Marine Mammals: Fisheries, Tourism and Management Issues" edited by Gales, Hindell, and Kirkwood (CSIRO, 2003). "Whales, Whaling, and Ocean Ecosystems" edited by Estes, DeMaster, Doak, Williams, and Brownell (University of California, 2006) considers the ways in which commercial depletion of whales has impacted ocean ecosystems, and how the recovery of depleted species may lead to further unintended consequences. "Leviathan" by Dolin (Norton, 2007) provides a detailed history of American whaling.

Perhaps because of the accessibility of gray whales along the western coastline of the United States, recent popular literature includes a number of books about that species. There is an account by Sullivan of the resumption of whaling by the Makah Indians of Washington state ("A Whale Hunt," Scribner, 2000), Peterson and Hogan's cultural history of human interactions with gray whales ("Sightings," National Geographic, 2002), Russell's documentation of gray whale natural history and migration ("Eye of the Whale," Island Press, 2004), and Thompson's description of gray whale behaviors, drawn from his many years as a whale watch guide ("Whales: Touching the Mystery," New Sage, 2006).

While personal accounts by those who accompanied whaling ships were popular in the early twentieth century, tales of transformation by personal interaction with whales and dolphins proliferate in the twenty-first century. Some of the work is based on reasonable scientific familiarity with the subject (e.g., Smolker's "To Touch a Wild Dolphin," Random House, 2001; Morton's "Listening to Whales," Ballantine, 2002; Visser's "Swimming with Orca," Penguin, 2005). There are a number of others, however, that derive from the author's conviction they have been chosen to channel cetacean thought processes (e.g., Wyllie's "Adventures Among Spiritual Intelligences," Wisdom Editions, 2001; Getten's "Communicating with Orcas: The Whale's Perspective," Hampton Roads, 2002; Taylor's "Souls in the Sea," Frog, 2003).

The contradiction between public fascination with marine mammals on the one hand, and pursuit of activities we know will destroy them on the other, continues. The twenty-first century may well bring the return of large-scale harvesting of marine mammals, not only for direct consumption, but as a means to reduce competition for commercially important fish species.

VII. International Perspectives

Attitudes about consumption of marine mammals differ across cultures that depend on traditional subsistence hunting practices (such as the Inuit, Aborigines, and some areas of the South Pacific); cultures that opportunistically use marine mammals to prop up collapsing fisheries (as is true throughout much of the Indian subcontinent, parts of Asia, Central and South America, and Africa); cultures that pursue relatively modern programs of whaling (including Japan and Norway); and cultures that currently forego whaling (many former whaling nations such as the United States, Canada, Australia, New Zealand, the United Kingdom, and South Africa).

As faulty as simplistic generalizations may be, one can recognize an important dividing line in global perspectives on marine mammals that is based more on economic considerations than fundamental differences in cultural attitudes toward nature. Wealthier countries enjoy the luxury of debating whether marine mammals should be harvested. Japan, Norway, the United States, Britain, Australia, and New Zealand are remarkably alike in their common appreciation of marine mammals as intelligent, amusing, and useful. The difference in those nations' behaviors toward marine mammals is one of time, and perhaps degree, for all have participated in the harvest of marine mammals and each currently reaps the benefits of the worldwide fascination with marine mammals. Less wealthy nations must face immediate considerations of survival before exploring programs devoted to environmental protection or species conservation. Marine mammals are viewed more directly in terms of immediate economic benefit. A major factor in the threat faced by a number of small cetacean populations is the readiness with which incidental takes (accidental entanglement in fishing nets) can be converted into a directed hunt in those areas where there is a market for the meat.

The enthusiasm with which a wide crosssection of nations have begun promoting whale and dolphin watching reinforces the notion that marine mammals are regarded neither as sacred nor profane in most parts of the world; they are primarily a commodity whose particular value can change from time to time. Surveys of attitudes in Australia, New Zealand, and the United States make it clear that, regardless of the qualities that participants may attribute to marine mammals, their primary value is in terms of satisfying human needs. This perspective appears even more entrenched in less affluent areas where marine mammals are harvested directly for food.

One of the most striking demonstrations of the role of marine mammals in modern cultural perspectives in affluent countries is the use of marine mammal images in corporate advertising. A survey by the author of corporate use of marine mammal images in magazines and television commercials (internationally) found over 100 different examples. Almost half the images used were of bottlenose dolphins. The next most frequent use was of killer whale images. Other species included humpback whale, sperm whale, right whale, beluga whale, false killer whale (*Pseudorca crassidens*), sea lion, walrus, spinner dolphin, humpback dolphin, and polar bear. In general, usage appeared to reflect anticipated familiarity on the part of the public for particular species (i.e., bottlenose dolphin, killer whale, humpback whale, and California sea lion), availability of professional quality images, and the extent to which the image symbolized the message of the advertisement (e.g., speed, power, size, intelligence).

The diversity of products marketed with the help of marine mammal images is extremely broad. In some cases, the connection between the product or service and marine mammals is obvious. A number of advertisements use images of marine mammals to promote travel to destinations where marine mammals may be observed (e.g., Olympic Airways in Europe, Air Nippon in Japan). In some cases, there is an identifiable link between the product or service and some perceived feature of the marine mammal. The ruggedness of a Leatherman tool has been highlighted with the help of a humpback whale; the warmth of Eddie Bauer clothing was symbolized by a polar bear; and a "school" of dolphins helped promote educational software for children (Fig. 11). More often the relevance of the image to the product is quite obscure. Marine mammal images have been used to sell aspirin, automobiles, batteries, beer, chewing gum, chocolates, cigarettes, computers, diapers, electronics, film, gold coins, jet skis, life insurance, orange juice, mobile phones, petrochemicals, potato chips, shower stalls, silverware, televisions, tires, video cameras, and a myriad of investment, real estate, interior decorating, and cosmetic services. One can only wonder about a cultural perspective that associates marine mammals with alcohol, tobacco, and petrochemicals.

Not surprisingly, use of marine mammal images in advertising occurred most frequently in more affluent countries, especially in Asia and Europe. North American and Australian use seemed to be more recent and less frequent, but a comprehensive assessment of corporate use of marine mammal images has yet to be conducted. It is clear, however, that over the past quarter century, increasing public attention to marine mammals has created a kind of "rock-star" status that elicits a classically conditioned positive emotional response to marine mammal images that can be exploited by marketing experts.

VIII. Conclusion

The one constant element in human perspectives on marine mammals since the beginning of Basque whaling is recognition of their economic significance. We have never stopped making money from them. They are still a resource. We still regard our needs as more critical than theirs. The proof can be seen in the peculiar and contradictory steps that we take to protect them. Consider, for example, the degree of attention that focused on "Humphrey" the "wrong-way whale" that wandered up the Sacramento River in 1985 and would not come out; the three gray whales that became caught in ice in Barrow, Alaska, in 1988 and could not get out; and the mother and calf humpback whale that spent 2 weeks in the Sacramento River in 2007 before getting themselves out. Tremendous resources in time, money, and emotions were devoted to "saving" these animals. Compare those situations with the decision to cull seals hanging out at fish ladders in Seattle a few

Kids learn better in a school of dolphins.

AdventureOnline.com engages your students with educational content based on the subjects they love – from dolphins to dog sledding.

AdventureOnline.com offers the interest-driven, real-time content that kids enjoy – and the reporting and assessment tools that teachers and parents need. Used in more than 2,400 schools during the 1999-2000 school year, AdventureOnline.com helps students learn reading, writing and math.

This fall, our newest product, AdventureOnline.com 2.0, will

launch an expanded site of four channels. In addition to the existing channel, Expeditions, the site will offer new daily and weekly educational activities, puzzles and games focused on Sports, Animals and Camping, as well as a Points-for-Performance rewards program.

AdventureOnline.com 1.0 is **FREE** until September 1, 2000, for teachers who register now. Register before September 1 and you'll also receive 50% off the price of membership to AdventureOnline.com 2.0. You'll pay only \$4.08/month (regularly \$8.16), with no obligation to finish the year! You will not be billed for the first month (\$4.08) until September 15, 2000. Visit www.adventureonline.com or call 1-888-609-0095, ext. 119.

years ago to prevent them from feeding on depleted salmon stocks. No expense was spared to “save” the whales from their own biological predispositions, while the seals were basically held accountable for the precarious status of salmon stocks decimated by human overfishing and habitat degradation. Japanese scientists have been ridiculed for suggesting that Antarctic minke whale (*Balaenoptera bonaerensis*) numbers need to be culled to promote the recovery of blue whales by reducing competition for prey. At the same time, pinniped populations in North America have been culled to promote the recovery of fisheries by reducing prey competition with humans. We pass laws to prevent tourists from approaching marine mammals too closely, but do little to prevent the countless deaths of marine species by a range of human activities. Once we killed marine mammals to get their oil, now we kill them by spilling oil on them. Once we chased and captured them for food, today we chase and capture them for amusement. Instead of using their baleen for corsets, we use their images to sell diapers and real estate.

Nonetheless, there does seem to be a groundswell of respect, hope, and compassion for cetaceans. Thousands of individuals all over

the world work tirelessly to assist marine mammals in need. When a humpback whale stranded on a beach near Brisbane, Australia in 1992, more than 5000 people showed up to save it. Our ability to form emotional attachments to individual animals seems boundless (Fig. 12). However, this encourages what right whale biologist Scott Krauss calls “Madison Avenue whale saving”; small-scale, high-profile publicity events that seem to be noble but do little to save marine mammal populations. Our activities will have little real conservation value as long as we ignore the intrinsic value and importance of marine mammals carrying out their natural behaviors in their natural habitat, unimpeded by the presence of humans or the pollution we produce.

We are faced with a fundamental conflict of interest: our need to exploit marine mammals for our own purpose and their need to be protected from our various forms of interference. Our interest in marine mammals is most often based on satisfaction of our own needs. We make them become what we hope they are and ignore what they maybe in reality. We see what we want to see. The sight of a whale or dolphin engaging in high energy activities visible above the surface is exciting for human observers (Fig. 13)—we want to get

P

closer and see more. The truth is that in many cases such behavior may signal an angry or otherwise distressed animal. Although the display may not always be related to the presence of a boat or swimmer, there is increasing evidence that such activities frequently indicate the animal does not want us there. Most people simply cannot interpret animal behavior properly, which makes it very likely that they will not know how to avoid disturbing whales and dolphins when they go out on the ocean. It is commendable that many would rather idolize marine mammals in the wild than colonize them in oceanaria, but naive idolization is as questionable as brute colonization.

If we are to achieve the status that Lavigne *et al.* (1999) have described (i.e., an aesthetic interest that reflects increased understanding and a change in ethical values), we must undergo a universal transformation in perspective: the ability to value something independently of its potential for meeting our needs. Until that point, we may continue to find less cruel ways to put marine mammals in our service, but their value will continue to be defined in anthropocentric terms. Philosophically, that may not seem to be a problem of significant proportion, but insofar as our behaviors put our needs ahead of theirs, marine mammals will continue to be at risk.

Acknowledgments

The ideas expressed reflect nearly 30 years of involvement with the whale and dolphin watching industry in Hawaii, Australia, Costa Rica, Ecuador, and occasional visits to Japan, New Zealand, Alaska, and New England. Many researchers, educators, operators, and members of the public have provided “grist for the mill.” I especially thank Greg Kaufman and the Pacific Whale Foundation for support throughout that time. The International Cetacean, Education and Research Center (ICERC Japan) has also provided support and encouragement. Trisha Lamb Furstein’s web-based bibliographies have been tremendously helpful to me. Joana Varawa provided critical and encouraging insight and much wisdom through her writings and in conversations we had on the island of Lanai.

Population Dynamics

PAUL R. WADE

“The immediate cause of the increase of population is the excess of the births above deaths”

When Thomas Malthus wrote his treatise on population growth in 1798, he understood that the study of population dynamics is most simply the study of fundamental life history characteristics such as birth and death rates. However, he also understood that the ultimate explanation for why populations increased or decreased was due to more complicated factors, such as changes in food supply and density-dependent limitations to growth. Much of the research on marine mammal population dynamics has traditionally focused on better definition of life history parameters such as survival and fecundity rates, age of sexual maturity, and longevity. These can, for example, be used to estimate a potential maximum rate of increase for a population. A sign that the study of marine mammal population dynamics has become increasingly sophisticated is the growing number of studies that examine how extrinsic factors can influence populations. These include environmental variability, disease and natural toxins, competition, and predation. There is also much continued interest in the role that density-dependence plays in controlling marine mammal populations. We are currently witnessing the return of many populations to levels limited by their carrying capacity following overexploitation by humans, which means that the study of density-dependence in marine mammals is no longer a theoretical discipline.

I. Rates of Population Increase

A. Population Growth of Long-Lived Animals

Most long-lived animals, such as marine mammals and large terrestrial mammals, have relatively slow intrinsic rates of increase compared to most other kinds of animals. These modest population growth rates are the consequence of their life history characteristics. Characteristics such as the age at which females start reproducing, the number of years between births, and how many years a female will live and reproduce, determine how quickly a population can increase. Most marine mammal species take many years to reach sexual maturity and have long gestation periods that result in the production of, at most, only one young a year. In fact, most species give birth only once every several years (Boyd *et al.*, 1999). Even when annual rates of survival are very high, these characteristics cause populations to grow slowly. Low rates of population growth make most species of marine mammal vulnerable to overexploitation, as shown by the rapid depletion of many whale populations by commercial whaling.

B. Measuring Population Growth

Population growth can be measured in two ways. In general, the most reliable estimates often come from abundance data collected over many years. Population abundance can be estimated from surveys or counts, and when repeated over several years, the trend (percentage change per year) in a population can be estimated (see chapters on ABUNDANCE ESTIMATION and POPULATION STATUS AND TRENDS). Specifically, the slope of a linear regression on the natural logarithm of abundance against time represents the rate of increase (r) of a population experiencing exponential growth. Because population growth is slow and population estimates are imprecise, 10 or more years may be required to directly measure population growth rates. Estimates of abundance for some species are so imprecise that it may be difficult to determine trends in abundance (Taylor *et al.*, 2007).

A less direct way of estimating population growth is from life history data. Estimates of age of sexual maturity, birth rate, juvenile and adult survival rate, and maximum age can be compiled in a Leslie matrix or similar model, which can then be used to estimate the rate of increase (usually estimated as λ , where $\lambda = e^r$). Although such calculations have been useful for exploring potential population growth rates, relatively few estimates of actual population growth have been made in this way. The main hindrance is the lack of direct data on survival rates of marine mammals. Only a few species have been amenable to survival estimation, usually from mark-recapture studies using individuals recognizable from tags, branding, unique scars, or coloration patterns, or other markings (see MARK AND RECAPTURE). Mark-recapture studies of survival or fecundity have been undertaken in California (*Zalophus californianus*) and Steller (*Eumetopias jubatus*) sea lions, bottlenose (*Tursiops truncatus*) and Hector's (*Cephalorhynchus hectori*) dolphins, polar bear (*Ursus maritimus*), manatee (*Trichechus manatus*), and killer (*Orcinus orca*), humpback (*Megaptera novaeangliae*), gray (*Eschrichtius robustus*), bowhead (*Balaena mysticetus*), and right (*Eubalaena* spp.) whales (Fujiwara and Caswell, 2001; Kendall *et al.*, 2004; Taylor *et al.*, 2006).

C. Taxonomic Differences

Although population growth is comparatively slow for all marine mammal species compared to most other vertebrates, there is a considerable range in life history strategies. For example, just within the cetaceans one can contrast a harbor porpoise (*Phocoena phocoena*) that becomes sexually mature after a few years, can give birth annually, and rarely lives past 12–15 years (Read and Hohn, 1995), with a bowhead whale that becomes sexually mature after perhaps 10–20 years, only gives birth every 3–5 years, and lives for decades, with some individuals apparently living much longer than 100 years. Broad patterns are evident in maximum population growth rates when available information from trend or life history data is examined for different taxonomic groups. Sea otters (*Enhydra lutris*), with maximum observed rates on the order of 17–20% per year (Estes, 1990), are capable of the fastest growth. Next are pinnipeds. Many have the potential to reproduce annually, with observed rates ranging from 8 to 13% for otariids [from northern fur seals (*Callorhinus ursinus*) at the low end to Antarctic fur seals (*Arctocephalus gazella*) at the high end] (Wickens and York, 1997), and 6–13% for phocids [from Hawaiian monk seals (*Monachus schauinslandi*) at the low end to harbor (*Phoca vitulina*) and gray (*Halichoerus grypus*) seals at the high end]. A puzzling species is the Steller sea lion, with the greatest observed increase of only about 3% per year, observed in the eastern North Pacific population; it is uncertain if this population has also

been affected by factors that have led to the decline and endangered status of the western North Pacific population.

Maximum annual rates of increase for mysticetes likely range from about 4 to 10%, or perhaps even higher (Best, 1993). Observed rates for gray and bowhead whales (3–4%) are at the low end, although the populations that have been studied are likely at high population levels relative to carrying capacity and therefore their growth rate may have already slowed (see Section III below). Model-based estimates suggest bowheads may be capable of 4–5% maximum rates, and gray whales of 5–7%. Southern right whales (*Eubalaena australis*) have shown the ability to increase at 7% per year, and humpback whales have been estimated to increase at 7–10% per year or higher. Estimates at the higher end are surprising given that 10% has been deduced to be the approximate theoretical upper limit for humpback whales from their life history. Estimates for other species, such as blue (*Balaenoptera musculus*) and fin (*Balaenoptera physalus*) whales, are relatively imprecise but mostly fall within a range of 4–8%. Manatees appear to have maximum population growth rates of at least 7% and perhaps higher, whereas dugongs (*Dugong dugon*) are likely only capable of growing at 5–6% per year. Much uncertainty exists about the maximum rates of increase of odontocetes. What little is known suggests this group generally has very low annual population growth rates, 2–3% in some species such as killer whales (Brault and Caswell, 1993), and most species are considered unlikely to have a maximum growth rate of more than 4% (Reilly and Barlow, 1986). There is speculation that a few species, such as the harbor porpoise, may have higher rates of increase because of their life histories, but such higher rates have yet to be documented. Age distributions of by-caught and stranded harbor porpoise support the hypothesis that maximum rates are ~4% for this species.

II. Extrinsic Factors Affecting Population Size

A. Environmental Variance

Another aspect of population dynamics is the study of the effects of extrinsic factors on population growth. The difficulty in precisely estimating population size and life history parameters has made the study of variation in population growth rates of marine mammals difficult. However, at least a few conclusions can be made. Long-lived animals with relatively older ages at sexual maturation and relatively slow population growths cannot respond quickly to favorable environmental conditions. Consequently, such species cannot decline too often or too rapidly when conditions are bad, or they would not have persisted on an evolutionary time-scale. Therefore, marine mammals have evolved life-history strategies that keep them relatively buffered from interannual variability in environmental conditions, at least compared to other animals such as small terrestrial mammals. Species with these traits are often referred to as “K-selected species,” meaning they have evolved to maintain relatively stable population sizes at or near the carrying capacity (typically represented by the letter “K”) of the environment (rather than fluctuating wildly as seen in small mammals such as the lemming, *Dicrostonyx* spp., or snowshoe hare, *Lepus americanus*). Cetaceans, in particular, should be less subject to large fluctuations in survival and fecundity from year to year than would be sea otters or pinnipeds.

Data sufficient to examine such patterns are relatively rare for marine mammals. Studies of pinnipeds provide the best evidence of the effect of changing oceanographic conditions, particularly because of the ability to closely monitor numbers of pups or adults at rookeries from one year to the next. El Niño oceanographic events, through reductions in prey availability, have led to dramatic changes in

survival and reproduction of several species of otariids in places such as California and the Galapagos Islands (Trillmich and Ono, 1991). These changes include lower fecundity, lower pup survival, and even lower adult survival during extreme events. In some cases, such as for the northern fur seal at San Miguel Island, conditions have been bad enough to result in nearly 100% mortality of pups in a given year. Similarly, fluctuations in cohort strength of crabeater seals (*Lobodon carcinophaga*) have been attributed to environmental factors such as sea ice extent and krill production and availability (Boveng and Bengtson, 1997), and survival of juvenile Hawaiian monk seals has been correlated with the location of the chlorophyll front in the North Pacific transition zone (Baker *et al.*, in press). Several populations of pinnipeds have experienced long-term (20–30 year) declines for which the cause has been debated. While some believe these declines are due to oceanographic regime shifts on that time scale, others believe that factors such as direct human-caused mortality or depletion of prey species by commercial fisheries may be at least partially to blame.

Cetaceans probably have similar, though less dramatic, responses to environmental change, but these changes are harder to detect. One of the first examples was that of pregnancy rates of fin whales off Iceland which were correlated with changes in food abundance. Recent studies collecting information about interannual changes in survival or fecundity have led to several other examples of correlations between population dynamics of cetaceans and environmental factors. An at-sea index of chinook salmon (*Oncorhynchus tshawytscha*) abundance is highly correlated with survival rates of fish-eating killer whales in British Columbia (Ford *et al.*, 2005). Production of gray whale calves is correlated with the extent of sea ice in the Bering Sea the previous summer (with greater ice cover presumably restricting access to food resources) (Perryman *et al.*, 2002). Intriguingly, calf production in North Atlantic right whales (*Eubalaena glacialis*) is correlated with the North Atlantic Oscillation index (a physical oceanographic measurement of ocean temperature), apparently through mechanisms that concentrate and favor production of their copepod prey (Greene and Pershing, 2004). Within the sirenians, manatees have been shown to experience higher mortality during years with intense coastal storms (Langtimm and Beck, 2003).

B. Disease and Natural Toxins

Many species of marine mammal have experienced large mortality events caused by disease or natural toxins. Disease can also affect reproductive rates as well, with a potentially important influence on population dynamics. Disease and toxin related die-offs are likely natural events for marine mammals. It is thought (though not proven) that these events may occur more frequently in populations near or at their carrying capacity due to nutritional stress, enhanced transmission of disease, and other related factors. There is also the suspicion that some of these die-offs have been ultimately triggered by anthropogenic causes, such as degraded habitat or exposure to contaminants, but this has also proven difficult to confirm from field studies. Three natural toxins that cause marine mammal deaths are saxitoxin, brevetoxin, and domoic acid, all of which come from harmful algal blooms. The frequency and severity of harmful algal blooms in some parts of the world have been linked to increased nutrient loading from human activities. The great majority of marine mammal die-offs from disease or toxins have been of coastal or nearshore species; whether this represents a true tendency (perhaps from anthropogenic causes) or is simply due to a greater probability of detection of these events (i.e., coastal species are more likely to strand) is unknown. Such die-offs are particularly dangerous for small populations.

Some mortality events from disease or toxins have been severe enough to be considered a significant influence on the dynamics of the effected population (see MASS MORTALITIES). Seal populations have been most dramatically affected, with die-offs of >18,000 and ~25,000 harbor seals in Europe from phocine distemper virus in 1988 and 2002, respectively, tens of thousands of Baikal seals (*Phoca siberica*) from canine distemper virus (CDV) in 1987–1988, and 10,000 Caspian seals (*Phoca caspica*) from CDV in 2000 (Gulland and Hall, 2007). Even more dramatically, the endangered Mediterranean monk seal (*Monachus monachus*) experienced a loss of 60–70% of its population off Africa in 1997 from a harmful algal bloom and morbillivirus, which has seriously compromised the long-term survival of this species. California sea lions have been effected by at least seven die-offs of hundreds of animals over the last 22 years, caused by leptospirosis or domoic acid. In 1998, 60% of New Zealand sea lion (*Phocarctos hookeri*) pups died, with the suspicion that a bacterial infection was the cause.

In the western North Atlantic Ocean, hundreds of bottlenose dolphins died in 1987–1988 from morbillivirus and possibly brevetoxin, and the event was thought to have caused a significant decline in the population. Other die-offs of hundreds of bottlenose dolphins have occurred along the coasts of Texas and Florida, with brevetoxin the most common cause. Humpback whales in the Atlantic have also experienced mass-mortality events on at least two occasions; in one case at least 14 whales died from saxitoxin poisoning from consuming dinoflagellates concentrated in fish prey. Sixteen humpback whales died in 2003 in Maine, with saxitoxin and domoic acid detected in two and three whales, respectively. It is not known if such mortality is frequent enough to exert a strong influence at the population level. Finally, Florida manatees have experienced at least five die-offs of tens of animals or more from brevetoxin over the last 25 years.

C. Competition

Competition from other species may influence the population dynamics of marine mammals, although there is little evidence for this. Whether this is due to competition being unimportant or whether it is simply too difficult to demonstrate is an open question. It is important to be clear on what is meant by competition. From an ecological perspective, prey overlap and competition are two different concepts and the latter may or may not occur with the former. The term “competition” is defined to be when one organism has a negative effect upon another by consuming, or controlling access to, a resource that is limited in availability. Therefore, demonstration that two species eat the same prey in the same location does not prove that competition exists between the two species; the prey resource may not be limiting, at least at that time and location, or the species may exploit the prey in different ways (such as at a different depths).

Many claims have been made about competition between whale species and other marine vertebrates in Antarctic waters. There is considerable prey overlap in the Antarctic between cetaceans, pinnipeds, and penguins, but studies are lacking that actually demonstrate competition. An increase in crabeater seals was directly attributed to a release from competition following the severe depletion of several species of baleen whales in the Antarctic, leading to an increased availability of krill. This explanation has recently been reevaluated in light of evidence of environmental influences on the population dynamics of Antarctic pinnipeds. Of many factors considered in a recent review of the decline of southern elephant seal (*Mirounga leonina*) around Antarctica, only competition and oceanographic change were considered plausible hypotheses; the authors concluded the

competition hypothesis was not the cause (McMahon *et al.*, 2005). It should be noted that some general textbooks (such as books on oceanography) state that competition for krill with Antarctic minke whales (*Balaenoptera bonaerensis*) has prevented the recovery of depleted blue whales in the Antarctic. However, competition between the two species has not been demonstrated, and recent information indicates the lack of recovery of blue whales in the Antarctic might be explained by previously unknown illegal catches by the former Soviet Union (Clapham *et al.*, 1999).

D. Predation

Many marine mammals, especially smaller ones, are preyed upon by other animals, but predation in the past had rarely been suggested to be a strong controlling factor in their population dynamics. In recent years, however, increased attention has been paid to the role of top predators in marine ecosystems. It has been suggested that sea otters may have declined in the Aleutian Islands of Alaska because of killer whale predation (Estes *et al.*, 1998). Pinnipeds, particularly pups, are often vulnerable to predation from predators such as leopard seals (*Hydrurga leptonyx*), great white sharks (*Carcharodon carcharias*), and killer whales. While such predation has been shown to affect the growth rate of the subpopulation at local rookeries, it is unclear if it exerts a strong influence on the dynamics of an entire population. For cetaceans, at least some (and perhaps all) pelagic dolphin species experience predation by sharks, and killer whales prey on many cetacean species. Again, even though predation of cetaceans occurs, it is difficult to know whether it is a dominant factor in the dynamics of these populations. From recent studies it appears that killer whale predation on gray whale calves on their first north-bound migration may account for a substantial portion of their natural mortality, though the gray whale population increased for over 20 years while apparently experiencing this source of mortality. In some areas a large proportion of humpback whales show rake-mark scars from killer whale attacks, the great majority of which were apparently acquired as calves. Despite this likely source of natural mortality, humpbacks in both the North Atlantic and Pacific have shown strong recovery from commercial exploitation.

Discussions about the influence of predators on the dynamics of marine species have often been placed in the broader context of an ongoing debate about the relative importance of “top-down” influences (predation or other direct removals such as human-caused kills) vs “bottom-up” influences (from oceanographic productivity) (Ainley *et al.*, 2007; Nicol *et al.*, 2007). For example, it has been hypothesized that killer whale predation caused the decline of southern sea lions (*Otaria flavescens*), southern elephant seals, and Antarctic minke whales in the Southern Ocean, but a review of the southern elephant seal decline concluded that predation was unlikely to be the cause and suggested that oceanographic change or competition were more plausible explanations (McMahon *et al.*, 2005).

An interesting debate has followed the hypothesis that killer whales caused the sequential decline of harbor seals, Steller sea lions, northern fur seals, and sea otters in the Aleutian Islands and Gulf of Alaska; with many articles arguing both for (Springer *et al.*, 2003) and against (Wade *et al.*, 2007) this hypothesis; see Estes *et al.* (2006) for an overview of this issue. In particular, the decline of Steller sea lions has stimulated strong arguments both for top-down causes (from direct takes in fisheries bycatch, intentional shooting, subsistence hunting, or killer whale predation) and for bottom-up processes (from oceanographic regime shift or competition for prey with commercial fisheries). It may never be possible to solve these

debates retrospectively, as it is often the case that the key data were not collected during the decline and cannot now be collected.

These extrinsic factors have been discussed independently, but there are likely many interactions between them. As one example, sea otters with moderate to severe encephalitis were estimated to be 3.7 times more likely to be killed by sharks than otters without that condition (Kreuder *et al.*, 2003). Several authors have treated deaths from predation as independent mortality that a population suffers, but it may be that predation mortality is mostly of more vulnerable individuals already known to have lower survival rates, such as sick or very young or old animals and therefore might be correlated to influences from either environmental change or density-dependence (causing nutritional stress). Populations still have the ability to increase while experiencing natural mortality, of which predation is only one component (eastern North Pacific gray whales are a good example of this).

III. Density-Dependence

A. Compensation

Another area of great interest is the role of density-dependence in controlling the population dynamics of marine mammals. It is generally accepted that marine mammal populations experience density-dependence. In other words, as populations become relatively larger, they tend to have lower population growth, and eventually stop increasing. This form of density-dependence is termed compensation. The level at which a population stabilizes is called its carrying capacity. Evidence has been found for density-dependence in life history parameters such as the age at sexual maturation. Females from a population at a level well below K become sexually mature and start reproducing at an earlier age than do females from a population at a level close to K . Presumably this is because of access to greater resources such as prey. For example, the age at sexual maturation apparently became lower for fin and sei whales in the Antarctic as their populations were depleted by commercial whaling.

It has been hypothesized that the mechanisms of the regulation of populations of long-lived mammals would follow a sequence as a population increased, with density-dependence first affecting the rate of immature survival, then the age at sexual maturation and the birth rate, and finally the adult survival rate (Eberhardt, 1977). This hypothesis partially follows from the recognition that a long-lived species which reaches sexual maturity late and has a low intrinsic rate of increase must maximize adult survival in order to persist. Adult females of long-lived species may be able to forgo reproduction to maximize individual survival when conditions are poor, but it is unclear if there is necessarily a specific sequence of effects in how density-dependence operates that is common to all marine mammals.

B. Linear vs Nonlinear Density-Dependence

It is difficult to assess how these changes in life history translate into changes in population growth, as few direct data are available on changes in population growth at different population sizes. One debate is whether marine mammals experience linear or nonlinear density-dependence. Linear density-dependence is a constant decline in the per capita population growth rate as a population increases, illustrated by the simple logistic population model (Fig. 1). Nonlinear density-dependence is where a population has no decline in the per capita growth rate as it increases until it reaches a level close to K , where it then has a rapid decline, illustrated by the θ -logistic population model where the value of θ is greater than 1 (Fig. 1). Both linear and nonlinear density-dependence occurs in single life-history parameters of marine mammals and other large mammals. However,

Figure 1 An illustration of two forms of density-dependence. “Linear” density dependence represents a constant decline in population growth per capita as the population level approaches carrying capacity (K). Per capita population growth is the number of animals added to the population divided by the total population size, which also represents the population growth rate. “Non-Linear” represents a curved response, where the population growth per capita does not decline until a population level close to K , where it declines rapidly. Both curves represent cases where the maximum population growth rate is 0.04 (4% per year).

population modeling indicates that nonlinear density-dependence in a single life history trait (such as fecundity) may not translate into nonlinear density-dependence at the population level, particularly if density-dependence in other life history traits is more linear (Taylor and DeMaster, 1993). The form of the density-dependence (linear vs nonlinear) will determine what population size will have the greatest increase in numbers from one year to the next, called the maximum net productivity level (MNPL). For long-lived animals, nonlinear density-dependence will generally lead to populations having their MNPL closer to carrying capacity (Fig. 2). A review concluded that most marine mammal populations likely have their MNPL between 50 and 85% of their carrying capacity. It has been shown, however, that it is very difficult to estimate MNPL for any marine mammal population given the data that are currently available (Ragen, 1995).

C. Density-Dependence and Management

These concepts of density-dependence have been incorporated into the management and conservation of marine mammals. Both the International Whaling Commission, in its proposed Revised Management Procedure (RMP) for the regulation of whale catches, and the US government, in managing human-caused mortality of marine mammals in US waters, refer to concepts like MNPL, with populations above MNPL considered “healthy.”

Many populations of pinnipeds and whales are recovering from unregulated catches that left them at severely depleted population levels. It will be interesting to observe the recovery of these populations over the next few decades, as many are likely to approach previous population levels and are expected to stop growing at some point. Examples of populations that have apparently reached carrying capacity include harbor seals in Washington (Jeffries *et al.*, 2003), harbor seals in Oregon (Brown *et al.*, 2005), and possibly eastern North Pacific gray whales (Moore *et al.*, 2001). It is important to understand when density-dependence is taking place, so that it can

Figure 2 Population growth (in numbers of animals added to the population each year) as a function of population level, expressed as a fraction of K . This quantity is also called the “net productivity,” and therefore the peak of this curve is referred to as the maximum net productivity level (MNPL). For linear density-dependence the MNPL is at one-half of K . For nonlinear density-dependence the MNPL is closer to K , in this case at $0.7K$.

be distinguished from human-caused effects on population growth that might require conservation action. It is to be expected that populations at or close to K may be subject to more environmental influence, because with populations at the limit of their resources, any drop in resources will potentially have dramatic effects. California sea lions and gray whales may be current examples of this.

D. Allee Effect (Depensation)

Density-dependence can also work in the opposite direction, where per capita population growth is slowed at very small population sizes (Fig. 3). This is called the Allee effect by ecologists (also called depensation by fisheries biologists). One simple example of the Allee effect would be a reduction in reproduction at very small population sizes due to the inability to find a mate. Allee effects could also occur from inbreeding depression associated with small populations, or from behavioral changes that might accompany a reduction to small numbers of animals, such as decreased foraging success or protection from predators. Unfortunately, the difficulties in studying the population dynamics of marine mammals are compounded by the difficulty of studying small populations, so it may take a long time before much is learned about depensation and its role in the dynamics of marine mammals (Fowler and Baker, 1991). Several severely depleted baleen whale populations have shown little or no recovery despite decades of apparent relief from human exploitation (Clapham *et al.*, in press), raising the possibility that these populations are experiencing Allee effects. However, it has been realized that many of these populations may have continued to experience human-caused mortality from a variety of sources, such as illegal whaling, entanglement in fishery gear, and collisions with ships. This makes it difficult to determine if depensation does play a significant role in the dynamics of small populations of cetaceans.

Similarly, many pinniped species were once hunted to commercial extinction and have since shown recovery, but it is rarely known how small these populations actually were at their low point. One exception is the remarkable story of northern elephant seals (*Mirounga angustirostris*), which were thought to be extinct around 1880 and are now thought to have numbered no more than about

Figure 3 An illustration of the Allee effect. One curve represents linear density-dependence without depensation (“No Allee effect”). The second curve represents linear density-dependence with depensation (“Allee effect”). Under depensation, population growth per capita declines at low population levels.

100 individuals around the turn of the century, concentrated in a single colony in Baja California, Mexico (Cooper and Stewart, 1983). The number of northern elephant seals now exceeds 80,000, and they have recolonized many breeding sites in the US and Mexico. However, the apparent lack of depensation in one population does not preclude it from being important to other populations or species. Although difficult to study, a decline in growth rate at small population sizes can substantially increase the risk of extinction for a population, so it will continue to be important to consider depensation despite the lack of solid evidence for its occurrence.

Population Status and Trends

JAY BARLOW AND RANDALL R. REEVES

FOR marine mammals, status is a measure of the size or general HEALTH of a population relative to some management standard. A trend is a measure of the rate at which a population grows or declines over some (usually long) time period. Taken together, status and trends form the basis for assessing whether management objectives are being met for a given population or management unit.

I. Status

Inherent in the concept of status is the evaluation of populations relative to some standard or metric. Absolute estimates of population size may be included in an assessment of the population status, but an evaluation of status is incomplete without evaluating the significance of this population size relative to some goal. The standards for evaluating the status of populations are typically related either to a harvest or to a conservation objective.

A. Harvest Objectives

Traditionally, to evaluate harvest objectives, population size was evaluated relative to the population level (MSYL) that would give the maximum sustainable yield (MSY). Populations are expected to decline as a result of harvests, but as population size decreases, the population growth rate is expected to increase to compensate for this harvest (*density dependence*). The implicit assumption is that populations are resource limited, and as density declines, more per-capita resources are available to support enhanced reproduction, survival, or both. Harvest and growth rates may balance each other over a

wide range of possible equilibrium population sizes, but typically harvest will be maximized at one specific equilibrium level (MSYL). Although the MSYL concept has persisted for many years, it was widely recognized by the 1970s that, in practice, it was seriously flawed as a basis for management. Management of populations at their MSYL is a knife-edge balancing act that requires constant conditions and near-perfect data. Usually, when populations slip below that level, the drastic management actions that are required cannot be implemented in time to prevent the collapse of the population as an economic resource. This realization has led to more risk-averse management models that strive to keep populations above their MSYL; this higher target level is sometimes called the optimum sustainable yield level.

Currently, few marine mammal species are managed with explicit harvest objectives. Although a moratorium on commercial whaling has been in place since 1986, the INTERNATIONAL WHALING COMMISSION (IWC) still maintains a harvest-based management framework for large whales [baleen whales, sperm whales (*Physeter macrocephalus*), and bottlenose whales (*Hyperoodon* spp.)]. To determine status, population size is compared to a standard that is based on MSYL. Protected stocks (PS) are less than 0.9MSYL; sustained management stocks (SMS) are between 0.9 and 1.2MSYL; and initial management stocks (IMS) are greater than 1.2MSYL. Acknowledging the risk of managing at the MSYL knife edge, the IWC has, since the mid-1970s, limited harvests to 90% of the estimated MSY. The IWC has been working on a “revised management procedure” (RMP) to replace this MSYL-based management when the moratorium on commercial whaling ends. The performance of the RMP has been tested in simulations where the objective is to maintain populations above 72% of their preexploitation population size.

The Stock Assessment Secretariat of the Canadian Department of Fisheries and Oceans coordinates the production of stock assessment reports for hunted species, notably including harp seals (*Pagophilus groenlandicus*), narwhals (*Monodon monoceros*), and bowhead whales (*Balaena mysticetus*). These reports, prepared by scientists in close consultation with representatives of regional bodies and hunting communities, are intended to provide the basis for managing harvests. However, in the absence of a legal framework equivalent to the US Marine Mammal Protection Act (see later), harvest objectives are *ad hoc*. A stock assessment report recently completed for the Hudson Bay-Foxe Basin stock of bowhead whales, for example, invokes “sustainability” as an implicit management objective, with no reference to recovery or maximizing yield.

B. Conservation Objectives

The goals of conservation efforts can range from preventing the extinction of species to returning populations to their carrying capacity level. The metrics used to measure the conservation status of populations range over this same spectrum.

When populations become very small or are declining rapidly, their status is often determined by estimating the probability of extinction within a defined time period. For example, the “critically endangered” category of the IUCN Red List (IUCN, 2001, 2006) includes species whose probability of EXTINCTION is estimated to be at least 50% within 10 years or three generations, whichever is longer. Clearly this is nature’s intensive care unit for the nearly hopeless cases. In the IUCN categories of “endangered” and “vulnerable,” the values change to 20% chance of extinction within 20 years or five generations and 10% chance within 10 years or three generations, respectively. The risk of extinction can be estimated using a technique

developed in conservation biology known as population viability analysis (PVA), which evaluates population size, trends in abundance, life history traits, natural variability, trends in habitat loss, and parameter uncertainty. These onerous data requirements have meant that very few marine mammal species or populations have been evaluated using PVA.

Lacking sufficient data to evaluate the risk of extinction in this manner, several surrogate variables may be measured that are highly correlated with extinction risk. Extinction is obviously correlated with declining abundance, and the IUCN uses total (continuing, irreversible, or not-understood) declines of 80, 50, and 20% over 10 years (or three generations) to classify species as critically endangered, endangered, or vulnerable, respectively. We know that small population size is itself an extinction risk factor, and the IUCN uses population sizes of 50, 250, and 1000 mature individuals to classify species into the same three categories. Other important factors that increase extinction risk include (1) having all individuals in a single location, (2) over-dispersal and the resulting loss of mating opportunities and social facilitation, (3) habitat degradation, and (4) extreme fluctuations in population size. The IUCN recognizes the compounding of risk factors and evaluates some of these factors in tandem with population size or trends. Under domestic legislation, the United States maintains a similar endangered species list with categories of “endangered” and “threatened.”

The IUCN’s development and adoption of quantitative criteria for Red List classifications prompted various national efforts to take a similar approach. For example, the Mammalogical Society of Japan has applied the IUCN criteria to all marine mammal populations in Japanese waters. The status assigned to many of these populations is worse than that indicated by the IUCN’s global listing for the species. There are, for example, critically endangered or endangered populations of finless porpoises (*Neophocaena phocaenoides*), striped dolphins (*Stenella coeruleoalba*), short-finned pilot whales (*Globicephala macrorhynchus*), and dugongs (*Dugong dugon*) in Japan, whereas these species, overall, are listed by IUCN as either “vulnerable (VU),” “data deficient (DD)” (inadequate information to assess risk of extinction), or “least concern (LC)” (out of danger but needing continued conservation measures). In Canada, the task of listing species and populations at risk falls on the Committee on the Status of Endangered Wildlife in Canada (COSEWIC). This group consists of technical experts as well as representatives of government agencies and nongovernmental organizations. Its listing decisions are based on status reports prepared by scientists familiar with the species or populations under review. COSEWIC is in the process of developing its own IUCN-style criteria for status determinations.

For species that are above the size at which extinction is a significant risk, status is usually measured relative to historical abundance or environmental carrying capacity (K). Even when the “official” definition of status is based on a percentage of K , historical abundance is often substituted because carrying capacity is so difficult to measure. Historical abundance is, itself, poorly known for many species. If there are no direct measures of historical abundance, it can be estimated by a method called “back-calculation” based on current abundance, a time series of annual human-caused mortality, and a model of population growth.

The US Marine Mammal Protection Act of 1972 is probably the most far-reaching and proactive national legislation for the conservation of marine mammals. It has two main conservation goals: to keep populations at their “optimum sustainable population” (OSP) levels and to keep populations as “functioning elements of their ecosystem.” OSP has been interpreted to be a range from a population’s

maximum net productivity level (typically thought to be between 60 and 80% of K for marine mammals) up to its carrying capacity. Populations below OSP are considered to be “depleted.” The US legislation is significant for having explicit goals to maintain populations near their natural levels instead of protecting them only after they have declined to dangerously low levels.

Similarly, in Europe, the Agreement on the Conservation of Small Cetaceans in the Baltic and North Seas (ASCOBANS) has a conservation goal to restore and/or maintain stocks at a level they would reach when there is the lowest possible anthropogenic influence. ASCOBANS has interpreted this objective to mean restoring and/or maintaining populations at or above 80% of K .

II. Trends

An upward or downward trend in population size is obviously a significant component in evaluating the status of a population; however, it is also one of the more difficult components to determine. Population trends have been directly estimated for only a tiny proportion of all cetacean populations. The primary problems are that population size cannot be estimated very precisely and population growth is typically slow.

Cetacean population size is usually estimated from line-transect SURVEYS. Trends can also be based on an index of relative abundance, such as the number of whales seen per hour on standard transects with consistent survey methods. In either case, the precision of the estimates is measured as a coefficient of variation ($CV = \text{standard deviation divided by the mean}$); CV s of 20% are considered very good and CV s of 30–50% are considered typical. Given their life-history constraints, cetacean populations can grow at a maximum rate of about 10% per year, and, for some slow-reproducing species [such as the killer whale (*Orcinus orca*) and sperm whale], maximum growth rates may be as low as 2–3%. There is no similar constraint on the rate at which populations can decline; however, there have been few instances where long-term rates of decline have been found to exceed 8% per year.

Statistical power is a measure of the probability of detecting a significant change in a population if that population is truly growing or declining. Power increases with the actual rate of change in population size and with the sample size (both the amount of survey effort and, more importantly, the length of the monitoring period). As a rule of thumb for cetaceans, at least 10 annual surveys with good precision ($CV < 20\%$) are required to yield a high probability (>80%) of detecting a 50% change in total population size. Taylor *et al.* (2007) found that in the US, where marine mammal monitoring is probably the best in the world, the majority of populations could decline by 50% without reliable statistical evidence of a decline. The situation is made even more difficult for endangered species [such as the baiji (*Lipotes vexillifer*) and vaquita (*Phocoena sinus*)], which become almost impossible to census as they become increasingly rare. A recent large-scale survey for baiji failed to find even a single individual (Turvey *et al.*, 2007), and the species is now considered “possible extinct” by IUCN. Similar to cetaceans, the detection of population trends for dugongs and manatees is extremely difficult.

The ability of scientists to detect trends in land-hauling pinniped populations is considerably better. Although total population size may be difficult to estimate, a segment of the population predictably returns to land to breed, give birth, or molt, and this segment can be counted accurately by ground-based observers or from aerial photographs. Growth or decline in this segment is taken as an index of trend for the entire population, so this kind of count is sometimes referred to as an index count. Index counts may be based, for example,

on the number of pups born or the number of total seals hauled out at the peak of the molting season. If index counts are used over a wide range of population sizes, ancillary research is typically required to ensure that the fraction of animals counted does not vary in a density-dependent manner (e.g., as per capita resources become scarce, the percentage of time spent foraging away from the beach might increase). Another factor making positive trends in pinniped populations easier to detect is that most are capable of growing at faster rates than cetaceans and sirenians. Abundance and trends are much harder to measure for pinnipeds that haul-out or pup on ice.

Porpoises, Overview

ANDREW J. READ

The porpoises are 1 of 10 families that constitute the suborder Odontoceti, or the modern toothed whales. The family Phocoenidae consists of six species, distributed in both hemispheres (Table 1). For many years, and in some areas still today, there

TABLE I
Living Species of Porpoises

Common name	Scientific name	Distribution
Harbor porpoise	<i>Phocoena phocoena</i>	Coastal Northern Hemisphere
Burmeister's porpoise	<i>Phocoena spinipinnis</i>	Coastal South America
Vaquita	<i>Phocoena sinus</i>	Gulf of California
Spectacled porpoise	<i>Phocoena dioptrica</i>	Southern Ocean
Dall's porpoise	<i>Phocoenoides dalli</i>	North Pacific
Finless porpoise	<i>Neophocaena phocaenoides</i>	Coastal South Asia

has been confusion regarding the terms “porpoise” and “dolphin.” In part, this is because some early taxonomic accounts included porpoises in the family Delphinidae, although all recent accounts separate the two groups. To confuse things further, fishermen have traditionally referred to bottlenose dolphins (*Tursiops* spp.) and other delphinid species as “porpoises” in many areas of the US. Despite their shared vernacular names, porpoises and dolphins are as phylogenetically distinct as are dogs and cats. These differences are manifested in their morphology, ecology, and behavior, as outlined below.

I. Origins

Our knowledge regarding the evolution of porpoises comes from inferences drawn from the fossil record and from the morphology and genotypes of living species. The earliest porpoise known is *Salumiophocaena stocktoni*, discovered in late Miocene strata of southern California, approximately 11 million years ago (Barnes, 1985). These early porpoises appeared at about the same time as the first dolphins. The dates of the origin of the two families are consistent with estimates of divergence between the cytochrome b genes of phocoenids and delphinids. Most other early fossil porpoises are known from the Pliocene in North and South America. Porpoises, dolphins, and monodontids, all members of the superfamily Delphinoidea, are likely to have descended from the Kentriodontidae, an extinct family of odontocetes. Like modern porpoises, the kentriodontids were rather small animals, approximately 2 m in length. Kentriodontids occurred in both the Atlantic and Pacific Oceans, but disappeared approximately 10 million years ago.

Analyses of the genome of living porpoises suggest that the finless porpoise (*Neophocaena phocaenoides*) is the most primitive, or basal, member of the family (Rosel *et al.*, 1995). This view is consistent with morphological evidence. Gaskin (1982) postulated that the earliest phocoenids radiated into temperate waters of both hemispheres from the tropics, where the finless porpoise is still found today. Other researchers (Barnes, 1985) maintain that phocoenids originated in temperate waters of the North Pacific Ocean, where the oldest fossils are located. With our current knowledge, it is not possible to resolve which of these two scenarios are correct. Molecular evidence indicates that all modern porpoises have evolved within the past few million years.

The nature of phylogenetic relationships among porpoises has been the subject of recent debate. Barnes (1985) suggested that the spectacled porpoise (*Phocoena dioptrica*) of the Southern Ocean is closely related to the Dall's porpoise (*Phocoenoides dalli*) of the North Pacific and that these two species should be classified as a subfamily, distinct

from the remaining four species. This view has not been supported by analysis of the molecular genome (Rosel *et al.*, 1995), however, which suggests a close phylogenetic relationship among the vaquita (*Phocoena sinus*), Burmeister's porpoise (*Phocoena spinipinnis*), and spectacled porpoise. Most current practices now separate the family into three genera: *Neophocaena*, *Phocoenoides*, and *Phocoena*. The first two genera are monotypic (the finless porpoise and Dall's porpoise) and the third contains four species (harbor porpoise *Phocoena phocoena*, vaquita, Burmeister's porpoise, and spectacled porpoise).

Periodic cycles of global cooling and warming have had profound effects on the modern biogeography of all cetaceans (Gaskin, 1982), and this holds true for the porpoises. For example, the distribution of the vaquita is currently restricted to the northern Gulf of California. In geographical terms, the closest relative of the vaquita is the harbor porpoise, which is found as far south as the coast of central California. Morphological and genetic evidence, however, indicate that the closest living relative of the vaquita is the Burmeister's porpoise, from the coastal waters of temperate South America. It is likely that, during a cool glacial period of the Pleistocene, ancestors of today's Burmeister's porpoises crossed the equator and were subsequently trapped in the Gulf of California by warming equatorial waters. This isolated population eventually gave rise to the vaquita.

The selective factors shaping the evolution of porpoises are only partially understood, but one important feature is paedomorphosis, the retention of juvenile characters in the adult form. The evolution of small size and early sexual maturation, when compared to most delphinids, is likely driven by paedomorphosis. This phenomenon may also explain convergent evolution with the delphinid genus *Cephalorhynchus*. The morphology, ecology, and behavior of these dolphins are remarkably similar to porpoises in many ways and they appear to have CONVERGED with porpoises in many aspects of their biology.

II. Morphology

Porpoises share many morphological attributes that distinguish them from other small cetaceans (Fig. 1). All six species are small, with no member of the family exceeding 250 cm in body length. Porpoises are stocky, robust animals, and lack the rostrum common to most delphinids. The appendages of most species are relatively small and, in the case of the finless porpoise, the dorsal fin is missing altogether. Many of these morphological features may be related to the thermal biology of porpoises and, particularly, to the challenges posed by small body size in a cold and conductive medium.

The skulls and postcranial skeletons of porpoises exhibit pronounced paedomorphosis (Barnes, 1985). In particular, the skulls of all porpoises are characterized by short rostra, large and rounded braincases, and delayed fusion of cranial sutures during ontogeny. As a result, the skulls of adult porpoises resemble those of juvenile specimens of other species. The same is true for some features of the postcranial skeleton. For example, the vertebral epiphyses of adult male harbor porpoises rarely display ankylosis, a feature used to diagnose physical maturity in delphinids. Several cranial features are diagnostic of the family, including raised protuberances on the premaxillae and the spatulate shape of the teeth. The latter feature is an easy way to distinguish porpoises from dolphins, which have conical teeth.

An unusual morphological feature of all phocoenid species, except for the Dall's porpoise, is the presence of epidermal tubercles along the leading edge of the dorsal fin. These small, raised protuberances develop shortly after birth and usually occur in several rows. Even the finless porpoise, which lacks a dorsal fin, possesses several rows of tubercles on its dorsal ridge. Tubercles are most prominent in the

Figure 1 This harbor porpoise (*Phocoena phocoena*) illustrates typical external morphology of the family *Phocoenidae*. Porpoises are small, stocky, robust cetaceans with short rostra and large, rounded braincases. Photograph by Ari Friedlaender.

Burmeister's porpoise and their presence provides the basis for the specific name *spinipinnis*. The function of these structures is unknown.

The pigmentation patterns of phocoenids vary considerably, although there are several features common to the family. Most porpoises possess patches of dark pigmentation surrounding the eye, although these patches are of varying prominence and contrast. The dark eye patch is particularly well developed in the spectacled porpoise. It is encircled by a narrow white line, which gives the species both its common and specific names. All porpoises (and most dolphins) exhibit a bridle, a system of stripes extending from the eye and blowhole to the apex of the melon. And most porpoises exhibit the general pattern of countershading, common to many odontocetes, of a dark dorsal cape and a lighter abdomen.

III. Ecology and Behavior

Our general knowledge of the ecology and behavior of porpoises is limited and these areas continue to be fertile subjects for research. Relatively few researchers have had the opportunity to study live vaquita, Burmeister's, or spectacled porpoises. The latter species is known primarily from a small number of STRANDINGS in remote areas of the southern hemisphere. In contrast, our knowledge of the ecology and behavior of harbor and finless porpoises is much more extensive (Read, 1999).

The radiation of phocoenids over the past few million years has allowed porpoises to colonize a variety of habitats in both hemispheres. The harbor porpoise, Burmeister's porpoise, and vaquita are coastal in nature, and the range of the finless porpoise extends well upstream into major river systems. The Dall's porpoise and spectacled porpoise are primarily pelagic animals.

There is little evidence of cooperative feeding in the family and it appears that individual porpoises usually forage alone. Most coastal species, such as the harbor and Burmeister's porpoise, feed on small pelagic fish, such as herring, anchovies, and capelin, and supplement this diet with demersal fishes. In contrast, Dall's porpoises feed primarily on the small mesopelagic fishes and squid that comprise the deep scattering layer. To date, DIVING BEHAVIOR has been studied for only the harbor porpoise, which can dive to depths of over 200m. Their small size makes it unlikely that any species of porpoise, even the pelagic Dall's porpoise, are exceptional divers. Dall's porpoises likely

take advantage of the daily vertical migration of their prey and feed at night when these mesopelagic fishes and squid are near the surface.

Porpoises are among the smallest and most paedomorphic cetaceans and these aspects of their biology are manifested in their reproductive biology. Compared to many delphinids, porpoises grow rapidly and reach sexual maturity at an early age, features promoted by paedomorphosis. For example, many female harbor porpoises attain sexual maturity in their third year of life, at an age where bottlenose dolphins are still accompanying their mothers. Both Dall's and harbor porpoises are capable of annual reproduction, and females of these species are often simultaneously lactating and pregnant. This demanding reproductive schedule is accompanied by a relatively brief lifespan—very few porpoises live longer than 20 years.

Although our knowledge of the social behavior of phocoenids is limited, we can say that, unlike many pelagic delphinids, porpoises usually occur alone or in small, fluid groups. This is also reflected in patterns of strandings. Porpoises generally strand singly, never in the large groups witnessed in some odontocete species. Occasionally, hundreds of porpoises have been observed together, but these are likely temporary aggregations, rather than stable groups. In general, it appears that porpoises typically exist in fission–fusion societies in which associations among individuals are extremely dynamic. The only long-term association known to occur is between a lactating female and her dependent calf. The duration of lactation varies among species, and perhaps among populations within species, but is unlikely to surpass 2 years in any phocoenid.

With the exception of the Dall's porpoise, porpoises are generally shy, unobtrusive animals that are difficult to sight and follow at sea. Unlike many delphinids, porpoises seldom, if ever, leap clear of the water. A typical surfacing sequence is characterized by a series of gentle rolls at the surface, followed by a longer submergence. Occasionally on calm days, harbor porpoises will lie quietly at the surface for short periods. Individuals seldom approach boats or ride the bow or stern waves of vessels. In contrast, Dall's porpoises are fast swimmers that often make a characteristic splash or “rooster-tail” when they surface. Dall's porpoises are also the only phocoenid that regularly approaches boats to ride the bow wave, a behavior they may have modified from riding the pressure waves produced in front of swimming baleen whales.

IV. Conservation

Most populations of phocoenids are affected adversely by human activities. Hunting, by-catches in commercial fisheries and habitat degradation have had profound impacts on the health and demography of many affected populations (Bjørge and Donovan, 1995). Only the spectacled porpoise of the Southern Ocean is largely free of the effects of human influences, although even this species has been taken as by-catch in fisheries off Tierra del Fuego. The nature of human activity posing a conservation threat varies from species to species, as does the conservation status of each species.

Porpoises living in coastal areas are affected by the modification, degradation, and destruction of habitat by humans. Particularly affected in this manner is the finless porpoise, which inhabits the temperate and tropical coasts of Asia and the Indian subcontinent, as well as the Yangtze River of China. Human activities, such as dredging, reclamation, pollution, and intense vessel traffic, are felt most keenly in coastal and riverine habitats where the density of humans is high. Thus, particular concern has been expressed for populations of finless porpoises in the South China Sea, adjacent waters, and the Yangtze River. Other coastal species of porpoises are not immune from such effects. Harbor porpoises,

for example, may be excluded from portions of their habitat in the North Atlantic and North Pacific by the use of high-intensity acoustic devices designed to keep pinnipeds away from salmon mariculture sites.

Harbor and Dall's porpoises have been hunted for their meat and blubber for many centuries. In the Danish Belt Sea, an annual hunt for harbor porpoises occurred from the fourteenth century until the early twentieth century. More than 1000 porpoises were taken annually between 1834 and 1874 in this hunt. Harbor porpoises have also been harvested from other areas, particularly the Bay of Fundy and western Greenland. A large-scale harpoon fishery for Dall's porpoises still exists off the coast of northern Japan. This hunt supplies meat for the domestic Japanese market, partially offsetting the reduction in the availability in whale meat following the moratorium in commercial whaling that began in 1986. The effects of this exploitation on populations of Dall's porpoises are not fully understood, but the magnitude of catches (more than 40,000 in 1988) is a cause for concern.

The most pressing and pervasive threat to populations of phocoenids is by-catch in commercial fisheries (Jefferson and Curry, 1994). Most porpoises are taken as by-catch in gill nets, often anchored on the bottom to catch demersal species. Porpoises seldom survive entanglement in this type of fishing gear. The causes of by-catches are unclear; it is uncertain, for example why animals with a sophisticated system of ECHOLLOCATION do not detect and avoid fishing nets (Nachtigall *et al.*, 1995). Nevertheless, all species of porpoises are taken as by-catch, sometimes in staggering numbers. The estimated annual mortality of harbor porpoises in Danish bottom gill net fisheries in the North Sea was almost 7000 between 1994 and 1998. The consequences of such large by-catches are undocumented, but have likely lead to past depletion. In some areas, such as the coastal waters of Peru, Burmeister's porpoises taken as by-catch gained commercial value for human consumption, so that the distinction between by-catches and directed hunting became blurred. By-catch is the most serious threat to the small endemic population of vaquitas in the upper Gulf of California. Only a few hundred vaquitas remain, and the species is still subject to by-catch in several gill net fisheries. The vaquita is the most endangered marine cetacean; its future depends on current conservation initiatives in Mexico. Unless all entangling nets are removed from the range of this species, it will likely join the Chinese river dolphin, or baiji (*Lipotes vexillifer*), as the second species of cetacean driven to extinction in modern times.

Predation on Marine Mammals

DAVID W. WELLER

I. Introduction

Although marine mammals are regarded as accomplished and sophisticated hunters, they too are preyed upon by a variety of terrestrial, avian, and aquatic predators. Predation is an ecological factor of significant influence on the behavior and organization of animal societies in general, and the need for protection from predation has likely been an important factor in the evolution of most marine mammal social systems. While the risk of predation is of little or no concern for some species, others exist under high levels of predatory pressure. A large portion of all marine mammals, ranging in size from the enormous blue whale (*Balaenoptera musculus*) to the relatively small sea otter (*Enhydra lutris*), are subjected to varying levels of predation. Responses to predators are complex, and include detection and avoidance, fleeing, seeking habitat features for cover, and active defense by individuals as well as coordinated groups.

While the topic of predation is expansive and multidimensional, the focus of the following review centers on the hunting and consumption of marine mammals by their predators. The definition of predation used here excludes parasitism, filter feeding, scavenging (carrion eating), or browsing, and is limited to situations in which an animal expends time and energy to locate living prey, and exerts additional effort to kill and consume it. Therefore, predation is distinguished from other forms of foraging in that it concludes with the death of an animal that offers some resistance against being discovered and/or being harmed.

II. Predation on Sireniens

The relatively slow moving and rather lethargic behavior of sireniens (manatees, *Trichechus* spp., and dugongs, *Dugong dugon*) makes them seem particularly vulnerable to predation. However, manatees and dugongs actually have few known natural predators, and appear to experience only occasional mortality due to predation. Although large sharks, crocodiles (*Crocodylus* spp.), and killer whales (*Orcinus orca*) are all considered to be potential predators, few records exist to confirm these suspicions (Anderson and Prince, 1985; Reeves *et al.*, 1992; Wells *et al.*, 1999). Evidence of predation, including tooth-scarring indicative of unsuccessful attacks by predators, has been only rarely observed during long-term field studies on West Indian manatees

(*Trichechus manatus*) in Florida and dugongs off Australia. The limited presence of marine predators in the relatively warm and shallow nearshore waters, rivers, and bays where these animals forage on marine vegetation may partially explain the paucity of observed predatory interactions. Further, the particularly thick skin and exceedingly dense bone characteristic of the sirenians may render them rather unpalatable and serve to deter potential predators.

Predation on sirenians does occur, however. For example, in South America, Amazon manatees (*Trichechus inunguis*) have been reported to be preyed on by jaguars (*Panthera onca*) and large sharks, and marine crocodiles may occasionally kill dugongs throughout their distribution (Reeves *et al.*, 1992; Wells *et al.*, 1999). Off western Australia, predation by killer whales on adult dugongs has been reported, including one occasion when 10 killer whales were observed attacking a group of approximately 40 dugongs in shallow water (Anderson and Prince, 1985). During this incident the dugongs were huddled tightly together in an antipredator response, while pieces of flesh and integument floated nearby in blood stained water. Residents of western Australia have also implicated “black porpoises” as predators of dugongs. However, what species these “porpoises” represent is entirely unclear. While some authors suggest that these “porpoise” attacks were likely to be killer whales, such records may also refer to one of several other mammal-killing cetaceans like the false killer whale (*Pseudorca crassidens*). It is conceivable, of course, that predation on sirenians is considerably higher than has been observed and reported. Predatory attacks on young animals, for example, may be particularly successful, and information regarding predator related mortality of species such as the West African (*Trichechus senegalensis*) and Amazon manatees that mainly occur in areas inaccessible to researchers is largely unknown.

III. Predation on Mustelids

Although sharks and killer whales represent the primary predators of sea otters, several terrestrial and avian predators have also been documented (Reeves *et al.*, 1992; Wells *et al.*, 1999). Coyotes (*Canis latrans*) are known to prey on recently weaned otters in parts of Alaska, and Russian brown bears (*Ursus arctos*) occasionally kill otters that haul-out along the shores of the Kamchatka Peninsula, Russia. Near Amchitka Island, Alaska, bald eagles (*Haliaeetus leucocephalus*) hunt sea otter pups (Sherrod *et al.*, 1975). Pups are particularly vulnerable to avian predation as they float unattended at the surface while their mothers are preoccupied with searching for food. The extraordinary buoyancy of young otter pups prevents them from readily submerging, and greatly reduces their chances of escaping attack by diving. Observations of bald eagles nabbing young otter pups from the surface of nearshore waters confirm that eagles use a hunting strategy similar to that used when capturing large fish. That is, pups are gathered from the water in the talons of an eagle, flown to the nest location, and meticulously devoured. Studies conducted on Amchitka Island between the 1950s and 1970s found that up to 28% of the prey remains in eagle nests were from sea otters. Interestingly, some nests contain high levels of otter remains while other nests have none. This finding suggests that some individual eagles may actually specialize on hunting sea otter pups.

While terrestrial and avian predation account for only a small portion of sea otter mortality, sharks represent a more formidable and common predator (Ames *et al.*, 1996). White shark (*Carcharodon carcharias*) attacks on sea otters along the California coast are thought to account for 9–15% of the total otter mortality recorded in this region. Curiously, there is little evidence from examination of white shark

stomach contents to suggest that sea otters are actually eaten by the individuals that attack them. Instead, otters are stalked and killed by white sharks off California but are apparently abandoned prior to consumption. The absence of sea otter remains in white shark stomachs cannot be considered conclusive at this time however, as only a small number of stomachs have been available for examination. Although other shark species are also suspected to occasionally kill sea otters, few specific details are available.

Killer whales are known predators of sea otters (Estes *et al.*, 1998; Hatfield *et al.*, 1998), but the small number of observed attacks suggests that otters are not preferred prey. Nonetheless, a substantial increase in the number killer whale attacks on sea otters was documented between 1992 and 1996 and corresponded with a notable decline in sea otter population levels over a large part of their western Alaska distribution (Estes *et al.*, 1998). It is unclear if this increase in observed killer whale attacks was due to greater observation effort, or represents a real increase in sea otter predation. If this change is merely related to increased observation effort, than killer whale predation on sea otters may not be as uncommon as previously suggested. However, if this finding represents a true increase in the rate of sea otter attacks it may be related to the relatively recent declines of other killer whale prey, such as Steller sea lions (*Eumetopias jubatus*) and harbor seals (*Phoca vitulina*).

IV. Predation on Pinnipeds

Of all the marine mammal groups, pinnipeds are probably subjected to the highest level of predation. While some pinniped species experience little or no predation pressure, others are so intensively hunted that important aspects of their natural history, including reproductive strategies, have evolved in response (Trillmich, 1984; Reidman, 1990; Wells *et al.*, 1999). Not even the largest pinnipeds such as the walrus (*Odobenus rosmarus*), bearded seal (*Erignathus barbatus*), and elephant seals (*Mirounga* spp.) are free from predation. Terrestrial predators of pinnipeds are particularly abundant in the subpolar and polar regions of the Northern Hemisphere, usually appearing in the form of polar bears (*Ursus maritimus*) and Arctic foxes (*Alopex lagopus*). Southern Hemisphere ice-seals are free from land predators, but instead have fierce aquatic predators such as the leopard seal (*Hydrurga leptonyx*) to contend with. Pinnipeds in temperate and tropical latitudes experience reduced terrestrial predation but are subjected to increased levels of attack by aquatic predators such as sharks and killer whales. When comparing Northern Hemisphere Arctic pinnipeds to Southern Hemisphere Antarctic pinnipeds, clearly divergent predator avoidance tactics are apparent. Arctic pinnipeds escape land predators by fleeing into the water while Antarctic pinnipeds escape aquatic predators by retreating onto ice.

All pinnipeds require a land or ice substrate for pupping, and this facet of their natural history makes them particularly vulnerable to attack in regions where terrestrial predators are present (Reidman, 1990). Golden jackals (*Canis aureus*), for example, are common at a Mediterranean monk seal (*Monachus monachus*) colony on the western coast of Mauritania, and have been reported to consume freshly dead monk seals and are suspected to also prey on living pups. Freshwater pinnipeds in Russia's Lake Baikal and in the Caspian Sea (*Pusa sibirica* and *P. caspica*, respectively) have no aquatic predators, but instead have an unusually high number of terrestrial adversaries. Wolves (*Canis lupus*) and eagles prey on newborn Caspian seals (*Pusa caspica*), and brown bears occasionally hunt Baikal seals (*Pusa sibirica*). Ringed seal pups (*Pusa hispida*) inhabiting Finland's Lake Saimaa and Russia's Lake Ladoga are preyed upon by red foxes

(*Vulpes vulpes*), and suspected to also suffer some level of mortality due to attacks by ravens (*Corvus corax*), wolves, dogs, wolverines (*Gulo gulo*), and other terrestrial predators (Reeves *et al.*, 1992). Similarly, brown bears, wolves, and avian predators including eagles and ravens, sometimes also kill spotted seals (*Phoca largha*) in the Sea of Okhotsk. Glaucous gulls (*Larus hyperboreus*) and ravens may occasionally kill ringed seal pups, and gulls sometimes peck at the eyes of gray seal pups (*Halichoerus grypus*) resulting in some level of mortality (Reeves *et al.*, 1992).

Additional terrestrial predators also hunt pinnipeds at their haul-out sites. Coyotes, for example, prey on harbor seal pups in the Pacific Northwest, and are responsible for at least 16% of the pup mortality within Puget Sound, Washington (Steiger *et al.*, 1985). Similarly, bears and mountain lions (*Felis concolor*) may have historically preyed on northern elephant seals (*Mirounga angustirostris*) along the California coast (Reidman, 1990). In the Southern Hemisphere, pumas (mountain lions) have been reported to prey on southern sea lion pups (*Otaria flavescens*). South African fur seals (*Arctocephalus pusillus*) that breed along the mainland coast of the southern African continent are preyed upon by brown hyenas (*Hyaena brunnea*) and black-backed jackals (*Canis mesomelas*), and South American sea lion pups (*Arctocephalus australis*) are probably attacked by mountain lions (Reeves *et al.*, 1992).

Arctic foxes have been described as hunters of small animals and birds, and as a scavenger of marine mammal remains left by polar bears. However, in parts of the eastern and western expanses of the Beaufort Sea, this fox is considered an active predator of newborn ringed seal pups (Smith, 1976). In early spring, ringed seals give birth and rest in “subnivean birth lairs”—ice caves complete with breathing holes constructed beneath the snow. These lairs provide both shelter from cold temperatures and protection from predators by providing a physical barrier that makes it more difficult for surface predators to detect a newborn pup. Nevertheless, foxes and polar bears enter and kill pups concealed within their subnivean homes with relative frequency. Keen olfaction allows foxes to locate lairs that may be buried under as much as 150 cm of snow. In the Beaufort Sea, Arctic foxes enter about 15% of the birth lairs present within an area. Although the annual average predation rate by Arctic foxes on ringed seal pups is about 26%, rates as high as 58% have been recorded (Smith, 1976). Ringed seals are also preyed upon by polar bears, and may occasionally be attacked by red foxes, wolverines, wolves, dogs, and several avian predators. As such, ringed seals are subjected to perhaps the highest level of predation experienced by any of the marine mammals.

A. Polar Bears

Throughout their circumpolar range, the major prey of polar bears consists of pinnipeds. Polar bears are versatile predators and are well adapted for catching Arctic pinnipeds (Stirling, 1988). Predation is particularly heavy on pups, as they represent an easily obtained food resource. Foraging strategies employed by polar bears range from sit-and-wait tactics to active stalking and pursuit of seals on ice and in the water. When stalking seals on ice, bears “creep” along with their heads held low, often momentarily hiding behind snowdrifts and irregularities in the ice. Despite their relative stealth and excellent ability to detect prey by olfaction, bears often have little success sneaking up on seals (Stirling, 1988). Observations of bears hunting, and in at least one instance capturing, free-swimming seals in ice-free waters, have also been reported. One of the sit-and-wait strategies employed by polar bears occurs while hunting ringed seals. Ringed seals forage for food under ice-covered waters throughout the winter, and must therefore maintain breathing holes in which to surface. Polar bears seek out

such breathing holes, and often patiently await the arrival of an unsuspecting seal. When a seal surfaces in the hole for a breath of air, the bear quickly grasps it and drags it from the water onto the ice.

The ringed seal is a main staple of polar bear diet, although in the Canadian Arctic, bearded seals and harp seals (*Pagophilus groenlandica*) are taken to a lesser extent (Reeves *et al.*, 1992). Harp and hooded seals (*Cystophora cristata*) are particularly vulnerable to predation on the spring pupping grounds, where polar bears may kill more pups than can be consumed. In Alaska, most of the ringed seals attacked by polar bears are over 6 years of age, while in the Canadian Arctic it is mainly 1 to 2-year-old seals that are killed. Polar bears are largely unsuccessful hunting adult ringed seals due to their nearly continuous antipredator vigilance. This vigilance behavior is characterized by constant head-lifting and scanning of the nearby environment for the presence of predators. In late spring, polar bears enter a period of intense feeding that corresponds with the onset of the ringed seal pupping season. During this time, bears prey heavily on pups by digging into birth lairs; adult female seals attempting to protect their pups are also occasionally killed.

Walrus are sometimes preyed upon by polar bears, but this massive obobenid represents a formidable adversary quite capable of killing predatory bears (Stirling, 1984). The extent of polar bear predation on walrus is not well known, and is likely to vary from region to region. Walrus calves, young juveniles, and sick individuals are most vulnerable to polar bear predation. While hunting walrus, bears often cause entire hauled out herds to “stampede” into the water by rushing toward them. Although most individuals in the stampede easily escape approaching bears, calves or young animals may be crushed or injured in the ensuing chaos, making subsequent capture substantially easier.

B. Pinnipeds

Several pinniped species are recognized as predators of other pinnipeds, and in some locations are responsible for a significant portion of the annual mortality incurred by regional populations (Reidman, 1990). The most ferocious pinniped predators include the leopard seal in the Southern Hemisphere and the walrus in the Northern Hemisphere. In addition, several sea lion species are notorious for feeding on pinnipeds. Two types of pinniped–pinniped predation occur, one at the intraspecific level (cannibalism, within species) and another at the interspecific level (between species). In some cases, particular individuals (usually males) specialize in the predation of pinnipeds. For instance, young male Steller sea lions are known to prey on harbor seals off Alaska, and have been noted to account for approximately 4–8% of the mortality reported for Northern fur seal pups (*Callorhinus ursinus*) at St. George Island, Alaska (Gentry and Johnson, 1981). Adult male Steller sea lions may also prey on other pinnipeds, as was recorded for one individual at Año Nuevo, California, who was observed feeding on a small California sea lion (*Zalophus californianus*). Similarly, Southern sea lions have been observed preying on South American fur seals (*Arctocephalus australis*), and at Punta San Juan, Peru, over 8% of the fur seal pups are killed by marauding sea lions during the breeding season. Off Macquarie Island in the sub-antarctic, one young male Hooker’s sea lion (*Phocartos hookeri*) was thought to be responsible for the mortality of 43% of the fur seal pups (*Arctocephalus gazella* and *A. tropicalis*) from a particular year. At the Snares Islands, New Zealand, Hooker’s sea lions have also been observed to prey on New Zealand fur seal pups (*Arctocephalus forsteri*). Finally, gray seals have been reported to consume pups of their own species, but it is unclear if this represents actual predation or merely cannibalistic scavenging of beach cast carcasses.

1. *Walrus* Walrus are primarily bottom or benthic feeders whose diet consists largely of bivalve mollusks, a variety of invertebrates, and fish. In addition, they also prey on marine mammals, and are known to feed on bearded seals, ringed seals, largha (spotted) seals, harp seals, and young walrus (Lowry and Fay, 1984). Adult and subadult male walrus are typically responsible for pinniped kills, but females in the Chukchi Sea have also been observed eating seals. Some walrus are habitual predators of other marine mammals. Individuals that regularly attack seals develop massive chest and shoulder muscles, have long and slender tusks, and their upper torsos and normally ivory colored tusks are stained amber from consuming the oil-rich blubber of their prey (Reeves *et al.*, 1992). In general, walrus kill pups and young individuals, but on occasion mature adult pinnipeds are also taken. Observations of attacks on harp seal pups and bearded seals are characterized by walrus impaling the prey with their tusks. Although very little of the skeletal muscle and bone of their mammalian prey are consumed, walrus methodically devour most, if not all, of the highly caloric hide and blubber.

Only since the 1970s have reports of seal-eating walrus become common (Lowry and Fay, 1984). This relatively recent phenomenon has been linked with the almost doubling of the Pacific walrus population between the 1960s and the early 1980s. Although Pacific walrus numbers are currently thought to be in decline, the nearly 20 year increase in population size certainly elevated the probability of contact between walrus and other pinniped species, and may help to explain the greater use of seals as a food source in the past several decades.

2. *Leopard Seals* The leopard seal is known to prey on penguins, sea birds, fish, squid, krill, and pinnipeds. In certain parts of their range, pinnipeds are an important part of leopard seal diet, while in other areas pinnipeds are rarely taken (Reidman, 1990). Leopard seals commonly hunt a variety of pinnipeds, but young crabeater seal pups (*Lobodon carcinophaga*) are probably the most frequently attacked and form an important part of the leopard seal diet between November and January (Siniff and Bengtson, 1977). After January, crabeater seal pups have physically developed to the point where they are better able to escape leopard seal predation, and the rate at which they are taken declines.

Parallel tooth scars resulting from unsuccessful leopard seal attacks are quite common on crabeater seals. A study of crabeater seals in 1976 reported that 78% of 85 adult seals handled for research purposes had scars likely to have resulted from interactions with leopard seals (Siniff and Bengtson, 1977). Fresh wounds were far more common on subadults than adults, suggesting that immature animals up to the end of their first year were most likely to be attacked, and it is thought that pups younger than 6 months are probably unlikely to survive encounters with leopard seals. The relatively high level of predation on crabeater seals is believed to represent a food source potentially more important to leopard seals than either krill or penguins.

3. *Sharks* Sharks represent an important predatory threat to a variety of temperate and tropically distributed pinnipeds (Reidman, 1990; Wells *et al.*, 1999). It is probable that all pinniped species, with the exception of inland lake seals, experience some level of shark predation. While the extent of shark attack on pinnipeds is not understood, it is nevertheless thought to play an important role in the population dynamics, life history, and behavior of some pinniped populations. For example, the high incidence of attacks by tiger (*Galeocerdo cuvier*) and white-tip sharks (*Triaenodon obesus*) on Galápagos fur seals (*Arctocephalus galapagoensis*) is thought to

Figure 1 Northern elephant seal (*Mirounga angustirostris*) with shark-inflicted wound near the hindflippers. Photo by Thomas A. Jefferson.

have contributed to their exceptionally long 3-year period of maternal investment. It has been suggested that this extended period of maternal care reduces the amount of time pups need to spend in the water foraging, which in turn significantly reduces the risk of shark predation (Trillmich, 1984).

White sharks are a common predator of pinnipeds, with seals, sea lions, and fur seals regarded as preferred prey in some regions of the world because of the high lipid stores contained within their blubber (Reidman, 1990). Gray seals and harbor seals are commonly hunted by white sharks off eastern Canada, and northern elephant seals, Steller sea lions, harbor seals, and California sea lions represent common shark prey in the northeastern Pacific. Southern Hemisphere white sharks focus their attacks primarily on fur seals off South Africa, Australia, New Zealand, South America, and the Galápagos Islands, but also occasionally prey on New Zealand and Australian (*Neophoca cinerea*) sea lions (Reidman, 1990).

Off central and northern California, the diet of white sharks consists largely of pinnipeds (Ainley *et al.*, 1981; Le Boeuf *et al.*, 1982). In particular, white sharks are a major predator of northern elephant seals throughout their entire breeding range, with seals of all age and sex classes vulnerable to attack. A large white shark is capable of killing and consuming elephant seals weighing as much as 500 kg and approximately 3.5 m in length (Reidman, 1990).

The hunting behavior of white sharks on northern elephant seals has been well described near the Farallon Islands off northern California (Ainley *et al.*, 1981; McCosker, 1985). White sharks typically attack elephant seals at or near the surface and usually within several kilometers of the islands. In most cases, white sharks approach their prey from below and to the rear, grasp them in their teeth and carry them underwater, release them, and then wait for the prey to die; usually as a result of excessive blood loss. Many shark attacks are unsuccessful, as evidenced by the high incidence of shark-related lacerations and scars on the bodies and appendages of pinnipeds that escape capture (Fig. 1). The nature of these injuries suggests that when attacked from the rear, foreflipper swimming sea lions are more likely to escape than are hindflipper swimming elephant and harbor seals. Most sea lions with evidence of shark-related injuries have lower body and hindflipper injuries, whereas the majority of surviving elephant and harbor seals bear upper body injuries. While sharks sometimes inflict massively disfiguring wounds

to pinnipeds, most injured seals that make it to land appear to survive. However, pregnant elephant seals that withstand shark-related injuries usually lose their pups, give birth to a stillborn, abandon the pup shortly after birth, or fail to wean the pup successfully.

In tropical regions, white sharks are less numerous and white-tip reef, gray reef (*Carcharhinus amblyrhynchos*), and especially tiger sharks represent the major pinniped predators. Tiger sharks hunt Hawaiian monk seals (*Monachus schauinslandi*) of all ages off the northwestern Hawaiian Islands (Alcorn and Kam, 1986). Although other predators like hammerhead (*Sphyrna* spp.) and mako sharks (*Isurus* spp.) also occur off northwestern Hawaii, they apparently do not attack monk seals with any regularity. Gray reef sharks are frequently present when tiger sharks kill monk seals, but their presence is thought to represent scavenging rather than direct predation.

A high number of monk seals bear shark-inflicted wounds and scars, indicating that not all predatory attacks are successful. Adult male monk seals seem to have the highest incidence of scarring, suggesting that animals of other age classes are less likely to survive attack (Hiruki *et al.*, 1993). Highly scarred males may also be attributed to the elevated aggressiveness in males during the breeding season, and their propensity to attack or chase approaching tiger sharks. In addition to direct kills of monk seals, the severity and timing of nonfatal injuries to individual females may reduce overall reproductive success. Field observations confirm that female monk seals suffering major, but non-fatal, shark-related injuries have shorter mean lactation periods, and overall lower pup survival. It has been suggested that the combination of lethal and nonlethal tiger shark attacks on Hawaiian monk seals may be hindering the recovery of this endangered population.

Pinnipeds (and cetaceans) are regularly tormented by a diminutive pest called the cookie-cutter shark (*Isistius brasiliensis*). This small squaloid shark, ranges in size from 14 to 50 cm, and inhabits deep tropical and subtropical waters of the Atlantic, Pacific, and Indian Oceans. By use of rasping jaws and teeth well suited to cutting, cookie cutter sharks attach themselves to their marine mammal victims and remove small circular plugs of skin and blubber. While these attacks are nonlethal, they represent a peculiar form of predation that falls outside the definition set forth at the beginning of this review, but is nevertheless of importance to recognize.

4. Killer Whales The diet of killer whales varies considerably between and within geographic regions. Some forms of killer whales, termed “transients,” are mammal eaters, while others, termed “residents,” base their diet on fish (Ford *et al.*, 1994; Ford and Ellis, 1999). Mammal-eating killer whales have been observed to hunt at least 14, and are suspected to take as many as 24, species of pinnipeds (Jefferson *et al.*, 1991). All pinniped species, with the exception of inland lake seals and the monk seals, probably endure some level of killer whale predation.

Pinnipeds comprise a substantial part of the diet for some transient killer whale populations, and observations of predatory events have been witnessed in a variety of locations from around the world. In subpolar and polar areas, where killer whales are most abundant, reports of attacks on pinnipeds are particularly common. Killer whales attack pinnipeds in both offshore and nearshore regions, and often in close proximity to terrestrial haul-out sites (Fig. 2).

Of all the pinniped species hunted by killer whales, southern elephant seals (*Mirounga leonina*), southern sea lions, harbor seals, Steller sea lions, walruses, and California sea lions have been most commonly recorded as prey species. During a 25-year period, approximately 62% of the transient killer whale attacks observed off British Columbia and Washington were on harbor seals (Ford and Ellis, 1999). Harbor

Figure 2 Killer whale (*Orcinus orca*) patrolling a harbor seal (*Phoca vitulina*) haul-out site. Photo by Robin W. Baird.

seals are particularly abundant in this part of the world, and appear to be relatively easy prey for killer whales to capture and kill, perhaps accounting for the apparent dietary preference on this pinniped species. Steller sea lions, which account for about 7% of all observed attacks, are far more difficult to capture, and the large size obtained by adult males combined with their pronounced canines make attack potentially more dangerous. Other less frequently taken pinniped prey includes California sea lions and northern elephant seals.

Pinnipeds are attacked by lone killer whales and by groups ranging in size from 2 to 30 or more, but the majority of reported attacks are by pods of 10 or less. Killer whales have often been referred to as “pack hunters” because of their tendency to forage cooperatively and employ coordinated maneuvers to capture mammalian prey (Baird and Dill, 1995; Baird, 2000). A well-described example of this coordination was witnessed in the Antarctic, where a group of killer whales was observed to work together to generate a wave large enough to sweep a crabeater seal off an ice floe and into the water so that it could be captured (Smith *et al.*, 1981).

Killer whales use a variety of strategies to kill pinnipeds, including ramming them with their rostrums or heads, flinging seals and sea lions high into the air with an abusive slap of their tail flukes, and violently shaking prey while grasped tightly in their mouths. Transient killer whales employ great stealth and remain silent while hunting, so as not to announce their presence to potential prey. Although transients typically hunt for prey near to shore where they are hidden by wave action and turbulence, they also are capable open water foragers. When whales encounter potential prey in open water, one observed hunting strategy is for group members to take turns rushing the prey and striking it with their flukes or ramming it with their heads. Once killed, the pinniped prey is shared among group members, similar to the food sharing behavior observed in social carnivores such as lions (*Panthera leo*) and wolves.

At Peninsula Valdés, Argentina, and on Possession Island, in the Crozet Island Archipelago, killer whales intentionally strand themselves in an effort to hunt sea lions and elephant seals that are on or near the beach. Southern seal lions and southern elephant seals are hunted off Peninsula Valdés (Lopez and Lopez, 1985), while on Possession Island, whales typically take newly weaned southern elephant seal pups (Guinet, 1991). In general, pups and small adult seals are most vulnerable, but adults are also occasionally killed. Once a seal or sea lion has been captured from the beach or nearshore area, they

are usually held in the mouth of a killer whale by one of the flippers or taken crossways in the mouth and vigorously shaken. Sometimes, captured pups are exchanged between members of the killer whale pod. Intentional stranding behavior also occurs in the absence of prey, suggesting that adult killer whales may actually teach their youngsters the finer aspects of this foraging strategy.

V. Predation on Cetaceans

Although killer whales and sharks are responsible for most attacks on whales, dolphins, and porpoises, other cetaceans such as false killer whales, pygmy killer whales (*Feresa attenuata*), and pilot whales (*Globicephala* spp.) also represent potential predatory threat. In addition to these aquatic predators, one terrestrial predator, the polar bear, successfully hunts beluga whales (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*) in Arctic areas (Smith and Sjare, 1990). River dolphins appear to be the only cetacean group free from natural predation, although it has been suggested that freshwater caiman in South America may occasionally take young dolphins (Leatherwood and Reeves, 1983). Finally, killer whales are likely to experience little or no mortality related to predation.

A. Blackfish

Three members of the delphinid family, including the false killer whale, pygmy killer whale, and short-finned pilot whale (*Globicephala macrorhynchus*), are thought to be hunters of other cetaceans. Each of these species have teeth and jaws suitable for killing and handling large mammalian prey, and all have been observed to at least occasionally prey on other dolphins. Of these three “blackfish,” the false killer whale is best known for attacks on small pelagic dolphins, and also has a record of harassing humpback (*Megaptera novaeangliae*) and sperm whales (*Physeter macrocephalus*). A series of observations, mainly by marine mammal observers onboard purse-seine boats fishing for yellowfin tuna (*Thunnus albacares*) in the eastern tropical Pacific (Perryman and Foster, 1980), have detailed false killer whale attacks on pantropical spotted (*Stenella attenuata*) and spinner dolphins (*S. Longirostris*). Although nearly two-dozen attacks were recorded, false killer whale predation on cetaceans outside of the eastern tropical Pacific is rare, suggesting that the high incidence of attack on the yellowfin tuna grounds may be site and circumstance specific. That is to say, false killer whales may be utilizing a prey resource related to tuna fishing operations (i.e., dolphins being released from temporary capture in fishing nets) which is unavailable outside of the eastern tropical Pacific.

Large whales, such as sperm whales and humpback whales, are also subjected to predatory advances by false killer whales. Recently, a group of false killer whales was observed harassing sperm whales off the Galápagos Islands (Palacios and Mate, 1996). In this event, no sperm whale mortality was recorded, but the false killer whales did inflict at least superficial injury to several individuals, and elicited noticeable fear reactions. Similar, albeit uncommon, events have also been suggested for interactions between false killer whales and humpback whales.

Pygmy killer whales have also been observed in predatory attacks on small dolphins during fishery operations in the eastern tropical Pacific, although observations of this nature are less common than those recorded for false killer whales. The predatory habits of pygmy killer whales on other cetaceans are poorly understood. In captivity, this species has been implicated in the death of a young pilot whale

and dusky dolphin (*Lagenorhynchus obscurus*), but it is unclear if these events led to consumption of the prey (Pryor *et al.*, 1965).

Similarly, few records regarding pilot whale predation on other cetaceans are available. Although pilot whales are not generally known to prey on marine mammals, records from the eastern tropical Pacific suggest that this species does chase, attack, and may occasionally eat dolphins during fishery operations (Perryman and Foster, 1980). The incidence at which these predatory events occur, however, is very low. In captivity, pilot whales have been noted to eat stillborn and young dolphins. Short-finned pilot whales have been observed harassing sperm whales in the Gulf of Mexico and off the Galápagos Islands, and although such harassment has been nonlethal, these events nevertheless often elicit a pronounced fear response, called a “marguerite formation”, by sperm whale groups (Weller *et al.*, 1996). The marguerite is a defensive formation, in which group members form a heads-in and tails-out circular arrangement resembling the petals of a flower. By placing the powerful flukes, a source of potential danger for predators, toward the outside and containing particularly vulnerable individuals, such as calves, on the inside of the formation, sperm whales can usually defend themselves from harm. This marguerite response has also been noted for sperm whale groups under lethal attack by killer whales (Pitman *et al.*, 2001) and when being hunted by whalers. Therefore, the formation of a marguerite in response to pilot whale harassment suggests that sperm whales do at times appear to be threatened by this species. It remains unclear, however, if such harassment by pilot whales represents actual predatory intent, or if such interactions are merely practice hunting or social play.

As suggested by the accounts presented here, interactions between false killer whales, pygmy killer whales, and pilot whales with other cetaceans are not particularly common. Of the lethal attacks recorded to date for each of these three blackfish species, all have been in relatively unnatural situations. That is, attacks have occurred either in captivity where species that might normally avoid each other are maintained in the same confines, or centered around the eastern tropical Pacific tuna fishing operations where smaller dolphins may become available prey due mainly to capture fatigue associated with the fishing industry. Therefore, it is difficult to assess the regularity of marine mammal predation by these several species, and the scarcity of observed predatory events suggests that marine mammal prey is likely to be secondary to an otherwise fish- and squid-based diet.

B. Sharks

Sharks represent a significant predatory threat to some populations of dolphins. Crude estimates of predation rates, as determined by the proportion of dolphins within a study population possessing shark-inflicted scars and injuries, vary greatly. Shark-related scars on odontocetes are particularly notable for some populations, while others go seemingly untouched. Results from several long-term photoidentification studies of bottlenose dolphins (*Tursiops truncatus* and *T. aduncus*) have documented shark bite scar rates as low as 1% off southern California, an intermediate rate of 22% in western Florida, and up to about 37% off eastern Australia (Corkeron *et al.*, 1987; Wells *et al.*, 1999; Connor *et al.*, 2000). The frequency of scars may also vary for different dolphin species within the same region. For example, off South Africa, where humpbacked dolphins (*Sousa chinensis*) and bottlenose dolphins overlap in distribution and habitat use, the former species has substantially more scarring related to shark attack than does the latter (Cockcroft *et al.*, 1989).

Interestingly, the proportion of individuals bearing crescent shaped shark bite wounds is considerably higher for nearshore species than it is for their offshore counterparts. This apparent discrepancy may be

attributable to a variety of factors. To date, most long-term studies on dolphin populations have been conducted nearshore, increasing the opportunity to observe shark scarring. Alternative explanations include the idea that predation on oceanic dolphins is less common overall, or that shark attacks in the open ocean are generally more successful. One theory that may at least partially explain why nearshore dolphins have higher rates of scarring is related to habitat features. The habitat of nearshore cetaceans offers a variety of “cover” features, such as kelp and surf, which may make escape from a predator more successful, while oceanic species have no such cover, and depend solely on fleeing or the protection offered by conspecifics within their social group to escape fatal attack (Wells *et al.*, 1999; Connor *et al.*, 2000).

Tiger sharks, dusky sharks (*Carcharhinus obscurus*), white sharks, and bull sharks (*C. leucas*) are most often implicated in attacks on nearshore dolphins and porpoises. Other sharks, including oceanic white-tip and hammerhead sharks have also been observed to occasionally attack dolphins. Tiger sharks are notorious predators of spinner dolphins (*Stenella longirostris*) off the Hawaiian Islands (Norris *et al.*, 1994), while white sharks prey on a variety of odontocetes ranging in size from the minute harbor porpoise (*Phocoena phocoena*) to more substantial beaked whales, and perhaps even newborn mysticete whales. Evidence of shark predation on baleen whales is relatively uncommon, but a report of a tiger shark attacking a young humpback whale has been recorded. Similarly, large sharks (and killer whales) were observed circling a group of sperm whales in which one adult female was giving birth, but no direct attack was noted. Although the numbers of observations regarding shark attack on large whales are few, it is reasonable to assume that some predatory events probably do occur at least occasionally.

While predation by sharks is of particular concern for cetaceans in the tropics and subtropics, attacks in other regions also occur. The remains of a complete southern right whale dolphin (*Lissodelphis peronii*) fetus as well as the genital region of an adult female were found in the stomach of a sleeping shark (*Somniosus pacificus*) off coastal Chile (Crovetto *et al.*, 1992). In addition, Greenland sharks (*S. squamulosus*) have been reported to prey upon narwhals in the eastern Canadian Arctic, and franciscana dolphins (*Ponotoporia blainvillei*) have been found in the stomachs of seven-gilled (*Heptranchias perlo*) and hammerhead sharks off Brazil (Leatherwood and Reeves, 1983). While each of these accounts is suggestive of predation, they should be considered with caution, as it is unclear if the aforementioned sharks actually attacked living dolphins or if the remains identified from stomach content analyses were attributable to scavenging.

C. Polar Bears

Although pinnipeds are the principal marine mammal prey of polar bears, they also actively hunt and occasionally consume narwhal and beluga whales (Lowry *et al.*, 1987; Smith and Sjare, 1990). Polar bears off western Alaska, for example, have been observed “fishing” beluga whales and narwhals out of small openings in the ice (Fig. 3), sometimes killing numbers far greater than can possibly be eaten. In one particular event, polar bears killed and dragged onto the ice at least 40 ice-entrapped beluga whales (Lowry *et al.*, 1987), and in a similar episode, a single male polar bear was seen to successfully capture 13 beluga whales from a small opening in the ice over a short period of time.

Beluga whales regularly swim into extremely shallow estuary and river channel areas. On rising tides, whales penetrate far into rivers and creeks, often moving into waters so shallow that they can rest on the bottom while a considerable portion of their body remains above

Figure 3 Polar bear (*Ursus maritimus*) hunting beluga whales (*Delphinapterus leucas*). Photo by Sue Flood/BBC Natural History Unit.

the surface. This behavior can sometimes result in partial stranding, but the animals are typically able to free themselves. On occasion, however, complete stranding occurs accidentally, during which time individual belugas remain beached until the return of the incoming tide. At least some beluga whale mortality results from polar bears feeding on stranded individuals (Smith, 1985). In addition to opportunistic foraging on temporarily beached whales, individual bears have been observed wading into shallow waters and chasing whales passing near to shore (Smith and Sjare, 1990). Predatory polar bears also actively stalk free-swimming belugas from ice edges. In this situation, bears either roam along the ice edge, or remain motionless while awaiting a group of beluga whales to move within striking range. When a whale passes near enough, a polar bear will launch itself from the ice and onto the back of the unsuspecting beluga. In one incident, a single polar bear was observed to use this hunting tactic to capture and kill two beluga whale calves within 24h. This hunting technique requires that bears accurately time their jumps, and more amazingly, handle and debilitate their prey in an aquatic medium. Further, once dead, the beluga must be pulled from the water and dragged onto the ice. In cases where this hunting technique has been directly observed, the captured belugas are generally young, smaller individuals.

Polar bears have also been observed to attempt attacks on belugas while swimming in pursuit of them (Smith, 1985; Smith and Sjare, 1990). Thus far, no successful attacks have been documented for this aquatic hunting tactic, and on at least one occasion, a group of belugas was seen to chase a polar bear out of the water with group coordinated threat behavior including tail lashing and repeated close approaches toward the swimming bear. Aquatic stalks by polar bears are largely unsuccessful due to the greater mobility and speed of whales in the water. In fact, the willingness of belugas to closely approach bears in the water, either out of curiosity or in a possible attempt to harass them, suggests that they have little fear of this predator when it is waterborne.

In contrast to the inshore habits of beluga whales, narwhals prefer deeper water, and are commonly sighted in considerable numbers offshore of beluga groups in the eastern Canadian Arctic. Polar bear predation on narwhals has been rarely observed, with the few attacks reported consisting of narwhals stranded on tidal flats or entrapped by ice. In one incident, three adult female narwhals and one neonate stranded on a tidal flat were being consumed by polar bears (Smith and Sjare, 1990). All three of the adult narwhals bore extensive claw marks and their blubber had been stripped dorsally from the head area back to the tailstock.

Figure 4 Killer whale (*Orcinus orca*) attacking a Dall's porpoise (*Phocoenoides dalli*). Photo by Robin W. Baird.

D. Killer Whales

In addition to pinnipeds, dugongs, and sea otters, mammal-hunting killer whales (termed transients) also prey upon some species of dolphins and porpoises, and even occasionally attack sperm and baleen whales (Baird, 2000). Transient killer whales are relentless hunters, spending up to 90% of each daylight period searching for food. In addition to marine mammal prey, terrestrial animals such as deer (*Odocoileus hemionus*) and moose (*Alces alces*) are also occasionally taken (Jefferson *et al.*, 1991). In these cases, killer whales opportunistically intercept individual deer and moose as they swim between coastal islands.

More than most other marine mammals, killer whales are social hunters, often working together to capture prey in a coordinated manner resembling that of pack hunting social carnivores like hyenas, wolves, and lions (Baird, 2000). Transients typically form slightly larger groups while hunting dolphins and porpoises, as compared to group sizes observed during pinniped attacks (Baird and Dill, 1995). Most hunts of small cetaceans have some component of chase, making more individuals necessary to prevent prey escape. Sometimes these high-speed chases result in a killer whale leaping free from the water with a dolphin or porpoise in its mouth. When dolphin prey are assembled in relatively large schools, killer whales often attempt to separate one or a few individuals from the group before commencing active pursuit. Once a prey item becomes exhausted, killer whales then attempt to kill the animal by breaching on it, ramming it from below, tossing it into the air, or grasping it in their teeth (Fig. 4).

A variety of dolphins and porpoises are hunted by killer whales. Off New Zealand, common dolphins (*Delphinus delphis*) are most commonly attacked, but bottlenose dolphins and dusky dolphins are also hunted (Visser, 1999). Stomach content analysis of a stranded killer whale off southern Brazil found the remains of three franciscana dolphins. In the Gulf of Mexico, a pod of killer whales chased and killed a pantropical spotted dolphin, and Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), Dall's porpoise (*Phocoenoides dalli*), and harbor porpoises are some of the more commonly hunted small cetaceans off the west coast of North America (Jefferson *et al.*, 1991; Baird, 2000; Pitman *et al.*, 2003). In addition to these relatively small cetaceans, larger prey, including northern bottlenose whales (*Hyperoodon ampullatus*) and long-finned pilot whales (*Globicephala*

melas) are also occasionally hunted by killer whales. In Arctic waters, killer whales sometimes herd beluga whales into shallow inlets and creek openings where they then rush into the group to capture young animals. Further, killer whales have been seen feeding on beluga whales and narwhals in open waters and on animals trapped by sea ice (Steltner *et al.*, 1984; Campbell *et al.*, 1988; Smith and Sjare, 1990).

An interesting study of contrasts exists for transient killer whales off British Columbia and in Prince William Sound, Alaska. Although transients in both regions apparently feed exclusively on marine mammals, harbor seals are the most common prey item of whales off British Columbia, while transients in Prince William Sound prey about equally on harbor seals and Dall's porpoises (Ford and Ellis, 1999; Saulitis *et al.*, 2000). Low harbor seal abundance in Prince William Sound may account for the apparent preference for porpoise prey in this region.

Although killer whales tend to focus their predatory attentions on pinnipeds and small odontocetes, numerous reports of attacks on sperm whales have also been recorded (Arnbom *et al.*, 1987; Pitman *et al.*, 2001). In most cases, the sperm whale groups being attacked contained one or more calves. Sperm whales are likely to be difficult for killer whales to kill, as they are excellent deep divers and can escape predation by descending to depth, possess sizable teeth capable of inflicting significant injuries, and actively defend group members when threatened. Regardless of the difficulty in hunting sperm whales, recent field observations from the Pacific noted killer whales successfully killing at least one adult member of a sperm whale group, and fatally injuring at least several others (Pitman *et al.*, 2001).

Killer whales have been noted to hunt all of the mysticete species except for pygmy right whales (*Caperea marginata*), but observations of attacks on baleen whales are not common. As is true for sperm whales, baleen whales are also difficult to kill, requiring extended effort and coordination between pod members. A typical strategy employed by killer whales during large whale hunts consists of first fatiguing the prey by active pursuit, followed then by delivery of debilitating attack. It has been suggested that attacking killer whales may grasp large whales by the flukes and pectoral flippers in an attempt to slow or stop their movement, or perhaps drown their prey by pulling them underwater (Silber *et al.*, 1990).

In the Gulf of California, researchers watched from a small airplane as a group of 15 killer whales attacked and killed a Bryde's whale (*Balaenoptera edeni*). During this event, the killer whales repeatedly swam on to the back and head of the Bryde's whale, a behavior speculated to be useful in hindering life-sustaining respiration of the animal under attack (Silber *et al.*, 1990). A similar incident was recorded off British Columbia (Hancock, 1965) where killer whales were observed to exhaust and kill a fleeing minke whale (*Balaenoptera acutorostrata*). Killer whales also attack humpback whales, but unlike the more passive escape tactics employed by some of the other mysticetes, humpbacks aggressively defend themselves from killer whales by thrashing at them with their tail flukes and flippers (Whitehead and Glass, 1985).

Of all the mysticetes, gray whales (*Eschrichtius robustus*) are probably most frequently attacked by killer whales. On an almost predictable basis each spring, killer whales in Monterey Bay, California, attack gray whales (Fig. 5). Young calves making their first northward migration are particularly vulnerable, even while under the watchful eye of their mothers (Baldrige, 1972; Goley and Straley, 1994). Records from beach cast gray whales along the coast of the Chukchi Sea show a similar pattern to that observed off California; whales with the highest incidence of killer whale-induced injuries (i.e., tooth scarring) were generally under 10 m long, suggesting that killer whales in this region also select young gray whales as their primary predatory target.

Figure 5 Killer whale (*Orcinus orca*) attack on California gray whales (*Eschrichtius robustus*). Photo by Sue Flood/BBC Natural History Unit.

Figure 6 Young western gray whale (*Eschrichtius robustus*) with evident killer whale (*Orcinus orca*) tooth scarring. Photo by David W. Weller.

Direct observations of killer whale attacks on large whales are relatively few, but several lines of evidence suggest that predatory interactions may occur more often than suspected. The presence of killer whale tooth rakes on the bodies, flippers, and flukes of many large whales can reach remarkably high proportions (Fig. 6). Photoidentification studies on humpback whales off Newfoundland and Labrador in the north Atlantic found that 33% of the individuals identified had killer whale inflicted tooth rakes on their bodies (Katona *et al.*, 1980). Scars on the flukes of 20–33% of humpback whale calves suggests that predation may be focused on young animals. A similar pattern has also been observed for western gray whales in the Okhotsk Sea, where nearly 34% of all whales photoidentified possess killer whale tooth rakes (Weller, unpublished). In this case, the western gray whale is critically endangered, making any level of killer whale predation significant. Bowhead whales (*Balaena mysticetus*) from the Bering, Chukchi, and Beaufort Sea populations have relatively low rates of killer whale tooth scarring, ranging from about 4 to 8% of the observed individuals (George *et al.*, 1994). In contrast, 31% of bowhead whales in the Davis Strait population show evidence of scars from killer whales.

The relatively high incidence of killer whale tooth scarring on some regional populations of large whales suggests that predatory attempts are probably more regular than indicated by field observations alone, and that many attacks are unsuccessful. Tooth rakes may not

be truly indicative of predation attempts by killer whales however, but may instead represent capture practice or instruction of predatory techniques for younger members of the group. Finally, rake marks may also result from killer whales testing large whales to assess the presence of particularly vulnerable individuals that may be easily separated from a group and killed.

Although killer whales exert considerable time and energy in pursuit and capture of large whales, they consume relatively little of their victims (Andrews, 1914). Reports from whaling ship logbooks and more recent field observations, suggest that killer whales often preferentially consume only the tongue, lips, and portions of the ventrum of large whales before abandoning them. This phenomenon is little understood, and stands in stark contrast to the behavior of terrestrial predators that consume all or most of their mammalian prey.

E. Humans

A review of predation on marine mammals would be incomplete without some mention of humans as predators. No other predator has the ability to harvest marine mammals at the same rate or intensity as man. While killer whales or polar bears may take tens of animals over relatively short periods of time, humans are capable of sometimes killing hundreds of individuals within hours. Although the ecology of the world's oceans is in part maintained by predator–prey interactions, human exploitation of marine mammal populations can have devastating consequences.

Predator–Prey Relationships

ANDREW W. TRITES

Most marine mammals are predators, but some are also preyed upon by other species. Theoretically, the interaction between marine mammals and their prey influences the structure and dynamics of marine ecosystems. Similarly, predators and prey have shaped each other's behaviors, physiologies, morphologies, and life-history strategies. However, there is little empirical evidence of these influences due to the relative scale and complexity of marine ecosystems and the inherent difficulties of observing and documenting marine mammal predator–prey interactions.

I. Evolutionary Time Scales

Predator–prey relationships have been likened to an evolutionary arms race—the prey become more difficult to capture and eat, while the predators perfect their abilities to catch and kill their prey. Just how strong these selective forces are probably depends on the strength of the interactions between the predators and their prey (Taylor, 1984).

As predators, marine mammals feed primarily upon fish, invertebrates, or zooplankton, which in turn feed primarily upon other species of fish, invertebrates, zooplankton, and phytoplankton (Fig. 1). To capture their prey, marine mammals have evolved special sensory abilities (e.g., vision and hearing), morphologies (e.g., dentition), and physiologies (e.g., diving and breath-holding abilities) (Trites *et al.*, 2006). They have also evolved specialized strategies to capture prey, such as cooperation to corral fish, or the production of curtains of air bubbles used by humpback whales (*Megaptera novaeangliae*) to capture herring. Marine mammals have also evolved specialized

Figure 1 A simplified depiction of the Bering Sea food web; (1) ice algae; (2) phytoplankton; (3) copepods; (4) mysids and euphausiids; (5) medusae; (6) hyperid amphipods; (7) seabirds; (8, 9) pelagic fishes; (10) walrus; (11) seals; (12) basket stars; (13) ascideans; (14) shrimps; (15) filter-feeding bivalves; (16) sand dollars; (17) sea stars; (18) crabs; (19) bottom feeding fishes; (20) polychaetes; (21) predatory gastropods; and (22) deposit feeding bivalves. From McConnaughey and McRoy (1976).

feeding behaviors to capture prey that move diurnally up and down the water column or to capture prey that move seasonally across broad geographic ranges. This in turn has likely influenced the life-history strategies of marine mammals and their prey. For example, baleen whales feed for about 6 months when plankton are abundant and concentrated in shallow water, and then fast for the remainder of the year when the plankton are too dispersed to make them worth finding.

As prey, marine mammals have had to escape aquatic and terrestrial predators (Taylor, 1984; Morisaka and Connor, 2007). Porpoise (phocoenidae) for example are preyed upon by killer whales (*Orcinus orca*) and may have evolved an echolocation and communication system through the selective pressures of predation that falls within a range of sounds that killer whales hear poorly or not at all (<2 and >100kHz). Other species such as pinnipeds can reduce their risk of being eaten by aquatic predators (sharks and killer whales) by hauling out and resting onshore; while species such as Steller sea lions (*Eumetopias jubatus*) and northern fur seals (*Callorhinus ursinus*) reduce their risk of being eaten by terrestrial predators [wolves (*Canis lupus*) and bears] by breeding and hauling out on offshore rocks and islands where terrestrial predators are absent. Other species, such as ringed seals (*Pusa hispida*), give birth in caverns formed between ice and snow to avoid predation by polar bears (*Ursus maritimus*).

Fish and other cold-blooded species of prey have also evolved a number of strategies to increase their chances of survival (Trites *et al.*, 2006). One is cryptic countershading that enables fish to blend in with the bottom when viewed from above, and avoid detection when seen from below against a bright sea surface. Many species of fish, invertebrates, and zooplankton take refuge from predators in the deep, dark waters during the day and move toward the surface to feed under the cover of night. Another strategy evoked by the prey of marine mammals is predator swamping, such as large aggregations of spawning salmon and herring (*Clupea* spp.) that reduce the numerical effect of predators on their prey populations. Schooling is another antipredator behavior that creates confusion through the sheer volume of stimuli from a fleeing school, making it difficult for a marine mammal to actively select and maintain pursuit of single individuals. Scattering and fleeing is yet another option to reduce predation and is used by some prey when attacked by bulk feeders such as baleen whales [e.g., humpback whales and capelin (*Mallotus villosus*)]. The line between feeding and fleeing is undoubtedly fine for species of prey and must be continually evaluated by prey to minimize vulnerability to predation.

Marine mammals may also have indirectly influenced the evolution of nontargeted species in their ecosystems by consuming the predators of these species (Estes, 1996). The best example of this is the apparent influence of sea otters (*Enhydra lutris*) on kelp and other marine algae. Most species of marine algae use secondary metabolites to defend against herbivores. However, marine algae in the North Pacific Ocean have lower levels of chemical defenses where sea otters occur compared to algae species inhabiting the southern oceans where sea otters are not present. Sea otter predation on sea urchins and other herbivores may have removed selective pressure for species of marine algae to defend themselves against herbivores. Because secondary metabolites are expensive to produce, this may have allowed algae, like kelp, to radiate and diversify without the added cost of evolving and producing antigrazer compounds.

II. Ecological Time Scales

On a shorter time scale than the evolutionary time scale, predators and prey can directly affect the relative abundance of each other, or

they can indirectly affect the abundance of other species. Their interaction may also affect the physical complexity of the marine environment (Katona and Whitehead, 1988; Bowen, 1997; Trites, 1997).

Predation by sea otters on sea urchins is probably the best example of how marine mammals can alter ecosystem structure and dynamics (Estes, 1996). Sea otters were hunted to near extinction in the late 1800s throughout their North Pacific range. Without predation, urchin populations grew unchecked and overgrazed the fleshy algae. Kelp did not replace the underwater barrens until reintroduced sea otters once again began preying upon sea urchins.

Primary production has been estimated to be three times higher in areas where sea otters are present compared to those areas where sea otters are absent, allowing those organisms that feed upon primary production to grow faster and attain larger sizes (e.g., mussels and barnacles). The increase in primary production may even alter settlement patterns of invertebrates. The kelp also provides habitat for fish and suspension feeding invertebrates to spawn, grow, and flourish. It can also change water motion and reduce onshore erosion and may even block the shoreward movement of barnacle larvae. Thus a top predator such as the sea otter can change the structure and dynamics of marine ecosystems.

Gray whales (*Eschrichtius rohustus*) and walrus (*Odobenus rosmarus*) are other species of marine mammals whose foraging behavior can also affect community structure. For example, gray whales turn over an estimated 9–27% of the bottom substrate each year in the Bering Sea. The feeding pits created by gray whales draw 2–30 times more scavengers and other invertebrates compared to adjacent sediments. The disturbed sediments may also help maintain the high abundance of gray whale prey and other early colonizing species. Similarly, walrus turn over bottom substrate in their search for clams and other bivalves. There is some evidence that they may feed selectively on certain size classes and certain species and that their defecation may result in the redistribution of sediment. Thus, the interaction of benthic feeding marine mammals with their prey can result in food for scavengers and habitat for other species.

Interactions between predators and prey also influence the shapes of their respective life tables (i.e., age-specific survival and pregnancy rates). In Quebec, Canada, for example, there are a number of freshwater lakes that are home to landlocked harbor seals (*Phoca vitulina*). Studies have found that the trout in these lakes are younger, grow faster, attain smaller sizes, and spawn at younger ages compared to adjacent lakes without seals. As for marine mammals, they typically have elevated mortality rates during their first few years of life. This is likely due to a number of factors, including their relative vulnerability to predators and their inexperience at capturing prey and securing optimum nutrition.

In the Gulf of Alaska and Bering Sea, killer whales have been implicated as a contributing factor, but not the main one, in the decline of Steller sea lions and harbor seals through the 1980s (Williams *et al.*, 2004). Field observations along the Aleutian Islands indicate that these population declines were followed by a decline of sea otters in the 1990s and that this decline was caused by killer whale predation. Some killer whales may have begun supplementing their diet with sea otters because they could not sustain themselves on the low numbers of remaining seals and sea lions. What ultimately caused the decline of Steller sea lions and began this spiraling change of events is a matter of considerable scientific debate. However, it is apparent from mathematical calculations of population sizes and energetic requirements that there are sufficient numbers of killer whales in Alaska to prevent the recovery of pinniped populations. Thus, it is conceivable that populations of pinnipeds and otters may not recover to former levels of

abundance until the predation by killer whales is reduced by a reduction in killer whale numbers or by a shift in killer whale diet to other species of mammals such as dolphins and porpoises.

In addition to directly affecting the abundance of their prey, marine mammals can indirectly affect the abundance of other species by outcompeting them or by consuming species the prey upon them (Trites, 1997). A case in point is harbor seals in British Columbia whose diet was about 4% salmon and 43% hake in the 1980s. Contrary to popular opinion, the harbor seals were likely benefiting salmon because they affected the abundance of hake, a species of fish that is one of the largest predators of salmon smolts. Further north in Alaska's Copper River Delta, harbor seals were culled in the 1960s to reduce the predation on salmon. However, the immediate result of the cull was not an increased number of salmon caught, but a decrease and failure of the razor clam (*Siliqua patula*) fishery. It turned out that the seals were primarily eating starry flounder (*Platichthys stellatus*), which fed on the razor clams. Without the seals, the predatory flounder population grew unchecked.

In the Antarctic, commercial whaling systematically removed over 84% of the baleen whales and freed an estimated 150 million tons of krill for other predators to consume each year (Knox, 1994). Species such as crabeater seals (*Lobodon carcinophaga*), Antarctic fur seals (*Arctocephalus gazella*), leopard seals (*Hydrurga leptonyx*), and penguins [chinstrap (*Pygoscelis antarcticus*), Adelle (*P. adeliae*), and macaroni (*Eudyptes chrysolophus*)] increased and moved the Antarctic marine ecosystem to new equilibrium levels. Increases were also observed in Antarctic minke whales (*Balaenoptera bonae-rensensis*) and squid-eating king penguins (*Aptenodytes patagonicus*) due perhaps to reductions in the respective abundance of blue whales (*Balaenoptera musculus*) and sperm whales (*Physeter macrocephalus*). All of these species appear to have directly benefited from an increase in prey, which was caused by the removal of whales. Penguins and seals may now be hindering the recovery of baleen whale stocks in the Antarctic.

Marine mammals are generally considered to be opportunistic foragers who select from a number of alternative prey according to availability. This is based on the relatively large number of different species that have been reported in the stomachs and feces of marine mammals. Steller sea lions, for example, are known to eat over 50 different species of fish, and even the occasional seabird. However, their diets are typically dominated by five or fewer species, suggesting that they may not be truly opportunistic feeders. Little is yet known about the choices that marine mammals make when foraging. Presumably what marine mammals eat is a function of nutritional value, ease of capture, and digestibility, all of which are invariably linked to the abundance of both predators and prey. These are complex biological interactions about which little is known.

Functional response curves represent rates of predation in relation to the density of prey (Mackinson *et al.*, 2003; Middlemas *et al.*, 2006). In most species, the rate of capture rises with the density of prey to some maximum level. These relationships between prey density and predation rates tend to be sigmoidal (nonlinear and asymptotic), indicating that there are maximum limits to the rate that predators can capture and process prey, which are independent of prey population size. Establishing these functional relationships for different species of prey is fundamental to fully understanding the foraging ecology of marine mammals. Establishing these relationships is beginning to be done for marine mammals and will require further experimentation in captivity or observational studies in the wild.

Ecosystem models are another technique for gaining insight into the effects of predator–prey relationships on ecosystem dynamics and

structure (Trites *et al.*, 1999; Morissette *et al.*, 2006). Using a series of mathematical equations to account for the flow of energy from one group of species to another, the models can estimate the extent of competition between species and the effect that changes in abundance of one species will have on other species in the ecosystem. One such ecosystem model describing the Gulf of St. Lawrence revealed that harp seals (*Pagophilus groenlandicus*), gray seals (*Halichoerus grypus*), and hooded seals (*Cystophora cristata*) negatively affect the abundance of the higher trophic level fish they target, which in turn reduces predation pressure on the prey of the species these seals eat. Another ecosystem model constructed for the eastern Bering Sea examined trophic relationships to determine whether the declines of Steller sea lions and forage fishes (such as herring) and the increases in pollock (*Pollachius* spp.) and flatfish between the 1970s and the 1980s were related to the commercial removal of whales.

Removing historic numbers of whales from the simulated Bering Sea ecosystem resulted in an increase in numbers of pollock. However, the increase was only in the order of 10–20%, not the 400% increase believed to have actually occurred. The ecosystem model suggested that the Bering Sea may exist in two alternative states (consisting of two different complexes of species) and that environmental shifts (from periods of cold to warm water years) may ultimately determine when and for how long these shifts occur. The model also suggested that curtailing fishing on pollock (a major prey of Steller sea lions) may affect the Steller sea lion negatively. The explanation for this counterintuitive prediction was that commercial fisheries primarily removed larger pollock than Steller sea lions consumed. Given that pollock are cannibalistic, increasing the size of the adult stock resulted in the increased predation of younger pollock, leaving fewer fish for Steller sea lions to consume. Thus, ecosystem models are useful tools for exploring the influence of predator–prey interactions on one another and on other components of their ecosystems.

III. Synthesis

Marine mammal predator–prey interactions occur over different spatial and temporal scales, making it difficult to empirically decipher the influences they have on one another and on their ecosystems. However, their coexistence suggests that marine mammal predators and their prey have had profound influences on each other's behaviors, physiologies, morphologies, and life-history strategies. The diversity of niches filled by marine mammals makes it difficult to generalize about the evolutionary consequences of their interactions with prey, beyond stating the obvious: marine mammals have adapted to catch food, while their prey have adapted to avoid being caught.

On the shorter ecological time scale, marine mammals can affect the abundance of other species by consuming or outcompeting them. They can also indirectly affect the abundance of nontargeted species by consuming one of their predators, and can have strong impacts on the overall dynamics and structure of their ecosystems. One of the best tools for understanding marine mammal predator–prey interactions is the ecosystem model. However, more work is required through experimental manipulations and observational studies to evaluate the choices made by marine mammals and the costs of obtaining different species of prey.

450 kg. Dwarf sperm whales are smaller at 2.7 m and 272 kg. Adults of both species are dark bluish-gray to blackish-brown dorsally and light below. On the side of the head between the eye and the flipper there is often a crescent-shaped, light colored mark referred to as a “false gill.” These whales have the shortest rostrum among living cetaceans, and the skull is markedly asymmetrical. The mandibles are delicate, and the teeth are very sharp, thin, and lack enamel. *K. breviceps* lacks teeth in the upper jaw, but *K. sima* may have up to three pairs of vestigial teeth in this position. Although now recognized as the sole genus within the family Kogiidae, originally these whales were placed within the Physeteridae, with the sperm whale, *Physeter macrocephalus*. Fossil forms of Kogiidae have been described rarely from fragments of teeth, cranium, and lower jaws of late Miocene to early Pliocene age. Most of these may be only distantly related to extant *Kogia* spp. However, *Praekogia cedrosensis*, described from the early Pliocene in the Almejas Formation on Isla Cedros Baja California, Mexico, is reported to clearly be ancestral to living *Kogia*. It is only since 1966 that two species of *Kogia* have been recognized, and no subspecies have been described. On the basis of recent evidence from the mitochondrial cytochrome *b* gene it has been suggested that *K. sima* may consist of two apparently parapatric species occupying the Atlantic and Indo-Pacific Oceans (Chivers *et al.*, 2005). Full recognition of this putative third *Kogia* sp. awaits further supporting evidence.

II. Distribution and Abundance

Dwarf and pygmy sperm whales occur worldwide in temperate and tropical waters of the Atlantic, Pacific, and Indian Oceans. Although rarely sighted at sea, these whales commonly strand in some regions, and much of the relatively little that is known of their ecology has been gleaned from such stranded animals. In the NE Atlantic most strandings occur in autumn and winter, but more broadly there is little indication for seasonality in the distribution or the migration of these whales. Evidence shows that *K. sima* may prefer warmer seas than *K. breviceps*. The precise at-sea DISTRIBUTION of *Kogia* spp. is unknown, as most records are based on stranded animals, but some evidence suggests *K. sima* may have a more pelagic distribution and feed in deeper water. Analysis of prey in stranded animals suggests that both species of *Kogia* generally inhabit waters along the continental shelf and slope in the epi- and mesopelagic zones.

Although many writers have stated that dwarf and pygmy sperm whales are rare, there is insufficient information to classify the world status of *Kogia* species; neither their population sizes nor trends are known (Baird *et al.*, 1996; Willis and Baird, 1998). The frequency with which *Kogia* strand on certain coasts, especially in southeastern United States and South Africa, suggests that in some regions they may be uncommon rather than rare.

III. Ecology

Kogia spp. feed mostly on mid and deepwater cephalopods but also consume fish and occasionally crustaceans, such as shrimp and crabs (McAlpine *et al.*, 1997; Santos *et al.*, 2006). Stomach contents that have been analyzed have contained cephalopod beaks from at least 55 species representing 15 families, although in NE Atlantic *K. breviceps* squids of the genus *Histioteuthis* predominate. It has been suggested that there may be some competition for prey between adult pygmy sperm whales and juvenile sperm whales. Most feeding seems to take place on or near the bottom, probably using ECHOLLOCATION to find prey. Kogiid hyoid anatomy suggests powerful suction feeding.

Pygmy and Dwarf Sperm Whales

Kogia breviceps and *K. sima*

DONALD F. McALPINE

I. Characteristics and Taxonomy

In form, *Kogia* spp. are porpoise-like and robust with a distinctive underslung lower jaw. This latter feature has been described as giving these whales a shark-like appearance (Fig. 1). Although height and position of the dorsal fin have been reported as distinguishing the two currently recognized species, they are probably not separable at sea except under exceptional circumstances. Pygmy sperm whales reach a maximum size of about 3.8 m and a weight of

Figure 1 (A) *Kogia breviceps*. The relatively short and more posteriorly positioned dorsal fin is useful in distinguishing this species from (B) *K. sima* (C. Brett Jarrett).

Little is known about disease in *Kogia*. Strandings of unhealthy pygmy and dwarf sperm whales have been attributed to degenerative heart disease, as well as being linked to possible immune system problems associated with the thymus gland. Pneumonia has also been observed in stranded animals. A novel trypanoplasm-like flagellate has been described from the blowhole of several stranded *K. breviceps* (Poynton *et al.*, 2001). *Kogia* specimens are frequently heavily infected with intestinal nematodes (*Anisakis* sp. and *Terranova cetecola*) and blubber-encysted larval cestodes (*Phyllobothrium delphini*). The parasitic crustacean, *Pennella balaenoptera*, has been observed embedded in the epidermal surface of both species of *Kogia*. Scarring indicates that these whales are attacked by lampreys. A white shark (*Carcharodon carcharias*) attack on a pygmy sperm whale has been documented, and pygmy sperm whale remains have been identified in killer whale (*Orcinus orca*) stomachs. Levels of PREDATION on *Kogia* are otherwise unknown. Heavy infestations with larval cestodes, which probably mature in elasmobranchs, suggest that shark attacks may be more common than the single literature report suggests.

IV. Behavior and Physiology

There have been no comprehensive behavioral studies of dwarf or pygmy sperm whales. Stranded animals that have been maintained in aquaria have usually survived no more than several months and usually only live for a few days. At sea, both species occur individually or in small groups of up to 6 (*K. breviceps*) or 10 (*K. sima*) animals of varying age and sex composition. Strandings usually involve single animals. Dwarf and pygmy sperm whales are reported to spend considerable time lying motionless at the surface with the back of the head exposed and the tail hanging down. *K. breviceps* is easily approached, but is timid and slow moving. Normal swimming speed is thought to be about 3knt. When surfacing, both species rise slowly, produce an inconspicuous blow, and dive without showing the flukes. Maximum dive durations of nearly 18 min have

been recorded, although most are much shorter (Scott *et al.*, 2001). Neither species is known to be highly vocal (Clarke, 2003).

Like *Physeter macrocephalus*, *Kogia* spp. have a spermaceti organ. However, unlike the sperm whale, current opinion suggests that buoyancy control is not the primary function of the melon. Rather, it has been suggested that its function is to produce, intensify, and actively focus sound used in echolocating prey during deep dives. An elongated balloon-like structure occupies the lower intestine of both species and is usually filled with dark reddish-brown liquid that may be released into the water during foraging or when disturbed.

V. Life history

K. sima reaches sexual maturity at about 2.1 m in length (Caldwell and Caldwell, 1989). In *K. breviceps* males are known to be sexually mature at about 2.7 m and females at a slightly smaller size. Gestation has been cited as 9 or 11 months, with the species about 1 m in length at birth.

VI. Interactions with Humans

The scarcity of pygmy and dwarf sperm whales and the fact that they are rarely encountered at sea mean that direct effects from humans are probably few. Although by-catch in the pelagic driftnet fishery has been observed, fisheries mortality appears to be very limited. However, there is growing evidence that *Kogia* spp. show a propensity to ingest ocean debris such as plastic bags, latex gloves, and balloons. In several cases such items have been documented to result in intestinal blockage and death in these whales (Stamper *et al.*, 2006). Their habit of lying quietly at the surface seems to have led to occasional ship strikes. Both species are taken infrequently in commercial harpoon fisheries in the Caribbean and Indian Oceans.

Pygmy Killer Whale

Feresa attenuata

MEGHAN A. DONAHUE AND WAYNE L. PERRYMAN

I. Characteristics and Taxonomy

The pygmy killer whale has a moderately robust body that narrows posteriorly to the dorsal fin, hence the name *attenuata* from the Latin “to make thin or taper” (Fig. 1). The head is round and blunt and lacks the beak typical of many dolphins. The head does not narrow or appear triangular when viewed from above as with the melon-headed whale (*Peponocephala electra*). The moderately long flippers are rounded at the tips with convex leading and concave trailing edges.

On the back and portions of the flanks and ventral surface, the pygmy killer whale is dark gray to black. A subtle, dark cape (an area of COLORATION extending from the forehead past the dorsal fin) and reaches the greatest distance down the side of the animal below the high, falcate dorsal fin. A paler gray area on each flank is usually present from the tail stock to the eye. Below, the pygmy killer has an irregularly

shaped white patch between the flippers, around the genitals, and occasionally on the tail stock. The lips are also edged with white.

The skull is broad and robust. The upper and lower jaws have less than 15 teeth each, a character that distinguishes the pygmy killer whale from the melon-headed whale, which typically has more than 20 teeth per row.

Length measurements from several specimens average 2.31 m (range 2.14–2.59 m). Differences in lengths between males and females have not been observed in measured specimens.

Although called “whale,” the pygmy killer whale, like its close relative, the killer whale (*Orcinus orca*), belongs taxonomically to the dolphin family, Delphinidae. Until 1952 this species was only known from two skulls collected in the nineteenth century. Since that time, a number of specimens have been collected from strandings and fishery catches around the world, yet the pygmy killer whale remains one of the least known of the small cetaceans.

II. Distribution and Abundance

Pygmy killer whales have been recorded in tropical and subtropical waters worldwide. Sightings have been relatively frequent in the eastern tropical Pacific, the Hawaiian Archipelago, and off Japan. The migratory status of this species cannot be determined based on available information. However, incidental catches and observations by fishermen suggest that it is a year-round resident at least in the regions of Sri Lanka and the Lesser Antilles.

Estimates of abundance have been made around the Hawaiian Islands, in the Eastern Tropical Pacific, and the Northern Gulf of Mexico. Between 1986 and 1990, five research vessel surveys were conducted in the eastern tropical Pacific and an abundance of 38,900 (CV = 0.305) pygmy killer whales was estimated for that area (Wade and Gerrodette, 1993). A shipboard line-transect survey of the entire Hawaiian Islands Exclusive Economic Zone (Barlow, 2003) resulted in an abundance estimate of 817 (CV = 1.12). Surveys in the Northern Gulf of Mexico between 1996 and 2001 resulted in an estimate of 408 (CV = 0.60) animals (Mullin and Fulling, 2004).

III. Ecology

Although the feeding habits of pygmy killer whales are not well known, remnants of cephalopods and small fish have been found in specimens from STRANDINGS and incidental fishery catches. Nothing is known of predators.

IV. Behavior and Physiology

Pygmy killer whales are found most commonly in small herds, ranging from 12 to 50 animals, although herds of 100 or more have been encountered. This species has been observed BOW RIDING, performing high leaps, and “spyhopping” (raising the head vertically out of the water).

Pygmy killer whales are suspected to be among the small whales that chase, attack, and sometimes eat dolphins (*Stenella* spp. and *Delphinus delphis*) involved in the purse-seine fishery for yellowfin tuna in the eastern tropical Pacific (Perryman and Foster, 1980). AGGRESSIVE BEHAVIOR has also been observed by two pygmy killer whales in captivity in Hawaii and South Africa, but a herd captured off Japan showed no such aggression when placed in an enclosure with other dolphins.

Acoustic recordings from the northern Indian Ocean indicate pygmy killer whale vocalizations have echolocation clicks similar to other comparably sized delphinids and are likely used for detection and classification of prey (Madsen *et al.*, 2004).

V. Life History

Little is known about this species' growth and reproduction. An estimated length at sexual maturity of 2 m based on 85% of the mean length at physical maturity (Laws, 1965) is consistent with data collected from three sexually mature males ranging in length from 2.07 to 2.61 m and three pregnant females ranging in length from 2.20 to 2.27 m. A lactating female, from a group of animals stranded in the British Virgin Islands, measuring 2.04 m constitutes the smallest known sexually mature female to date (Mignucci-Giannoni *et al.*, 1999).

VI. Interactions with Humans

Pygmy killer whales have been caught directly and incidentally in fisheries. Small-cetacean fisheries in St. Vincent and Indonesia have been known to catch pygmy killer whales, but they comprise a small proportion of the catch and these catches are thought to have little effect on the population in those areas. Monitoring of fisheries in which pygmy killer whales are caught incidentally has not been extensive. Mortality in these fisheries, such as those around Sri Lanka, could be greater than documented and may have a significant impact on stocks in those regions. In Sri Lanka, pygmy killer whales have also been harpooned and used as bait in long-line fisheries for sharks, billfish, and other oceanic fishes (Leatherwood and Reeves, 1989).

Pygmy Right Whale

Caperea marginata

CATHERINE M. KEMPER

I. Characteristics and Taxonomy

The pygmy right whale is the smallest baleen whale and the only member of the family Neobalaenidae (Fig. 1). There is conflicting evidence regarding the evolutionary history of this enigmatic species (Sasaki *et al.*, 2005). Some studies align it more closely to the gray whale (*Eschrichtius robustus*, Eschrichtiidae) and rorquals (Balaenopteridae) than to right (*Eubalaena* spp.) and bowhead (*Balaena mysticetus*) whales (Balaenidae). No fossil neobalaenids have been described. [A reported fossil, *Neobalaena simpsoni*, from Chile is believed to be related to Balaenidae, not Neobalaenidae (Cabrera, personal communications, 2007.)] Geographical variation has not been studied and no subspecies are recognized.

Diagnostic features of the pygmy right whale include long, narrow, creamy-white baleen plates with an outer margin of brown or black and very fine bristles (Sekiguchi *et al.*, 1992); a clearly visible band of white gum at the base of the baleen; a moderately arched rostrum that becomes more pronounced as the animal grows; a small, falcate dorsal fin placed about 25–30% of body length from the tail; and shallow throat creases in some animals. The overall body shape of adults is stouter than that of the rorquals but not as broad as in right and bowhead whales. From above, the head is broadest at the eyes and narrows sharply into a long and narrow rostrum on which a medial ridge may be present (Matsuoka *et al.*, 2005). The flukes are very broad and have a deep medial notch. The body is medium to dark gray

Figure 1 The smallest baleen whale is the pygmy right whale (*Caperea marginata*); it achieves a maximum length of about 6.5 m. (C. Brett Jarrett).

Figure 2 The pygmy right whale has a distinctively curved jaw line and “throws” its head out of the water while swimming at the surface. These features help to identify it “at sea.” Photo credit: Barbara Parker/South Australian Museum.

above and white to pale gray below. There is some evidence that young animals may not be as dark as older ones. There is a dark eye patch and fairly distinct pale gray chevrons across the back above and anterior to the flipper (Kemper *et al.*, 1997; Matsuoka *et al.*, 2005). The oval scars of cookie-cutter sharks *Isistius* spp. are often present and abundant on large animals. The flippers are small, narrow, and rounded at the tip, and are medium to dark gray above (contrasting with the pale color of the sides of the body) and paler below. Mandibular and rostral hairs persist into adulthood but there are no callosities as in true right whales. The baleen plates number 213–262 on each side (Ivashin *et al.*, 1972; Budylenko *et al.*, 1973).

At sea, pygmy right whales may be confused with minke whales, *Balaenoptera acutorostrata* and *B. bonaerensis*, but close inspection should reveal some of the diagnostic features noted earlier. The blunter rostrum and strongly curved lower jaw of the pygmy right whale and its habit of swimming with its head “thrown” out of the water at an angle should also help identify it (Fig. 2).

The skull and skeleton of the pygmy right whale are unlike those of any other cetacean (Hale, 1964). The supraoccipital bone is very long, extending well forward on the skull. The ear bone has a distinctive wrinkle on its outer surface and is squarish in outline. The mandible is broad and has no coronoid process. The ribs are very broad, flat, and numerous (18 pairs), extending well along the body. All seven cervical vertebrae are fused and the total number of vertebrae is only 44. The flipper has four digits.

Little information on the pygmy right whale’s internal anatomy has been published. Ivashin *et al.* (1972) and Budylenko *et al.* (1973) described and weighed body organs, including the reproductive organs, of a few sexually mature whales captured by soviet whaling

ships. The heart and lungs were relatively small, suggesting that the species is not a deep diver (Ross *et al.*, 1975). Reeb and Best (1999) made a detailed study of the larynx and concluded that this organ was considerably different from that of other baleen whales.

II. Distribution and Abundance

This species is found only in the Southern Hemisphere (Fig. 3). It is circumpolar, between about 30° and 55°S, with records from southern Africa, South America, Australia, and New Zealand (Baker, 1985; Kemper, 2002). It has also been recorded in the vicinity of the Falkland and Crozet islands and in the open ocean of the South Atlantic (Baker, 1985), southwestern Pacific Ocean, and Southern Ocean south of Australia (Matsuoka *et al.*, 2005). There are no estimates of abundance but judging by the number of strandings in Australia and New Zealand, it is likely to be reasonably common in that region.

III. Ecology

The pygmy right whale lives in temperate and subantarctic regions where water temperatures are between about 5° and 20°C (Baker, 1985). It has been seen in oceanic and neritic environments where some individuals have spent up to 2 months very close to shore, possibly feeding while there (Kemper, 2002). Seasonal movements inshore may be related to the availability of food during spring and summer (Ross *et al.*, 1975; Sekiguchi *et al.*, 1992). Although oceanic feeding has not been observed, animals collected there had full stomachs (Ivashin *et al.*, 1972) or were seen defecating (Matsuoka *et al.*, 2005), both of which indicate recent feeding. The little information available on diet shows that copepods, euphausiids, and possibly other small plankton are eaten. It has been suggested that the subtropical convergence, where sea surface temperatures are 9–13°C and plankton is abundant (Kawamura, 1974), is an important feeding area for pygmy right whales. Strandings and inshore sightings are often in shallow, protected bays. The predators of pygmy right whales are not known.

IV. Behavior and Physiology

The surface behavior of pygmy right whales is inconspicuous (Ross *et al.*, 1975; Kemper *et al.*, 1997; Matsuoka *et al.*, 2005), but because so few observations have been reported the complete repertoire may not have been recorded. Swimming speeds of 3–8 knt have been noted, and the whale is also capable of very fast acceleration and speed, leaving a conspicuous wake when doing so (Fig. 2). One underwater observation of swimming noted that the body action was very flexed (Ross *et al.*, 1975). When pygmy right whales dive they remain submerged for up to 4 min and surface briefly before diving again (Ivashin *et al.*, 1972; Matsuoka *et al.*, 2005). This behavior

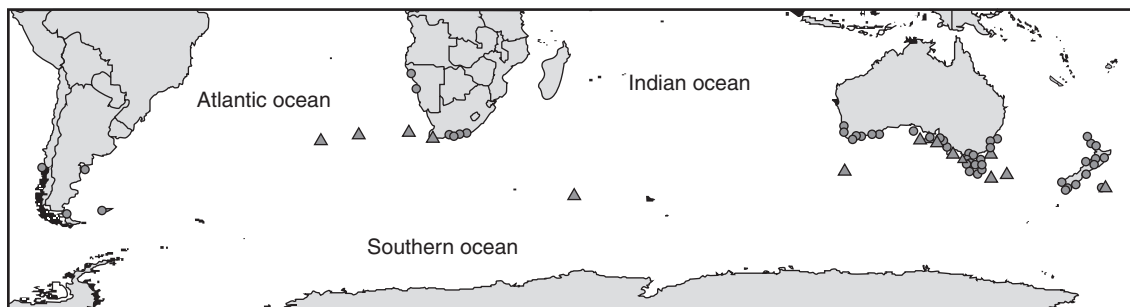

Figure 3 Distribution of the pygmy right whale. Symbols show position only, not number, of records. Circle, strandings or entanglements; triangle, sightings (including captures).

is consistent with shallow dives. The blow is inconspicuous and, when visible, is small and oval. The sounds of one solitary juvenile consisted of pairs or trios of short, thump-like pulses or tone bursts with a down-sweep in frequency and decaying in amplitude. Most energy was between 60 and 120 Hz (Dawbin and Cato, 1992).

Less than 25 sightings of pygmy right whales “at sea” have been recorded. They have been seen with pilot (*Globicephala melas*), sei (*Balaenoptera borealis*), and minke whales and with dolphins. Sightings close to the coast tend to be of one or two animals, and those in the oceanic environment have been of groups up to 80 individuals. Strandings usually involve only one whale but adult female/juvenile pairs have been recorded in some cases (Kemper *et al.*, 1997). Strandings throughout the year in Australia and New Zealand suggest that the species does not migrate north–south as do most other baleen whales.

V. Life History

Relatively little is known of the life history of pygmy right whales. Length at birth is about 2m and at weaning, about 3.0–3.5m (Ross *et al.*, 1975; Kemper, 2002). Most animals are physically mature at around 6m (Kemper and Leppard, 1999), and maximum length and weight are 6.5m and 3430kg (Budylenko *et al.*, 1973). Females are slightly longer than males. Sexual maturity may occur at lengths of greater than 5m. The calving interval, mating season, and gestation period are not known. The calving season is protracted (Pavey, 1992), possibly year-round. Life expectancy is not known and no age estimates have been made.

VI. Interactions with Humans

Pygmy right whales were never targeted by whalers, although they were at times taken opportunistically. Intentional killing by inshore fisheries and incidental captures in fishing nets are known (Kemper, 2002). None have been kept in captivity. Toxic contaminants are not believed to be a threat to this species because tissue levels of organochlorines and heavy metals measured in a few animals have been low (Kemper *et al.*, 1994).

R

Remoras

DAGMAR FERTL AND ANDRÉ M. LANDRY, JR.

Remora, suckerfish, diskfish, and sucker are some of the names describing eight species of marine fishes in the Family Echeneidae (=Echenedidae) Fischer, 1978; Nelson *et al.*, 2004). Remoras inhabit tropical and subtropical waters worldwide, except for the whitefin sharksucker (=whitefin remora, *Echeneis neucratoides*), which is restricted to the western Atlantic Ocean (Fischer, 1978).

I. Remora Biology

Remoras use a suction disk to attach to sharks, rays, bony fishes, sea turtles, cetaceans, sirenians, and ships and other floating objects (O'Toole, 2002). When attached to these hosts, remoras appear to swim upside down, but the disk is really on top of their head. The oval-shaped disk is a modified dorsal fin that has split and flattened to form a series of transverse, plate-like fin rays (disk lamellae) that resemble slats of a venetian blind (Fig. 1). When these fin rays are lifted, a strong vacuum is created between the remora's disk and its host (Fulcher and Motta, 2006).

The tenacity with which remoras attach to their hosts is best illustrated by the practice of sea turtle fishing by fishermen in the Caribbean and off China and northern Australia (Gudger, 1919), and in Yemen and Kenya, where it continues to this day. A fisherman ties a line around the tail of a remora and throws the fish into the water. The remora tightly attaches itself to a turtle, and the remora and its "catch" are then hauled ashore.

Suspected benefits of a remora's association with their hosts include transportation, protection from predators, increased courtship/reproduction potential, enhanced respiration, and expanded feeding opportunities (Fertl and Landry, 1999; Silva and Sazima, 2003). Remoras opportunistically feed on parasitic copepods (which constitute the bulk of their diet), zooplankton and smaller nekton, food scraps from meals of their hosts, and sloughing epidermal tissue and feces of the host (Cressey and Lachner, 1970; Williams *et al.*, 2003).

II. Marine Mammal Hosts

Adult remoras typically attach to the body of a marine mammal (Figs 2, 3). At least three remora species utilize marine mammals as hosts: whalesucker (*Remora australis* = *Remilegia australis*), sharksucker (*Echeneis naucrates*), and whitefin sharksucker (Fertl and Landry, 1999; Williams *et al.*, 2003). Remoras associate with at least 20 cetacean and 2 sirenian species [dugong (*Dugong dugon*) and

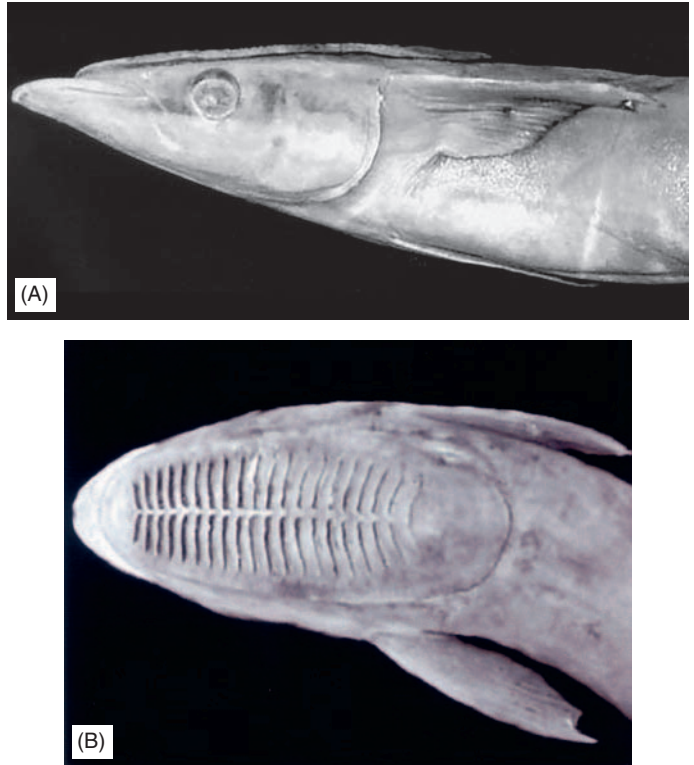

Figure 1 (A) Lateral and (B) dorsal view of the head of a remora, with suction disk visible. Photographs by W.H. Dailey.

West Indian manatee (*Trichechus manatus*)]. The whalesucker has most often been collected and identified from cetaceans, hence, its common name (Rice and Caldwell, 1961; Fertl and Landry, 1999). The sharksucker has also been collected from common bottlenose dolphins (*Tursiops truncatus*) (Fertl and Landry, 1999, 2002; Noke, 2004). Two species of remora have been collected from West Indian manatees; these were positively identified as the whitefin sharksucker and the sharksucker (Williams *et al.*, 2003).

The remora's suction mode of attachment does not hurt the host or leave scars, as has been suggested. However, a temporary mark resembling the disk imprint may be seen. Wounds attributed to remoras are most likely caused by cookiecutter sharks (*Isistius brasiliensis*) or Pacific lampreys (*Lampetra tridentate* = *Entosphenus tridentatus*), which actually bite or rasp their prey or host.

To what degree a remora might irritate its host is uncertain. A remora may slide all over its host's body, possibly tickling the animal.

Figure 3 Sharksucker (*Echeneis naucrates*) attached to a West Indian manatee (*Trichechus manatus*) off Aguadilla, Puerto Rico. Photo by Edwin Rivera-Colon, La Casa del Buzo.

Animals observed with remoras sliding over their bodies sometime will jerk and even roll over (Ritter, 2002; Ritter and Brunnschweiler, 2003). Dolphins of various species leap with remoras attached to them, perhaps to dislodge the “hitchhiker” (Fish *et al.*, 2006; Weihs *et al.*, 2006). There are also reports of dolphins dislodging remoras from themselves or their calves and then biting them (Wedekin *et al.*, 2007). Large remoras or multiple remoras on the same host may produce a hydrodynamic drag.

III. Problems with Remora Identifications

The whalesucker’s preference for cetaceans leads many observers to assume that any remora spotted on a cetacean is this species. Most remora–marine mammal associations described in the literature are based on visual or photographic observations of a remote, free-swimming host and its passenger(s) rather than specimens collected from strandings or whaling victims. Host records determined from remote observations should be considered problematic, as the identification of remoras to species is difficult without the actual specimen in hand (Fertl and Landry, 1999; Sazima, 2006).

The whalesucker and other host-specific remoras are typically pelagic forms with a specialized morphology consisting of large disks, short stout bodies, and reduced fin size (when compared to those of inshore counterparts) (Fertl and Landry, 1999). More commonly reported remoras are slender-bodied, inshore forms, such as the sharksucker, that are least particular about their hosts. The possibility that small, slender remoras, as well as more stocky remoras photographed on cetaceans, may represent different life history stages of one species further complicates positive identification from afar.

Reproductive Behavior

MICHAEL A. FEDAK, BEN WILSON AND
PADDY P. POMEROY

I. Introduction

Taking a very broad view, the “function” of marine mammals is to convert prey into offspring. Reproductive behavior is an important part of the process by which this is brought about and must serve to create a situation in which the young can safely be born and nurtured, and one which facilitates mating with suitable

partners. But in long-lived animals, reproduction has to be linked to the process of gathering the resources for both current and future survival. Because many marine mammals do not feed where they reproduce, they also must locate breeding areas where reproduction and parental care can take place without compromising nutritional requirements before, during, and after the current effort. Here we will consider the basic problems that the animals must solve to reproduce, and give some illustrative examples of their behavior. We will take a broad, strategic view and look at reproductive behavior in a life history context, and consider how animals balance their needs for resources and reproduction.

A. The Basic Problems to Be Overcome

Although they spend most of their time in the water, seals give birth on ice or on land, and most newborn pups require a period ashore before being able to cope with life at sea. The vulnerability of pinnipeds on land means that suitable breeding sites need to be isolated from potential predators, limiting the choice of suitable ones. Pinnipeds do not feed while ashore. The widely separated and patchy distribution of resources that typifies most marine ecosystems means that animals are often widely separated from one another while foraging, and suitable breeding sites are often few and far between. This necessarily requires the use of stored reserves for periods of days to months. The geographical separation of feeding and breeding sites and the reliance on stored reserves are arguably the most important determinants of seal reproductive strategies and life history patterns.

Whales can give birth, nurse, and mate at sea but conditions suitable for the birth of young are often not suitable for foraging, so these two phases of their annual cycle often take place in widely separated geographical locations. Long migrations between breeding and foraging locations may still be necessary. And while foraging, individuals might be widely separated from potential mates, creating difficulties for locating suitable mates. Little food may be available during the birthing and the mating period, which therefore can require stored energy and materials for its success. Therefore, even though some whales are not constrained to spend time ashore for breeding, in many cases they face some of the same problems as pinnipeds.

Both seals and whales must move to breeding areas and choose a suitable breeding site where they can safely give birth, protect, and feed their young. They must choose a mate, copulate, and produce fertilized eggs. They must protect and feed their young and provide them with the resources and guidance needed to become nutritionally independent and give them a good chance to reach maturity and recruit into the breeding population. Then the adults must reestablish successful foraging patterns to provide resources for their own survival and reproductive success in the following year(s).

The marine habit and the geographic and energetic constraints acting on marine mammals have shaped their life histories and reproductive behaviors to create some of the most dramatic and extreme (some might even say bizarre) reproductive patterns among mammals.

B. The Importance of Size

Marine mammals as a group contain some of the largest mammals in existence as well as possibly the largest animal to have ever existed. The size adopted by the various species is such an obvious characteristic that we often look past to other features of the animals without considering its fundamental importance to behavior. Yet size stands out as being of fundamental importance as to how they these animals organize their reproductive behaviors. Because of the scaled relationship between body volume or mass (M) and metabolic rate (MR),

where $MR \propto M^{0.75}$, size has obvious implications for diving and foraging behavior. Larger species and individuals will require more prey each year but they may be able to dive for longer and go longer without food and thus be able to contend with less predictable or more widely distributed food distribution. Large size has equally fundamental implications for variations in reproductive behavior within and between species. Size in large part determines how long animals can fast during reproduction as well as how often they must leave the vicinity of their pups or of potential mates to look for food. In general, bigger animals can maintain their presence on beaches for longer and can breed farther from food sources. Size also sets the relationship between the duration and the efficiency of lactation (energy used in the process divided by energy stored in the pup). It sets the weaning mass of offspring and the relative cost to the mother of achieving offspring of that mass; larger mothers can produce larger pups without putting themselves at risk. The metabolic overheads (i.e., the amount of energy required to support the metabolism of mother and pup during lactation) are relatively lower for large animals in relation to the stored resources available and delivered to offspring. Size can affect the capability of animals (particularly males) to secure mates and, because of its influence on attendance patterns, size can determine the sort of strategies used to gain access to females; larger males can maintain residence for longer on breeding sites. So, size certainly matters in setting the strategies and behaviors used to accomplish reproduction.

Although seals and whales face common problems, the fact that whales do not come ashore to carry out any aspects of reproduction has meant that we have learned about their behavior in very different ways. Behavioral observations of cetaceans are largely confined to activities visible from the surface and “hands-on” techniques are much more difficult to apply. Cetaceans also have greater opportunity for complex social interactions throughout the periods of mating and parental care because parents, offspring, and other members of the social group can remain in contact during the extended times occupied by reproductive activities. The different methodologies used have also led to separation in the approaches used in the study of the two groups, resulting in emphasis placed on different aspects of behavior. It is therefore expedient to treat the two groups separately for much of the remainder of this discussion, even though we will be considering the same basic strategic goals.

II. Pinnipeds

We consider the strategies of reproductive behavior within the simple life history model (Fig. 1) in which the animal's mass or condition is viewed as the fundamental state variable that determines the constraints on reproductive success. It considers the life history as an annual cycle of terrestrial and aquatic phases split between foraging, breeding, and molt (see legend for details). Virtually all species can be fit into this conceptual framework and most aspects of reproductive behavior and the links with foraging and molting can be incorporated within it, in terms of how they affect fecundity and offspring quality. As such, the model provides a useful framework within which to describe the requirements of behavior. Some pinnipeds mate exclusively in water, with concomitant underwater displays, often by sound but by males; we do not detail these in this general overview.

A. Transition from Foraging to Breeding: Locating a Suitable Place to Breed

This involves behavior on a wide range of geographical scales, from global to a few meters. Animals must choose a geographical

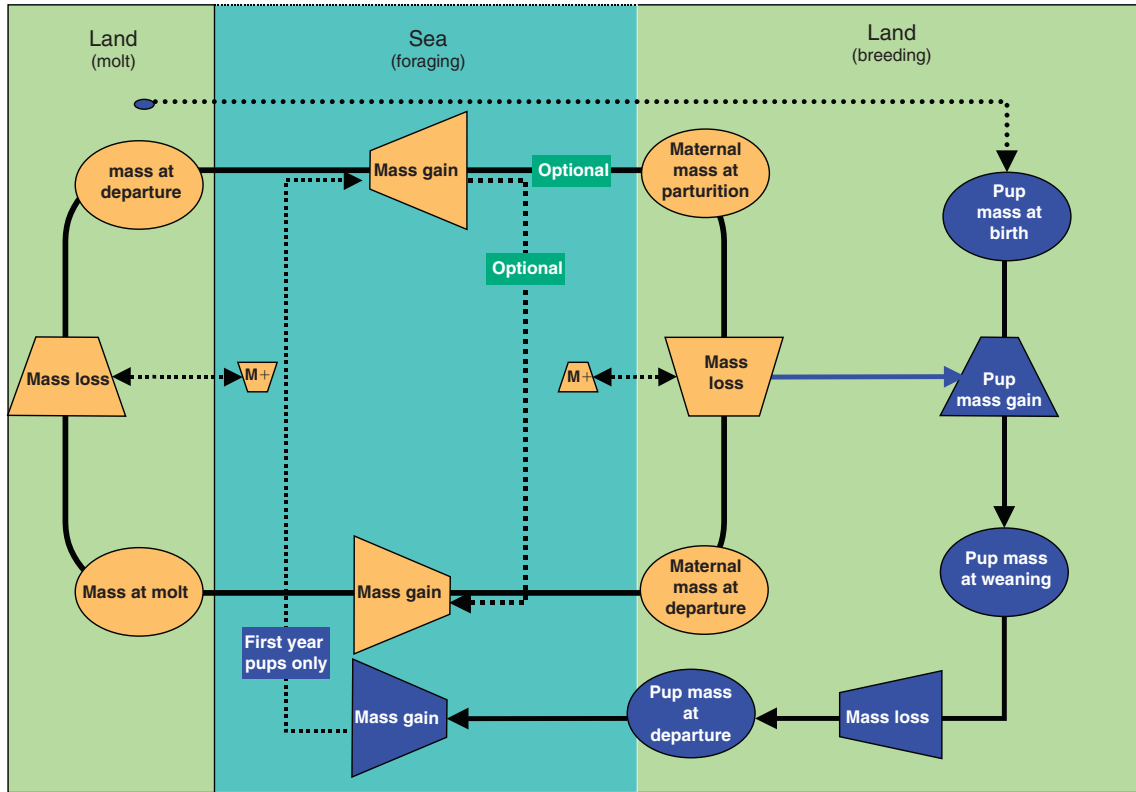

Figure 1 A diagram of a model of female pinniped life history with mass (as a surrogate for condition) as a state variable determining reproductive success through fecundity and pup quality. Trapezoids represent mass gain and loss. Ovals denote mass at the start and end of lactation and molt. Dotted lines represent optional paths. Some species and/or individuals (particularly smaller phocids and otariid species and smaller individuals of some phocids) may top up body mass during breeding and molt by returning to the sea to feed. Pups usually bypass molt during their first year and do not breed until they have reached a certain critical mass or condition. Females may opt not to produce a pup in years when they are below a critical mass or condition. Pups that are larger or in better condition at weaning are likely to both be able to remain on the beach longer and depart in better condition. They have a better chance of surviving and to breed earlier. That is, in this model, mass and condition determine the path taken and the resulting reproductive success, rather than age per se (see Arnborn *et al.*, 1997 and Boyd, this volume). In the context of this model, reproductive behavior acts to provide access to suitable mates, influence the transfer of resources to pups and its efficiency, and protect the investment in offspring.

area, a suitable site within that area (such as a particular beach or ice flow), particular conditions within that site, and a position relative to other animals in the colony. This selection needs to be accomplished in a timely way so that parturition can occur on time, and suitable mates are available.

The transition from foraging to reproduction can be considered to occur as soon as animals switch from a period of net gain of resources to net expenditure of body stores to support the travel to breeding sites. It is not likely to be a sharp boundary as animals may encounter food during their trip but a reduction in resource acquisition is likely because animals must leave prime foraging areas to make their way back to breeding sites. The critical issue for the individual animals is that they arrive at the breeding site in sufficiently good condition to support the breeding expenditure and the activities until successful foraging is reestablished. In the case of many otariids, this means that females must have sufficient reserves to sustain themselves and their pups until the mother's first successful foraging bout, which could be weeks after the animals leave the breeding beaches. Condition in males will in part determine how

long they can remain defending their access to females. In the case of the larger phocids, animals must have sufficient body condition to support the entire breeding effort. Smaller phocids or those with easy access to food may supplement stored reserves with foraging (Bowen *et al.*, in press). It could be argued that the expenditure during this phase should be added to those of reproduction, but we know of no studies that have attempted to do this. Navigational skills and previous experience of suitable sites allow the minimum time and energy to be expended.

1. Large Scale Movements: Choosing a Geographical Location

Many species have been shown to have the navigational skills to return to previously used breeding sites from great distances, but the methods they use to accomplish this navigational challenge remain largely unknown. Both southern (*Mirounga leonina*) and northern (*M. angustirostris*) elephant seals have been tracked making directed trips of 1000–3000 km between breeding and foraging locations, arriving on the same beaches they used for breeding the previous season (Le Boeuf *et al.*, 2000; Biuw *et al.*, 2007). Their great

size (males may weigh over 3000 kg and females average 500 kg) is important in making such trips energetically feasible. Many other larger species are similarly capable. Smaller species may need a supply of food on-route or feed closer to where they breed as the reproductive season approaches. It seems likely that the evolution of large body size in pinnipeds may have had much to do with enabling the uncoupling of geographical locations of feeding from those of breeding (but see Boyd, 1998 for a contrary view).

2. The Local Scale: Choosing a Breeding Site Within a Locality At a local scale, animals tend to breed where there are other seals present. This aggregative sociality is a key feature of pinniped behavior, although it is modified by the animals' state. The first animals to breed in a season tend to be the older, more experienced animals, and their presence encourages others to come ashore. Once a seal has chosen a breeding site, it tends to be used again and again. This breeding site fidelity means that the same rookeries tend to be used over a long term, and is shown by Weddell seals (*Leptonychotes weddellii*) (Croxall and Hiby, 1983), gray seals (*Halichoerus grypus*) (see later), northern elephant seals (Huber, 1987), Antarctic fur seals (*Arctocephalus gazella*), (Lunn and Boyd, 1991), and is probably widespread. Scottish gray seals are faithful to their previous pupping sites. Females return to pup within an average distance of 55 m on North Rona and 24 m on the Isle of May from their previous breeding sites (Pomeroy *et al.*, 1994, 2000a, b). Males that return also show very similar spatial fidelity at both colonies (Twiss *et al.*, 1994; Pomeroy *et al.*, 2000a, b).

Some seal species display philopatry; i.e., they return to breed at the location where they were born, e.g., fur seals (Gentry, 1999), southern elephant seals (Hindell and Little, 1988). Gray seals also display philopatry, sometimes with surprising accuracy (Pomeroy *et al.*, 2000a, b). It is possible to envisage at least two ways that new colonies may form. First, in a growing population, when space at an established colony has become limiting, pregnant females arriving to breed may be forced to move elsewhere if the available habitat is being used. In this scenario, the new colony should be reasonably close to the original one. Younger, primiparous females that breed later in the season may be forced to use an otherwise unoccupied location, and once there, others join them. The main criteria listed for breeding habitats are isolation (protection from land-based predators) and access to resources nearby. Few seals stray far from the sea. Otariids require a plentiful supply of food within reach of the breeding location, otherwise the breeding attempt may fail, but most phocids are functionally divorced from foraging requirements at breeding time by their ability to store resources, principally as blubber. Thus, phocids may use breeding locations far removed from their foraging grounds (e.g., gray seals, northern and southern elephant seals). Harbor seals (*Phoca vitulina*) represent an intermediate breeding and feeding strategy where mothers supplement their stored reserves with food acquired during foraging trips late in the lactation period (Boness *et al.*, 1994).

3. Choosing a Position Within a Site: The Individual Scale The local topography of the breeding location plays an important role in determining the particular location where pups are born. A featureless surface with unlimited access to the sea such as a sandbank offers the simplest case in which animals choose little except their distance from the sea. Additional resources, such as pools of water, may act as foci for breeding animals. However, seals breeding on many islands or beaches typically arrive at the breeding area through specific access routes. Restricted access produces a radiated pattern of colonization, but also creates thoroughfares where there is continual traffic as animals arrive and leave the colony. Pup mortality in these locations can be substantial (Anderson *et al.*, 1975).

The degree of topographic variation on a breeding colony at a scale relevant to seals is a primary determinant of their distribution within a site. In fact, the degree of topographical variation on the breeding colony probably also defines the scale of site fidelity shown by gray seals at two Scottish colonies, and may explain why fidelity is less apparent at relatively flat open locales like Sable Island (see later, Pomeroy *et al.*, 2000a, b; Boness and James, 1979).

Conservation or management considerations often require information on how animals may use available habitat, particularly where multiple use or potential conflicts occur. Habitat classification within a fine scale Global Information System (GIS) context has been used to identify suitable breeding areas for gray seals, and this was used to make a successful prediction of expansion of breeding areas at the Isle of May colony during the 1990s (Twiss *et al.*, 1999, 2000).

4. Assessment of Breeding Locations and Site Choice Seals that breed on land come ashore for a variable period before parturition occurs. For southern elephant seals this averages 4.5 days; for gray seals the average time ashore before parturition tends to be 2–3 days, although some animals are present at breeding locations for at least a month prior to parturition. This prepartum period appears to involve some assessment of the breeding location. Female gray seals emerge from the water, looking around intently and sniffing continuously, before making tentative moves inshore. Pregnant females collect together in groups near access points where they remain inactive, and any disturbance is likely to make them return to the sea. In some cases final selection of the pupping site occurs immediately prior to parturition when females move inland, and during this movement they can be seen sniffing the ground. Pomeroy *et al.* (1994) found many cases of females returning to the sea before coming ashore again to pup, sometimes in a different location to that chosen originally. Options for changing the pupping site are often limited to the prepartum period, since in most species, once the pup is born, it is not easy for mother and pup to change location together.

B. Investing in Young After Birth

Parental care in the pinnipeds is the exclusive domain of the mother in all but one species (see later for the single exception). Males take no part in the rearing process and the only part they play in breeding is to contribute sperm during mating. In fact, the process of mating is not without risk to the current offspring. Pups may become separated from their mothers or be the subject of aggressive behavior from males or females at this time, as well as running the risk of being crushed by males. Therefore, maternal care does not consist simply of feeding but includes all behaviors associated with the pup's welfare, such as maintenance of contact, vigilance, and defense against potential aggressors. A mother has finite resources available to service each breeding attempt and, once the pup is born, she has ultimate control over the feeding schedule and its duration. Mothers must gauge their reproductive effort according to the resources they have available, to do enough for the pup to have a good chance of survival without prejudicing the mother's survival or future breeding chances. The costs for mothers that expend too heavily in 1 year are reduced fecundity and lower breeding success in the next year (Pomeroy *et al.*, 1999). Consequently, the fundamental maternal trade-off is one of efficiency: supplying resources to the offspring at a low or acceptable expense. The single most important influence of the efficiency of the process is the "physiological time" it takes to accomplish it (Anderson and Fedak, 1987). For most phocids at least, maternal maintenance during the lactation fast must occur in parallel with the demands of feeding

the pup. The shorter this time, the smaller the fraction of maternal resources that are lost as heat (generated by the combined metabolism of mother and pup) and the greater the fraction that can appear as pup growth or remain as maternal condition.

The conflict, between pups' demands for resources and the requirement of mothers to limit expenditure to that which does not incur a threat to themselves, is exemplified by a study of southern elephant seal pups fed as twins. In this case, mothers did not expend resources beyond the level expected for a single pup, so that the cut-off point in this case was fixed by the mother (Arnbom *et al.*, 1997).

1. Maintaining Contact with Pups Seal breeding colonies are typically sensory-rich environments. Many animals are crowded into a restricted area, with the associated sights, smells, noise, and action associated with such a situation. A mother must maintain contact with her pup because, in general, neighbors react aggressively to foreign pups and pups that move away from their mothers may be injured or lose contact with their mothers and starve. At birth, a mother immediately sniffs and interacts with the neonate (Kovacs, 1987). By the time the first feed has been completed, mothers have established a bond with their pup that becomes progressively stronger as lactation proceeds. In most species, pups vocalize almost as soon as they are born, with mothers displaying a varying degree of competence in discriminating their own pup's call (fur seals, reviewed in Gentry, 1998, McCulloch *et al.*, 1999). In gray seals which commute from the breeding beach to the water during lactation, a returning mother looks, sniffs and (presumably) listens when she approaches her pupping site. Often several pups are inspected before one is fed. Reunions involve the approach by the mother, sniffing and flipping of the pup, and finally presenting the nipple to feed. Other pups trying to feed at this time are often dissuaded by aggression, but may also be excluded by the mother turning away. Some gray seal mothers (particularly at the expanding colony on the Isle of May, Scotland) are poor discriminators and feed any pups that approach them. Not surprisingly, these mothers rarely wean large offspring (see earlier).

Otariid mothers leave their pups unattended for several days while they forage for food and must recognize their offspring on their return. The primary mechanisms allowing this to occur successfully are smell and sound recognition.

2. Providing Protection Until the pup is born, many species of seals are tolerant of other conspecifics, so that, for example, large groups of pregnant female gray seals may lie very close to each other, often touching. As soon as the pup is born, this tolerance disappears and the mother becomes fiercely protective of the pup, defending a radius (typically 1.5 body lengths) around it. Any intruders into this space experience an escalating aggressive response, beginning with threats, approaches, then vocalizations, flipping, lunges, and finally at the most extreme, contact involving biting and flipping. Tolerance of conspecifics varies between mothers, but it is not known yet whether this reflects some form of kinship recognition, familiarity based on nonrelated associations, or simply individual variation in response.

There is a single instance of a role for paternal care in pinnipeds, where male Galapagos sea lions (*Zalophus wollebaeki*) mob sharks around colonies, reviewed in Trillmich (1996).

C. Lactation and Weaning

The process of lactation is demanding for mothers; most phocid species that fast during lactation lose 30–40% of their postpartum

mass, much of it blubber, producing the highest fat milk known in the animal world (up to 60% lipid) in the process. In most phocids the lactation period is short but intense (hooded seals 4 days, pup growth rate 6.0 kg/day; gray seals 18 days, pup growth rate 2.0 kg/day; southern elephant seals 23 days, pup growth rate 4.2 kg/day). Such growth rates can only be achieved by having energy-dense milk, frequent feeds (every 4–5 h in gray seals) and efficient conversion of maternal resources by the offspring. The concentrated milk also conserves water, which may be of short supply. Otariids have less absolute reserves available, although these may be relatively similar to those of phocids (Costa and Trillmich, 1988), and sustain their energy requirements by foraging throughout their extended but less intense lactation periods. This means that otariid pups receive feeds at intervals several days apart.

Weaning is abrupt in most phocids, as females depart from the rookery to return to the sea, leaving the pups on the beach. In most cases, mating has already occurred and indeed observation of a successful mating is a good indication of a female's imminent departure. However, there is considerable individual variation in the time that mothers spend with pups after mating; some may remain for several days before returning to the sea. In many otariid species, a long lactation period allows offspring to develop swimming, diving, and foraging while having the option of maternal milk as a food source. As a result, otariid mothers may have a much more prolonged weaning process, as offspring may still be with their mothers in the second year after birth (Horning, and Trillmich, 1997).

D. Locating and Selecting a Mate

Reproduction is the single most important action which individuals of any species carry out in their lifetimes. As such, mate choice is an important consideration. Circumstances dictate the degree of choice likely, in that the distribution of females at breeding time controls the mating patterns seen. For example, solitary hooded seal (*Cystophora cristata*) mothers on fast ice are unlikely to have many options in available mates and may simply mate with the male that has waited persistently beside her until she entered estrus. However, it seems likely that the successful male may have had to defend this position in encounters with others attempting to gain this opportunity. In this situation, males give the appearance of being monogamous. By contrast, large aggregations of female southern elephant seals make it possible for males to attempt to control access for mating, with the result that extreme polygyny occurs. Males in this situation compete vigorously among themselves, as the potential breeding rewards for successful males can be substantial. However, the priorities of each sex are rarely symmetrical. Female elephant seals may be considered to have exercised mate choice just after they arrive at the breeding beach. The 4.5 days spent ashore prior to parturition provide an opportunity to assess the stability and safety of the harems they enter and the qualities of the males guarding it. If pregnant females are disturbed during this pre-parturition period, they often change locations.

E. Female Mating Behavior

1. Resisting Advances Female seals are not receptive to males until they enter estrus. In gray seals, this occurs around day 15 of the average 18-day lactation period. Males that attempt to mate before the female is receptive receive a robust and clear message from the

female indicating her unwillingness. Initially, a female will threaten males that approach and her subsequent vocalizations at a persistent male can alert surrounding females to his presence. Neighboring females may join in this threat display to dissuade the male, although in a very few cases, fights between male and female may develop. Because of the sexual dimorphism common to most polygynous mammals, some males tend to be favored in such encounters. Females dissuade males using the same repertoire of aggressive behaviors as described earlier, but with the additional consideration that males attempting copulation are likely to have tried to mount the female. In this situation, the female's mobility and lack of cooperation, together with the aggressive display, is usually enough to make the male withdraw. Experienced males rarely attempt more than a preliminary investigation into female status and seem particularly adept at gauging a female's receptivity.

The ability of females to resist premature advances is perhaps at its most dramatic in elephant seals, where males can be more than 10 times the mass of the females with which they mate. Even here, in a species in which males are not known for their gentility, females can repel unwanted advances. Males holding harems frequently access the receptivity of females by "heading" them; i.e., they approach and rest their heads on the neck of candidate females. If the females are not receptive, they move their hind flippers rapidly from side to side in a swimming motion, slapping the side of the testing male. Most males take heed and move quickly on to test other females.

2. *Signaling Receptiveness/Estrus* It is not clear exactly how estrus is signaled in most species. Although the general behavioral indications are simply that a female's initial aggressive response to a mating attempt declines to acceptance and passivity, it is not clear what cues a male uses to judge the situation. Olfaction is probably important as males can be seen sniffing during their approach around females (Gentry, 1998). A successful mating may also signal to other males that a female is receptive. Some females approach males and apparently solicit their attention.

3. *Choosing a Mate* In reality, mate choice may range from having a single candidate and therefore a passive default, or be an active process involving the assessment of, or competition between a number of candidates. Competition may even be between sperm, where multiple matings occur (e.g., gray seals, elephant seals, some fur seals). The most comprehensive studies so far come from gray seals and elephant seals. Females that occupy prime sites on gray seal breeding colonies tend to have dominant males nearby (Pomeroy *et al.*, 1994; Twiss *et al.*, 1994; Pomeroy *et al.*, 2000a, b), and most mate with the dominant male. However, the number of pups they produce that are fathered by that male does not reflect the male's behavioral dominance or his mating success (Worthington Wilmer *et al.*, 2000). The reasons for this are not yet clear, but may lie in different attendance patterns of individual females at breeding colonies. There is some anecdotal and circumstantial evidence of mate choice in gray seals. At North Rona, where approximately 1200 pups are born each year, the father of a pup born to female J8 in 1986 was seen next to her in 1993, but both were at the other end of the island from where they had been in 1986 (Amos *et al.*, 1995). The pup born to J8 the following year was indeed fathered by the male seen with her in 1993. A more unusual occurrence was observed in 1997, when a known female left her peripheral pupping site to move about 80 m to the center of the colony where she was mated by a dominant male. She then returned to her pup and the attentions of a peripheral male at her pupping site. Females have been seen initiating copulations, but males initiate most of them.

F. Male Mating Behavior

A male's reproductive success is dependent on the number of offspring he manages to sire and how many of those eventually manage to reproduce as adults. The first part of this requires successful matings and to achieve these, males must be able to take up a place among breeding females, avoid or out-compete other males, and gain a successful copulation. The second part of his reproductive success is less straightforward, since it is possible to achieve many matings without producing any surviving offspring, let alone grand-offspring. Males employ a variety of strategies to achieve success.

1. *Maintaining Access to Females* The first prerequisite is simply to be around breeding females. Males must coordinate their efforts with the availability of receptive females. One of the most effective ways of gaining success for males is to spend a long time on the breeding colony, but this is costly, both in energetic terms, since males usually fast, and in potential injuries inflicted by competing males (Twiss *et al.*, 1998). For these reasons, large size tends to correlate with male success, so that the largest males tend to have advantages of increased energy reserves and in competitive abilities (Deutsch *et al.*, 1990).

2. *Monogamy—Polygamy* As already discussed, the potential for polygamy in these animals depends on the distribution of females (2.5 above). Although the terms monogamy and polygamy usually apply to mating patterns of species, they may be applied to the tactics which individuals employ either throughout, or during phases of, their lifetimes. However, without complete knowledge of the reproductive histories of individual animals, it is difficult to make generalizations. Evidence from genetic studies can provide useful insights in these areas. In general, the evidence to date from genetics supports the general observational conclusions on mating patterns, for example in southern elephant seals and in gray seals, although some queries have been raised. One such is the failure of apparently dominant males to account for as many paternities as predicted (Amos *et al.*, 1993a, b). Male reproductive longevities are as important as their within-season success (Worthington Wilmer *et al.*, 1999). Long-lived, reproductively active males may accrue a greater success than live-fast die-young males whose activities are conspicuous (Twiss *et al.*, 2006).

3. *Keeping Other Males Away* As with many mammals, the risks inherent in engaging in fights over breeding have led to a formalized ritual of aggressive displays in many pinniped species. Dominance hierarchies are common, so that disputes lead to fewer actual fights than otherwise might be expected. Fights do occur, but usually between closely matched opponents where the preliminary assessments could not determine a clear outcome (Arnborn *et al.*, 1997; Deutsch *et al.*, 1990; Twiss *et al.*, 1998). In gray seals, males attempt to control access to groups of females by threatening intruders with open mouth displays, hisses, and vocalizations. Intruders are chased away, but serious challengers may produce fights, which can last up to an hour and leave either or both combatants seriously injured. It is common for losers of such fights to disappear from the breeding colony.

4. *Optional Strategies* Given the high cost of engaging in the mainstream competition for mating opportunities, it is not surprising that alternative strategies exist. Younger less experienced males are seen around the periphery of breeding colonies and may acquire experience gradually. Some males employ a cryptic tactic, using their similarity to females to gain a position amongst females, making the most of their opportunities when the dominant male is engaged elsewhere.

It is becoming increasingly evident that aquatic mating may occur to a greater extent than suspected and that the phenotypic qualities that are successful on land may not necessarily be the same for males adopting this mating pattern.

G. Mating

In most observable species, males usually initiate copulations. Males often act to immobilize the female in some way by biting the back of the neck. On land, the male's weight applied via his body or flippers can help to position the female. In the water, because animals are near neutrally buoyant, the male's weight is less important in restraint. In gray seals breeding on land, a male attempts to mount the female by maneuvering alongside, then throwing his head and shoulders over the female's back. Her response is almost always aggressive, but a female in estrus will accept the male's advances if he persists and manages to grasp the skin of her neck in his jaws. This act is the single best predictor of a female's acquiescence. At the same time, the male tries to achieve intromission by repeated pelvic thrusts, whereas the female either cooperates by lying still, or resists by moving her rear as much as possible. Gray seals also mate underwater. There too, males grasp the females by the back of the neck in their jaws. Because the male cannot restrain the female as easily, she has greater opportunity to avoid the mating. Obviously, both must breathe and move together to the surface when necessary. It is not clear how the need to breathe is communicated to the other partner but cooperation is evident. In both situations, when a successful mating is achieved, the pair remains relatively motionless, for anything as brief as 5 min. or as long as 40 min. (gray seals, Twiss *et al.*, 1998). The function of such long copulations is not known, since males indulging in long copulations are leaving other females unguarded. It is thought that ejaculation occurs toward the end of the copulatory period, and females have been observed to have rhythmic contractions of the lower abdomen in the later stages of copulations. Re-mating of a female may take place soon after a copulation, either by the same or a different male.

H. Social Structure

Seals are not often regarded as particularly social animals, yet they exhibit philopatry and breeding site fidelity, are long-lived, and often haul out in groups segregated by age and sex. Gray seals breeding on N. Rona Island exhibited spatial structure in average relatedness of neighbors, such that mothers breeding in central areas were more related to the rest of the colony than those breeding at the periphery (Pomeroy *et al.*, 2001). In addition, taking site fidelity into account, some dyads occurred together more often than would be expected, if their typical movement patterns operated at random, leading to the conclusion that these mothers change pupping locations together (Pomeroy *et al.*, 2005). It remains to be seen if such phenomena are widespread.

I. The Transition to Foraging

1. Post Weaning Behavior of Mothers The mothers of most otariids repeatedly leave their pups to feed and gather the resources to support continued lactation. For them, weaning does not therefore represent a dramatic change in behavior. They simply fail to return. Some species such as the Galapagos fur seal (*Arctocephalus*

galapogoensis) may give birth to the subsequent pup before the prior pup is weaned, but this pattern is unusual. For most, animals may shift to nonbreeding haul-out locations and engage in longer and more distant foraging trips. But for phocid mothers, weaning occasions can abruptly change in behavior. Typically, soon after mating occurs one or a few times, mothers abandon their pups, leave their position in the colony, and quickly enter the sea. In some species (particularly among otariids) animals may be seen traveling away from breeding sites in groups, but in many phocids, departure appears solitary. Pups are normally left behind. The "decision" to leave is a critical one in relation to the state of body energy reserves. Good foraging areas may be distant from breeding locations, and have changed in position and value while animals were breeding. Mothers must have sufficient stored reserves to enable them to reach these without putting themselves at unacceptable risk.

2. Post Weaning Behavior of Pups Weaning occasions dramatic changes in behavior for pups as well. Once pups are weaned, they no longer have the protection of their mothers. They no longer nurse and begin to fast for a time before the transition to nutritional independence. Otariid pups undergo what may be thought of as temporary weaning, when their mothers depart to sea to feed in between bouts of lactation. They have experience of being left unattended prior to true weaning and show some of the behaviors of weaned pups early in development. In either case, pups typically move to areas where they can avoid contact with adults and may often congregate in large groups. In many cases, this movement is stimulated by aggressive encounters with other mothers and adult males within the colony. In elephant seals, mothers leave the weaned pup behind in the harem, possibly at a central location within it. Other mothers will act aggressively to the approach of pups other than their own, and this tends to move unattended pups around with a net movement to the periphery of the harem. Within a day of weaning, pups are usually out of the harems and then move around the beaches in an apparently undirected way. When encountering other pups, they tend to remain with them. The end result of this mobility is that large numbers of pups end up in "crèches" at places on beaches where no harems are present.

Phocid pups often remain in such "crèche" groups, associated with breeding sites, for periods from days to months after weaning. The function of the time spent in these "post weaning fasts" is not understood but is thought to involve a period of physiological, behavioral, and/or social development. Pups may interact with one another, exhibiting some variants of adult behavior. For example, male elephant seal pups often engage in mock fights that involve the rearing up and head strikes seen in the battles between breeding males. Pups of both sexes tend to move into shallow inshore water or fresh water ponds during the night and swim and dive. Dive depths as great as 271 m have been observed in pups from Macquarie Island during this time (Hindell *et al.*, 1999) but in general dives are short and shallow. An increasing fraction of the day is spent in the water until departure on the first foraging trip, typically after about 30–45 days and after about 35% of the mass attained by weaning has been lost. There is some evidence that pups that remain ashore longer have better diving abilities when they enter the sea, which may help to explain the value of the post breeding fast (Noren *et al.*, 2005).

For pups too, the decision as to when to leave is potentially difficult and critical. Phocid pups have no prior experience of foraging locations. They tend to leave as individuals, not forming into groups to avoid predators and in any case, any other pups departing after weaning are similarly naïve. The way they choose to locate foraging sites and the cues they use to help them remain largely unknown.

For example, southern elephant seal pups may travel to locations thousands of kilometers away from where they were born before establishing successful foraging. Telemetry devices on elephant seal pups born on Macquarie Island sent back track and dive behavior information, which was used to estimate changes in buoyancy and body condition of pups over their first foraging trip. Pups often traveled 30–50 days before beginning to fatten. These data, combined with survivorship information (McMahon *et al.*, 2000) and estimates of the animals' body condition at weaning and departure suggested that pups that are larger and fatter have the best chance of surviving through their first years of life. Fat content on its own may be less critical than protein stores in determining likelihood of survival to the time successful foraging is established (Bennett *et al.*, 2007).

Interestingly, even in otariids and phocids with unusually precocious young where the opportunity for mothers to lead pups to food seems to exist, it is not exercised. Walrus (*Odobenus rosmarus*) seem to be the only exception to this. Pups travel with mothers prior to weaning and nurse at sea, giving them the opportunity to get geographical information on where to feed. It seems likely that if mothers could direct pups to food, they could obviate the need for a fraction of the material resources given to pups with this information. It seems surprising that this is rarely done.

III. Odobenids, Sirenians, and Sea Otters (*Enhydra lutris*)

These groups are unique in many ways, showing some particularly interesting variations in reproductive behavior and other life history features. Detailed accounts can be found in Fay (1982) for Walrus, O'Shea *et al.* (1995) for sirenians, and Riedman and Estes (1990) for sea otters. We mention these groups only briefly here, emphasizing a few unusual features of reproductive situation and behavior, and we ignore altogether another marine mammal, the polar bear (*Ursus maritimus*).

Sirenians are unique in being the only group of mammalian marine herbivores. This different lifestyle has led to unusual distribution patterns and some unusual breeding behavior. Individuals of both sexes move about in response to resources such as food and fresh water. In the case of manatees (*Trichechus* spp.) at the extreme northern edge of their range in Florida, warm water sources such as power plants and warm springs cause them to congregate in large groups. They seem dependent on these at times of exceptionally cold weather, but they do not breed in these groups and this opportunistic proximity is not utilized to bring the sexes together for mating. Both males and females can range widely at other times. Locating mates seems to be the result of chance encounters between males and females in estrus. Little is known about how males locate estrus females but increased mobility of estrus females may increase chances of encounters with males. When a female comes into estrus (lasting up to 3–4 weeks), “mating herds” of hopeful males surround her. The normally quite and gentle appearance of the species in general is belied at this time with aggressive behavior between males trying to secure mating opportunities. During estrus period, females may mate with several males. Calves are born underwater and nurse there. They travel with their mothers for 1–4 years. Contact between mothers and young is maintained in part acoustically.

Walrus, too, show some important unique features in their breeding behavior. They are a polygynous group. Males display, interact aggressively, and mate in the water. Although pups are born on ice or land, they nurse in the water. They are the only pinniped group

where maternal foraging and maternal care occur simultaneously. Young move about with mothers when they feed. One of the most common observations of nursing in water is when mothers stay at the surface, oriented vertically with their heads out, the pups nurse upside down with the hind flippers at the surface and their heads down below at the nipples (Miller and Boness, 1983).

We only mention sea otters to the extent of noting that they, too, do not breed colonially and also give birth at sea. We are left with the intriguing question: if the ability to give birth at sea, nurse in the water, and lead pups to food is possible in walrus and sea otters, why do these patterns not occur more often in the “mainstream” pinnipeds. Clearly they are possible options in the pinnipeds as we see later, they are for cetaceans.

IV. Cetaceans

Unlike pinnipeds, odobenids, and otters, cetaceans have evolved a behavioral and anatomical suite of adaptations allowing them to mate, give birth, suckle, and nurture their young entirely in water. Freed of the spatial and the temporal constraints imposed by reliance on land or ice to breed, the cetaceans have developed a wide diversity of social systems and life history strategies quite unlike those of the pinnipeds. Although some cetaceans, principally the larger mysticetes, compartmentalize breeding to a temporally and spatially discrete component in their lives, the majority breed and acquire resources simultaneously. Further, consecutive breeding attempts themselves may be superimposed upon each other, with females concurrently rearing calves from different breeding attempts and even contributing directly to the survival of their offspring's own offspring.

Having no need of land to reproduce has assuredly led to the success and ubiquitous nature of the cetaceans, but for the same reason has also severely hampered our abilities to understand them. At the most basic level, discrete acts like copulation and birth in most species have never been observed let alone quantified, while comparing the success of different tactics employed by individuals within populations remains somewhat of a Holy Grail. What is known is pieced together from anatomical studies, whaling operations, live captures, individual identification, genetic analyses, and interspecies comparisons (Lockyer, 2007). From these fragments, it is clear that the cetaceans have much to teach us about the ecological determinants of reproductive and social behavior, and even offer potential to broaden our understanding of mammalian reproductive behavior as a whole (Connor *et al.*, 1998).

A. Seasonality of Reproduction

For the majority of cetaceans, reproduction has a seasonal component. For the mysticetes [with the possible exception of Bryde's whales (*Balaenoptera edeni*), (Lockyer, 1984)], breeding occurs as a discrete phase of each year with other aspects, principally feeding, being either reduced or halted entirely. The best known species shuttle on an annual basis between productive feeding regions and areas associated with parturition, early nursing, courtship, and mating. The reproductive behavior of gray whales (*Eschrichtius robustus*) is a prime example. Northern Pacific populations migrate from high latitude temperate or polar waters after a summer of feeding, southward along North American and Asian coasts to breed in sheltered coastal waters. Although almost all whales migrate, whether reproducing or not, the pregnant females move south earlier than males and then 80 or so days later return north again following behind the males and newly mated females (Jones and Swartz, 1984).

Humpback (*Megaptera novaeangliae*) and right (*Eubalaena* spp.) whales follow similar patterns, but the behavior of rorquals, such as the blue (*Balaenoptera musculus*), fin (*B. physalus*), and minke (*B. acutorostrata*) whale are more poorly known and, though seasonal, it is as yet unclear when and where breeding actually occurs.

The lives of the odontocete cetaceans are less obviously compartmentalized and breeding takes place simultaneously with other activities. Detecting breeding seasons is consequently harder and usually estimated from parameters such as the first appearance of neonates at sea, fetal maturity in stranded or captured animals, and seasonal changes in testes. From such studies, it appears that the majority of odontocetes extend their breeding activities over protracted seasons. Interestingly, those that remain in high latitude areas tend to reproduce at the opposite time of year to neighboring mysticetes. Harbor porpoises (*Phocoena phocoena*) in the north Atlantic, for example, ovulate, mate, and give birth in spring and early summer (Read and Hohn, 1995) whereas seasonally sympatric humpback whales migrate south to breed in winter. Furthermore within species, the specific timing of reproduction may vary by region or population. Bottlenose dolphins (*Tursiops* spp.), for example, show diffuse seasonal peaks in reproduction but these vary in their timing with location (Urian *et al.*, 1996).

The reasons why mysticetes and odontocetes adopt such differing behavioral and physiological strategies toward the seasonality of reproduction remains poorly understood. Body size clearly allows the mysticetes to store sufficient reserves to forego feeding and dedicate a substantial proportion of the year exclusively to breeding. As most odontocetes are smaller, it is tempting to assume that they have less capacity to fast during a discrete breeding season, however they are of similar body size or larger than the highly seasonally breeding pinnipeds. It therefore remains a possibility that odontocetes, and females in particular, have protracted breeding seasons, simply because other aspects of their lives allow it. For all cetaceans, it is likely that food availability, risk of predation, water temperature, and sea or river conditions are important in dictating which season is actually selected to breed (Corkeron and Connor, 1999).

B. Gathering Resources to Invest in Reproduction

At times outside of specific breeding seasons, mysticetes gravitate toward areas that maximize their potential for prey consumption. Migrations into productive, often high latitude, areas are therefore common. The duration and the rate of energy acquisition appears to be important in determining subsequent reproductive interval, ovulation rate, and fecundity (Lockyer, 1987). For odontocetes, such migrations are less evident, and suggest that their reproductive capabilities allow them to remain in their foraging areas year round. A notable and unusual exception is found in sperm whales (*Physeter macrocephalus*). Females remain in tropical or subtropical waters year round, whereas the sexually dimorphic males migrate from productive high latitude feeding areas toward the equator and their mates to breed. The extreme sexual dimorphism (with males weighing up to 3 times as much as females) may necessitate such migrations to regions especially rich in prey.

C. Locating a Suitable Place to Breed

Breeding in cetaceans can be broken down into three phases: giving birth, suckling young, and mating. Because, gestation in most cetaceans is close to 12 months these three activities generally

occur at a similar time of year and are therefore often considered as if they were one event. However, the factors that influence each differ and thus the choice of breeding habitats may well represent a compromise for the individuals concerned. The processes of giving birth and suckling young may benefit from waters with low predator abundance while these characteristics will be of less importance for mating. Examples of differences in locations for these activities are rare especially in odontocetes where examples of specific sites used for any breeding activities over others are themselves uncommon. One study of harbor porpoises in the North Sea found significantly higher proportions of calves in a specific coastal area relative to neighboring waters, though the reasons why this area was favored is as yet unknown (Sonntag *et al.*, 1999). Mysticetes offer more concrete examples of breeding areas. Those most studied include humpback, gray, and right whales, which typically breed near coasts, with the latter two species favoring sheltered shallow waters. As we might expect, they also offer some evidence of the differing requirements of raising young and mating, with females with newborn calves favoring slightly different areas to the other breeding individuals (Jones and Swartz, 1984; Craig and Herman, 2000). Since the ways in which breeding sites selected by whales actually perform their function are unknown (in contrast to the choice of breeding sites by pinnipeds) we have no information on whether availability of these habitats actually limit the size or behavior of cetacean populations.

Underlying all of the issues associated with mysticete migrations to breeding sites is the controversy over why the mysticetes migrate at all. Sheltered shallow waters are not unique to the tropics, and some mysticetes, such as the bowhead whale (*Balaena mysticetus*), are entirely capable of breeding in the same polar waters in which they feed. Factors that pose direct benefits to adults do not appear to withstand scrutiny while the thermal constraints on calves do not seem likely when neonate mysticetes are larger than most adult odontocetes and are probably already thermoneutral in colder waters. Instead, relatively novel possibilities such as calf predation by killer whales (*Orcinus orca*) might lie as the root cause of such enormous migrations for those species large enough to be capable of making them (Corkeron and Connor, 1999). See also MIGRATION AND MOVEMENT PATTERNS, this volume.

Gray whales appear to navigate to and from their breeding areas by following the coastal margins of their respective continents. In contrast, the north-south migrations of humpback whales, seem to be deflected by coastlines, currents, and underwater topography rather than guided by them (Dawbin, 1966). How these whales find locations such as the Hawaiian Islands each year in waters as large as the Pacific is still unknown. Use of celestial, acoustic, or magnetic markers are distinct possibilities.

D. Giving Birth

Few cetacean births have been observed in the wild, but in captive odontocetes, most births are accomplished rapidly without direct assistance from conspecifics. However, there are scattered reports of animals seemingly helping in the birth process, either pulling the fetus or placenta clear off the birth canal. The frequency of such activities, if they occur at all in wild populations, is unknown. Because wild births have been so rarely observed, little is known about how females might reduce the risks of predation and separation in the moments after birth. The proficient swimming abilities of newborn calves permit mother and neonate to rapidly vacate an area where the birth occurred and so minimize the attentions of predators whereas the social nature of cetaceans may permit increased

predator detection and defense. Newborn calves adopt a swimming posture alongside their mothers, permitting tactile communication, camouflage, and slipstreaming.

E. Investing in Young After Birth

Parental care in cetaceans is predominantly the responsibility of the mother, although male and female kin as well as unrelated females may provide additional care.

1. Maintaining Contact and Providing Protection All cetaceans are born nutritionally dependent on their mothers, but with births occurring without the spatial certainties of land or ice, there is potential for calves to become separated from their mothers and therefore rapidly starve or become prey. For those species that suspend foraging during breeding, females can devote almost continuous attention to their calves. Species that continue foraging, face a problem as the diving abilities of calves may be insufficient to follow their foraging mothers. Babysitting among this latter group appears to be common solution, with an apparent continuum among the odontocetes. This can range from females of similar breeding status schooling with one another and presumably taking turns guarding calves (Wells *et al.*, 1987) or at least acting as a spatial point of reference, through to related females and their adolescent young accompanying mothers and their neonates (Whitehead, 1996). It may even extend to a system demonstrated by killer and pilot (*Globicephala* spp.) whales (apparently unique among mammals) of stable kin groups with neither male nor female dispersal but instead investment in raising their own (females only) and related offspring (females and males) (Bigg *et al.*, 1990; Amos *et al.*, 1993a, b). Despite such behavioral safeguards, however, cetacean mobility makes separations between mother or care-giver and calf inevitable. Individually specific calls (see SIGNATURE WHISTLES, this volume) are thought to be important in reuniting individuals in species like the bottlenose dolphin. However, such mechanisms take time to develop, and neonate mortality, though low compared with other mammals, accounts for a significant fraction of cetacean deaths.

Our understanding of cetacean reproductive behavior is undoubtedly hampered by the potential ambiguity of the behavior that can be observed. This is particularly prevalent in aspects involving spatial proximity of individuals and apparently altruistic or cooperative behavior. The social complexities of cetacean societies and considerable component that appears to be learnt and practiced makes context an essential component of any behavioral observation. Babysitting is an attractive and logical concept that has been frequently described but the appearance of a calf with an adult animal other than its mother may result for other more reproductively selfish motives. Young inexperienced female bottlenose dolphins, for example, may temporarily kidnap calves and thereby improve their own maternal skills (Mann and Smuts, 1998) whereas males or females may benefit from capturing and killing another's young (Patterson *et al.*, 1998).

2. Lactation and Weaning Cetacean calves do not suffer the constraints experienced by phocid seals which need to rapidly transfer resources to the pup in order to resume feeding nor endure the periods of maternal absence experienced by otariid pups. Instead, female cetaceans take their mobile calves with them and are generally only separated for the length of a foraging dive. Thus, calves have the opportunity to suckle frequently and match milk intake with energy expenditure and growth. However, suckling itself poses a behavioral challenge for cetaceans. The two mammary teats in all female cetaceans are located either side of the genital opening on

her ventral side, about two-thirds of the way down her body. For pinnipeds, mother and pup can simply lie at right angles to each other on land or ice but for cetaceans, in-water suckling is more complex. To suckle, the calf must either hold its breath, or have the mother roll onto her side and hold hers. Furthermore one member must orient on a different trajectory to the other in order to make firm contact between mother's teat and calf's beak. Thus the pair must slow or halt progress, necessitating suckling in brief bouts lasting only a few seconds, and by default the cooperation of both parties. The presence of bristles on the rostra of neonate cetaceans are thought to help calves orient during suckling whereas a filled margin on their tongues and muscular control of milk ejection by the mother likely aid efficient milk transfer during the abbreviated suckling events. Given the extreme evolutionary sculpting of the anatomy of the cetaceans, it is somewhat perplexing that the mammary teats are universally located in such an awkward position. The sirenians have their mammary teats located posterior to the pectoral flippers, and so a calf can suckle from a cow without either party having to significantly change from a normal orientation. It is intriguing to wonder why an apparently awkward system has been so conserved in the cetaceans.

Mysticete calves are generally weaned within a year of birth, and in migratory species this coincides with the pair reaching high latitude feeding grounds. Weaning may or may not precipitate separation of cow and calf, but in its timing offers opportunities for the mother to train a calf in migration routes, the location of feeding areas, and potentially facilitate membership of feeding assemblages. Lactation in the majority of odontocetes is longer, and in some cases far longer, with weaning appearing to be gradual and occurring over a period of months or years. Lactose, for example has been detected in the stomachs of sperm whales up to 13 years of age (Best *et al.*, 1984). Such long-term maternal investment suggests that many components of odontocete development require a considerable period of learning and training. Foraging tactics in odontocetes (see Foraging Strategies and Tactics, this volume) are often performed in groups and, while it is unknown what proportion are cooperative or exploitative, their complexity is clear, as is the need for a high degree of interindividual coordination and practice (Guinet, 1991). Calves may learn through observation or dedicated tutoring. The prolonged lactation and consequent investment in young allows calves to develop to a high level before facing nutritional independence. Spatial independence may be even longer in coming if it occurs at all. Bottlenose dolphins probably wean around 18 months after birth, but remain closely associated with their mothers for at least 4 years (Wells *et al.*, 1987). Young killer and pilot whales may never separate from their mothers, drawing comparison with elephant matriarchal societies where the eldest animals may function as long-term information stores and guardians for their offspring and offspring's offspring.

F. Locating and Selecting a Mate

1. Female Mating Behavior The number of offspring that female cetaceans produce in a lifetime varies. Some porpoises and gray and humpback whales may at times give birth on an annual or a biennial cycle, and have the potential to produce between a dozen and twenty offspring in a lifetime. Others produce much fewer. Female killer whales, for example, may only produce five to six young in their entire lives. Whether twenty or five, these numbers are small given the huge investment in time and resources that each calf receives, and therefore the choice of an appropriate mate to father them is a major component of the reproductive fitness for individual females.

1. Choosing a Mate In short, we have little solid information on how female cetaceans choose mates. In any species or population there are many potential junctures where a female may be making behavioral or physiological decisions, both before conception and afterward. In some instances, females may have the opportunity to simply select a particular male with which to copulate from a range of alternatives. Clapham (1996) has proposed such a case for humpback whales, where males engage in communal display behaviors on the breeding grounds without showing any defense of resources. Females would have opportunities to approach males based on the quality of their displays, or choose males who have worked out dominance relationships among themselves. Female bottlenose dolphins are frequently seen being attended by single or alliances of males (Wells *et al.*, 1987; Connor *et al.*, 1996). Although males may have opportunities to herd a female against her will, the females may also have the opportunity to reject or maintain that contact. Females have been observed rebutting the copulation attempts of males by fleeing or rolling upside down at the surface so that males don't have access to their genital opening.

After copulation, females may have a range of behavioral and physiological options to influence the probability of conception. The number of subsequent males with which she mates would influence the probability of a particular male being the father. The large volumes of sperm produced by males of several cetacean species (see later) suggest that females do mate with several males and that competition between the sperm themselves may be a frequent occurrence in such species. Repeatedly mating with a particular male would also significantly bias the odds. Whether or not an egg is available for fertilization is also critical and it appears that ovulation itself may be related to mating and therefore has the potential to be under the female's control.

Even after fertilization has occurred, there are opportunities to select whether or not to continue investment in a particular partner's offspring. These may range from selective abortion, energetic investment in the fetus, and the subsequent level of parental care expended in the calf. At present we have little information to determine whether such behavioral and physiological decisions are actually made, but since such evidence has been found widely in birds and terrestrial mammals it is entirely possible that such options are open to female cetaceans as well.

2. Male Mating Behavior The reproductive behavior displayed by males is a function of the social and the physical environments in which they live and compete. As with the diversity of habitats and lifestyles exhibited by the cetaceans, males of different species and populations show a huge range of tactics to maximize their reproductive potential (see MATING SYSTEMS, this volume). At a most basic level, males should behave to optimize the number of their own sperm competing to fertilize a female's egg and limit the number of those of competitors. Thus males may increase the probability of obtaining copulations by signaling their quality to females and competing males, through physical or acoustic displays (e.g., postural displays in bottlenose dolphins, songs of humpback whales, sperm whale vocalizations, etc.), ornamentation or body scarring (teeth and scars in beaked whales), intermale combat (humpback whales), extreme body size (sperm whales), or simply tracking the long-distance migrations of females (humpback, gray and right whales). Males may attempt to guard receptive or potentially receptive mates to reduce the probability of competitors mating and increase the number of copulations they can obtain themselves. The alliances

formed between male bottlenose dolphins may be an example of such behavior (Connor *et al.*, 1996) where pairs or trios of males may trade off their exclusive access to a female in order to ensure that other males cannot gain mating opportunities. The absence of such alliances in some other populations of bottlenose dolphins (Wilson *et al.*, 1993) suggest that such tactics are context specific and influenced by factors such as the relative abundance of receptive females and potential for males to monopolize them.

Even once copulation has occurred, competition between males need not be over. Gray, bowhead and right whales, harbor porpoises, and several species of dolphins all have testes substantially larger than their body size would suggest. Large quantities of sperm and the ability to copulate frequently may allow males to flush away or dilute the sperm and consequent reproductive chances of others males.

Males may also be able to increase the effective pool of receptive females by influencing the fate of other males' calves. Infanticide is common among terrestrial mammals and is often carried out by males in order to force females to switch from investing resources into a previous calf not sired by themselves and become reproductively receptive again. It is unknown if such behavior occurs in cetacean societies but the violent deaths of young bottlenose dolphins in some populations suggest that males may exploit such options (Patterson *et al.*, 1998).

The long lives and intricate social organization of cetaceans, particularly odontocetes, also offers males the opportunity to increase their fitness, not by maximizing their potential to father offspring, but by investing in their kin. The lack of male dispersal in killer and pilot whales (Bigg *et al.*, 1990; Amos *et al.*, 1993a, b) and absence of interbreeding within pod members, suggest that males may remain with their maternally derived relatives in order to provide some degree of care or protection and thus increase their own inclusive fitness.

G. Mating

Cetaceans live in a three-dimensional environment that facilitates copulation from a variety of orientations. Common positions include ventrum to ventrum with the pair orientated in the same directions or the male may mount the female from a nonparallel position. Intromission may last only a few seconds or far longer and involve vigorous thrusting or a more passive attitude. Mating may be preceded and followed by prolonged periods of courtship and petting and mating episodes (see COURTSHIP, this volume) may be repeated over periods of minutes, hours, or days.

H. The Transition to the Non-breeding Season

Although copulation and parturition is generally seasonal in cetaceans, investment in reproduction for females is an almost continuous process after reaching sexual maturity. Baleen whales that migrate from breeding grounds with neonate calves, wean them on the feeding grounds, and may either have a few months of intensive feeding before returning to the breeding grounds to mate or be already pregnant following copulation the previous year. Female odontocetes frequently superimpose reproductive events by both being pregnant and lactating or suckling more than one generation of calves at the same time. Perhaps the most intriguing situation is demonstrated by female pilot whales, which appear to cease ovulating after age 40 and yet continue to lactate for well over a decade

(Marsh and Kasuya, 1991). In doing so, they have the potential to not only extend long-term care to their own offspring but also have the potential to influence the fate of their offspring's own offspring.

Ribbon Seal

Histiophoca fasciata

LLOYD LOWRY AND PETER BOVENC

I. Characteristics and Taxonomy

The ribbon seal is one of the least well known of all the world’s pinnipeds. The species has been placed by some in the genus *Phoca* based on cranial morphology (Burns and Fay, 1970), but molecular studies (Árnason *et al.*, 1995; Mouchaty *et al.*, 1995) indicate that ribbon seals belong in the separate genus, *Histiophoca* (Carr and Perry, 1997; Rice, 1998; Davis *et al.*, 2004). Its scientific name, *Histiophoca fasciata*, means the banded “actor-seal” in Latin.

Ribbon seals are distinctively marked (Naito and Oshima, 1976). Pups are born with a long, white pelage called lanugo (Fig. 1), and for the first year after the lanugo is shed their coat is silver–gray with a dark blue–black back (Fig. 2). Older seals have a dark background with a set of light bands encircling the head, the posterior trunk, and each front flipper. In males the background color is nearly black and the bands almost white (Fig. 3). Females have a similar pattern with much less contrast (Fig. 1). Adult seals are generally 1.5–1.75 m long (nose to tail) and weigh 70–110 kg. They are considerably more slender than other northern ice-inhabiting seals.

The skull of the ribbon seal is relatively short and broad. Their dentition is similar to that of other phocid seals, usually with 34 small teeth (Burns, 1981).

II. Distribution and Abundance

The distribution of ribbon seals is restricted to the northern North Pacific Ocean, where they are seen most commonly in the Okhotsk and Bering seas (Fig. 4). In those regions during the late winter and spring, ribbon seals are commonly seen hauled out on sea ice in the ice front region. They stay associated with the ice until it disappears in May–June. During the summer and fall ribbon seals are rarely seen hauled out on ice or land, and the presumption that they spend those months living a pelagic lifestyle (Burns, 1981) has recently been corroborated by tracking with satellite-linked tags. Ribbon seals tagged in the spring of 2005 near the eastern coast of

Kamchatka spent the summer and fall at sea throughout the Bering Sea and the Aleutian Islands, whereas roughly half of the seals that were tagged in the central Bering Sea in 2007 moved to the Chukchi and Beaufort seas during summer and fall. Reported sightings from

summer–fall have been at sea near the Pribilof Islands, ashore in the eastern Aleutian Islands, and at the ice edge in the northern Chukchi Sea (Kelly, 1988). It is unclear whether or not mixing occurs between seals from the Okhotsk and the Bering Sea regions.

Ribbon seals are difficult to count because of their wide distribution in remote regions, and the fact that they spend little time out of the water. Abundance estimates have been produced by both Russian and US scientists, but they are of unknown accuracy. Burns (1981) presented population estimates for the early 1970s of 140,000 for the Okhotsk Sea and 90–100,000 for the Bering Sea. Fedoseev (2000) gives much higher estimates for the Okhotsk Sea, and indicates an average population size of 370,000 during 1968–1990. In both the Bering and the Okhotsk seas abundance has fluctuated markedly due to increases and decreases in harvests conducted by the former Soviet Union (Burns, 1981; Fedoseev, 2000). There are no recent abundance estimates for either region.

III. Ecology

The ribbon seal is considered to be a pagophilic (ice-loving) species, and sea ice provides them an essential platform that is used for pupping, nursing their pups, and molting. During the pupping and molting period they primarily use the ice front, where there is a mix of floes and open water (Burns, 1970). The location of the ice front is usually on the continental shelf not far from the continental shelf break.

With their long necks, large eyes, and slender bodies, ribbon seals look quite different from other northern seals. Although the meaning of these characteristics is not fully understood, it seems likely that they are adaptations to a lifestyle that includes spending many consecutive months at sea. Another unusual characteristic is an air sac that connects to the trachea and extends over the ribs (Burns, 1981). When inflated this organ could provide extra buoyancy making it easier for seals to float or rest in the water.

During the spring when they are in the ice front, ribbon seals eat shrimps, squids, and a variety of fishes including arctic cod, saffron cod, pollock, Pacific cod, capelin, and flatfishes (Shustov, 1965; Frost and Lowry, 1980). Little is known about feeding habits during the summer, fall, and winter, which are the seasons when they must feed most intensively. A study of winter–spring feeding near Hokkaido, Japan found walleye pollock to be the main prey item (Deguchi *et al.*, 2004).

The ice front region used by ribbon seals is south of the normal range of polar bears (*Ursus maritimus*), so these seals probably rarely encounter bears. During the pelagic phase of their life they undoubtedly encounter killer whales (*Orcinus orca*), and perhaps sharks, but no predation events have been reported (Kelly, 1988).

IV. Behavior and Physiology

Compared with other seals, the eyes of ribbon seals are quite large. However, they seem to have poor vision in air so this may be an adaptation for improved eyesight under water. When hauled out on the ice they are relatively easy to approach (Burns, 1981), but it isn't clear whether this lack of vigilance is due to their not being subject to polar bear predation or to sensory limitations. Ribbon seals move across the ice with a characteristic snakelike side-to-side motion, unlike other ice seals which hump across the ice. When captured on the ice with a net, many individuals cease to struggle, an apparent “play dead” strategy that is uncharacteristic of pinnipeds and is of unclear adaptive significance.

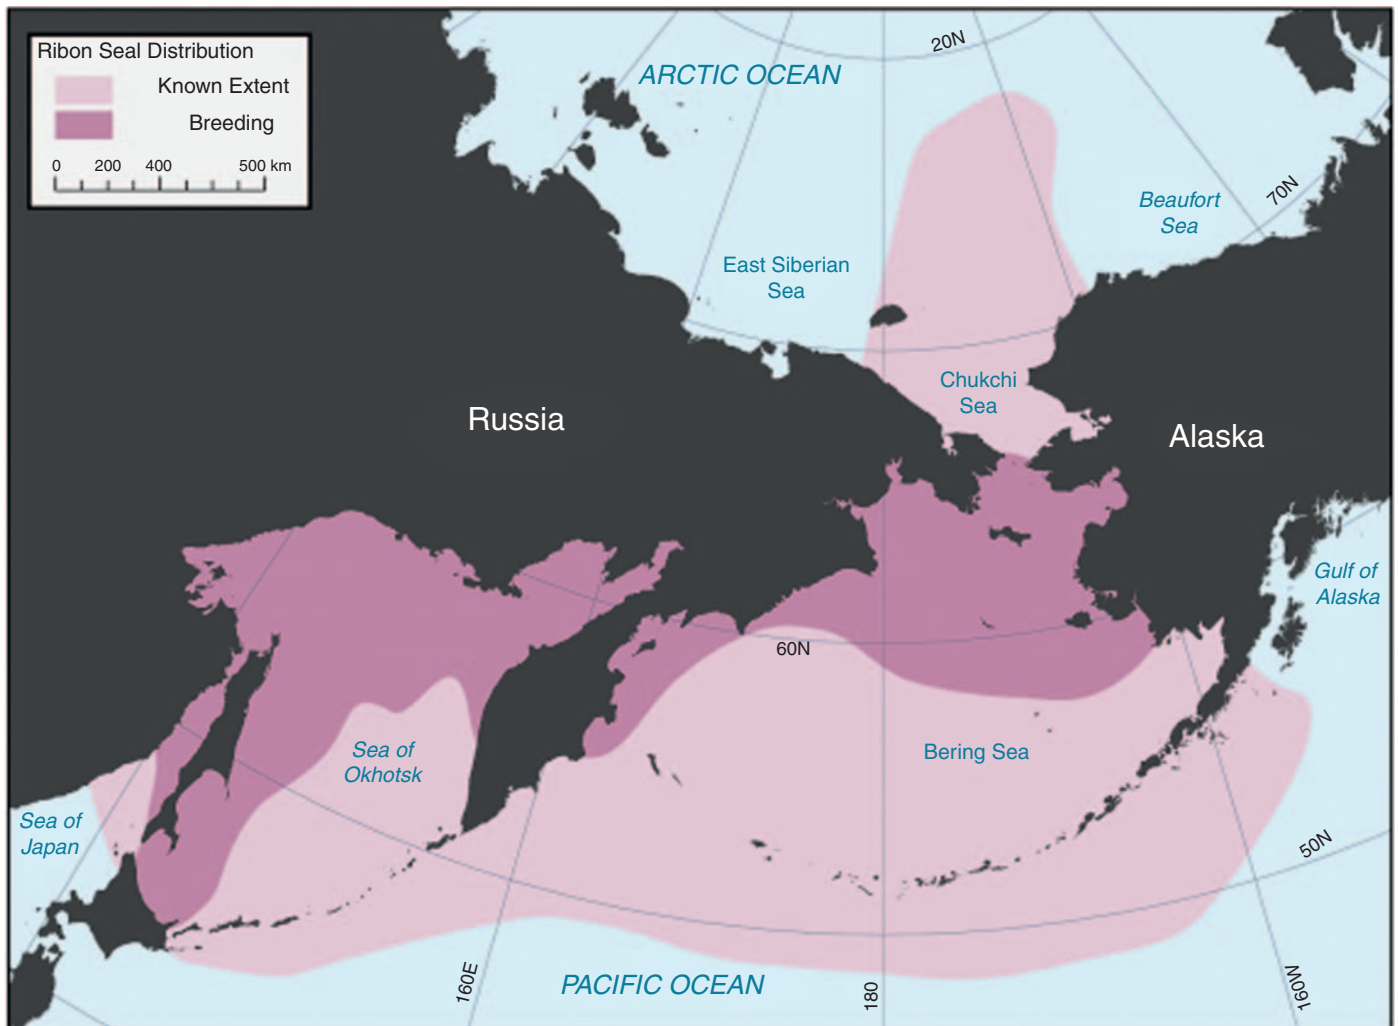

Figure 4 The geographic distribution of ribbon seals.

Two kinds of underwater sounds were recorded from ribbon seals in the ice near St. Lawrence Island in spring (Watkins and Ray, 1977). One was described as a “puffing” sound, and the other a “downward sweeping” sound. Based on analogy with sounds made by other seals, researchers speculated that the ribbon seal sounds probably function in reproductive or territorial behavior.

Ribbon seals have not been the subject of detailed physiological studies that have recently been done on many other pinnipeds. Some studies of respiratory physiology and blood parameters suggest adaptations for a pelagic existence and deep diving (Burns, 1981).

V. Life History

Ribbon seals give birth in the ice front during March–April. Newborn pups weigh about 10kg, and their weight doubles during a 3–4 week nursing period. Adult male ribbon seals do not accompany females during the early part of the nursing period, and little is known about their breeding structure. After weaning ribbon seals grow quite rapidly and reach sexual maturity at 3–5 years of age. The peak of breeding occurs in late April and early May, and seals molt shortly thereafter. The maximum lifespan is probably 25–30 years

(Burns, 1981). As mentioned earlier, little is known of the activities of ribbon seals during other months of their life when they are living pelagically.

VI. Interactions with Humans

Ribbon seals were harvested in substantial numbers in both the Okhotsk and the Bering seas by the former Soviet Union for oil, skins, and animal food. Commercial harvests began in 1961, and in the Bering Sea takes peaked in the mid-1960s at about 22,000 per year (Fedoseev, 1976). With signs of overharvest, quotas were reduced, but 10,000 to 15,000 were taken per year from the sea of Okhotsk in 1990–1993 (Grachev, 2006). More recently, commercial harvests are believed to have virtually ceased.

Their offshore distribution mostly keeps ribbon seals away from coastal hunters, but a few are taken in Alaska by Eskimos at villages in the Bering Strait region (Kelly, 1988). Other than directed harvesting, ribbon seals have few interactions with humans. They are infrequently caught incidental to commercial fishing operations in Alaska and on the high seas (Stewart and Everitt, 1983).

Right Whale Dolphins

LISSODELPHIS BOREALIS, L. PERONII AND
JESSICA D. LIPSKY

Right whale dolphins are known for their distinctive black and white color patterns and lack of a dorsal fin. These characteristics make these species easy to identify at sea. Although these species were first described in the beginning of the nineteenth century, their overall biology, life history, taxonomy, and behavior are still poorly known.

I. Characters and Taxonomic Relationships

The two species of right whale dolphins have very different pigmentation patterns. The northern right whale dolphin (*Lissodelphis borealis* Peale, 1848) is mainly black with a white ventral patch that runs from the fluke notch to the throat region (Fig. 1). This band widens slightly at the urogenital area in males and to a greater extent in females (Leatherwood and Walker, 1979). There is another small white patch on the ventral tip of the rostrum and on the underside of the flippers. The southern right whale dolphin [*L. borealis* (Lacépède, 1804)] has a similar white ventral patch; however, it extends higher on the posterior flanks (Figs 2 and 3). The back of the dolphin is black, and the white area reaches a high point midway along the body, dipping down at the flipper insertion and covering most of the head and rostrum. Newborn calves are usually dark gray or brown, attaining adult coloration after the first year of life.

There have been reported sightings of anomalously pigmented right whale dolphins. Visser *et al.* (2004) observed four melanistic southern right whale dolphins off the coast of New Zealand. Instead of the white patch on the ventral portion of the body, these dolphins were all black (Visser *et al.*, 2004). There have also been other recorded sightings of all white animals (Watson, 1981) and partial whites, darks and gray dolphins, (Newcomer *et al.*, 1996).

Right whale dolphins can grow to lengths of 3m; males tend to grow larger than females (Leatherwood and Walker, 1979). Weights have been recorded up to 116kg (Jefferson *et al.*, 1994). The flippers are slender and pointed at the tips. The flukes have a median notch that is moderately deep with concave trailing edges. The teeth are small and sharp, ranging in numbers from 37 to 54 per row in the northern species and 39 to 50 in the southern species, with more teeth in the lower jaw (Jefferson *et al.*, 1994).

Recent classifications have placed the right whale dolphins in a monogeneric delphinid subfamily Lissodelphinae or in the subfamily Delphininae. However, based on an analysis of cytochrome *b* (mtDNA) sequences, LeDuc *et al.* (1999) tentatively placed them in the subfamily Lissodelphinae with *Lagenorhynchus* spp. and *Cephalorhynchus* spp.

II. Distribution and Ecology

Right whale dolphins are found in cool-temperate and subarctic waters in the North Pacific and circumpolar subantarctic and cool-temperate waters in the Southern Ocean (Fig. 4). Right whale dolphins tend to be offshore oceanic cetaceans, with rare sightings inshore except *L. peronii* which has been observed inshore off the coasts of Chile and Namibia in areas with major upwelling (Aguayo, 1975; Rose and Payne, 1991). In the North Pacific, northern right

Figure 3 *Lissodelphis peronii with calf off the coast of South America. Photo courtesy of Laura Morse.*

whale dolphins range from Kuril Islands, Russia, south to Sanriku, Honshu, Japan, extending eastward to the Gulf of Alaska and south to southern California (Rice, 1998). They are distributed approximately from 34°N to 55°N and 145°W to 118°E. Occasional movements south of 30°N are associated with anomalous cold-water temperatures. In the Southern Hemisphere, southern right whale dolphins are found most commonly between 25°S and 55°S in the eastern South Pacific and between 30°S and 65°S in the western South Pacific. They are found most often between the subtropical and the Antarctic convergences, with distributions reflecting the variability in these oceanographic features (Gaskin, 1968). It has also been observed that the range of the southern right whale dolphin often extends northward along eastern cold-water boundary currents. An example of this can be shown with the occurrence of a stranding of the southern species off the coast of Brazil in 1995, where the warm Brazil current meets the cold Malvinas current. A

single male stranded at the Juréia-Itatins Ecological Station in southeastern Brazil (between latitudes 24°17'–24°40'S and longitudes 47°00'–47°30'W) north of its typically observed range. The species had never been seen in this region before (Martuscelli *et al.*, 1996). It is thought that the Malvinas current is a major feature in the occurrence of marine mammals in this area.

Migration of both *Lissodelphis* species is not entirely known or understood. In northern right whale dolphins, there appears to be an inshore shift in winter and spring off California, which coincides with peak abundance of their primary food source (squid) (Leatherwood and Walker, 1979). Forney and Barlow (1998) found that northern right whale dolphin abundance was greatest off the Southern California Bight in winter, whereas in the summer there were no sightings made in this area. In addition, they observed a greater abundance of *L. borealis* offshore in summer and a greater abundance inshore on the Southern California Bight continental shelf in winter (Forney and

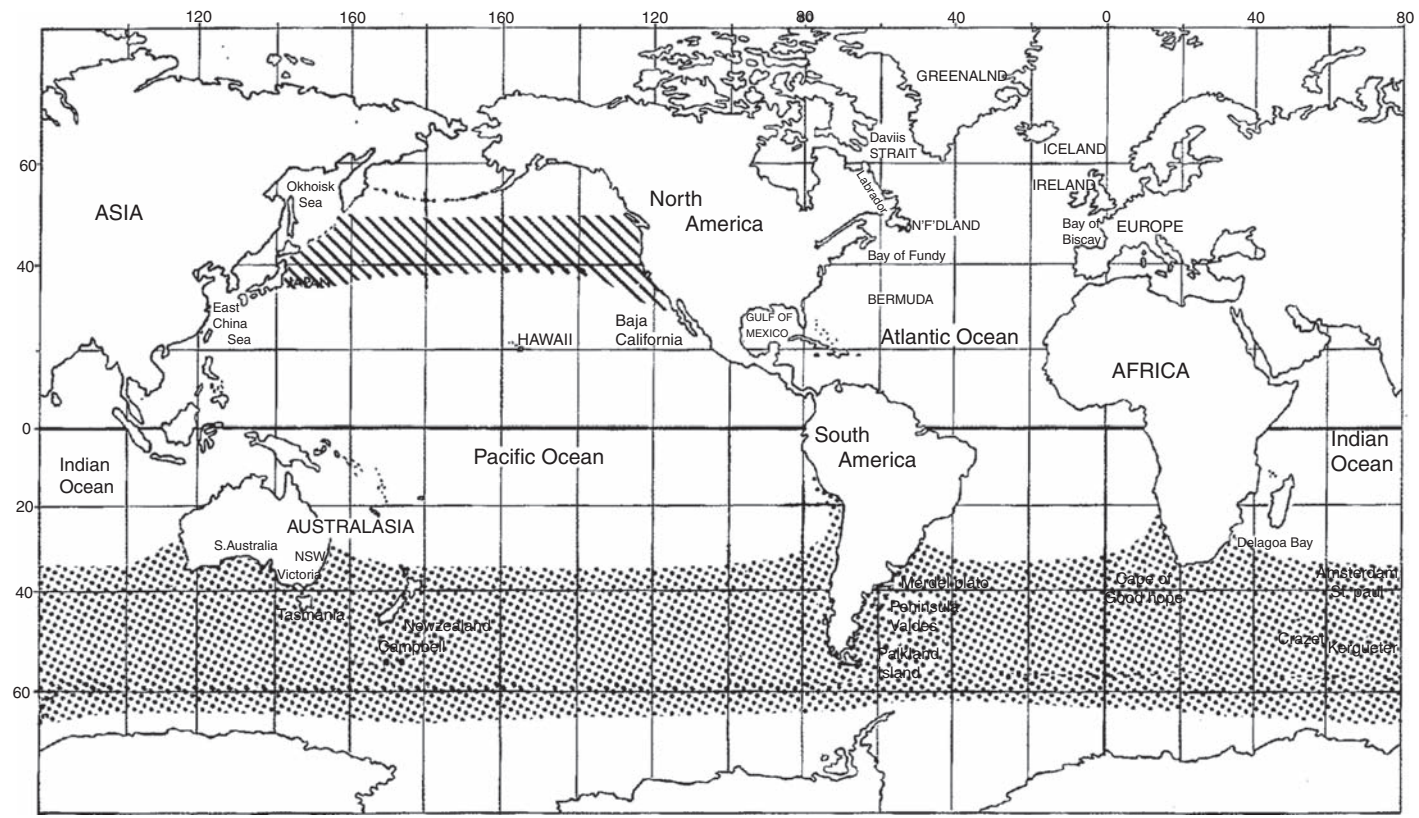

Figure 4 Approximate ranges of *Lissodelphis borealis* (hatched) and *L. peronii* (stippled).

Barlow, 1998). Southern right whale dolphins tend to occur year-round in a localized area off Namibia, Africa, where high-productivity waters prevail (Newcomer *et al.*, 1996). Off the coast of Chile, southern right whale dolphins are present year-round and have been discovered to migrate northward during winter and spring. Food sources, which are affected by changing water temperatures, appear to be a factor in this species' migration. In addition, these two species are commonly found in oceanic, deep waters, on highly productive continental shelves, or sometimes where deep waters approach the coast.

Northern right whale dolphins have been observed to associate with 14 other species of marine mammals in the North Pacific Ocean. They are mainly observed with Pacific white-sided dolphins, *Lagenorhynchus obliquidens*, which share a similar distribution and habitat (Klumov, 1959; Leatherwood and Walker, 1979). They are also commonly found with pilot whales, *Globicephala macro-rhynchus* and Risso's dolphins, *Grampus griseus* (Leatherwood and Walker, 1979). Southern right whale dolphins are associated most often with pilot whales (*Globicephala melas*) and dolphins of the genus *Lagenorhynchus* (Jefferson *et al.*, 1994).

Yazdi (2002) described a possible hybrid of southern right whale dolphins with the dusky dolphin (*Lagenorhynchus obscurus*) off the coast of Argentina. Similar phenotypic characteristics were observed from photographic data. These anomalous dolphins have a slender body and the sharp contrasting line between the white ventral patch and the black dorsal part of the body similar to the southern right whale dolphin. Additionally, these possible hybrids have a light gray patch at the peduncle region similar to the dusky dolphin. This anomalous dolphin does have a dorsal fin but one that is much smaller and more triangular than in the dusky dolphin and located approximately two-thirds back on the body. The presence of the modified dorsal fin suggests that this anomalous dolphin is not representative of a color variant of the southern right whale dolphin (Yazdi, 2002).

PREDATION on right whale dolphins is poorly known; however, killer whales and large shark species are occasional predators. There are two records of predation on southern right whale dolphins, a 0.87-m southern right whale dolphin fetus was found in a 3.6-m sleeper shark (*Somniosus cf. pacificus*) off the coast of Valdivia, Chile in 1990 (Corvetto *et al.*, 1992) and a 1.7-m Patagonian toothfish taken off central Chile in 1983 had a 0.86-m southern right whale dolphin neonate in its stomach (Van Waerebeek *et al.*, 1991).

The northern right whale dolphin has been observed to feed primarily on squid and lanternfish; however, other prey species include Pacific hake, saury, and mesopelagic fishes (Leatherwood and Walker, 1979). The southern right whale dolphin feeds primarily on various squid and fish species.

Strandings of northern and southern right whale dolphins are uncommon. However, a single mass stranding of three southern right whale dolphins was recorded in New Zealand in 1952 (Fraser, 1955). An apparent increase in strandings of *L. peronii* is possibly the result of discarded animals from a rapidly developing swordfish gillnet fishery off northern Chile (Van Waerebeek *et al.*, 1991).

III. Behavior and Life History

Right whale dolphins tend to be gregarious animals, often traveling in groups of up to 2000–3000 in the North Pacific (Leatherwood and Walker, 1979) and up to 1000 in the southern species (Gaskin, 1968). Herds are characterized by four main configurations, including V-shaped herds, "chorus line" formation herds, tightly packed herds with no identifiable subgroups, and herds with subgroups within the main group (Leatherwood and Walker, 1979). Both forms have been observed to travel slowly or quickly; this is

associated with surfacing modes, breathing intervals, and travel speeds. Right whale dolphins can travel up to 40 km/h (Leatherwood and Reeves, 1983). In some instances, right whale dolphins will bow ride on vessels, especially in the presence of other species, although sometimes they will actively avoid approaching vessels. Aerial behavior such as breaching, belly flops, and side and fluke slaps are not uncommon, especially in the fast swimming mode.

Information on growth and reproduction for right whale dolphins is limited. Twenty-three specimens have been examined in the eastern North Pacific, and their data suggest that males attain sexual maturity between 212 and 220 cm and females at about 200 cm (Leatherwood and Walker, 1979). In November 1990 and 1991, 229 northern right whale dolphins were obtained from the Japanese squid drift net fishery and examined for total length, age, and sex (Ferrero and Walker, 1993). Ferrero and Walker (1993) found that the average length for sexually mature males is 214.7 cm and 199.8 cm for females in the northern species. In addition, they calculated that the age at the onset of sexual maturity for males is approximately 9.9 years and for females it is approximately 9.7 years (Ferrero and Walker, 1993). In the western North Pacific, other reports indicate that females attain sexual maturity between 206 and 212 cm (Jefferson *et al.*, 1994). Northern right whale dolphin neonates range between 80 and 100 cm at birth (Jefferson *et al.*, 1994). Ferrero and Walker (1993) found that for northern right whale dolphins length at birth ranged between an average of 99.7 and 103.8 cm using three different methods of length estimation. The calving season is unknown; however, small calves are often seen in winter or in early spring. In the Southern Ocean, right whale dolphin reproductive biology is largely unknown. Two females measuring 218 and 229 cm and one male measuring 251 cm have been examined and were all sexually mature (Jefferson *et al.*, 1994).

Sound production in northern right whale dolphins has been recorded (Fish and Turl, 1976). Clicks with high repetition rates were recorded, with few whistles. Sound production in southern right whale dolphins has not been described. There have been few attempts to capture live animals due to the difficulty in maintaining these oceanic species. A northern right whale dolphin was captured live and held for 15 months; however, most live captures have not survived more than 3 weeks (Walker, 1975). There have been no reported attempts to capture live southern right whale dolphins.

IV. Conservation Status

In the nineteenth century, whalers occasionally took northern right whale dolphins. Although there is currently no direct fishery for right whale dolphins, the northern species is occasionally taken in Japan's harpoon fishery and in the Japanese and Russian purse-seine fisheries (Klumov, 1959). In addition, a few individuals were taken in Japan's salmon gillnet fishery (International Whaling Commission, 1983) and in California's shark and swordfish driftnet fishery. The majority of right whale dolphin bycatches in recent years occurred in the North Pacific squid driftnet fisheries operated by Japan, Korea, and Taiwan (Jefferson *et al.*, 1994). The squid fisheries began in 1978 with small incidental takes of 300–400 dolphins until the mid-1980s when incidental takes were on the order of 15,000–24,000 dolphins per year (Mangel, 1993). It is thought that the stock in this area has been depleted to 24–73% of its pre-exploitation level (Mangel, 1993). In the past southern right whale dolphins have been taken off Chile and Peru for use of their meat and blubber for human consumption or use as crab bait (Newcomer *et al.*, 1996). Since 1989 there has been an increase in southern right whale dolphin bycatches in the developing swordfish gillnet fishery off Chile (Van Waerebeek *et al.*, 1991).

The effects of POLLUTION and contaminants on right whale dolphins in general are currently unknown. Given the nature of the pelagic habitat of the northern species, the effects of pollution are probably minimal. However, seasonal shifts in migration and distribution could possibly have a negative impact on these species. Minh *et al.* (2000) estimated the concentrations of polychlorinated biphenyls (PBCs) in cetaceans in the North Pacific. They found that in one northern right whale dolphin individual in their study contained high concentrations of PCBs such that the exceeded levels were associated with immunosuppression in harbor seals. In another study, Jones *et al.* (1999) found that concentrations of halogenated aromatic hydrocarbons (HAHs) in open ocean cetaceans (southern right whale dolphins) had intermediate levels whereas coastal species had the highest levels of contaminants. So while research shows that *Lissodelphis* species are susceptible to marine pollutants, more research in ecotoxicology is needed.

Right Whales

Eubalaena glacialis, *E. japonica*, and *E. australis*

ROBERT D. KENNEY

I. Characteristics and Taxonomy

A. Scientific and Common Names

Three species of right whales are currently recognized: North Atlantic right whale, *Eubalaena glacialis* (Müller, 1776); North Pacific right whale, *E. japonica* (Lacépède, 1818); and southern right whale, *E. australis* (Desmoulins, 1822). The generic name *Eubalaena* means “true whale;” the meanings of specific epithets are: *glacialis* = “of the ice,” *japonica* = “Japanese,” and *australis* = “southern.” Müller based his original description of *E. glacialis* on the “nördcaper” of Norwegian whalers. He did not specify a type locality; Eschricht and Reinhardt (1866) subsequently designated it as North Cape, Norway. Synonyms include *biscayensis* (Eschricht, 1860) and *nordcaper* (Lacépède, 1804). The type specimen of *E. australis* is a skeleton from Algoa Bay, Cape of Good Hope, South Africa in the Museum National d’Histoire Naturelle, Paris. Synonyms include *antarctica* (Lesson, 1828), *antipodarum* (Gray, 1843), and *temminckii* (Gray, 1864).

Lacépède's description of *E. japonica* was based upon an illustration by a Japanese artist; the type locality is Japan. A synonym is *sieboldii* (Gray, 1864) (Hershkovitz, 1966; Mead and Brownell, 2005).

Conventional wisdom holds that the common name “right whale” comes from English whalers, who designated this as the “right” (i.e., correct) whale to hunt because it occurred near shore, swam slowly enough to be caught from a small boat propelled by sails or oars, floated when dead, and yielded large amounts of valuable oil and BALEEN. Early writers, however (e.g. Eschricht and Reinhardt, 1866) considered “right” to mean “true” or “proper,” meaning showing the characteristics typical of whales generally, as later formally recognized in the Latin generic name *Eubalaena*. Other common names in English include black right whale and black whale.

B. Systematics and Nomenclature

There has been disagreement on two questions of balaenid systematics and nomenclature—concerning the number of extant species of right whales and whether or not bowhead whales (*Balaena mysticetus*) and right whales are congeneric (see Reeves and Kenney, 2003 and Perrin and Reeves, 2004 for reviews). Northern and Southern Hemisphere right whales were long treated as distinct species (Cummings, 1985). Rice (1998) concluded that there was no evidence for consistent morphological differences and that only one globally distributed species should be recognized. Rosenbaum *et al.* (2000) showed clear, long-established mitochondrial DNA differences among right whale lineages in the North Atlantic, North Pacific, and Southern Hemisphere—concluding that three species should be recognized and that North Pacific and southern right whales are more closely related to one another than either is to North Atlantic right whales. Those results have been confirmed by both nuclear DNA markers (Gaines *et al.*, 2005) and the genetics of whale lice on right whales (Kaliszewska *et al.*, 2005). The conclusions have been accepted by the INTERNATIONAL WHALING COMMISSION'S scientific committee (IWC, 2001a) and broadly by marine mammalogists (Mead and Brownell, 2005), but not universally (Baker *et al.*, 2003). The question is more a philosophical one, between phylogenetic and biological species concepts, but under either concept the two-species northern–southern classification is taxonomically invalid.

On the question of the correct generic name for right whales, Eschricht and Reinhardt (1866) published the first widely read, detailed comparison between bowheads and right whales, and maintained both species in the same genus. Rice (1998) reviewed the published comparisons and concluded that there was no scientific evidence from either morphology or genetics for recognizing the separate right whale genus *Eubalaena* (published by J. E. Gray; see Box 1), and that those differences that do exist are less than those between species of *Balaenoptera*. The consensus mitochondrial, nuclear, and combined phylogenetic trees (Gaines *et al.*, 2005) appear to show little genetic divergence between bowheads and the three right whale species. Others (Schevill, 1986; Bannister *et al.*, 1999; Rosenbaum *et al.*, 2000) have argued that maintaining the generic-level separation was justified, in part, for reasons of nomenclatural stability. IWC (2001a), and Mead and Brownell (2005) have accepted that rationale and recognized the right whales as *Eubalaena* spp. That conclusion (although not the underlying justification) has been confirmed by a very recent study of balaenid systematics based on a detailed morphological analysis of all known species, both extant and fossil (Churchill, 2007). The results showed a crown Balaenidae containing two sister clades—one a monophyletic *Eubalaena* and the other containing *Balaena* and *Balaenella*.

BOX 1: Taxonomic Rules, J. E. Gray, and Right Whale Names

There is a set of very specific rules, the International Code of Zoological Nomenclature, for determining the correct scientific name to apply to any particular animal taxon. One important aspect of the Code is the rule of priority—when determining the valid name for any species (or genus or higher level category), the first published name applied should be used. For example, the original descriptions of all three right whale species included them in the genus *Balaena* (=“whale”), a name published by Linnaeus in 1758. If biological evidence supports classifying right whales as a distinct genus from bowheads, the name *Eubalaena*, published by J. E. Gray in 1864, is the oldest name available applicable only to the right whales and therefore the valid name by the rule of priority.

John Edward Gray (1800–1875) was an English zoologist and an important figure in the history of cetacean taxonomy. He began his career at the British Museum at about age 15 as a volunteer insect collector, received a temporary appointment in 1824 to catalog reptiles, and was Keeper of Zoology from 1840 until his retirement only 2 months before his death 35 years later. In his years at the museum, he published well over 1000 papers, including half of the 200 catalogs issued by the museum during his time. *Eubalaena* is not the only cetacean name he coined; 15 or 16 of the currently accepted names of the 85–90 extant species and 40+ genera, 11 of the 14 family names (all except Eschrichtiidae, Kogiidae, and Lipotidae), and many of the subfamily names were authored by Gray. One might conclude that he was particularly knowledgeable about cetacean taxonomy. However, he worked at what was arguably the world's most influential museum of his day and apparently had a penchant for creating new species, genera, and higher taxa. He has been called one of the most notorious taxonomic “splitters” of all time. He also authored at least four other generic names for right whales, and in a single publication in 1871 he counted six genera and 14 species of right whales.

The rule of priority can be set aside under certain circumstances in order to maintain nomenclatural stability. If a taxonomic name is in common usage for a long period and then is discovered to be a junior synonym of an older published name, the International Committee on Zoological Nomenclature can be petitioned to suppress the senior synonym and conserve the junior synonym as the accepted name. For example, the binomial *Tursiops truncatus* (Montagu, 1821) for the common bottlenose dolphin has been conserved by suppression of the senior synonym *T. nesarnack* (Lacépède, 1804) (Rice, 1984, 1998). However, whether right whales and bowheads represent one or two genera is not simply a question of names, but of biological classification. The International Code of Zoological Nomenclature specifically “refrains from infringing upon taxonomic judgment, which must not be made subject to regulation or restraint” (Ride *et al.*, 1985). Invoking the rule of stability in the case of the right whales' generic name is a misapplication of the Code, and rigorous application of the scientific method would suggest that the null hypothesis (i.e., there is no significant generic-level difference between bowhead and right whales) should stand until rejected by evidence. The study by Churchill (2007) now has provided the evidence to

conclude that the three living right whale species do comprise a phylogenetic lineage distinct from the bowhead and are rightly classified into a separate genus. One must remember, however, that systematic classifications are scientific hypotheses, subject to revision after further study.

C. Description

Right whales have an extremely robust body form, bordering on rotund, with a thick blubber layer and the girth at times exceeding 60% of total body length (Omura *et al.*, 1969; Cummings, 1985; Reeves and Kenney, 2003; Fig. 1). The body is mostly black, sometimes with irregular white ventral patches. Some individuals may have a mottled appearance, and calves may sometimes be lighter colored. There is no dorsal fin. The pectoral flippers, which retain all five digits, are large, broad, and blunt. The flukes are very broad (up of 40% of body length), black on both dorsal and ventral surfaces, deeply notched, and smoothly tapered to the tips. Calves are 4.5–6 m long at birth; typical adults are 13–16 m. North Pacific right whales attain larger maximum sizes than the other species, up to 18 m and over 100 metric tons.

The head is relatively large, comprising about one-quarter to one-third of the total body length. The upper jaw is somewhat arched, and the margin of the lower lip forms a very pronounced curve. There are 200–270 baleen plates on each side of the upper jaw, and there is a gap between the two rows of plates at the anterior end of the upper jaw (Nemoto, 1970; Pivorunas, 1979). The baleen plates are relatively narrow and 2–2.8 m long, with very fine fringing hairs. The tongue is massive and solidly muscular.

The most conspicuous external characteristics of right whales are the callosities on the head (Payne and Dorsey, 1983). These are irregular patches of thickened, keratinized tissue, which are inhabited by dense populations of specialized amphipod crustaceans, known as cyamids or “whale lice” (see Box 2). At least three species of whale lice occur on right whales: *Cyamis gracilis*, *C. ovalis*, and *C. erraticus* (Rowntree, 1996; Kaliszewska *et al.*, 2005). In southern right whales the callosities are also inhabited by barnacles, *Tubicinella* sp. The callosities occur at the tip of the snout (called the “bonnet” by whalers), on the lower lips and chin, above the eyes, and in front of and behind the blowholes (Figs 1 and 2). The callosities are congenital and not caused externally, as their beginnings are present in fetuses and neonates, but the pattern is not fully developed and colonized by cyamids until the whale is at least several months old (Fig. 2). The

callosity patterns are unique to individuals and are therefore extremely useful as a natural “tag,” which allows repeated identification of individuals by photographs (Payne *et al.*, 1983; Kraus *et al.*, 1986).

BOX 2: Are Whale Lice Parasites?

Two species are said to be symbiotic when they live intimately associated with each other, with the exact nature of the relationship depending on the fitness costs and benefits incurred by each species (Townsend *et al.*, 2003). In the symbiosis involving right whales and cyamids, it can be assumed that the cyamid benefits from the relationship by having a place to live and a ready food supply. If the right whale also benefits, the association is defined as mutualism; if the whale receives neither benefits nor costs, the association is commensalism; and if the whale is harmed, the association is parasitism. Most sources refer to cyamids as parasites or ectoparasites. It is known that they do feed on the whale’s skin (Schell *et al.*, 2000), however, there is scant evidence that their presence or feeding causes any harm to the whale. Leung (1976) concluded that “whale-lice cause certain damage to the whale skin when the young begin to maintain their livelihood, and the injury is a result of piercing the tissue in which they shelter for safety and for food,” but did not actually show any harm to the whale. Similarly, while it is possible to construct various hypotheses for potential benefits provided to the whale by the cyamids, there is no evidence to test or confirm these theories. It therefore seems that the conservative course would be to consider cyamids as ectocommensals of right whales until convincing evidence demonstrating otherwise has been shown.

The closest relative of the right whale is the bowhead whale. Bowheads may be somewhat longer, are substantially stouter, have relatively larger heads (about 40% of body length) with a more arched appearance, have much longer baleen plates (up to 5.2 m long), and completely lack callosities.

D. Fossil Record and Evolution

Five fossil species of *Balaena* have been described from deposits of late Miocene, Pliocene, or Pleistocene age (2–10 million years old) from Europe and North America: *B. affinis*, *B. etrusca*, *B. montalioni*,

Figure 1 *The North Atlantic right whale (c. Brett Jarrett).*

Figure 2 A mother-calf pair of North Atlantic right whales sighted off the coast of Florida on 9 January 1992. The mother, #1001 (“Fermata”), was the first animal included in the North Atlantic photo-identification catalog, from photographs taken in Cape Cod Bay by W. A. Watkins and W. E. Schevill in March 1978. This was her fifth known calf. A gray area on the calf’s rostrum shows where the callosity will develop, and colonizing whale lice can be seen along the curved margin of its lips. “Fermata” was last seen in September of that same year in the Bay of Fundy, and is now presumed dead. Photograph by the author from Airship Shamu (courtesy of Sea World).

B. primigenius, and *B. prisca* (Barnes and McLeod, 1984; McLeod *et al.*, 1993). The last of these is similar enough to modern bowheads (*B. mysticetus*) that it may, in fact, not be a separate species. There is then a long gap in the balaenid FOSSIL RECORD to *Morenocetus parvus*, the oldest known member of the family, found in early Miocene (23 million years old) deposits in South America. Molecular phylogenies generally agree that Balaenidae is the most primitive clade of extant mysticetes (Árnason *et al.*, 1992; Hatch *et al.*, 2006).

II. Distribution and Abundance

Right whales are found in the middle latitudes of both the Northern and the Southern Hemispheres, between approximately 20° and 60°S and N latitudes (Cummings, 1985; Reeves and Kenney, 2003; Fig. 3). There are three geographically isolated populations currently recognized as separate species: in the North Atlantic, North Pacific, and Southern Ocean. The populations are kept separated by Arctic ice and warm equatorial waters so that there is no interchange between populations, and apparently has not been for millions of years (Rosenbaum *et al.*, 2000; Gaines *et al.*, 2005; Kaliszewska *et al.*, 2005).

A. North Atlantic Right Whales

The historical range of North Atlantic right whales apparently extended as far south as Florida and northwestern Africa and as far north as Labrador, southern Greenland, Iceland, and Norway (Cummings, 1985; Reeves *et al.*, 2007). The traditional hypothesis has been that there were separate stocks with little interchange on

the western and the eastern sides of the basin; however, analysis of some nineteenth century whaling specimens in European museums shows that they do not differ genetically from living western individuals (Rosenbaum *et al.*, 2000), and there have been one or two right whales seen in the eastern North Atlantic in recent years that were known individuals from the western stock (Jacobsen *et al.*, 2004). It is possible that the structure of a right whale population is that a particular ocean basin is inhabited by a single breeding population without long-term genetic isolation of stocks, but where return to traditional habitats learned from the mother (matrilateral habitat fidelity) maintains shorter-term separation between two or more subsets of the population.

The present range of western North Atlantic right whales, from Florida to Nova Scotia with very occasional occurrence beyond those limits, is much reduced from its historical extent (Winn *et al.*, 1986; Kenney *et al.*, 2001; Kraus and Rolland, 2007). The best estimate of present abundance is about 400 animals (NARWC, 2006). In the eastern North Atlantic, there have been only a handful of right whale sightings in the last few decades (reviewed in Reeves and Kenney, 2003). It is not known whether these represent a small remnant eastern stock or whether some or all of them are individuals from the known western population.

B. North Pacific Right Whales

The historical range in the North Pacific was similarly much more extensive than today. Right whales occurred from Japan and northern Mexico north to the Sea of Okhotsk, Bering Sea, and Gulf of Alaska (Scarff, 1986, 1991; Clapham *et al.*, 2004). Recent sightings are extremely rare, primarily in the Sea of Okhotsk (Brownell *et al.*, 2001) and eastern Bering Sea (Clapham *et al.*, 2004; Sheldon *et al.*, 2005; Wade *et al.*, 2006). There are no reliable estimates of abundance, and there may be even fewer whales than in the North Atlantic. Wade *et al.* (2006) reported that 23 individuals had been identified so far in the southeastern Bering Sea. There are also insufficient genetic or resighting data to address whether there is support for the traditional separation into eastern and western stocks (Brownell *et al.*, 2001).

C. Southern Right Whales

Right whales are known from several areas of the Southern Ocean. Multiple stocks have been hypothesized, including Argentina/Brazil, South Africa, east Africa/Mozambique, western Australia, southeastern Australia, New Zealand, and Chile (Cummings, 1985; Best *et al.*, 2001; IWC, 2001b; Patenaude *et al.*, 2007). Additional stocks have been hypothesized for the central Indian Ocean, the Campbell and Auckland Islands in the southwestern Pacific, and Tristan da Cunha in the central South Atlantic. There have also been suggestions of even finer stock structuring, e.g., between Argentina and Brazil in the western South Atlantic or between Namibia and South Africa in the eastern South Atlantic. There is incomplete genetic isolation separation between stocks, especially between geographically adjacent stocks.

Right whale populations in Argentina, South Africa, and Australia are presently the largest and the best studied. The total abundance of southern right whales was estimated as of 1997 at 7571 animals, with the three well-studied stocks increasing at 7–8% annually (IWC, 2001b). Given that there were no estimates available for some stocks, and a population increasing at 7% doubles every 10 years, total abundance could currently exceed 15,000 animals.

Figure 3 Worldwide range of right whales (*Eubalaena glacialis*, *E. japonica*, and *E. australis*). Much of what is shown here is relatively speculative based on sparse historical records of whaling catches and the available recent sightings. Most recent data come from areas relatively nearshore, with few or no data for the pelagic areas between the known coastal habitats.

III. Ecology

A. Diet

Right whales feed entirely on zooplankton, especially on large calanoid copepods (crustaceans approximately the size of a grain of rice) (Nemoto, 1970; Cummings, 1985; Baumgartner *et al.*, 2007). At times they also feed on smaller copepods, krill (larger shrimp-like crustaceans), pteropods (tiny planktonic snails), or the planktonic larval stages of BARNACLES and other crustaceans. The details of their diet likely differ between regions, e.g., it is likely that krill comprise a higher proportion of the DIET in southern right whales. It is also likely that right whales can be somewhat opportunistic regarding prey species, FEEDING on any prey of a size that can be filtered efficiently by the baleen, which does not swim strongly enough to escape, and which is concentrated into sufficiently dense patches to trigger feeding behavior. For example, there have been observations of North Atlantic right whales in the Bay of Fundy feeding on aggregations of salps.

B. Habitat

Right whales migrate annually between high-latitude feeding grounds and low-latitude calving and breeding grounds (Cummings, 1985; Reeves and Kenney, 2003). There are substantial differences in the locations where most research has been conducted between the Northern and the Southern Hemispheres; therefore, there is often a lack of directly comparable information for different populations.

Feeding takes place in spring, summer, and fall in higher-latitude feeding grounds, where ocean temperatures are cooler and overall biological productivity is much higher. The best known right whale feeding grounds are in the western North Atlantic (Winn *et al.*, 1986). These habitats are in nearshore and shelf waters, where some combination of bottom topography, water column structure and stratification, and currents acts to physically aggregate zooplankton into extremely

dense concentrations (Kenney and Wishner, 1995; Baumgartner *et al.*, 2007). The densest zooplankton concentrations measured in the North Atlantic were found by sampling near right whales. There are probably also offshore feeding grounds, in locations not yet known, based on historical whaling records and on the fact that some known whales are often missing from the known habitats for months or years at a time. There must also have been other feeding grounds in the past, when the range of North Atlantic right whales was more extensive.

Feeding grounds for the other species of right whales are much more poorly known. In the North Pacific, based on historical whaling records and the few recent sightings, the principal feeding grounds were most likely in the Sea of Okhotsk, central and eastern Bering Sea, and Gulf of Alaska (Clapham *et al.*, 2004). All of these feeding areas are much more pelagic or offshore than the well-studied North Atlantic habitats. In the Southern Ocean, right whale feeding grounds also appear to be mostly in offshore, pelagic regions. Southern right whale feeding grounds are likely to be found associated with areas of extremely high productivity; limited sighting data available show most whales in the regions between the subtropical and Antarctic convergences (IWC, 2001b).

Calving in right whales occurs during winter. Where the calving grounds are known, they are in shallow coastal regions or bays. The only known current calving ground in the western North Atlantic is in coastal waters near Georgia and northeastern Florida (Winn *et al.*, 1986; Kraus and Rolland, 2007). In that calving ground, right whales show a clear preference for waters in a relatively narrow depth and temperature range—13–19 m and 13–16°C (Keller *et al.*, 2006). It has been speculated that other coastal areas, including Delaware Bay and Cape Cod Bay, may have been calving grounds before the population was depleted by whaling (Reeves *et al.*, 1978). It has been noted, for example, that Cape Cod is similar topographically to Península Valdés in Argentina and is located at about the same latitude (Payne,

1995). In the eastern North Atlantic, Cintra Bay in northwestern Africa is believed to have been a historical right whale calving ground (Reeves, 2001). It is possible that areas near the Azores and Madeira, as well as the Bay of Biscay, were also calving grounds. In the North Pacific, no right whale calving grounds have ever been discovered. In the Southern Hemisphere, shallow coastal waters and bays in many areas are currently known to be southern right whale calving areas or hypothesized to have been calving grounds historically, including Argentina, Brazil, Falkland Islands, Tristan de Cunha, Namibia, South Africa, Mozambique, Kerguelen Island, Australia, New Zealand, Auckland Islands, and Chile (IWC, 2001b).

Breeding or mating also occurs during the winter. Because of the 3-year female reproductive cycle, breeding can take place geographically distant from calving (Knowlton *et al.*, 1994; Kraus *et al.*, 2001, 2007). In the western North Atlantic, the location of the majority of the population during the winter is not known, and adult males are nearly absent from the calving ground (Brown *et al.*, 2001). Breeding must occur wherever the adult population spends the winter, but it is not known whether there are specific, distinct winter habitats or whether the whales are broadly dispersed across wide regions of the North Atlantic.

In southern right whales, at least some mating behavior occurs in or near the calving grounds, although there may be small-scale segregation of breeding adults from females with calves (Payne, 1995). In Argentina, because females are observed infrequently in these breeding groups in the year prior to calving, it is possible either that the mating which actually leads to conception occurs in some other, unknown habitat or that receptive females only visit coastal waters for very brief periods.

Circumstantial evidence suggests that learning is an important component of habitat selection in right whales (Malik *et al.*, 1999; Frasier *et al.*, 2007). Calves apparently learn the locations of feeding grounds by accompanying their mothers during the first year of life and then return to those same habitats for the rest of their lives. This pattern of matrilineal habitat fidelity seems to be common in migratory whale species; resighting and genetic data demonstrate that it is responsible for population structuring in North Atlantic humpback whales (Clapham, 1996).

C. Predators

Potential predators of right whales include killer whales (*Orcinus orca*) and large sharks, and it is more likely that any predators would attack calves or juveniles. There have been few direct observations of killer whale attacks on right whales, and Mehta *et al.* (2007) concluded that the spacing of tooth rakes on the flukes of North Atlantic right whales was inconsistent with killer whales and more likely from smaller animals such as false killer whales. Reeves *et al.* (2006) reviewed the arguments for and against the hypothesis that migration in large baleen whales to low-latitude calving grounds evolved in response to killer predation on calves in higher latitudes. Predation by sharks similarly may have been one of the selective pressures leading to the evolution of right whales' use of cooler waters in very shallow coastal habitats for calving, since sharks prefer warmer waters and at least white sharks are known to often attack their prey from below (Klimley, 1994).

IV. Behavior and Physiology

Right whales are observed to frequently perform highly energetic behaviors at or above the surface of the water. These aerial behaviors include BREACHING (jumping partly or almost completely above the surface), LOBTAILING (violently slapping the surface with the flukes), and FLIPPERING (slapping the surface with a pectoral flipper). The functions of these behaviors are not known (Whitehead, 1985). They

Figure 4 A “skimming” North Atlantic right whale feeding on zooplankton near the surface. The rough black areas of the “bonnet” are the whale’s skin, whereas the white areas are comprised of whale lice. Photograph by William Watkins.

Figure 5 Aerial view of a feeding North Atlantic right whale in the Gulf of Maine. Photograph by Peter Duley (courtesy of Northeast Fisheries Science Center).

all produce very loud sounds, which may sometimes have a communicative and/or aggressive function. Right whales in Argentina and South Africa have been observed to lift their flukes above the surface, where the flukes act like a sail and allow the wind to push the whale horizontally (Payne, 1995). This “tail-sailing” behavior has not been reported in other habitats.

Right whales are “skimmers” (Nemoto, 1970; Pivorunas, 1979; Baumgartner *et al.*, 2007; Figs 4 and 5). They feed by swimming forward with the mouth agape. Water flows into the opening at the front, and out through the baleen, straining their prey from the water. Feeding can occur at or just below the surface, where it can be observed easily, or at depth. At times, right whales apparently feed very close to the bottom, because they are observed to surface at the end of an extended dive with mud on the head. Typical feeding dives last for 10–20 min (Winn *et al.*, 1995; Baumgartner *et al.*, 2007).

Courtship in right whales often involves aggregations of whales termed “surface-active groups” (Donnelly, 1967; Payne and Dorsey, 1983; Kraus and Hatch, 2001; Kraus *et al.*, 2007). These are usually centered around a single female and may involve large numbers of males; groups of more than 20 animals have been observed. Often the female is belly-up at the surface, whereas the males stroke her with their flippers or attempt to push her under. There is evidence that the female

initiates the interaction by vocalizing. In the North Atlantic, surface-active groups are observed in all seasons, even though calving is highly synchronous and restricted to winter. Therefore much of the observed activity does not lead to fertilization and may serve a social function. The female may simply use the interactions to assess male quality for later mating. The interactions between males in the group generally involve very little of the violence and aggressiveness seen in humpback whales. One theory is that right whales engage in sperm competition (Brownell and Ralls, 1986), where the volume of semen is important in displacing the sperm of other males mating with the same female. Right whale testes may be the largest of any animal, at 2 m long and 500 kg each.

Right whale vocalizations are primarily low-frequency moans, groans, belches, and pulses (Cummings, 1985; Thomson and Richardson, 1995; Parks and Clark, 2007). Most acoustic energy produced is below 500 Hz, with some sounds up to 1500–2000 Hz. The functions of these sounds are not well understood. Hypothesized functions include maintenance of contact between separated individuals, threats or other aggressive signals, and social signals, including their possible involvement in surface-active group behavior.

V. Life History

Information on the age at maturity in right whales is not available from whaling data as it is for other whale species taken by twentieth century industrial whaling. The information must be derived from photoidentification studies that track known individuals from birth. The youngest mature female in the western North Atlantic was 4 at maturity and 5 at first calving (Knowlton *et al.*, 1994). From both North Atlantic and Southern Hemisphere data, the average age at first calving is closer to 9 or 10 years (Best *et al.*, 2001; Cooke *et al.*, 2001; Kraus *et al.*, 2001, 2007). Age at maturity is not yet known for males, as there is no external method for identifying paternity. Genetic studies may be better able to identify fathers of calves and begin to provide data for age of maturity in males (Frasier *et al.*, 2007).

Growth is relatively rapid from birth to weaning at about age 1, by which time the calf approximately doubles in body length to 9–11 m (Brown *et al.*, 2001). Available data on growth after age 1 are not entirely consistent. For example, in the North Atlantic, growth also can be relatively rapid in year 2, by which time total length may reach 12–13 m, and thereafter is much slower. However, South African right whales apparently grow little between ages 1 and 4 (Best and Schell, 1996). Growth after age 1 is likely to be dependent on feeding success. The western North Atlantic female that matured at age 4 remained with her mother well into her second year, possibly growing much faster than the typical rate by nursing for a longer period. Right whales are believed to reach sexual maturity at body lengths of 13–16 m.

There are very few data on longevity. Aging baleen whales is an extremely difficult problem. Japanese attempts to use the wax plug found in the auditory canal from the North Pacific right whales taken for research in 1956–1968 were not successful (Omura *et al.*, 1969). The oldest known right whale to date was in the North Atlantic (Kraus and Rolland, 2007). A mother–calf pair near Fort Lauderdale, Florida, was pursued and shot at by fishermen on March 24, 1935. The calf was killed, but the mother escaped. A photograph of her published in the New York *Herald Tribune* at the time was later matched to photographs taken in Cape Cod Bay (by pioneering right whale researcher William E. Schevill) in April 1959. She was also photographed in 1980, 1985, and 1992. On August 13, 1995 she was photographed offshore, with a large, gaping wound on the head apparently caused by a ship strike. It is unlikely she could have survived that injury. Assuming she was at least 10 years old in 1935, she would have been at least 70 years old in 1995, and may have been

substantially older. Research on bowhead whales suggests that they live substantially longer (George *et al.*, 1999).

The typical reproductive cycle in mature females is 3 years between births (Kraus *et al.*, 2007). The gestation period is approximately 1 year (Best, 1994), and weaning occurs at about 1 year of age (Hamilton *et al.*, 1995). The female then takes a third year to replenish her energy stores, although it is possible for a female who has been especially successful at feeding to skip the resting year and calve after only a 2-year interval (one case observed in the North Atlantic, and at least one in Argentina). An alternative explanation for an observed 2-year interval is calf mortality soon after birth and subsequent avoidance by the mother of the high energetic demands of lactation; documented twice in Australia. This presumes that the mother–calf pair is sighted during the brief interval between birth and death of the calf. Otherwise what would be observed is an apparent 5-year interval, of which 25 were recorded in the North Atlantic between 1980 and 1998 (Kraus *et al.*, 2001). Calving has been observed very rarely; in other instances, known females have been sighted in the calving ground both before and after the calf was born.

VI. Interactions with Humans

A. Whaling

North Atlantic right whales were the first whales to be harvested commercially by the Basques along the Atlantic coast of western Europe as early as the eleventh century (Aguilar, 1986; Reeves and Smith, 2006; Reeves *et al.*, 2007). The whales were killed primarily for oil, which was sold across Europe, as the technology of the time did not permit preservation and widespread transportation of meat. As populations nearest shore were depleted, Basque whaling expanded to more distant waters, reaching eastern Canada by 1530. Basque whaling in Canada was centered in the Strait of Belle Isle between Labrador and Newfoundland and took 300–500 whales per year at its peak. Catches were declining by 1610–1620 and ended in 1713, by which time they had taken as many as 40,000 whales. Recent evidence from genetic sampling of whale bones from that era is that nearly all of the whales landed by the Basques in the Strait of Belle Isle were bowheads (Frasier *et al.*, 2007). It is not clear whether or not Basque whaling beyond the Bay of Biscay impacted North Atlantic right whales, and if it did, where that occurred (Reeves *et al.*, 2007).

Local shore-based right WHALING in North America began soon after the establishment of permanent colonies during the early seventeenth century (reviewed in Reeves *et al.*, 2007). Peak catches were in the early eighteenth century (e.g., 86 in Nantucket, Massachusetts in 1726; 111 in Long Island, New York in 1707), and right whales in western North Atlantic waters may have been effectively extinct as a basis for a commercial fishery by the middle of the eighteenth century. The familiar Yankee whaling industry soon developed as a high-seas fishery targeting sperm whales; however, the whalers continued to opportunistically take any right whales encountered. Yankee whaling (including ships from several European nations) spread to the South Atlantic by 1775, into the South Pacific in 1789, and into the North Pacific by 1820. The Japanese had also begun their own shore-based fishery, which took some coastal migrant right whales, in the late sixteenth century.

The traditional high-seas Yankee whale fishery finally ended in the early twentieth century, when it was replaced by modern industrial whaling. Total right whale catches (although records are not complete) were at least 38,000 in the South Atlantic, 39,000 in the South Pacific, 1300 in the Indian Ocean, 15,000 in the North Pacific, and at least a few hundred in the North Atlantic. Some shore-based whaling in the eastern United States persisted into the 1920s, but it was minor, with only 8 taken in Long Island after 1900. In the North Atlantic, the last episode

of intensive right whaling was in the late nineteenth and the early twentieth century off Norway, Iceland, and Scotland, and the last right whales taken were at Madeira, 1 in 1952 and 2 in 1967. All right whale populations worldwide were protected from commercial whaling in the 1930s by the first International Convention for the Regulation of Whaling. However, the Japanese took 23 North Pacific right whales in the 1940s and 13 more under special scientific research permits between 1956 and 1968, some illegal takes of right whales along the coast of Brazil were reported in the 1950s, there was a significant amount of illegal Soviet taking of right whales in the North Pacific and Southern Ocean into the 1960s (Brownell *et al.*, 2001; Clapham *et al.*, 2004), and it is possible that there has been illegal right whaling elsewhere in the world.

B. Ship Strikes

The most significant human-related source of mortality at present in western North Atlantic right whales is collision with large ships (Knowlton and Kraus, 2001; Kraus *et al.*, 2005; Knowlton and Brown, 2007; Waring *et al.*, 2007). Between 1970 and 2005, 24 right whales were known to have been killed by ships, and 3 others were last seen with serious and probably fatal injuries. There are probably additional mortalities that are never discovered because the carcasses are lost at sea. Ship collisions may be less of a mortality factor in other oceans, where right whales spend less time in nearshore habitats or where the level of industrial development is lower, although at least three probable ship-strike mortalities have been recorded in recent years off the Brazilian coast (Greig *et al.*, 2001).

C. Entanglements

The second most important human-related mortality factor in western North Atlantic right whales is incidental capture in commercial fishing gear (Johnson, 2005; Johnson *et al.*, 2007; Waring *et al.*, 2007). The gear involved is fixed gear (set in one location rather than towed behind a vessel), including sink gill nets, drift nets, and a variety of pot and trap fisheries. In 1970–2005, 6 right whales are known to have been killed by ENTANGLEMENTS and 13 others were seriously injured but disappeared and probably died. It is not always known whether entanglements occur in actively fishing gear or in gear that has been lost, damaged, or moved by storms or vessels (often termed “ghost” gear). There are few data on entanglement mortalities in other populations.

Entanglement seems to be very common in right whales. Many entanglements involve the tail, where the leading edges of the flukes begin, and leave characteristic scars afterward. Over 75% of whales in the western North Atlantic carry such scars, and some individuals have been entangled two or three times (Hamilton *et al.*, 2007). Entanglements are therefore often not lethal. They may be more dangerous in younger animals, who might grow into a relatively benign entanglement until it becomes life-threatening (Moore *et al.*, 2007).

D. Climate Change

Right whales are feeding specialists, with a relatively narrow range of acceptable prey characteristics and requiring prey to be concentrated in exceptionally high densities. The development of right whale feeding grounds is closely linked to physical phenomena such as water structure, currents, and temperature (Kenney and Wishner, 1995; Baumgartner *et al.*, 2007). This may make right whales more sensitive than other species to impacts from global climate change, with detectable environmentally induced variability in reproduction in recent years (Greene and Pershing, 2004; Leaper *et al.*, 2006; Kenney, 2007).

Any possible impacts may be increased because of matrilineal fidelity to their feeding grounds, and possibly a relatively low ability to locate new feeding grounds when conditions change.

E. Other Human Impacts

There are a number of other potential human impacts on right whales (reviewed by Katona and Kraus, 1999; Reeves and Kenney, 2003; Kraus and Rolland, 2007).

1. Habitat loss due to high levels of human activity is mentioned frequently as a possible impact. Right whales no longer occur in Delaware Bay, eastern United States; Table Bay, South Africa; Wellington Harbor, New Zealand; or Derwent River, Tasmania. However, a plausible alternative explanation is that they were extirpated by whaling and have never reoccupied the habitat due to matrilineal habitat fidelity.
2. Pollution is another potential impact that is mentioned frequently but where evidence is sparse. Oil spills may be a bigger threat to right whales than to other baleen whales because their very fine baleen might be fouled more easily. Blubber samples show a presence of toxic contaminants, but at lower levels than in cetaceans that feed at higher trophic levels (Woodley *et al.*, 1991; Weisbrod *et al.*, 2000). A recent concern is that some contaminants may act as hormone mimics, affecting reproduction, or as immune system suppressants. They may be exposed via the food chain to naturally occurring biotoxins produced by phytoplankton, such as “red-tide” dinoflagellates (Durbin *et al.*, 2002).
3. Man-made noise may have the potential for interfering with acoustic communication, particularly since the major noise source, shipping, is also concentrated in the lower frequencies (Parks and Clark, 2007).
4. Effects of intensive commercial fisheries may alter ecosystem structure, increasing the abundance of other species that feed on zooplankton, particularly small fishes with lower economic value than the larger species harvested by FISHERIES.
5. The long-term effects of extreme population depletion by whaling might include reduced genetic diversity and associated health and reproductive problems (Frasier *et al.*, 2007).

Figure 1 An adult ringed seal (*Pusa hispida*) on Svalbard with a VHF transmitter on its back.

constitute a well marked clade designated as tribe Phocini, which is distinguished from all other phocids by a unique karyotype ($2n = 32$), and a white lanugo (natal fur). Five subspecies are recognized, three are found in marine waters, whereas two subspecies are limited to freshwater areas.

Ph. hispida is the most widely distributed subspecies, occurring across northern regions of Canada, Alaska, Greenland, Svalbard, and Russia. This subspecies also includes animals found in freshwater areas in northern Canada such as in Lake Nettilling on Baffin Island and in Lake Melville in Labrador, but these animals have received little study.

Ph. botnica occurs throughout the northern Baltic Sea, primarily in the Gulf of Bothnia and Gulf of Finland; *Ph. ladogensis* is confined to the freshwater Lake Ladoga in western Russia. Some animals are thought to transit into the Gulf of Finland, and *Ph. saimensis* are found in southeast Finland in a series of landlocked interconnected lakes of Saimaa, Haukivesi, Orivesi, Puruvesi, and Pyhäselkä; *Ph. ochotensis* is found in the western, northern, and northeastern portions of the Sea of Okhotsk ranging south to the northern coast of Hokkaido on the west and to Mys Lopatka, Kamchatka in the east.

II. Distribution and Abundance

The ringed seal is northern circumpolar in distribution (Fig. 2). Although often considered as an inshore species, they have been observed at the North Pole and large numbers of animals are found in stable offshore pack-ice in polar regions. In North America they occur throughout the Arctic, extending as far south as the Labrador coast of Canada in the east. They are found throughout James and Hudson Bays, the Beaufort Sea, and extend as far south as Norton Sound along the Alaskan coast in the west. Ringed seals are found all along the coast of Greenland, but on the west coast are most abundant north of the Arctic circle. They are also common around Svalbard, but are rare around Iceland. Remnant populations are also found in the Baltic Sea, primarily in the Gulf of Bothnia, in Lake Saimaa in southeastern Finland and Lake Ladoga in western Russia, not far from the Gulf of Finland portion of the eastern Baltic Sea. They also occur along the northern coast of Russia, including the White Sea and are found in the Sea of Okhotsk off eastern Russia.

In general, seal ecology is characterized by marine feeding combined with a need to haul out on a solid substrate for reproduction or molting. Although hauled out under these conditions they are often concentrated in large numbers, which facilitates attempts to estimate abundance using aerial surveys. These surveys often attempt to count total numbers of hauled-out animals such as pups, then use a model incorporating information on haul-out patterns or a combination of

Ringed Seal *Pusa hispida*

M.O. HAMMILL

I. Characteristics and Taxonomy

The ringed seal (Fig. 1) is among the smallest of pinnipeds, with adults reaching a maximum length of 1.3–1.5 m and weighing up to 100 kg prior to breeding. Males and females are similar in size, with males about 3% larger than females. Pelage descriptions vary slightly depending on the observer's perception. The ventral surface is normally light grey, whereas the dorsal area is variously described as being black with whitish-silvery rings, or silvery grey with black spots producing rings on its back. Its common name is derived from the characteristic ringed pattern on the pelage. The claws on the front flippers are quite rugged and are used to scratch open and maintain holes in the ice, which animals return to repeat to breathe and use to haul out on the ice. During the breeding season, the males emit a strong, pungent odor (Ryg *et al.*, 1992). The odor is produced by modified sebaceous glands that are concentrated in the facial region of the males. On account of this odor, some early descriptions and engravings of ringed seals refer to them as *Pusa (Phoca) foetida*.

The ringed seal is a member of the subfamily Phocinae of the family Phocidae. Within this subfamily, *Pusa hispida*, along with four other genera, the *Phoca*, *Halichoerus*, *Histriophoca*, and *Pagophilus*

Figure 2 Map showing the circumpolar distribution of ringed seals (*Pusa hispida*) in dark gray.

reproductive rates and survival rates to estimate total population size. Ringed seals present a major challenge to estimating total population size because of their remote location, they are hidden from view in snow caves (lair) during the breeding season and do not form large aggregations on the ice (compared to other species) during the molt. Unfortunately, the factors that might affect the proportion of animals hauled-out on the ice at any one time, such as ice conditions, age, and sex, stage of molt, and weather conditions are poorly understood. Therefore, any population figure is very likely to be an underestimate and highly uncertain. Very crude estimates of abundance suggest that ringed seal numbers are in the order of 1–1.5 million for Alaska, 1.5 million in Canada, 215,000–2 million around Greenland, 7600 in Svalbard, in eastern Russia, 800,000+ in the Sea of Okhotsk and another 70,000–80,000 in the Bering Sea. Recent surveys estimate ringed seal abundance of around 260 animals in Lake Saimaa, 3000–5000 in Lake Ladoga, and 4000 in the Baltic Sea resulting in a total on the order of 3.6–5.9 million animals.

III. Ecology

Higher densities of ringed seals are observed in areas that combine stable first-year ice with a certain amount of irregular features such as pressure ridging or frozen in pieces of ice that would encourage snow drift formation, in areas <200-m deep. Within the fast-ice

habitat, mature animals occur in the prime areas, with juveniles restricted to less stable ice toward the entrance to bays or toward the offshore edge of the fast-ice.

Ringed seals keep open breathing holes by scratching at the ice using the claws on their foreflippers. As snow builds up over top of these holes, or in areas with snow drifts on the ice, animals may open new holes and dig out caves in the snow using their foreflippers. Also known as subnivean lairs, animals of all age classes and both sexes may haul out in these lairs during winter and early spring to rest. The lairs provide protection from predators and shelter from the wind and cold ambient temperatures.

Over 30 different food species have been identified as ringed seal prey, including both fish and invertebrates prey. Dominant prey among marine animals include Arctic (Polar) cod (*Boreogadus saida*), capelin (*Mallotus villosus*), redfish (*Sebastes* sp.), snailfish (*Liparis* sp.), Greenland halibut (*Reinhardtius hippoglossoides*), and sculpins (Cottidae), and pelagic crustaceans such as amphipods (*Parathemisto libellua*), mysids (*Mysis oculata*), euphausiids (*Thysanoessa* sp.), decapods (*Lebbeus* sp.), and cephalopods (*Gonatus* sp.). Among freshwater subspecies, smelt (*Osmerus eperlanus*), vendace (*Coregonus albula*), ruffe (*Gymnocephalus cernuus*), burbot (*Lota lota*), three spined stickleback (*Gasterosteus aculeatus*), perch (*Perca fluviatilis*), roach (*Rutilus rutilus*), whitefish (*Coregonus lavaretus*), trout (*Salmo trutta*), four-horn sculpin (*Triglopsis quadricornis*) are

dominant prey for the Ladoga seal. Dominant prey for Lake Saimaa seal include vendace, smelt, whitefish, perch, roach, and burbot as well as the crustacean (*Mysis relicta*). Ringed seals are themselves important prey for polar bears, and to some extent for walrus (*Odobenus rosmarus*), Greenland shark (*Somniosus microcephalus*), and killer whales (*Orinus orca*).

IV. Behavior and Physiology

Mating occurs in the water, and males are thought to defend underwater territories, around a few females, but this has not been observed directly. There is some evidence of philopatry among mature animals, but juveniles may undertake extensive movements, for example animals captured in the Beaufort Sea in Canada, tagged and released have been recovered from as far away as Siberia, Russia. Although capable of diving to 300 m, most dives go to depths of 100 m or less.

V. Life History

Ringed seals reach sexual maturity at the age of 4–6 years for females and males respectively. They can be long-lived, with animals up to 45 years old having been recorded. Females give birth to a single, white-coated pup. The pups are born during March–April. At birth they weigh about 5.4 kg (SE = 0.4, N = 6) and are 63 cm (SE = 1.3, N = 11) long. The pups are weaned after 39 days (range = 36–41 days), weighing about 22 kg, for a gain of 0.43 kg/day. The young begin to lose (molt) the white fur or lanugo after 2–3 weeks. The first hair coat has a similar pattern to that of the adult pelage, but the hair is slightly longer in the first year and has a fine texture. These molted young are known as silver jars. As among other phocids, mating occurs at the time of weaning. There is a delay of implantation of 89 days and active gestation of 241 days.

The pups are normally born in a subnivean lair and as the pups grow, they may dig small tunnels off to the sides of the lair. The lower critical temperature for dry ringed seal pups is -25°C , but this increases to above 0°C for young pups that are wet. Temperatures inside the lairs are 0 to $+2^{\circ}\text{C}$, when ambient temperatures may be as low as -15 to -27°C . Because a dry and exposed pup appears to be capable of coping with ambient conditions, it has been suggested that the lair may play a more important role protecting pups from predators such as polar bears (*Ursus maritimus*), arctic fox (*Alopex lagopus*) and birds such as ravens (*Corvus corax*) or gulls (*Larus hyperboreus*), by hiding the young from view and slowing access by forcing the predator to dig through the lair walls or roof, giving the young some chance to escape. Young ringed seal pups are capable of entering the water soon after birth and diving to depths of as much as 80 m. This precociousness is thought to have evolved in the face of intense predation pressure. During lactation alternative lairs may be used, and if disturbed, both breathing holes and lairs may be abandoned and new lairs formed. The small body size of the ringed seal may be another adaptation to predation pressure, since smaller animals could make use of smaller snow drifts to dig out their subnivean lairs.

VI. Interactions with Humans

Ringed seals have had a long history of exploitation by humans. In Arctic regions, they are an important component of native subsistence hunts for food, dog food, and also the sale of skins. In the Baltic Sea, they were heavily exploited and are sometimes accused of having a negative impact on commercial fisheries although this is more

often attributed to the larger grey seal (*Halichoerus grypus*). Seals are also caught incidentally in fishing gear in Lake Saimaa and Lake Ladoga. In 2002, 480 seals were caught incidentally in Lake Ladoga out of a population of 3000–5000 animals.

Unlike many other seal species, ringed seals tend to be solitary and are widely dispersed, which provides some protection from direct commercial exploitation. The presence of stable ice, and sufficient snow for the snow lairs are important for pup growth and survival. Global warming could reduce snow cover, or may result in lairs melting open earlier and will lead to a decline in stable ice cover. Animals born without the protection of lairs, or where the lairs may open prematurely suffer extremely high mortality from predation by bears, foxes, and avian predators as well. Ringed seal pups need a solid platform during lactation. In areas where the ice is less stable, pups tend to be smaller, and may suffer higher mortality because milk energy must either be diverted to generating heat from spending more time in the water, or early separation (weaning) from the female. Incidental catches in commercial fisheries and coastal development are having a negative impact, particularly on the smaller freshwater subspecies. High catch levels and population declines have already resulted in some areas in Lake Saimaa and Lake Ladoga being abandoned by seals, and pose significant conservation threats to these two subspecies. Hydroelectric development in these areas, resulting in rapidly changing water levels, may lead to the collapse of lairs, particularly along the shoreline, where the largest snow banks are located, resulting in the death of animals. Oil spills would be expected to have only a limited direct impact on ringed seals because they rely on the thick blubber layer, not the fur to keep warm (with the exception of very young, white-coated pups), and the noxious fumes associated with oil spills would result in many animals moving away from the spill area. However, there may be indirect effects if oil spills affect prey abundance. Studies in areas where drilling or production are occurring have not shown a reduction in the number of seal holes or lairs, indicating that animals do not abandon these areas with elevation noise of traffic zones. Seismic exploration activity could cause temporary or permanent hearing damage, and might affect seal behavior as animals may spend more time at the surface to avoid exposure to airgun noise. High contaminants levels, primarily polychlorinated biphenyls (PCBs), were associated with large scale reproductive failure among ringed seals in the Baltic Sea.

Risso's Dolphin

Grampus griseus

ROBIN W. BAIRD

I. Characteristics and Taxonomy

Risso's dolphin (*Grampus griseus*) is the fifth largest member of the family Delphinidae, with adults of both sexes reaching up to about 4 m in length (Fig. 1). The common name comes from the person (M. Risso) who described the type specimen to G. Cuvier in 1812. Risso's dolphins are unusual looking for a variety of reasons. Their anterior body is extremely robust, tapering to a relatively narrow tail stock, and they have one of the tallest dorsal fins in proportion to body length of any cetacean (Fig. 2). The bulbous head has a distinct vertical crease or cleft along the anterior surface of the melon. Color patterns change dramatically with age. Infants are gray to brown dorsally and creamy-white ventrally, with a white anchor-shaped patch between the pectoral flippers and white around the mouth. Calves then darken to nearly black, while retaining the ventral white patch. As they mature they lighten (except for the dorsal fin, which remains dark in adults in most populations), and the majority of the dorsal and the lateral surfaces of the body become covered with distinctive linear scars, most of which are presumably caused by intraspecific interactions. Older animals can appear almost completely white on the dorsal surface or when swimming just beneath the surface. No evidence of sexual dimorphism has been reported. From a distance Risso's dolphins are most frequently confused with killer whales (*Orcinus orca*) due to the large size of their dorsal fin.

Dentition is unusual, with most individuals having no teeth in the upper jaw and only a small number (two to seven pairs) in the lower jaw. Based on genetic similarity, Risso's dolphins are most closely related to false killer whales (*Pseudorca crassidens*), melon-headed

whales (*Peponocephala electra*), pygmy killer whales (*Feresa attenuata*), and pilot whales (*Globicephala* spp.). No subspecies are currently recognized.

II. Distribution and Abundance

Risso's dolphins are distributed worldwide in temperate and tropical oceans, with an apparent preference for steep shelf-edge habitats between about 400- and 1000-m deep. In the North Pacific they can be found as far north as the Gulf of Alaska and the Kamtchatka Peninsula, in the South Pacific to Tierra del Fuego and New Zealand. In the North Atlantic they have been documented as far north as southern Greenland and southern Norway. They are found throughout the Mediterranean and the Indian Ocean. No worldwide population estimates exist, although a number of regional estimates

Figure 2 The Risso's dolphin has one of the tallest dorsal fins in relation to body size of any cetacean. Linear scars on Risso's dolphins can often cover the majority of the body surface. Photo © Annie B. Douglas.

Figure 1 The Risso's dolphin is one of the largest dolphins, with a robust body that nevertheless possesses a narrow tail stock (C. Brett Jarrett).

are available. No information on population trends are available. In most areas where their ranges overlap Risso's dolphins are more common than other closely related species, such as pilot whales, false killer whales, melon-headed whales, or pygmy killer whales, although less common than the smaller delphinids. Some evidence of population division exists both between and within ocean basins, based on morphological, genetic, and distribution data, although population boundaries have not been clearly delineated. Seasonal north-south shifts in density have been suggested off the west coast of North America.

III. Ecology

Risso's dolphins are thought to feed almost entirely on squid (both neritic and oceanic species), and limited behavioral research suggests that they feed primarily at night. Diet may vary by age and sex (Cockroft *et al.*, 1993). No evidence of predation by either killer whales (*O. orca*) or large sharks is available, although both likely prey on Risso's dolphins at least occasionally. Mass strandings of this species are very rare. The range of Risso's dolphins seems to be limited by water temperature, with animals most common in waters between 15°C and 20°C and rarely found in waters below 10°C.

IV. Behavior and Physiology

Risso's dolphins are relatively gregarious in nature, typically traveling in groups of 10–50 individuals, with the largest group observed estimated to contain over 4000 individuals. Stable groups of adults have been documented within larger aggregations. Based on the age structure of a school killed in a drive fishery in Japan, it has been suggested that mature male Risso's dolphins move among groups. Risso's dolphins frequently travel with other cetaceans. Off southern California they have been documented to “bow ride” on and apparently harass gray whales (*Eschrichtius robustus*), and are often seen “surfing” in swells. Aggressive behavior directed toward short-finned pilot whales (*Globicephala macrorhynchus*) has been observed. No studies on diving behavior have been undertaken.

V. Life History

Life history information for this species is relatively limited (Amano and Miyazaki, 2004). Gestation has been estimated at 13–14 months and calving interval at 2.4 years. There appears to be a peak in calving seasonality during the winter months in the eastern Pacific and in the summer/fall months in the western Pacific. Age at sexual maturity is thought to be 8–10 years for females and 10–12 years for males. The oldest Risso's dolphin estimated by examining growth layer groups in the teeth was 34.5 years old.

IV. Interactions with Humans

Interactions with humans are diverse. Although they occasionally bow-ride on vessels, in most cases Risso's seem indifferent to vessels or actively avoid them. Risso's dolphins have been recorded stealing bait from longlines in a number of areas and have been killed as bycatch, as well as being deliberately killed as a result of such interactions. Risso's dolphins are also killed accidentally in gillnet and seine-net fishing around the world, and have been recorded ingesting plastic and with high levels of contaminants in tissues. Small numbers of Risso's dolphins have been killed in small-scale whaling operations around the world, and off Sri Lanka and possibly Japan these takes may seriously jeopardize the local population. Risso's dolphins have been held in aquaria in both Japan and the United States, although

they are relatively uncommon in captivity compared to other species of cetaceans. A number of hybrids with bottlenose dolphins (*Tursiops truncatus*) have been documented in Japanese aquaria.

River Dolphins

RANDALL R. REEVES AND ANTHONY R. MARTIN

Most people are surprised to learn that some species of dolphins, and even one porpoise population, live either entirely or partly in freshwater rivers and lakes. Three species have adapted so thoroughly to freshwater habitats, over millions of years, that they now look very different from their marine-dwelling ancestors. A fourth species, the franciscana, looks similar to those three, is most closely related to one of them, and likely once lived in rivers as well, but it is now found only in coastal marine waters. These four dolphin species, collectively (and ambiguously) known as river dolphins, exhibit some extreme characteristics in their morphology and sensory systems. Until quite recently, their similarities persuaded taxonomists that they were closely related, but genetic evidence shows that they have been separated for millions of years,

Figure 1 A boto surfaces in its typical riverine habitat, Mamirauá, Brazil, August 2005. Photo by A. R. Martin and P. Gallego.

Figure 2 A male boto waves plant material in the air, an action that may function as part of a social or sexual display. Mamirauá, Brazil, March 2006. Photos by A. R. Martin and P. Gallego.

and that their morphological similarity is due largely to convergent evolution. In other words, separately and progressively they have adapted their form and function to life in a similar habitat. They are also among the most seriously threatened cetaceans because their habitat and resources must be shared with many millions of people.

I. Definition and Distribution

In Rice's (1998) evaluation of aquatic mammal SYSTEMATICS, he assigned the term "river dolphin" to the "peculiar long-snouted" dolphins in four single-species genera: *Platanista* (the South Asian river dolphin, known as bhulan in Pakistan, susu in India, and shushuk in Bangladesh), *Lipotes* (the Chinese or Yangtze river dolphin, known as baiji in China), *Inia* (the Amazon and Orinoco river dolphin, or boto), and *Pontoporia* (the franciscana, or La Plata dolphin). Rice placed each genus in a separate family, but Heyning (see River Dolphins, Relationships) recognized two clades: Platanistidae, containing only *Platanista*, and Iniidae, containing the other three genera. Although the genera *Lipotes* and *Pontoporia* are clearly monospecific, it had been customary until recently to recognize two species of *Platanista*—the Indus dolphin (*P. minor*) and the Ganges dolphin (*P. gangetica*). They are now provisionally regarded as subspecies: *P. gangetica minor* in the Indus drainage of Pakistan and *P. g. gangetica* in the Ganges, Brahmaputra, Megna, Karnaphuli, and Sangu drainage systems of India, Bangladesh, and Nepal (Fig. 1). There are three separate populations of the boto (*Inia geoffrensis*): the Bolivian subspecies *I. g. boliviensis* in the Madeira River drainage above the Teotonio Rapids at Porto Velho, the Amazonian subspecies *I. g. geoffrensis* distributed throughout the Amazon drainage basin except the upper Madeira system, and the Orinoco subspecies *I. g. humboldtiana* distributed throughout the Orinoco drainage basin (Fig. 2; see AMAZON RIVER DOLPHIN). The Bolivian form differs from the others in some fundamental morphological characters (e.g., number of teeth), and may deserve recognition as a separate species (Banguera-Hinestroza *et al.*, 2002). The baiji (*Lipotes vexillifer*) is, or was, endemic to China's Yangtze River system. In the past, it also occurred at least seasonally in the two large lakes, Dongting and Poyang, appended to the middle reaches of the Yangtze and in the neighboring Qiantang River. A comprehensive survey of the known current range in 2006 failed to encounter a single baiji, and no reliable sightings had been reported in several years before then,

so the species may already be extinct. If so, its demise was due to conflict with humans sharing its habitat (see later), and it was the first small cetacean to have been wiped out by man.

The outlier in this group, the franciscana (*Pontoporia blainvillei*), lives in coastal marine waters of eastern South America, including the estuary of the Rio de la Plata (River Plate) between Argentina and Uruguay. The modern river dolphins therefore occur in only two continents, South America and Asia. Most questions regarding their origins and how they evolved remain unresolved. In the case of *Inia*, for example, one hypothesis is that their ancestors entered the Amazon basin from the Pacific Ocean approximately 15 million years ago, whereas another is that they entered from the Atlantic Ocean only 1.8–5 million years ago.

II. Behavior and Ecology

Little is known about river dolphin societies, and they probably vary from species to species. A long-term study of botos in Brazil suggests that they have no long-term affiliations, except in the case of mothers and offspring, and that adult males (which are much larger than females) compete for sexual favors both by fighting and by displaying objects (Fig. 2, inset). Males are often wounded in fights, and are heavily scarred by tooth-rakes, leading to depigmentation of the skin and at least contributing to the bright pink coloration for which the species is well known (Martin and da Silva, 2006). For much of the year, females retreat into the furthest reaches of the flooded forest with their calves, whereas adult males mostly remain on the large rivers. This degree of sexual segregation is unusual in dolphins, and its function is unclear, but it may be related to the needs or protection of the calves (Martin and da Silva, 2004a). River dolphins seem not to be highly social, with observed group sizes rarely exceeding 10 or 15 individuals. Yet the densities at which they exist, expressed in terms of individuals per unit area of water surface, sometimes far exceed those of marine cetaceans. For example, botos and tucuxis in portions of the upper Amazon system typically occur in densities of 1–10 individuals/km² (Vidal *et al.*, 1997).

Controversy has surrounded the question of whether river dolphins, like their marine counterparts, communicate with high-pitched

whistles. Studies of the boto have been complicated by the fact that most of its range is shared with a delphinid (*Sotalia fluviatilis*) that is known to whistle. The question has not yet been answered unequivocally, but very high-frequency whistles of unusual form have been reported from Ecuador in the apparent absence of *Sotalia* (May-Collado and Wartzok, 2007), so it now seems likely that botos do use whistles, as do (did) baijis (Wang and Wang, 2006).

The small-scale distribution of river dolphins is far from random. They tend to congregate at particular points in a river, especially at confluences (where rivers or streams converge), sharp bends, sandbanks, and near the downstream ends of islands. In a study of the distribution of Ganges dolphins in Nepal's Karnali River, Smith (1993) found the animals primarily in eddy countercurrent systems of the main river channel. Such areas of interrupted flow occur when fine sand or silt is deposited as a result of stream convergence. It is not entirely clear why the dolphins are attracted to these sites, but it likely has some relation to prey availability and energy saving. As Smith (1993) points out, positions within eddies "require minimal energy to maintain but are near high-velocity currents where the dolphins can take advantage of passing fish." Large confluences may contain tens of dolphins at a given time, but such concentrations appear to be adventitious rather than formed for social reasons. In other words, noninteracting individuals are found in close proximity due to the clumped nature of resources and refugia in the river systems where they are found. Indus dolphins and botos have similar behavior in terms of habitat preferences and the nature of feeding aggregations.

River dolphins have a number of physical characteristics that set them apart from other cetaceans. All have evolved relatively small eyes, probably because VISION is of limited value in silt-laden water, but the Indus and the Ganges dolphins have moved so far along this path that their eyes now lack a crystalline lens, rendering them functionally blind. At most, they may be able to perceive gross differences between light and dark. These dolphins usually swim on their side, with one flipper (most often the right one) trailing near the river bottom and the body oriented so that the tail end is somewhat higher in the water column than the head. Their head nods constantly as they scan acoustically for prey and obstacles. Indus and Ganges dolphins remain active day and night. All river dolphins are endowed with a sophisticated biosonar system, but those other than the Indus and the Ganges dolphins also have good vision. Other physical adaptations to freshwater environments, where maneuverability may be important in shallow areas and flooded forest, are large flippers and flexible bodies. The river dolphins of the Indus, Ganges, and Amazon/Orinoco all share these characteristics, and at least the boto can even swim backward.

All river dolphins have adapted to living in a highly dynamic environment. Although much of their habitat is silty, they also occur in areas where the water is clear, as in the upper reaches of the Ganges, or "black" (stained by tannic acid), as in many Amazon and Orinoco tributaries. Water levels in the Amazon can vary seasonally by as much as 10–13 m. During the low-water season, the dolphins (and other fauna) are restricted to the deep channels of lakes and rivers, whereas during the flood season they can range widely. Amazon dolphins penetrate into rain forests and venture onto grasslands during the floods. Their DIET seems diverse, with at least 45 fish species from 18 families, in addition to crabs and river turtles, represented in examined stomach contents (Best, 1984). Both schooling and non-schooling fish species are eaten. Botos are the only modern cetaceans with a differentiated dentition. The teeth in the front half of the jaw are conical, whereas those in the latter half have a flange on the inside portion of the crown, more reminiscent of molars (for crushing) than canines or incisors (for biting and holding). Presumably,

this feature is related to the hard-bodied or spiny character of some of their prey (e.g., armored catfishes, even turtles); large catfish are often torn into smaller pieces before being eaten.

III. Threats and Conservation Concerns

Any description of the river dolphins must include a section on their conservation status. They include within their ranks some of the most endangered aquatic mammals (Reeves *et al.*, 2000; Jefferson and Smith, 2002). As mentioned earlier, the baiji is either the most critically endangered cetacean species or it is already extinct (Turvey *et al.*, 2007). Discovered by Western science as recently as 1918, it was apparently still common and widely distributed along the entire Yangtze River, from near the Three Gorges to Shanghai, when China's Great Leap Forward began in the autumn of 1958. From that time, baijis were probably hunted to some extent for meat, oil, and leather. Although protected legally since the early 1980s, they continued to die accidentally in fishing gear, from collisions with powered vessels, and from exposure to underwater blasting during harbor construction, in addition to suffering from the effects of overfishing, pollution, industrial and vessel noise, and the damming of Yangtze tributaries. Efforts to protect the baiji (as well as the Yangtze population of finless porpoises) have been far from adequate. China's commitment to industrial and agricultural development of the Yangtze basin makes its interest in preserving the natural environment pale by comparison.

The Indus and the Ganges dolphins are also classified as endangered, with the former numbering about a thousand and the latter possibly in the low thousands. Indus dolphins occur today only in the main channel of the river, although historically they also inhabited several large tributaries (Sutlej, Ravi, Chenab, and Jhelum). Their population has been fragmented by irrigation dams, and the subpopulations trapped upriver of these dams have progressively gone extinct. Now, only two or three subpopulations of Indus dolphins are large enough to be viable. The Ganges dolphin has also lost large segments of upstream habitat as a result of dam construction, but its generally broader distribution makes it less immediately threatened with extinction. Similar to the baiji, the Indus and the Ganges dolphins have been subjected to incidental capture in fishing gear, especially gill nets. An additional concern for the Ganges dolphin is that fishermen in some parts of India and Bangladesh use dolphin oil as an attractant while fishing for a highly esteemed species of catfish. This means that there is a demand for carcasses and a disincentive for releasing live dolphins found in nets. Also, some tribal people in remote reaches of the Ganges and the Brahmaputra basins still hunt dolphins for food. A proposed seismic profiling survey in the Brahmaputra River in Assam in 2006–2007 brought international attention to the emergent risks to Asian river dolphins from oil and gas development.

Because the Amazon has not yet experienced as much modification or resource extraction as other great rivers, boto populations there appear relatively healthy. The Mamirauá reserve, an area of 11,240 km² of flooded forest in the central Amazon, had an estimated 13,000 animals in the early years of the twenty-first century (Martin and da Silva, 2004b). This density cannot be extrapolated across the species' range because Mamirauá is unusually productive and has an extremely high density of botos. Nonetheless, the total range-wide population is likely in the high tens of thousands at least. This rosy picture is unlikely to last, however. More and more hydroelectric dams are fragmenting the boto's range, riverside human populations are burgeoning, bringing increasing resource extraction, and in recent years large numbers of botos have been killed in Brazil for use as fish bait.

Ultimately, all river cetaceans are threatened by the transformation of their habitat to serve human needs. In addition to impeding the natural movements of dolphins and other aquatic organisms, dams in southern Asia divert water to irrigate farm fields and supply homes and businesses in an arid landscape, reducing directly the amount of habitat available to the dolphins. As water becomes an increasingly strategic resource in a warming world with expanding human populations, the prospects for freshwater cetaceans are certain to deteriorate even further.

River Dolphins, Evolutionary History and Affinities

CHRISTIAN DE MUIZON

The term “river dolphins” or Platanistoids has been traditionally used to include the recent odontocetes that live in freshwater and are not members of the other clades of odontocetes: delphinoids, ziphioids, and physeteroids. Their affinities to other groups of odontocetes were unresolved, mainly because they have many plesiomorphic characters (e.g., Slijper, 1936; Simpson, 1945). There are four genera of living “river dolphins” (*Platanista*, *Lipotes*, *Inia*, and *Pontoporia*). Other (partly) freshwater odontocetes include *Orcaella* (Irrawadi River) and *Sotalia* (Amazon River) are not included in the Platanistoidea because they are clearly related to the marine dolphins, Delphinidae. Although it was previously assumed that platanistoids were monophyletic, this is almost certainly not the case, and some of their included taxa have been regarded as closely related to several groups of fossil odontocetes: e.g., the Squalodontidae, the Eurhinodelphinidae, the “Acrodelphinidae.” There is now consensus that Platanistoidea is para- or polyphyletic (Muizon, 1984, 1987, 1988, 1991, 1994; Heyning, 1989; Fordyce, 1994; Messenger and McGuire, 1998; Fig. 1).

The genus *Platanista* appears to be an early diverging group of odontocetes, Platanistoidea, and the three other genera (*Lipotes*,

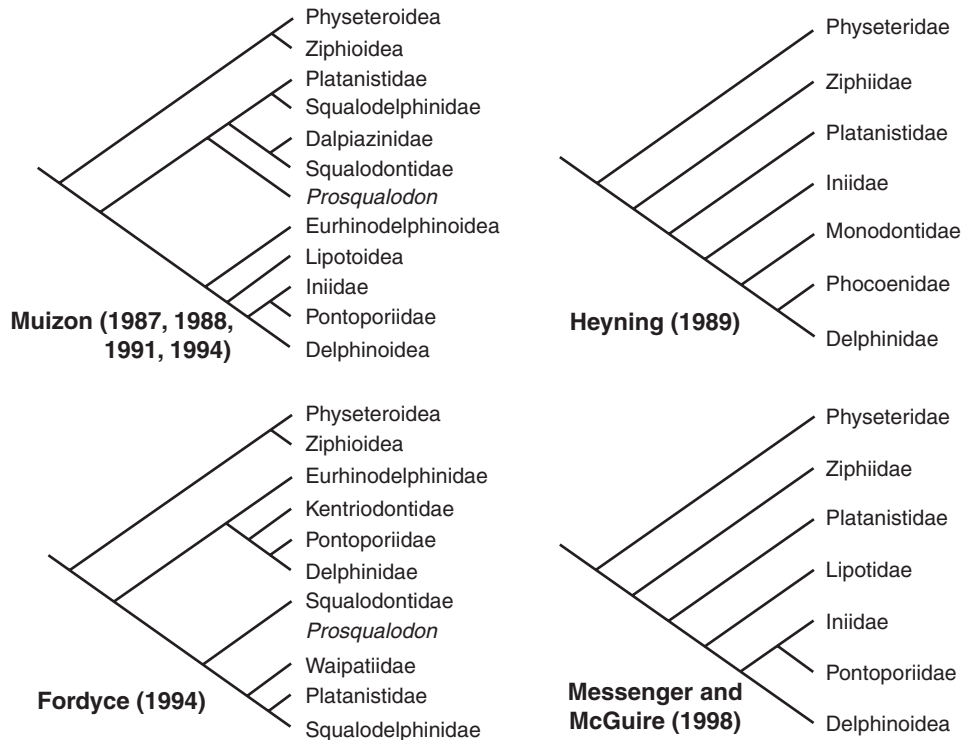

Figure 1 Cladograms of hypotheses on the affinities of “river dolphins.”

Pontoporia, and *Inia*) are regarded as closely related to the Delphinoidea. Platanistoidea was a diversified and widely distributed group during the Oligocene and the Miocene. This group includes the modern Platanistidae as well as the fossil families Prosqualodontidae, Squalodontidae, Waipatiidae, Squalodelphinidae, and possibly the Dalpiazinidae. The other “river dolphins” are included with the Delphinoidea within the monophyletic infraorder Delphinida. There is no consensus on their position within the Delphinida, although they are generally regarded as basal taxa.

I. Platanistoidea

This monophyletic superfamily of odontocetes includes one recent genus (*Platanista*) and approximately 15 fossil taxa (Fordyce and Muizon, 2000). The monophyly of the Platanistoidea is supported by several synapomorphies such as the reduction or loss of the coracoid process of the scapula, the development of articular ridge or peg on the periotic, and the ventral deflection of the anterior process of the periotic (Fordyce, 1994; Muizon, 1994). This superfamily includes five (possibly six) families: the Squalodontidae, the Prosqualodontidae, the Waipatiidae, the Squalodelphinidae, and the Platanistidae. In contrast to their recent representative, all the fossil platanistoids are marine, which indicates that adaptation to freshwater environment is probably a derived condition.

A. Squalodontidae

Squalodonts (literally shark-toothed) are the most common fossil platanistoids. They have a heterodont dentition, where the posterior teeth are triangular with serrated edges (similar to some sharks). Heterodonty is primitively present in all cetaceans, and not restricted to platanistoids. In the past, this condition was used to include clades in platanistoids, but this view has been abandoned. The squalodontid

genera based on partial or complete skulls are *Squalodon*, *Kelloggia* (a possible synonym of *Squalodon*), *Eosqualodon*, and ?*Phoberodon*. Synapomorphies of Squalodontidae as defined by Fordyce (1994) are essentially based on the morphology of one of the earbones, the periotic, a bone which is unknown in *Phoberodon*, *Eosqualodon*, and *Kelloggia*. The monophyly and content of the Squalodontidae has still to be evaluated by careful anatomy and further fossil finds. *Patriocetus* was also included in Squalodontidae (Rothausen, 1968), but this needs to be confirmed.

The Squalodontidae are cosmopolitan basal platanistoids. All their remains were found in marine coastal environment. *Squalodon* is present in the Miocene of Europe, Asia, and North America; *Eosqualodon* is present in the Miocene of Europe; *Kelloggia* is present in the late Oligocene of Asia; *Phoberodon* is from the early Miocene of South America. Undescribed squalodontids have also been found in Australia and New Zealand (Fordyce and Muizon, 2000). Squalodontids are relatively large odontocetes approaching the size of the living *Mesoplodon*. They had a long rostrum with strongly procumbent anterior teeth (Fig. 2). In fact, the medial incisors were almost horizontal. The teeth were strongly heterodont. The vertex was low and the skull was symmetrical. As all platanistoids, the Squalodontidae have enlarged and slightly concave premaxillary fossae anterolateral to the nares. These fossae received premaxillary sacs of the nasal tract. Premaxillary sacs are tightly related to the presence of nasal plugs and melon and their presence in the Squalodontidae is an indication of efficient echolocation ability.

B. Prosqualodontidae

The single genus *Prosqualodon* is included in this family. Initially placed in the Squalodontidae (e.g., Simpson, 1945; Rothausen, 1968), *Prosqualodon* has been removed from this family by Muizon

Figure 2 Skulls of *Squalodontidae*. (A) *Eosqualodon langewieschei* (late Oligocene, Germany), reconstruction of the skull in dorsal view (from Rothausen, 1968, modified). (B) *Squalodon bellunensis* (early Miocene, Italy), reconstruction of the skull in dorsal view (from Rothausen, 1968, modified). (C) *S. bellunensis* (early Miocene, Italy), skull and mandible (IGUP 26131, 26132, 26133) in lateral view. (D) *Squalodon bariensis* (early Miocene, France), skull (apex of the rostrum missing) in ventral view (MHNL Dr 15). (A) and (B) are reproduced with permission of *Paläontologische Zeitschrift*.

(1991) because it does not possess the synapomorphies of the auditory region observed in the other platanistoids; however, it was maintained in the superfamily because it bears the scapula synapomorphies of the group. This suggests that *Prosqualodon* is the sister group of the other platanistoids. However, *Prosqualodon* has sometimes been included in the infraorder Delphinida on the basis of the presence of a synapomorphy of the palatine (presence of a lateral lamina as defined by Muizon, 1988) but these may not be homologous.

Figure 3 Skull (MLP 5–9) of *Prosqualodon australis* (early Miocene, Argentina) in dorsal (A) and lateral (B) views.

Prosqualodon is a southern genus that has been found so far in the early Miocene of Argentina, Australia, and New Zealand. It is a medium-sized odontocete, and its size ranges from a small *Globicephala* to a large *Tursiops*. As squalodontids, it had heterodont teeth. The anterior teeth are elongated conical and project anteroventrally; the posterior teeth are triangular, low, transversely compressed with a rugose enamel and bear several denticles on their anterior and posterior crests. The rostrum is short, the vertex is symmetrical, and the braincase is lower than in the *Squalodon*. Premaxillary fossae are clearly present but they are less developed and shallower than in *Squalodon* (Fig. 3).

C. Dalpiazinidae

The single known genus of this family, *Dalpiazina*, is probably related to the Platanistoidea given the presence of several similarities with *Squalodon* (Muizon 1991, 1994), although critical synapomorphies are not observable in the preserved fossils. *Dalpiazina* is a medium-sized odontocete (small *Tursiops*). The rostrum is relatively long and bears homodont dentition. It is known from the early

Figure 4 Skulls of squalodelphinids. (A) *Squalodelphis fabianii* (early Miocene, Italy), a, skull and mandible (IGUP 26134) in dorsal view. (B) The same in lateral view (note the thickness of the supraorbital region). (C) Reconstruction of the skull of *Medocinia tetragorhina* (early Miocene of France), in dorsal view. (D) The same in lateral view (from Muizon, 1988). Reproduced with permission of the Bulletin du Muséum national d'Histoire naturelle.

Miocene of Italy and some possible dalpiazinids have been discovered in New Zealand (Fordyce *et al.*, 1994).

D. Waipatiidae

Waipatia is well documented by a relatively complete skull with ear bones and partial skeleton. This genus displays the synapomorphies of the auditory region of the platanistoids and, although its scapula is unknown, is best placed in this superfamily than in any other group of odontocete (Fordyce, 1994; Fordyce and Muizon, 2000). It is a medium-sized platanistoid similar in size to *Tursiops*. The rostrum is long and slender (Fig 4). It bears heterodont teeth but the posterior triangular and double-rooted teeth are smaller than in the Squalodontidae. The incisors are conical and strongly procumbent. The skull roof is very low as in squalodontids. The skull of *Waipatia* shows clear directional asymmetry of the bones. The fossae for the premaxillary sacs are well developed and the premaxillae extend posterior to the nasals and contact the frontals on the vertex as in the other platanistoids. *Waipatia maerewhenua*, the only species unambiguously pertaining to this family is from the late Oligocene of New Zealand.

Sulakocetus is a primitive odontocete from the late Oligocene of the Caucasus (Asia) that has been referred to platanistoids. It bears heterodont dentition but its posterior double-rooted teeth are small as in *Waipatia*. One of its earbones, the tympanic, is squalodont-like, and the scapula bears a small coracoid process, indicating that it is not a platanistoid. However, it is probable that the small (reduced) size of the process represent an incipient development of the platanistoid condition. This genus has been classified by Fordyce and Muizon (2000) as a possible Waipatiidae.

E. Squalodelphinidae

This family includes the genera *Notocetus*, *Medocinia*, *Phocageneus*, and *Squalodelphis*. The four taxa are based on reasonably well-preserved skulls and/or ear bones. The Squalodelphinidae present the

platanistoid synapomorphies of the scapula (loss of the coracoid process, anterior position of the acromion) and of the ear region (e.g., sub-circular fossa, articular ridge of the periotic, morphology of the apex of the tympanic; see Muizon 1987, 1994). The Squalodelphinidae are cosmopolitan and marine. *Notocetus* is from the early Miocene of South America and New Zealand; *Squalodelphis* and *Medocinia* are from the early to middle Miocene of Europe; *Phocageneus* is from the early Miocene of North America. The Squalodelphinidae are medium-sized odontocetes similar in size to the living *Tursiops*. The rostrum is of moderate length and slender (Fig. 5). The teeth are more or less homodont: the posterior teeth are single rooted but they are clearly lower and more triangular than the anterior. An interesting characteristic of the Squalodelphinidae is the thickening of the supraorbital region of the skull (maxilla and/or frontal; Fig 5B and D), reminiscent of the specialized supraorbital morphology of Platanistidae (see later, Fig. 6).

F. Platanistidae

Platanistids are represented in the fossil record by two genera, *Zarhachis* and *Pomatodelphis* (Fig. 6). They both present all the Platanistoid synapomorphies of the ear region, palatine, and scapula. The main characteristic of the Platanistidae is the development of large maxillary (*Platanista*) or maxillofrontal (*Zarhachis*, *Pomatodelphis*) crests, which are already incipiently developed in the Squalodelphinidae (see earlier discussion). A peculiarity of *Platanista* is that the palatine is entirely covered by the maxilla and the pterygoid. In *Zarhachis* and *Pomatodelphis* this condition is incipiently developed since the palatine is partially covered (Muizon 1987, 1994) and the visible portion of the bone is displaced laterally. Both genera have a very long and slender rostrum bearing homodont teeth. *Zarhachis* is slightly larger than *Pomatodelphis* and similar in size to a small *Mesoplodon*. *Allodelphis* has been regarded as a platanistid; however, this genus is still too poorly known to be referred unambiguously to this family. It is regarded here as a possible Platanistoidea, which has

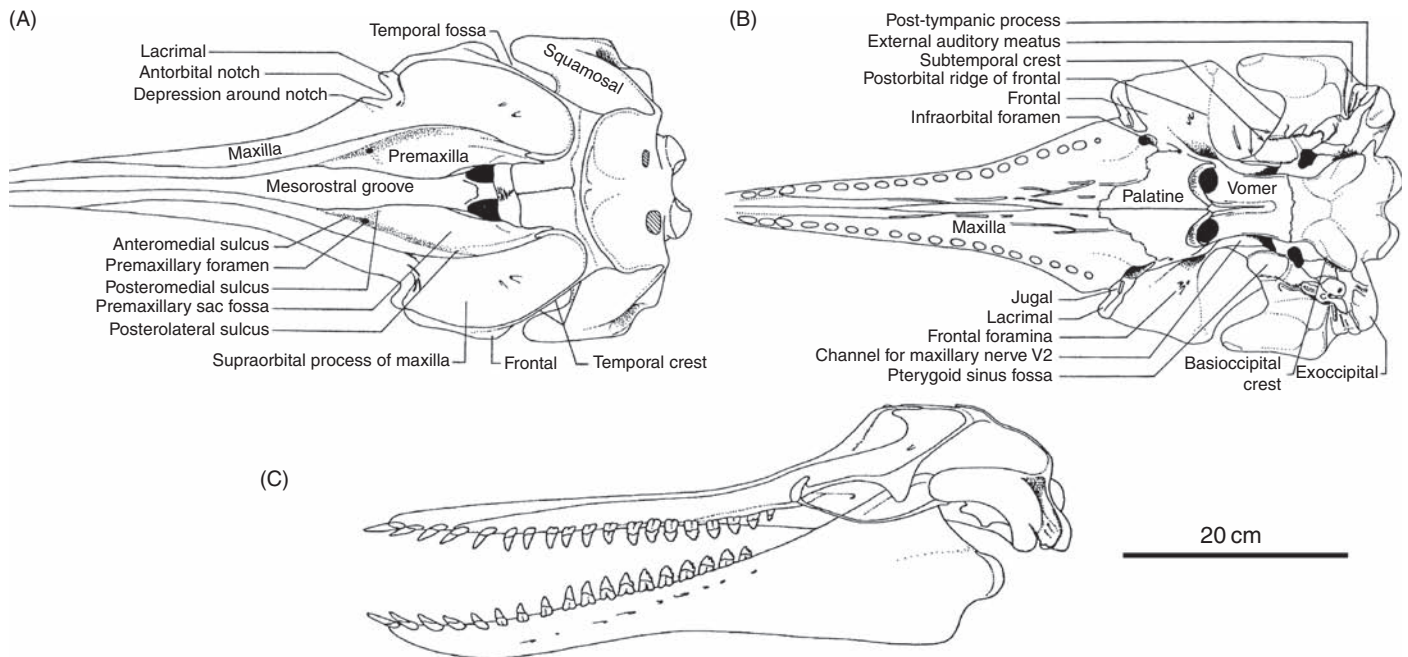

Figure 5 Reconstruction of the skull of *Waipatia maerewhenua* (late Oligocene, New Zealand). (A) Dorsal view; (B) ventral view; (C) lateral view (from Fordyce, 1994, modified). Reproduced with permission of the San Diego Society of Natural History.

to be confirmed by a better knowledge of its anatomy. *Zarhachis* and *Pomatodelphis* were found in marine deposits. They are from the middle Miocene of North America and Europe (*Pomatodelphis* only). No fossil Platanistids have been found, so far, neither in the southern Hemisphere nor in Asia.

II. Non-platanistoid “River Dolphins”

Non-platanistoid river dolphins are represented by the recent families Lipotidae (*Lipotes*), Iniidae (*Inia*), and Pontoporiidae (*Pontoporia*). Most authors recognize separate families for the three modern genera, but others place all in one family (Iniidae; Heyning, 1989), or two, Pontoporiidae (*Pontoporia* and *Lipotes*) and Iniidae (*Inia*; Fordyce, 1994). Fordyce and Muizon (2000) include these three families in the infraorder Delphinida on the basis of several synapomorphies: the development of a lateral lamina of the palatine, the sigmoid morphology of the involucrum of the tympanic and its posterior excavation, the development of a ventral rim on the ventromedial face of the anterior process of the periotic and the increase in size of the processus muscularis of the malleus. The Lipotidae are the earliest divergent Delphinida. The other Delphinida [Iniioidea (Iniidae + Pontoporiidae) and Delphinoidea] differ from the Lipotidae in the following synapomorphies: e.g., the reduction of the anterior process of the periotic, which loses the bullar facet; increase in size of the processus muscularis of the malleus, which is distinctly more developed than the manubrium, the presence of a pair of ventral processes on the anterior region of the sternal manubrium (Muizon, 1988). The second diverging clade is the Iniioidea. The third clade, the Delphinoidea have an apomorphic thickening of the apex of the anterior process of the periotic and a great reduction of the dorsal portion of the transverse process of the atlas. Therefore, the Delphinida include three superfamilies of odontocetes, the Lipotoidea, the Iniioidea, and the Delphinoidea (Muizon, 1988).

A. Lipotoidea

This superfamily includes a single family with two genera. *Lipotes* (Recent, China) and *Parapontoporia* (Neogene, West coast of North America). *Prolipotes* from the Miocene of China is based on a non-diagnostic mandible fragment and is regarded as an incertae sedis (Fordyce and Muizon, 2000). *Parapontoporia* (Fig. 7) is regarded here as a lipotid, although classified by its author (Barnes 1985) in the Pontoporiidae. The skull of *Parapontoporia* presents a distinct narrowing at the base of the rostrum, which is always present in *Lipotes* and generally absent in pontoporiids (when present in *Pontoporia* it is weak); *Parapontoporia* does not bear the premaxillary eminences which are present in all pontoporiids and iniids; the nasals of *Parapontoporia* tend to be subvertical and not subhorizontal as in pontoporiids.

Parapontoporia is the only fossil lipotid for which well-preserved skull material is available. Although its braincase is only slightly larger than that of *Lipotes*, its rostrum is almost twice as long. The asymmetry is less pronounced than in *Lipotes*. The teeth are small, single-cusped, and numerous (~80 on each side). In *Lipotes* the number of teeth varies from approximately 30 to 36. Lipotids are known in the Northern Hemisphere only (China and California) and it is possible that the evolution of the family took place in the Northern Pacific.

B. Iniioidea

This superfamily includes the Iniidae and Pontoporiidae. The two families share synapomorphies of the periotic (great reduction of the anterior and posterior processes), malleus (unique extreme development of the processus muscularis), premaxilla (presence of premaxillary eminences), maxilla (frontomaxillary crests: dorsal inflexion of the postorbital edges of the maxilla and frontal). The superfamily is documented by a few well-established fossil genera mostly from South America.

Figure 6 Skulls of *Platanistidae*. (A) *Pomatodelphis* cf. *inaequalis* (middle Miocene, Maryland, USA), skull (USNM 187414) in dorsal view. (B) *Zarhachis flagellator* (middle Miocene, Maryland, USA), skull (most of the rostrum missing) in dorsal view (USNM 10911).

The Iniidae are represented in the fossil record by a single genus known by relatively well-preserved cranial remains: *Ischyrorhynchus*. The genera *Sauroctes*, *Plicodontinia*, *Hesperocetus*, *Hesperoinia*, and *Lonchodelphis* that have been related to the Iniidae, are based on non-diagnostic rostra, mandible fragments or isolated teeth, and may or may not pertain to this family. *Goniodelphis*, is based on a partial skull, which probably belongs to an iniid. However, because of its incompleteness, this specimen has been questionably referred to the family by Fordyce and Muizon (2000).

One of the major characteristic of the Iniidae (*Ischyrorhynchus* and *Inia*) is the development of a frontal hump on the vertex, which is expanded at its apex. Iniidae also present an extreme reduction of the posterior process of the periotic.

Ischyrorhynchus is approximately 30% larger than *Inia* and its rostrum is relatively longer. Besides these features, *Ischyrorhynchus* is very similar to the recent iniid. It is from the late Miocene of the Paraná Basin (Argentina) and, therefore, was living in a freshwater environment.

The Pontoporiidae are known by two fossil genera based on well-preserved cranial remains (with associated ear bones): *Pliopontos* and *Brachydelphis* (Fig. 8). *Pontistes* is another pontoporiid and is based on a single partial skull with a well-preserved vertex. *Pontivaga*

Figure 7 Reconstruction of the skull of *Parapontoporia sternbergi* (early Pliocene, California, USA). (A) Dorsal, (B) ventral, and (C) lateral views (from Barnes, 1985 modified). Reproduced with permission of the Contribution in Science, Los Angeles County Museum of Natural History.

has been referred to pontoporiids, however this genus, which is based on a partial mandible is regarded as an incertae sedis. The Pontoporiidae share synapomorphies such as a low vertex with flat, more-or-less horizontal nasals and the posterior, blade-like extension of the posterior process of the periotic.

Pliopontos is 50% larger than *Pontoporia*. As in the recent taxon, the rostrum is long and slender with sharp small teeth. Except for its size, *Pliopontos* is very similar to *Pontoporia*. It is from the early Pliocene of Peru and was marine. *Brachydelphis* is a much less classical pontoporiid. It has a very short rostrum, which is as long as the braincase. The latter is much larger than in *Pontoporia* and similar in size to that of *Pliopontos*. Because of these unique features for a pontoporiid, *Brachydelphis* has been placed in its own subfamily, the Brachydelphininae. It is from the Middle Miocene of Peru and was living in a marine environment.

III. Conclusions

There is near consensus that the odontocetes traditionally placed in the “river dolphins” (the “Platanistoidea” of Simpson 1945) belong to two different groups of dolphins and are polyphyletic: the Platanistoidea and the Delphinida (Lipotoidea and Inioidea). The Platanistoidea represent the sister group of a clade, which includes the Delphinida and the

Figure 8 Skulls of *Pontoporiidae*: *Pliopontos littoralis* (early Pliocene, Peru), reconstruction of the skull in (A) dorsal, (B) ventral, (C) and lateral views (from Muizon, 1984); *Brachydelphys mazeasi* (middle Miocene, Peru), reconstruction of the skull in dorsal (D), ventral (E), and lateral (F) views (from Muizon, 1988). Reproduced with permission of the Institut Français d'Études Andines.

fossil superfamily Eurhinodelphinoidea (Fig. 1). The non-platanistoid “river dolphins” do not represent a monophyletic grouping. In contrast, an exhaustive analysis of cetaceans phylogeny by Geisler and Sanders (2003) did find monophyly of river dolphins but polyphyly of the Delphinoidea. These results are contradicted by all other morphological and molecular analyses (Cassens *et al.*, 2000, Nikaido *et al.*, 2001).

Fossil platanistoids are diverse and distributed into several families. Fossil Lipotids and Inioids are still relatively scarce but can be easily related to one of the three non-Platanistoid families of “river dolphins.” Most fossil “river dolphins” are from marine environments and the adaptation to freshwater is a convergence at least in three modern groups: the Platanistidae, the Lipotidae, and the Iniidae. Adaptation to this environment also appeared independently in two delphinoids (*Orcaella* and *Sotalia*).

Rookeries

GEORGE ANTHONY ANTONELIS

Pinnipeds reproduce in a wide range of marine habitats, including various forms of ice, tidal flats, rock outcroppings, and coastal beaches (Scheffer, 1958). Some species form annual breeding aggregations at traditional locations known as rookeries. These reproductive sites are an integral component of the animals' life history patterns, resulting from a complex suite of adaptive factors involving physiology, morphology, ecology, and distribution. Rookery-breeding pinnipeds exhibit varying forms of polygyny (Boness, 1991); this mode of social organization is believed to have evolved as a consequence of two key traits, parturition on solid substrate and offshore marine foraging (Bartholomew, 1970). The influence of these traits in conjunction with phylogenetic and ecological constraints has likely influenced the development of the polygynous mating systems observed on rookeries today (Emlen and Oring, 1977; Stirling, 1983; Boness, 1991; Boyd, 1991).

Rookery-breeding pinnipeds are subdivided into two families, Otariidae and Phocidae. Rookeries are formed by all otariids (15 species) and three phocids [2 species of elephant seal, *Mirounga angustirostris* and *M. leonina*, and gray seals, *Halichoerus grypus* (Reeves *et al.*, 1992; Rice, 1998)]. This chapter describes the salient social-biological, physical-geographical, and environmental characteristics of pinniped rookeries and provides information on the ecological context in which they occur.

I. Social-Biological Characteristics

Rookeries are formed at specific times and locations, which optimize the reproductive success and survival of offspring (Bartholomew, 1970; Stirling, 1983; Boyd, 1991). After foraging at sea during the nonbreeding season, adult males return to rookeries and begin establishing territories shortly before or about the same time as the arrival of parturient females. Overt aggression, frequent threat vocalizations, and ritualized boundary displays are common among males when establishing and defending territories (Fig. 1).

Figure 1 Adult male California sea lions (*Zalophus californianus*) compete for territories at San Miguel Island, California (NMFS, George Antonelis).

Males also attempt to herd females in an effort to keep them within their areas of influence (Fig. 2). Adult females come ashore to find suitable parturition sites and tend to be highly gregarious. Parturient females frequently threaten one another either vocally or visually and are often aggressive toward offspring of other females. Otariid females suckle their pups for about 4–12 months, although longer periods have been documented for some species (Oftedal *et al.*, 1987; Bowen, 1991). Lactation of rookery-breeding phocid females lasts about 0.5 (gray seals) to 1.0 (elephant seals) month. Estrus occurs early in lactation for otariids and late in lactation for phocids (Oftedal *et al.*, 1987). Most copulations occur on land at or near the parturition site, but a few species commonly breed aquatically in the intertidal zone where males maintain aquatic territories. Otariid females intermittently leave the rookery to forage between suckling periods, and phocid females fast on land during the entire lactation period. Thus, some pinniped rookeries may be occupied continuously, but most breeding is completed within a relatively short time period of about 2 months.

Sexual dimorphism is apparent on pinniped rookeries, as adult males usually have distinctly different characteristics and are larger than females. Each sex and species emits stereotypic vocalizations for long- and short-distance communication (Stirling and Warneke, 1971; Miller, 1991). Males emit loud long-distance threat calls toward other males. Lactating otariid females also emit loud pup attraction calls on rookeries to locate their offspring among hundreds of pups. Short-distance threat vocalizations are common on all pinniped rookeries and have less amplitude than long-distance calls. Noise from rookeries initially may be perceived as a cacophony of sounds, but what seems to be chaos is really a well-organized social structure that has evolved over millions of years.

Figure 2 A much larger and darker adult male *California sea lion* (*Zalophus californianus*) attempts to block an adult female from leaving his territory at San Miguel Island, California (NMFS, George Antonelis).

Figure 3 *California sea lions* (*Zalophus californianus*) are highly polygynous and form dense aggregations on rookeries commonly found along the shoreline at breeding sites on the California Channel Islands (NMFS, George Antonelis).

II. Physical–Geographical Characteristics

Pinniped rookeries are typically found on remote offshore islands, although some occur on mainland beaches. Rookeries are formed near shoreline just above the tidal zone in a variety of substrates, including sand, cobble or boulder beaches, rock shelves, and caves. Breeding aggregations usually occur within several hundred meters of the shoreline and also may occur on hillsides or cliffs overlooking the ocean (Fig. 3). Low-growing vegetation such as low grasses or shrubs is common on some rookeries.

The formation of rookeries on substrate near but above the tidal zone provides several functions that reinforce continued use of each site. To insure survival to weaning, neonates are usually born in locations where high tides do not wash them away from their mothers or compromise their ability to thermoregulate (Fig. 4). The gregariousness of females at these nearshore locations facilitates the ability of territorial males to monopolize estrous females, a key component of their complex polygynous mating system (Emlen and Oring,

Figure 4 A female *California sea lion* (*Zalophus californianus*) suckles her pup in a location protected from the surf on San Miguel Island, California (NMFS, George Antonelis).

1977). During anomalous conditions, however, storm surf associated with El Niño events has flooded pinniped rookeries, resulting in significant neonatal mortality and disruption of their polygynous social structure (Trillmich and Ono, 1991). Such events demonstrate the need for rookeries to occur above normal fluctuations in tide height.

Although pinniped rookeries must be located above the tidal zone, they must also be close enough to the water to facilitate access for thermoregulation, foraging trips by lactating females, or escape from terrestrial predators. During high air temperatures in tropical and temperate environments, many rookery-breeding otariids are known to move regularly to the intertidal zone for cooling.

III. Environmental Characteristics

Environmental characteristics related to the formation, timing, and use of pinniped rookeries vary among species and are likely stimulated by proximate factors such as photoperiod, nutrition, and climate, which ultimately relate to survival and reproductive success (Boyd, 1991). The relative importance of these factors is believed to differ according to species on spatial and temporal scales. Pinniped rookeries occur most commonly during the spring and the summer months when climatic conditions are relatively warm and the frequency of inclement weather diminishes. Such conditions increase the probability of offspring survival, especially in subpolar climates. Rookery-breeding phocids are the exceptions and form aggregations on rookeries in the fall and the winter.

Most rookeries occur in locations where oceanographic conditions result in high productivity. High productivity increases the availability of potential prey resources vital for the foraging success of otariid females, which must feed intermittently during lactation. Rookery-breeding phocid females do not forage during lactation and rely completely on the energy stores obtained before parturition. The availability of prey near rookeries is therefore much more important to otariids than to phocids. However, the availability of prey for pups either before or after weaning may be an essential component for successful transition to foraging self-sufficiency for the young of most pinnipeds born on rookeries.

Ross Seal

Ommatophoca rossii

JEANNETTE A. THOMAS AND TRACEY ROGERS

I. Characteristics and Taxonomy

Less is known about the Ross seal than any other pinniped (see Scheffer, 1958; King, 1969; Reeves *et al.*, 1992; Nowak, 1999 for general reviews). It belongs to the family Phocidae and subfamily Monacinae. There is a single species in the genus. Common names include the big-eyed seal and the singing seal. The closest relatives are the other Antarctic seals (crabeater, *Lobodon carcinophagus*; leopard, *Hydrurga leptonyx*; and Weddell, *Leptonychotes weddellii*) and the monk seals (Caribbean, *Monachus tropicalis*; Mediterranean, *M. monachus*; and Hawaiian, *M. schauinslandi*).

As with other phocids, Ross seals crawl on their belly and are not capable of an upright stance or moving the hind limbs forward. The head is proportionally smaller compared to the body than in other Monacinae and the snout is exceptionally short. The neck is thick and short. The Ross seal often assumes a posture with the head raised and mouth open, pointing upward. Because of this posture they have been called the “singing seal” (Fig. 1). However, this is a misnomer, because the seal rarely emits sound in this posture. More likely the open mouth displays teeth, and thrusting-out of the striped chest serves as an aggressive posture.

The skull has an exceptionally large orbit (hence the Greek name *omma* or eye). The zygomatic arch extends well below the palate, supporting part of the skull weight when placed on a table. As with other Antarctic pinnipeds, it is assumed they have a tapetum, which assists in seeing in low-light levels during the austral winter and during deep dives, and a nictitating membrane that protects their eyes from blowing snow and allows opening their eyes in salt water. Condylbasal length has been measured at 244 mm in males and 242 mm in females. The mastoid width of the skull is at 172 and 170 mm in males and in females, respectively. The soft palate is very long, extending posterior to the level of the occipital condyles. The trachea is expanded, and powerful muscles of the tongue and pharynx assist in swallowing large prey. The external ear is absent. The nostrils are normally closed and opened under voluntary control when seals need to respire. They have 15–17 short mystacial whiskers on each lip, only 10–42 mm in length, and superciliary vibrissae. All vibrissae are smooth and not beaded.

The mouth is small. The incisors and canines are small and recurved, an adaptation for holding slippery cephalopods. The front teeth are not procumbent and the seals do not maintain breathing holes by “ice sawing,” as the Antarctic Weddell seal does. The cheek teeth are reduced, homodont, and often barely breaking the gum line.

Black claws are reduced and probably useful for gripping the ice or scratching. The phalanges are greatly elongated. The fore and hind flippers are proportionally longer than in other phocids, the latter being 22% as long as the body.

The seals stay warm with a thick fur coat and a layer of subcutaneous fat. They have short, black fur on their back, with grayish silver streaks along their sides that transition into a solid silvery white belly with some spotting along the boundary line. They have a unique color pattern of vivid light silver strips running from the lower jaw to the chest and alongside the neck. A lanugo is present in the newborn, which is long, thick, and soft black on the back, fading into a bright yellow underbelly. This yellowish color may change into silver as the pup grows.

There is no marked sexual dimorphism in body size, but females tend to be slightly larger. Adult males reach 1.7–2.1 m and adult females are 1.9–2.5 m in length. Weight ranges from 129 to 216 kg in adult males and 159 to 201 kg in adult females, with pregnant females obtaining the greatest weights. Post-breeding and newly molted animals average about 1.3 m in girth and weigh about 158 kg and at this time there is no significant difference between the weight of males and females.

II. Distribution and Abundance

This solitary seal has a circumpolar distribution around Antarctica, occurring in tight pack ice. Ross seals (estimated at 1–2% of Antarctic pinnipeds) are the least abundant of all the Antarctic pinniped species. Logistics for accurate surveys of this species are difficult because it requires icebreaker support in the dense pack-ice habitat and Ross seals generally are located far from permanent research bases, precluding land-based aerial surveys. This species is rarely sighted during other types of Antarctic research, making population estimates difficult.

Figure 1 Ross seal (*C. Brett Jarrett*).

Estimates range from as low as 20,000–50,000 according to Scheffer (1958), to as high as 220,000 according to Erickson *et al.* (1971). A recent international program, the Antarctic Pack Ice Seal (APIS) study aimed to conduct a systematic, continent-wide census and derive a circumpolar estimate of Ross seal population abundance; however results from different regions within this study are still being compiled. The highest recorded density of Ross seals is 2.9/km².

Distribution of the Ross seal varies with life history stage. During the austral spring and summer when they breed, they are restricted to the heavy, consolidated inner pack ice. In late summer through to early autumn, when they molt, they haul out farther north nearer the ice edge on large stable ice floes. From January to February until the breeding season of the following austral spring, they remain in the open water north or the pack ice. So, although Ross seals give birth and mate in the pack ice, they spend most of the year living and foraging in the open waters north of the pack ice. Immature and nonbreeding seals spend up to 12 months of the year in open-water pelagic habitats.

Before 1945, there were fewer than 45 sightings of the species. Only with the use of icebreakers into the dense pack ice were more recent sightings obtained, but most often sightings were opportunistic. Ross seals are only seen when hauled out on the ice, which restricts sighting to times when the seals are breeding and molting, because outside this time they are in open water. Sightings usually are of single animals, but small groups occur in local areas; groups have been observed in areas of sparse ice, possibly due to the lack of suitable haul-out platforms. Occasionally, single seals are seen in southern Australia and some subantarctic islands, such as the South Sandwich, Falkland, Scott, and South Orkney Islands and Heard Island.

III. Ecology

The diet of a Ross seal is primarily cephalopods, even larger species than other Antarctic seals eat. Midwater fish and krill are also eaten. Based on stomach contents analysis, the diet of the Ross seal is 47% squid, 34% fish, and 19% invertebrates. Their specialized diet reduces competition with other Antarctic seals or whales. Their secluded habitat during the breeding season may give them access to food types which are not available to pelagic species of cetaceans or to other Antarctic seals, such as Weddell, leopard, or crabeater seals. Some investigators believe the variable distribution of the species is due to the distribution of their prey, ice type, or both.

Of all the Antarctic phocids, the Ross seal inhabits the densest ice areas, so they have little exposure to predators, such as killer whales and leopard seals, during the breeding season. However, during their open-water swimming they probably are susceptible to predators of other Antarctic seals, like killer whales and leopard seals. Little is known about predation on Ross seals and they do not bear scars that would indicate leopard seal predation as are commonly seen on

crabeater seals. Ross seals are sympatric with leopard seals while they breed and molt, so the lack of scarring could indicate total hunting success by leopard seals on this smaller seal or that young Ross seals travel north to open water after weaning to avoid predation. Killer whales (*Orcinus orca*) are known to take other Antarctic seals, so likely would feed on Ross seals if not for habitat segregation.

IV. Behavior and Physiology

The species is solitary and the seals do not congregate in large breeding colonies. Although mating has not been observed, it is assumed to be in water, the same as with other Antarctic seals.

Ross seals produce up to five call types; one is an explosive noise emitted with the mouth open, but probably through the nares (Rogers, 2003; Stacey, 2006). Underwater calls are made with the mouth closed. They produce a series of pulsed chugs, both on land and in water. In water, they have an unusual two-parted whistle with harmonics that decreases and increases to produce a “W-shaped” sonogram; authors referred to this as a tonal siren call. Ross seals siren calls are heard underwater in the pack ice from mid-October but the greatest number of calls are heard from December through to mid-January. The sounds are low in amplitude compared to other Antarctic phocid calls and generally are not heard in the same areas and times as Weddell, crabeater, or leopard seals, who often call simultaneously.

Ross seals exhibit a distinct diel pattern of haul out in late summer while they are in the pack ice, with most seals hauled out during the midday and in the water during the night. This difference in sightability due to time of day makes accurate population estimates difficult. Stewart (cited in Reeves *et al.*, 1992) documented the diving behavior of one Ross seal with a microprocessor-based dive recorder glued to its back. Most dives were deeper than 100 m and lasted around 6 min. The deepest dive was 212 m and for 10 min.

V. Life History

No breeding concentrations of Ross seals have been observed, and they do not use traditional hauling out sites. The mating system is promiscuous, with males and females encountering each other for a short time and having no long-term pair bond. Mating occurs after the pup weans in December through to early January, coinciding with a peak in underwater vocalizations and molt that soon follows. Because of the need to synchronize the time of pupping to annual ice conditions, Ross seals exhibit a delayed implantation of 2 months. This delay in pregnancy allows the mother to molt, feed, and recover from the dramatic weight loss associated with lactation before the next fetus starts to develop.

Mother Ross seals haul out in dense pack ice to give birth during the austral spring (November and December), with peak pupping between 3 and 18 November. Typically, a single pup is born. When

disturbed, a mother vocalizes to her pup and the pup responds with a bawl sound and moves close to the mother. An observation of a newborn pup reported it swimming in icy water from one floe to another. Pups wean after about 1 month of nursing.

Subadult seals are rarely seen as they are presumably in open water north of the pack ice. Longevity is unknown, but is at least 21 years. The exact age of sexual maturity is uncertain, but based on analysis of reproductive tracts is estimated at 3–4 years of age in females and 2–7 years in males. At birth, pups are 105–120 cm in length and weigh 17–27 kg.

VI. Interactions with Humans

Ross seals have little fear of humans because there are no natural land predators in Antarctica (unlike pinnipeds in the Arctic who adapt to polar bear predators). There is no record of extensive harvest of this species, except for scientific collection. A variety of Antarctic investigators from Britain, France, America, Soviet Union, Australia, and New Zealand reported sightings of Ross seals from ships. However, there have been no ice-camp or land-based studies of this species.

Although no major threats to Ross seal populations have been identified, changes in pack ice due to climate change may influence their pack-ice habitat and prey distribution. The Ross seal is totally protected under the Antarctic Treaty and the Convention for the Conservation of Antarctic Seals. In January 1998, the Environmental Protection Protocol to the Antarctic Treaty was ratified, implementing environmental measures such as the banning of mining and oil drilling in Antarctica for at least 50 years, along with the banning of refuse disposal and the use of pesticides in the region. Because the species inhabits dense pack ice, it is doubtful that ecotourism has an impact on it.

Rough-Toothed Dolphin

Steno bredanensis

THOMAS A. JEFFERSON

I. Characteristics and Taxonomy

Rough-toothed dolphins are named for the vertical ridges, or wrinkles, on their teeth, which give them a roughened appearance. Other English common names include black porpoise, steno, and slopehead.

The rough-toothed dolphin is very distinctive when seen at close quarters. It is the only long-beaked dolphin with a smoothly sloping melon that does not contain any hint of a crease as it blends into the upper beak (Fig. 1). These dolphins are not particularly slender, and the anterior part of the body may be stocky. The large flippers are set farther back on the body than in most other small cetaceans. They are equal to about 17–19% of the body length. The dorsal fin is tall and generally only slightly falcate. Some large males have a hump of connective tissue posterior to the anus, which gives the appearance of a pronounced keel. Weight is up to 155 kg. Males grow to larger sizes than females (known maximums of 265 and 255 cm, respectively); some evidence suggests they may occasionally reach 280 cm. Females may have proportionately longer beaks (Miyazaki, 1980; Miyazaki and Perrin, 1994).

The color pattern is moderately complex but consists generally of shades of black, white, and gray (Fig. 1). The body is countershaded, with a white belly and black to dark gray back. The sides are a medium shade of gray and are separated from the darker back by the margins of a dorsal cape that is narrow between the blowhole and the dorsal fin and wider behind the fin. The lower sides and mouth area are often dotted with white patches, splotches, and spots. In warm tropical waters, the belly and the lower jaw may be tinged with pink. Some of the white spots are thought to be scars from bites inflicted by cookie-cutter sharks and perhaps squid. Young animals (Fig. 2) have a muted color pattern and generally lack the white spots (Miyazaki and Perrin, 1994).

The skull (adult CBL ~472–555 mm) can be distinguished from those of all other dolphins (except humpback dolphins, *Sousa* spp.) by their size and combination of long beak, concave rostral and maxillary margins, long mandibular symphysis, and large temporal fossae. Tooth counts can be used to distinguish them from humpback dolphins: rough-toothed dolphins have 19–26 teeth in each upper tooth row and 19–28 teeth in each lower row, and humpback dolphins usually have greater than 30. The teeth are ridged. Other differences from the skull of the humpback dolphin are the relatively large orbits

and the prominent and long cylindrical ridge on the ventral part of the frontal bones in rough-toothed dolphins (Van Waerebeek *et al.*, 1999). The postcranial skeleton is heavily built, and total vertebral counts generally range from 65 to 67.

Traditionally, morphological characters have been used to infer a close relationship between the rough-toothed dolphin and two other genera of dolphins (*Sotalia* spp., the tucuxi and costero; and *Sousa* spp., the humpback dolphins). Recent genetic analyses (LeDuc *et al.*, 1999) have supported the relationship with *Sotalia* (in the subfamily Stenoninae), but not with *Sousa*, which groups phylogenetically with the Delphininae. In captivity, hybrids between *Steno* and *Tursiops truncatus* (common bottlenose dolphin) have been born (Dohl *et al.*, 1974).

II. Distribution and Abundance

The rough-toothed dolphin is a tropical to warm temperate species and is found in oceanic waters worldwide (Miyazaki and Perrin, 1994). For instance, it prefers waters greater than 1500-m deep off Hawaii (Baird *et al.*, 2008). However, it can also be found over the continental shelf in some shallow, coastal waters (e.g., Brazil–Flores and Ximinez, 1997). Records from the Atlantic Ocean are mostly from between the southeastern United States and southern

Brazil across to the Iberian Peninsula and tropical West Africa, with some (probably extralimital) records from the English Channel and the North Sea. The normal range includes the Gulf of Mexico, Caribbean Sea, and Mediterranean Sea. In the Pacific, it occurs from central Japan and northern Australia across to southern Baja California, Mexico, and southern Peru. In the eastern tropical Pacific, it is generally associated with warm tropical waters lacking major upwelling. The range includes the southern Gulf of California and the South China Sea. Records from the west coast of the continental United States and New Zealand are considered extralimital. In the poorly studied Indian Ocean, there are only a few scattered records, but the species probably has an extensive distribution there north of about 20°S.

There are no estimates of global abundance, and surveys to estimate abundance have not been conducted in most parts of the species' range. However, about 985 occur in the northern Gulf of Mexico (Mullin and Fulling, 2004) and about 146,000 are found in the eastern tropical Pacific (Wade and Gerrodette, 1993). Almost nothing is known about population or stock structure in this species.

III. Ecology

The ecology of the species is quite poorly studied (Miyazaki and Perrin, 1994). There have been only a few reports of feeding habits. In the wild, it feeds on a variety of fish and cephalopod species, some coastal and some oceanic. Some large fish may be taken, as suggested by the robust dentition of the species. Algae have been found in the stomachs of stranded specimens, but they may have been ingested incidentally.

Rough-toothed dolphins frequently associate with other species of cetaceans, especially other delphinids in the eastern tropical Pacific, where they also often associate with flotsam. Lone animals have been seen with short-finned pilot whales (*Globicephala macrorhynchus*) and Fraser's dolphins (*Lagenodelphis hosei*) in the Sulu Sea.

Little is known of diseases and pathology, but Japanese animals have been observed with osteopathological conditions. Only a handful of internal parasites have been recorded, although there are undoubtedly others. Externally, cyamid whale lice have been observed, and the cookie-cutter shark is a partial predator.

IV. Behavior and Physiology

Detailed, long-term behavioral ecology studies on rough-toothed dolphins have only been conducted in the past decade or so, and our

knowledge is only beginning to accumulate. There now have been such studies in several areas, including the Canary Islands, Caribbean (Honduras), and Hawaii (Ritter, 2002; Gotz *et al.*, 2006; Kuczaj and Yeater, 2007). They are found in moderate-sized groups, most commonly of 10–20, although larger groups have been seen in some areas—up to 50 in the Canary Islands (Ritter, 2002), over 50 in the eastern tropical Pacific, 300 in Hawaii, and 160 in the Mediterranean. Mass STRANDINGS have been recorded in several areas.

These animals are not generally fast swimmers and they often appear rather sluggish in the wild. They do ride bow waves and are known for their habit of skimming along the surface at moderate speed with a distinctive splash. Synchronous swimming in tight formation is common, and recently it has been suggested to facilitate “eavesdropping” on the echolocation clicks of other individuals (Gotz *et al.*, 2006; Kuczaj and Yeater, 2007). Although not highly acrobatic, various leaps and other aerial behaviors have been seen. Photoidentification of individual dolphins has only recently been conducted, and preliminary results suggest that rough-toothed dolphins may have more stability in their associations than do other species of small delphinids (Kuczaj and Yeater, 2007). Few studies of site fidelity have been conducted, but in the Hawaiian Islands, site fidelity appears to be high and inter-island movements relatively rare (Baird *et al.*, 2008).

Although the maximum recorded dive was only 70 m, rough-toothed dolphins can probably dive much deeper than this. Behavioral and morphological evidence suggests that they are well adapted for long, deep dives. Submergences of up to 15 min have been recorded. A variety of clicks and whistles have been recorded from these dolphins. Highly directional ECHOLOCATION clicks, with some pulses as high as 200 kHz, are known.

The physiology of the rough-toothed dolphin has not been well studied, and not much is known, other than that they have some anatomical adaptations that tend to be associated with deep-diving.

V. Life History

Detailed studies of life history have only been conducted in Japanese waters. There, males reach sexual maturity at about 14 years and 225 cm, and females at 10 years and 210–220 cm. The maximum age is 32–36 years, although some animals may live significantly longer (Miyazaki, 1980; Miyazaki and Perrin, 1994). Length at birth is thought to be about 1 m.

VI. Interactions with Humans

Rough-toothed dolphins have been held captive in a number of oceanaria, and some success has been encountered in keeping them alive in the captive environment, especially in Hawaii (Dohl *et al.*, 1974). One lived for over 12 years in captivity. They have been found to be bold and inventive, and one “creative porpoise” at Sea Life Park in Hawaii astounded its trainers by grasping the concept of inventing novel behaviors (Pryor *et al.*, 1969). Although they generally do not survive long, several live-stranded animals have also been kept captive, and some have been released back to sea.

Although not generally the major target, rough-toothed dolphins have been taken in directed dolphin fisheries in Japan, Sri Lanka, Indonesia, the Solomon Islands, Papua New Guinea, St. Vincent, West Africa, and possibly St. Helena in the South Atlantic (Miyazaki and Perrin, 1994). Probably much more significant is the incidental kill of dolphins in fishing nets. Takes in tuna purse-seine nets are known for the eastern tropical Pacific, and gillnet catches have been documented at least in Sri Lanka, Brazil, and the offshore North

Pacific. This is one of the main species involved in stealing bait from fishermen’s hooks off Hawaii, and sometimes animals get caught on the hooks as well (Nitta and Henderson, 1993). Undocumented catches probably occur in most other areas of the range as well.

Habitat degradation impacts and effects of pollutants are probably somewhat less severe for this species than for other, more-coastal small cetaceans. Although little directed work has been done on environmental contaminants, relatively low levels of PCBs and DDTs have been recorded from the few specimens examined so far (O’Shea *et al.*, 1980). However, conservation-oriented studies are almost nonexistent, and therefore the uncertainty that exists about population status for this species should be acknowledged.

S

Scrimshaw

STUART M. FRANK

Scrimshaw is an occupational handicraft of mariners employing by-products of the whale fishery, often in combination with other found materials. Indigenous to the whaling industry, where it was typically a pursuit of leisure time at sea, it was also adopted in other trades and was occasionally practiced ashore (Flayderman, 1972). It arose among Pacific Ocean whalers circa 1817–1824, persisted throughout the classic “hand-whaling” era of sailing-ship days into the twentieth century, and persisted in degraded form among “modern” whalers on factory ships and shore stations until the industry shut down in the third quarter of the twentieth century (Basseches *et al.*, 1991). Since the early twentieth century, similar materials and techniques have simultaneously been employed by non-mariner artisans for both commercial and hobbyist purposes.

There is no consensus regarding etymology. Plausible and eccentric theories alike have been advanced without any creditable evidentiary basis, whereas academic lexicography (notoriously inconclusive respecting nautical terms) fails to present any convincing hypothesis. The term—also rendered skrimshank, skimshander, skrimshander, and skrimshonting—first appeared in American shipboard usage circa 1826, when the recreational practice of scrimshaw was less than a decade progressed. It originally referred not to whalers’ private diversions, but to the fairly common practice whereby crewmen were required to make articles for ship’s work (such as tools, tool handles, thole pins, belaying pins, and tackle falls). Sperm whale BONE is ideally suited to such uses: on any “greasy luck” voyage it was in plentiful supply at no cost, its workability is equivalent to the best cabinetmaking hardwoods, its tensile strength is greater than oak, and for many applications its self-lubricating properties were highly desirable. Such was analogously the case regarding the adaptability of cetacean bone and ivory to whales’ recreational handicrafts, to which the term “scrimshaw” (and its many variants) came to refer by the 1830s.

I. Materials and Species

Materials associated most commonly with scrimshaw are the ivory teeth and skeletal bone of the SPERM WHALE (*Physeter macrocephalus*), the ivory tusks of the WALRUS (*Odobenus rosmarus*), and the BALEEN of various mysticete species (the toothless, baleen-bearing whales). In the nineteenth century the principal prey species were, roughly in descending order of importance, sperm whale, right whales (*Eubalaena* spp.), Arctic bowhead (*Balaena mysticetus*), gray whale (*Eschrichtius robustus*), and humpback (*Megaptera*

novaeangliae). These and the long-finned pilot whale or so-called “blackfish” (*Globicephala melas*), which was hunted primarily from shore, were taken primarily for oil, the mysticetes secondarily for baleen. [The fast-swimming blue whale (*Balaenoptera musculus*) and fin whale (*Balaenoptera physalus*) could not be hunted effectively prior to the introduction of steam propulsion and heavy-caliber harpoon cannons in the late nineteenth century.] From the late sixteenth century, by reason of geographical proximity of Arctic habitats and similar uses of their meat and oil, the hunt for walrus was intimately conjoined with commercial whaling. Later, even when whalers were no longer taking walrus themselves, they characteristically obtained walrus tusks through barter with indigenous Northern peoples.

Commercial uses of walrus ivory were few; there was no significant commercial application for cetacean skeletal bone until the twentieth century (when it was ground and desiccated into industrial-grade meal and fertilizer). The utility and market value of baleen (“whalebone”) were subject to mercurial fluctuations of fashion, and sperm whale teeth had little or no commodity value. They thus became available for whalers’ recreational use, as did teeth of the Antarctic elephant seal (*Mirounga leonina*), the lower mandibles of various dolphins and porpoises, and tusks of the elusive NARWHAL (*Monodon monoceros*). (Narwhal ivory proved too difficult and brittle for anything much beyond canes and analogous shafts, such as hatracks or bedposts.)

The characteristic pigment for highlighting engraved scrimshaw was lampblack, which is essentially a viscous suspension of carbon particles in oil. (The notion that sailors used tobacco juice for this is a colorful fabrication with no basis in fact.) Lampblack, collected easily from lamps, stoves, and tryworks (shipboard oil-rendering apparatus), was in abundant supply on a whale ship. Colors were introduced almost at the outset: Edward Burdett was using sealing wax and other pigments by 1827 (Fig. 1); full polychrome scrimshaw debuted within the next decade. Sealing wax had the advantages of being universally available, relatively inexpensive, brilliantly colored, and colorfast. Applied properly, it has proven resilient and tenacious, the color as vivid today as when the scrimshaw was new. Improper application—if the cuts are too smooth or insufficiently contoured to grab and hold the wax—results in significant losses from handling and natural desiccation. Sealing wax had the disadvantage of offering only a limited spectrum of colors, all strong. Ambient pigments, however, could be mixed and blended, affording greater subtlety. From the characteristic leeching of pigment into the substrata of some polychrome scrimshaw, a phenomenon that occurs with water- and alcohol-soluble colors but not with waxes or heavy oil-based pigments, it is clear that ambient colors were also favored. Store-bought inks, homemade dyes extracted from berries, and greens from common verdigris seem to predominate; however, their composition has not been investigated comprehensively.

Inlay and other secondary materials—rare on engraved scrimshaw but often encountered on “built” or “architectonic” scrimshaw—were typically obtained at little or no cost, such as other marine byproducts (tortoise shell, mother-of-pearl, sea shells), various woods brought from home or obtained in various ports of call (including exotic tropical species from Africa and Polynesia), and miscellaneous bits of metal (fastenings and finials were often crafted from silver- or copper-alloy coins, typically coins minted in Mexico and South America).

II. Scrimshaw Precursors

Medieval European artistic productions in walrus ivory and cetacean bone were many, but the whalers themselves had no part

Figure 1 Pan bone plaque by Edward Burdett (1805–1833) of Nantucket, circa 1828. The earliest known scrimshaw artist, Burdett was active from 1824 until he was killed by a whale in 1833. His work is characterized by a bold, confident style, with deep blacks and red sealing-wax highlights. He was serving as a mate in the *William Tell* when he engraved this section of sperm whale bone, inscribed “William Tell. of New York. homeward bound. in the latitude of. 50 13. S. longitude] 80. W. got shipwrecked”; “lost her rudder & c.”; “by. E. Burdett.” 15.7 × 31.8 cm. Kendall Collection, New Bedford Whaling Museum.

in them beyond gathering the raw materials. Cetacean bone panels and stiletos survive from the Viking era, some incised with rope patterns and animal figures, and cetacean bones served as beams in vernacular buildings in Norway and the Friesian Islands, but even these do not appear to have been made by whalers and are not known to have been part of their occupational culture. Monastic artisans in Denmark and East Anglia carved walrus ivory and cetacean bone into votive art, primarily altar pieces, friezes, and crosses, whereas craftsmen at Cologne and elsewhere produced secular game pieces and chessmen from the same materials. So important was the “Royal Fish” to the Viking economy that a highly sophisticated body of law evolved to regulate whaling itself and the ownership, taxation, distribution, and export of whale products, whether acquired fortuitously (from stranded carcasses) or by hunting. Pliny the Elder (first century C.E.), Olaus Magnus (1555), Conrad von Gessner (1558), and Ambroise Pare (1582) listed the uses of baleen for whips, springs, garment stays, and umbrella ribs; the emergence of pelagic Arctic whaling in the seventeenth century encouraged a search for new applications, especially in Holland. The search, however, proved fruitless and was abandoned by circa 1630, occasioning the appearance of sailor-made baleen objects: there was simply no longer any reason to restrain whalers from using baleen for their private diversions (two centuries later the same principle would make sperm whale teeth available for scrimshaw).

Ditty boxes were the first manifestation of whalers’ work. Typically, these have polished baleen sides bent to the oval shape of a wooden bottom 30–35 cm long, to which the baleen is fastened with copper nails and fitted with a wooden top. Two made in 1631 by an anonymous Rotterdam whaling commandeur have baleen sides incised with portraits of whaleships, the wooden tops relief

carved with the Dutch lion rampant surrounded by nautical symbols, human figures, and decorative borders. A few North Friesian whalemens—artists of the next generation are known by name. Jacob Floer of Amrum engraved buildings, trees, and geometrical borders on the baleen sides of an oval box, signed and dated 1661. Peter Lorenzen of Sylt signed and dated another in 1687. The form continued for the duration of Arctic whaling and was perpetuated with myriad variations by American and British scrimshaw artists in the nineteenth century.

Another early form was the mangle (paddle for folding cloth). An Amsterdam whaling commandeur decorated one with carved geometric ornaments, signed, dated, and inscribed, “Cornelis Floerensen Bettelem. Niet sonder Godt [Not without God]. Anno 1641.” A century later, a North Friesian whaling master, Lødde Rachtsen of Hooge, made one for his daughter’s dowry: it has a pierced-work handle and carved geometric and floral decorations, the broadside portrait of a spouting bowhead whale, and a carved inscription dated 1745. Respecting technical aspects of execution and the iconography of their decoration, this kind of piece is the direct ancestor of the sperm whalemens’ decorated baleen corset—busks of the nineteenth century.

III. Origins and Practice

Pictorial engraving on sperm whale teeth—the quintessential manifestation of scrimshaw—resulted from changing circumstances in the fishery in the aftermath of the Napoleonic wars (of which the American theater was the so-called War of 1812). It arose collectively among British and American whalers in the 1820s in the Hawaiian Islands, where (beginning in 1819) the fleets customarily laid over for weeks on end between seasonal cruises, providing ample opportunities for fraternization and foment.

In the late seventeenth century, British colonists on the Atlantic seacoast of New York and Massachusetts hunted right whales along shore—an ancillary day fishery, prosecuted by fishers and farmers in rowboats launched from sandy beaches. In the eighteenth century, expanding markets occasioned offshore cruises in small sailing vessels. The discovery of sperm whales in proximity to New England is ascribed by tradition to Captain Christopher Hussey of Nantucket when he was blown off course while right whaling in 1712. The colonists tuned their technology to accommodate sperm whaling, pioneered the refining of sperm whale oil and the manufacture of spermaceti candles (America's first industry), and developed thriving export networks. Whaling evolved into a full-time occupation, and a distinctive caste of whaler-mariners emerged with its own occupational culture. Scrimshaw would become an integral component of this culture, but it took a whole century for the right circumstances to gel.

Colonial whaling cruises were seasonal, following the Atlantic trade winds on comparatively short passages to and from the grounds. Only a few whales were required to fill the hold before heading home, usually after only a few weeks. The opening of the Pacific grounds in the 1790s changed shipboard dynamics dramatically. Voyages necessarily became longer, as much as 3 or 4 years by the 1840s. The larger catch that was required to make long voyages profitable mandated larger vessels with larger crews so that three–five whaleboats could be launched for the hunt. The effective result was overmanning and an unprecedented abundance of shipboard leisure—long outward and homeward passages, and idle weeks, even months between whales, when there was little to do but maintain the ship and wait. Most sailors worked “watch-on-watch” in 4h shifts, day and night, whenever the ship was underway, but whaleship crews had most nights off: the hunt could not be prosecuted effectively in darkness, and cutting in (flensing) a carcass with sharp blubber spades was dangerous enough even in daylight. Apart from rendering blubber already on hand, there was little work to do evenings. More than in any other seafaring trade, the nineteenth-century whalers had time to spare. They filled it with reading, journal-keeping, drawing, singing, dancing, gamming (visiting among ships at sea), and a host of other diversions.

At the critical juncture, just when things were ripe for scrimshaw, teeth were in short supply. For in the meanwhile, the China Trade, pioneered in the 1780s, had established a network of Far East destinations and products that involved barter with Pacific islanders to obtain goods for Canton. China traders soon realized that many island cultures placed great value on whale teeth, from which they crafted various totemic and decorative objects. Teeth could be obtained cheaply from whalers (there being no other market), so the China merchants bought them up for barter in the Pacific. Such scrimshaw as there was in the eighteenth century was therefore limited primarily to implements made of skeletal bone—straightedges, hand tools, a few early swifts (yam-winders), and corset husks; of these, comparatively few were made prior to the florescence of scrimshaw commencing in the 1820s.

Captain David Porter of the US Naval frigate *Essex* was the inadvertent catalyst for the emergence of scrimshaw. Porter's wartime purpose had been to inflict depredations on British shipping and to disrupt British whaling in the Pacific. His narrative (published in 1815, reissued in an expanded edition in 1821) was valued by mariners for its explicit accounts of conditions in the Marquesas and Galapagos Islands and on the coast of Chile and Peru. It also incidentally revealed the barter value of whales' teeth in Polynesia and disclosed particulars of how they could be gathered cheaply—this at just around the time the vanguard of the whaling fleet reached Hawaii (1819). There was soon a surplus of whales' teeth on the

Figure 2 *Genesis of scrimshaw, circa 1817. The oversize tooth is inscribed “This is the tooth of a sperm whale that was caught near the Galapagos Islands by the crew of the ship Adam [of London], and made 100 barrels of oil in the year 1817.” Produced in the wake of the Napoleonic Wars, when the British and American whaling fleets were endeavoring to recover their former prowess in the Pacific, it is believed to be the earliest full-scale work of engraved pictorial scrimshaw on a sperm whale tooth. Length 23.5cm. Kendall Collection, New Bedford Whaling Museum.*

Pacific market; as the teeth were no longer valuable as a commodity, they could be relegated to sailors for private use.

Accordingly, the earliest authentic date on any pictorial sperm whale scrimshaw is 1817—a tooth commemorating a whale taken by the ship *Adam* of London off the Galapagos Islands (Fig. 2); the earliest provisionally identifiable whaler-engraver of sperm whale ivory is J. S. King, whaling master of London and Liverpool, to whom two teeth are attributed, one perhaps as early as 1821. These suggest a possible British genesis of pictorial scrimshaw; however, the earliest definitively attributable work is by an American, Edward Burdett of Nantucket, who first went whaling from his native port in 1821 and was scrimshandering by 1824. Fellow Nantucketer Frederick Myrick was the first to sign and date his scrimshaw—three dozen teeth produced during 1828–1829 as a seaman aboard the Nantucket ship *Susan*. Two teeth by Burdett and two “*Susan’s Teeth*” by Myrick were accessioned by the East India Marine Society of Salem, Massachusetts, prior to 1831, while both artists were still living—the first scrimshaw to enter a museum collection. That Myrick's work was listed generically as “Tooth of a Sperm Whale, curiously carved” and “Another, carved by the same hand,” with no mention of the exquisitely engraved pictures on them, nor of the artist's name (both are signed), nor of the term “scrimshaw”, testifies to the newness of the genre, perhaps also to the low esteem in which sailors' hobby work was held by the great merchants of Salem at the time.

In the 1830s, scrimshaw became widely generalized. On some whaling vessels virtually the entire ship's company participated. In his journal of the New Bedford bark *Abigail* during 1836–1838, Captain William Hathaway Reynard remarked, “The cooper is going ahead making tools for scrimsham. We had a fracas betwixt the cook and the stewart [sic] ... All hands employed in scrimsa.” In other ships the best ivory and bone may have been relinquished to some particularly talented member of the crew, such as Joseph Bogart Hersey of Cape Cod on the Provincetown schooner *Esquimaux* in 1843: “This afternoon we commenced sawing up the large whale's jaws ... the bone proved to be pretty good and yielded several canes,

fids, and busks. I employed a part of my time in engrav[ing] or flowering two busks. Being slightly skilled in the art of flowering; that is drawing and painting upon bone; steam boats, flower pots, monuments, balloons, landscapes; I have many demands made upon my generosity, and I do not wish to slight any; I of course work for all.”

The whaleship labor force was very young on average, with green hands often in their early teens; common seamen and even seasoned harpooners were rarely over 30. Among the greatest scrimshaw artists, Frederick Myrick retired from whaling and from scrimshaw at age 21, Edward Burdett was barely 28 when he was killed by a whale, and Welsh ship’s surgeon W. L. Roderick left the fishery at 29. Nevertheless, although in the minority, older hands contributed mightily. Seaman Silas Davenport may have been in his forties when he constructed a fine swift of bone and ebony. Former whaleman N. S. Finney was still engraving walrus ivory on commission in San Francisco in his sixties. Ship’s carpenters and coopers-trained craftsmen with skills well adapted to scrimshaw, especially architectural pieces were normally older than the average crewman. So, too, whaling captains, many of whom were devoted scrimshaw artists: Manuel Eno cut brilliant polychrome portraits into whale ivory right up to the time he was lost at sea at age 55; Frederick Howland Smith was scrimshandering from age 14 until he retired at 61; and the grand old man, Captain Ben Cleveland, was still making napkin rings, mantle ornaments, gadgets in the 1920s, at age 80.

Scrimshaw was quintessentially a diversion of the whalemens ample leisure hours, to fill time, and produce mementos, as gifts for loved ones at home. It was occupationally rooted in and wholly indigenous to the deepwater whaling trade, but was eventually also adopted by merchant sailors, navy tars, and occasionally the seafaring wives and children of whaling masters.

Unfortunately, practitioners in whatever trade rarely signed or dated their work, and family provenance has seldom preserved details of the origins of legacy pieces. Thus, scrimshaw has hitherto been mostly anonymous, the names of only a handful of practitioners known. However, systematic forensic studies commencing in the 1980s have made stylistic and iconographical attributions increasingly possible, and the names and works of a few hundred individual artists are now documented with varying degrees of specificity.

IV. Taxonomy

Scrimshaw took many forms. Henry Cheever mentions whalers “working up sperm whales’ jaws and teeth and right whale [baleen] into boxes, swifts, reels, canes, whips, folders, stamps, and all sorts of things, according to their ingenuity” (The Whale and His Captors, 1850), and Herman Melville alludes to “lively sketches of whales and whaling-scenes, graven by the fishermen themselves on Sperm Whale-teeth, or ladies’ busks wrought out of the Right Whale-bone, and other like skimshander articles, as the whalemens call the numerous little ingenious contrivances they elaborately carve out of the rough material in the hours of ocean leisure” (Moby-Dick, 1851). Various tools were used for cutting and polishing, but forensic scrutiny corroborates Melville’s observation that the ordinary knife predominated: “Some of them [the whaleman-artisans] have little boxes of dentistical-looking implements, specially intended for the skimshandering business. But in general, they toil with their jack-knives alone; and, with that almost omnipotent tool of the sailor, they will turn you out any thing you please, in the way of a mariner’s fancy.”

Scrimshaw objects intended for practical use included hand tools, kitchen gadgets, sewing implements, toys, and even full-sized furniture. Some, such as fids, straightedges, tool handles, seam-rubbers,

Figure 3 Pie crimper in the form of a mermaid, New Bedford, circa 1875. Practical in origin, these classic kitchen implements inspired some of the scrimshaw’s most creative forms and elaborate ornamentation. The jagging wheel was used for crimping pie crusts; they often also had ivory forks to puncture the top of the crust. This one was made aboard the New Bedford ship *Europa*, Captain James H. McKenzie, during 1871–1876. Length 18 cm. Kendall Collection, New Bedford Whaling Museum.

napkin rings, and even some canes, could be carved or turned from a single piece of ivory or bone. Although they had a specific function, corset busks (made of bone, walrus ivory, or baleen) were often elaborately engraved; even apart from being products of painstaking labor, as intimate undergarments they were not bestowed casually. Other implements were constructed from two or more pieces joined or hinged together—pie crimpers with rotating jagging wheels and fold-out forks (Fig. 3), canes with shafts of one material, pummels of another, and inlay of a third. The most elaborate forms were truly “built” and may properly be called architectural or architectonic. Swifts (yarn winders) have numerous moving parts, with metal pinions and ribbon fastenings (Fig. 4). Bird cages, a labor-intensive technical challenge, could run the gamut of Victorian complexity. Sewing boxes, ditty boxes, chests of drawers, lap secretaries, pocket-watch stands, mantle ornaments, and other composite constructions typically employed combinations of wood, ivory, and bone and may have, hinged lids, internal compartments, legs, finials, handles, drawers, drawer pulls, inlay, and all kinds of ornamentation.

The quintessential form of purely decorative scrimshaw is engraved ivory and bone, usually rendered in a single medium—a tooth or pair of teeth; a tusk or pair; or a plaque, strip, or section of sperm whale panbone (jawbone). Finished teeth were sometimes set into wooden, silver, or coin-silver mounts; plaques might be framed by the artist; engraved strips of baleen could become oval boxes. Alternately, teeth and tusks could be carved into stand-alone sculptural forms, such as human or animal figures, or could become the components of complex ship models.

There were no rules and few precedents governing the choice of subject matter for pictures on scrimshaw. The earliest work by the anonymous Adam engraver, J. S. King, Edward Burdett, and Frederick Myrick was almost exclusively devoted to ship portraiture and whaling scenes. Figures of Columbia, Liberty, and Britannia appeared by around 1830. The ensuing generation enlarged the vocabulary to include patriotic portraiture (notably of Washington

Figure 4 Swift of sperm whale ivory and skeletal bone by Captain James M. Clark of Rochester, Massachusetts, circa 1835–1850. Made by a Yankee whaling captain, this exquisite piece typifies the best of the scrimshaw genre. It is inlaid with abalone shell and baleen, fastened with copper, tied with silk ribbons, fitted with two turnscrews in the form of clenched fists, and has a silver presentation plaque inscribed “R W Vose from Jas Clark.” Height 40.7cm. Swifts were a distinctly American form, used for winding the yarn employed in knitting and occasionally other domestic handicrafts and cottage industries. Kendall Collection, New Bedford Whaling Museum.

and Lafayette), inanimate patriotic devices, female portraiture, landscape, naval engagements, sentimental family scenes, and mortuary motifs (Fig. 5). Gradually, these were canonized as standard genre conventions. Some individual artists developed distinctive styles and themes. George Hilliott’s polychrome teeth dialectically juxtapose a Polynesian wahinee in a grass skirt on one side and a New England lady in a fashionable gown on the other. The anonymous “Banknote engraver” did meticulous portraits with banknote-like borders (hence the pseudonym). The “Eagle Artisan” engraved red-and-black American eagles and bold portraits. The “Lambeth Busk Engraver” made busks with London vignettes; a prime example features Lambeth Palace. Much naval scrimshaw is adorned with patriotic devices and naval engagements. Like whalers’ scrimshaw, some examples refer to specific vessels and events. A notable British example is credited to HMS Beagle on the same voyage on which Darwin evolved his theory of natural selection. Edward Yorke McCauley—later an admiral and noted Egyptologist—when he was a young midshipman aboard the U.S. Frigate Powhattan on Perry’s
