Diving Physiology

GERALD L. KOOYMAN

I. Introduction

Ever since humankind has lived by and gone down to the sea, we have been awestruck by the creatures that make it their home. First we feared them, later we ate them, and now we try to emulate them with humble attempts to set “world” diving records. At present the record for a descent-assisted dive is at 214 m during a breath hold which lasted a little less than 4.5 min. Many marine mammals exceed that depth within the first few months of life. Premier divers such as elephant seals (*Mirounga* spp.) and sperm whales (*Physeter macrocephalus*) will occasionally dive to depths beyond a kilometer (Table I). The spectacular abilities of marine birds and mammals to dive deep and for long periods of time are a source of interest and curiosity for marine scientists and amateurs alike.

When marine mammals descend below the sea’s surface they leave behind the thin skin of the earth’s atmosphere with one of its essential ingredients to all vertebrate life—oxygen. They begin a journey that is incredible in diverse ways. The magnitude of incredulity varies according to the species, but for all, even the most humble of marine mammals such as the sea otter (*Enhydra lutris*), much if not most of the experience is beyond our imagination. Unlike flying, in which our technology now enables us to fly faster, higher, and further than any bird, bat, or pterosaur ever has or did, marine mammals, particular those that dive to great depths, explore and exploit a realm that overwhelms much of our technology and which enables us to gain only fleeting glimpses of what their environment is like. Recently we have enlisted the animals themselves to help us discover more about this cold, dark world without oxygen, where awesome hydrostatic pressures always prevail. However, “crittercams” will only give us fleeting glimpses, under very special conditions, with those few species that lend themselves to the attachment of these cameras. Life in the deep blue remains a mystery. So too do the means that enable diving mammals to exploit this habitat.

This chapter discusses some of what is known about adaptations to breath holding and overcoming the crushing effects of pressure. These adaptations are unique among vertebrates. Even after our primordial fish ancestors overcame great obstacles to adapt to the terrestrial environment, and eventually to spread throughout all land habitats of the world, the sea continued to be a rich habitat that would bring great success to those species that exploited it. Some air-breathing vertebrates are doing just that. In fact, this has occurred

several times in the history of vertebrates as they reinvaded the sea. The marine reptiles of the Mesozoic were diverse, abundant, and no doubt very capable divers. They had at least one major advantage over marine mammals, a small brain. The brains of mammals require a substantial share of the oxygen being supplied to the body, and it is an obligate need with very little reserve for those times when supply is interrupted. Within 3 min after blood flow and oxygen transport to the human brain is interrupted, there is irreversible damage. This sensitivity of large, complex brains to a grave need for oxygen makes it seem a contradiction that animals who routinely breath hold many times every day are all so smart. Proportionately in terms of brain size relative to body size, several cetacean species have some of the largest brains of mammals. Despite this “handicap” marine mammals have been an extremely successful group that are found in all the world’s oceans, in extremely large numbers, and have the biomass of some species matching that of any of the formerly abundant terrestrial mammals of the world.

What is the secret of their success? Some routinely dive to depths of several hundred meters, and a few species may occasionally descend from 1 to 2 km (Table I). Although these depths may seem just a superficial range compared to the ocean limit of 11 km, with an average depth of 3.5 km, the range used by most marine mammals is in the zone of greatest oceanic life. Nevertheless, this region of cold, dark waters requires special adaptations enabling the animal to endure low temperatures and find prey in the “dark.” Marine mammal diving skill provides a dramatic contrast to human capacities. On average we can dive to a few meters for about 30 sec. The super athletes, who make a career of setting records such as the record breath-hold dive of 214 m, require mechanical aids of weights, pulleys, and drop lines. To extend our depth beyond these few meters humans have gone to costly extremes in mechanical devices. Most deep submersibles are usually limited to several hundred meters depth, but ALVIN, the workhorse of the scientific submersibles, can go as deep as 4500 m.

Adaptations of marine mammals to the marine environment are diverse in order for them to become successful marine predators. They involve many systems in and out of the body, ranging from external body shape to overcome the high density and viscosity of water to the sensory systems necessary to find their way and to detect prey and predator. Space will allow for only a few of the numerous

adaptations necessary for a successful marine mammal. The following paragraphs discuss adaptations to hypoxia and pressure. These paragraphs address pelagic, offshore deep divers in which the adaptations are the most extreme.

II. Adaptations to Hypoxia

A. Oxygen Stores and their Distribution

An increased total body O₂ store is considered an essential factor in the breath-hold capacity of diving mammals. The oxygen consumed by body metabolism during a breath hold is stored in three compartments, the respiratory system, the blood, and the body musculature. The theoretical maximum amount of oxygen available in each compartment is a function of several criteria. The respiratory oxygen store is dependent on lung volume and the concentration of oxygen in the lung at the start of a breath hold. The blood and muscle oxygen stores are dependent on blood volume and muscle mass, and the concentration of the oxygen-binding proteins of hemoglobin in blood, and myoglobin in muscle. From the measurements of myoglobin concentration in the muscles of many species of divers it is clear that one of the most consistent hallmarks of oxygen storage in all marine mammals that dive to depth is an elevated myoglobin concentration (Kooyman and Ponganis, 1997; Kooyman *et al.*, 1999). This trait is more characteristic of deep divers than any changes in blood volume, hemoglobin concentration, or respiratory volumes. However, increased blood volume and hemoglobin concentration often contribute to elevated oxygen storage.

As the distribution of oxygen stores vary among species, so do the ranges of the total oxygen store (Table I). In humans the total store is 20 ml O₂/kg body mass, which is about a fifth of the nearly 100 ml O₂/kg body mass in elephant seals (*Mirounga* spp.). Using the seal as our basic model it is noted that most of its oxygen is in blood and muscle. The large amount relative to terrestrial animals, using the human average as a standard, is a result of a blood volume 3 times, a hemoglobin concentration 1.5 times, and a myoglobin concentration approximately 10 times the human value. In seals the lung is a minor source of oxygen, as it is in most other marine mammals. It is less than 5% of the total in part because seals exhale to 50% of their total lung capacity just before diving. Furthermore, at depth the lung is collapsed and does not exchange gas.

TABLE I
Distribution and Quantity of Oxygen Stores, Maximum and Routine Diving Depths, and Durations for Some Marine Mammals

Species	Body mass (kg)	Total store (ml/kg)	Lung	Blood (%)	Muscle	Routine depth (m)	Maximum depth (m)	Routine duration (min)	Maximum duration (min)
Human	70	20	24	57	15	5	214	0.25	6
Weddell seal	400	87	5	66	29	200	741	15	93
Elephant seal	400	97	4	71	25	500	1,653	25	120
California sea lion	100	40	21	45	34	40	275	2.5	10
Bottlenose dolphin	200	36	34	27	39		535		
Cuvier's beaked whale	3,000					1,070	1,888	58	85
Sperm whale	10,000	77	10	58	34	500	2,035	40	73

Note: There is an extensive list of diving capabilities of many species of diving animals at: <http://polaris.nipr.ac.jp/~penguin/penguiness/index.html>

B. Cardiovascular Responses

The cardiovascular response to breath holding falls into at least two categories of whether the dive is extended or of routine duration for that species. Measurements of cardiovascular and metabolic responses under these circumstances are very limited for any species and most measurements are from seals. Diving mammals are arrhythmic breathers with pauses between each series of breaths. The resting maintenance heart rate is probably most closely reflected in the rate during the respiratory pause or apnea. Using the heart rate during apnea as a basis of comparison for heart rates during a routine dive, the heart rates during the dive are lower than the rate of a resting apneusis, and this occurs despite the fact that the mammal is swimming. When an extended dive is performed, the heart rate is even lower than that during routine diving. Because no measurements of blood flow distribution have been directly measured during dives of marine mammals, it is by extrapolation from indirect measures of other organ functions that allude to what may be occurring. During routine dives it is likely that gastric, renal, and hepatic functions are reduced to a small amount, but no more than what can be compensated for by higher than normal performance during the short, breathing intervals at the surface. Muscle may utilize a small part of the circulating blood oxygen, but it probably relies on its internal store of oxygen bound to myoglobin for much of aerobic metabolic needs.

Extended dives, those that are 3–5 times the routine dives, are uncommon. They are most likely to occur because of some urgent need such as a Weddell seal (*Leptonychotes weddellii*) searching for a new hole under sea ice, or an elephant seal hiding at depth to escape notice from a passing pod of killer whales (*Orcinus orca*) near the surface. The cardiovascular response in these extreme cases may be a limitation of blood flow to obligate aerobic tissues, the most conspicuous of which is the brain. Having no internal store of oxygen, and a need to be at full functional capacity, a constant supply of oxygen and other metabolites provided by the blood, as well as transport of waste products of metabolism from the brain, means that constant blood flow is essential. There is a lesser need for transport of oxygen to the heart because of a reduced work load (the slower heart rate) and small store of internal oxygen. Blood flow to muscle is reduced to a trickle as it draws from the large oxygen store within the muscle and the internal store of glycogen for the production of the high energy compounds of adenosine triphosphate (ATP). The high concentration of myoglobin in *all* mammals that dive to depths greater than about 100m indicates that myoglobin is a key adaptation for diving. Blood flow would be a liability since the affinity of myoglobin for oxygen is much higher than is the affinity of hemoglobin for oxygen. Consequently, any flow to muscle that had utilized much of its oxygen store would strip oxygen from the circulating blood and deprive more vital organs such as the brain from oxygen. A reduced blood flow to muscle also decreases cardiac output needs and, hence, the work of the heart and its oxygen consumption. Thus, the degree of muscle blood flow reduction during long and short dives is key to understanding the management of oxygen stores. Unfortunately, little is known about this crucial topic. Unlike other organs, muscle is widely distributed in the body, and the vascularity is diffuse. Consequently, it is an intractable problem which has not lent itself to study.

Muscle also has a great capacity for anaerobic metabolism and tolerance for high concentrations of the metabolic end product of lactic acid which is stored in the form of lactate. Nevertheless muscle must continue to function for locomotion either continuously as a Weddell seal swims below the sea ice, or intermittently as in an

elephant seal as it drifts in the depths, but in the end must call upon muscle to provide the locomotion to return to the surface. In contrast, the splanchnic organs may shut down or greatly reduce function until the diving mammal returns to the surface.

C. Metabolic Responses

The cessation of metabolic function in the splanchnic organs will reduce metabolic rate substantially since these organs functioning at normal rates account for nearly 50% of the total resting metabolism of the animal. In addition the heart is beating more slowly and performing less work, which may also be the case for striated muscle. In the cold environment at depth some tissues may also be cooling which would result in an additional savings in energy consumption. The final result is to lower the overall metabolic rate to below the resting level during these short and metastable conditions.

D. Anaerobic Metabolism

Dominating the many factors that affect how long an animal may breath hold is the amount of oxygen available and its rate of utilization. Through oxygen supported metabolic pathways 18 times more high energy ATP is produced from glucose than through anaerobic processes. Furthermore, carbon dioxide and water, the end products of oxygen supported catabolism are less polluting to the cells and circulation than those of anaerobic catabolism. Finally, nerve cells, especially within the brain, are completely dependent on aerobic metabolism. Therefore, the duration of time an animal may breath hold is most strongly affected by the availability of oxygen, with subsidiary support from anaerobic glycolysis and creatine phosphate catabolism. Although an animal may extend its dive considerably by relying on anaerobic glycolysis, the subsequent recovery is in turn extensive because of the time required to process lactic acid and restore the acid base balance of the cells and circulatory system. For routine dives that occur in sequence over many hours aerobic metabolism is the only practical option. Oxygen supported metabolic pathways are also the only means of producing ATP that is derived from catabolism of fat and protein.

E. Aerobic Diving Limit

The only diving mammal in which there has been a detailed correlation of the diving duration and the postdive blood lactate concentration is the Weddell seal (Fig. 1) (Kooyman *et al.*, 1980; Ponganis *et al.*, 1993). The source of the lactate has been shown to be from muscle, in which it accumulates rapidly as muscle oxygen is depleted. After the seal surfaces, there is increased blood flow to muscle and much of the lactate is flushed into the circulation and gradually disappears over several minutes. If the seal should dive again before all of the blood lactate is processed, it will continue to decline over the course of the dive unless that dive exceeds what has been termed the aerobic diving limit (ADL). The ADL is defined as the diving duration beyond which there is a net increase in lactate production (Kooyman, 1985). This rise in lactate concentration first occurs primarily in muscle, and eventually diffuses from the organ into the circulation where it can be measured easily. It has been proposed that this threshold be called the diving lactate threshold (DLT) to avoid confusion about the numerous ways that the ADL has been derived since the first measurements were made on Weddell seals (Butler and Jones, 1997). From those measurements it was also shown that with some reasonable accuracy the ADL could be obtained from the quotient of the O₂ store divided by metabolic rate, the calculated ADL (cADL). Because this limit predicts basic information

Figure 1 Peak concentration of lactate in arterial blood after dives of different duration in adult Weddell seals. The inflection represents the transitions from completely aerobic dives and is considered the aerobic diving limit (ADL) or diving lactate threshold (DLT). Red circles reflect blood values of dives in which there is no net production of lactate, and blue circles are those in which there was a net production.

about the foraging behavior of diving animals as well as clarifying physiological responses and models to breath holding, it has been calculated for many diving species. Some of the most intriguing calculations have been made for the elephant seal, a continuous diver who appears to allow no surface time for recovery from dives exceeding the cADL. There are several possibilities that could resolve this puzzle. A recent computer simulation of oxygen store depletion provides a physiological model of aerobic diving that may clarify this problem, and provide direction for further studies.

This comprehensive, numerical model uses as its data source the Weddell seal because there is extensive information on this species. The calculations in the model are based on or derived from available data on cardiac output, O_2 depletion rates of blood and muscle, blood flow patterns in various organs, and the diving metabolic rates that may occur in the Weddell seal. The model demonstrates how the matching or mismatching of oxygen transport and regional oxygen consumption can affect the ADL. This theoretical treatment of the ADL goes a long way in understanding how oxygen must be managed during a dive, and in particular, explains how 31% of the body O_2 store remains unconsumed under the most optimal cardiac output conditions. The model also shows that only 49% of the muscle oxygen provision comes from the internal store during the longest possible aerobic dive. In regard to recovery from an extended dive, the oxygen replenishment rate is much more rapid than the reconversion of lactate to glycogen (Davis and Kanatous, 1999).

Assuming that the model can be applied to other aquatic species, it may help to explain the enigma of the serial dives in the elephant seal which exceed previous cADLs. However, the model does not take into account the influence of creatine phosphate to support the few dives that may appear to exceed the ADL, and for which some have invoked some unusual hypometabolic responses. Because creatine phosphate concentration is 15–20 mmol/kg in mammals, this is enough to have a significant effect on the magnitude of the ADL

and the production of energy without oxygen, but before measurable amounts of lactate are produced (Butler and Jones, 1997).

III. Adaptations to Pressure

Once a marine mammal descends below the surface it not only must deal with the lack of oxygen but also with the effects of pressure. This is one of the most imposing physical variables to which vertebrates must adjust (Kooyman, 1989). We become especially sensitive to pressure during the most modest dive to depth because our airspaces such as the middle ear and facial sinuses make us acutely aware of any difference between the ambient pressure and our internal pressure. More subtle is the effect of pressure on the lung. For humans the lung is an important oxygen store, but in deep-diving mammals the lung is not an important oxygen store. Over a long period of evolution the main function of the vertebrate lung became the exchange of gases between blood and air. During the descent to depth, this function is diminished in deep-diving marine mammals. As the transfer of gases between the lung and blood slackens or ceases, the rise in nitrogen partial pressure within the lung is not matched in the blood. The lack of gas exchange also results in the avoidance of nitrogen narcosis and oxygen toxicity. Even with this adaptation there is still the pure physical effect of hydrostatic pressure on the nervous system. In terrestrial mammals pressure causes over stimulation or uncoordinated nerve conduction and dysfunction called high pressure nervous syndrome (HPNS). How do marine mammals manage to avoid these problems that are manifested in their terrestrial relatives?

The pressure within all airspaces must closely match that of the ambient pressure or suffer damage to the membranes and blood vessels lining the space and a breakdown in normal function. There are at least three major airspaces within most mammals that are liabilities for diving. First are the facial sinuses. Any experienced diver or airline passenger is aware that flying or diving during or soon after having a head cold is a bad idea. The blockage that may ensue during rapid pressure changes can cause extreme pain and serious damage to tissues and blood vessels lining the walls of these cavities. Marine mammals do not have this problem because they have no facial sinuses. Thus, one problem is dealt with by the absence of the airspace.

Similar to all other mammals there is a cavity that forms the middle ear. This is a rigid structure that has little or no compressibility. A pressure differential is prevented, at least for seals and sea lions, because of a complex vascular sinus lining the wall of the middle ear cavity. As the pressure within the middle ear cavity begins to fall below that of the vascular tree, the blood sinuses volume increases. This is a result of the close match between ambient pressure and blood pressure transferred from one fluid (sea water) to another (blood). Another problem is resolved by the reduction of an airspace by hydraulic compression through the vascular system.

Third, the largest airspace of all, and potentially the most problematic is the lung. Volume pressure curves of the chest wall and lung of the ribbon seal, *Histriophoca fasciata*, show that both the chest and the lung are nearly limitless in the degree of compression collapse that they can tolerate. This must be so for other diving mammals as well, and in less detailed studies it has been shown that there is exceptional compressibility in other seals, sea lions, and dolphins. Dolphins and other toothed whales show the most extreme modifications within the lung among marine mammals, or any other mammal. Most notable is the reinforcement of peripheral airways, the loss of respiratory bronchioles, and the presence of a series of bronchial sphincters. Sea lions also have robust cartilaginous airway reinforcement extending to the

Figure 2 Arterial N_2 tensions in elephant seals and a Weddell seal. The elephant seal submersion (yellow diamonds) were simulated in a water filled hydraulic compression chamber to pressures equivalent to a sea water depth of 136m. Compression began at zero; at 11 min pressure was released and at 14min the submersion ended. The Weddell seal (red circles) made a free dive to 89m under Antarctic ice. Maximum depth was reached at 5 min, and the dive ended after 8 min.

alveolar sac, but there are no bronchial sphincters. In seals there is no cartilage in the terminal airway, but the walls are thickened by connective tissue and smooth muscle, which reduces their compliance to less than that of the alveoli. Hence, during compression the more compliant alveoli collapse first and the gases within these alveoli are squeezed into the upper airway spaces.

These airways enable a graded collapse of the lung to occur during a dive to depth. The result is that most of the lung air is forced into the upper airways where gas exchange with the blood ceases. It has been shown that blood P_{aN_2} in seals only rises slightly, no matter how deep the dive. During simulated and actual dives to depth, the P_{aN_2} of the elephant seal, *Mirounga angustirostris*, peaked at 300 kPa and equilibrated to 200 kPa where it was approximately the same as venous P_{N_2} (Kooyman *et al.*, 1972). This was independent of the ambient pressure from 30 to 136 m (1460 kPa). Similar values were obtained for Weddell seals diving voluntarily to depths as great as 230 m (2400 kPa) (Fig. 2) (Falke *et al.*, 1985). These small increases in P_{aN_2} indicate that lung collapse in both species occurred between 20–50 m. The early occurrence of lung collapse in seals makes the lung almost useless as an O_2 store, but it limits N_2 absorption during the dive. These N_2 values are below the minimum P_{N_2} of 330 kPa found to be necessary for bubble formation in cats, and it is assumed that a similar threshold for bubble formation prevails in marine mammals. An additional benefit of early lung collapse is that it eliminates the likelihood of nitrogen narcosis. This condition is often experienced by SCUBA divers descending to depths greater than 30 m. At these depths tissue nitrogen level is at least 399 kPa; greater than the P_{aN_2} measured in seals. A final thought is the intriguing condition of elephant seals at sea when they spend 90% of their time underwater and at depths greater than 100 m. At these times the lung does not do what it was originally evolved to do, i.e., to exchange gas with the blood and with the atmosphere. Instead it is collapsed to

a solid organ, and the alveoli become unavailable for gas exchange. Nevertheless, there are recent incidences of Cuvier's (*Ziphius cavirostris*) and Blainville (*Mesoplodon densirostris*) beaked whale strandings that are shrouded in mystery. Fatal strandings of these species were associated with US Navy sonar experiments. Postmortem dissections of some of the beaked whales showed the presence of gas bubbles that appeared to have occurred *in vivo* (Jepson *et al.*, 2003). We know that these species make extreme dives while hunting for prey (Tyack *et al.*, 2006). Is it possible that gas bubbles could have formed during abnormal diving behavior related to the sonar tests, which resulted in decompression sickness?

Finally, in humans and other nonaquatic animals descending to depths of more than 100 m and at rates of 100 m/min the mechanical compression on nervous tissue can cause HPNS. The symptoms are modest to severe tremors throughout the body that can become so severe as to be incapacitating. The range of depths and rate of descent are modest compared to that of some deep-diving marine mammals. Surely a well-adapted mammal does not experience HPNS, which leads to the compelling question of what the difference is between the neural makeup of a marine mammal that protects it from experiencing HPNS and that of a terrestrial mammal that is susceptible to HPNS. We must conclude that the structure of the nervous system is modified in a unique way for a life at high pressure.

IV. Epilogue: Mysteries of the Deep

Our understanding of the physiology of diving in marine mammals is still elementary. These animals have adapted to some of the most extreme conditions on the planet. What we can learn from them about hypoxia and pressure is of much intellectual interest as well as of clinical significance. In addition to the brief summary presented, there is a host of other adaptations not mentioned and

in some cases not studied. Some of these are, blood and muscle interactions under extreme hypoxia, acoustical and visual sensing under the extreme conditions of depth where pressure is intense, the cold is penetrating, and light from the surface is at times nil. Many organisms have adapted to a life under these various conditions, but marine mammals commute to the depths, and where they excel is in their adaptability to rapid changes in these extremes as they move from the conditions at the interface of air and water to those of several hundred meters to even a few kilometers beneath the surface.

Dugong *Dugong dugon*

HELENE MARSH

The dugong (*Dugong dugon*) looks rather like a cross between a rotund dolphin and a walrus. Its body, flippers, and fluke resemble those of a dolphin without a dorsal fin. Dugongs can be difficult to distinguish from dolphins in the wild, especially as they often occur in muddy water. They surface very discreetly, often with only their

nostrils showing above the water. Dugongs tend to move more slowly than dolphins and lack a dorsal fin. The Dugong's head looks somewhat like that of a walrus without the long tusks. Growing to a length of up to about 3m, the dugong is the only extant plant-eating mammal that spends all its life in the sea. The other sea cows (or sirenians), the three species of manatee, all use fresh water to varying degrees (Reynolds and Odell, 1991).

I. Characteristics and Taxonomy

Adults are gray in color but often appear brown from the air or from a boat. Older “scarback” individuals may have a large area of unpigmented skin on the back above the pectoral fins. The dugong's head is distinctive with the mouth opening ventrally beneath a broad, flat muzzle. The tusks of mature males and some old females erupt on either side of the head. The eyes are small and not prominent. Externally the ears consist of only small openings, one on either side of the head. The flippers are short and, unlike those of the West Indian and West African manatees, lack nails. There are two mammary glands, each opening via a single teat situated in the “armpit” or axilla. The mammarys are somewhat reminiscent of the breasts of human females, a similarity which probably explains the legendary links between mermaids and sirenians. Hindlimbs are absent. Unlike manatees, which have a paddle-shaped tail, the tail of the dugong is triangular like that of a whale (Fig. 1).

There is one species of Dugong, *Dugong dugon*, in the family Dugongidae. The only other recent (but extinct) dugongid is *Hydrodamalis*, Steller's sea cow. Dugongidae and Trichechidae (manatees) are the two modern families of Sirenia.

II. Distribution and Abundance

The dugong has a large range. Its extent of occurrence is some 140,000km of coastline across more than 40 countries and includes tropical and subtropical coastal and island waters from East Africa to Vanuatu, between about 26° and 27° north and south of the equator (Marsh, 2006). Timed depth recorders show that dugongs spend most of their time feeding in shallow water less than 10m deep (Chilvers *et al.*, 2004), suggesting a potential area of occupancy of more than 125,000km². The dugong's historic distribution was broadly coincident with the tropical Indo-Pacific distribution of its seagrass food plants. It is believed that throughout most of its range outside Australia and the Arabian region, the dugong is currently represented by relict populations separated by large areas where it is close to extinction or extinct. The degree to which dugong numbers have dwindled, and their range fragmented, is not known. It is encouraging that dugongs still seem to be present at the high latitude limits to their range, Okinawa Japan, Mozambique, Shark Bay, and Moreton Bay Australia, New Caledonia, and Vanuatu.

Over most of its range, the dugong is known only from incidental sightings, accidental drownings, and the anecdotal reports of fishermen. However, within Australia, extensive aerial surveys have resulted in a more comprehensive knowledge of dugong distribution. A significant proportion of the world's dugongs is found in northern Australian waters from Moreton Bay in the east to Shark Bay in the west. Dedicated aerial surveys of dugong populations in Australian waters indicate that dugongs are the most abundant marine mammal in the inshore waters of northern Australia. Some areas of suitable habitat have not been surveyed. Nonetheless, the available population estimates sum to about 85,000 dugongs (Marsh *et al.*, 2002, 2003). This accuracy of these estimates is unknown as there is still uncertainty about the correction factor used for the number of animals that are not available to observers due to water turbidity.

Figure 1 Gentle vegetarians, dugongs often frequent muddy near-shore and estuarine waters that make it hard to positively identify them. Slow moving and lacking any hint of a dorsal fin, dugongs can be confused with dolphins, especially at a distance.

III. Ecology

Dugongs are mostly seagrass specialists, uprooting whole plants when they are accessible, leaving long serpentine furrows depleted of seagrass in seagrass meadows. When the whole plant cannot be uprooted, dugongs feed only on the leaves. Dugongs forage for the rhizomes of some seagrasses, presumably because seagrass rhizomes tend to have higher starch concentrations than seagrass leaves, which tend to be higher in nitrogen. Dugongs switch between species of seagrasses as their availability changes. The preferred seagrasses are relatively low in fiber, high in available nutrients such as nitrogen and starch, and easily masticated. Experiments simulating dugong grazing indicate that feeding dugongs alter both the species composition and the nutrient qualities of seagrass communities. Like large terrestrial herbivores, dugongs can maintain grazing lawns. If dugongs become locally extirpated, seagrass meadows are likely to deteriorate as dugong habitat. Dugongs also eat invertebrates, both incidentally and deliberately, especially in winter at the high latitude limits to their range.

Dugongs frequent coastal waters. Major concentrations of dugongs tend to occur in wide shallow protected bays, wide shallow mangrove channels, and in the lee of large inshore islands where there are sizable seagrass beds. Dugongs are also regularly observed in deeper water further offshore in areas where the continental shelf is wide, shallow, and protected. This distribution reflects that of deepwater seagrasses. Dugong feeding scars have been observed at depths of up to 33 m in seagrass beds off northeastern Queensland, however, evidence from timed depth recorders deployed on 15 dugongs caught in northern Australia, indicate that dugongs spend about half of their daily activities within 1.5 m of the sea surface and more than 70% of their time less than 3 m from the sea surface.

Dugongs may be short of food for several reasons, including habitat loss, seagrass dieback, decline in the nutrient quality of available seagrass, or a reduction in the time available for feeding due to disturbance from boat traffic. Experience from various parts of northern Australia suggests that episodic losses of hundreds of square

kilometers of seagrass are associated with extreme weather events such as some cyclones and floods. For example, approximately 1000 km² of seagrass was lost in Hervey Bay in Queensland in 1992–1993, because of high turbidities resulting from flooding of local rivers and runoff turbulence from a cyclone. Such events can cause extensive damage to seagrass communities through severe wave action, shifting sand, adverse changes in salinity, and light reduction. Dugongs respond to large-scale seagrass dieback by using at least two strategies (1) move away from the affected area, and/or (2) postpone breeding. Episodic seagrass diebacks occur relatively frequently in some regions and this frequency may be increased by climate change. Thus it will be imperative to consider seagrass diebacks in marine planning and dugong management.

IV. Behavior and Physiology

Knowledge of the social behavior of dugongs is rudimentary. The habits and habitats of dugongs make them difficult to observe and the lack of distinct size classes or obvious sexual dimorphism limits the data obtained from direct observation. The only definite long-lasting social unit is the cow and her calf. Most dugongs are sighted in groups of one or two animals. Large aggregations of up to several hundred animals are regularly seen at some locations but the composition of such groups appears fluid. Despite this gregariousness, little is known of the structure and function of dugong herds. Recent observations of focal animals in dugong herds in relatively clear water using a blimp-mounted video camera indicated that dugongs change their nearest neighbor every few minutes. One of the functions of herds seems to be maintaining the seagrass meadow at the stage favored by dugongs.

As with many other mammals, the mating behavior of dugongs seems to vary with location. Mating herds have been observed at several locations along the Queensland and Northern Territory coasts. In these herds, splashing and fighting precede mating. The presumed female swims, turns, twists, and thrashes as she attempts to escape from her persistent entourage. Members of this entourage engage in bouts of violent fighting before attempting to mount the female in a form of pack rape (Fig. 2). In contrast, in Shark Bay, Western Australia, presumed male dugongs defend mutually exclusive territories in which unique behaviors are displayed in order to attract females. It is not known whether this behavior occurs elsewhere in the dugong's range.

Seventy dugongs were fitted with satellite PTTs and/or GPS transmitters in subtropical and tropical waters of Queensland and the Northern Territory, Australia (Sheppard *et al.*, 2006). Most movements have been localized to the vicinity of seagrass beds and seem to be commuting movements dictated by the tide. Twenty-eight of the 70 dugongs were also fitted with timed depth recorders. The dugongs were tracked for periods ranging from 15 to 551 days and exhibited a large range of individualistic movement behaviors; 26 individuals were relatively sedentary (moving <15 km) while 44 made large-scale movements (>15 km) of up to 560 km from their capture sites. Male and female animals, including cows with calves, undertook large-scale movements. The body lengths of these dugongs ranged from 1.9 to 3 m. At least some of the movements were return movements to the capture location, suggesting that such movements are ranging rather than dispersal movements. Solitary individuals or small groups of dugongs are occasionally recorded in the waters of isolated oceanic islands, such as the Seychelles and Cocos (Keeling) Islands after years of apparent absence, suggesting that dugongs are capable of crossing ocean trenches.

Figure 2 Part of a mating herd of Dugongs. Several males are attempting to embrace the female and mate with her. Drawing by Lucy Smith, reproduced from Bryden et al. (1993), with permission.

V. Life History

Dugongs are long lived with a low reproductive rate, long generation time, and a high investment in each offspring. Like the teeth of other marine mammals, dugong tusks accumulate “growth layer groups” that are used to estimate age, rather like the growth rings of a tree. The oldest dugong whose tusks have been examined for age determination was estimated to be 73 years old when she died. Females do not bear their first calf until they are at least 6 and up to 17 years old. Gestation is approximately 13 months. The usual litter size is one. The calf suckles for 18 months or so and the period between successive births is very variable; estimates range from 3 to 7 years. Dugongs start eating seagrasses soon after birth and grow rapidly during the suckling period. Population simulations indicate that a dugong population is unlikely to be able to increase more than 5% per year, making the dugong highly susceptible to overexploitation by humans.

VI. Interactions with Humans

Dugongs are vulnerable to human impacts because of their life history and their dependence on seagrasses that are restricted to coastal habitats, which are often under pressure from human activities. The sustainable level of anthropogenic mortality is likely to be in the order of about 2% of the female population per year. This rate will be lower in areas where their reproductive rate has been reduced by food shortage.

Accidental entangling in gill and mesh nets set by commercial fishers is considered to be a major, but largely unquantified, cause of dugong mortality in most countries in the dugong’s range. Shark nets set for bather protection have been another source of dugong mortality in Queensland, Australia. Between 1962 and 1999, shark nets set on swimming beaches in Queensland netted some 800 dugongs. The rate of decline in the catch per beach in the shark nets over this 40-year period averaged about 8% per year. If the shark net catches are a reliable index of the overall decline in the dugong population from all causes, the population of dugongs along the urban coast of Queensland in the mid-1990s was only a small fraction of that in the 1960s.

Triggered by the evidence of dugong decline, their statutory responsibilities and more generic conservation concerns, the relevant management agencies are attempting to address all known human impacts on dugongs along the urban coast of Queensland

between about 15° 30’S and 28°S by a comprehensive series of management interventions. These initiatives include generic initiatives to protect the marine environment such as the establishment and rezoning of an extensive series of large-scale multiple use marine protected areas, especially the 348,000km² Great Barrier Reef World Heritage Area, and interventions to improve water quality. In addition, there have been a series of more dugong-relevant initiatives including (1) banning the commercial dugong oil industry in the 1960s; (2) partnerships between management agency staff and indigenous traditional owners to develop a mutually acceptable, legal framework for sustainable dugong hunting at culturally relevant scales; (3) the replacement of shark nets by baited hooks at most locations; (4) the establishment of Dugong Protection Areas in the Great Barrier Reef Region and Hervey Bay in 1997; (5) voluntary vessel lanes and/or speed restrictions to protect dugongs from vessel strikes in several major dugong habitats; (6) a review of the use of the herbicide diuron, which has been detected in both dugong tissues and the sediments associated with seagrass beds; (7) a marine wildlife carcass salvage program; and (8) a dugong research strategy which includes a dugong monitoring program based on aerial surveys. The results of 20 years of aerial surveys suggest that the management intervention has been successful and that dugong numbers are now stable at the spatial scale of the entire urban coast of Queensland although numbers in individual bays fluctuate in response to changes in the quality of the seagrass habitat.

Dugong meat tastes like beef or pork. Dugong hunting for food and oil was once widespread throughout the dugong’s range and still occurs in at least 31 countries. Today the dugong is legally protected in most countries. Members of Aboriginal and Torres Strait Islander communities in northern Australia and villagers in Western Province in Papua New Guinea are still permitted to hunt and modeling evidence suggests that the level of hunting is not sustainable in Torres Strait between Australia and Papua New Guinea and along the adjacent remote coastal waters of Cape York. The indigenous peoples of northern Australia and Papua New Guinea consider dugong hunting to be an important expression of their cultural identity and dugong meat is still an important food source in some remote regions of northern Australia and Papua New Guinea. Dugong oil extracted by boiling the parts of the dugong not used for food, such as the head, is used as a panacea for aches, pains, and many illnesses. A dugong yields about 35% of its body weight in usable meat and fat and on average approximately 18l of oil.

It is increasingly recognized that arrangements to insure that indigenous hunting of dugongs is sustainable will require the active participation of relevant indigenous communities. The Australian Government has recently formalized this approach in a 2005 policy entitled “Sustainable harvest of marine turtles and dugongs in Australia—A national partnership approach.”

The World Conservation Union (IUCN) classifies the dugong as vulnerable to extinction at a global scale on the basis of anecdotal evidence of declines in its abundance throughout most of its range. In recent years—there has been an encouraging and widespread increase in interest in dugong biology and management. Nonetheless, the difficulties of ameliorating adverse influences on dugongs in the highly populated developing countries that comprise most of its range emphasize the importance of the remote regions of tropical Australia to dugong conservation.

It is vital that dugong management is coordinated at a biologically appropriate scale, which dugong movements suggest is hundreds of kilometers. The October 2007 signing of a memorandum of understanding concerning the conservation and management of dugongs and their habitats throughout their range is a very encouraging first step to resolving the mismatch between the biological and the geopolitical scales at which dugong management has occurred to date.

Dusky Dolphin

Lagenorhynchus obscurus

KOEN VAN WAEREBEEK AND BERND WÜRSIG

I. Characteristics and Taxonomy

The dusky dolphin was described by John W. Gray in 1828 from a stuffed skin and a single skull shipped to the British Museum from the Cape of Good Hope. No subspecies are recognized. Because of their morphological similarities, the stocky dusky dolphin from the Southern Hemisphere and the Pacific white-sided dolphin, *Lagenorhynchus obliquidens*, from the northern Pacific Ocean are considered phylogenetically closely related species despite the absence of a fossil record. Some researchers suggested that *L. obliquidens* could almost equally well be regarded as a subspecies of the dusky dolphin. However, a close scrutiny of morphological and life history parameters does not support this premise. Cytochrome *b* sequence analysis is consistent with the “sister species” hypothesis; the divergence date is estimated at 1.9–3.0 million years ago (Cipriano, 1997; Cassens *et al.*, 2003).

The smallish dusky dolphin can be recognized by its short beak and the bluish black to dark gray of the dorsal field contrasting with the white belly, as well as the light gray of the thoracic patch and two-pronged flank patch. The dark lips and eye patch also stand out. The falcate dorsal fin is two-toned with a dark leading edge (Fig. 1). Unlike in *L. obliquidens*, the linear dorsal flank blaze does not extend farther anteriorly than about mid-body. Heavily pigmented specimens are found off Peru and Argentina. The holotype of *Delphinus fitzroyi* (Waterhouse, 1838) caught off Argentina from Darwin’s ship *Beagle* was such a melanistic form. Various cases of anomalous, piebald pigmentation are probably equivalent to so-called partial albinism. Tooth counts range for both upper and lower half jaw 26–39, with some differences between populations.

Both males and females off Peru reach sexual maturity at about 175 cm; average adult size is approximately 185 cm, while the largest two known individuals measured 211 (male) and 205 cm (female), based on 693 specimens. Dusky dolphins rarely exceed 100 kg in weight. No significant dimorphism is present in morphology, including coloration patterns, except that in adult males the dorsal fin is more curved, has a broader base, and a greater surface area than in females, presumably a secondary sexual characteristic. Dusky dolphins from southwestern Africa and New Zealand are some 8–10 cm shorter than Peruvian specimens of both sexes, which supports a conclusion of discrete populations based on cranial variability and molecular genetics studies. Mature skulls from South West Africa and New Zealand are on average 8.5% (3.1 cm) shorter than skulls from Peru and Chile (Van Waerebeek, 1992a; 1993a, b; Cassens *et al.*, 2003, 2005).

Possible hybrids have been described between a dusky dolphin and a southern right whale dolphin, *Lissodelphis peronii* (Yazdi, 2002) and between a dusky dolphin and a long-beaked common dolphin, *Delphinus capensis* (Reyes, 1996). Analysis of nine microsatellite loci and two mitochondrial gene fragments suggest that dusky dolphins from Argentina and South West Africa recently separated (*ca.* 2000 generations ago) from an ancestral Atlantic population and since then diverged without considerable gene flow (Cassens *et al.*, 2005). There are low levels of genetic differentiation among most populations. Only the Peruvian dusky dolphin stock is highly differentiated, especially at mitochondrial loci, suggesting that major

Figure 1 A dusky dolphin in a somersault leap off New Zealand. This acrobatic leap type indicates a high behavioral social level by the individual, and very likely its group. Photo by B. Würsig

fluctuations in its population size have led to an increased rate of genetic drift. No genetic subdivision was detected within the Peruvian and African stocks (Cassens *et al.*, 2005). Nor was any subdivision among regions found in New Zealand, where at least one, if not two, historical population expansions were proposed (Harlin *et al.*, 2003).

II. Distribution and Abundance

Dusky dolphins are distributed around South America, from northern Peru south to Cape Horn and from southern Patagonia north to about 36°S, including the Falkland Islands (Malvinas); off southwestern Africa from False Bay, South Africa to Lobito Bay, Angola; and in New Zealand waters, including off Chatham and Campbell Islands. Populations of unknown size inhabit waters surrounding oceanic islands of the Tristan da Cunha Archipelago in the mid-Atlantic, the Prince Edward Islands, and Crozet and Amsterdam Island in the southern Indian Ocean (Van Waerebeek *et al.*, 1995). The species has been recently confirmed from southern Australia but seems to be rare there (Gill *et al.*, 2000). What appeared to be a possible distribution gap between 36–46°S off Chilean Patagonia (Van Waerebeek, 1992b) can be attributed to minimal observer effort, as sightings are now confirmed from that region. There is increasing evidence that dusky dolphins may occasionally venture into waters of the Southern Ocean South of the Antarctic Polar Front (Van Waerebeek *et al.*, in press).

In a 15,000 nmi² fishing area off Argentina, abundance was estimated as 7252 dolphins (Dans *et al.*, 1997a). No abundance estimates are available at the scale of an entire population. However, dusky dolphins are the most common small cetaceans on the Patagonian Shelf (Schiavini *et al.*, 1999) and one of three most abundant species in Peru's coastal waters.

Sightings and morphological and molecular genetic evidence suggest a disjunct distribution across oceans and the existence of discrete stocks confined to continental shelves and oceanic island groups, with indication of some level of male dispersal along coasts (Van Waerebeek *et al.*, 1995; Cassens *et al.*, 2003, 2005).

III. Ecology

Dusky dolphins inhabit predominantly neritic waters above continental shelves and slopes but can also be found over deep water if close to continents or islands. These coastal habits explain the discontinuous distribution across the temperate southern ocean and the reproductive isolation of populations. They seem to prefer waters with sea-surface temperatures of 10–18°C (Brownell and Cipriano, 1999), but lower temperatures have been reported.

Dusky dolphins over the extensive continental shelf off Argentina forage cooperatively on small schooling fishes during the day. On the east coast of New Zealand, where deep oceanic waters reach close to shore, animals typically feed at night on prey associated with the deep scattering layer (Würsig *et al.*, 1997). Some of these same dolphins, identified by natural marks on their bodies, have been found to feed during the day in the Marlborough Sounds on the northern edge of the South Island of New Zealand, reinforcing a generally held belief that these animals adapt behaviorally relative to habitat and prey availability patterns (Markowitz *et al.*, 2003).

Prey items include a wide variety of fish and squid species. Dominant are small schooling fishes such as anchovies, lantern fishes, pilchards, and sculpins, but also hakes, horse mackerel, hoki, red cod, and a large number of squid species, i.e., of the genera *Notodarus*, *Todaroides*, and *Loligo* amongst others. The 80% anchovy diet component (by weight) found by McKinnon (1994) in Peru, suggesting an almost exclusive dependence on this prey, is now understood to have been biased by localized and short-term sampling. New evidence indicates that Peruvian dusky dolphins are opportunistic feeders that will readily feed on other prey species where and when anchovy is not abundant. In New Zealand, dusky dolphins feed on a variety of fish and squid species; lantern fish, hoki, and squid are predominant (Cipriano, 1992; Würsig *et al.*, 1997). In a small sample from Argentina, anchovy represented 46% by weight of the diet (Alonso *et al.*, 1998).

Killer whales (*Orcinus orca*) are occasional predators, and dusky dolphins within about 5 km of shore, when killer whales approach, will enter very shallow water to avoid them (Würsig and Würsig, 1980). In Golfo Nuevo, Argentina, mothers with calves and smaller groups, as well as groups exhibiting resting behavior, were found in the shallowest waters, supporting the hypothesis that movement to shallower water is related to increased safety for individuals (Garaffo, 2007). This is also the case for dusky dolphins in open ocean New Zealand waters (Weir, 2007).

Prevalence of helminth parasites in dusky dolphin is reported for Peruvian and Argentine stocks only. *Anisakis simplex*, *Nasitrema* sp., *Phyllobothrium delphini*, *Braunina cordiformis*, *Hadwenius* sp., and *Pholeter gastrophylus* are common, while *Crassicauda* sp., *Halocercus* sp., and *Corynosoma australe* are rare, with some significant differences between the Pacific and Atlantic populations (Van Waerebeek *et al.*, 1993; Dans *et al.*, 1999). The epidemiology of diseases has been studied in some detail in Peruvian dusky dolphins. Endemic presence was established for poxvirus, papillomavirus, a herpes-like virus, and *Brucella* sp. Genital diseases in a large sample ($N = 502$) included ovarian cysts, ovarian, and uterine tumours, vaginal calculi, abscesses of the broad ligament and testicular lesions of unknown aetiology (Van Bresseem *et al.*, 1994, 2000, 2006; Van Bresseem and Van Waerebeek, 1996).

IV. Behavior and Physiology

Although dusky dolphins can move over great distances—a range of 780 km is confirmed—no well-defined seasonal migration patterns are apparent. However, the Argentina and New Zealand populations exhibit inshore–offshore movements both on a diurnal and on a seasonal scale (Würsig *et al.*, 1997).

Surface feeding activity typically happens in large groups, accompanied with extensive aerial display. It is believed that such aerial activity helps synchronize cooperative foraging and after-feeding social (including sexual) activities (Würsig and Würsig, 1980; Würsig *et al.*, 1989). Individual dolphins alter their foraging strategies and prey types on a seasonal/regional basis (Markowitz *et al.*, 2003; Würsig *et al.*, 2007).

In New Zealand, during the morning, dolphin groups are spread out, leaping often, and are closest to shore. Around midday, the dolphins tend to rest in tight groups. They then spread out again and move offshore in late afternoon/early evening. Groups of hundreds of individuals exhibit coordinated travel and noisy leaps. At night, the dolphins forage (and presumably feed) in small subgroups at the shallowest dive depths but individually dive down to as deep as 130 m (Würsig *et al.*, 2007). In coastal Peru, dusky dolphins are commonly seen together with long-beaked common dolphins in large feeding aggregations of many hundreds or thousands of individuals, which in turn attract thousands of guano-producing seabirds (cormorants, pelicans, boobies) that dive among the dolphins. These spectacular aggregations can be observed from shore-based vantage points, especially in winter. Alternatively, large numbers of dolphins may be spread out over a huge area, in what appears to be a single meta-group travelling in the same direction. However, circumstances of gillnet entanglement suggest that Peruvian dusky dolphins may also engage in nocturnal foraging. Dusky dolphins sometimes associate with short-beaked common dolphins, *Delphinus delphis*, off New Zealand and with southern right whale dolphins, *L. peronii*, in Namibia. School sizes vary from only 3–5 individuals to the more common dozen or so, and occasionally up to about 2000 (the latter off Kaikoura, New Zealand, in April–May; Markowitz, 2004). Most of the species' echolocation signals have bimodal frequency spectra with a low-frequency peak between 40 and 50 kHz and a high-frequency peak between 80 and 110 kHz. The wave form and spectrum of the echolocation signals are similar to those of other dolphins measured in the field (Au and Würsig, 2004).

V. Life History

In Peru and New Zealand, most births occur in late winter (August, September, and October), but a few neonates appear during other seasons. Growth rate of fetuses is 0.261 cm/day. Neonatal length of Peruvian dusky dolphins averages 91 cm at 9.6 kg. Gestation lasts for 12.9 months, followed by 12 months of lactation and a resting period of 3.7 months. The size of adult testes increases, reaching a maximum in September and October, in synchrony with the peak period of conception (Van Waerebeek and Read, 1994). The largest single-testis mass was 5120 g, proportionately among the highest of any mammal. Very large testes size, relative lack of sexual dimorphism, and apparent lack of aggressive behavior between males suggest a promiscuous mating system and sperm competition (Van Waerebeek, 1992a).

In Peru, sexual maturity for females is estimated at 4.3–5 years and for males at 3.8–4.7 years. The lower values, which are the most recent, possibly indicate a density-dependent response to heavy exploitation (Chávez-Lisambarth, 1998) or an adaptation to an unstable environment with recurring El Niño–Southern Oscillation (ENSO) events. Anomalous dentine deposition during El Niño years

Figure 2 In the early 1990s thousands of dusky dolphins were landed in Peruvian ports each year. Photo by K. Van Waerebeek

off Peru may reflect low foraging success. Female Argentinean dusky dolphins mature at 6.3 years of age and, in contrast with Peru and New Zealand, summer is the prime birth season (Dans *et al.*, 1997b).

VI. Interactions with Humans

In the absence of global abundance estimates, the status of the dusky dolphin remains indeterminate. Unknown numbers are caught in gill nets in New Zealand waters, although current catches have dropped from those of the 1970s and 1980s. Some 200 dusky dolphins were incidentally captured off Kaikoura in 1984 (Brownell and Cipriano, 1999). Off Argentina, from 1982–1994, a variable number of Patagonian dusky dolphins, typically a few hundred each year, died in midwater trawls (Dans *et al.*, 1997a). Arguably of greatest concern are fishery-related mortality levels in Peruvian coastal waters, where both directed and accidental entanglements in artisanal drift nets, as well as harpooning, have killed thousands each year since 1985. In the 1991–1993 period, an estimated 7000 animals per annum were captured (Fig. 2), an exploitation thought to be unsustainable (Van Waerebeek and Reyes, 1994). In 1994, in a single port an estimated 1272 (SE 227) dusky dolphins were landed in a 7-month period (Van Waerebeek *et al.*, 1997). Although the second (1994) ban on the landing and sale of dolphins is believed to have reduced direct captures and landings in Peru, no measures were adopted to address bycatch, and unknown numbers of dolphins continue to be killed in fisheries. Indications are that the trend of a significant decline in the proportion of dusky dolphins in the overall cetacean take from 77.5% (in 1985–1990) down to 52.8% (1991–1993) has continued. Nowadays, captured dolphins are routinely used as shark bait in both longline and drift gillnet fisheries, and in at least in some ports dolphin meat is landed clandestinely and sold in public markets. While legislation has helped to curb visible trade, the lack of inspections, especially on boats at sea, has failed to stop the exploitation.

Only a few individuals have been exhibited, in aquaria in New Zealand, South Africa, and Australia, largely because dusky dolphins adapt rather poorly and have failed to reproduce successfully in captivity. There is increasing concern about impacts of dolphin-based tourism in New Zealand and Argentina, and several studies of the problem have been conducted. A moratorium on dusky dolphin tourism in New Zealand, established in 1999, is currently under review (Würsig *et al.*, 2007).

E

Eared Seals

Otariidae

ROGER L. GENTRY

The Otariidae, or “eared seals,” evolved around the rim of the North Pacific Ocean 11–12 million years ago and subsequently spread into the Southern Hemisphere. Around three million years ago, sea lions diverged from the fur seals that preceded them. The two are distinguishable by their pelage. Sea lions have a single coat of hair whereas fur seals have stiff outer guard hairs emerging from a dense, thick layer of fine underfur, which is waterproof, thereby providing thermoregulation.

Otariids comprise 16 species (Table I). All breeding sites they use are between 60°S and 55°N latitude. Eight species breed in temperate latitudes, two in subpolar, and two in equatorial regions (King, 1989). The sea lions use only temperate or equatorial regions, but fur seals use all three. No species of otariids mate on ice, but at least two encounter snow during breeding and pup rearing. Four species mate on the shores of deserts where the climate is ameliorated by fog or cool ocean winds. Only two species of fur seals and three species of sea lions still inhabit the North Pacific waters where otariids evolved. Otariids never occupied the North Atlantic Ocean, perhaps because

the Central American seaway was closed when the family dispersed into the Southern Hemisphere.

Otariids use both island and mainland sites, but at present, island sites predominate worldwide. Islands offer a combination of freedom from terrestrial predators (including humans), cooling winds for THERMOREGULATION, and closer access to offshore prey concentrations than most mainland sites provide. The preferred substrate for mating is rock or sand, rarely soil or mud. All species mate on open ground except some small populations of Hooker’s sea lions (see Table I for Scientific names), which use forested sites.

I. Unique Traits

Otariids are truly amphibious in that they feed at sea but, mate and rear their young on land. Therefore, their anatomy strikes a balance between functioning in air and underwater.

Unlike other pinnipeds or cetaceans, otariids have an external ear flap (hence their scientific and common names), an air filled auditory canal, and a middle ear structure very similar to a terrestrial ear. Otariids hear best in the frequency range of 2–12kHz. In contrast, dolphins and porpoises that rely on a sophisticated echolocation system to feed hear best from 8 to 90kHz or higher. This difference suggests that otariids either do not echolocate or do so in a rudimentary way.

Laboratory tests have demonstrated that sea lions have excellent visual acuity at low-light levels. Large eyes, an all-rod retina, and a well-developed reflective layer (tapeta lucidum) account for this ability (see Vision, this volume). These features suggest that eared seals feed visually in the dark (at night, in deep water, or both). However, they maintain good visual acuity in air in bright light by being able to close down their pupil to a pinhole. Well developed, highly enervated vibrissae may provide tactile cues that combine with visual cues for feeding in the dark.

Locomotion also points out the balance between their terrestrial and aquatic lives. Unlike phocids, otariids can rotate their rear flippers forward and walk or run using all four limbs (see Locomotion, Terrestrial, this volume). They can outrun a human over slippery rocks. Using their chin and their long, strong front flippers, they can climb steeply sloping surfaces, which means they can take advantage of broken, rocky terrain for BREEDING SITES. They swim using the

TABLE I
Otariids, Eared Seals

Common name	Scientific name	Location	Approximate numbers	Trend
Northern fur seal	<i>Callorhinus ursinus</i>	Subpolar	1,400,000	Stable
Antarctic fur seal	<i>Arctocephalus gazella</i>	Subpolar	3,000,000	Increasing
Sub-antarctic fur seal	<i>A. tropicalis</i>	High temperate	>310,000	Increasing
Juan Fernandez fur seal	<i>A. philippii</i>	Temperate	18,000	Increasing
Guadalupe fur seal	<i>A. townsendi</i>	Temperate	>7000	Increasing
Cape fur seal	<i>A. pusillus pusillus</i>	Temperate	1,700,000	Increasing
Australian fur seal	<i>A. pusillus doriferus</i>	Temperate	>60,000	Stable
South American fur seal	<i>A. australis</i>	Temperate	>285,000	Increasing
New Zealand fur seal	<i>A. forsteri</i>	Temperate	135,000	Increasing
Galapagos fur seal	<i>A. galapagoensis</i>	Temperate	40,000	Fluctuating
Galapagos sea lion	<i>Zalophus wollebaeki</i>	Temperate	40,000	Fluctuating
California sea lion	<i>Z. californianus</i>	Temperate	>188,000	Increasing
Japanese sea lion	<i>Z. japonicus</i>	Temperate	Extinct	
Steller sea lion	<i>Eumetopias jubatus</i>	High temperate	>76,000	Decreasing
Hooker’s sea lion	<i>Phocarctos hookeri</i>	Temperate	13,000	Stable
Australian sea lion	<i>Neophoca cinerea</i>	Temperate	12,000	Stable
Southern sea lion	<i>Otaria flavescens</i>	Temperate	275,000	Decreasing

front flippers powered by well-developed pectoral muscles, while the rear flippers trail behind and are used only in turning and stopping. Otariids are quick, graceful swimmers that can leap free of the water and “porpoise” to breathe while swimming fast. They can execute a forward somersault while surfing.

Laboratory tests have also shown that otariids have well-developed cognitive abilities. They can perform complex learning tasks and have excellent memories, abilities that are perhaps related to their role as high-level consumers which depend on patchy prey to survive.

Otariids must reduce heat loss to cold ocean waters, but simultaneously have the ability to lose body heat while on land in the sun. A **BLUBBER** layer (abetted by the underfur in fur seals) reduces heat loss to water. To promote heat loss on land, otariids use shade, immersion in tide pools or spray, flipper waving or panting. At least one species urinates on its rear flippers for evaporative cooling. Only the flippers are naked, so evaporative cooling from sweat is ineffective. A few animals drink seawater, but usually only at the beginning of fasting at the start of the breeding season. As in **VISION** and **HEARING**, the primary adaptations for thermoregulation and water balance seem to be for life at sea, with secondary adaptations for life on land.

II. Diet

Otariids tend to be generalist feeders, taking a wide variety of prey. For example, the northern fur seal takes at least 63 species of prey over its full range. Fur seals and sea lions tend to feed on dissimilar prey. Fur seals often feed in deep water beyond the continental shelf break on small squid or fish, especially myctophids (lantern fish). The Antarctic fur seal takes krill as well as fish, and the New Zealand fur seal supplements fish with rock lobster. Sea lions tend to feed on or near the continental shelf and tend to take larger or more mature stages of prey than are used by fur seals (e.g., adult halibut). Hooker’s and Australian sea lions specialize in squid and octopus, which are hunted on the bottom and under rocks. Several species of sea lions are known to eat the young of other seals, one species exhibits cannibalism, and several are known to eat penguins or other birds. For an as yet unexplained reason, otariids (especially sea lions) intentionally swallow fist-sized rocks.

III. Maternal Strategy

Otariids differ from phocids in that the females of all species continue to feed while they are lactating (see Pinnipedia Physiology, this volume). Otariid mothers capture prey and within a few days time transfer the energy it contains to their young on shore in the form of milk fat. They make a series of brief, regular nursing visits to shore from birth to weaning, an interval that varies with latitude. In contrast, most phocid mothers gather energy from prey for several months, lay it down as extensive blubber reserves, and then deliver it to their young in a single, prolonged nursing bout that may last a few weeks at most.

Feeding during lactation has widespread implications for otariid natural history. Eared seal mothers are restricted in how long they may be absent for foraging by the limited fasting abilities of their newborn pups. To meet this restriction, mothers must find abundant prey of a given type close enough to the colony that they can commute between the two and still experience a net energetic gain for themselves and their young. The number of sites that meet these conditions and that have the proper terrain, cooling winds, absence of predators, and other factors are relatively few. Otariids tend to gather in large numbers (up to hundreds of thousands) on the few sites in the world that meet these specific restrictions and to form dense aggregations there. Therefore, largely because of maternal commuting, otariids tend to breed in a few large dense colonies that are most often on

islands. Most phocids do not commute for foraging and therefore tend to breed dispersed as pairs or in small numbers on a large number of dispersed sites. Among phocids, only elephant seals (*Mirounga* spp.) form colonies that superficially resemble those of otariids (few sites, large dense groups).

The details of otariid maternal strategies vary considerably according to the local foraging environment. As a generalization, the duration of the maternal feeding trip, duration of nursing visits, and fat content of the milk all increase with increasing distance to feeding locations. However, the amount of milk fat and its delivery schedule are both constrained by the need to wean the young at a particular age. At high latitudes this age is 4 months, which allows a mother and young time to migrate to lower latitudes before winter begins. At temperate latitudes the age is 9–12 months, which allows females to bear young annually without having to support two simultaneously. The two species at the equator are not limited by season, but by the rate at which mothers can bring their pups to the size needed for independent foraging. In good years, Galapagos fur seal mothers may achieve this in 12 months. However, when periodic El Nino events disrupt the food supply, they may not achieve it until age 3 years.

IV. Reproductive Adaptations

Otariids and phocids both possess a postpartum estrus (Riedman, 1990). The uterus is Y shaped with two “horns,” one of which holds the full-term fetus while the other prepares to receive the new blastocyst soon after birth. In all but one species of otariid, females enter estrus and mate during the 4- to 11-day perinatal nursing period. (The exception is the California sea lion, which mates about 23 days postpartum, well beyond its perinatal nursing period.) Because the perinatal period may be the females’ longest single shore visit of the year, estrus at that time gives adult males the longest uninterrupted chance to mate with them. The process is quite efficient; pregnancy rates may exceed 93% for some age groups of females.

Dense gatherings have produced the most striking feature of the otariids, namely sexual dimorphism in body size and appearance (Fig. 1). In each species the adult male is 2–4.5 times the size of the female. Looking across species, there is more dissimilarity in the appearance of males as a group than there is among females as a group. These differences in body size and appearance probably result from the dissimilar selection pressures that the two sexes are under. Unlike females, in which fitness is measured by the quality of the single young they bear, male fitness is measured by the number of offspring produced. This means that males attempt to obtain the largest possible number of mates but females do not. Increased size not only gives males an advantage in fights related to obtaining mates, it also allows them to fast longer and thus remain among estrous females longer than males of smaller size. Male otariids weigh from 200 to 1000 kg and can fast for 12 weeks, although a fast of 4–6 weeks is more common.

V. Mating System

In all species, males defend space on the land sites that females use for giving birth and nursing their young (Riedman, 1990). In two species (California sea lions and Juan Fernandez fur seals) males also partition some of the aquatic areas where females gather. Defending space gives males exclusive reproductive access to all females on that site. Failure to obtain space among females means having low reproductive success because of the characteristics of estrus (see later). In very few cases do males defend the actual females on a site rather than the boundaries around the site they use.

Figure 1 Sexual dimorphism in otariids, note the large male and smaller female (C. Brett Jarrett)

Defended space in otariids should be referred to as territories not as leks. The reason is that, except possibly in the California sea lion, otariid females do not actively choose their mates as in a lek system. Instead, females choose their parturition site and then mate with any nearby male when estrus occurs. Females may use the exact same parturition site for 10 years or more, whereas the males that defend these sites change every breeding season or two.

All otariids are polygynous; average adult sex ratios of up to 10 females per male are common. Although the sex ratio at birth is near unity, males have higher mortality rates during maturation than females, and some males that reach adulthood are excluded from mating by the territorial system, which leaves more mating females than males. The average adult sex ratio is difficult to determine because a variable number of females will be at sea on any given day.

Sexual receptivity in female otariids is usually terminated by the physical act of coitus. For that reason, receptivity may last only minutes per year, and most females (85–90%) copulate only once. No second estrus is known to occur later in the year, even for females that fail to mate immediately postpartum. The advantage to females of a single copulation is that they can dispense with mating and quickly resume feeding to support their young. The advantage to males is that they can inseminate more females with fewer copulations in a shorter period of time. Most virgin females mate on the same grounds as more mature females, but at the end of the breeding season. For these reasons, males that do not acquire territory on traditional pieces of ground at predictable times of year find many fewer mates than males that do.

Female otariids have an open society that features a loose, size-related dominance system. Larger, older, more experienced females generally have more access to favored rest sites, water, or shade than younger, smaller females. However, no evidence has been found for hierarchies of individuals. Also, no evidence has been found for any social bond between adult females, including those between mothers and their previous female offspring. The society is open in the sense that females can enter and leave it frequently without loss of social status. It thus fits with, and may have resulted from, the need of females to forage specific to the needs of their nursing offspring.

Females maintain close spacing while on shore. All sea lions plus the South African fur seal are thigmotactic (seek full body contact with others); spacing in the other species varies seasonally and with the radiant load (less contact on hot days). Despite their close spacing on shore, females are simultaneously aggressive toward each other.

Fights that draw blood are uncommon, but females threaten each other frequently in various ways.

The offspring of otariids are precocial. Some can swim on the day of birth but most defer swimming for a month or more. Sexual dimorphism is evident at birth. In one species (northern fur seal) it exists as early in embryonic development as the sexes can be distinguished. During the lactation period, otariid pups tend to form dense aggregations and to avoid contact with adult males, which may bite and kill any pup that approaches them. Pups engage in play bouts that feature many of the components of adult aggressive behavior, sexual behavior, and prey handling in mixed order. These patterns appear to be innate in that pups born in captivity display behavior that they cannot have witnessed. Sneak suckling, especially in starvelings, occurs probably in all otariids. In some species (Steller's sea lion), some females that lose their pups may actually foster a foreign pup.

Weaning is difficult to observe and document. It has been studied well in only two species (northern and Antarctic fur seals). In both species, most pups leave shore before their mothers, thereby weaning themselves at 4 months, just prior to migrating. In non-migratory species, varying degrees of mother–young conflict exist at weaning, depending on environmental conditions, age at weaning, and presence of younger offspring.

Outside the breeding season, when no adult males are present, weaned juveniles may reside among the females and young. Juvenile females may remain there during the breeding season, but juvenile males are usually excluded from breeding areas and may gather on nearby all-male landing areas. In some areas of the world, several species of seals may mix on these landing areas. Juvenile males spend much time play fighting and occasionally make brief running forays into breeding areas or wait offshore to intercept females departing on foraging trips. Copulations sometimes occur in these circumstances.

VI. Foraging Behavior

Otariids usually only dive deeply when foraging. This summary is based on the dive records for females, which have been studied more thoroughly than males. Most otariids feed in the water column, sometimes over very deep water. Dive depths measured in the field reflect the vertical distribution of the prey more than the physiological limits of the divers. These depths are usually less than 450 m, and dives to more than 200 m are uncommon. Dive durations are usually less than 12 min,

and dives of more than 5–7 min are uncommon. Most dives of otariids (more than 85% for individuals) are aerobic, i.e., the duration of most dives does not exceed the estimated oxygen that animals take down stored in hemoglobin or myoglobin. Diving occurs at all hours, but nighttime diving predominates. The dive depth may change with time of day, suggesting that the otariid is following the daily migration of prey toward the surface at dusk and toward deep water at dawn. There is as yet no evidence of cooperative feeding by otariids (such as group attacks by killer whales), but coordinated group diving has been observed.

VII. Population Trends

Starting in the sixteenth century, otariids were harvested for furs, hides, blubber, various organs, or, in the case of Steller sea lions, vibrissae (for cleaning opium pipes). By the end of the nineteenth century, sealers had obliterated many stocks and reduced many species to near extinction. Stocks recovered throughout the twentieth century in varying degrees. After a long lag time, the Antarctic fur seal recovered at a rate of 10% per year, the highest known for any otariid population. Recovery for most species was nearer 5–7%. The Japanese sea lion is probably extinct. Some populations (Hooker's sea lion, Australian sea lion, see Table I) are small but apparently stable, whereas others are small but growing (Guadalupe and Juan Fernandez fur seals). Two species (Galapagos fur seal and sea lion) experience intermittent declines and recoveries related to El Niño events. The northern fur seal has been declining at various rates from 1956 to the present. The only otariid species presently of concern to managers is the Steller sea lion, which is rapidly declining for as yet unknown reasons. Worldwide, fur seal populations tend to be increasing faster than sea lion populations and outnumber them by an order of magnitude (nearly 7 million fur seals worldwide compared to just over 600,000 sea lions, Table I). The diet and place of foraging differ between the two groups and may explain these differences. It could be the habit of feeding beyond the continental shelf, like a fur seal, that has accounted for the present rapid growth of the California sea lion population.

Earless Seals

Phocidae

MIKE O. HAMMILL

I. Systematics

The family Phocidae, consists of the earless or "true" seals. They are distinguished from sea lions and fur seals (family Otariidae), by the absence of external visible ear pinnae, internal testes, generally larger size and the inability to draw their hind limbs forward under their body when on land (King, 1983).

This latter character, the absence of tusks, and a notched tongue also distinguishes them from the family Odobenidae (walruses).

There has been considerable debate as to whether pinnipeds were diphyletic or monophyletic in origin. The diphyletic view suggests that odobenids and otariids are related to the bears (Ursidae), and that phocids were more closely linked to the otters, weasels, and skunks (Mustelidae). However, a re-evaluation of morphological evidence and the application of molecular techniques supports the monophyletic hypothesis, with pinnipeds descending from arctoid carnivores, a group which includes the bears (Arnason *et al.*, 1995).

The Phocidae can be divided into two sub-families: the Monachinae, with $2n = 34$ chromosomes, consisting of the southern phocids, the southern and northern elephant seals and the monk seals; and the Phocinae, or northern seals, with $2n = 34$ chromosomes (bearded seal, *Erignatus barbatus* and hooded seal, *Cystophora cristata*) and $2n = 32$ chromosomes (in the remaining seven species; Table I). The separation between these two groups has been confirmed in molecular studies, but the relationships among members within the sub-families are uncertain. More recent work indicates that the gray seal (*Halichoerus grypus*) may not be sufficiently separated from the ringed seal to warrant its own genus, and the closer relationship between ribbon and harp seals (*Histiophoca fasciata* and *Pagophilus groenlandicus*, respectively) than of either to the *Phoca* group (Carr and Perry, 1997). This implies that the harp seal should be moved from the genus *Phoca* and retain its old name *Pagophilus groenlandicus*. Support has also been found for grouping the ribbon, harp and hooded together, but the use of karyotypic data as a diagnostic landmark in the phylogenetic analysis, may be sufficient to maintain the separation (Table I).

II. Distribution

Phocids are found throughout all of the world's major oceans except for the Indian Ocean. Twelve species breed on ice, six species breed on land, including the West Indies monk seal, which is probably extinct. The gray seal breeds on both land and on ice (Fig. 1). Among the ice-breeding seals, eight species breed primarily on the pack ice. Four species breed on land-fast ice. Phocids in the Northern Hemisphere have also colonized freshwater areas; these include the harbor seal (*Phoca vitulina mellonae*) in freshwater lakes of northern Quebec; the ringed seal (*Pusa hispida ladogensis* and *Pusa hispida saimensis*) in Lakes Lagoda and Saimaa in Russia and Finland, respectively; and the Baikal seal (*Pusa sibirica*) in Lake Baikal in Siberia. Ringed seals are also frequent in Nettelling Lake on Baffin Island in northern Canada.

Pinnipeds are adapted to marine foraging but must haul out on land or ice for parturition and successful rearing of offspring. Marine adaptations include a thick blubber layer for insulation, modifications in limbs and body shape to improve hydrodynamics and agility, and anatomical and physiological changes to improve diving performance.

III. Ecology

Although young seals do not have to deal with the energetic costs associated with reproduction they must learn to identify and capture sufficient prey for survival and to support growth. Young harbor seals are capable of following their mothers in the water soon after birth, but are unable to duplicate the diving performance of the older female (Beck *et al.*, 2003). As harbor seal pups develop, they develop the ability to control and reduce their heart rate to conserve oxygen while diving. Blood oxygen stores increase quickly, but by the time animals are weaned muscle oxygen stores are still much lower

TABLE I
Members of the Family Phocidae, General Distribution and Breeding Habitat

Common name	Latin name	Subspecies	Distribution	Breeding habitat
Northern Hemisphere				
Gray seal	<i>Halichoerus grypus</i>		North Atlantic	Land, ice breeder
Harp seal	<i>Pagophilus groenlandicus</i>		North Atlantic	Pack-ice breeder
Harbor seal	<i>Phoca vitulina</i>	<i>P.v. vitulina</i>	Atlantic, Pacific Oceans. Arctic regions	Land breeder
		<i>P.v. concolor</i>		
		<i>P.v. stejnegeri</i>		
		<i>P.v. richardsi</i>		
		<i>P.v. mellonae</i>		
Spotted seal	<i>Phoca largha</i>		North Pacific, Chukchi Sea	Pack-ice breeder
Caspian seal	<i>Pusa caspica</i>		Caspian Sea	Fast-ice breeder
Ringed seal	<i>Phoca hispida</i>	<i>P.h. hispida</i>	Arctic regions, Baltic Sea	Fast-ice breeder
		<i>P.h. botnica</i>		
		<i>P.h. ochotensis</i>		
		<i>P.h. krascheninikovi</i>		
		<i>P.h. saimensis</i>		
		<i>P.h. ladogensis</i>		
Hooded seal	<i>Cystophora cristata</i>		North Atlantic	Pack-ice breeder
Bearded seal	<i>Erignathus barbatus</i>	<i>E.b. barbatus</i>	Arctic	Pack-ice breeder
		<i>E.b. nauticus</i>		
Baikal seal	<i>Pusa sibirica</i>		Lake Baikal, Siberia	Fast-ice breeder
Northern elephant seal	<i>Mirounga angustirostris</i>		North Pacific	Land breeder
Ribbon seal	<i>Histiophoca fasciata</i>		North Pacific (Chukchi, Bering and Okhotsk Seas)	Pack-ice breeder
Hawaiian monk seal	<i>Monachus schauinslandi</i>		Pacific Ocean (Hawaiian Islands)	Land breeder
Mediterranean monk seal	<i>Monachus monachus</i>		Mediterranean Sea, Black Sea, Atlantic (Northwest African coast)	Land breeder
West Indian monk seal	<i>Monachus tropicalis</i>		Caribbean Sea–Gulf of Mexico area	Land breeder
Southern Hemisphere				
Southern elephant seal	<i>Mirounga leonina</i>		Subantarctic, Antarctic, southern South America	Land breeder
Weddell seal	<i>Leptonychotes weddellii</i>		Antarctic	Fast-ice breeder
Ross seal	<i>Ommatophoca rossi</i>		Antarctic	Pack-ice breeder
Leopard seal	<i>Hydrurga leptonyx</i>		Antarctic	Pack-ice breeder
Crabeater seal	<i>Lobodon carcinophagus</i>		Antarctic	Pack-ice breeder

Figure 1 Gray seal pup in white coat. This fur is called laguno.

than those of yearlings. Thus newly weaned animals are limited in their physiological capacity to forage compared to older animals. Consequently, it would be expected that young animals would prefer shallower areas compared to older animals. However, there is evidence to suggest that juvenile Hawaiian monk seals and gray seals forage in deeper water, while adults, particularly females forage in shallower areas. This exclusion of juveniles to peripheral areas might be one mechanism affecting population growth, since juveniles with their smaller size and diving capabilities would have more difficulties finding sufficient prey to meet their energy requirements, than would the larger more experienced adults.

Pup mortality during the lactation period is normally quite low. Among land breeding species, trampling and wounds caused by interactions between adults may encourage infection, which may result in death of the pup. This problem is more aggravated in crowded colonies where the number of interactions would increase. In Arctic ice breeding species, predation by bears, foxes, and birds such as ravens (*Corvus* sp.) and gulls (*Larus* sp.) in the case of ringed seal pups are an important source of pup mortality, although the

effects of predation are reduced by the use of lairs. Ringed seal pups are also quite active and are capable swimmers at a very young age. However, swimming incurs a high metabolic cost owing to the minimum blubber thickness. Repeated disturbance may affect growth and survival. Surface predators are not present in the southern polar regions, but leopard seals and killer whales are important marine predators. In the pack ice, pups may drown or be crushed as a result of storms causing the breakup and rafting of the ice.

IV. Behavior and Physiology

Compared to otariids, phocids generally spend more time at sea, swim more slowly, and dive deeper and for longer periods. Southern elephant seals may dive to over 1200m and remain below the surface for up to 120 min (Le Boeuf and Laws, 1994). Other deep-diving phocids include northern elephant seals (*Mirounga* sp., 1500m), Weddell seals (*Leptonychotes weddellii*, 700 m), and recent hooded seal dives to 1400m have been documented. Phocids have adopted what is sometimes referred to as a “slow-lane” strategy to reduce energy use during diving (Burns *et al.*, 2007). This is achieved through a combination of (1) apnea with exhalation upon initiation of diving to minimize buoyancy- and pressure-related problems; (2) an enhanced oxygen carrying capacity which is accomplished by a greater blood volume, an increase red cell mass (hematocrit) within the blood cell volume, a greater hemoglobin concentration in the red blood cells, and possibly a higher content of oxygen-carrying myoglobin in the muscles; (3) a generally larger body size to maximize oxygen carrying abilities while minimizing mass-specific energy demands while diving.

The characteristic phocid lactation strategy consists of building-up energy reserves throughout the year, fasting during lactation and lactating for a short period. The utilization of fat reserves to satisfy their own energy requirements and the costs of providing milk for her pup has favored selection for large body size, because energy stores scale to $\text{Mass}^{1.0-1.19}$, whereas metabolic requirements scale to $\text{Mass}^{0.75}$. Thus increased body size increases energy storing capabilities at a greater rate than increasing mass-specific energy requirements. This has led to larger body size in phocid females than among otariid females (phocid females: mean = 229kg, median = 141kg; otariid females mean = 80kg, median = 55kg). The need to build up energy reserves over the year probably adds about 12% to the daily energy requirements of a female phocid, but it also allows the spatial and temporal separation of feeding and reproduction.

To minimize the metabolic costs associated with lactation, phocids have shortened the lactation period to 4–50 days instead of the months seen in otariids and odobenids. This is achieved by remaining beside the pup, providing more opportunities for the pup to suckle, and producing a very fat-rich milk, which increases the energy transfer per volume of milk consumed. In the elephant seals the fat content is very low at the beginning of lactation ($\approx 10\%$), but increases to about 50% fat by mid-lactation. In harp, gray, and Weddell seals, the milk fat content increases from around 40% to between 50% and 65% fat by mid lactation, while in hooded seals there is relatively little change in fat content of the milk (55–68%) over the short 4-day lactation period.

V. Life History

Phocids whelp on the ice, isolated islands, or inaccessible beaches. This makes it more difficult for terrestrial predators to approach seals undetected. Some ice-breeding species, such as the Baikal seal and the ringed seal, are also protected by using small caves or lairs under the snow to such predators as humans, polar bears (*Ursus maritimus*), Arctic foxes (*Alopex lagopus*), and birds (*Corvus* sp.;

Larus sp.). These lairs also provide shelter from cold ambient temperatures. Current global warming trends will likely result in the reduction of suitable ice habitat for many phocids, particularly in the more temperate regions of their distribution. This will impact not only seal populations, but also predators that rely on seals as food.

Sexual maturity is delayed in phocids. Some females are sexually mature at the age of 3+ years, but the mean age of sexual maturity is normally around 4–6 years, although it may vary with the population size and availability of resources. In Northwest Atlantic harp seals the mean age of sexual maturity among females may vary from 5.8 to 4.1 years. These changes have mirrored changes in population size due to exploitation. As the population has increased, the mean age of sexual maturity has also increased. It is currently around 5.3 years. Normally about 80% of the adult females are pregnant, but some interannual variability in adult reproductive rates can occur and in recent years the age-specific pregnancy rates among adults have been less than 75%. Extremely low ($\approx 60\%$) adult reproductive rates have been documented in some years among ringed seals in the Beaufort Sea and Hudson Bay areas of northern Canada. These changes may be related to changes in ice conditions and availability of food resources.

Males become sexually mature around the same time or slightly later than females, but recently mature males appear to be incapable of defending access to females until 2 or more years after they are sexually mature. Sexually monomorphic species have the longest life expectancies. For example, ringed seals aged 45 years old have been reported. The life expectancy of sexually dimorphic species is much shorter particularly among males. In elephant seals, which show perhaps the most extreme level of sexual dimorphism, males are sexually mature at about 5 years of age, but they seldom achieve any rank within the colony until the age of 8 years. The greatest reproductive success occurs between the ages of 9 and 12 years and males die by the age of 14 years.

The female phocid reproductive cycle is characterized by parturition, a short lactation period (4–50 days), copulation near the end of lactation, embryonic diapause (≈ 3 months), and active fetal growth (≈ 9 months). In most temperate species implantation occurs during late summer–early autumn when light levels are decreasing, and pupping occurs during the spring, when light levels are increasing. However, an irregular pattern is seen among gray seals. Gray seals in the United Kingdom give birth during the fall and implantation occurs during the spring. Implantation of the embryo occurs after the molt, when female energy reserves are at a minimum. Embryonic diapause provides females a means of terminating reproduction if conditions are poor before her investment becomes too costly. It also leads to synchronization of reproductive activity.

Stability of the whelping habitat and vulnerability to predation appear to be two important factors that have influenced the duration of lactation within the phocid group. Pups on the unstable, drifting pack ice nurse for only 4 days in the hooded seal, to as much as 30 days among the crabeater and Ross seals (*Lobodon carcinophaga* and *Ommatophoca rossii*; mean = 18 days). In contrast, the longest lactation periods are found among the fast ice breeding Weddell, Baikal, and ringed seals (mean = 57 days). The lengthy lactation period among the very small ringed and Baikal seals may be related to their small size and their relative inability to store and deliver energy quickly to their offspring. The Weddell seal, which weighs around 450kg, is almost 4 times heavier than the diminutive ringed seal. The lengthy nursing period of Weddell seal pups may keep the young away from the fast ice edges where their exposure to aquatic predators such as leopard seals and killer whales would be greater. The duration of lactation among land-breeding phocids is intermediate to that of the fast ice and pack ice animals with an average of 32 days.

The “fasting strategy” is certainly characteristic of lactation in the largest phocids such as the elephant seals and in the hooded seal. Facultative feeding occurs among female Weddell, bearded, harp, and gray seals, while feeding appears to be obligatory among the smaller phocids (≤ 100 kg), such as the harbor and ringed seals. Feeding may be necessary because females are unable to store sufficient energy to satisfy their own energy requirements, plus energy required for lactation. The need to continue foraging during lactation means that females must leave their pups in a safe area while they forage or the pup must accompany the female. In both instances, the spatial separation between whelping sites and foraging areas is limited. In the ringed seal, females scrape out lairs beneath the snow to haul out in. Females leave their pups to feed under the ice, but remain close enough to help the pup move to an alternate lair if a predator approaches. Among harbor seals, foraging activity is restricted during the early stages of lactation. In large groups, as lactation advances, some females leave their pups unattended while they forage. In areas where only small groups are seen, the pups may follow the females over extensive distances of as much as 30 km away from the original haulout site.

Fewer studies have examined male energy expenditures during breeding owing in part to the difficulties associated with handling large, dangerous, and aggressive animals, or their inaccessibility in the case of males that spend much of their time in water. Daily energy expenditures of males during the breeding season are much lower than those of females, because they do not incur the costs of milk production. However, once females wean their pups they resume feeding. This contrasts with males, who continue fasting to maximize their access to successively receptive females as the breeding season advances. Elephant, gray, and hooded seals appear to terminate breeding activity when fat levels have declined to levels similar to those observed in females. This suggests that the overall reproductive effort is similar between the two sexes.

At birth, phocid neonates are larger than otariid neonates. When female body size is taken into account, phocid and otariid mass at birth represents about 10% of their mother's mass. The pups are quite lean at birth with a fat content of 5–8%. Notable exceptions are hooded, harbor, and bearded seals which are larger relative to other species with a mass at birth equal to about 12–13% of the maternal mass. Harbor, hooded, and bearded seal pups also differ from otariid and other phocid pups by the presence of a thin blubber layer at birth. Fat content represents 11–14% of the total body mass in harbor and hooded seal pups at birth. Phocid pups gain weight rapidly, achieving a weaning mass 2–5 times their birth mass in a period of 4–50 days, but mass at weaning is relatively constant across species, being equivalent to 25–30% of the mother's mass. Among hooded, harp, and gray seal pups, 65–75% of the milk energy is deposited primarily as fat. Elephant, hooded, harp, ringed, and gray seal pups are 40–50% fat at weaning, while species with very active pups such as Weddell, bearded, and harbor seals may contain only 34–37% fat at weaning. The rate of mass gain is inversely related to the duration of the lactation period when expressed relative to the female's metabolic mass. The lowest rates of relative mass gain are seen among Hawaiian monk seals, bearded, harbor, and ringed seals, species where the pups are very active and begin entering the water early during lactation. Ice-breeding neonate phocids such as harp, ringed, ribbon, Caspian, Baikal, and Larga seals are born with a white, relatively long fur called lanugo (Fig. 1). The white color may provide some protective camouflage on the white snow from predators. However, the lanugo may be more effective in its role as an insulator, particularly to the very young pup who has not yet developed a thick layer

Figure 2 Gray seal pups that are molting, shedding their lanugo. Such partially molted or ragged-jacket and weaned animals are called beaters. Adult female on right.

of blubber for insulation. The structure and color of this fur permits short-wave energy received from the sun to be transmitted through the fur, where it is absorbed by the dark skin. It also traps heat energy radiated from the animal's skin and thus acts like a greenhouse, heating up the air trapped within the fur, but limiting heat loss to the outside air. Among species where the young enter the water very soon after birth (e.g., harbor seals, bearded seals, and hooded seals), the young are born with a thin layer of blubber, and the lanugo is shed or molted within the uterus. This is because blubber acts as a much better insulator in water than fur. Among harbor seals, 5–30% of the pups are born with a white lanugo, depending on the region, but this is quickly replaced by a grayish pelage similar to that of adults. In bearded seal the shedding of the lanugo begins *in utero*, but is completed after birth. In the hooded seal, the fetal fur is expelled in small clumps on the ice with the placenta, which was referred to as silver dollars by commercial sealers. At birth the pups are covered by blue (dorsal) and silver (ventral) fur that is much thicker and longer than the adult fur and at this stage the pups are known as bluebacks. Hooded seal pups differ from harbor and bearded seals in that they do not enter the water until they are weaned. However, in this species lactation lasts for only 4 days. The remaining species that whelp on the ice in the Northern Hemisphere tend to give birth to pups with a white lanugo, which may afford some protection against surface predators. Gray seals have their pups on both the land and on the ice, but the pups are born with a white lanugo, which is eventually molted to leave a dark spotted fur in the case of males or a silvery spotted fur in the case of females (Fig. 2). Neonates of the southern ice-breeding seals, such as Weddell, crabeater, leopard, and Ross seals, are born with a gray, brown, or grayish-brown pelage. Southern ice breeding phocids are not exposed to surface predators other than man and hence the white lanugo may not be required. Elephant and monk seal pups are born on land with a black pelage.

The study of mating systems among phocids has relied heavily on behavioral observations of animals in the breeding areas. Male reproductive success has been evaluated by a male's ability to monopolize females or by the number of copulations observed. However, DNA techniques have suggested that the evaluation of reproductive success may be more complex, with the existence of alternative mating strategies within a population. In captive harbor seals, behavioral observations during courtship were not reliable indices of paternity, while in one population of gray seals, large males sired significantly fewer pups than would otherwise have been indicated from their observed mating opportunities. Females tended to produce several

Figure 3 Two male hooded seals fighting on pack ice in the Gulf of St. Lawrence, Canada. Note the inflatable sac on the male on the left.

pups fathered by the same male, who in many cases was not the large attendant male.

Phocids breeding on land prefer islands or isolated beaches, where threats from predation are reduced. The combination of habitat limitations and synchronization of reproductive activity encourages the aggregation of females. Males are not involved in caring for the pup. Therefore, the best strategy for males is to copulate with as many females as possible, while the strategy of females is to successfully rear her pup. Males will attempt to prevent other males from having access to females. In phocids, this may involve defending a geographical area, but if the female moves, the male will follow to defend a new space around the female. The number of females that can be defended is limited by habitat features and the skills of defending males. Large, open beaches are more difficult for a male to control than more topographically irregular sites, where geographical barriers will aid established males to limit the approach of intruding males. Reproductive success will also be affected by the fighting and signaling ability of males and how long they can remain beside females without leaving to feed. In male hooded seals a series of displays involving the inflatable nasal sac and nasal septum are often associated with the approach of other males (Figs 3 and 4). Not all approaches result in combat, suggesting some signaling occurs. The gradual evolution toward large size observed in females, which permitted the separation of reproduction and feeding, would also have operated on males as well. Larger males could spend more time ashore fasting. Larger males would also be favored over small males in combat, although experience and individual skill development would also be contributing factors. The greatest degree of polygyny seen among phocids is exhibited by the elephant seals, who may defend harems containing upward of 100 females. Southern elephant seal males may weigh up to 3700 kg, while northern elephant seal males may reach 2300 kg. In both species the males are typically 5–6 times larger than the females. Males arrive on the whelping area just before the females and the most successful males remain on the beaches fasting until the last females leave about 3 months later.

In other species the development of polygyny is more variable. Gray seals copulate on land and occasionally in water. Males at 350 kg are about 50% larger than females. In some areas in the British Isles, they control access to as many as 7.5 females, while

Figure 4 Male hooded seal with inflated sac. The walls of the sac are actually part of the nasal septum.

in the open beaches and ice breeding areas in Canada, males are only able to control access to 1.3–2.6 females. The development of polygyny would be limited by the three-dimensional nature of the marine environment. Among hooded seals the marked sexual dimorphism observed in many terrestrial mating species is also observed. Male hooded seals weigh up to 440 kg, while females may reach about 290 kg. The hooded seal male begins to defend one female about midway through the short 4-day lactation period. Once the pup is weaned, he accompanies the female into the water, mates with her, and then returns to the ice and will attempt to establish himself beside another female. Since pupping occurs over a 2- to 3-week period, males have opportunities for multiple matings during that period. Mating success will be affected by his ability to defend access to females against other males and by the amount of time he can spend on the ice before his energy reserves are depleted. Less is known about the structure of mating systems of phocids that copulate primarily in water. The development of polygyny would be limited by the three-dimensional nature of the marine environment. Among the phocids that copulate in the water, little difference in

body size is seen between males and females, or in some cases such as bearded seals and Weddell seals the females appear to be slightly larger. In these cases, smaller size may favor underwater agility. The mating system of harp seals has been referred to as promiscuous, but little information is available. Males do haul out, but no displays or fighting are observed on the ice. Extensive vocal activity within harp seal whelping patches has been recorded, and groups of males are observed often patrolling leads, vocalizing and diving. It is possible that male harp seals are displaying to females, suggesting more of a lek-type system, but there is insufficient data to comment further. Among ringed seals, the presence of predators in the fast ice such as bears, foxes, and humans select against aggregation, while the need to continue feeding during lactation, in an area generally considered to have low productivity would also be a contributing factor. In this species, some underwater vocal activity has been recorded, but unlike the underwater vocalizations of the widely dispersed bearded seal that can be heard over distances of 25 km, the underwater vocalizations of the ringed seal are relatively weak, limiting their use as a signal to potential mates. However, the males emit a strong odor during the breeding season owing to the enlargement and increased secretion activity of sebaceous and apocrine glands in the muzzle region. The strong odor may serve as a signal to inform both females and other males that a breathing hole is used or belongs to a particular male. In harbor seals, the females move with their pups between haulout sites and foraging areas. Males are unable to defend females or sites against other males. As the time that females will become receptive approaches, males reduce the size of the range that they occupy, but remain in the water, making repeated short dives that are associated with underwater vocal displays. Some males establish themselves near haulout sites, some near foraging areas used by females, while others appear to establish themselves on transit routes between haulout sites and foraging areas. It has been suggested that a "lekking" type of mating system occurs in this species. In the Antarctic Weddell seal, males appear to defend underwater territories around breathing holes and cracks.

Many early studies relied on stomach content material from hunted animals, fecal collections, and entrapments in fishing gear to provide information on diving and foraging activity. During the last decade, major technological advances have provided researchers with satellite transmitters, time-depth recorders, stomach temperature probes, and video recorders to study diving and foraging activity.

Phocids feed on a wide variety of prey, including invertebrates such as amphipods, mysids, squid, and krill, and vertebrate prey such as fish. Birds have been recorded in the diet of some species such as the leopard seal (*Hydrurga leptonyx*) and harp seal. Leopard seals also prey on other seal species and cannibalism has been reported in gray seals. Diet composition may change seasonally, geographically, and with age. Newly weaned pups of ringed and harp seals begin foraging on zooplankton in their initial attempts to forage independently and then become more piscivorous as their skills develop. Phocids feed primarily on smaller prey that can be consumed whole, but large prey may be taken. Under certain conditions where prey are very abundant or accessible, e.g., when fish are caught in nets, seals may consume only pieces from fish.

Little is known about factors affecting prey choice. Research has indicated that in harp and harbor seals feeding preferences occur for particular types and sizes of prey that may be independent of local abundance. Harp seals digest capelin more efficiently than they do most other prey, and throughout their range capelin forms an important component of their diet, while other species such as commercially important Atlantic cod (*Gadus morhua*) form only a very minor

component in the overall diet. While foraging phocids must balance their intake of oxygen and the distribution of oxygen for locomotion, body maintenance, and processing of food (specific dynamic action or heat increment of feeding). Their approach to balancing these sometimes conflicting needs will influence their foraging strategy. A seal may process (digest) food while actively swimming and foraging. If it uses only aerobic metabolism, then the consumption of oxygen required to process the food will reduce the amount of time spent diving and collecting food. If the seal attempts to maintain the duration of diving, then the switch to anaerobic conditions will force the animal to rest at the surface until lactic acid levels are reduced. A second strategy is to forage and then spend time resting at the surface, hauled out on the ice or on land until food processing is completed. However, resting at the surface increases vulnerability to surface predators such as sharks or killer whales, while returning to shore or ice involves time lost due to transit and may limit the distances that foraging can occur away from haulout sites. A third strategy involves foraging and then if successful, reducing locomotory costs by drifting during the surfacing phase of the dive, allowing food processing to occur. Many phocids may utilize these first two strategies. Weddell, ringed, harp, and hood seals are often seen hauled out on the ice and occasionally on land. Harbor and gray seals may forage in offshore areas, but rarely spend more than a few days away from haulout sites. The third strategy appears to be utilized by elephant seals, which spend almost 8–9 months of the year at sea.

Male and female phocids have different reproductive strategies, which carry over into different foraging strategies as well. Among phocids, mating occurs at the end of lactation. Females begin foraging almost immediately and some recovery in mass has been observed prior to the moult which occurs 1–4 months later. Since females must support a developing fetus, it might be important that a minimum threshold be attained to ensure implantation and continued fetal development. After implantation females initially gain mass quickly. Then, the rate of mass gain appears to be slow, possibly to avoid increasing energy costs of transport associated with gaining mass too early in the season. About 4 months prior to birth, the rate of mass gain increases once again. This coincides with the period when fetal support costs are highest and females would store energy to carry them through lactation. Many males continue to lose mass throughout the breeding season until just after the molt. Since males only need to rebuild energy reserves in time for the subsequent breeding season, the rate of post-molt mass gain is slow. Gray seals, elephant seals, and hooded seals are three species where important differences in foraging activity have been observed. Among gray seals, females undertake periods of intensive foraging postbreeding and postmolting, whereas males replenish reserves predominantly during the few months preceding the breeding season; females perform longer dives, spend more time in more restricted feeding areas, and are more selective and feed on higher quality pelagic prey than males. Northern elephant seals, differ slightly in that males and females have similar postbreeding foraging patterns, with both sexes accumulating body reserves following the breeding season. However, in northern elephant seals, females are dispersed over a broad geographical area across the northeastern Pacific from the coast to as far west as 150°W, but tend to remain between 44°N and 52°N. Foraging occurs both offshore and during transit between inshore and offshore areas. Diurnal changes in diving depths are observed, indicating that they are foraging on vertically migrating prey in the pelagic and mesopelagic environment. Their principal prey are mesopelagic squid and fish. Males utilize a different foraging strategy by foraging little while en route to particular foraging areas along

continental margins of Washington State to as far north as the Aleutian Islands. Once on site, repeated, uniform flat-bottomed dives predominate diving, with little diurnal variability, suggesting intensive foraging activity, possibly on benthic prey such as energy-rich elasmobranchs and cyclostomes (sharks, skates, ratfish, and hagfish). While at sea both species dive continuously, spending almost 90% of their total time at sea submerged, leading to the suggestion that they should be called surfacers instead of divers. At the opposite end of the size spectrum, a very different strategy is seen among harbor seals. Although capable of diving to depths of 500 m, harbor seals rarely dive deeper than 65 m and in some studies an average of 65% of diving activity occurs at depths of less than 4 m. Visual and telemetry data, indicate that harbor seals in some areas spend most of their time very close to the coast in shallow water areas. Foraging distances rarely exceed 50 km away from haulout sites. Little difference is seen between males and females in dive depths and foraging distances away from haulout sites outside of the breeding season.

Echolocation

WHITLOW W.L. AU

Echolocation is the process in which an animal obtains an assessment of its environment by emitting sounds and listening to echoes as the sound waves reflect off different objects in the environment. In a very general sense any animal that can emit sounds may be able to hear echoes from large obstacles (i.e., humans yelling in a canyon); however, such a process is not considered echolocation. The term “echolocation” is reserved for a specialized acoustic adaptation by animals who utilize this capability on a regular basis to forage for prey, navigate, and avoid predators. Echolocating dolphins are often searching for entities that are considerably smaller than themselves and must make fine discrimination of these objects. Over the eons of time, this specialized adaptation has been continually refined under evolutionary pressures.

Echolocation in bats was suspected as early as 1912, but it was not until 1938 when G. Pierce and D. Griffin that provided evidence of bats emitting ultrasonic pulses using an ultrasonic detector that the concept began to gain acceptance. Echolocation in dolphins was suspected around 1947 as was evidenced in the personal notes of A. McBride (1956), the first curator of Marine Studio (later Marineland) in Florida. However, it was not until 1960 that Norris and colleagues (1961) performed the first unequivocal demonstration of echolocation in dolphins by placing rubber suction cups over the eyes of an Atlantic bottlenose dolphin (*Tursiops truncatus*) and observing that the animal was able to swim and avoid various obstacles. Ultrasonic pulses were also detected as the blindfolded dolphin swam and avoided obstacles, such as a vertical maze of suspended pipes.

Since the Norris demonstration, considerable progress has been made in our understanding of the echolocation capabilities of dolphins. Most of the research has been done with the Atlantic bottlenose dolphin, the most common dolphin in captivity. Research in dolphin echolocation can be divided into the following areas: (1) sound production mechanism and propagation in the dolphin's head, (2) sound reception and auditory capabilities, (3) sound transmission and the characteristics of echolocation signals, (4) target detection capabilities, (5) target discrimination capabilities, (6) auditory nervous system function and capabilities, and (7) signal processing modeling. This article addresses each of the first six areas, providing the most recent findings in most cases along with some fundamental capabilities.

I. Sound Production Mechanism and Propagation in the Dolphin's Head

The head of a dolphin shown in Fig. 1 is a very complex structure with unique air sacs and special sound-conducting fats. One of the most perplexing issues that has eluded researchers since the discovery of echolocation has been the location and mechanism of sound production in dolphins. In the mid-1980s, Cranford (1988) began using modern X-ray computer tomography (CT) and magnetic resonance imaging techniques to study the internal structure within a dolphin's head. These non-invasive techniques allowed Cranford to study the relative position, shape, and density of various structures in the dolphin's head and helped him to conclude that a structure called the monkey lip-dorsal bursae (MLDB) in the dolphin nasal complex was the location of the sound generator.

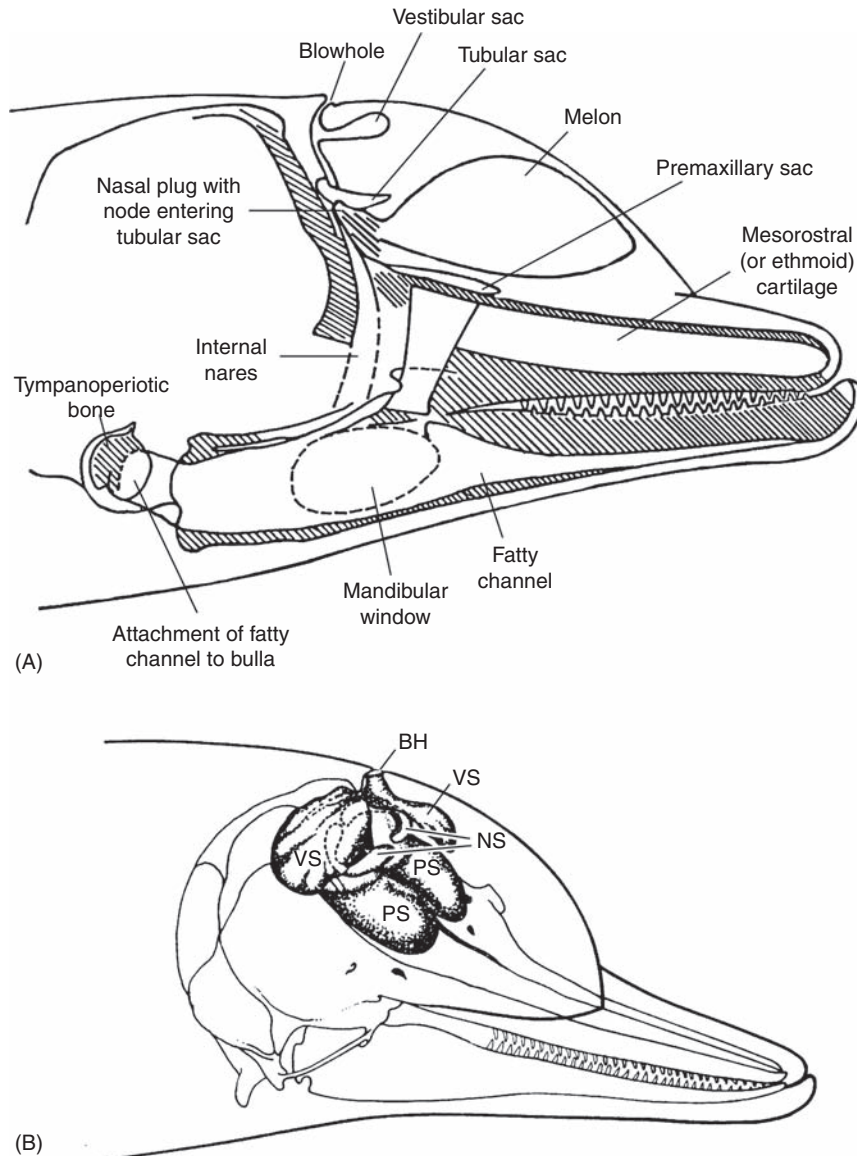

Figure 1 (A) Schematic of a dolphin's head (adapted from Norris, 1968) and (B) three-dimensional diagram of the air sacs in a dolphin's head. PS, premaxillary sac; VS, vestibular sac; NS, nasofrontal (tubular) sac; AS, accessory sac. Adapted from Purves and Pilleri (1983).

Eventually, Cranford *et al.* (1997) used high-speed video of the phonic lips (previously referred to as the monkey lips) with simultaneous hydrophone observations of echolocation signals. There are two sets of phonic lips, associated with the two nares in the dolphin's nasal complex. Cranford and colleagues have obtained additional high-speed video observation of movements in both sets of phonic lips during the production of echolocation signals and whistles.

The numerical simulation of sound propagation in the head of a dolphin by Aroyan (2001) has provided considerable understanding of the role of the air sacs, skull, and melon in the propagation of sounds in a dolphin's head. One of the interesting problems Aroyan considered was that of a plane wave propagating toward the head of a dolphin (as depicted in Fig. 2A); to determine where sounds would focus in the dolphin's head in a similar manner to the process used by geologists to determine the epicenter of an

earthquake. He numerically solved the three-dimensional wave equation (also shown in Fig. 2) using a finite-difference technique and a supercomputer. The density and sound velocity structure of the dolphin's head were estimated from the CT scan results of Cranford. The grid points represent a pictorial illustration of how the head of a dolphin may be mathematically subdivided so that the solution of the wave equation is numerically determined at each grid point. The results for the geometry depicted in Fig. 2A are shown in Fig. 2B, with focal regions at the two auditory bullas and at the MLDB region of the nasal system, supporting Cranford's earlier suspicion of the MLDB being the site of the sound generator for echolocation sounds.

Aroyan then placed a hypothetical sound source at the MLDB region and numerically solved the three-dimensional wave equation as the sound propagated through the dolphin's head into the water. He

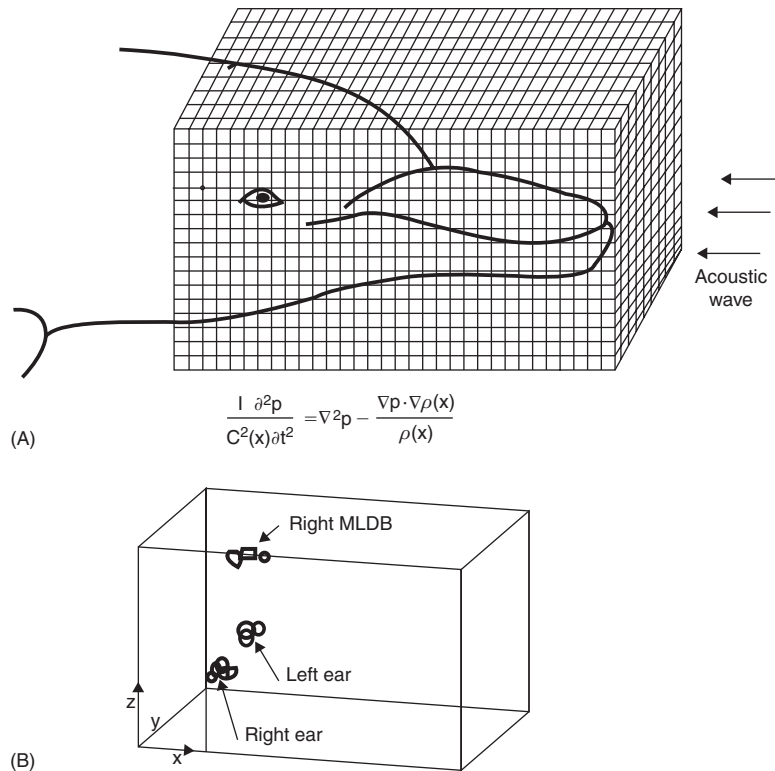

Figure 2 (A) Configuration of numerical simulation of sound propagation in the head of a dolphin to determine acoustic focal regions and (B) results of numerical simulation for the geometry depicted. After Aroyan (2001).

Figure 3 Relative reception sensitivity of hearing at different locations around a dolphin's head. The higher the number, the more sensitive the region. Adapted from Møhl et al. (1999).

found that the skull, the various air sacs, and the non-homogeneous melon all played important roles in forming the beam in which sounds are transmitted into the free field. The specific characteristics of this beam are discussed in Section II. He also showed that if a hypothetical sound source was placed at the larynx, the resulting beam in the free field was not compatible to the actual beam measured for dolphins, therefore, essentially eliminating the larynx as a possible site for a sound generator.

II. Sound Reception and Auditory Capabilities

A. Auditory Capabilities

Dolphins do not have pinnae and their external auditory meatus is but a pinhole with vestigial fibrous tissues connecting the surface to the tympanic structure. Kenneth Norris was the first to postulate that sound enters the dolphin's auditory system through the thin posterior portion of the mandible (see Fig. 3) and is transmitted via a

fat-filled canal to the tympano-periotic bone, which contains the middle and inner ears. Electrophysiological measurements, such as the one by Bullock *et al.* (1968), were conducted that provided evidence to support Norris' theory. However, the acoustic conditions for both experiments were less than ideal: the subjects were confined to small holding tanks and their heads were held near the surface to keep the electrodes from shorting out by the water. The acoustic propagation for such a situation can be extremely variable, with the sound pressure level changing drastically because of multipath propagation, on the order of 10–20 dB.

Møhl *et al.* (1999) took a slightly different electrophysiological approach by measuring the brain stem-evoked potential of a bottlenose dolphin that was trained to beach itself on a rubberized mat.

A special suction cup hydrophone having a water interface between the piezoelectric element and the skin of the dolphin was positioned at different locations on the dolphin's head. By performing the measurement in air, the point at which sound from the piezoelectric element enters into the dolphin could be firmly established. Acoustic energy will only propagate toward the dolphin's skin and energy propagating in any other direction will be reflected back at the boundary of the suction cup. Møhl and colleagues positioned the suction cup hydrophone at different locations around the dolphin's head, and at each location, the amount of attenuation needed to obtain the evoked potential threshold was determined. Their results are shown in Fig. 3, where the circles indicate the different positions of the suction cup and the number within each circle represents the amount of attenuation needed to achieve threshold. Therefore, a larger number is indicative of a more sensitive region of sound reception. The dashed line indicates the area of the pan bone or mandibular window shown in Fig. 1A. These results indicated that the area just forward of the pan bone area of the dolphin's lower jaw is the most sensitive area of sound reception, which seems to be inconsistent with Norris' pan bone theory. However, the numerical simulations of acoustic propagation by Aroyan suggest that sounds that enter the dolphin's lower jaw just forward of the pan bone actually propagate below the skin surface to the pan bone and enter into the lower jaw through the pan bone.

The hearing sensitivity of a dolphin was first measured accurately in 1967 by Dr. Scott Johnson in a pioneering experiment. Johnson

found that the upper limit of hearing of an Atlantic bottlenose dolphin was 150 kHz. Since Johnson's research, audiograms have been determined for the harbor porpoise (*Phocoena phocoena*), Amazon River dolphin (*Inia geoffrensis*), beluga whale (*Delphinapterus leucas*), false killer whale (*Pseudorca crassidens*), Chinese river dolphin (*Lipotes vexillifer*), Risso's dolphin (*Grampus griseus*), Tucuxi (*Sotalia fluviatilis*), and killer whale (*Orcinus orca*). The audiograms for these odontocetes are shown in Fig. 4.

One of the most interesting features of these audiograms is the high upper frequency limit of hearing extending beyond 100 kHz. This is rather remarkable when the wide range of sizes of the animals depicted in Fig. 4 is considered. The largest animal represented in Fig. 4 is the killer whale, which weighed about 3,600 kg and was about 5 m in length compared to the smallest animal, the harbor porpoise, which typically weighs about 33 kg and is about 1.3 m in length. The typical rule of thumb in mammalian hearing is that larger animals tend to have limited high-frequency hearing capabilities. A killer whale is considerably larger than the smallest dolphin, yet its upper limit of hearing is approximately 120 kHz, and may therefore represent an exception to the norm. Another interesting feature of Fig. 4 is the fact that the maximum sensitivity (lowest point in the graph) for the different odontocetes is very similar within 10 dB.

Although dolphins do not have pinnae, the auditory system of the dolphins is directional. Sounds are received best when the source is directly in front of an animal. The receiving beam pattern of a *T. truncatus* in both horizontal and vertical planes is shown in Fig. 5. Several features of the beam patterns are worth pointing out. First, the beam becomes wider as the frequency decreases. Planar transducers also behave in a similar fashion with their beam becoming narrower as the frequency increases. Second, the major axis of the beam in the vertical plane is pointed upward with respect to the tooth line by about 5–10°. Third, the major axis in the horizontal plane is pointing directly in front of the animal parallel to the longitudinal axis of the dolphin. The receiving beam pattern can also be discussed in terms of the spatial variation in the hearing sensitivity of the dolphin. Therefore, the dolphin has the best high-frequency hearing sensitivity when sounds approach from the front and poorer sensitivity as the sound sources move to other locations about the animal's head.

Figure 4 Audiograms for 11 species of odontocetes.

III. Sound Transmission and the Characteristics of Echolocation Signals

There is a distinct difference in the echolocation signals used by odontocetes that produce whistle signals and those that do not whistle. Whistling dolphins project short, almost exponentially decaying signals with durations of 40–70 μsec and bandwidths of tens of kilohertz. Non-whistling dolphins and porpoises project signals with longer durations of 120–200 μsec and with narrow bandwidths that are typically less than 10 kHz. An example of a typical echolocation signal produced by an Atlantic bottlenose dolphin is shown in Fig. 6, along with a typical echolocation signal produced by a harbor porpoise (a non-whistling animal). Whether riverine dolphins produce whistles is still an open question; however, these dolphins emit signals that are of the broadband, short duration variety. Most

odontocete species produce whistles, and only a few, such as the harbor porpoise, Commerson's dolphin (*Cephalorhynchus commersonii*), Hector's dolphin (*C. hectori*), Dall's porpoise (*Phocoenoides dalli*), and pygmy sperm whale (*Kogia breviceps*), are known to not whistle.

The amplitudes of the echolocation signals also are very different between whistling and non-whistling odontocetes. Whistling dolphins, such as *T. truncatus*, *P. crassidens*, and *D. leucas*, can project echolocation signals with peak-to-peak amplitudes as high as 225 dB re 1 mPa. The center frequency of the signals used by whistling dolphins is affected by the level of the outgoing signal. The center frequency of clicks varies almost linearly with the peak-to-peak amplitude. Non-whistling dolphins and porpoises, such as *P. phocoena* and *Phocoenoides dalli*, emit signals that normally do not exceed 170 dB re 1 mPa. Peak-to-peak source level measurements for *P. phocoena* by,

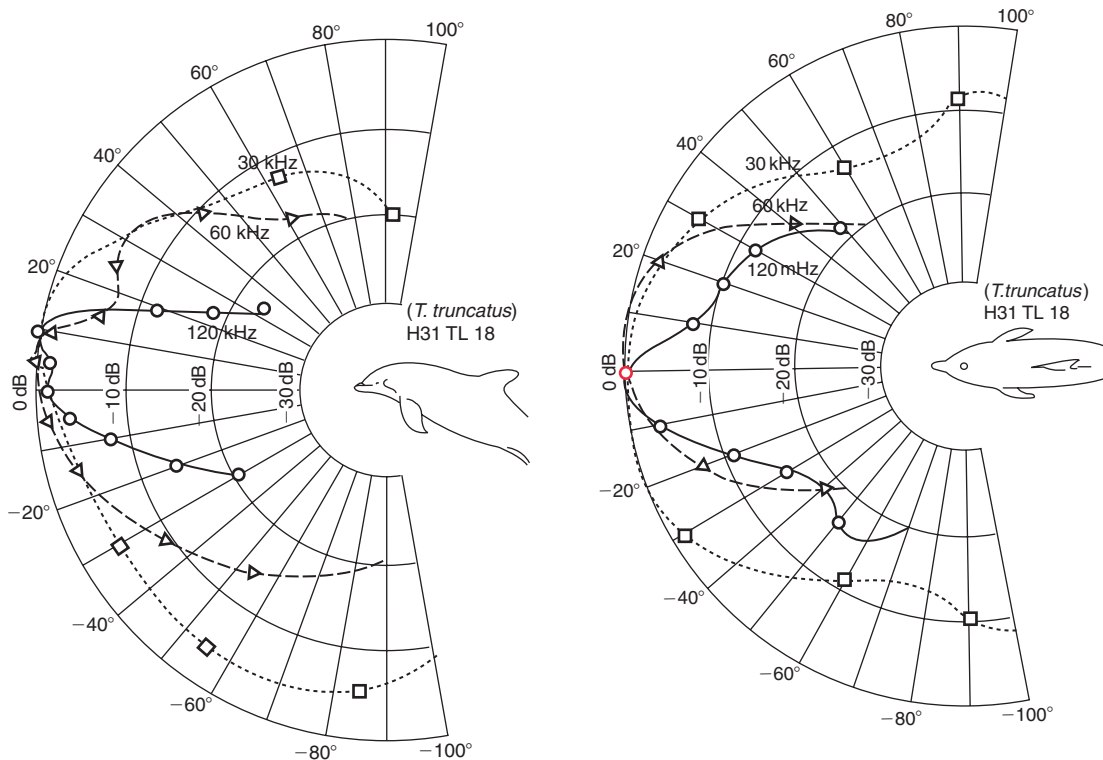

Figure 5 The receiving beam patterns in the horizontal and vertical planes for different frequencies. Adapted from Au (1993).

Figure 6 Typical echolocation signal emitted by *T. truncatus* (a whistling dolphin) and *P. phocoena* (a non-whistling porpoise). The source level (SL) is the peak-to-peak sound pressure level referenced to 1 mPa at 1 m.

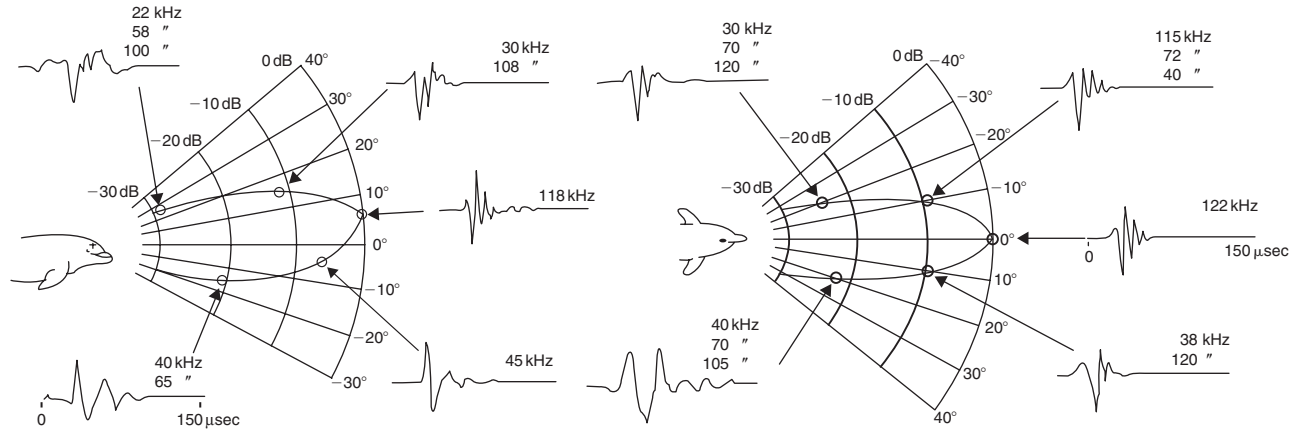

Figure 7 The transmission beam pattern in horizontal and vertical planes. The signals shown with each beam pattern are all the same signal captured simultaneously by five hydrophones located about the dolphin's head. After Au (1993).

Figure 8 The waveform of an echolocation signal detected by hydrophones spaced about the head of a porpoise (*P. phocoena*). After Au et al. (1999).

while the animal was performing a target detection task, indicated an average peak-to-peak source level of only 160 dB, which is considerably smaller than the 210–225 dB used by *T. truncatus*, *P. crassidens*, and *D. leucas*. The center frequency of the *P. phocoena* signal, which is typically between 120 and 145 kHz, does not depend on the level of the projected sonar signals.

Echolocation signals are projected from a dolphin's head in a beam. An example of the transmitting beam pattern for a *T. truncatus* in both horizontal and vertical planes is shown in Fig. 7. The signal shown at different angles about the animal's head is the same signal captured by an array of hydrophones. Note that only the signal traveling along the major axis of the beam is undistorted. This phenomenon occurs in horizontal and vertical planes. The numbers above each signal are the maxima in the frequency spectra of the signals, in order of descending amplitude. The further away from the major axis of the beam, the more the signal is changed. This property of the beam makes it very difficult to measure echolocation signals in the wild. Occasionally,

dolphins in the wild may actually swim directly toward a hydrophone so that relatively true measurements can be made.

Beam pattern measurements have also been conducted for *D. leucas*, *P. crassidens*, and *P. phocoena*. The signals from all of these animals, with the exception of *P. phocoena*, exhibit changes in frequency content when the measuring hydrophone is located away from the major axis. However, in the case of *P. phocoena*, the signals detected by hydrophones located away from the major axis are not distorted, as can be seen in Fig. 8. Distortion does not occur because the signal has a relatively narrow bandwidth.

One of the most fundamental properties of a sonar system is its maximum detection range. A simple way to determine the maximum target detection range of sonar is to gradually move a specific target away from the sonar until the target can no longer be detected. Au (1993) used a 7.62-diameter water-filled stainless-steel sphere as the target to determine the maximum detection range of *T. truncatus*. The target was moved progressively away from an echolocating

Figure 9 Target detection performance as a function of range for *T. truncatus* and *P. phocoena*. After Au (1993) and Kastelein et al. (1999).

dolphin until the animal could no longer detect its presence. Stringent psychophysical techniques were used and many sessions were conducted in order to stabilize performance and to determine the probability of detection as a function of range. Kastelein *et al.* (1999) used the same type of target (7.62-cm diameter water-filled stainless-steel sphere) as Au and colleagues to determine the sonar detection capability of *P. phocoena*. The results of both experiments are shown in Fig. 9.

The 50% correct detection threshold for the bottlenose dolphin occurred at a range of 113m. The 50-percent correct detection threshold for the harbor porpoise was approximately 26m. An experiment by Au and Snyder took place in Kaneohe Bay, Hawaii, a bay that has a high level of noise and the bottlenose dolphin's hearing was masked by the background noise level. The harbor porpoise target detection experiment was performed at a location in the Netherlands, where the ambient background noise was moderate, between 100 and 150kHz. Therefore, the harbor porpoise was not masked by background noise and yet its detection threshold was considerably shorter than *Tursiops*. The difference in the two-way propagation losses for 113 and 26m is 36dB. The bottlenose dolphin typically produces clicks that are 50–60dB greater than that of the harbor porpoise. Therefore, the large difference in the levels of projected signals can account for most, but not all, of the very large difference in the detection threshold ranges of both animals. If the target detection experiment with *T. truncatus* were conducted in a body of water with a low ambient background noise, the dolphin's target detection range would be much longer and, in that case, the difference in the two-way transmission would probably match the difference between the source levels used by the two different species.

IV. Target Discrimination Capabilities

There have been many target discrimination experiments involving echolocating dolphins. Unfortunately, in many of these experiments the reflection characteristics of the targets were not measured or were measured with tone-burst signals instead of with a simulated dolphin-like signal. The experiment involving wall thickness discrimination by an echolocating dolphin is one that provided appropriate echo characteristics of the targets (Au, 1993). In this experiment, the

Figure 10 Performance of an echolocating dolphin in the wall thickness discrimination experiment. Adapted from Au (1993).

dolphin was presented with two hollow aluminum targets separated by 20° at a range of 8m. The standard target had a wall thickness of 0.63cm and the comparison targets had wall thicknesses that were different than the standard by ± 0.8 , ± 0.4 , ± 0.3 , and ± 0.2 mm. All the targets had a length of 12.7cm. On any given trial, the standard and comparison were introduced into the water separated by $\pm 20^\circ$ about the center axis. The dolphin was required to swim into a hoop and echolocate the targets when a screen was lowered out of the way and then touch a paddle that was on the same side of the center line as the standard target. Two sets of targets were available so that the position of the standard could be switched on any given trial.

The results of the wall thickness experiment are shown in Fig. 10. The dolphin performed very well with correct responses in the mid-90 percentile. The animal's correct response performance became progressively worse as the difference in wall thickness decreased. The 75% correct performance threshold was 0.27mm for the case in which the comparison targets were thinner than the standard target and 0.23mm when the comparison targets were thicker than the standard.

Echoes from the standard target and the 20.3mm comparison target are shown in Fig. 11. There are several cues that the animal might have used in order to perform this discrimination. One cue is the difference in the time delay between the first and the second echo component for both the standard and the comparison target. If this cue was used, it suggests that the dolphin could discriminate differences of about 0.5–0.6 μ sec. Another cue could be the difference in the time-separation pitch (TSP). When humans are presented with two correlated broadband acoustic signal separated by time T , a TSP equal to $1/T$ can be perceived. TSP stimuli also have a frequency spectrum that is rippled. The third possible cue is the difference in the frequency spectra of the echoes. The frequency spectrum of the echo from -0.3 mm comparison target is shifted between 2 and 3kHz from the spectrum of the standard target. If the dolphin was using this cue, it suggests that the animal was able to perceive a frequency difference of 2–3kHz in the broadband echoes.

The fact that echolocating dolphins can produce signals with peak frequencies between 100 and 135kHz implies a relatively fast nervous system response because the time between periods of

Figure 11 Echoes from the standard and the -0.3mm targets. The top two traces are the echo waveforms, the middle trace is the envelope of the echo waveforms overlaid upon each other, and the bottom curve is the spectra of the echoes. Adapted from Au (1993).

Figure 12 Brain stem-evoked potential latency for different animals. Adapted from Ridgway (1983).

sound transmission and the auditory response can be short, on the order of $7\text{--}10\ \mu\text{sec}$. The speed of the auditory response can be determined by performing an electrophysiological experiment in which the time difference between the projection of the stimulus and the onset of the brain stem response is measured. This time difference is typically referred to as the latency of response. A comparison of the latency for a variety of mammals is shown in Fig. 12. In order to

Figure 13 Results of the phantom echo experiment. After Au (1993).

fully appreciate Fig. 12, it is important to understand that the brain stem-evoked potential consists of several waves (indicated by Roman numerals) that arrive at the measuring electrodes at slightly different times. From Fig. 12, it is obvious that dolphins have an extremely fast auditory nervous response, faster than that of a rat. The acoustic stimulus must travel into the inner ear where the cochlea nerves discharge and send the electrical pulses to higher auditory centers and eventually to the brain stem. What is very astonishing is the fact that a rat's head is considerably smaller than that of dolphins, yet dolphins have shorter responses than the rat.

The response time of the auditory system of a dolphin can be estimated by performing an integration time experiment. Target detection experiments use phantom echoes to determine this (Au, 1993). The phantom echo generator would digitize the outgoing signal, which was detected by a hydrophone 1.5m in front of the dolphin stationing in a hoop. The digitized signal was stored in the memory of a personal computer, and at the appropriate time delay representing the two-way transit time for a target at 20m , the "echo," was sent back to the dolphin via a small transducer located 2m in front of the animal. In the initial phase, a single echo was sent to the dolphin and the dolphin's hearing threshold for the single echo was determined by varying the amplitude of the echo in a staircase fashion. In the second phase, two echoes were separated by a variable spacing that was sent back to the dolphin. The dolphin's threshold was obtained by varying the amplitude of the whole echo in a staircase fashion for various separation times between the two echoes.

The results of the phantom echo experiment are shown in Fig. 13. For an echo consisting of a single click, the threshold is shown on the ordinate of the curve. Then two echoes were sent back to the animal with a separation time of $50\ \mu\text{sec}$. The threshold for the two-click echo at $50\ \mu\text{sec}$ was approximately 3dB lower than for the single click threshold. This was expected because the two-click echo had twice the amount or 3dB more energy than the single click echo, and the dolphin auditory system, like most mammals, behaves as an energy detector. As the time separation between the two clicks increased to 200msec , the dolphin's threshold remained very constant. However, when the time separation increased to $250\ \mu\text{sec}$ and beyond, the dolphin's threshold began to move toward the threshold for a single click echo. The solid line in Fig. 13 represents the output

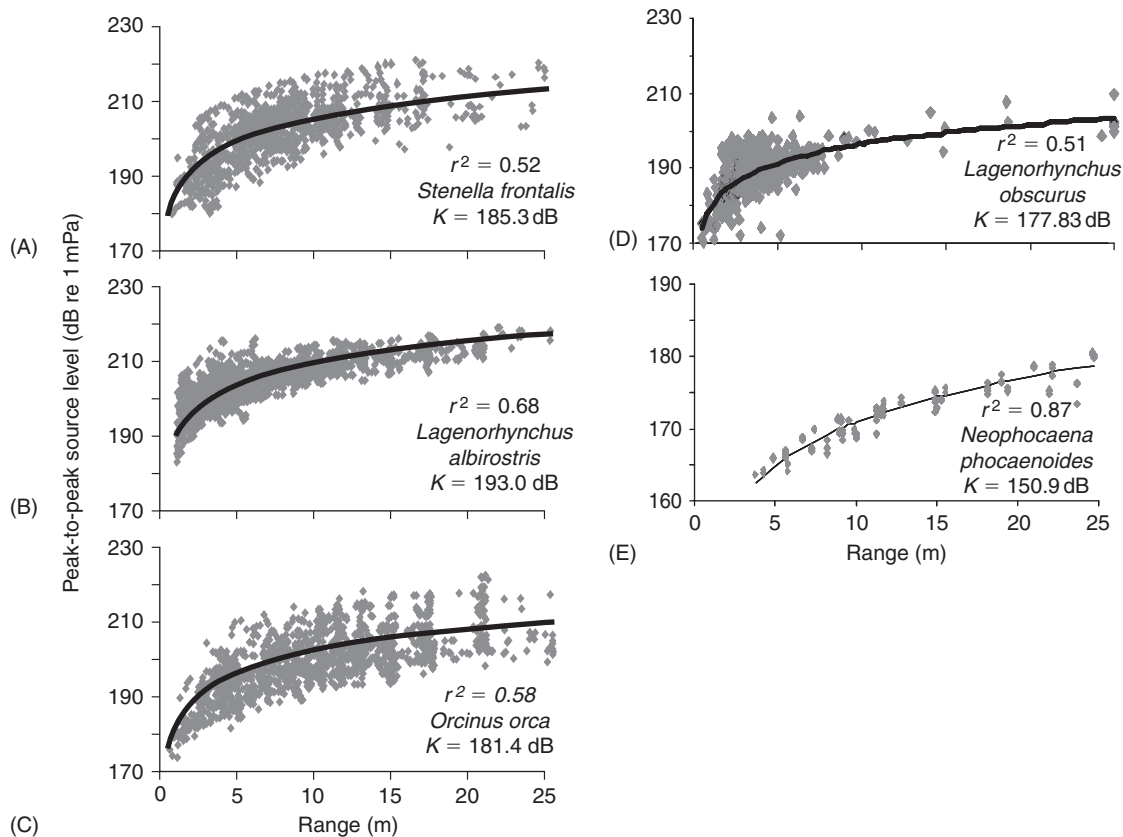

Figure 14 Source level of echolocation signals from five species of odontocetes as a function of range. The data in (A)–(C) are from Au and Benoit-Bird (2003), in (D) from Au and Wursig (2004), and (E) from Li et al. (2006).

of an energy detector having an integration of $264\mu\text{sec}$. The energy detector response with a $264\mu\text{sec}$ integration time best fits the animal results. This integration time is extremely small compared to the integration time of any other mammal.

V. Echolocation Signals of Free-Swimming Dolphins

It has only been recently that detailed studies of dolphin echolocation in the wild have been undertaken using a multiple hydrophone array so that the echolocating animal could be localized. One remarkable finding is that the echolocation signals measured with five different species of odontocetes in widely separate locations, suggest that these animals use a form of time-varying gain or automatic gain control. Time-varying gain is a technique used in technological sonar by which the gain of the receiver increased with time as a function of $40 \log R$, where R is the range in meters, to compensate for two-way spherical spreading losses that the signal and echo experience while propagating the target and back. Dolphins instead, vary the peak-to-peak source level (sound pressure level reference to 1 m in front of any projector) so that the further away a target is the greater the output level of the echolocation signal or conversely, the closer the target the lower the output level. Such variation in the output level of five species of free swimming dolphins are shown in Fig. 14. The solid line is the curve $K + 20 \log R$, that best fit the data with the r^2 value shown for each species. Not only are the data shown in Fig. 14 from five different species of odontocetes, but the measurements were made at widely separated locations. The data for

Stenella frontalis were obtained in the waters of the Bahama Islands, *Lagenorhynchus alborostris* in the waters of Iceland, *Orcinus orca* in the waters of Vancouver Island, British Columbia, *Lagenorhynchus obscurus* in the waters of Kailoura, New Zealand, and *Neophocaena phocaenoides* in the Yangtze River of China.

The dynamic control of the echolocation source level is probably not the result of a cognitive process, but rather a natural consequence of how echolocation clicks are produced. Dolphins typically emit echolocation clicks at a rate that allow the echoes to return to the animal before the next click is emitted. Consequently, the repetition rate increases as an animal closes on a target. The clicks are produced within the nasal system of the dolphins by manipulating the air flow through the phonic lips, previously referred to as the MLDB complex. Dolphins initially pressurize their nasal system and then emit a click train with the clicks occurring at relatively low repetition rate and the animal continually adjusting the rate as targets are located. If the dolphin chooses to keep the amount of acoustic energy emitted relatively constant (or within certain limits for each pressurization cycle), then the amplitude of the signal can be high when the repetition rate is low but must continually decrease as the repetition rate increases. The data are consistent with the notion that there is a dynamic coupling between reception of echoes, repetition rate, and source level of transmitted signals.

VI. Conclusions

Dolphins have very keen echolocation capabilities, much keener than any man-made sonar, especially in a shallow water environment.

The use of relatively short broadband echolocation signals by whistling dolphins is probably the most important factor in the dolphin's good discrimination capabilities. The broad frequency range of hearing extending over 10 octaves and the good peak sensitivity of 30–40 dB re 1 mPa are certainly contributing factors in the dolphin's echolocation capabilities. Another feature of the dolphin's auditory system that contributes to its good echolocation capabilities is the extremely rapid response of its auditory nervous system. The auditory nervous system of the dolphin probably responds faster than that of any other animal if the relative dimensions of the auditory system are taken into account. Finally, dolphins are extremely mobile and can investigate objects at different aspects and angles to maximize the amount of echo information from objects and thus enhance their echolocation capabilities.

Ecological Effects of Marine Mammals

JAMES A. ESTES

There are two ways in which marine mammals and their ecosystems can interact. One encompasses the effects of the ecosystem on marine mammals; the other, the effects of marine mammals on their ecosystems (Fig. 1). Ocean scientists in general and marine mammalogists in particular often consider their worlds from the former perspective. However, the latter perspective should also be of interest for two main reasons. First, there is a large and growing body of evidence from diverse ecosystems for the ecological importance of large vertebrate consumers, including several marine mammal species (Pace *et al.*, 1999; Shurin *et al.*, 2002). And second, significant ecological effects of marine mammals are implied from their great abundance, high trophic status, high metabolic rates, and the resulting fact that some of these consumers co-opt significant proportions of their ecosystem's primary production (Estes *et al.*, 2006). Many marine mammal species have been depleted through overexploitation for protein, oil, and other products. A few others have increased dramatically in recent years due to protection from human harassment or perhaps other factors. If marine mammals are important drivers of ecosystem structure and function, the ecological effects resulting from these changes in their abundance could be substantial. It follows that the structure and function of future world oceans may depend critically on the way in which the distribution and abundance of marine mammals are managed.

Figure 1 Cartoon drawing illustrating the various interactions between marine mammals and their ecosystems.

I. Conceptualizing and Understanding Interaction Web Processes

A. The Nature of Species Interactions

Before considering the ecological roles of marine mammals in marine ecosystems, it is important to reflect on the diverse ways in which species interact with one another and how these processes can be understood. The influence of any one species on another can be categorized broadly as positive, negative, or neutral. The most ubiquitous and important species interactions probably are those that occur between consumers and their prey. Consumers are fueled by the things they eat and thus the influences of prey on their consumers are usually positive. Prey are killed by the things that eat them and thus the influences of consumers on their prey are usually negative. Competitive interactions between any two species are defined by reciprocal negativity. These interactions can be weak or strong, symmetrical or asymmetric, and manifested through exploitation of a shared resource or behavioral interference. Mutualisms are defined by reciprocal positive relationships. Like competitive interactions, these can be weak or strong, symmetrical or asymmetric. Unlike competitive interactions, mutualisms take many forms.

B. Bottom-Up vs Top-Down Forcing

Bottom-up forcing occurs when the distribution and abundance of species are influenced by production and the efficiency of energy transfer upward through the food web. Top-down forcing occurs when the distribution and abundance of species are influenced by the impacts of consumers on their prey (Hunter and Price, 1992). These processes are not mutually exclusive nor do they act independently from one another. Bottom-up effects are ubiquitous in nature whereas top-down effects may not be. The important questions for this chapter are whether or not top-down forcing processes influence the structure and organization of marine mammal-dominated ecosystems and if so, the relative degree to which variation in bottom-up vs top-down forcing is responsible for changes in the distribution and abundance of marine mammals and their prey.

C. Direct Vs Indirect Effects

Species may interact with one another directly or indirectly. The direct effects of one species on another are those that occur in the absence of intervening species. Indirect effects, in contrast, include one or more intervening species. The indirect effect of predators on lower trophic status species through top-down forcing is known as a trophic cascade (Paine, 1980). It is important to recognize that for any community of species there are vastly more potential indirect than direct interactions (Estes, 2005).

D. Alternate Stable States

Contrary to a widely held view that underlies much of natural resource management and conservation, the same assemblage of species in similar physical settings does not necessarily organize itself in a single manner. In fact, there is growing evidence for alternate stable-state systems, among which the nature of species interactions and the abundances and distributions of species can differ substantially (Scheffer *et al.*, 2001). There are numerous specific causes for this seemingly peculiar feature of ecosystem behavior (Doak *et al.*, 2008). Cultural differences in foraging behavior can develop among individuals within a species as the result of serendipitous events that may be entirely lost to specific explanation. In general, alternate stable

states arise within similar species assemblages because the transition vectors (i.e., the forces that drive population change following a perturbation) are commonly strongly non-linear and the pathways of historical context are highly unpredictable. Given this well-known feature of ecosystem dynamics on the one hand and the fact that so many marine mammal populations and their ecosystems have been extensively perturbed by various human-induced influences on the other, there is strong likelihood that the recovery of these systems will lead to alternate states.

II. Approaches to Understanding

While the distribution and abundance of species are relatively easy to observe and measure, species interactions are invisible and therefore difficult to grasp. Two approaches (philosophies) have been employed in efforts to observe and measure the strength of species interactions.

A. Perturbation Approaches

Perturbation-based approaches derive from the assumption that species interactions maintain ecosystems in equilibrium or quasi-equilibrium states, and thus that the interaction web pathways and their strengths can be observed and measured from responses to single species perturbations. Perturbation experiments have been done in three general ways. One of these is through purposeful manipulations, ideally conducted in a controlled and replicated manner. Properly executed over adequate scales of space and time, experiments of this nature provide the least equivocal evidence for species interactions. Most marine mammals cannot be purposefully manipulated for logistic, ethical, and legal reasons. Thus natural experiments based on fortuitous perturbations is another approach that has been used to understand the ecological roles of these and other large, mobile species. Yet another approach is to use historical records to infer the nature of species interactions through the retrospective analysis of patterns of covariation in the abundance of species over time. The scales of such historical analyses have varied from decades or centuries in the case of records obtained by modern humans, to millions of years for those based on the geological record.

B. Constructionist Approaches

Finding informative perturbations and using them to answer specific questions can be challenging. An alternative approach to understanding species interactions is to construct model interaction webs from information on species distributions, abundances, diets, metabolic rates, life histories, behaviors, etc., and then to observe how the model system responds to perturbations of interest. The Ecopath/Ecosim/Ecospace family of mass balance models is one well-known example of this approach (Pauly *et al.*, 2000), although the coupling of energetics and demography to estimate the strength of both bottom-up and top-down trophic effects and a variety of other methods have also been used. By and large, these constructionist approaches are more useful in evaluating the plausibility of particular hypotheses than in predicting population or ecosystem change.

III. Case Studies

A. Otters

Sea (*Enhydra lutris*) otters and the nearshore habitats in which they live provide the clearest and most compelling evidence for the ecological effects of a marine mammal. One reason for the utility of

this particular system is that the Pacific maritime fur trade perturbed sea otter populations in such a way that their ecological effects could be observed on appropriate scales of space and time. Another helpful attribute is that many of the key species in the sea otter's coastal ecosystem are easy to observe, measure, and experimentally manipulate. Studies built around the decline and recovery of sea otters have shown that they limit the size, abundance, and distribution of their benthic invertebrate prey in both soft-sediment and rocky-reef habitats. These and other studies have further demonstrated that the control of herbivorous sea urchins by sea otter predation helps to maintain kelp forests on shallow reefs across much of the North Pacific Ocean (Estes and Duggins, 1995). This trophic cascade from otters to sea urchins to kelp indirectly affects other species and ecosystem processes through increased production, the creation of three-dimensional habitat (the kelp forest), and reduced water flow. The interactions resulting from sea otter predation may have exerted strong selective influences on various other species (Steinberg *et al.*, 1995; Estes *et al.*, 2005).

North American otters also have important ecosystem-level effects, which are founded on a characteristic high latitude sea-to-land production gradient. By foraging at sea and defecating at traditional land-based sprainting sites, North American otters vector nutrients from the sea to the land, thereby increasing secondary production, altering plant species composition, and generating habitat heterogeneity across coastal landscapes. In areas where sea otters and North American otters coexist, sea otters may enhance the effects of North American otters by increasing production and fish abundance in the coastal marine ecosystem.

The direct and indirect effects of sea otters and North American otters are discussed in the chapter on OTTERS, MARINE.

B. Sirenians

Like sea otters, sirenians live in coastal marine systems where many of the species with which they interact can be observed and manipulated. Because sirenians are exclusively herbivores, their direct impacts are on aquatic plant assemblages.

Dugongs (*Dugong dugon*) in the tropical southwest Pacific Ocean provide the clearest evidence for the ecological effects of sirenians. Foraging dugongs uproot seagrasses, reducing their overall biomass, and creating heterogeneous habitats. These effects are clearly evident in seagrass meadows and have even been used to determine the presence or absence of dugongs in particular areas. By generating organic detritus, disturbing the substrate, and suspending sediments, dugong foraging has numerous effects on seagrass species composition and succession, as well as on associated species of invertebrates and fishes.

The intensity of dugong foraging on seagrass meadows varies seasonally in Western Australia because of changes in dugong habitat utilization in response to the risk of tiger shark (*Galeocerdo cuvier*) predation. When large tiger sharks are present during the warm season, dugongs tend to forsake the shallower seagrass-dominated habitats in favor of deeper channels where presumably they are better able to avoid shark attacks. Dugongs also change the way they feed in seagrass meadows (more cropping and less substrate excavation) when sharks are abundant. Large sharks therefore reduce the overall impact of dugong foraging in seagrass-dominated systems.

Although the kelp-eating Steller's sea cow (*Hydrodamalis gigas*) has been extinct for 250 years, the possible role of this species as an herbivore in kelp forest ecosystems is the subject of long-standing interest and speculation. Grazing sea cows may have created light

gaps in the surface canopy-forming kelps, thereby increasing benthic illumination and releasing the competitively subordinate under story kelps from light limitation. Steller's sea cows are believed by most experts to have succumbed to extinction from direct human exploitation. However, others have argued that sea cows may only have been able to persist through an indirect asymmetric mutualism with sea otters, and thus that the sea cow's demise may have been caused or at least facilitated by kelp forest collapses resulting from human overexploitation of sea otters.

Because manatees (*Trichechus* spp.) tend to inhabit highly turbid tropical rivers and streams, relatively little is known of their effects in these systems.

C. Pinnipeds

The ecological effects of pinnipeds are poorly known, due in part to the perspective from which they have been studied and in part to the absence of opportunity. With several notable exceptions, the interactions between pinnipeds and their prey have commonly been viewed from a bottom-up perspective. Furthermore, the areas of the ocean where pinnipeds feed are intrinsically more difficult to study than those described above for marine otters and sirenians.

Despite these limiting perspectives and the limited opportunities for empirically based studies, there are reasons to suspect that pinnipeds are strong interactors in some ecosystems. Pinnipeds have relatively high field metabolic rates and live at high population densities compared with terrestrial carnivores of comparable body size. Pinniped foraging ranges are often limited by distance from shore, thus concentrating their potential ecological effects in relatively narrow bands of coastal habitat.

The most compelling case study of a consumer-induced effect by pinnipeds involves harbor seals (*Phoca vitulina*) trapped in the lakes of eastern Canada. As freshwater lakes were formed following the retreating Pleistocene ice sheet, harbor seals survived in some of these but not others, thus providing the opportunity to contrast lake systems with and without seals. Such contrasts suggest that seal predation affected the size, species composition, and life history patterns of salmonids (Power and Gregoire, 1978). Smaller scale studies have been done on the influences of benthic feeding walrus in the western Arctic. Walrus not only reduce prey biomass, they create pits in the substrate that accumulate detritus, thus facilitating a detritivore-based food web. The only other substantive efforts to document the ecological effects of pinnipeds come from constructionist approaches, most of which have focused on competition between pinnipeds and fisheries.

The distribution, abundance, and behavior of several pinniped species may be influenced by the realization or risk of predation. Various recent population declines have been attributed to predation by sharks and killer whales (*Orcinus orca*). Striking behavioral contrasts in the reaction of pagophilic (ice-associated) pinnipeds to humans between the Northern (fright reactions) and Southern Hemispheres (generally tame) are purportedly due in large measure to the differential risk of predation from polar bears (*Ursus maritimus*) and humans in the Northern Hemisphere.

D. Cetaceans

The potential influence of cetaceans on marine ecosystems is intriguing because of the antiquity of cetacean evolution, the diversity of foraging modes employed by various mysticetes and odontocetes, and because cetaceans comprise far more consumer biomass

than other marine mammal groups (Estes *et al.*, 2006). This latter feature suggests not only large effects of cetaceans on their associated ecosystems, but a release from any such effects following the overexploitation of whales by industrial whaling. As is generally true for pinnipeds, the ecological effects of small cetaceans are mostly unexplored, for likely the same reasons.

The great whales are thought to be ecologically important because of their influences as predators, as prey, and as detritus (Fig. 1).

1. As Predators Gray whale (*Eschrichtius robustus*) foraging on the Bering Sea shelf probably provides the clearest example of consumer-induced effects by a large cetacean. Gray whales consume various epibenthic and infaunal invertebrates, in the process re-suspending large quantities of sediment and nutrients. Gray whale feeding pits contain 50% less invertebrate biomass, and a fauna dominated more by free-living scavenger amphipods compared with the tube-building amphipods and polychaetes that characterize unexploited sites. The rate of sediment re-suspension from gray whale feeding is substantial, equaling or exceeding the rate of sediment input from the major rivers that enter the Bering Sea. This latter process must have a wide range of influences on marine fishes, birds, and mammals in the highly productive Bering Sea Ecosystem.

Other consumer-induced effects by great whales are known or suspected. The depletion of once abundant krill-feeding mysticetes by industrial whaling in the Southern Ocean purportedly led to more abundant krill, in turn resulting in improved body condition, earlier reproduction, and population increases by other krill-feeding species, including the smaller-bodied mysticetes and odontocetes, penguins, and various pinnipeds. Similar kinds of effects likely occurred in squid-based food webs following the reduction of sperm whales. Time series analyses further suggest that predatory fishes and piscivorous or semi-piscivorous whales once competed for what may have been a jointly limiting forage-fish prey base in both the North Atlantic and North Pacific Oceans.

2. As Prey Because of their large size, great abundance, and high energy density, the great whales represent a valuable nutritional resource for both human and animal consumers. At least one large predator, the killer whale, is known to attack and consume great whales. These behemoths therefore were quite possibly an important prey resource for killer whales, especially prior to industrial whaling. Modern industrial whaling may have facilitated this interaction by dispatching the living whales, advertising their locations through the sounds produced by exploding harpoons and preventing the carcasses from sinking by injecting them with gas, thereby greatly extending the periods of time carcasses were available on the ocean's surface to scavenging by killer whales. The reduction of great whales through industrial whaling and the sudden elimination of harvested carcasses as a food resource for killer whales at the end of the industrial whaling era, may have caused transient killer whales to expand their diets to include smaller marine mammal species, ultimately resulting in population declines of some of these. Although there are numerous records of attacks by killer whales on various great whales, and living whales commonly have rake marks on their flukes from failed killer whale attacks, the importance of consumer-prey interactions between killer whales and large whales is much contended.

3. As Detritus Dead whales that are not immediately consumed either wash ashore or sink to the sea floor. Although whale falls only constitute an estimated 0.3% of the particulate organic flux to the seafloor, these materials are highly concentrated so that the area in

the immediate vicinity of a fallen carcass receives the equivalent of several thousand years of organic carbon input in a single pulse. A diverse assemblage of species (approximately 370 in the North Pacific Ocean alone) utilizes these carcasses, some of which appear to be obligate associates of whale falls.

Whale falls typically undergo a succession of stages upon reaching the sea floor. These include an initial *mobile-scavenger stage*, in which organisms like sleeper sharks (*Somniosus* spp.), hagfish, crabs, and amphipods remove flesh from the carcass; an *enrichment-opportunist stage* in which invertebrates and heterotrophic bacteria colonize the organic carbon-rich skeleton and surrounding sediments; a *sulfophilic stage* in which chemoautotrophic organisms exploit the sulfide emitting anaerobic decomposition of skeletal lipids; and a *reef stage* in which organisms exploit the physical structure of inorganic skeletal remains. Because the first three of these stages may require decades to run their course, the effects of whaling on deep sea assemblages are perhaps only now becoming manifest.

Marine mammals in general and large whales in particular provide important nutritional resources to various terrestrial vertebrates, including bears, foxes, eagles, and condors. The demise of the California condor (*Gymnogyps californianus*) may have been facilitated by the whaling-induced reduction in stranded carcasses.

IV. Density-Mediated Vs Trait-Mediated Effects

The aforementioned examples all are of what have been referred to as *density-mediated effects*, or those for which the interaction strength is determined by mass-energy relationships between consumers and prey. Consumers can also influence their ecosystems through *trait-mediated effects* or behavioral responses to the risk of being eaten. Trait-mediated effects have been referred to under the rubric of "the ecology of fear." Although the study of trait-mediated effects is still in its infancy, various and sundry examples illustrate their potential importance to the dynamics of consumer-prey interactions involving marine mammals (Box 1). Density- and trait-mediated effects usually are complementary rather than antagonistic, with trait-mediated effects likely being the more important of the two in some instances.

V. Future Directions

Although marine mammals clearly can have important and far-reaching effects on marine ecosystems, at this juncture the support for this contention comes mostly from theory, analogy with other species and ecosystems, and a smattering of case studies (Bowen, 1997). What might scientists do to better understand the ecological roles of marine mammals in the sea? One useful approach would be to document associated changes in the ecosystem as marine mammal populations grow or decline, keeping in mind and controlling for the potentially confounding influences of other environmental factors. Another potentially useful approach would be to use theory and interdisciplinary synthesis to better define the limits of ecosystem behavior. Modeling approaches involving demography, energetics, and behavior could be used to answer such important questions as whether killer whale/marine mammal assemblages are sustainable without killer whale predation on great whales, and if marine mammal population changes are more sensitive to bottom-up or top-down forcing. These latter approaches cannot provide definitive answers, but they can establish the plausibility of hypothesized processes,

which is an important step in the search. Finally, marine mammalogists should continue to expand their conceptual visions and conduct their research in the company of interdisciplinary collaborators.

Box 1

Trait-mediated effects of consumers on their prey may complement density-mediated effects, establishing qualitatively new pathways of important species interactions and even exceeding or overriding the more traditionally understood density-mediated effects in some systems (Wirsing *et al.*, in press). The following select examples illustrate the range of known or suspected trait-mediated effects in marine mammal-dominated systems.

- Great whale migrations from high-latitude foraging areas to low-latitude breeding and calving sites were once thought to function primarily as a means of energy conservation through reduced heat loss in the warmer tropical or subtropical oceans. Subsequent analyses, and the fact that not all large whales migrate toward the equator to reproduce, cast doubt on this explanation. An alternative (and still contended) hypothesis is that large whales migrate to low-productivity tropical waters to reduce the risk of predation by killer whales on the highly vulnerable newborn calves.
- Dugongs spend more time feeding in shallow seagrass meadows during the cool seasons, when large sharks are rare, than during the warm seasons when large sharks are relatively abundant. This behavioral response to the risk of attack by sharks reduces the intensity of disturbance and herbivory by dugongs just as though they were actually being eaten by the predator.
- As sea otters re-colonized long unoccupied habitats in British Columbia, they foraged on the abundant red sea urchins (*Strongylocentrotus franciscanus*) in kelp-deforested ecosystems that had developed in their absence. The damaged urchin tests and other uneaten remains were dropped to the seafloor where they elicited a flight response by healthy conspecifics. Kelps re-colonized areas from which the urchins had fled just as though they had been directly removed by sea otter predation.

Ecology, Overview

BERND WÜRSIG

Marine mammals have entered just about all ocean habitats, and several mighty rivers and inshore seas as well. Only the deep abyss is foreign to them, but—remarkably—elephant seals (*Mirounga* spp.), sperm whales (*Physeter macrocephalus*), and several other toothed whales can “easily” dive to depths that exceed 1000 m, where it is cold and dark and where the pressure is 100 times and more what we experience on land. Perhaps just as remarkable is the fact that some of these divers, the pinnipeds, are also able to live on land, where they mate, give birth, and molt.

Morphologic, physiologic, and behavioral adaptations to the environments of marine mammals are largely driven by their food and the habitats of their prey. Although there are various ways that ecological adaptations can be divided, this article does so by several broad-based general habitat types: open ocean, semipelagic, coastal, and riverine feeding and breeding habitats and—for pinnipeds and the polar bear (*Ursus maritimus*)—their obligatory stint on land to breed.

I. Open Ocean

There are two major types of open ocean marine mammals: “surface dwellers” and “deep divers.”

A. Surface Dwellers

In most of the open ocean or pelagic zone, smaller toothed whales and dolphins spend their entire lives within about 200 m of the surface. The near-surface environment is low in primary and secondary productivity except in latitudes higher than about 40° north and south of the equator. Therefore, these pelagic cetaceans travel great distances in search of food, often in large herds of hundreds to thousands. The large herds may be for better detection of prey, possible cooperative prey herding, and enhanced detection of predators such as deep water sharks and the larger cousins of dolphins, killer whales (*Orcinus orca*). All of these capabilities may be enhanced by several species traveling together, in so-called multispecies aggregations. An example in the eastern tropical Pacific (ETP), where a dolphin herd may travel over 1000 km in 1 week, is the co-occurrence of spinner (*Stenella longirostris*), pantropical spotted (*S. attenuata*), and common (*Delphinus* spp.) dolphins. These dolphins are slim-bodied (or “sleek”), built for speed and long-distance endurance. They do not have the thick blood (packed with red blood cells) so characteristic of deep divers. Instead, they feed on sporadically encountered near-surface fishes and squid, or at night on animals that rise to within several hundred meters of the surface in association with the deep scattering layer (DSL). Their occurrence in large schools has another function: the school is the social, breeding, and calf care-giving unit, and these nomadic wanderers tend to be within their “complete” society at all times (Norris and Dohl, 1980). Exceptions are when young males, e.g., may form separate bachelor herds or bands or when adult males move among breeding herds (as in sperm whales).

While several species of baleen whales migrate through deep water, they tend to feed on rich areas of invertebrates and fishes that are found more often close to shore. However, others habitually feed in open ocean waters. As is the case for the surface-dwelling odontocetes, baleen whales most often feed within about 200 m of the surface, as none of them are exceptionally deep divers. The balaenopterid whales termed rorquals, blue (*Balaenoptera musculus*), fin (*B. physalus*), sei (*B. borealis*), and Bryde’s and Eden’s whales (*B. brydei* and/or *B. edeni*) are good examples of oft-pelagic, near-surface feeders. Blue and fin whales tend to feed on euphausiid crustaceans, or krill; whereas sei and Bryde’s whales feed more commonly on shoals of fishes. All of them lunge through their food rapidly. The balaenid right (*Eubalaena* spp.) and bowhead whales (*Balaena mysticetus*) often surface-skim feed in the open ocean of productive high latitudes, whereas gray whales (*Eschrichtius robustus*) feed on ampeliscid (tube-dwelling) amphipods. The latter do so in waters less than 200 m deep, both near shore, and far away from land in the Bering, Chukchi, and Beaufort Seas. Although rorquals are built for speed so that they can lunge into food rapidly, balaenid and gray whales tend to a more rotund body shape, with great blubber storage capability for long fasts (Berta and Sumich, 1999).

Many pinnipeds also feed near the surface and, at times, up to several hundred kilometers from shore. The smaller true seals (such as ringed seals, e.g., *Pusa hispida*) and all of the eared seals are not deep divers and therefore stay near the surface in those generally higher latitude waters where they find themselves in the open sea. Near-surface feeding pinnipeds are not likely to be out on truly oceanic seas further than several hundred kilometers from land.

Northern fur seals (*Callorhinus ursinus*), however, are often found in deep pelagic waters of the north Pacific (Costa, 1993).

B. Deep Divers

Many of the larger toothed whales and a few true seals dive “deeply,” or below about 500 m. Sperm whales are likely to be the champion divers. They routinely feed at depths around 500 m on fishes and squid, but can also dive to 2000 m and more in search of the larger truly pelagic squid. Although we know little of the dive capabilities of other deep-diving odontocetes—pilot whales (*Globicephala* spp.), beaked whales (family Ziphiidae), dwarf and pygmy sperm whales (family Kogiidae), and the false killer whale (*Pseudorca crassidens*) are good examples—it is likely that all of them are capable of greater than 500-m dives as they feed largely on mid-sized deep water fishes (often of the family Myctophidae) and squids. Curiously, the largest dolphin-like (or delphinid) cetacean, the killer whale, appears to feed without diving deeply. It is possible, but remains unproved, that some smaller toothed whales can evade killer whales by diving down.

The champion pinniped divers are northern (*Mirounga angustirostris*) and southern (*M. leonina*) elephant seals as well as the Weddell (*Leptonychotes weddellii*) and probably several other large true (or phocid) seals. They can (but do not often) dive down to 1000 m and beyond. They feed on fishes and squid at these depths, but it has been surmised that at least some deep dives are “resting dives” as the animals conserve energy while their metabolism is largely shut down at depth. Such possible rest (or “sleep”) may even help them evade detection by predators such as most active sharks, who are not deep divers, and killer whales. Because elephant seals spend only about 15% of their time at the surface, it is not really correct to call them “divers.” Their life is underwater and they are indeed “surfacers” who come up only for life-sustaining air (LeBoeuf and Laws, 1994).

All deep divers have adapted physiologically and morphologically for the task. Blood and muscles have changed to hold as much oxygen as possible, and peripheral vasoconstriction and shutting off non-vital body functions during a dive take place.

II. Semipelagic

Quite a few marine mammals habitually occur in the zone between shallow and deep water, often at the edge of the continental shelf or some other underwater feature. There is high productivity there, caused by upwelling or current systems as sea meets land, and it makes sense that this is a major point of aggregation. Sperm whales off Kaikoura, on the South Island of New Zealand, feed in such a zone near the deep Hikurangi Trench about 10 km out. However, the sperm whales are often within 1–5 km from shore, in productive waters 200–600 m in the deep, shore side of the trench. Blue whales of Monterey Bay, California, do so as well, as they take advantage of large stands of krill to enter the area in late summer. Dall’s porpoises (*Phocoenoides dalli*) are also found in some abundance in Monterey Bay, not as frequently in very shallow nor very deep waters, but on the edge of the productive Monterey Canyon. Dozens of species and hundreds of geographic examples could be cited as those that occur in such productive “neither nearshore nor open ocean” zones (Evans, 1987; Reynolds and Rommel, 1999).

Several dolphins are “semipelagic” in another sense. They seek out deep productive waters in areas close to shore so that they can feed in the open sea yet retreat to the shallows, often into bays and inlets or onto expansive shoals during rest. Spinner dolphins of the tropical islands of the Pacific have such a habit. During the day, they rest and socialize within island bays and lagoons, even entering atolls

through narrow passes in some areas. It is believed that nearshore rest is to avoid large oceanic swells and trade winds, as well as predation by large oceanic sharks. At night, these dolphins head out to sea, often only 1–5 km from land off abruptly rising volcanic islands or coral atolls. The dolphins meet the DSL as it comes to within several hundred meters of the surface at night and thus have a food resource available that these only-average divers could not obtain during the day, when the DSL is 600 m or more below. Atlantic spotted dolphins (*Stenella frontalis*) appear to do the same, but have daytime rest over an expansive shallow area: the Grand Banks of the Bahamas, only 6–10 m deep.

Pinniped females that go on foraging dives in between nursing their young on land, such as Galapagos fur seals (*Arctocephalus galapagoensis*), also use the productive shelf and drop-off waters to feed while—in their case—needing to return to land to take care of their young.

III. Coastal

Many marine mammals can be termed “coastal,” and because all of the various taxonomic orders and suborders have coastal representatives, one to several examples of each group are given here.

The most coastal baleen whale is undoubtedly the gray whale, for it feeds in shallow waters of the Bering Sea, usually but not always near coasts; travels on its immense migration from the Bering Sea to Baja California, Mexico—and back—along the coast; and mates and calves near and in coastal lagoons of the subtropics. It is likely that this rather slow cetacean hugs the coastline for safety (mainly, one surmises, for its young) against shark and killer whale predation. It probably also uses the coast to navigate. It would not be surprising, although present information is not clear on this point, if gray whales use the depth contours, rocky outcroppings of headlands, and other near-coastal features as signs of location as surely as we find our way to and from the supermarket. The coastline also allows them to find clouds of mysids, small aggregating invertebrates, among kelp beds, and to occasionally feed on stands of in-benthic invertebrates while on migration. A second “coastal” animal is the humpback whale (*Megaptera novaeangliae*), for it feeds in bays and inlets, breeds near islands, and only uses deep oceanic waters to get to and from these ends of migration. In the northeast Pacific, humpbacks feed in the fjord-like bays of southern Alaska and breed around the Hawaiian and Mexican Revillagigedo islands.

Odontocete cetaceans have many coastal representatives, with the best studied of them being the bottlenose dolphin (*Tursiops truncatus*). While separate populations of this highly adaptable species can exist in deep oceanic waters as well, it is the coastal form that has taken our fancy and makes for one of the better captive animals, presumably because it feels at home in small groups and with confines of cliffs, rocks, bayous, and channels. Bottlenose dolphins variably nose and poke their way among rocks to feed; feed on schooling fishes in the nearshore, at times trapping schools against a beach or cliff; feed on the bottom; and encircle prey as a cooperating group in the open coastal sea. Dolphins of the *Cephalorhynchus* genus of Southern Oceans tend toward coastal living, as do the humpback dolphins of the genus *Sousa*, harbor porpoises (*Phocoena phocoena*), and beluga whales (*Delphinapterus leucas*) of the Arctic. Interestingly, these animals tend toward fission–fusion societies, traveling in subgroups of variable size from day to day. It is likely that they aggregate in small groups for greatest efficiency in hunting, and that the social or breeding unit consists of all of the small groups of an area that get together at some time throughout a year, but never

all at once. Most but not all coastal waters are turbid as well, and it may be that echolocation and communicative sounds are particularly well developed in these animals.

Many pinnipeds have coastal representatives, especially for the physically smaller species. California sea lions (*Zalophus californianus*) rest on the shore and feed in the coastal zone, hardly ever venturing further than several kilometers from land. Harbor seals (*Phoca vitulina*) and the two endangered tropical monk seals (*Monachus* spp.) do so as well.

Sea otters (*Enhydra lutris*), marine otters of Chile (*Lontra felina*), and the sirenians are all coastal shallow-water feeders. Otters feed on invertebrates on the bottom or on kelp-associated fishes. While many populations of sea and marine otters do not frequently haul out on land, they use kelp beds as resting stations and perhaps as a means to hide from sharks and killer whales (Estes and Duggins, 1995). The West Indian manatee (*Trichechus manatus*) and the dugong (*Dugong dugon*), the latter largely of the nearshore Indian Ocean, feed on seagrasses and are thereby restricted to the shallows (Reynolds and Odell, 1991).

IV. Riverine

While the term “marine mammals” is meant for mammals that take all or most of their food from the sea, several species are included that have gone to a largely freshwater environment. Because these have close taxonomic affiliations to several other marine mammals, this inclusion makes sense.

There are several obligate river dolphins: the susu and bhulan [now listed as subspecies within one species (*Platanista gangetica*)] of the Indian subcontinent; the baiji (*Lipotes vexillifer*) of the Yangtze River of China (recently declared likely to be extinct, Turvey *et al.*, 2007); and the boto or Amazon river dolphin (*Inia geoffrensis*) that also occurs in the Orinoco basin of South America. These dolphins live their lives in mighty rivers, feeding on invertebrates and fishes, generally in small groups numbering fewer than about six animals. Their eyes have adapted to the less saline environment and their kidneys do not need to process the salty foods of the ocean. It is likely that they would not survive in salt water. The Amazonian manatee (*Trichechus inunguis*) is also restricted to the extensive freshwater system of the Amazon basin.

In addition to obligate river dolphins and the Amazonian manatee, there are several mammals that are facultative, those who have populations that occur in rivers and those who go in and out of rivers to the adjacent ocean. Of the first type are finless porpoises (*Neophocaena phocaenoides*) that occur throughout nearshore waters of southern Asia and a bit of the Indian Ocean, but have a thoroughly freshwater population in the Yangtze River. Recent work shows that the freshwater form has eyes, skin, and kidneys that are adaptively different from their ocean-going conspecifics. As well, the diminutive tucuxi dolphin (*Sotalia fluviatilis*) occurs nearshore along much of the tropical Atlantic Central and South American coast, but as separate populations in the Amazon River basin. Of the second type of marine mammals, where some go in and out of rivers as members of the same population, are Irrawaddy dolphins (*Orcaella brevirostris*), bottlenose dolphins, belugas, West Indian manatees, and West African manatees (*Trichechus senegalensis*). To date, there are no well-defined morphologic or physiologic differences between those who are frequent in freshwaters more than others, and it is assumed that this wide salinity tolerance is itself an adaptation that allows exploitation of food resources in ecologically diverse realms. Belugas seem to enter rivers more often during a concentrated

period of skin sloughing or molt; these are the only whales with a well-defined molting period, although all whales and dolphins are “constantly” shedding their outer skin.

Almost all pinnipeds are generally tied to the sea to feed, but a form of the harbor seal and the Asian Lake Baikal (freshwater) and Caspian Sea (somewhat salty) seals (*Pusa* spp.) occur in land-locked areas. They occur in remnants of areas that were once connected to oceans.

V. Life on Land

Polar bears do considerable feeding on land or ice, pinnipeds all need to come to land to give birth, and sea otters do so variably by population. Off California, sea otters give birth in the water, but are usually surrounded and buoyed by *Macrocystis* spp. giant kelp fronds. While some pinnipeds, such as the walrus (*Odobenus rosmarus*) and Weddell seals, mate in water, others do so on solid land or ice, and all females need to come to solid substrates to give birth and to suckle their young. Indeed, most newborn pinnipeds (and the polar bear) are not yet a marine mammals and would become overexposed rapidly and die if they were to be dunked into water. The natal pelt of most true or phocid seals is a downy fur, or lanugo, that holds insulating hair but is not waterproof; they have brown fat, a type of lipid that breaks down rapidly to generate heat; and they instinctively huddle near mother and each other to stay warm (Stirling, 1988; Berta and Sumich, 1999, on polar bears).

Pinnipeds have shortened and greatly changed fore and hind flippers, modified beautifully for swift and precise movement in water. However, they have had to compromise their morphology to keep a bit of it—so very necessary for procreation—available for life on land. It is now known that early cetaceans lived a similarly dual existence, with morphologic, physiologic, and likely behavioral compromises to survive in both realms. It is tempting to speculate whether pinnipeds, given another 20 million years of evolution, could make the same total transition to the sea.

Elephant Seals

Mirounga angustirostris and *M. leonina*

MARK A. HINDELL AND WILLIAM F. PERRIN

I. Characteristics and Taxonomy

The northern elephant seal (*Mirounga angustirostris*) and the southern elephant seal (*M. leonina*) are the largest pinnipeds (Ling and Bryden, 1981; McGinnis and Schusterman, 1981). The most striking characteristic of both species is the pronounced sexual dimorphism, with males weighing 8–10 times more than females. Male southern elephant seals have been recorded to weigh 3700 kg, whereas females only weigh between 400 and 800 kg. This makes the elephant seal the most sexually dimorphic mammal (Fig. 1). There are other pronounced secondary sexual differences in morphology, all of which are related to the highly polygynous mating strategy of the species. Most notable of these is the large proboscis of the male that plays a key part in dominance displays with other males (Sanvito et al., 2007a).

The evolutionary origins of the species are unclear, with estimates of the divergence from a common ancestor ranging from as little as 10,000 years ago to as far back as the Pleistocene. Morphological differences between the species are, however, quite distinct and they are readily differentiated. The southern species is larger, with northern elephant seals rarely reaching more than 2300 kg. In both species, adult females exhibit a considerable range in body weight and there are no clear differences between them in this feature. Adult males of the northern species have a longer proboscis than the southern species. Northern elephant seals also have a more developed chest shield, a region of the neck, chest, and shoulders of thickened and scared skin associated with fighting. In the northern species, this has a distinctive red coloration. Females lack the proboscis and chest shields, but northern females are distinguished by a noticeably narrower and flatter nose than in the southern species.

II. Distribution and Abundance

Despite their physical similarities, the two species have very different geographic distributions, with at least 8000 km separating them. Southern elephant seals have a more extensive range, with breeding sites on islands scattered right around the subantarctic (Fig. 2). Very occasionally, pups are even born on the Antarctic mainland. The range extends north to Patagonia and the Falkland Islands (Las Malvinas) (Lewis et al., 2006a). Studies have indicated that when not ashore during the breeding season or for their annual molt, southern elephant seals utilize most of the Southern Ocean ranging from waters north of the Antarctic Polar Front (sometimes called the Antarctic Convergence) to the high Antarctic pack ice. There is some separation of feeding areas between the sexes, with males tending to feed in the more southerly waters associated with the Antarctic continental shelf.

Northern elephant seals have a limited breeding distribution, pupping at approximately 15 colonies between Point Raines in northern California to the Baja California Peninsula in Mexico (Fig. 3). Most of the colonies occur on offshore islands, but a small number occur on the mainland coast. As with southern elephant seals, the

Figure 1 Northern elephant seal (C. Brett Jarrett).

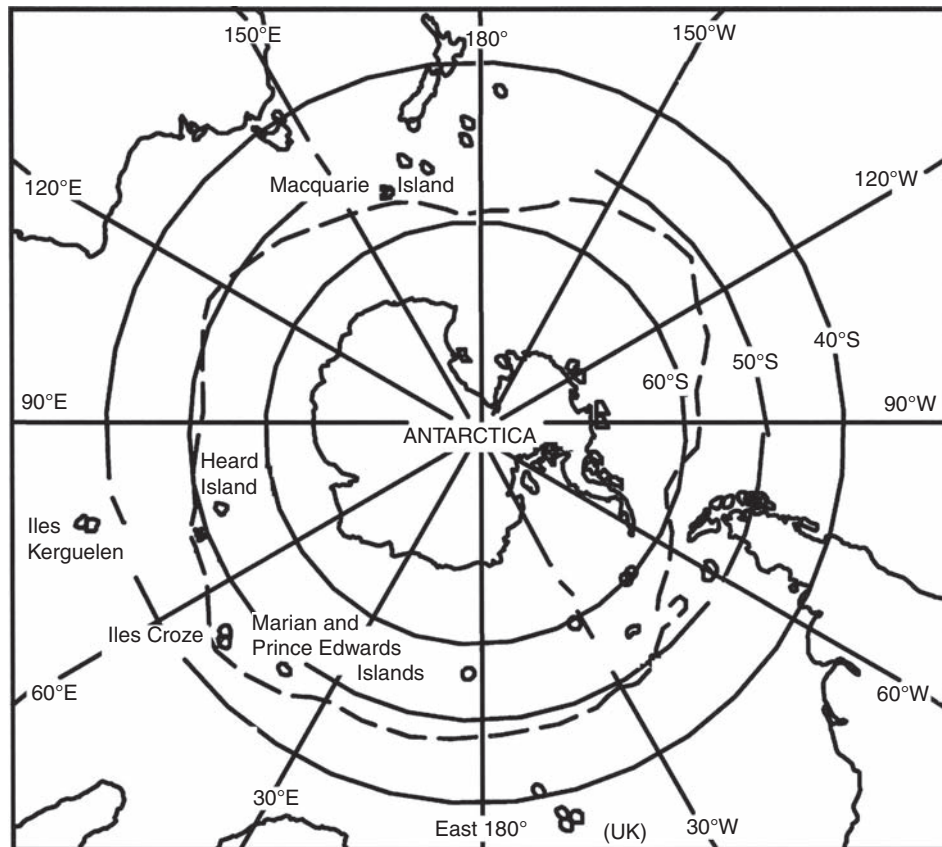

Figure 2 Map of the Southern Ocean indicating the major southern elephant seal breeding islands (named in map).

northern species disperses widely during the non-breeding phase of its annual cycle. Many individuals travel northward along the North American coast to feed in the Gulf of Alaska and the Aleutian Islands, which is a round trip of more than 10,000 km. This MIGRATION is even more remarkable as many individuals make it twice

per year, returning to their southern breeding grounds to molt. The northern species also exhibits sexual differences in foraging areas, with males tending to use the more northerly areas and females heading in a more northwesterly direction and feeding in deep oceanic waters of the North Pacific Ocean.

Figure 3 Map of the West coast of North America indicating the major northern elephant seal breeding sites.

Northern elephant seals are presently undergoing a rapid population increase and range extension, whereas the southern species is currently experiencing a decline in two of its three major populations.

Population declines in the order of 50% have been recorded in both the southern Indian and the southern Pacific Ocean populations since the 1950s and 1960s, whereas the populations in the South Atlantic are stable or increasing. For example, the relatively small breeding population at Prince Edward Island declined at least 66.3% between 1977 and 2004 (Bester and Hofmeyr, 2005). The estimated total population size for southern elephant seals in 2000 was 640,000. Modeling suggests that the declines are due to relatively small changes in fecundity and survival (McMahon *et al.*, 2005a), but the underlying causes are presently unclear. Two plausible hypotheses are that they are related to interspecific competition or to environmental change causing change in food availability (McMahon *et al.*, 2005b; Pistorius *et al.*, 2005).

Conversely, northern elephant seal populations are currently increasing at a rate of approximately 6% per annum. This is the latest phase in one of the most remarkable population recoveries of any mammal. The total number of northern elephant seals in 1890 is thought to have been less than 100 individuals after 50 years of intensive and indiscriminate hunting by sealers. The last published estimates of the population put the total population at 127,000 in 1991. The expansion may have slowed in some regions (e.g., no change in abundance was detected at one of the San Benito Islands in Mexico between 1980 and 2001) (García-Aguilar and Morales-Bojorquez, 2005).

As a direct consequence of the extensive hunting in the nineteenth century, northern elephant seals passed through an intense genetic bottleneck, which has seen almost all genetic variation removed from the population. The relatively recent expansion onto several islands has not yet resulted in discernible genetic variation between the breeding groups.

In contrast, southern elephant seals have quite a clear genetic structure, with four distinct stocks: the southern Pacific Ocean, the south Atlantic, the southern Indian Ocean, and a small, but increasing population at Peninsula Valdes in Argentina. The integrity of the subpopulations appears to be maintained by the extremely low inter-change rates between populations. Although genetically distinct, animals from the subpopulations are indistinguishable from each other in external features.

III. Ecology

Elephant seals spend more than 80% of their annual cycle at sea, making long migrations to favorable foraging areas and feeding intensively to build up the blubber stores required to support them during breeding and molting haulouts (van den Hoff, 2001). The seals prey on deep-water squid and fish (Daneri and Carlini, 2002; van den Hoff *et al.*, 2003) and, as a result, have developed the remarkable ability to dive to depths in excess of 1500 m and for as long as 120 min (Le Boeuf and Laws, 1994). While these values are the extremes of those recorded, even the average values are impressive. Adult females routinely make dives of 20 min and reach depths of 400–800 m. Paradoxically, although the males generally dive for longer, about 30 min, they often do not go as deep. This is a reflection of their tendency to feed over continental shelves, whereas females use deeper open water. Age-related shifts occur (Field *et al.*, 2007), which may accomplish niche expansion and resource partitioning (Lewis *et al.*, 2006b; Field *et al.*, 2007). For example, in the Antarctic, juvenile males remain within the pack ice to forage on the shelf (Baillieul *et al.*, 2007); similar behavior is observed for juvenile males on the Patagonian shelf (Campagna *et al.*, 2007).

Foraging activity and success vary with oceanography features such as sea-surface temperature (SST) and events in both hemispheres (Bradshaw *et al.*, 2004; Campagna *et al.*, 2006; Simmons *et al.*, 2007), as do the prey species taken (Piatkowski *et al.*, 2002; Crocker *et al.*, 2006).

IV. Behavior and Physiology

Elephant seals spend as much as 90% of the time submerged, the majority of it hunting for food, but other behaviors, such as traveling from place to place, and apparently even resting, take place at depths of more than 200 m. A number of morphological and physiological adaptations and behaviors make this, and prolonged fasting ashore, possible (Hindell *et al.*, 2000; Lester and Costa, 2006; Davis *et al.*, 2007).

Monachine seals all have an unusual annual molt, which entails the shedding of epidermal tissue in addition to the hair. The rich supplies of blood required at the body surface for the new skin and hair require the animals to leave the water in order to conserve body heat. The seals therefore spend 3–5 weeks fasting ashore during this time, once again relying on stored blubber to supply their energy requirements (Champagne *et al.*, 2006). Primiparous females tend to molt and haul out earlier than other breeding females (Kirkman *et al.*, 2004); timing of molting also varies over other age/sex classes (Kirkman *et al.*, 2003).

Both species of elephant seal are highly polygynous, with large, dominant males (alpha males) presiding over large aggregations of females known as “harems.” Competition between males for the alpha position is intense and leads to spectacular fights. Successful males will have almost exclusive access to harems consisting of up to 100 females and so the reproductive benefits of success are very

high. This has led to the evolution of the pronounced secondary sexual characteristics of immense body size and exaggerated proboscis. Vocalizations also contribute to the struggle for females; they have been found to convey significant information on age, size, and resource-holding potential (Sanvito *et al.*, 2007b).

V. Life History

Age at first breeding in females ranges from 3 to 8 years, with average values varying with species, population status, and environmental changes (Sydeman and Nur, 1994). There are tradeoffs between fecundity and survival. In one study of the northern elephant seal, maternal survival was inversely related to age of primiparity, although this was not found in a similar study of the southern species (Pistorius *et al.*, 2004).

The annual breeding cycle begins when the largest males haul out on deserted beaches (in August for *M. leonina* and in December for *M. angustirostris*). Pregnant females then haul out in large numbers, aggregating into harems, and giving birth to their single pup 2–5 days after arriving. The females stay with their pup throughout the ensuing lactation period, never feeding and relying on their thick BLUBBER layer to sustain them and to supply many liters of milk required by the rapidly growing pup. At birth the pups weigh between 30 and 40 kg in both species, but by the time they wean, southern elephant seal pups weigh approximately 120–130 kg and northern elephant pups weigh approximately 140–150 kg. The difference in weaning weight is due to the slight difference in the duration of lactation in the two species, with southern elephant seals weaning at 23–25 days and northern elephant seals at 26–28 days.

Several days before weaning their pups, the females come into estrus and are mated by the dominant males. Although fertilization takes place at this time, the blastocyst does not implant until several months later. This ability, known as delayed implantation, is common to many pinnipeds. Once the pup is weaned, the females depart to sea, leaving the pups to fend for themselves. The pups spend the next 4–6 weeks teaching themselves to swim and hunt, during which time they rely heavily on the large reserves of blubber that they got from their mothers while suckling. When the pups eventually leave their natal beaches they spend the next 6 months at sea. This is a difficult time for the pups and as many as 30% of them die at this time.

VI. Human Interactions

Today, both species of elephant seal are relatively free of adverse interactions with humans. Southern elephant seals are only rarely captured in the nets of Southern Ocean fishing fleets, and this has never been reported for the northern species. There are some grounds for concern that some large-scale fisheries may be competing with the seals for preferred prey species, but this is difficult to quantify given the current paucity of information on the diet of both species. Present impacts may be minimal, but increasing fishing activity may result in significant competition in future (Hindell *et al.*, 2003).

However, both species have a long history of direct exploitation by humans as they were hunted extensively during the 1800s for their blubber, which yielded an unusually high-quality oil. In the case of the northern elephant seal, this hunting was so intense that the populations were reduced to a small group breeding on a single island by 1890. The more widespread and southerly distribution of the southern species meant that the exploitation was less intensive. Nonetheless, the seals were reduced dramatically at all of their major breeding sites.

The exploitation of southern elephant seals also continued longer than that of northern elephant seals, with commercial operations continuing until 1919 at Macquarie Island and until 1964 at South Georgia.

Anthropogenic climate change may affect elephant seals; evidence of correlations between population–dynamics parameters and ENSO may provide insights into the likely impacts of the change (McMahon and Burton, 2005).

Endangered Species and Populations

RICHARD MERRICK, GREGORY K. SILBER, DOUGLAS P. DEMASTER, AND JOHN E. REYNOLDS, III

I. Introduction

Utilization of marine mammals was an integral part of life in early human coastal communities, but humans probably had little effect on most marine mammal populations until commercial exploitation began in the late 1700s for seals and a century later for whales. Vessels traveled to progressively more distant locations, hunting and processing efficiency improved, and commercial applications of marine mammal products expanded. The peak of the southern sealing industry occurred in 1821, when *Lloyd's Register* included 164 sealing vessels. However, by 1830, most seal populations had been depleted, and *Lloyd's Register* only showed one full-time sealing vessel. Commercial whaling reached a zenith (at least for large whales) in the 1930–1940s, and declined markedly in the 1970s because of reduced marine mammal population sizes, development of (synthetic) substitutes for some whale products, and international conservationist pressures.

By the beginning of the twentieth century, many marine mammal populations had reached perilously low levels. Indeed, human exploitation resulted in the extinction of the Steller's sea cow (*Hydrodamalis gigas*) (in 1768, only 27 years after its discovery by Russian explorers), the North Atlantic population of the gray whale (*Eschrichtius robustus*), and the Atlantic sea mink (*Mustela macrondon*). The Caribbean monk seal (*Monachus tropicalis*) and the Japanese sea lion (*Zalophus californianus japonicus*) also became extinct in the twentieth century as a result of human interactions, although not necessarily hunting. Sadly, we must report that, in the short time since our writing for the first issue of this encyclopedia, another species, the "baiji" or Chinese river dolphin (*Lipotes vexillifer*), has been declared extinct (Turvey *et al.*, 2007). Several other species, including the vaquita (*Phocoena sinus*), Hawaiian (*Monachus schauinslandi*) and Mediterranean (*M. monachus*) monk seals, West Indian manatee (*Trichechus manatus*), and North Pacific (*Eubalaena japonica*) and North Atlantic (*E. glacialis*) right whales are now in as precarious a state as the "baiji" faced during the years prior to its extinction. For these species, conservation decisions in the next decade will be critical to long-term persistence.

Eschricht and Reinhardt (1861) and Scammon (1874) foresaw the extinction crisis for marine mammals and warned that certain species or populations of marine mammals had reached dangerously low levels. The increasing recognition of this crisis led to specific measures designed to recover these populations, and also to heightened worldwide concern to prevent the extinction of marine mammals. Some specific efforts included: (1) the 1911 North Pacific Fur Seal Convention (protecting northern fur seals, *Callorhinus ursinus* and sea otters, *Enhydra lutris* (see www.intfish.net/treaties/furseals11.htm); (2) the 1931 League of Nation's "Convention for the Regulation of Whaling" banning the whaling of right whales

in all oceans (see www.intfish.net/treaties/whales31.htm); (3) the 1972 “Convention for the Conservation of Antarctic Seals”; (4) the 1991 “Agreement on the Conservation of Small Cetaceans of the Baltic and North Seas (ASCOBANS)” and “Agreement on the Conservation of Cetaceans in the Black Sea, Mediterranean Sea, and contiguous Atlantic area (ACCOBAMS)”]; and (5) the International Whaling Commission’s global moratorium on commercial whaling in 1986. Other efforts have been more inclusive, such as the US Marine Mammal Protection Act (US MMPA) which protects all marine mammals (endangered or not) within USA territorial waters. Still other efforts, such as those by the International Union for the Conservation of Nature and Natural Resources (IUCN), the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), the US Endangered Species Act (ESA), and the Canadian Species At Risk Act (SARA) have focused on recovering marine mammal species or populations threatened with extinction on a global scale.

Because of these activities, most marine mammal harvests have ceased, and many formerly endangered species or populations are recovering, including the Southern Hemisphere population of fur seals (*Arctocephalus* spp.), the Northern and Southern Hemisphere populations of elephant seals (*Mirounga* spp.), the western Arctic bowhead whale (*Balaena mysticetus*) population, and the Northern Hemisphere populations of humpback whales (*Megaptera novaeangliae*). In 1994, the eastern North Pacific population of gray whales became the first marine mammal species, subspecies, or distinct population segment (DPS) to be formally declared recovered under the US List of Endangered and Threatened Wildlife and Plants. It is important to focus on such recoveries, and apply the lessons learned to promote the recovery of other depleted populations and species.

Most conservation efforts have been directed at reversing the impacts of commercial exploitation. Unfortunately, as harvests have declined or even ceased, other anthropogenic threats have arisen, including those having direct (e.g., fishery by-catches, vessel strikes) or indirect (e.g., loss of prey to commercial fisheries) impacts. These threats have kept some marine mammal populations at low levels and slowed the recovery of others. Although attempts have—and are—being made to reduce bycatch, ship strikes, and other human threats, only time will tell if these can be mitigated. Furthermore, new challenges are now emerging, which will have to be addressed by future generations. These include anthropogenic activities related to habitat destruction, degradation of water quality, disturbance of animals (e.g., anthropogenic noise), bioaccumulation of toxins, and global climate change (including ocean acidification). These impacts are less obvious than direct mortalities and are not easily studied or measured, but may be equally as deadly.

The greatest future threat to all marine species is global climate change. For some marine mammal species, climatic impacts will be profound. For species such as bowhead whales, polar bears (*Ursus maritimus*), and pagophilic seals which depend on ice, changes in distributions are already occurring due to the retreating ice sheets (Derocher *et al.*, 2004). Retreating ice also renders polar areas more accessible to humans (e.g., trans-polar shipping), exposing species in these regions to anthropogenic additional impacts (e.g., noise disturbance) (US Marine Mammal Commission, 2006). For temperate species, the impacts from global climate change are less clear. Rising sea levels and increases in the number or severity of storms, while potentially catastrophic to coastal human communities, would likely have little effect on most marine mammal populations, particularly pelagic ones. However, changes in ocean productivity resulting from sea temperature increases, changes in currents, ocean acidification,

increases in storms, and greater river run-off may have significant biotic impacts. These could change an entire ecosystem’s carrying capacity, affecting the system’s ability to support marine mammals at pre-exploitation abundance levels.

In this chapter, we focus on marine mammals that require protection in order to survive well into the twenty-first century and beyond. We give reasons why some marine mammals are in critical condition today, and we identify lessons and trends that may help explain why some groups recover and others do not. We provide definitions of criteria under which such groups are classified by legislation, conventions, or other approaches such as the IUCN Red List of Threatened Animals, CITES, the MMPA, and the US ESA. Finally, we highlight the types of data and information that, if collected, would be helpful in conservation and recovery efforts.

II. Why Do Marine Mammal Populations Become Endangered or Fail to Recover?

What makes a species endangered? One can define an endangered species based solely on demographic characteristics; i.e., the abundance of the species is so low *or* abundance is declining so precipitously *or* the species range has retracted so greatly that the species is in danger of becoming extinct. Note that while an endangered species may be synonymous with a taxonomic species, it can also be defined as a DPS of the species. An alternate approach is to consider a species endangered because of threats which could lead to its extinction. Ultimately, what makes a species endangered is some marked change to the species itself or to its ecosystem (e.g., increased exploitation, loss of habitats, etc.). Many, if not most, marine mammal species considered to be at risk of extinction reached this situation as a result of human activity (i.e., harvesting). Only in recent decades have humans affected marine mammal habitat sufficiently to place species at risk. These more recent habitat impacts now place more marine mammal species at risk of extinction, even those not formerly at risk due to harvesting.

Various aspects of marine mammal demography also contribute to their extinction vulnerability. Marine mammals generally exhibit low reproductive potential, maturing at a late age and giving birth to few offspring. This strategy means that once a population is reduced, it will be slow to recover. Moreover, even pristine populations of some marine mammal species or subspecies were fairly small [e.g., killer whales (*Orcinus orca*), monk seals (*Monachus* spp.)]. Such low abundance would certainly make the species vulnerable to extinction and incapable of withstanding significantly increased predation (e.g., the Steller’s sea cow). This innate vulnerability, coupled with various environmental threats, has led to the precarious status of some species and populations.

A. Life History

Life-history attributes are biological characteristics of a species that maximize the fitness, and include such traits as age at sexual maturity, age-specific survival, sex- and age-specific growth rates, reproductive interval (or its inverse, the reproductive rate), and longevity. Life-history attributes dictate the potential for population growth. Biologists identify two extreme types of life history strategies among species: the “*r*-strategists” in which the ability to reproduce quickly is critical (and which typically have a high fecundity, small body size, short generation time, and wide dispersal of offspring, each of whom has a low probability of survival to adulthood), and the “*K*-strategists” in which the ability to compete successfully for

limited resources is critical (and which typically exhibit a large body size, long-life expectancy, and produce fewer offspring that require extensive parental care until they mature). For further details on r and K strategies, see Pianka (1970) and Reynolds *et al.* (2000).

The life histories of plant and animal species lie along a continuum between these two extremes. As a group, marine mammals are *extremely* close to the K end of the spectrum. K-strategists generally adapt poorly to changing conditions, so human impacts on their environments can severely compromise population recovery. When the abundance of marine mammal populations is low, these species are vulnerable to extinction from events (e.g., epizootics and demographic and environmental stochasticity) that would not otherwise be threatening at higher population levels. Consider the North Atlantic right whale, in which longevity may approach or even exceed a century and in which reproduction may not occur until age 10 and thereafter only once every 3–5 years. After right whale populations were markedly reduced due to commercial exploitation, it was biologically impossible for the species to quickly rebound. Moreover, at low population levels, competition for copepod prey with r-selected finfish species can make recovery even less likely or further delayed. Right whales are simply not adapted to rapid recovery (from either overharvesting or from anthropogenic impacts to their habitats), and when population abundances are low, extinction vulnerability is extremely high. Likewise for other marine mammal species, life-history strategies provide points of vulnerability.

B. Environmental Threats

Although commercial harvests peaked some time ago for most marine mammals, harvesting of seals, small cetaceans, and even the great whales (i.e., fin, *Balaenoptera physalus* and minke whales, *Balaenoptera acutorostrata*) continues today. Even with regulations in place, there have been occasional blatant violations. The Russian government has made available modern whalers' log books, which show that quotas and protective regulations for some populations of endangered species, including the North Pacific right whale, were ignored as late as the 1970s (Danilov-Danil'yan and Yablokov, 1995), and it would not be surprising if other nations also ignored some whaling regulations. Thus, some species or populations thought to have been protected for decades were only protected on paper.

Both natural and anthropogenic habitat alterations can affect the abundance of marine mammals. Frequently, changes to coastal and marine environments occur in subtle and diverse ways, making it difficult to tease apart the various possible impacts to marine mammals. A telling example involved the die-off in 1987–1988 of Atlantic coastal bottlenose dolphins (*Tursiops truncatus*) along the southeastern coast of the United States. At least 740 animals died, prompting the National Marine Fisheries Service to list the population as depleted under the MMPA. Cause of death was first suggested to be ingestion of brevetoxin; later, scientists indicated that high-contaminant loads were involved; and later still, other scientists noted the presence of morbillivirus in preserved tissues of dolphins from the die-off. As noted by Reynolds *et al.* (2000), the precise interplay between the natural toxins, anthropogenic toxicants, viral infections, immune dysfunction, opportunistic infections, and death are still unclear.

The dolphin die-off illustrates that habitat change (whether natural or human induced) may compromise population health and make large numbers of animals susceptible to natural pathogens. In a relatively large population, such as coastal bottlenose dolphins, the problem is serious. For a species like the Mediterranean monk sea (*Monachus monachus*), which suffered a disastrous die-off in 1997

due to as-yet-undetermined causes (perhaps either saxitoxin poisoning or morbillivirus, or some combination of these or other causes), the problem becomes critical when an already small population is further reduced over a matter of weeks.

Changes in prey availability also seriously impact the viability of marine mammal populations. In two cases involving endangered marine mammals—the western population of the Steller sea lion (*Eumetopias jubatus*) and the French Frigate Shoals Hawaiian monk seal—the commercial harvesting of the preferred prey of these species has been suggested as an important cause of their population declines. Natural fluctuations in prey availability (e.g., El Niño Southern Oscillation events) can precipitate marine mammal population declines, but these events have only a transient impact on species with robust population sizes.

It is relatively easy to count how many animals are killed by hunters or through incidental takes. However, it is exceedingly difficult (due to both the variety and magnitude of effects and to potential synergisms) to quantify the impacts of chemical and noise pollution, harvesting of marine mammal prey, and other effects on marine mammal habitats which may compromise, or at least retard, the recovery of populations.

III. Which Marine Mammals Are Endangered?

Although there are a number of lists of protected species both regionally and globally, we provide three widely accepted lists of protected marine mammals. Table I lists endangered and threatened (from the US ESA) and depleted (from the MMPA) species and populations. Table II lists marine mammals included in Appendices I and II of CITES. Table III lists those marine mammals classified by the IUCN as Endangered (E), Critically Endangered (CE), and Vulnerable (V). Similar listings exist under the Canadian SARA.

Of the species listed in Tables I–III, the status of some is more critical than others. The western North Atlantic population of humpback whales, which numbers more than 10,000 individuals, is far more abundant than the populations of vaquitas (perhaps 150 individuals left; Jaramillo-Legorreta *et al.*, 2007), North Atlantic right whales (somewhat more than 300), and Mediterranean monk seals (around 300 left in the wake of an epizootic in 1997, which killed over half of the members of the largest colony in northwestern Africa). Species or populations which are critically endangered based on a very small population size (hundreds of animals), and therefore require immediate, effective conservation efforts include:

- *Cetaceans*: Indus river dolphin (*Platanista gangetica minor*), vaquita, North Pacific and North Atlantic right whales, several populations of blue whales (*Balaenoptera musculus*), western North Pacific gray whale, Cook Inlet and St. Lawrence River beluga whales (*Delphinapterus leucas*), and North Atlantic Arctic bowhead whales.
- *Pinnipeds*: Mediterranean monk seal, Saimaa ringed seal (*Pusa hispida saimensis*), and several populations of Atlantic walrus (*Odobenus rosmarus rosmarus*).
- *Sirenians*: Several populations of dugongs (*Dugong dugon*), as well as West African (*Trichechus senegalensis*) and West Indian manatees.

Objectively classifying populations according to their precise level of vulnerability is very difficult as predicting extinction probabilities is fraught with uncertainty. However, the above species are relatively simple to classify because their population sizes are so very low. Apart from population size, a variety of qualitative and quantitative

TABLE I
Marine Mammal Species and Populations Listed Under the United States Endangered Species Act (ESA) and Marine Mammal Protection Act (MMPA) as Endangered (E), Threatened (T), and Depleted (D)

<i>Order/species</i>	<i>Common name</i>	<i>Range</i>	<i>Status</i>
Cetacea			
<i>Lipotes vexillifer</i>	Baiji	Changjiang (Yangtze) River, China	E/D
<i>Platanista minor</i> (= <i>P. gangetica minor</i>)	Indus river dolphin	Indus River and tributaries, Pakistan	E/D
<i>Phocoena sinus</i>	Vaquita	Northern Gulf of California, Mexico	E/D
<i>Stenella attenuata</i>	Northeastern offshore spotted dolphin	Eastern tropical Pacific Ocean	D
<i>Stenella longirostris</i>	Eastern spinner dolphin	Eastern tropical Pacific Ocean	D
<i>Tursiops truncatus</i>	Mid-Atlantic coastal bottlenose dolphin	Atlantic coastal waters, New York to Florida	D
<i>Eubalaena glacialis</i> (= <i>Balaena glacialis glacialis</i>)	Northern right whale	North Atlantic, North Pacific Oceans; Bering Sea; Sea of Okhotsk	E/D
<i>Eubalaena australis</i> (= <i>Balaena glacialis australis</i>)	Southern right whale	South Atlantic, South Pacific, Indian, and Southern Oceans	E/D
<i>Balaena mysticetus</i>	Bowhead whale	Arctic Ocean and adjacent seas	E/D
<i>Megaptera novaeangliae</i>	Humpback whale	Oceanic, all oceans	E/D
<i>Balaenoptera musculus</i>	Blue whale	Oceanic, all oceans	E/D
<i>Balaenoptera physalus</i>	Finback or fin whale	Oceanic, all oceans	E/D
<i>Eschrichtius robustus</i>	Western North Pacific gray whale	Western North Pacific Ocean	E/D
<i>Balaenoptera borealis</i>	Sei whale	Oceanic, all oceans	E/D
<i>Physeter macrocephalus</i>	Sperm whale	Oceanic, all oceans	E/D
Carnivora			
<i>Lutra felina</i>	Marine otter	Western South America; Peru to southern Chile	E/D
<i>Enhydra lutris nereis</i>	Southern sea otter	Central California coast	T/D
<i>Monachus schauinslandi</i>	Hawaiian monk seal	Hawaiian Archipelago	E/D
<i>Monachus tropicalis</i>	Caribbean monk seal	Caribbean Sea and Bahamas (probably extinct)	E/D
<i>Monachus monachus</i>	Mediterranean monk seal	Mediterranean Sea; northwest African coast	E/D
<i>Arctocephalus townsendi</i>	Guadalupe fur seal	Baja California, Mexico, to southern California	T/D
<i>Callorhinus ursinus</i>	Northern fur seal	North Pacific Rim from California to Japan	D
<i>Eumetopias jubatus</i>	Western North Pacific Steller sea lion	North Pacific Rim from Japan to Prince William Sound, Alaska (east of 144°W longitude)	E/D
<i>E. jubatus</i>	Eastern North Pacific Steller sea lion	North Pacific Rim from Prince William Sound, Alaska, to California (east of 144°W longitude)	T/D
<i>Phoca hispida saimensis</i> (= <i>Pusa hispida saimensis</i>)	Saimaa seal	Lake Saimaa, Finland	E/D
Sirenia			
<i>Trichechus manatus</i>	West Indian manatee	Caribbean Sea and North Atlantic from southeastern United States to Brazil; and Greater Antilles Islands	E/D
<i>Trichechus inunguis</i>	Amazonian manatee	Amazon River basin of South America	E/D
<i>Trichechus senegalensis</i>	West African manatee	West Africa coasts and rivers; Senegal to Angola	T/D
<i>Dugong dugon</i>	Dugong	Northern Indian Ocean from Madagascar to Indonesia, Philippines, Australia, southern China, Palau	E/D

Note: Species listed under the ESA as E or T are also listed under the MMPA as D. However, there are a few species listed under the MMPA as depleted that are not listed under the ESA. Equivalent species names used by Rice (1998) appear in parentheses.

approaches are used to assess extinction risk. The IUCN approach (www.iucnredlist.org/info/categories_criteria2001) is the most widely used; under this approach, extinction vulnerability is based on population size (or population trends), or on the extent of historical habitat occupied, or on a population viability analysis. However, other approaches are also used around the world and it is important to understand which approach is being used when reference is made to in danger of extinction.

IV. Recovery and Non-recovery of Species and Populations: Lessons and Trends

One intriguing question is why some marine mammal populations have recovered from low population sizes (even when effective conservation measures have been absent) while others have remained low and in danger of extinction (Clapham *et al.*, 2008). In most cases, the answer lies in differences in life histories or differences

TABLE II
Marine Mammals Listed by CITES Under Appendices I and II

Order/species	Common name	Appendix
Cetacea		
<i>Balaena mysticetus</i>	Bowhead	I
<i>Balaenoptera acutorostrata</i>	Minke whale	I
<i>B. borealis</i>	Sei whale	I
<i>B. edeni</i>	Bryde's whale	I
<i>B. musculus</i>	Blue whale	I
<i>B. physalus</i>	Fin whale	I

<i>T. senegalensis</i>	West African manatee	V

Note: Where more than one classification category is given for a particular species in this table, it means that different populations or populations of that species are threatened at different levels of severity. Similarly, a particular classification does not necessarily mean that a species is threatened range wide at that level; rather the classification may reflect the status of only one population or population. Equivalent species names listed by Rice (1998) appear in parentheses.

non-existent. In contrast, right whale populations in the Southern Hemisphere have increased at estimated rates of 7–8% per annum for a number of years and these populations now total over 7500 individuals.

Both the Southern and Northern Hemisphere right whale populations were severely reduced by commercial whaling in the nineteenth and early- to mid-twentieth centuries. However, the responses of these populations to the cessation of harvesting have been very different. As these populations represent closely related species which are likely ecological equivalents (in marginally different ecosystems) and display similar life-history traits, the differences in life-history patterns are not likely to be responsible for the differences in recovery ability. Changes in competitive relationships within their respective ecosystems might also be operative, but these are very difficult to identify. A more likely explanation for the lack of recovery of North Atlantic right whales is continued levels of anthropogenic serious injury and mortality. NOAA Fisheries has recorded 38 ship strike-related mortalities and injuries of North Atlantic right whales during 1978–2002 and six right whales were known to be seriously injured or died between 2000 and 2004. The actual number is almost certainly higher because not all carcasses are reported. Because of low population abundance and low reproductive ability, the North Atlantic right whale population cannot sustain even this level of mortality. The right whale's recovery in the North Atlantic may also be constrained by its diet, which is highly focused on only one or two species of copepods; other large whale species have broader diets and seem more able to utilize additional prey types when necessary. Large increases during the last decade in the abundance of Atlantic herring (*Clupea harengus*) and mackerel (species which also consume copepods) may mean that the Northwest Atlantic ecosystem can no longer support as many right whales as it did historically. Southern Hemisphere right whales do not appear to be exposed to the same level of anthropogenic mortality, and it is unclear whether these populations experience any significant competition for prey.

Sympatric marine mammal populations of distantly related species can also show divergent population growth rates. Humpback whales, which occur sympatrically with right whales in the North Atlantic, exhibit a positive recovery trajectory (possibly as high as 3–6% per year) while right whale abundance remains extremely low and relatively stable (Waring *et al.*, 2007). The north–south distribution of the two species is relatively similar (although the southern breeding ground of humpback whales is further south than the southern limit of the right whale's distribution). However, right whales generally occur closer to shore than humpbacks, perhaps exposing the former to greater human impacts from commercial fishing and shipping. Although right and humpback whales feed at different trophic levels, the recovery of humpbacks suggests that human activities, rather than marine habitat changes, are affecting recovery of the North Atlantic right whale population.

Gray whales provide an example of a recovery in one population and a concurrent lack of recovery in a geographically distant population of the same species. The eastern North Pacific gray whale population has increased during the past 30 years to pre-exploitation levels (i.e., 15,000–20,000 animals) (although a recent publication by Alter *et al.* (2007) has questioned this assessment). As a result of this increase, the population was removed from the US List of Endangered and Threatened Wildlife in 1994. In contrast, the western North Pacific gray whale population is small and remains listed as endangered. Again, the discrepancies in growth rates between the two populations are difficult to interpret. Gray whales migrate

very close to shore and are likely subject to the same types of human threats. Both populations are ecologically similar and have nearly identical life history patterns. So far, scientists have been unable to identify what is hampering the recovery of the western North Pacific population. It is likely, however, to be some form of human activity (such as entanglements in fishing gear, ship strikes, directed and illegal hunting, pollution, or other types of habitat degradation) or an unidentified ecological change.

V. Improving the Recovery of Species and Populations

To recover an endangered species from extinction, it should be recognized that conservation measures needed to halt (and reverse) declines in abundance will not be effective without an understanding of (1) the life history of the species or population; (2) the species or population structure; and (3) the effects of human activities on the species or population.

A. Information on Life Histories of Endangered Species

Information on age-specific rates of birth and survival is critical to assessing recovery potential. It is important to determine whether recovery is being hindered by inadequate reproduction, inadequate recruitment to the adult population, and/or low adult survival. For some populations, both reproduction and survival will be found to be inadequate to support recovery. However, once reliable data on life-history parameters are available, it should be possible to identify the proximate cause of the reduced survival or reproduction, and then implement strategies to rectify this situation.

For example, juvenile mortality was found to be very high in Hawaiian monk seals within three of their six extant breeding colonies. Researchers determined that part of this mortality was due to adult male monk seals mobbing and killing adult females and pups. In response to this situation, researchers removed many (but not all) of the adult male monk seals in one area where the mobbing was most severe. The result was an immediate and almost total elimination of additional deaths caused by mobbing in that colony.

Another example involves California's southern sea otter population, which in the late 1970s and early 1980s was reported to be in decline due to low survival of juveniles and adults. Using observer data obtained from several commercial fisheries operating along the central California coast, it was determined that the incidental mortality of sea otters captured in the set gill net fishery for Pacific halibut was too high. The State of California subsequently passed legislation which moved this fishery further offshore, where interactions with sea otters were thought unlikely. Following this management action, population recovery ensued.

Sorting out the proximate and ultimate causes of a decline is rarely this simple. Although a tremendous amount can be known about the life history of an affected group (e.g., all evidence about the Steller sea lion decline pointed toward reduced juvenile and adult survival as the ultimate cause), this knowledge does not always help to direct management efforts. In such cases, management agencies are required (although they may fall short) to manage in a way that “errs on the side of the animal.” This means that managers are required to be cautious in authorizing human activities which may have a non-negligible probability of adversely affecting listed species or the habitats upon which they depend.

In summary, it is possible to take actions that directly promote the recovery of listed populations. However, without knowledge of the life-history parameters impeding recovery (as well as knowledge about the underlying cause of the population bottleneck), it is often impossible to know the appropriate conservation measures. Unfortunately, the requisite research to determine rates of reproduction and survival in wild populations is expensive and difficult. As well, it often takes several years of collecting such data to obtain estimates precise enough to evaluate different hypotheses about population recovery or to test the effectiveness of proposed or enacted management measures. Nonetheless, without such information, most recovery efforts are severely hampered.

B. Information on the Population Structure of Endangered Species

Although national legislation such as the US ESA and Canada's SARA (see Introduction) would, by their very names, appear to approach conservation at the species level, the actual intent of the US Congress in passing the ESA was that management should be local or regional, and directed at populations or subpopulations. Management at the species level can lead to loss of biological diversity if local populations are extirpated, even though the species as a whole is healthy. The importance of management at the population level is emphasized by the case of Steller sea lions. In 1990, the species was designated as threatened under the US ESA. By the late 1990s, however, scientists had demonstrated that (a) there were two discrete populations of the Steller sea lions; (b) the eastern population was smaller than the western population, but was stable and possibly increasing in numbers; and (c) the western population was in precipitous decline, with animal counts at some sites declining by 90% or more since the late 1970s. Accordingly, the ESA listing was modified in 1997 so that the western population was reclassified as endangered, whereas the eastern population remained listed as threatened.

The Steller sea lion example illustrates some important points. First, with endangered marine mammals (and other organisms as well), "distinct population segments" (or "distinct vertebrate populations," e.g., as defined below according to the US ESA) need to be identified so that management and conservation efforts can focus on the most critical groups and areas. However, even with published guidelines for DPS designations, the actual designation is often more of an art than a science; a more standardized approach to genetic analyses would probably provide for better DPS definitions (Fallon, 2008). Secondly, even though many populations and species may be accorded special protection, taxonomic subunits are often more in need of management intervention than the species as a whole. Unfortunately, in some cases, management still occurs at the species level. Worse, the general public has frequently developed serious misconceptions about management practices and equated the precarious status of a species (e.g., the North Atlantic right whale) with the status of all species in a taxonomic group (e.g., the baleen whales).

C. Information on the Effects of Human Activities on Endangered Species

Recovery of a species (or DPS) requires that threats be removed or, at the least, mitigated. If the threat is as simple as over-harvesting, then the required management actions are usually obvious. However, the causes for population declines or lack of recovery are,

in many cases, obscure or difficult to address. Firstly, the complexity of marine systems often makes it difficult to know what threats are causing the declines. Secondly, it is difficult to gauge whether a threat has the potential to significantly impact a marine species. Finally, translating the threat into specific effects on life-history traits may be all but impossible. Nonetheless, current efforts to implement ecosystem approaches to management (Merrick *et al.*, 2007) and initiatives for monitoring marine mammal health (<http://www.nmfs.noaa.gov/pr/health>) provide some hope that such threats may be ameliorated.

VI. Laws and Legislation to Recover Endangered Species

Endangered marine mammal species are currently protected by a variety of domestic and international laws and treaties, and collaborative efforts by nations, individuals, and organizations to reduce takes and prevent extinctions. Some efforts have been inclusive, protecting ALL marine mammals, endangered or not, within a country's territorial waters (i.e., the US MMPA). Other efforts, by groups such as the IUCN (now called the World Conservation Union) and the CITES have focused on species or populations threatened with extinction on a global scale. In almost all cases, at least four criteria have been considered in prioritizing the focus of these activities: (1) population size and demography; (2) the extent to which human activities adversely affect the animals of concern, either directly or indirectly; (3) the adequacy and protection of habitat deemed necessary for survival; and (4) the extent of markets and trade in products from the populations and species of concern. Recently, quantitative criteria have begun to be developed which should reduce the subjectivity involved in categorizing species as endangered or threatened (IUCN, 2000; DeMaster *et al.*, 2004).

The US ESA has weathered significant challenges since its enactment over 30 years ago. Although amended, the Act and its intent remain largely unchanged. The Act aims to "provide a means whereby the ecosystems upon which endangered species and threatened species depend may be conserved, [and] to provide a program for the conservation of such endangered species and threatened species..." Currently, 34 marine mammal species or populations are identified as "depleted" under either the ESA List of Endangered and Threatened Wildlife and Plants or the MMPA (Table I). Recovery plans have been prepared for 22 of these, and a number of plans are in the process of being drafted or updated. As noted earlier, only one marine mammal population (the eastern North Pacific population of gray whales) has been removed from the list.

This record may be viewed as not particularly good by some. However, relative lack of successes (i.e., de-listings) cannot be attributed to (a) inefficiencies of the ESA, (b) those charged with implementing the Act, or (c) lack of efforts by managers or conservation advocates. Challenges exist in collecting adequate data on populations and threats, on newly arising threats, and on conflicts with other human interests. In addition, as previously mentioned, even unimpeded recovery rates for most marine mammal species are relatively slow compared to many other taxa.

Other nations are taking related steps to recover marine mammal populations at risk of extinction. However, in many parts of the world, protective efforts and measures are minimal or inconsistent. Lack of firm enforcement of existing legislation or the total lack of legislation in many countries may be a key factor hampering worldwide efforts to recover endangered species.

Acknowledgments

Our grateful thanks to Dr. Fred Serchuk and Chris Uyeda of NOAA for the editing and helpful comments provided on an earlier draft of this manuscript.

Endocrine Systems

SHANNON ATKINSON, DAVID ST. AUBIN,
AND RUDY M. ORTIZ

I. Introduction

Endocrine systems function by regulating and integrating physiological processes to meet specific needs of the organism and facilitate adaptation to dynamic and chronic environmental changes or perturbations. Internally, hormone systems are constantly changing in response to environmental cues such as photoperiod, temperature, energetic demands, food and water availability, and reproductive status or season. Hormones are the chemical substances that are typically produced and released into circulation by specialized cells that are localized in small glands or organs. Because of their great potency and ability to broadly influence bodily functions, hormones are regulated by an exquisite set of negative and positive feedback loops that may link several organs. For the most part, endocrine systems in marine mammals follow the basic organization and chemical characteristics of other mammals. Nevertheless, it is intriguing to examine how these systems allow marine mammals to meet the peculiar challenges imposed by their environment. The following sections will review and highlight our current understanding of endocrine systems and how they respond to either natural or artificially manipulated environments to enhance our knowledge of hormone functions in marine mammals.

II. Neuroendocrine Perception of Environmental Changes

Many species of marine mammals inhabit highly variable ecosystems that possess dramatic seasonal changes in environmental variables such as air and water temperature, salinity, photoperiod, and prey resources. Some marine mammals experience migrations that are associated with similar effects. For example, mysticetes exploit productive cold waters at high latitudes during the long days of summer but retreat to tropical habitats in the fall to bear calves under less challenging conditions. Daylength appears to be an important cue for many life history traits, including the initiation of migration patterns as well as several aspects of reproduction. Pinnipeds, particularly those in polar environments, seasonally partition activities such as breeding and molting to take advantage of favorable conditions that will increase the survival of offspring or allow recovery from fasts necessitated by long periods ashore (Atkinson, 1997). West Indian manatees regularly move in and out of freshwater and marine habitats that vary greatly in salinity without any apparent consequence on their ability to regulate body water and electrolytes (Ortiz *et al.*, 1998). These are but a few examples that illustrate the dynamic environmental conditions that stimulate a host of different endocrine systems to allow the animals to properly adapt and thrive.

While limited work has been done on the neuroendocrinology of marine mammals, it is clear that the sensory systems that predominate are vision, hearing, olfaction, and likely gustation. All of these systems link directly to the brain stimulating the hypothalamus, pineal, and hippocampus (St. Aubin, 2001). Most of the hypothalamic effects are transferred to the pituitary gland or hypophysis, a small, compound structure located at the base of the brain. The glandular portion (adenohypophysis) produces a set of hormones (Fig. 1) that

Figure 1 An overview of endocrine organs and hormones in a marine mammal.

either directly elicit tissue responses (e.g., growth hormone (GH), prolactin, and gonadotropins) or modulate the activity of other endocrine glands (e.g., adrenocorticotropic hormone (ACTH) and thyrotropin or thyroid-stimulating hormone (TSH)). Early investigators on whaling vessels were impressed by the size of the pituitary in mysticetes (up to 53.5 g in a blue whale, *Balenoptera musculus*), although on a body weight basis, it is unremarkable. Nevertheless, the abundance of the tissue afforded the opportunity for extensive studies to extract and characterize the principal hypophyseal hormones. Fin whale, *B. physalus*, ACTH was found to be identical to that of humans, whereas blue whale TSH more closely resembled that of non-primates. Studies on beluga whales (*Delphinapterus leucas*) and bottlenose dolphins, (*Tursiops truncatus*), as well as Steller sea lions (*Eumetopias jubatus*), harbor seals (*Phoca vitulina*), and ringed seals (*Phoca hispida*) have shown that synthetic ACTH and bovine TSH are capable of eliciting expected responses from the target glands, demonstrating at least some homology in the structure of these hormones among various groups of mammals (St. Aubin and Dierauf, 2001; Mashburn and Atkinson, 2004, 2007a).

III. Thyroid Hormones

Early investigators were as impressed by the size of the cetacean thyroid as they were by the pituitary, to the degree that large whales were considered as a possible commercial source for thyroxine (T₄), the principal hormone synthesized by the gland. It was not only the size, but the proportions of the thyroid that called attention to

the importance of this gland in cetaceans (St. Aubin, 2001); beluga whales have 3 times more thyroid tissue per unit body weight than a thoroughbred horse, and bottlenose dolphins have nearly twice as much thyroid as do humans (400 vs 250 mg/kg).

Stimulation of the thyroid gland follows a somewhat typical pattern of hormone biosynthesis and secretion in that the initial stimulus comes from the hypothalamus in the form of thyrotropic releasing hormone (TRH). TRH acts on the pituitary to produce and secrete thyroid stimulating hormone (TSH). TSH is carried via the circulatory system to the thyroid gland whereby it stimulates the production of the thyroid hormones (TH). Two major forms of TH exist, thyroxine (T₄) and triiodothyronine (T₃), with both present in the bioactive free form (fT₄ and fT₃) as well as the globulin-bound form. FreeT₃ is the physiologically active TH and T₄ is converted to T₃ by mono-deiodination. Most assays measure either the free form or total form (TT₄ or TT₃), the latter being the sum of the free plus bound forms (Oki and Atkinson, 2004). In Steller sea lions, T₄ constitutes the primary form (97%) in circulation with only 3% in TT₃ (Myers *et al.*, 2007). Additionally, the free forms only account for 0.02% and 0.01% for fT₄ and fT₃, respectively. Thyroid hormones play an important role in metabolism and in regulating homeostasis of the body. Both T₄ and T₃ effect metabolism by calorogenic and thermogenic actions related to lipid, protein, and carbohydrate metabolism. T₄ stimulates oxidative phosphorylation and mitochondrial respiration, which increase the animal's metabolic rate and subsequent metabolic heat production (St. Aubin *et al.*, 1996; Oki and Atkinson, 2004; Myers *et al.*, 2007). TH are also necessary for normal growth and development, especially in critical developmental periods. Early researchers compared terrestrial mammals to aquatic mammals and concluded that the metabolic rate of aquatic mammals must be elevated to counteract the heat loss from living in cold water. The size of the thyroid gland in cetaceans was used as evidence for this physiological adaptation. Subsequent studies failed to demonstrate a difference in metabolic rates of terrestrial mammals and aquatic mammals. In pinnipeds, circulating TH levels and the basal metabolic rate are comparable to those in terrestrial mammals, but surprisingly, the blood TH concentrations are lower than in West Indian manatees, (*Trichechus manatus*), a species with a distinctly lower metabolism (Ortiz *et al.*, 2000). Assumptions about the metabolic rate cannot be based solely on circulating TH levels.

Concentrations of TH tend to be highest in pups of all pinniped species examined to date (Engelhardt and Ferguson, 1980; Haulena *et al.*, 1998; Myers *et al.*, 2006). Circulating levels in neonatal pinnipeds are understandably high in view of the need for metabolically derived heat until their lanugo coat gains insulating ability and blubber reserves are established. Thereafter, seasonal fluctuations in the blood levels of T₄ and T₃ have been correlated with changing metabolic needs. Among cetaceans, the seasonality of TH activity in beluga whales is characterized by marked elevation in circulating levels of T₄ and T₃ and by histological evidence of intense cellular activity in the thyroid gland during the summer (St. Aubin, 2001). Colloid reserves are depleted by columnar follicular cells, in contrast to the quiescent appearance of the gland in spring and fall when low cuboidal cells surround abundant stores of TH. The implications of this burst of thyroid activity are broad, favoring mobilization of blubber, and promoting the effects of other agents such as GH. It also coincides with a unique event in beluga epidermis, cell production is enhanced, presumably under the influence of TH, and superficial turnover is accelerated by the relatively warm (10–15°C) freshwater environment. Taken together, these events constitute a true molt, lacking only the production of a hair coat to be fully analogous to

the process in a pinniped. No comparable transformation has been described in any other cetacean; only the rubbing behavior of killer whales (*Orcinus orca*), on the cobbles of Telegraph Cove, British Columbia, hints of a seasonal pulse in epidermal growth. Studies on circulating levels of TH in Atlantic bottlenose dolphins have not revealed significant annual variation, even though the 15°C range of water temperatures experienced by these animals is equivalent to that encountered by belugas (St. Aubin, 2001).

As in terrestrial fur-bearing mammals, TH are seasonally elevated to promote hair growth in pinnipeds during the annual molt (Ashwell-Erickson *et al.*, 1986; Boily, 1996; Oki and Atkinson, 2004). Controversy in the literature regarding the degree of association between visible molt and thyroid activity in pinnipeds may derive from the difficulty in recognizing when hair growth is actually stimulated by elevated TH. Hair loss, the overt sign of molting, may be enhanced by increased levels of cortisol at a time when T_4 and T_4 levels are low. Cortisol suppresses the secretion of TSH from the pituitary and inhibits the deiodination of T_4 to T_3 . The fluctuations in circulating levels of metabolically potent substances such as cortisol and TH during the molt draw attention to how intensely pinnipeds are physiologically affected at that stage of their annual cycle.

IV. Substrate Metabolism

Marine mammals exhibit a number of different behaviors that can produce highly variable responses in substrate-level metabolism that are regulated by various endocrine systems. Phocid seals experience prolonged periods (months) of food and water deprivation as a natural component of their life history to which they are well adapted. Otariids also exhibit natural periods of food deprivation, but the durations are not as long. Because the strictly water-borne animals such as cetaceans and sirenians commonly migrate great distances, it is thought that they will exhibit periods of intermittent caloric restriction. Thus, whether the period of food deprivation or fasting is natural or imposed, almost all marine mammals experience caloric restriction, necessitating the stimulation of robust physiological regulation of substrates to maintain homeostasis. While it is well-recognized that TH play a critical role in regulating metabolism, this section will focus on other hormones as TH were discussed previously. Hundreds of hormones contribute to substrate metabolism in vertebrates either directly or indirectly; however, only a few have been studied in marine mammals. In most mammals, glucose is the primary substrate contributing to the animal's metabolic rate; however, in phocids and likely all marine mammals, carbohydrates contribute very little (<10%) (Keith and Ortiz, 1989; Champagne *et al.*, 2006). Thus, it is not surprising that for those marine mammals examined, insulin does not appear to contribute to the regulation of glucose as levels are relatively low (Kirby and Ortiz, 1994; Ortiz *et al.*, 2003b; Champagne *et al.*, 2005). The bolus infusion of glucose (glucose tolerance test; GTT) led to only a transient stimulation of insulin secretion suggesting that the pancreas of marine mammals is insensitive to a high-carbohydrate load (Kirby and Ortiz, 1994). Because of the lack of carbohydrate in the diet, this finding should not be that surprising, but rather more indicative of the adaptive mechanisms these animals have evolved to deal with this environmental constraint. Furthermore, the relatively slow clearance of glucose from circulation following a bolus infusion is indicative of insulin resistance (Kirby and Ortiz, 1994), which combined with a chronic state of hyperglycemia in many species makes these animals

appear, clinically like diabetic/obese humans (Ortiz *et al.*, 2003b; Champagne *et al.*, 2005). While changes in plasma glucagon or insulin:glucagon ratios have been reported in fasting elephant seals suggesting that it may contribute to glucose metabolism (Ortiz *et al.*, 2003b; Champagne *et al.*, 2005), these levels have yet to be definitively shown to contribute to glucose metabolism. In lactating female elephant seals, the changes in endogenous glucose production were not associated with expected changes in insulin:glucagon ratios or glucagon concentrations (Champagne *et al.*, 2006). The possibility exists that these studies failed to measure the concentrations at the key periods when the dynamic changes are occurring to contribute to glucose metabolism; however, the paucity of available data would suggest that the counterregulatory insulin–glucagon mechanism does not contribute appreciably to carbohydrate metabolism.

Lipids or fatty acids are the primary substrates contributing to the metabolism of marine mammals. During periods commonly associated with elevated levels of fatty acid mobilization such as prolonged fasting (postweaning, molt, breeding, etc.), increased levels of cortisol, GH, and ghrelin have been observed. A synchronous pattern of free fatty acid and GH concentrations was reported in harp seals. In addition, a significant correlation between plasma GH and free fatty acids in fasting elephant seal pups was detected suggesting that GH contributes to fatty acid metabolism (Ortiz *et al.*, 2003b). The gene encoding GH in the finback whale (*Balaenoptera physalus*) has been cloned and characterized with the data on this suggesting that the GH gene in cetaceans appears to be evolving more slowly than in other artiodactyls (Tsubokawa *et al.*, 1980; Wallis *et al.*, 2005).

The glucocorticoid, cortisol, consistently increases during fasting conditions in pinnipeds and likely contributes to the mobilization of fatty acids to support the animal's metabolism (Ortiz *et al.*, 2001, 2003a, b). As its name implies, cortisol can also stimulate gluconeogenesis and thus likely contributes to carbohydrate metabolism. A bolus injection of the catecholamine, epinephrine, induced an increase in plasma glucose within 25 min in Weddell seals (*Leptonychotes weddellii*) suggesting that catecholamines stimulate glycolysis in marine mammals (Hochachka *et al.*, 1995).

Leptin is a relatively newly discovered hormone that has received considerable attention in marine mammals recently. Leptin is a product of the *ob* gene in mammals and is primarily produced in adipocytes. In humans and other mammals, its plasma concentration is correlated with the animal's body mass or lipid stores. Its primary role in terrestrial mammals is to signal the brain to inhibit food intake and to provide an index of the body's energy reserves. For these reasons, it is not surprising that leptin has received considerable attention in recent studies. However, the data from those marine mammals studied suggest that leptin does not stimulate typical mammalian responses with respect to energy balance. In fasting elephant seal pups (*Mirounga angustirostris*), plasma leptin concentrations were not correlated with body fat and fasting did not affect plasma concentrations (Ortiz *et al.*, 2001; Ortiz *et al.*, 2003a, b). No consistent changes in serum leptin concentrations were observed in acutely fasted Steller sea lions and levels were also not correlated with body fat. In contrast, plasma leptin decreased over 5 days of fasting in Antarctic fur seals (*Arctocephalus gazelle*) (Arnould *et al.*, 2002). Serum leptin decreased between the reproductive/breeding and molting seasons in adult southern elephant seals suggesting that leptin may serve as a permissive hormone contributing to the reproductive effort of marine mammals as it does in humans (Guilherme *et al.*, 2004). Under natural conditions, adult southern elephant seals have the highest reported average concentrations (9.5 ng/ml) of any marine mammal. Interestingly, serum leptin is stimulated by adrenocorticotropin (ACTH), with mean levels

approaching 15 ng/ml (Mashburn and Atkinson, 2008). Whether ACTH directly stimulates the *ob* gene or promotes its stimulatory actions via another hormone is unknown; however, this indicates that the *ob* gene is inducible in marine mammals and that it can be stimulated exogenously to increase circulating levels in a relatively short period of time (<30 min). Unfortunately, these studies do not elucidate the physiological role of these hormones, they do provide an index of their potential contribution to regulating substrate metabolism and a basis from which to design future studies to assess their physiological function.

V. Adrenal Hormones

The adrenal gland in mammals is comprised of two distinct tissue layers, the cortex and medulla. The medulla is the primary site of catecholamine (epinephrine and norepinephrine) synthesis and release. The cortex is divided into three distinct regions or zones characterized by distinct cortical cell types: (1) zona glomerulosa, (2) zona fasciculata, and (3) zona reticularis. Cells of the zona glomerulosa are primarily responsible for synthesizing and releasing the mineralocorticoid, aldosterone, which directs the reabsorption of Na^+ . The zona glomerulosa is particularly well developed in young seals suggesting that a fully functional system for the regulation of Na^+ is intact by the time these animals are born (Bryden, 1994). Cells of the zona fasciculata are primarily responsible for synthesizing and releasing the glucocorticoids, cortisol, corticosterone, and cortisone. The positive correlations among adrenal steroids (aldosterone, cortisol, and corticosterone) exhibited by bottlenose dolphins suggest that an active pituitary–adrenal axis is present in these animals (Ortiz and Worthy, 2000). Cells that comprise the zona reticularis serve as the border between the cortex and medulla, but can produce and release small amounts of androgens. This zone's androgenic capacity in marine mammals has not been evaluated; however, it is well recognized that the glomerulosa and fasciculata produce the aforementioned steroids in marine mammals. Pinnipeds have been reported to produce the glucocorticoids, corticosterone, cortisone, and cortisol (St. Aubin and Geraci, 1986; Liggins *et al.*, 1993; Boily, 1996; Gardiner and Hall, 1997; Ortiz *et al.*, 2001; Engelhard *et al.*, 2002; Guinet *et al.*, 2004; Mashburn and Atkinson, 2004; Oki and Atkinson, 2004; Mashburn and Atkinson, 2008), while corticosterone and cortisol have been detected in dolphins (St. Aubin *et al.*, 1996; Ortiz and Worthy, 2000), and cortisol in manatees (Ortiz *et al.*, 1998). The precise physiological function of glucocorticoids in marine mammals has not been delineated, but it is expected that they contribute in a typical mammalian fashion to glucohomeostasis. This is supported by a number of studies in which changes in circulating glucose are associated with changes in plasma cortisol. Phocid seals have the highest cortisol production rate (when corrected for surface area) reported for any species studied (Liggins *et al.*, 1993), in addition to relatively high-metabolic clearance rates. The relatively high levels of cortisol found in most phocid seals can be attributed to production rates that far exceed the metabolic clearance rates (Liggins *et al.*, 1993). Under normal conditions, the levels of cortisol found in otariids are more similar to those observed in terrestrial mammals. Thus, it has been suggested that the relative hypercortisolemia is adaptive to facilitate the deep and extensive dives that are more common in phocids.

Because adrenal hormones are primarily stimulated in response to “stressful” cues, their primary functions are to support metabolism during stressful events by liberating glucose and fatty acids. In those marine mammals examined, the bolus infusion of ACTH produces a predictable increase in cortisol and corticosterone (Mashburn and

Atkinson, 2008). While acute handling and restraint does not appear to influence plasma cortisol and aldosterone concentrations in seals and dolphins (St. Aubin *et al.*, 1996; Ortiz and Worthy, 2000; Ortiz *et al.*, 2001; Engelhard *et al.*, 2002), prolonged restraint and encirclement was associated with elevated plasma aldosterone concentrations in dolphins (St. Aubin *et al.*, 1996). Repeated handling also had no effect on circulating plasma cortisol in southern elephant seals suggesting that these animals can become rapidly desensitized to frequent handling procedures in the field, which is important since this can be a common research practice in many studies involving some marine mammals (Engelhard *et al.*, 2002).

Because routine handling and manipulation of animals could potentially disrupt biochemical and hormonal homeostasis in some of these animals, if they have not become desensitized to these procedures, alternative methods of sampling animals are required. Recently, considerable attention has been dedicated to evaluating fecal hormone levels, primarily adrenal steroids (but also androgens and estrogens) to circumvent the need to restrain or even handle an animal to obtain a blood/tissue sample (Mashburn and Atkinson, 2004; Petrauskas *et al.*, 2006). This is particularly important for field applications or when working with very large animals that cannot be easily restrained or immobilized. Protocols to reproducibly measure urinary steroid (and protein) levels in smaller captive animals have been implemented with great success and usefulness (Hong *et al.*, 1982; Ortiz *et al.*, 1998, 2002a, b, 2003a, b). Protocols using salivary samples have also been used with equal success (Pietraszek and Atkinson, 1994; Petrauskas *et al.*, 2006). These alternative methods of sample collections will expand our abilities to enhance our understanding of the impacts of dynamically changing environmental cues on not only adrenal hormones but hormones from other endocrine systems as well.

VI. Osmoregulation

In mammals, a large number of hormones are known to contribute to water and electrolyte balance, but hormones most commonly attributed to osmoregulation are angiotensin (Ang I, II, or III), atrial natriuretic peptide (ANP), aldosterone, and vasopressin (AVP). Renin converts angiotensinogen to angiotensin I (Ang I), which is quickly converted to Ang II (the most potent angiotensin) by angiotensin-converting enzyme (ACE). Subsequently Ang II stimulates the release of aldosterone from the zona glomerulosa in the adrenal gland, which in turn induces the reabsorption of Na^+ from the distal tubule of the nephron and the colon resulting in a decrease in excreted Na^+ . Collectively, renin, Ang II, and aldosterone comprise the renin–angiotensin–aldosterone system (RAAS). Functional and responsive RAAS have been identified in pinnipeds (Ortiz *et al.*, 2000b, 2002a, b; Ortiz *et al.*, 2006), dolphins (Malvin *et al.*, 1978), and manatees (Ortiz *et al.*, 1998). The sensitivity of RAAS in West Indian manatees is much greater than in pinnipeds and bottlenose dolphins, which would be expected since manatees are commonly found in Na^+ depleted environments and do not drink seawater. Oral intubation of West Indian manatees resulted in a neuroendocrine stress response, producing an increase in RAAS (Ortiz *et al.*, 1998).

Probably the first published account of a bioassay using extracted cetacean tissues was performed by Eichelberger and his colleagues (1940). Extracted renin from the kidney of a bottlenose dolphin was injected into dogs at two doses (concentrations not reported), 4 and 2 ml. In the initial trial, 4 ml of extract induced an immediate increase (48%) in blood pressure (BP), and remained 38% higher than

control pressure for 10 min. In a separate trial, an initial 2 ml dose of extract induced a 21% increase in BP; however, it was not sustained. A second 2 ml dose resulted in a 27% increase in BP, which also was not sustained. However, the two doses collectively were able to induce a 9% increase in BP that was sustained. A third dose of 2 ml produced a 20% increase in BP that sustained an additional 4% increase in BP. These experiments demonstrated that (1) renin in dolphins (and probably all cetaceans) causes a vascular pressor effect as in other mammals; (2) the pressor effect is dose dependent; and (3) the response is graded until a threshold is reached, which results in a sustained elevation in BP. These important early studies shed light on the sensitivity and kinetics of the renin-induced increase in BP and suggest that RAAS regulates BP as well as water and electrolyte balance in marine mammals as in terrestrial mammals.

Although most seals live in salt water, they likely don't drink and captive animals residing in freshwater may be susceptible to hyponatremia (reduced plasma Na^+), which appears to be reconciled via the pituitary-adrenal axis. Early infusion studies with Baikal (*Phoca sibirica*) and ringed seals demonstrated an increase in fractional clearance of Na^+ following infusion of hyperosmotic saline indicating that tubular Na^+ reabsorption was reduced (and likely aldosterone) (Hong *et al.*, 1982). However, a negative correlation between excreted aldosterone and excreted Na^+ was not observed prompting a question of the role of RAAS in seals. More recently, similar studies with northern elephant seal pups (*Mirounga angustirostris*) demonstrated a similar increase in fractional excretion of Na^+ , but in the presence of elevated aldosterone suggesting that an alternative, and likely non-hormonal, mechanism mediated the increased fractional excretion of Na^+ (Ortiz *et al.*, 2002b). In this case, increased glomerular filtration rate (GFR) overcame the aldosterone-mediated retention of Na^+ suggesting that renal hemodynamics play a critical role in regulating water and electrolytes in pinnipeds, especially during conditions of increased Na^+ load, which may be observed during feeding.

While aldosterone and Ang II can also serve to reabsorb water, the most potent anti-diuretic agent is vasopressin, which stimulates the synthesis of water channels (aquaporins) in the collecting duct of the kidney. Detectable levels of AVP have been reported for pinnipeds (Hong *et al.*, 1982; Skog and Folkow, 1994; Zenteno-Savin and Castellini, 1998; Ortiz *et al.*, 2000a, b, 2002a, b, 2006), cetaceans (Ortiz and Worthy, 2000), and manatees (Ortiz *et al.*, 1998). Although not conclusive, a number of studies provide compelling evidence to suggest that tubular water reabsorption is mediated by AVP in seals as in terrestrial mammals. The intravenous infusion of pitressin (synthetic AVP) in a water-loaded harbor seal resulted in an immediate decrease in urine flow rate along with concomitant increases in urinary electrolyte concentrations. Pitressin infusions induced an increase in urine osmolality and in osmotic clearance, which was greater than urine volume suggesting that free water reabsorption was increased (or free water clearance was reduced). More recently, a bolus infusion of AVP in fasting elephant seal pups paradoxically induced a diuresis associated with increased osmotic clearance (primarily natriuresis) and not reduced free water clearance (Ortiz *et al.*, 2003c). Additionally, this infusion of AVP acutely increased plasma cortisol and aldosterone in the presence of reduced plasma renin activity suggesting that AVP possesses natriuretic and neuronendocrine capabilities (similar to some terrestrial mammals). Under force-fasted conditions, Baikal and ringed seals exhibited an increase in excreted AVP associated with a concomitant decrease in urine flow rate and increase in urine osmolality (Hong *et al.*, 1982). A positive and significant correlation between urine osmolality and excreted AVP was also demonstrated in Baikal and

ringed seals further suggesting that the observed increase in urine osmolality was attributed to an increase in tubular water reabsorption via AVP stimulation. Furthermore, in gray seals (*Halichoerus grypus*), force-fasted conditions induced an increase in urine osmolality in conjunction with an increase in plasma osmolality and AVP (Skog and Folkow, 1994). However, in naturally fasting, postweaned northern elephant seal pups urine osmolality increased despite decreased plasma AVP. These latter data were refuted recently, using a much larger sample of fasting pups to demonstrate that plasma AVP concentrations are constant and relatively low with no change in plasma osmolality (Ortiz *et al.*, 2000b). Also, under conditions of isotonic and hypertonic saline infusion, increased urinary AVP excretion was negatively correlated with reduced free water clearance and positively correlated with urinary cAMP excretion suggesting that AVP mediates free water reabsorption via a cAMP-mediated mechanism in the collecting duct as in terrestrial animals during stimulatory conditions such as feeding (Ortiz *et al.*, 2002b). The only other known bioassay of cetacean tissue was that of plasma-extracted AVP on water retention in water-loaded rats by measuring the electrical conductivity of the urine. In most of the dolphin samples measured by bioassay, AVP was not detected. For those samples that showed detectable amounts of AVP, concentrations were very low, as were the amounts from pituitary extracts. Also, the lack of a correlation between urine flow rate and plasma AVP concentrations in fasting dolphins led researchers to contend that AVP does not significantly regulate urine volume and thus water retention in these animals. However, significantly greater concentrations of AVP have been measured recently in free-ranging dolphins, which may be the result of advances in assay techniques for hormone measurements (Ortiz and Worthy, 2000). Increased plasma osmolality appears to stimulate AVP release in manatees, like in terrestrial mammals; however, the anti-diuretic actions of AVP in manatees have yet to be elucidated (Ortiz *et al.*, 1998).

Atrial distention, induced by increased cardiac pressure (volume), is the primary mechanism for the release of ANP. The actions of ANP oppose those of Ang II and aldosterone by inhibiting the synthesis and release of renin, thereby resulting in an increase in excreted Na^+ . Levels of ANP have only been reported for pinnipeds (Zenteno-Savin and Castellini, 1998; Ortiz *et al.*, 2002a, b). A bolus infusion of AVP in fasting elephant seal pups increased the urinary excretion of the natriuretic factor, urodilatin, that may partially explain the observed natriuresis in this case (Ortiz *et al.*, 2003c). Beyond this, the natriuretic effects of ANP and its related peptides have not been further examined in marine mammals.

VII. Diving

For logistical reasons, examining the effects of diving on the various endocrine systems is difficult, and trying to elucidate the function of these systems during diving would be even more so. Nonetheless, a few studies have evaluated the effects of diving or sleep apnea. Diving has profound effects on blood flow to the kidneys and glomerular filtration (Murdaugh *et al.*, 1961; Zapol *et al.*, 1979; Davis *et al.*, 1983), resulting in a decrease in renal activity, which could alter the response of vasoactive hormones (i.e., Ang II, AVP, ANP). Voluntary bouts of sleep apnea in elephant and Weddell seal pups reduced heart rate associated with a decrease in Ang II and AVP (vasoconstrictors), and an increase in ANP (vasoconstrictor inhibitor) (Zenteno-Savin and Castellini, 1998). This increase in ANP was attributed to an increase in cardiac pressure, which is a known stimulus of ANP release. The changes in vasoactive hormones

observed during sleep apnea are likely to occur during breath-hold diving as well, based on the available data on renal blood flow during diving and the direction of change in vasoactive hormones during sleep apnea.

Diving is also associated with an increase in epinephrine that likely contributes to diving bradycardia, peripheral vasoconstriction, and inhibition of pancreatic insulin release to maintain circulating plasma glucose concentrations (Hochachka *et al.*, 1995). The inhibition of insulin results in a reduced insulin:glucagon ratio that is also important for the post-dive recovery to facilitate lactate clearance and maintain glucose for aerobic metabolism. The hormone erythropoietin (EPO) stimulates the production and release of red blood cells in response to tissue hypoxia (Richmond *et al.*, 2005). Thus, it is not surprising that age-related increases in hematocrit and hemoglobin are correlated with increased concentrations of EPO suggesting that EPO contributes to the development of blood oxygen stores in marine mammals. While leptin does not appear to contribute to the regulation of substrate-level metabolism or energy balance, it may contribute to pulmonary surfactant production and thus, may play a role in diving physiology (Hammond *et al.*, 2005).

VIII. Reproduction

As with many of the endocrine systems, reproductive activity is controlled by the hypothalamus secreting gonadotrophic releasing hormone (GnRH) which acts on the anterior pituitary. The pituitary in turn releases the gonadotrophins, luteinizing hormone (LH) and follicle stimulating hormone (FSH). The two gonadotrophins collectively act on the ovaries and testes to stimulate follicle development and spermatogenesis, respectively (Atkinson, 1997). Through follicular development the granulosa cells of the antral follicles produce estrogen and upon luteinization of these cells (and subsequent ovulation), progesterone is produced. Estrogen promotes cellular hydration and proliferation, while progesterone promotes fat deposition and smooth muscle relaxation. In the testes, testosterone is produced by the Leydig cells and acts on the seminiferous tubules to stimulate spermatogenesis (Atkinson and Yoshioka, 2007).

Collectively, the sex steroids—estrogen, testosterone, and progesterone—are measured in low concentrations (typically <0.5 ng/ml for each steroid) in the circulation of prepubertal mammals and fluctuate very little. The onset of sexual maturity is detected by seasonal fluctuations of each of the sex steroids.

Reproduction in most marine mammals is a highly seasonal (Atkinson and Yoshioka, 2007). In particular, the high-latitude pinnipeds have tight synchrony of various reproductive events and the associated behaviors. With the exception of one species of pinniped (the Australian sea lion, *Neophoca cinerea*), all seals are annual breeders with their estrous cycles synchronized by parturition (Atkinson, 1997). Most pinnipeds are seasonally monoestrous with ovulation occurring once per year. The duration of estrus, or the period of sexual receptivity, is a function of elevated estrogen. Steroid hormone peaks in circulating concentrations of estrogen followed 1–2 days later by elevated progesterone have been characterized for several species of pinniped and reflects preovulatory follicular maturation and subsequent corpus luteum formation (Pietraszek and Atkinson, 1994). Once ovulation has occurred progesterone concentrations in the circulation are elevated regardless of whether or not conception takes place (Atkinson *et al.*, 1999). The conceptus of pinnipeds undergoes an embryonic diapause of variable length, with 1–5 months being reported. While the reactivation of the blastocyst signals at the end of diapause, the exact cue remains

somewhat elusive (Boyd, 1991). As the size of the corpus luteum increases just before the embryonic reactivation, it is thought that the ovary is functional in cuing the end of the diapause. However, the scientific literature on the subject also implicates photoperiod as being an environmental cue. Active or placental gestation is sustained by progesterone that is produced by the corpus luteum which atrophies at parturition. Lactation is extremely variable in pinnipeds ranging from 4 days to up to 36 months, with the phocid seals having shorter more defined lactational periods than the otariids (Atkinson, 1997). Prolactin is important in development of mammary glands in anticipation of lactation and in maintaining early lactation. Prolactin concentrations are high before parturition and reach a peak 0–3 days after birth declining to non-detectable concentrations before the end of lactation. As in terrestrial mammals, prolactin is under inhibitory dopaminergic control. Prolactin does not decline precipitously when lactation is stopped abruptly and when prolactin is inhibited, the postovulatory rise in progesterone is suppressed, indicating prolactin may play a controlling role in ovulation and luteal development in pinnipeds.

In male pinnipeds circulating concentrations of testosterone exhibit seasonal elevations preceding the breeding season (Atkinson and Gilmartin, 1992). The seasonal elevations appear to be tighter with increasing latitude. The increase in testosterone prior to the breeding season is followed by an increase in cortisol, at least in Weddell seals and Steller sea lions.

LH and FSH have been measured in both odontocetes and mysticetes, with females having higher concentrations than males (Atkinson and Yoshioka, 2007). As with the pinnipeds, prepubertal cetaceans are characterized by low circulating concentrations of the sex steroids. Reproductive cycles in female cetaceans are highly variable, with some falling into relatively narrow time frames, such as in belugas, whereas others show very little seasonality. Odontocetes such as bottlenose dolphins and killer whales, which have been studied extensively in captivity (West *et al.*, 2000), and false killer whales (*Pseudorca crassidens*) demonstrate some of the variability possible within a species. Some adult female whales may be seasonally polyestrous, with up to seven cycles per year, whereas others may be anestrous for a year or more. In addition, elevated progesterone concentrations up to 10 months in a non-pregnant captive female false killer whale were recorded.

Estrous cycle lengths have been best described for killer whales (Robeck *et al.*, 1993). They exhibit a 41-day estrous cycles, divided into a 7-19-day luteal phase, dominated by progesterone, and a follicular phase. Progesterone is increasingly the predominant hormone responsible for sustaining pregnancy, and is commonly used as a diagnostic indicator for pregnancy detection. As many cetaceans exhibit annual reproduction cycles, it is clear that conception can occur during lactation. It has also been reported for many cetaceans that extended periods of anestrus can occur; these are characterized by low or undetectable levels of the sex steroids followed by measurable ovarian activity.

Endocrinology of male cetaceans has not been studied extensively when compared to their female counterparts. As with female cetaceans, male sex steroids (i.e., testosterone) are low in immature animals. Once sexual maturity is reached, testosterone is correlated with testes weight in several of species (Atkinson and Yoshioka, 2007). As with most of the pinnipeds, testosterone concentrations in circulation are highest prior to peak sperm density and the peak period of the female breeding activity. Testosterone levels in male bottlenose dolphins tend to be higher in spring and fall, roughly coinciding with calving peaks (gestation is approximately 12 months), although individual

males show varying patterns from year to year and are capable of impregnating females in almost any month. Seasonal constraints on breeding would appear to be less critical in tropical and subtropical species than in those exploiting more polar habitats. An exception would be river dolphins exposed to drastic seasonal fluctuations in habitat associated with dry and rainy seasons. Synchrony of reproductive activity, and by inference reproductive hormones, is likely an important consideration.

The challenges associated with conducting endocrine studies on cetaceans are largely logistical and several studies have been conducted on both captive and free-ranging cetaceans to develop non-invasive or novel methods of sample collection. Monitoring of estrous cycles and the detection of pregnancy has been attempted in saliva, feces, ocular secretions, milk, and blubber in addition to the standard serum or plasma (Pietraszek and Atkinson, 1994; Theodorou and Atkinson, 1998; West *et al.*, 2000). Most of these media were successful in the detection of progesterone, with the exception of saliva and ocular secretions from false killer whales (Atkinson *et al.*, 1999).

Numerous factors have been implicated in altering the endocrine status of marine mammals. Social suppression of reproduction in both male and female cetaceans has been suggested (Atkinson and Yoshioka, 2007). Anthropogenic chemicals such as organochlorines and polybrominated compounds, have been shown to have endocrine disrupting effects that are detrimental to normal reproduction. It is likely large-scale changes in environmental (e.g., Global warming) may also impact reproduction through several mechanisms, including nutritional stress and immunosuppression. Factors that alter normal reproductive functioning are likely to be the topics of enhanced research in the future.

IX. Circadian Patterns and Melatonin

The biological clock controlling the circadian pattern of behavior and many physiological processes is a neural network located in the suprachiasmatic nucleus (SCN) of the basal hypothalamus. The SCN is responsible for the circadian rhythm of hormones in mammals. There is a direct link between photoperiod, pituitary, and pineal gland hormone secretion.

Melatonin is the hormone most commonly associated with photoperiodism in mammals (St. Aubin, 2001). It is produced primarily by the pineal gland (epiphysis) located above the third ventricle of the brain. Daylight suppresses the production of melatonin, which regulates the activity of the hypothalamus, pituitary, and, indirectly, the gonads, adrenals and thyroid. Melatonin secretion ceases in Weddell seals under continuous natural light. Unfortunately, the hormone and its activity have received relatively little attention in the marine mammal literature. This deficit is ironic, as the pineal gland of the newborn southern elephant seal can weigh over 9g, which is the size of the brain of a hamster, the subject of so much of the research on melatonin.

The exceedingly high plasma levels of melatonin in newborn seals draw attention to the important role of this hormone in the survival of animals born under harsh environmental conditions. Concentrations (69,000ng/ml) in southern elephant seals at birth, but fall steadily during the ensuing 7–10 days. A similar pattern has been observed in harp (*Pagophilus groenlandicus*), gray, Weddell, and northern elephant seals (Stokkan *et al.*, 1995). It has been postulated that the hormone promotes the generation of the TH and cortisol, which in turn accelerate metabolism and provides the heat necessary to withstand the extreme conditions experienced at the time of birth. Cortisol in

Alaskan harbor seals did not show a diurnal rhythm in winter, only in summer (Oki and Atkinson, 2004).

Marked seasonality is evident in the size of the pineal in southern elephant seals. The gland is largest in the winter dark period and the high circulating levels of melatonin at that time presumably suppress gonadal function. In terrestrial mammals melatonin acts in the mediobasal hypothalamus through dopaminergic receptors that inhibit GnRH. Melatonin levels are uniformly low during the spring breeding season. A circadian rhythm in melatonin secretion is evident during the winter, but equivocal during the summer.

The literature on melatonin in cetaceans is sparse when compared to pinnipeds. The very presence of a discernible pineal gland had been uncertain, but was eventually identified in a number of cetacean species. Extrapineal sources of melatonin, such as from the retina, likely augment the role of the small gland in integrating photoperiod with metabolic functions. One might expect that polar cetaceans such as belugas and narwhals (*Monodon monoceros*), need to entrain their endocrine physiology with seasonal changes marked by day length, similar to high-latitude pinnipeds.

X. Conclusions

The ecosystems in which marine mammals reside have required the morphology and physiology of these species to evolve to be able to cope with the challenging environments. One of the major systems that allows the body to maintain homeostasis is the endocrine system. The sensory systems of marine mammals, like terrestrial mammals, link directly to the brain and the master glands, the hypothalamus and pituitary.

The metabolism of marine mammals is driven by the oxidation of fatty acids and appears to be regulated by the glucocorticoid, cortisol, and the protein hormone, growth hormone. During diving conditions, the adrenal products, cortisol and epinephrine, may contribute to glucose metabolism. The counterregulatory insulin-glucagon mechanism typical of terrestrial mammals does not appear to contribute appreciably to the regulation of carbohydrate, which should not be surprising since carbohydrate contribution to the animals metabolism is minimal. Leptin also does not appear to contribute to energy balance in those animals studied, but may play a role in reproduction and diving. The TH are essential in regulating metabolism and thermogenesis, but also in early growth and development. All groups of marine mammals possess an active and functional RAAS that contributes to renal Na⁺ reabsorption and likely blood pressure. Under natural conditions, AVP is relatively low and likely not contributing to renal water reabsorption in pinnipeds and dolphins; however, during isotonic and hypertonic infusion, AVP appears to mediate renal water reabsorption in seals. While not definitive, it likely plays a similar role in manatees. Reproduction in many marine mammals is highly synchronized, requiring tight endocrine controls to ensure success. Also linking to the synchrony of seasons is the pineal gland and its production of melatonin.

Important advances in analytical techniques such as development of fecal, urinary, salivary, and tissue hormone measurement protocols; increased sensitivities of RIAs and EIAs; and improved antibody production have enhanced our ability to detect low levels of hormones and expanded our ability to measure a greater variety of hormones. All of these advancements will increase our understanding of the endocrine systems in marine mammals and their needs to adapt to changing environments.

Energetics

DANIEL P. COSTA

I. Introduction

Energetics provide a method to quantitatively assess the effort animals spend acquiring resources, as well as the relative way in which they allocate those resources. Energy flow models are analogous to cost–benefit models used in economics. Costs take the form of energy expended to acquire and process prey, and to maintain body functions. The energetic benefits are manifest as food energy used for growth and reproduction. Measurement of energy acquisition and allocation provide a quantitative assessment of how animals organize their daily or seasonal activities, and how they prioritize their behaviors. Thus, energy flow can be described as what goes into the animal as food and what comes out in the form of growth, reproduction, repair, waste, or metabolic work. Survival requires a positive balance between the costs of maintenance and the acquisition of food energy. If a marine mammal cannot compensate for decreases in energy acquisition, it must either reduce its overall rate of energy expenditure or utilize stored energy reserves. Conversely, in order to grow and reproduce, animals must obtain more energy than is needed to survive. Marine mammals undergo profound variations in this feast or famine dynamic equilibrium as they can gain significant amounts of food energy while feeding in highly productive environments, followed by prolonged negative energy balance while fasting during migration or reproduction (Brodie, 1975; Costa, 1993; Lockyer, 1993) (Fig. 1).

The balance of how energy acquisition and expenditure is achieved differs for individual species and environments. For

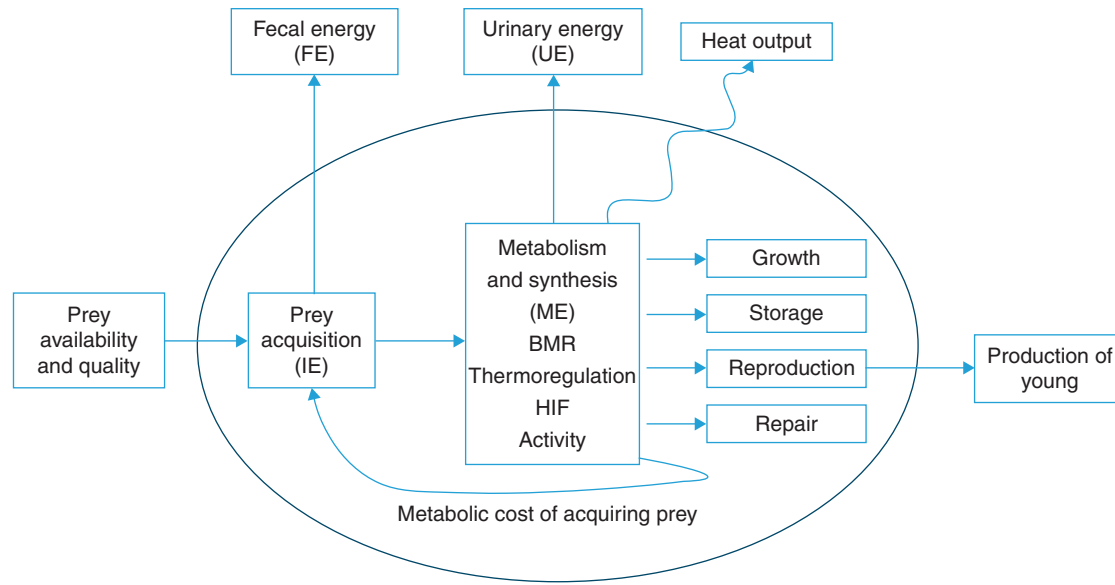

Figure 1 A conceptual diagram of energy flow through a typical mammal. The outer oval represents the animal. Anything that passes through that envelope is material (straight line) or energy (waved line) entering or leaving the animal. IE, ingested energy; ME, metabolic energy; FE, fecal energy; and UE, urinary energy.

Figure 2 A minke whale, *Balaenoptera acutorostrata*, feeding in the Antarctic ice. Photograph by Dan Costa.

some species, sea otters (*Enhydra lutris*), sea lions, and fur seals (Otariidae), very high rates of energy expenditure are met by high rates of energy acquisition (Costa and Williams, 2000). These animals preferentially live in nearshore environments or upwelling regions where food is abundant (Costa, 1993). Sirenians represent the opposite extreme. These marine mammals exhibit comparatively low existence costs and are able to survive on a low-quality diet. They have adapted to a diet of grasses that is in high abundance but of low quality, energetically. They are able to do this because; they live in the climatically benign tropics where maintenance costs are low (Gallivan and Best, 1980; Gallivan *et al.*, 1983; Irvine, 1983).

The seasonal migrations of large cetaceans demonstrate this interrelationship between energetic demand, energy availability, and local productivity (Brodie, 1975). Although maintenance costs may be elevated in polar regions, the ability to take advantage of the seasonally high productivity associated with the sea ice during the polar summer more than compensates (Fig. 2). When confronted with the high energetic costs of reproduction and of winter conditions,

the mysticete whales opt for the more benign tropics. Further, their large body size makes the cost of migration extremely low (see Locomotion, this volume). While prey availability may be low in the tropics, so too are the existence costs, especially for a large animal that is able to utilize energy reserves stored in the blubber.

A conceptual diagram of the relationship between energy acquisition and allocation is shown in Fig. 1. The rate of energy consumed by the animal is referred to as Ingested Energy (IE). The energy that remains after the losses associated with the production of feces and urine is the Metabolic Energy (ME). This is the energy available for maintenance and repair, growth or reproduction. Energy expended for maintenance includes key processes such as basal metabolism, digestion (heat increment of feeding, HIF), thermoregulation, and activity (locomotion, grooming, feeding, etc.). The rate of prey energy acquired is directly related to the availability and quality of prey. As prey becomes less available, the cost of finding it increases and the animal spends a greater proportion of its time and therefore energy searching for it. Eventually, there is a threshold when more energy is spent searching for prey than is obtained and the animal goes into negative energy balance (Winship *et al.*, 2002; Rosen and Trites, 2005). While the best situation is to have access to abundant high energy prey, in some scenarios low-quality prey that is more abundant may be more optimal than searching for high-quality prey that is difficult to find.

II. Energy Acquisition

Not all of the ingested material consumed is digestible. Food energy remaining after digestion and elimination of Fecal Energy (FE) is known as the Apparently Digested Energy (ADE). The proportion of ADE to IE is called the assimilation efficiency and ranges from 88% to 97.9%, for a diet of fish to 72.2% for invertebrate prey with a high chitin content (Martensson *et al.*, 1994; Lawson *et al.*, 1997; Costa and Williams, 2000; Rosen and Trites, 2000). The assimilation efficiency decreases as the rate of prey intake increases, but is greater when a diet composed of different species of fish with

different proximate compositions is consumed (Trumble and Castellini, 2005). Sirenians extract less energy from their food than other marine mammals (84.6%), because plant material, which contains cellulose and requires bacterial fermentation to digest, is harder to digest. However, they are more efficient than other hindgut fermenters, such as horses, *Equus caballus* (45–59%) (Burn, 1986).

Chemical energy lost as urea and other metabolic end products in the urine is defined as Urinary Energy (UE). Metabolizable Energy (ME) is the net energy remaining after fecal and urinary energy loss, and represents the energy available for growth or reproduction and for supporting metabolic processes such as work (locomotion) and respiration (thermoregulation, maintenance metabolism, HIF). The ME for pinnipeds varies between 78.3% for a squid diet to 91.6% for an anchovy diet (Costa and Williams, 2000).

III. Energy Expenditure

A. Cost of Maintenance Functions

Maintenance costs are those associated with homeostasis and include basal metabolism, HIF, repair (molt, fighting disease, and/or parasites), thermoregulation, and activity (see Thermoregulation and Locomotion, this volume).

1. Basal Metabolism It has generally been assumed that the basal metabolic rates of aquatic mammals are elevated when compared to terrestrial mammals of similar size. The current view of basal metabolic rates of marine mammal is more complex as many studies did not conform to standardized criteria for measurements of basal metabolism (Lavigne *et al.*, 1986). These criteria require that the subjects be adults, resting, thermoneutral, non-reproductive, and post-absorptive. This has been further confused by the expectation that all marine mammals should employ the same metabolic response. Specialization for marine living has occurred independently in three mammalian orders: the sirenians, cetaceans, and carnivores. Further, within the carnivores there are three separate transitions to a marine existence: pinnipeds, sea otters, and polar bears, *Ursus maritimus*. Based on this diversity, we might expect different metabolic adaptations between the groups (Fig. 3). West Indian manatees, *Trichechus manatus*, have BMRs lower than values predicted, while phocid seals have BMRs closer to those of similar sized terrestrial mammals. Conversely, sea otters, otariids, and odontocetes appear to have BMRs greater than terrestrial mammals of equal size.

The BMR of an animal is not constant, but varies seasonally (Rosen and Renouf, 1995; Williams *et al.*, 2007), with the animal's nutritional state (Rosen and Trites, 1999), as well as with the animal's body composition (Rea and Costa, 1992). Some species such as sirenians and walrus, *Odobenus rosmarus*, have dense bone, whereas seals may be composed of as much as 50% fat. When metabolic rates are expressed relative to body mass, a disproportionate amount of fat or particularly dense bone will lower the apparent metabolic rate. This is due to the low metabolic rates of bone and adipose tissue in comparison to lean tissue. Many marine mammals undergo prolonged fasts that are accompanied by profound changes in body composition. Most of the mass change during fasting is due to loss of adipose tissue with a comparatively smaller change in lean tissue. For example, northern elephant seal females, *Mirounga angustirostris*, lose 42% of their initial mass, but of this only 14.9% comes from lean tissue with 57.9% coming from adipose tissue (Costa *et al.*, 1986). This results in an overall change in body composition of 39% fat at parturition to 24% fat at weaning (see Pinnipedia Physiology, this volume). Since lean mass is the primary contributor to whole

Figure 3 Resting metabolic rate (RMR) of marine mammals in relation to body mass. Measurements were made for the animals resting in water. The solid line denotes the predicted metabolic rate for equal sized terrestrial animals; the dashed line represents 2 times the predicted levels. Species included are: Odontoceti—*Stenella attenuata*, *Tursiops truncatus*; Phocidae—*Phoca vitulina*, *Phoca hispida*, *Leptonychotes weddellii*, *Pagophilus groenlandicus*, *Haliocoerus grypus*; Otariidae—*Zalophus californianus*; Sirenia—*Trichechus manatus*.

animal metabolism, the animals whole body metabolism is likely to change little even though there has been a major change in its body mass (Rea and Costa, 1992).

The ability to digest and process the greater amount of prey associated with the higher metabolic rates of marine mammals may have also required changes in their morphology. Specifically, all carnivorous marine mammals, regardless of their ancestry (carnivore or herbivore) have comparatively longer small intestines than similarly sized terrestrial carnivores. Further, there is a high correlation between small intestine length and BMR in mammals (Williams *et al.*, 2001).

2. Heat Increment of Feeding When food is consumed, the animal's metabolic rate increases over fasting levels. The HIF, also known as the Specific Dynamic Action (SDA), may be considered the "tax" that is required to process food energy for conversion to Metabolizable Energy (ME). The magnitude of energy allocated to HIF varies between 5% and 17% of the ME (Costa and Kooyman, 1984; Markussen *et al.*, 1994; Rosen and Trites, 1997). In addition, the duration of HIF following a meal will depend on the amount of food consumed and its composition. In many mammals, the HIF is considered excess or waste heat. However, sea otters incorporate the additional heat produced from HIF to meet their high thermoregulatory costs associated with their small size (they are the smallest marine mammal) (Costa and Kooyman, 1984). While grooming, feeding, and swimming sea otters use the heat produced from activity to supplement their thermoregulatory needs, while at rest sea otters incorporate the heat produced from HIF to augment their thermoregulatory needs (Fig. 4).

3. Fur vs Blubber It is important to consider the potential differences in the energy budgets of animals that use fur or blubber for insulation. The overall time–energy budget of an animal that uses fur (fur seal or sea otter) is fundamentally different from an animal that uses blubber (sea lion, seal, or dolphin). Although fur is not a living

Figure 4 The thermal budget of sea otters relies on heat production above BMR (or SMR). The contribution of HIF (or SDA) to the overall metabolism is highest immediately after feeding and reaches zero within 390 min after feeding. As HIF decreases the animal becomes more active and thus compensates for the decrease in heat production from HIF (Costa and Kooyman, 1984).

tissue, it requires the maintenance of an air layer, which is done by frequent grooming. Sea otters spend up to 16% of their day grooming. While sea lions, seals and dolphins, spend no time grooming, they must take in sufficient food to lay down a thick blubber layer, which is a living tissue and must be supplied with blood. Furthermore, blubber serves dual roles as an insulator and as an energy store. During fasting or periods of low food availability a marine mammal must balance its utilization of blubber for energy needs with the potential loss of the blubber layer as an insulator. For pinnipeds a way of increasing blood flow to the skin and keeping thermoregulatory costs low while ashore is to huddle together. This reduces their effective surface area that is exposed to the cold (Fig. 5). Such behavior is commonly observed in cold climates and can change during the day. For example, in the morning when it is cold, animals clump together and as it gets warmer they separate. Finally, huddling behavior is less common in fur seals, as there isn't much of an incentive to huddle if you use fur for insulation.

B. Cost of Growth and Reproduction

For growth and reproduction to occur, an animal must acquire energy and nutrients in excess of that required for supporting maintenance functions. These additional energetic costs vary with the species of marine mammal, the sex, and reproductive pattern. In pinnipeds, polar bears, sea otters (and probably mysticetes and sirenians) the cost of reproduction in males is limited to the cost of finding and maintaining access to estrous females. Evolution favors a pattern of energy expenditure that maximizes reproductive success in males. The costs associated with reproduction in aquatic and terrestrially breeding males is quite similar when normalized for differences in body mass. Larger body size is preferred in terrestrially breeding male pinnipeds since it confers both an advantage in fighting and allows the male to maintain terrestrial territories longer (Fig. 6) (see Pinnipedia Physiology, this volume). In addition, larger animals can fast longer because they have a lower mass specific metabolic rate than smaller animals (Costa, 1993). In species that compete

Figure 5 A group of California sea lions, *Zalophus californianus*, huddling on a California beach. A behavior typical in the cool winter months or during the cool mornings. Photograph by Dan Costa.

Figure 6 The extreme difference in body size between a male (on top) and female (underneath) northern elephant seal (*Mirounga angustirostris*). The animals are copulating in this picture. Photograph by Dan Costa.

for females in the water, males are comparatively smaller than the species that breed on land. For the aquatic breeders, underwater agility is more important than large size when competing for mates.

The cost of reproduction for females can be broken down into the energetic requirements of gestation and lactation. The cost of gestation is small relative to the cost of lactation. Even given the strikingly different reproductive patterns in marine mammals, there is little variation in fetal mass at birth among marine mammals, but as a group they appear to invest more energy into fetal birth mass (and thus more into gestation) than terrestrially mammals (Fig. 7). This higher investment in gestation by all marine mammals except polar bears is associated with the production of precocial young (Fig. 8). The young of cetaceans, sirenians, pinnipeds, and sea otters need to be capable of dealing with life in the water or on a crowded rookery within seconds of birth. As a group marine mammals exhibit considerable variation in both the duration and pattern of maternal investment (Fig. 9). Phocid seals and mysticete whales have extremely short lactation durations, which are compensated for by higher rates of energy transfer that enable the young to grow rapidly (Fig. 10).

Although phocid pups are weaned early, they still rely on maternally derived energy, stored as blubber, for weeks or months after weaning. The disadvantage of this rapid growth is that most of the

mass and energy is stored as fat with proportionately little protein. The advantage of longer lactation is that young get more protein and other nutrients allowing greater growth of lean tissue. However, longer lactation is energetically more expensive (Costa, 1991a, b, 1993).

Figure 7 Birth mass plotted in relation to maternal mass for marine and terrestrial mammals. Species of marine mammals included are: *Odontoceti*—*Inia geoffrensis*, *Pontoporia blainvillei*, *Stenella attenuata*, *Globicephala melaena*, *Physeter macrocephalus*, *T. truncatus*, *Phocoena spinnipinnis*, *P. phocoena*, *Delphinapterus leucas*; *Mysticeti*—*Balaenoptera musculus*, *B. physalus*, *B. acuto-rostrata*, *B. borealis*, *Megaptera novaengliae*, *Eschrichtius robustus*; *Phocidae*—*Mirounga angustirostris*, *M. leonina*, *Cystophora cristata*, *Phoca vitulina*, *P. hispida*, *Leptonychotes weddelli*, *Monachus schauinslandi*, *Pagophilus groenlandicus*, *Erignathus barbatus*, *Lobodon carcinophagus*, *Histiophoca fasciata*, *Haliocoerus grypus*; *Otariidae*—*Arctocephalus gazella*, *A. forsteri*, *A. galapagoensis*, *A. tropicalis*, *A. pusillus*, *Callorhinus ursinus*, *Zalophus californianus*, *Neophoca cinerea*, *Eumatopias jubatus*, *Otaria byronia*; *Sirenia*—*Dugong dugon*, *Trichechus manatus*.

Figure 8 A harbor seal (*Phoca vitulina*), mother and pup on a California beach. The pup was recently born and shows the extreme level of precociality typical for marine mammals. In harbor seals the pup is born with the adult pelage and it can go to sea within an hour of birth. Photograph by Dan Costa.

1. Variation in Milk Composition The rapid growth of marine mammal young is made possible by the ingestion of extremely lipid rich milk. With a few exceptions, terrestrial animals produce milk that is low in fat; cows, *Bos taurus* and humans, *Homo sapiens*, produce milk that contains 3.7% and 3.8% milk fat, respectively. Lipid-rich milk allows the mother to transfer high levels of energy in a very short period. Hooded seals, *Cystophora cristata*, are most impressive with a 4-day lactation interval and a milk fat of 65% lipid (Bowen *et al.*, 1985). In view of this, it is not surprising that marine mammals with the highest growth rates produce milk with the highest lipid content.

Lactation also enables mothers to optimize the delivery of energy to their young. The energy content of the milk is independent of the type or quality of prey consumed, or the distance or time taken to obtain it. Although milk is ultimately derived from the prey consumed, a mother can process, concentrate, or utilize stored reserves to produce milk. For example, some species feed on fish, while others feed on fish or squid. Yet, all of these species provision their offspring with milk of significantly greater energy density than the prey consumed (Costa, 1991b).

2. Body Size and Maternal Resources: The Role of Maternal Overhead Fasting during lactation is a unique component of the

Figure 9 Time to weaning plotted as a function of maternal mass for marine mammals. Lactation durations of phocid seals and mysticete whales are shorter than in all other marine mammals. Species are same as in Fig. 3.

Figure 10 Growth rate of suckling marine mammals as a function of maternal mass. Lines represent least squares regressions for each taxonomic group. Species are same as in Fig. 3.

life history pattern of marine mammals (Costa, 1993; Oftedal, 2000). With the exception of bears, no other mammal is capable of producing milk without feeding. By undertaking this energetic challenge, mysticetes and pinnipeds are able to separate where and when they feed from where and when they breed. In mysticete whales, this allows them to feed in the highly productive polar regions of the world's oceans, but retain the thermal advantage of breeding in the calm tropical regions (Fig. 2) (Brodie, 1975). Migrating to warmer waters for parturition reduces the thermal demands on the newborn calf and additional thermal savings for the mother.

Figure 11 A recently born northern elephant seal (*Mirounga angustirostris*) pup suckles from its' mother (below) is compared to a recently weaned pup (30 days old). The mother does not eat or drink during the 26- to 28-day lactation interval, and after weaning the pup fasts for 2–3 months before going to sea. Elephant seals, like many true seals, fast during the entire lactation interval. Photograph by Dan Costa.

Figure 12 A Galapagos sea lion (*Zalophus wollebaeki*) female suckling her pup on left, and on a trip to sea on right. Fur seals and sea lions intermittently suckle their pup on shore between trips to sea to forage. Photograph by Dan Costa.

Among pinnipeds, the separation of feeding from lactation is necessary to allow for terrestrial parturition (Bartholomew, 1970). Most phocids store sufficient energy reserves for the entire lactation period, whereas all otariids must feed during lactation (see Pinnipedia Physiology and Pinniped Reproduction, this volume) (Costa, 1991a, b). A phocid mother typically remains on or near the rookery continuously from the birth of the pup until it is weaned; whereas milk is produced from body reserves stored prior to parturition (Fig. 11). Although some phocids feed during lactation, most of the maternal investment is derived from body stores. Their reproductive pattern is less constrained by the time it takes to travel and exploit distant prey, which allows utilization of a more dispersed or patchy food resource (Costa, 1993). By spreading out the acquisition of prey energy required for lactation over many months at sea, northern elephant seal females only need to increase their daily food intake by 12% to cover the entire cost of lactation.

The ability of a marine mammal female to fast while providing milk to her offspring is related to the size of her energy and nutrient reserves and the rate at which she utilizes them. When food resources are far from the breeding grounds, as may occur for some phocids and large mysticete whales, the optimal solution is to maximize the amount of energy and nutrients provided to the young and to minimize the amount of energy expended on the mother. The term “metabolic overhead” refers to the amount of energy a female expends on herself while onshore (seals) or while in the calving grounds (whales). Larger females have a lower metabolic overhead than smaller females. This is because maintenance metabolism scales as $\text{mass}^{0.75}$, and fat stores scale as $\text{mass}^{1.0}$. As body size increases, energy reserves increase proportionately faster than maintenance metabolism.

3. Energy Investment and Trip Duration Many phocids fast throughout the lactation interval, whereas otariid females feed intermittently between suckling bouts onshore (Fig. 12) (Costa, 1991a, b). Otariid mothers modify the timing and patterning of energy and nutrient investment to optimize energy delivery to their young (Boyd, 1998; Trillmich and Weissing, 2006). Otariid mothers making short feeding trips that provide their pups with less milk energy than mothers that make long trips. In comparison to otariids, phocids may have a reproductive pattern that is better suited for dealing

with dispersed or unpredictable prey, or prey that is located at great distances from the rookery (Costa, 1993). However, fasting during lactation places a limit on the duration of investment and this limits the total amount of energy that a phocid mother can invest in her pup.

Phocids are buffered from short-term fluctuations in prey availability due to their unique reproductive pattern. In phocids, reproductive performance (maternal investment) during a given season reflects prey availability over the preceding year and represents the mother's foraging activities over a much larger spatial and temporal scale than the foraging activities of otariids (Costa, 1993). It follows that the weaning mass of a phocid pup is an indicator of the mother's foraging success over the previous year, whereas the subsequent post-weaning survival of the pup is related to both its weaning mass (energy reserves provided by the mother) and the resources available to the pup after weaning.

C. Field Metabolic Rates

A number of approaches have been used to study the metabolic rate of animals at sea. One approach, time budget analysis, sums the daily metabolic costs associated with various activities (Williams *et al.*, 2004). Other methods rely on predictive relationships between physiological variables and metabolic rate. For example, metabolic costs can be indirectly assessed by measurements of changes in body mass and composition, variations in heart rate or ventilation rate, or with the dilution of isotopically labeled water (Folkow and Blix, 1992; Boyd *et al.*, 1999; Costa and Gales, 2000).

Field metabolic rates (FMR) provide insight into the energetic strategies used by marine mammals (Costa, 1993; Costa and Gales, 2003). The best data exist for pinnipeds and the common bottlenose dolphin, *Tursiops truncatus* (Fig. 13), and indicate that foraging otariids and bottlenose dolphins expend energy at 6 times the predicted basal metabolic level (Costa and Williams, 2000). In contrast, the metabolic rate of diving elephant seals (*Mirounga* spp.) and Weddell, *Leptonychotes weddellii*, seals are only 1.5–3 times the predicted basal rate (Castellini *et al.*, 1992). The lower diving metabolic rate of phocid seals contributes to their superb diving ability (Costa, 1993) (see Diving Physiology, this volume). The importance of the thermal environment on field metabolic rate can also be seen in Galapagos fur seals, *Arctocephalus galapagoensis*, which due to the warm equatorial climate have a substantially reduced field metabolic rate compared to other otariids (Trillmich and Kooyman, 2001). An interesting consequence of the high metabolic rate of marine mammals is that the presence of a few foraging individual can have a significant impact on community structure (Estes *et al.*, 1998; Springer *et al.*, 2003).

FMR are quite variable both between and within species (Fig. 13). Such variation is thought to be associated with year-to-year changes in both the abundance and availability of prey (Costa, 2007). In response to reduced availability of prey, fur seals and sea lions mothers increased their foraging effort in an effort to keep the duration of their foraging trip the same. However, there reaches a point where they can no longer increase their foraging effort and have to spend more time at sea to obtain the same amount of prey energy. If a mother spends more time to deliver the same amount of energy, the offspring receives less overall energy. As a result, more of the offspring's energy is spent on maintenance and its growth will slow and in the worst case the pup will eventually die.

1. Energetics of Prey Choice The amount of work, and therefore energy expenditure that an animal puts into locating prey varies

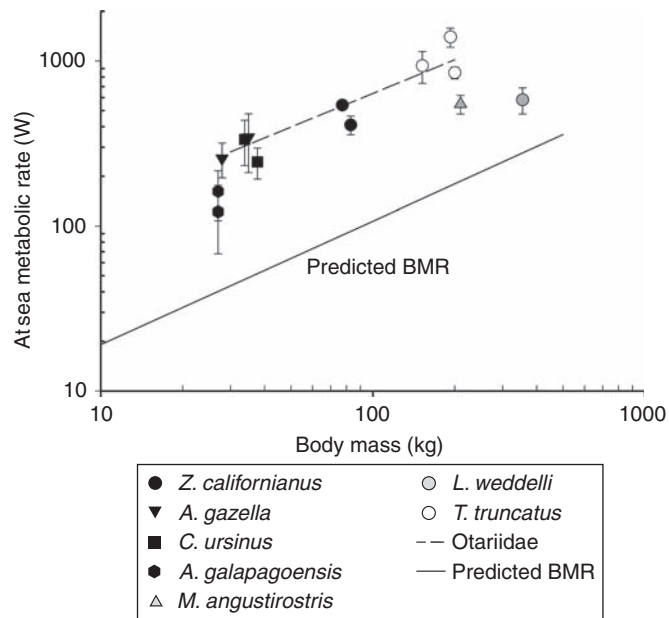

Figure 13 At sea metabolic rate measurements determined from the O-18 doubly labeled water method as a function of body mass. Data on Weddell seals (*Leptonychotes weddellii*) were measured using open circuit respirometry on seals diving from an ice hole. The solid line represents the predicted basal metabolic rate for a terrestrial animal of equal size; the dashed line is the best-fit linear regression for the otariidae with the exception of the data from *Arctocephalus galapagoensis* ($r^2 = 0.53$). Error bars represent \pm one standard deviation. Multiple points for each species reflect measurements taken over different years and show the range of interannual variation within a species.

as a function of the energy content, availability, and location of the prey both geographically as well as its depth in the water column. Both size and proximate composition (fat, carbohydrate, protein, and water content) affect the energy content of prey. Prey availability varies as a function of the absolute abundance of prey (amount of prey per unit of habitat) and its distribution in the environment. A predator is more efficient when foraging on prey that is clumped than on prey that is evenly dispersed. Similarly, prey that is near the surface is easier to obtain than prey located at depth. Marine mammals forage in areas where prey has been concentrated as a result of oceanographic processes like eddies, fronts, and upwelling regions associated with bottom topography.

Sea otters provide an excellent example of the factors that determine the energetics of prey choice (Fig. 14) (Riedman and Estes, 1990). In recently occupied areas, sea otters feed on preferred prey items like clams, abalone, *Haliotis* spp., or sea urchins. In such environments they find large, energy-rich, abundant prey that is easy to handle, consume, and digest. In such situations, lower quality prey items (turban snails, sea stars, mussels, chitons) are generally not eaten. These items may be abundant, but they are energy poor, and difficult to eat and digest. As the abundance and size of their preferred prey declines, sea otters switch to less preferred but more accessible prey like turban snails, kelp crabs, and in some cases, chitons and sea stars. Some sea otters specialize on different types of prey and are more efficient predators than non-specialists (Estes *et al.*, 2003).

Figure 14 A California sea otter feeds on a crab. Photograph by Dan Costa.

Polar bears represent another example of optimal prey choice and its relation to the prey energy quality. Feeding predominately on ring seals, *Phoca hispida*, polar bears eat the energy-rich blubber layer and leave behind the lean “core” of the carcass (Stirling and McEwan, 1975). Due to its high lipid content the blubber has a per unit mass energy content almost 10 times greater than that of the lean tissue of the ring seal. Thus, polar bears consume the most energy dense part of the ring seal and then move on to find another kill.

2. Variations in Foraging Energetics Different foraging behaviors are associated with different metabolic costs. For example, in sea lions benthic foraging is more expensive than epipelagic or near surface feeding (Costa and Gales, 2000, 2003). The gulping behavior of blue, *Balaenoptera musculus*, fin, *B. physalus*, and other whales of the family Balaenopteridae also appears to be quite costly due to the tremendous drag created as they open their enormous mouths to engulf entire schools of prey (Croll *et al.*, 2001). The blue whale finds a school of krill, and opens its mouth engulfing the entire school of krill. The whale then expels the water through its baleen plates, retaining the krill in its mouth. Consider how much drag, and thus increased effort, it takes to swim with an open mouth the size of a blue whale through the water!

Entrapment and Entanglement

JON LIEN

Fishermen use a variety of techniques to capture fish. A common method is the use of gill nets that hang passively in the water, like curtains, and ensnare fish that blunder into them, or with barriers such as cod traps that direct the fish into traps that hold them until they are removed.

Because fishing nets are an unusual barrier, cryptic, and hard to detect, they on occasion catch marine mammals. When non-target species are accidentally caught in nets, they are termed *bycatch*. Bycatches of some species of marine mammals, such as harbor porpoises, *Phocoena phocoena*, are common in several areas. Because of the strength of modern materials now used in constructing nets, even larger species of cetaceans are sometimes captured incidentally in fishing gear. Such entrapments seriously threaten the North Atlantic right whale, *Eubalaena glacialis*, population (Johnson *et al.*, 2007). Any species can be captured in nets. However, humpback whales, *Megaptera novaeangliae*, perhaps because of their abundance in coastal waters where nets are commonly used or because of the many barnacles they carry, seem extremely vulnerable to entanglement in fishing gear. I present here a case history of whale entrapment from Newfoundland and Labrador, Canada; there are other areas of the world with entrapment and entanglement problems of many species of marine mammals (Lien, 1995).

In the late 1970s, humpback whales were seen in greater numbers in inshore waters of Newfoundland and Labrador as the bait fish capelin, *Mallotus villous*, which is their major prey, was seriously depleted offshore on the Grand Banks. The humpbacks moved inshore to feed on spawning capelin that occurs in the same areas where fishermen place their nets. Inevitably, this meant trouble. Fishermen began to report whale collisions which left nets badly damaged. On occasion, humpback whales would actually be caught and held in the nets. Initially, about 50% of the animals that were caught died. Because this was a new anthropogenic source of mortality in this recovering humpback population, it was a serious conservation concern.

Because of the problem, a program was established by the Whale Research Group of Memorial University of Newfoundland to aid both the whales and the fishermen when incidental captures occurred. Fishermen anywhere along Newfoundland and Labrador's 17,000 km of coastline that accidentally caught a whale could call the Entrapment Assistance Program by a toll-free phone number. A trained team would be dispatched to release the whale alive and to save as much of the fishing gear as possible. Because there were real benefits for fishermen in minimizing gear losses and lost fishing time, they cooperated very well with the program, and it benefited whales as well. Humpback mortality as a result of entrapment was reduced to about 10% of the animals that were captured. Those fewer whales died before help could reach the animal.

However, during the 1980s, groundfish populations were being seriously depleted by overfishing. To make a living, fishermen responded by fishing more nets, and inshore effort increased dramatically. With more barriers, the frequency of collisions and entrapments by whales increased. In one fishing season, the Entrapment Assistance Program received over 150 reports of entrapped humpback whales. In addition, other species, such as common minke whales, *Balaenoptera*

acutorostrata, were also being caught. The program to release whales was extremely busy and effective. However, it was apparent that something was required to prevent collisions.

It was not practical to expect fishermen to stop fishing or to substantially modify where or how they fished. Instead, because cetaceans are acoustic specialists, scientists experimented with electronic devices that could be placed on nets. The hypothesis was that noisier nets would better alert the whales to their presence so they could avoid them. The alarms emitted higher frequency sounds that cetaceans could hear but were not detected by groundfish. Thus, fish catches would not be similarly reduced. Such devices were used successfully in areas where the likelihood of collisions was high. Acoustic alarms reduced collisions by about 80%. This was good news for both whales and fishermen. Such devices have now been used in many parts of the world and relative to all manner of marine mammals, with variable success (Barlow and Cameron, 2003).

Other news was not good for fishermen, however. By 1992, groundfish populations were so seriously depleted by fishing that a moratorium on fishing was established. All nets were removed from the water. Collisions and entrapments of whales were reduced to near zero. The moratorium on groundfish fishing continued until 1998, when small quotas were once again established. Closures and greatly reduced quotas on other species of groundfish followed by 1994.

The quotas that were established were very small compared to historical levels, so far fewer nets were used than before. The reduction in the number of nets kept accidents with humpbacks low. In addition, quotas were allocated in shares to individual fishermen. Thus, each fisherman did not have to fish competitively but was assured of a fair portion of fish that they could catch when they wanted, usually when they could realize the best prices for fish. In Newfoundland, best prices occur in the fall, and most fishing occurred then, a period when whale abundance inshore is relatively low. This combination of lower total fishing effort and a shift in fishing effort to a different season had kept collisions and entrapments to a very low level.

The Entrapment Assistance Program continues to be available to release whales carefully and to aid fishermen in retrieving fishing gear. In areas where whale abundance is high, some fishermen continue to use alarms on nets. However, at present, the incidental capture of humpback whales in traditional inshore nets of Newfoundland and Labrador is a relatively minor problem for both whales and fishermen. Because inshore fisheries are dynamic and changing activities that importantly affect the environment, they must be monitored continuously.

For example, in Newfoundland waters, recently developed fisheries for crab, turbot, and flounder are causing trouble for whales, often quite far from shore. Humpback whales can be caught easily, and the weight of the long strings of fishing nets or pots are able to hold these large animals. A dockside education program has been developed to ensure that fishermen know how to properly release an animal they catch.

Estrus and Estrous Behavior

DARYL J. BONESS

Estrus is a state of sexual receptivity during which the female will accept the male and is capable of conceiving. This behavioral state is under hormonal regulation involving the ovary and pituitary gland, and precedes or coincides with ovulation (i.e., production of an egg). The existing anatomical and physiological evidence suggests that the physiological process underlying estrus in marine mammals is comparable to that in other mammals.

Our knowledge about estrus, estrous behavior, and the estrous cycle in marine mammals is highly variable. Among cetaceans, most of it is derived from studies of the ovaries and reproductive tracts of animals killed during whaling or collected from beached and stranded specimens. The little behavioral information that is available comes mostly from studies of captive animals although some comes from observations of free-ranging animals. Among pinnipeds, we know far more from behavioral observations and physiological studies, but this is concentrated on those species that mate on land. There is almost a complete void of information on aquatically mating species, which comprise about half the pinnipeds and the majority of the phocids or true seals. Estrous cycles in marine mammals are relatively long compared to terrestrial mammals, usually a year or more, and are seasonal and synchronous within a species or population.

I. Hormones and Anatomy of Estrus

As noted earlier, the hormonal cycle associated with estrus and reproduction in marine mammals appears to be similar to what happens in other mammals. High plasma concentrations of estrogens at the time of parturition decline rapidly and then begin a sharp rise again (Fig. 1; Boyd, 1991) as the cells surrounding the follicle, known as the theca interna, secrete estrogen. This rise in estrogen, along with a decline in progesterone, which inhibits follicle growth, is responsible for the rapid follicular growth in the ovary and the onset of estrous behavior. At the same time the follicle grows, the epithelium of the ovary thins and eventually ruptures, marking ovulation.

In the marine carnivores [pinnipeds, sea otters (*Enhydra lutris*), and polar bears (*Ursus maritimus*)], the period of anestrus, following ovulation and fertilization of the egg, involves a delay in implantation of the fertilized egg (Daniel, 1981). This phenomenon does not appear to occur in cetaceans, and is thought to have an adaptive function that allows females to disassociate the time of mating from parturition. The effect of the failure to implant is that it suspends development for a period of time and can subsequently work to help produce highly synchronized births, which is an important component of the mating system of pinnipeds especially. The physiology of delayed implantation is not well understood. Efforts to try to

Figure 1 A schematic of estrogen and progesterone levels in the circulatory system of female seals in relation to the timing of various reproductive events. Modified from Boyd et al. (1999).

artificially induce implantation using ovarian steroids failed, suggesting these hormones are not what trigger implantation. However, a recent hormonal study on free-ranging northern fur seals (*Callorhinus ursinus*) found that androgens, “male hormones,” which are produced by females, might play a role in delayed implantation in female fur seals (Browne et al., 2006).

All marine mammals have a reproductive tract that has two uterine horns (bicornuate) terminating at the ovaries, which are of equal size and have a common blood source. In pinnipeds, reproduction alternates between the right and left ovary and horn in successive reproductive periods. This is not the case in cetaceans, however. Among baleen whales, both ovaries are equally functioning, whereas in many odontocetes the left ovary appears to function early in life and the right one later in life (Boyd et al., 1999).

II. Timing of Estrus and Estrous Cycles

In pinnipeds, most of our knowledge about the timing of estrus comes from behavioral observations of mounting and mating behavior. Most species are monestrous, with the exception being the walrus (*Odobenus rosmarus*), which has two estrous periods within a year. The double estrus in walrus is undoubtedly linked to the 15-month gestation. With this long gestation, parturition occurs when there are few reproductively active males available, yet there is a postpartum estrus. The second estrus occurs 9–10 months after birth, during the peak of male sexual activity. Otariid seals show relatively little variation in the timing of estrus, with it occurring early in lactation during what has been called the perinatal period and within 4–14 days following parturition for most species. In a few species (California sea lions, *Zalophus californianus*; Steller sea lions, *Eumetopias jubatus*; and Galapagos fur seals, *Arctocephalus galapagoensis*), estrus occurs after maternal foraging trips begin, which may be as much as a month after parturition. Although a postpartum estrus may be an ancestral condition, the nearly yearlong lactation in otariids, along with the dispersal of males away from breeding sites after mating, would have selected for estrus to be early in lactation

and shortly after parturition. Linked to this ecological pattern of spatial separation between breeding on land and feeding at sea is the existence of delayed implantation in seals, which tends to synchronize parturition, and thus estrus (Wells et al., 1999). The benefit to otariid females being receptive shortly after parturition would then be having access to the most competitive and highest quality males because they are present on land.

In phocid seals the timing of estrus is more variable with respect to parturition, ranging from about 5 days to between 1 and 2 months after parturition. In fact, for phocids estrus tends to occur in late lactation or after pups have been weaned, although this may not be the case for Mediterranean monk seals (*Monachus monachus*), which appears to have a 5-month lactation period and little seasonality in breeding. This accompanies a very different lactation pattern from that of otariids. All phocids, with the exception of the Mediterranean monk seal, have a short lactation ranging from 4 to 60 days. Although those phocids that have extremely short lactation periods will come into estrus within 2 weeks of parturition like most otariids, those species that lactate for a month or more have shifted estrus away from being juxtaposed to parturition if this was the ancestral pattern. Reasons for this difference between otariids and phocids are unclear. It may relate to phocid females being in estrus for longer periods of time, providing for greater opportunities to mate with multiple males and thereby increasing the quality of males fertilizing their offspring through sperm competition.

The duration of estrus in otariids appears to be very short based on observed copulatory behavior. In most species, females are observed mating once, although about 30% of females in some species are seen mating twice, and in several more recent studies DNA analyses indicate that fertilization of a female was by a male other than the one observed mating with her (see later for a possible explanation). The observed multiple matings still appear to occur within a 2-day period. We know nothing about the duration of estrus in the aquatically mating phocids, but for all three of the species that mate on land, estrus lasts for several days. Based on the spread of observed copulations, it may last up to 13 days in the northern elephant seal (*Mirounga angustirostris*) and 5–7 days in the southern elephant

(*M. leonina*) and gray seals (*Halichoerus gryppus*). However, there is evidence in some of these phocids that females may use copulation as a strategy to avoid injury and harassment as they try to leave the breeding grounds (Mesnick and Le Boeuf, 1991). Thus it is possible that estrus has ended sooner than indicated by observed copulations.

An estrous period several days long is common in the sea otter as well, a species in which females are known to mate with more than one male (Riedman and Estes, 1990). Sea otters have an annual cycle like most pinnipeds. Female sea otters typically become receptive within a few days of weaning their pup and receptivity lasts 3–4 days. It is possible that ovulation is induced by copulation in this species, as other mustelids exhibit induced ovulation. There is evidence of polyestrus in females that are not impregnated successfully during an initial estrus.

Little is known about the details of the reproductive cycle of polar bears. There is a breeding season between March and May, when females come into estrus (Stirling, 1998). Anecdotal evidence suggests that estrus occurs over multiple days with “courtship behavior” that may be necessary to stimulate ovulation. Individual females have extended periods of maternal care and do not become receptive annually. Intervals between estrus may be as low as 2 years but more typically average over 3 years.

The cycles of cetaceans are much more variable than the cycles of other marine mammals. Many of the mysticete whales have a 2-year cycle, including the fin (*Balaenoptera physalus*), blue (*Balaenoptera musculus*), sei (*Balaenoptera borealis*), humpback (*Megaptera novaeangliae*), and gray (*Eschrichtius robustus*) whales. The fin whale, e.g., becomes receptive in the winter in low latitude, warm water, where mating occurs, and then migrates to cooler high latitudes where it feeds through the summer. In the fall it again migrates to low latitudes to give birth, and after a second migration to cooler water for feeding and lactation the female weans the calf and has a period of anestrus for 5–6 months before becoming receptive again, having made another migration to warm, low-latitude waters. The Northern (*Eubalaena glacialis*) and Southern (*E. australis*) right whales, and bowhead whale (*Balaena mysticetus*) may have an even longer interval of 3–4 years between estrous periods, whereas the minke whale (*Balaenoptera acutorostrata*) appears to have an annual cycle (Perrin *et al.*, 1984).

Odontocetes have an annual breeding season with most mating occurring over a diffuse 2- to 5-month peak for many species studied (Mann *et al.*, 2000). However, the estrous cycles of individual animals are not likely to be annual in many species because of multi-year lactation periods, which may inhibit cycling. Lactation periods in excess of a year are common among odontocetes and may last up to 3.5 years in some species. Unfortunately, more behavioral studies in which individual animals are followed are needed. However, even this has its drawbacks in that copulatory behavior in some dolphins may have a non-sexual social component that could make it difficult to obtain a clear understanding of the estrous cycle from behavior. Data from reproductive tracts of dead odontocetes suggest that females of most or even all species are polyestrus.

Captive studies have provided some useful insights into the estrous cycle of non-lactating odontocetes. For example, one study showed that bottlenose dolphins (*Tursiops* spp.) ovulate spontaneously and have a 21- to 42-day estrous cycle. Also, a 3-year study with two short-beaked common dolphin (*Delphinus delphis*) females and with four common bottlenose dolphin (*Tursiops truncatus*) females found somewhat similar results with respect to periods of estrus and anestrus. The common dolphin females exhibit extended anestrus of 1–2 years but also cycled as many as 7 times within a year. There

was no seasonality to these cycles. The bottlenose dolphin females also had a yearlong anestrus followed by polyestrus, although the maximum number of cycles within a year was only three. Along with this reduced number of cycles compared to the common dolphin the cycles were seasonal, occurring only in April and May.

Sirenians (manatees, *Trichechus* spp. and dugongs, *Dugong dugon*) appear to follow a similar pattern as the cetaceans with a multiyear lactation that results in an estrous cycle of 2 or more years (Wells *et al.*, 1999). Among sirenians, after weaning a calf, females may also undergo polyestrus before becoming impregnated. Breeding may not be continuous, as 33% and 56% of a sample of ovaries from manatees and dugongs, respectively, showed that females were neither pregnant nor lactating. Little is known about the length of estrus in sirenians. However, given that males and females tend to be solitary and need to search out each other for reproduction, it is likely that estrus is relatively long and ovulation might be induced. Mating or estrus groups, consisting of one female and multiple males trying to mate with the female, in manatees and dugongs last for variable periods of time, from a few hours to several days.

III. Estrous Behavior and Signals

The behavior of female gray and elephant seals gives one the impression that they do not come into estrus, except that they ultimately do mate before departing from the breeding colony. Females generally show no soliciting behavior and appear to protest mounting attempts by males right up to the time they leave. However, upon closer observation, subtle differences in the behavior of females do become apparent. For example, females may reduce the duration of their protests when they are in estrus, but they may do this selectively to “potentially high-quality” males. In southern elephant seals, males reportedly will move from female to female, placing their head across the female’s back and waiting for her reaction before either moving on or subsequently attempting to try to mount her. In northern elephant seals near the end of lactation, a female will not respond vocally to the harem master when he places his foreflipper over her back and she may even show a lordosis response by spreading her flippers and raising her tail end.

Most likely there are cues that signal the sexual status of these phocid females. For example, in the gray seal, attempts by males to mount females are not indiscriminate. They begin about a week before females are first observed copulating and increase in frequency linearly during that period (Fig. 2; Boness and James, 1979). As gray or elephant seal males do not routinely sniff the head or tail end of females prior to attempting to mount them, the existence of olfactory signals is less clear than for otariids, in which sniffing behavior preceding mounting is typical (see later). Possible explanations for the selective mounting by gray seal males could be that they use either the body shape of females that are becoming depleted from fasting or the increased rotundness of their pups as a signal of their sexual status.

Another interesting example of behavior that likely indicates signaling (probably chemical) of estrus occurs in polar bears. As noted earlier, males and females are solitary and must find each other for reproduction. Males have been observed detecting the tracks of a female and following them up to 100 km to find the female (Stirling, 1998). Manatee and dugong females may increase the range of their movements when they become estrous to increase the likelihood of encountering males.

Our best information about estrous behavior in pinnipeds comes from some elegant experimental work by Roger Gentry in his 19-year

Figure 2 Mean number of attempted copulations with females by gray seal males as a function of the number of days postpartum for the females. The arrow represents the average time of onset of estrus, defined by the first observed copulation. Modified from Boness and James (1979).

study of the northern fur seal in Alaska (Gentry, 1998). These studies involved capturing groups of females, controlling their access to males, manipulating the size and age of males to which the females were given access, and using surrogates in place of males. Field observations found that prior to estrus, males engaged in sniffing the nose and mouth of females and that sniffing the tail region sometimes followed this. Investigation of the latter often led to a lordosis response. With this in mind, the studies were designed to determine the role of the male in triggering estrus, terminating it, determining the change in behavior of females, confirming the importance of olfactory cues, and understanding the mechanism of how estrus is terminated.

Gentry's studies showed that females prevented from copulating did not prolong estrus nor recycle and receptivity lasted an average of 34 h. A non-estrous female's behavior changed dramatically within as short as a 5-min period, going from being aggressive to a male to emitting low-level estrous vocalization and showing lordosis. The change was reflexive in that either artificial means or a male elicited it. Copulation by a territorial male usually terminated estrous behavior within 15 min, whereas a juvenile or senescent male copulation did not terminate estrus quickly. All copulation led to fertilization, however. Males that actively suppressed the aggressive behavior of females appeared to enhance the speed with which females became receptive. Finally, there appears to be a "vaginal code" based on male size and thrusting pattern for the termination of estrus following copulation.

We are only at the very early stages of beginning to understand about the pre-estrous and estrous behavior of cetacean females. In one study of captive spinner dolphins (*Stenella longirostris*), an attempt was made to correlate behavioral and hormonal patterns, examining behaviors that could have a sexual function. The behaviors included genital-to-genital contact, beak-to-genital contact, other-to-genital contact, ventral presentation, chases, and non-genital contact. The only behavior that showed any relationship with hormonal states indicative of estrus was beak-to-genital contact. This involved females inserting her beak into the genital slit of the male, most

often during the follicular phase of her estrous cycle. One question that remains is to what extent such behavior in captivity represents normal behavior in the wild.

Studies of bottlenose dolphins in Shark Bay, Australia have shown that males form consortships with females that are receptive and try to control access to them. It is unclear how males detect the sexual status of these females, but the consortships are not formed with females that are non-receptive. Females may not have a choice in these consortships, which often involve coordinated activity by male coalitions to control the female.

There is growing evidence from behavioral observations of whales in the wild that females may choose which males that mate or that they may incite competition, as has been demonstrated in some pinnipeds. For example, individual female right whales will move into shallow water or raise their tails to avoid mating by certain males. They also mate with more than one male, providing the opportunity for sperm competition. Female humpback whales lead competing males on high-speed chases. Humpback whales are noted for their song, which is only sung by males. There is some evidence to suggest that females may use these male songs as a basis upon which to choose males.

IV. Reproductive Senescence

Reproductive senescence can be a decline in maternal performance or a complete cessation of reproduction, i.e., no estrus cycling involving ovulation. A number of studies of pinnipeds have shown a decline in maternal performance by older females, but females continued to cycle and produce offspring until they died (Bowen *et al.*, 2006). In contrast, physiological data has shown at least one species of cetacean, the short-finned pilot whale (*Globicephala macrorhynchus*), that ceases cycling and producing offspring more than 10 years before the end of their life expectancy (Mann *et al.*, 2000). In several other cetacean species markedly reduced fertility rates in older females also suggest senescence in estrus cycling may occur. The reasons why senescence would evolve in marine mammals or other mammals, for that matter, are unclear. However, two hypotheses that have been proposed are that females in species that have high levels of maternal investment may benefit by continuing to rear their last and preceding offspring still under their care, or by enhancing their offsprings' success by helping to rear grand-offspring.

While gradual progress is being made in our understanding of estrus and estrous behavior in marine mammals, there is still much to be learned, especially in those species where sexual behavior is entirely aquatic. Some of our greatest opportunities may come from new technologies at hand that are being used on animals in the wild, such as the animal-borne video systems or tags that can record and store vocalizations made by an animal or by surrounding animals. We also can expect to learn more from detailed studies of animals in captivity.

interact with animals. Their complexity is compounded because highly charged subjective opinions and passions run high. This article highlights just how complex and multidimensional these issues are. It is meant to be a starting point for a discussion of different perspectives; none is more important than others. What is important is that we all agree that ethics is an essential element in any discussion of human interactions with other animals.

Since I wrote the original version of this essay for the first edition of this encyclopedia (2002), things have gotten worse for numerous aquatic animals including marine mammals. Human-induced (anthropogenic) assaults on aquatic ecosystems and on individuals due to climate change, recreation, and over-fishing have increased globally (Bekoff, 2007a and references therein; see also For cod's sake, act now, 2006; Mackenzie, 2006; Osinga and 't Hart, 2006; Raloff, 2006). The Food and Agricultural Organization of the United Nations (FAO) noted in February 2006 that their “...most recent global assessment of wild fish stocks found that out of the almost 600 major commercial species groups monitored by the Organization, 52 percent are fully exploited while 25 percent are either overexploited (17%), depleted (7%) or recovering from depletion (1%). Twenty percent are moderately exploited, with just three percent ranked as underexploited” (Food and agricultural organization of the United Nations, 2006). There are also problems with non-target species getting caught due to fishing activities. For example, in 1990, about 42 million marine mammals and sea birds were caught in drift nets as squid and tuna were being harvested (Fox, 1997). About 129,000 Olive Ridley turtles (*Lepidochelys olivacea*) have died over the past 13 years because they suffocate in the nets of fishing boats not using mandatory turtle-excluder devices. Experts fear that the movement of giant ships and artificial illumination would put the turtles in even deeper trouble in the years ahead. Whales also are non-target victims of fishing nets. In 2003 the World Wildlife Fund reported that nearly 1000 whales, dolphins, and porpoises drowned daily after becoming entangled in fishing nets and other equipment (Verrengia, 2003). Annually, more than 300,000 individuals may perish because of fishing activities. And while there is a global moratorium on commercial whaling since 1986, Japan and Iceland continue to hunt as part of what they call “scientific programs.” Norway has objected to the moratorium and runs commercial whaling operations.

Here I focus on human–dolphin and human–whale encounters (e.g., hunting, keeping animals in captivity, swimming programs, using them for entertainment), for ethical questions that arise when considering these types of highly visible interactions can be used as illustrations for human encounters with other marine mammals, including the pinnipeds [seals, sea lions, and the walrus (*Odobenus rosmarus*)], manatees (*Trichechus* spp), and polar bears (*Ursus maritimus*). Understandably, there is much and growing public interest in these rendezvous. Individuals of these species are sentient beings (capable of experiencing pleasure and pain) and sentience must influence how we interact with them (Bekoff, 2006a, b, c, 2007b). In scientific research there are always surprises. New scientific data appear that force us to rethink what we know and to revise our stereotypes. For example, spindle cells, which were long thought to exist only in humans and other great apes, have been discovered in humpback whales (*Megaptera novaeangliae*), fin whales (*Balaenoptera physalus*), killer whales (*Orcinus orca*), and sperm whales (*Physeter macrocephalus*) in the same area of their brains as spindle cells in human brains (Coghlan, 2006). This brain region is linked with social organization, empathy, and intuition about the feelings of others, as well as rapid gut reactions. Spindle cells are important in processing emotions. There is also a growing database showing that fish are sentient beings that experience pain and suffering (Sneddon, 2003; Moccia and Duncan, 2004).

Ethics and Marine Mammals

MARC BEKOFF

The whale in the sea, like the wolf (*Canis lupus*) on land, constituted not only a symbol of wildness but also a fulcrum for projecting attitudes of conquest and utilitarianism and, eventually, more contemporary perceptions of preservation and protection.

Stephen R. Kellert R(1996)

I. Humans and Other Animals: Multidimensional Encounters

Humans are a curious lot, and our intrusions, intentional, and inadvertent, have significant impacts on other people, non-human animal beings (“animals”) plants, water, the atmosphere, and inanimate landscapes. Often our influence is subtle and long term. Our relationship with other animals is a complex, ambiguous, challenging, and frustrating affair, and we must continually reassess how we should interact with our non-human kin. Often we live with deep contradictions about what we do and what we believe we morally should do.

There are many important and difficult issues that demand serious consideration in discussions of the ethics of how human beings

Dolphins, whales, and other marine mammals have often been fabricated to be the animals we want them to be. Most descriptions of dolphins and other cetaceans picture them as highly intelligent and capable of experiencing pleasure and pain with remarkable social and cognitive skills. Indeed, dolphins and other marine mammals seem to fulfill some criteria of “personhood” in that they are alive, aware of their surroundings, sentient, and may have a sense of self. Why, then, do some people feel comfortable intruding into their worlds if it will cause pain and suffering? Toni Frohoff (1998, p. 84) has poignantly noted: “Currently we are walking a fine line in our relationship with cetaceans. The same attraction that motivates us to protect them from harm is also what drives us to be close to them, to have them ‘within reach.’” It is because dolphins and other marine mammals are thought to be attractive, harmless, endowed with mystical qualities, or to be of economic value as commodities for show or food that we seek them out. However, we may bring much harm to them in our efforts to include them in our lives, even in ways that do not involve killing them.

Many issues that are pertinent when considering marine mammals are also raised when discussing other mammals such as terrestrial CARNIVORES. Wolves and whales have been among the most persecuted of animals during the last three centuries, wolves because they were feared predators and whales because of their economic value. The near EXTINCTION of both wolves and some whales was important in setting environmental policies. However, while many people swim and wade with dolphins, few if any truly dance or howl with wolves. Thus, the close contact that many humans have with some marine mammals leads to other questions that are unique to these encounters.

A. What Should We Do?

Human impacts on other animals, intentional and inadvertent, are universal. A major question in need of serious debate is should we ever interfere in other animals’ lives—when might human interference be permissible? Thus, should we let other animals be and not intentionally interfere in their lives? Or, should we hunt them for food whenever we so wish? Should we hunt only when there are no alternative food sources? Should we interfere in other animals’ lives when we have spoiled their habitats or when they are sick, provide food when there is not enough food to go around, provide care to young if a parent does not, stop aggressive encounters, stop predators in their tracks, or translocate individuals from one place to another, including zoos, wildlife and marine theme parks, and aquariums? Should human interests always trump those of other animals? If not, then when should the interests of other animals trump our own?

The question of when humans *should* intrude is a difficult one. However, just because we *can* do something does not mean that we *should* or *have* to do it. Furthermore, just because some intrusions may be *relatively* less injurious than others, this line of reasoning places us on a very slippery slope and can, in the end, lead to narrow or selfish anthropocentric claims. Even in situations when humans have good intentions, those intentions are not always enough.

This article discusses some basic principles that underlie the use and exploitation of marine mammals, especially whales and dolphins, presents a few general questions, and discusses some representative examples. Definitive answers to these and other questions are quite elusive, but open discussion can provide guidelines for proactive decision-making. All too often we are left in the position of trying to rectify messy and difficult situations that we have created; proactivity needs to become the *modus operandi* for future actions. For many questions about how animals should be treated by humans there are

no “right” or “wrong” answers. However, there are better and worse answers. Perhaps it will turn out that in some cases what we think is the “right” action is not when the big picture is carefully analyzed.

It is essential to remember that even if wild or captive marine mammals develop close social bonds with humans, these animals are socialized or habituated individuals, but they are not domesticated animals. Often people remark that individuals who interact closely with humans have become domesticated. However, domestication does not happen to an individual during his or her lifetime. Domestication is a long-term evolutionary process during which humans selectively breed animals for desirable traits. “Domesticated” and “socialized” or “habituated” are not synonyms.

B. Human Responsibilities

It is generally accepted that humans have unique responsibilities to other living organisms (and to inanimate environments). Our unique responsibilities stem from our (at least most of us) being moral agents who are responsible for our actions. It is usually assumed that neither animals nor young human infants and mentally impaired adults are moral agents. Rather, they are moral patients, not usually held responsible for their actions. They do not know “right” from “wrong” or “good” from “bad.” Nature, too, cannot be good or bad, although the consequences of natural acts can be better (good) or worse (bad). Nature simply is. We do not have to apologize for nature’s ways. Nor should her ways—her supposed cruelty and ruthlessness—be used as excuses for what we do to other animals (including humans).

It is important to stress that most, if not all, other animals depend on our goodwill and mercy. Individuals can choose to be intrusive, abusive, or compassionate. We do not have to do something because someone else wants us to do it. We do not have to do something just because we can do it. Each of us is responsible for our choices.

II. The Moral Status of Animals: Animal Rights and Animal Welfare

In current discussions about the moral status of animals, there is an obvious “progressive” trend for greater protection for wild and captive animals. (This might be due in part to an increasing number of people moving from farms and rural areas to more urban environments.) This is clearly the case for marine mammals (Kellert, 1999). In a survey of American’s perception of marine mammals, most respondents were opposed to commercial WHALING, often for ethical reasons. Concern was also expressed for the commercial exploitation of seals, sea otters (*Enhydra lutris*), walrus, and polar bears. Most Americans also objected to commercial whaling by native peoples or the resumption of killing gray whales (*Eschrichtius robustus*). A majority of Alaskans opposed oil and gas development if it injured or killed marine mammals. There was also an unsuccessful effort prior to the reauthorization of the Marine Mammal Protection Act in 1988 to prohibit any invasive research involving marine mammals unless that research would directly benefit the subject of the research.

In recent years, philosophers and scientists have devoted increasing attention to questions about the moral status of animals. Many people support a position called the *rights* view. To say that an animal has a right to have an interest protected means that the animal has a claim, or entitlement, to have that interest protected even if it would benefit us to do otherwise. Humans have an obligation to honor that claim for other animals (just as they do for humans who cannot protect their own interests). Thus, if a wild dolphin has a

right to feed, then humans have an obligation to allow her to do so and not do anything to interfere with her feeding activities. Likewise, if a dolphin has a right to life, she cannot be used in war games, warfare, or other activities in which death is possible.

Animal rights advocates stress that animal's lives are valuable in and of themselves (they have inherent value) and that their lives are not valuable because of what they can do for humans (their utility) or because they look or behave like us. Animals are not property or "things," but rather they are living organisms that are worthy of our compassion, respect, friendship, and support. Animals are not "lesser" or "not as valuable" as humans; they are not property that can be abused or dominated. Human benefits are irrelevant for determining how animals should be treated.

Many people believe that the rights view and the *animal welfare* view are identical. They are not. Animal welfarists focus on individual's usefulness to humans. They practice *utilitarianism*, in which the general rule of thumb is that the right actions are those that maximize utility summed over all those who are affected by the actions. Often welfarists/utilitarians are called "wise users." They believe that while humans should not abuse or exploit animals, as long as we make the animals' lives comfortable, physically and psychologically, we are taking care of them and respecting their welfare. Welfarists are concerned with the quality of animals' lives. However, welfarists do not believe that animals' lives are valuable in and of themselves. Many conservation biologists and environmentalists are utilitarians who are willing to trade off individuals' lives for the perceived good of higher levels of organization such as populations, species, or ecosystems.

The welfarists' rule of thumb, and it is not a moral rule, is that it is permissible to use animals if the relationship between the costs to the animals and the benefits to the humans is such that the costs are less than the benefits. Welfarists believe that if animals experience comfort, appear happy, experience some of life's pleasures, and are free from prolonged or intense pain, fear, hunger, and other unpleasant states, then we are fulfilling our obligations to them. If individuals show normal growth and reproduction and are free from disease, injury, malnutrition, and other types of pain and suffering, they are doing well. Thus, welfarists argue that using animals in experiments, slaughtering them for human consumption, and using them for treating human disorders (e.g., dolphin-assisted therapy, DAT, programs) are permissible as long as these activities are conducted in a humane way. Welfarists do not want animals to suffer from any unnecessary pain, but they sometimes disagree among themselves about what pain is necessary and what humane care really is. Welfarists agree that the pain and death animals experience are sometimes justified because of the benefits that humans derive. The ends—human benefits—justify the means—the use of animals.

III. Hunting Whales

Whale HUNTING brings to light numerous issues that reflect utilitarian thinking. Whales are frequently viewed as commodities, whether they are hunted centers or whether it is economical. Rarely are the costs to the individuals entered into the equation. In the past, many people thought that whales were an inexhaustible resource and historically there were few restrictions on killing them. When whale watching became popular, whales were more valuable alive than dead. They went from being a consumptive to a non-consumptive resource.

Political and sociocultural motives also play a role in whale hunting. Various indigenous people (e.g., the Makah in Washington State) want to be able to hunt whales (in the Makah case, gray whales)

because their ancestors did so, because it was part of their cultural heritage. They claim that the tradition of whale hunting defines "who they are."

The revival of aboriginal whaling is controversial in various parts of the world and involves species other than the gray whale. When the target species is on the brink of extinction, few argue that any type of whaling is permissible. Likewise, when killing whales is essential for food, few argue against the practice. However, when the whales are not endangered, people disagree about continuing to kill whales or reestablishing this practice. Some argue that whale hunting is permissible because it is part of the heritage of a given indigenous group (it is cultural revival), whereas others argue that there are other cultural practices that are no longer followed and little effort to regain them. Why is whaling hunting so important if it is not essential for sustenance?

Methods of killing whales also are controversial. For example, the Makah used a rifle to kill a whale who had been wounded by a harpoon. A majority of Americans oppose the use of weaponry. Hunting whales produces much pain and suffering. Chasing and stalking individuals compromises their physical and psychological well-being and death usually is not instantaneous, frequently taking upward of 10 min. Furthermore, family groups are broken up. All in all, hunting whales and other animals, including such marine mammals as seals, raises numerous difficult ethical issues.

IV. Keeping Animals in Captivity

A. Swimming with Dolphins

"Swim with dolphin" and "petting pool" programs are very controversial. Such proffered reasons as "it's fun," "aren't the animals cute," or "it's a spiritual experience" are insufficient to justify these practices. Much attention has been given to the question of whether human encounters with dolphins may have negative effects on the dolphins. Human-dolphin interactions may be noisy and stressful. One study reported that captive dolphins showed enlarged adrenals, especially those individuals exposed to humans on numerous occasions. The long-term effects of swim programs on dolphin behavior and well-being still need to be studied systematically, but evidence shows that the stress associated with these programs may have long-term effects on the dolphins.

Swim programs are risky to humans. Dolphins are large and strong animals. While higher risks seem to be experienced more in non-controlled swims, there are also serious risks in controlled swims that might be fatal. "Controlled" refers to situations when all interactions are directed by trainers who give the dolphins commands at all times. "Non-controlled" means interactions are allowed to occur spontaneously.

It is also important to know if DAT programs truly work. While some researchers claim that DAT is an effective therapeutic intervention for several disorders (e.g., depression, autism, cerebral palsy, mental retardation) others disagree. Criticisms center on the use of improper statistical methods and the lack of controlled studies. It is often very difficult to assess experimentally the positive effects of animals on people. In many programs, no other animals, including such domesticated species as dogs, were used as controls to see if they might be as or more effective than dolphins.

Another question that is also important to consider is whether programs that involve interactions with captive dolphins help to educate people about these and perhaps other animals. More research is needed to determine if contacts with dolphins actually change people's attitudes about them. Intuitions are not enough. To date, there

is no solid evidence that interactive captive programs with dolphins are more effective educationally than non-interactive programs. Indeed, some marine biologists fear that these programs may send the message that it is permissible to take animals from the wild and bring them into captivity and keep them in small tanks where they are bored, deprived, and needlessly die. There are also serious concerns about the fate of dolphins once they are too old or aggressive to partake in swim programs. Yet another concern centers on the possibility that these programs may teach people to expect the same kinds of interactions from free-ranging wild animals.

While there have been attempts to regulate swimming programs, little has actually been accomplished. In the United States, federal regulations controlling these programs, mandated in 1998 (after a delay of 4 years before finalizing them) by the US Department of Agriculture's Animal and Plant Health Inspection Service (APHIS) were suspended in April 1999 soon after they were invoked because, according to their press release: "It has come to our attention that the language in the new regulations may be confusing to some. Therefore, we are suspending enforcement of the regulations in order to take a closer look at the language and make it more understandable." (www.aphis.usda.gov/lpa/press/1999/04/dolphin.txt) During this process, there are no regulations for these popular programs. Some people believe the federal regulations were suspended because of pressure from the lucrative industries that exploit dolphins.

B. Petting and Feeding Programs

Petting and feeding programs allow people to pet and feed captive dolphins. Many of these programs may not be adequately supervised or monitored. There are some major concerns with these programs, including that dolphins may be unable to avoid encounters with humans and may be highly stressed, the water in which dolphins and humans interact is often heavily chlorinated and may be unhealthy for dolphins (and humans), dolphins may be fed foreign objects that can harm them, and there seems to be little, if any, education value to these programs. There are few data that speak to these and other concerns and this information is needed to determine if petting and feeding programs can be properly regulated. One of the main questions is whether dolphins can be accessible to people in these programs and still be protected from harm.

While feeding and harassing wild dolphins is illegal in the United States, and there are severe penalties for engaging in these activities, this is not so for other countries. There are documented instances of wild dolphins being fed firecrackers, golf balls, plastic objects, balloons, and fish baits with hooks (so that hooked dolphins can be caught). Provisioning dolphins with fish has been associated with a change in the social behavior of free-ranging Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) in Monkey Mia, Australia. Dolphins who have been fed also change their foraging behavior and frequent heavily trafficked harbors and marinas. Some get struck by boats. People have also been seriously injured trying to feed wild dolphins. The National Marine Fisheries Service and other organizations are mounting highly visible campaigns to stop the feeding and harassment of wild dolphins. It also has been noted that some problems associated with feeding terrestrial mammals (changes in foraging patterns and hunting skills) are relevant to concerns about the feeding of dolphins.

Clearly, much more information is needed concerning petting and feeding programs for captive and wild animals. Especially needed are data concerning the effects of these programs on dolphin mortality,

health, and psychological and emotional well-being. It is also important to counter the possibility that feeding captive dolphins may send the message that it is permissible to feed wild individuals.

C. Zoos: Aquariums and Marine Theme Parks

The existence of zoos, including aquariums and marine theme parks, raises many important and difficult ethical questions. Certainly, numerous people are interested in exotic animals, including marine mammals. Kellert found that a majority of Americans objected to the captive display of marine mammals in zoos and aquariums if there were no demonstrated educational and scientific benefits. They were concerned with the care given to captive individuals. To date, no unequivocal data show that there are any significant educational and scientific benefits that help the animals, despite beliefs that such benefits accrue. An average zoo visitor spends only about 30sec–2min at a typical exhibit and only reads some signs about the animals. A number of surveys have shown that visiting zoos to be entertained was the predominant reason people went to the zoo. In one study at the Edinburgh Zoo in Scotland, only 4% of zoo visitors went there to be educated, and no one specifically stated they went to support conservation. To date, very few empirical data support the notion that much educational information is learned and retained that helps the animals in the future. Indeed, some people worry that keeping animals in captivity for humans to view carries the message that it is all right to do so.

Many questions center on how individuals are captured, transported, and kept in various types of captive situations. Animals often are injured and otherwise stressed during capture and transport. Family groups may be broken up and the social structure of populations decimated. The effects of changing the social structure of wild populations are little known. Well-intentioned people often argue that the lives of captive animals are better, of higher quality, than those of wild relatives, but available data for marine mammals suggest that this claim is not well supported. From an ethical perspective, one must consider whether this claim is even relevant, for keeping animals in captivity radically alters numerous behavior patterns that have evolved over millennia. Predation, starvation, and disease are part of what it is to be wild. Is a longer unnatural life in captivity better than a shorter natural life in the wild?

Breeding surplus animals for profit (e.g., polar bears who become the center of media parades and then are moved to other zoos when their resource value or utility is fully exploited) also demands serious discussion. Similarly, the trading, donating, or loaning of unwanted or surplus animals who cannot be released into the wild—treating them as property—also raises numerous ethical questions.

The benefits of keeping marine mammals in captivity, to the animals themselves, remain unknown. Because the social and physical environments of marine mammals are virtually impossible to replicate in captivity, ethical questions arise when these animals are maintained in unnatural environments. There can be little doubt that the quality of life is compromised. In captivity, evolved patterns of foraging, care giving, and migrating are lost as are natural patterns of social organization (group size and composition). In captivity, for practical reasons, group sizes may be much smaller than those observed in wild relatives. Stereotyped behaviors often result from conditions of captivity, as do self-mutilation and unusually high levels of aggression. Furthermore, individuals often cannot escape from the glaring eye of the public and cannot choose when and where to rest.

There also seems to be higher mortality (spontaneous abortions, still-births) in captive vs wild individuals (especially killer whales). There is also higher mortality for adult killer whales in captivity. Limited data on annual survival rates suggest that there is high mortality during acclimation to captivity and differences in annual survival rates among different species and age classes within species.

There is little evidence that people leave zoos or aquariums with any long-lasting sentiments or knowledge that benefit either the animals they have seen or their wild relatives. Furthermore, few zoos are engaged in conservation efforts for marine mammals. The Association of Zoos and Aquariums (AZA) which oversees zoos in the United States and grants accreditation if they meet certain standards, admits in its *own* executive summary that “Little to no systematic research has been conducted on the impact of visits to zoos and aquariums on visitor conservation knowledge, awareness, affect, or behavior.”

Many ethical concerns are also raised because first and foremost, zoos are businesses and their bottom line centers on money. It costs an enormous amount of money to bring marine mammals into captivity and to keep them there. It has been suggested that the money used to capture, transport, and keep animals in captivity would be better used to do research in the wild. Also, much money is spent on public relations and not on the animals themselves. Some feel that the images of nature that are represented to the public are a manufactured corporate point of view that centers more on what the public wants than what is good for the animals. Witness the existence of numerous “Flippers” (the prototypical dolphin) and “Shamus” (the model killer whale) whose lives do not resemble even closely the lives of free-living conspecifics or relatives.

Similar questions are raised when considering research on captive animals. Certainly, information may be gathered about various aspects of their lives (e.g., maternal behavior, self-recognition, social behavior, communication, and cognitive capacities). However, research on captive animals is being increasingly carefully scrutinized by some researchers, philosophers, many universities, and various funding agencies. Some relevant questions include: Is it ever permissible to keep individuals in captivity regardless of their utility, is the knowledge that is gained by studying captive individuals justified by keeping them in cages or tanks, and could more reliable data be collected under more natural conditions? Very little still is known about the life histories of most marine mammals. For many people it is the benefits that the captive individuals and other members of their (or other) species might accrue that is central, not the benefits that humans might gain. However, rarely are results used to benefit the animals other than in learning about medical treatments and husbandry to make their lives in captivity better. Rarely do wild individuals benefit from work done on captive relatives.

V. Research Ethics

In addition to questions concerned with how humans treat other animals, the study of ethics also considers questions dealing with such areas as (1) the context of research (where it is done, are local people involved when researchers “go into the field” in countries other than their own, are local customs and beliefs about native fauna respected); (2) scientific integrity (researchers’ responsibility for integrity in data collection, analysis, and dissemination); (3) the ownership of data (do data “belong” to any single person or to the team that is involved in their collection, analysis, and dissemination); (4) authorship (whose names should appear on a publication and in what order); and (5) individual responsibility for the integrity of a project as a whole and for the integrity of the results. A good deal of

trust is involved in all research, and questions that arise in these general areas require, and are receiving, much attention in the scientific community. Studies of marine mammals often require large teams of people, some of whom have never met, and it is important for all individuals to realize that each is responsible not only for his or her involvement, but for the composite product that is generated.

Another area of concern, some aspects of which are included in this volume, is research methodology (trapping, marking, tracking, and observing animals; experimentally manipulating social groups, food supply, and habitat). Often, human intrusions have major effects on animals’ behavior even if they are unintentional. For example, the mere handling of individuals can influence their behavior and their acceptance back into a group, as can fitting individuals with various telemetric devices. Tracking or stalking animals can lead to changes in their activity patterns so that they spend more time avoiding humans than feeding or giving care. Most data come from animals other than marine mammals, and future studies of the effects of various methods are needed. Ethical considerations require that we learn about the effects of research methodologies and attempt to avoid them. In some cases the methods used may preclude collecting data relevant to the questions at hand.

VI. Ecotourism

Ecotourism (whale watching, swimming with wild dolphins, photographing animals, visiting pinniped rookeries), some aspects of which are discussed in this volume, also raises numerous ethical questions concerning human intrusions into the lives of other animals. When, if ever, this activity is justified requires serious debate. People often try to interact with wild marine mammals but do not attempt to pet wild zebras (*Equus* spp.) or lions (*Panthera leo*). What principles underlie these differences in attitude?

Whether ecotourism is less intrusive on the lives of marine mammals than various research practices awaits further study. Indeed, there are observations of humans causing seal pups to stampede and being trampled and of humans striking and injuring animals with boats. It is essential to educate the public of possible negative effects of ecotourism.

VII. The Future: Being Proactive

Kellert’s study of American perceptions of marine mammals and their management shows clearly that most people support the various goals of the US Marine Mammal Protection Act. Most are willing to “render significant sacrifices to sustain and enhance marine mammal populations and species ... These findings clearly indicate that marine mammals possess considerable aesthetic, scientific, and moral support among the great majority of Americans today” (1999, pp. iv–v).

It is in the best traditions of science to ask questions about ethics; it is not anti-science to question what we do when we interact with other animals. Ethics can enrich our views of other animals in their own worlds and in our different worlds and help us to see that their lives are worthy of respect, admiration, and appreciation. Indeed, it is out of respect, admiration, and appreciation that many humans seek out the company of whales, dolphins, polar bears, and other marine mammals.

Many ethical issues are extremely difficult to reconcile and generate highly charged and deep emotional and passionate responses. Achieving a win-win situation for animals and humans will be very difficult. However, it is clear that the increasingly detailed attention

being given to various sorts of human–marine mammal interactions is showing that there are innumerable negative effects on the lives of the animals. While many negative influences have been anticipated or are not surprising, the severity of human influences has not been fully appreciated. We must be careful not to love these animals to their (or our) deaths. Humans are indeed dangerous to marine mammals and they are dangerous to us.

The study of ethics can also broaden the range of possible ways in which we interact with other animals without compromising their lives. Ethical discussions can help us see alternatives to past actions that have not served us or other animals well. Thus, the study of ethics can be enriching to other animals and to us. If we believe that ethical considerations are stifling and create unnecessary hurdles over which we must jump in order to get done what we want to accomplish, then we will lose rich opportunities to learn more about other animals and also ourselves. Our greatest discoveries come when our ethical relationships with other animals are respectful and not exploitive.

Allowing human interests always to trump the interests of other animals is not the best strategy if we are to solve the numerous and complex problems at hand. We need to learn as much as we can about the lives of wild animals. Our ethical obligations also require us to learn about the innumerable ways in which we influence animals' lives when we study them in the wild and in captivity and what effects captivity has on them. As we learn more about how we influence other animals, we will be able to adopt proactive, rather than reactive, strategies.

The fragility of the natural order requires that people work harmoniously so as not to destroy nature's wholeness, goodness, and generosity. The separation of “us” (humans) from “them” (other animals) engenders a false dichotomy, the result of which is a distancing that erodes, rather than enriches, the possible numerous relationships that can develop among all animal life.

Public education is critical. However, it does not always work (Cunningham-Smith *et al.*, 2006). To disseminate information about what is called the “human dimension,” administrators of zoos, wildlife theme parks, aquariums, and areas where animals roam freely should inform visitors of how they may influence the behavior of animals they want to see. Tourism companies, nature clubs and societies, and schools can do the same. By treading lightly, humans can enjoy the company of other animals without making them pay for our interest in their fascinating lives. Our curiosity about other animals need not harm them.

Many marine mammals are closely linked to the wholeness of many ecosystems, and how they fare is tightly associated with how communities and ecosystems fare. By paying close attention to what we do to them, and why we do, what we do, where, and when we do it, we can help maintain the health of individuals, species, populations, and ecosystems. Concerning animal welfare, we can always do better. Quite often, “good welfare” is not “good enough.”

Acknowledgments

I thank Toni Frohoff, Robert Hofman, Dale Jamieson, Naomi Rose, and Trevor Spradlin for comments on a previous draft of this paper. Trevor Spradlin kindly sent me voluminous material dealing with human–dolphin interactions, much of which I can only summarize here. Support for summary statements can be found, for the most part, in J. R. Twiss, Jr., and R. R. Reeves (eds.) “Conservation and Management of Marine Mammals,” Smithsonian Institution Press, Washington, DC, and in other sections of this encyclopedia.

kingdom, have also died out because of human activities. It is thought that a total of 1190 species of plants and animals have gone extinct since 1600 (Smith *et al.*, 1993). When this is combined with the countless number of fungi, protists, and bacteria that have disappeared without notice, it is easy to see why this human decimation of the Earth's living organisms may easily rank among one of the most major mass extinctions that are a part of our planet's history.

Until recently, the effect of human activities has been primarily felt by those species whose members are relatively large and conspicuous. The great Pleistocene extinctions of mammoths and horses in North America, along with the demise in more recent times of many species of large, flightless birds, are examples of this. Being relatively large, it would be expected that marine mammals would have suffered the same fate as their terrestrial counterparts. The size and remoteness of the habitat of most marine mammals, however, spared them the slaughter and resultant slide toward extinction until more recently. In the last few hundred years, technology gave humans the ability to seek out and kill these animals throughout the vast expanses of the ocean, and many marine mammal species have been brought to the verge of extinction. Lack of profitability from increased costs inherent in trying to find fewer animals, coupled with increased public awareness of and resistance to the destruction, has brought a halt to the exploitation of many of these marine mammals, and in some cases the numbers of certain species are on the rise. This fortunate development came too late for three species of marine mammal: Steller's sea cow (*Hydrodamalis gigas*), the Caribbean monk seal (*Monachus tropicalis*), and the Japanese sea lion (*Zalophus japonicus*). Most recently the river dolphin of the Yantee River (the baiji, *Lipotes vexillifer*) has become extinct. In addition, one population has become extinct in recent times, the Atlantic gray whale (*Eschrichtius robustus*). Direct human destruction was the primary cause of these extinctions, and in all cases the story is one of human ignorance, shortsightedness, and greed.

I. Steller's Sea Cow

In the late autumn of 1741, a Russian exploratory vessel, the *Saint Peter*, wrecked on a bleak, uninhabited island near the western end of the Aleutian chain (Ford, 1966). This island was completely isolated, save for smaller nearby Copper Island, and was over 200 miles from the nearest Russian settlement on the Kamchatka peninsula. As food supplies were practically non-existent in the winter, it was a joyous occasion when it was discovered that the nearshore waters around the island were inhabited by huge, slow-moving, previously unknown marine mammals. These were Steller's sea cows, later named after the naturalist accompanying the voyage, Georg Wilhelm Steller. Upon killing, this animal provided large quantities of beef-like meat and almond-tasting oil. Throughout the winter, the crew members of the *Saint Peter* slaughtered sea cows. When in the summer of 1742, the men who survived the winter reached Kamchatka, they spread the word of the wealth in furs to be had in the Bering Sea and Alaska and of the huge sea cow that would provide food necessary for the required long voyages. From then on, fur traders and hunters would stop at Bering Island and Copper Island to slaughter these animals and stock their vessels with meat and oil. In addition, parties hunting fur-bearing animals would winter on these islands and dine on sea cow meat (Stejneger, 1887). By 1754, the sea cow was gone from Copper Island. With its disappearance 14 years later from Bering Island, *Hydrodamalis gigas* was extinct (Haley, 1978).

What little is known about this species comes from the observations and written accounts of Georg Steller and from bones found

Extinctions, Specific

DEBORAH A. DUFFIELD

Extinguishment of species has been occurring since the dawn of life on Earth. Sometimes this process is a gradual one, with a few species disappearing over a long period of time. Occasionally, the process appears to be quite rapid and widespread; such mass extinctions often result in the disappearance of many of the flora and fauna on Earth in a relatively short period of time. Such a mass extinction is currently taking place, only this time the cause is not climatic, tectonic, or cosmic, but rather is the result of the activities of one species, *Homo sapiens* (Domning, 1999). It is well established that many species of animals have disappeared over the last 400 years because of humans, including such well-known examples as the passenger pigeon, dodo, quagga, and great auk. Many other lesser-known species of animals, along with many representatives of the plant

on Bering and Copper Islands. Members of this species were large, fusiform animals with a relatively small head and a horizontally flatted tail. Individuals grew to about 25 ft in length and probably weighed upward of 4 tons. They had short forelimbs with no digits, a tough hide, and thick layers of fat for insulation. These characteristics permitted the animals to survive in the frigid, storm-tossed waters of the north Pacific, far from the tropical areas inhabited by their nearest living relatives, manatees, and dugongs (Domning, 1978). Like other SIRENIANS, these animals were herbivorous, grazing on the large kelp beds that grew in the shallow waters around the Commander Islands. They had no teeth, but rather two flat, horny chewing plates, one in each jaw, between which the animals mashed kelp. Steller observed that they spent most of their day feeding, head down, with their backs exposed. They lived in shallow, sandy areas, preferring the mouths of running streams with their input of freshwater. They may not have been capable of diving (or if so, only near the surface), a characteristic that would have restricted them to the intertidal area outward to the seaward edge and to the surface of this zone (Reeves *et al.*, 1992).

This shallow restricted range, coupled with their slow-moving and docile habits, made Steller's sea cows easy prey for human hunters, even those with relatively primitive weapons and boats. Grazing animals could be easily approached, harpooned, dragged ashore, and butchered (Stejneger, 1936). Often a wounded animal would escape from its killers and swim out to sea. It has been estimated that only one out of every five sea cows killed was actually utilized for food. Even though this species apparently lived all along the rim of the North Pacific into the late Pleistocene, by the early eighteenth century it was confined as a relict population to the shallow waters around the Commander Islands. This reduction of numbers was thought to be possibly a result of hunting by indigenous peoples (Whitmore, 1977). In 1741, the population was estimated to be no more than 2000 individuals, and relentless hunting pressure, together with the wasteful harvest method, led the complete extermination of Steller's sea cow by 1768 (Stejneger, 1887). Even though there have been reports of sightings in the North Pacific of animals reputed to be sea cows, some as recently as 1977, it is almost certain that *H. gigas* was driven to extinction over 200 years ago.

II. Caribbean Monk Seal

Nearly 300 years before the Bering expedition and almost half a world away, the demise of another species of marine mammal at the hands of Europeans began. In 1494, on his second voyage to the Caribbean, Columbus discovered the Caribbean monk seal (*Monachus tropicalis*) on the coast of Santo Domingo (Hispaniola). He ordered his men to kill eight of these "sea wolves" for food, and from that time on the killing never ceased (King, 1983). Probably confined to sandy beaches on remote islands and atolls because of centuries of aboriginal hunting on large islands and the mainland, the monk seals were sought out and ruthlessly slaughtered by fishermen, turtle hunters, buccaneers, and organized sealers. In the Bahamas, up to 100 seals per night were known to be killed (Maxwell, 1967). By the mid-nineteenth century, many zoologists thought that the Caribbean monk seal was already extinct. However, in 1886 a small herd was discovered near the Yucatan peninsula, and because so little was known about the species, North American museums sent expeditions out to gather specimens. One of these expeditions killed 49 seals, 5 of which were pregnant females with near-term fetuses (Ward, 1887). For a species in such precarious circumstances, such activities of science were also of no help. The last confirmed sighting was reported by C. Bernard Lewis, Director of the Institute of Jamaica, who

said that until 1952 a small colony existed at Seranilla Bank, halfway between Jamaica and Honduras (Rice, 1973). Since that time, although some pinnipeds have been sighted in the Caribbean (these probably being individuals of other seal or sea lion species outside of their normal range), no confirmable sighting of a monk seal in the Caribbean has been made. In 1996, the International Union for the Conservation of Nature declared *M. tropicalis* extinct.

Even though known to Europeans for over 400 years, little scientific information was obtained concerning the Caribbean monk seal before its disappearance. The species belongs to the family Phocidae, and with the Mediterranean monk seal (*Monachus monachus*) and the Hawaiian monk seal (*Monachus schauinslandi*) comprise the genus *Monachus*. The Caribbean species was apparently very similar to the other two monk seals, with males reaching 6–7 ft in length, and females somewhat smaller. The fur of adults was brown on back with a gray tinge and yellowish on the underside. The fur of pups was dark to black. Pupping probably peaked in December, a time different from that of the other two species (Kenyon, 1981). At the time of Columbus, the range of the seal included the shores and islands of the Caribbean Sea and Gulf of Mexico, eastward to the Bahamas and Florida Keys and westward to the Yucatan Peninsula and the Central American coast. The most primitive of all the seals, the three monk seal species probably evolved in areas remote from land predators and never learned to flee nor defend themselves from animals such as humans. In effect, they were "genetically tame" and could easily be clubbed to death by human exploiters (Kenyon, 1981). Like all monk seals, *M. tropicalis* would have been very sensitive to human disturbance, a fact that usually leads to poor reproduction and pup survival (Bonner, 1990). As humans spread through the Caribbean, these characteristics would ensure that the species declined quickly. It became so scarce by 1887 that it was referred to as an "almost mythical species" (Allen, 1887). Its persecution and demise continued, however, and sometime after 1900 the species went into its inexorable slide to extinction. Although it probably survived until the 1950s, represented mostly by old individuals past reproductive age, the species was doomed due to human slaughter and habitat destruction (Kenyon, 1977). Hoping that the species might somehow have survived in some remote area, extensive surveys were conducted of suitable monk seal habitat in both 1973 and 1984. Sadly, no evidence of the Caribbean monk seal was found, only signs of human habitation and use (LeBoeuf *et al.*, 1986). Although reports of sightings have surfaced into the last decade, the species is almost certainly extinct. As stated by biologist Karl Kenyon (1977): "My conclusion from the 1973 survey is that the Caribbean monk seal has been extinct since the early 1950s. The fact that I saw no monk seals was not as important as the fact of ubiquitous human presence ... Even if a few old Caribbean monk seals had survived to the 1970s, all available evidence leads me to believe that there is no hope that the species can recover. Man has now dominated its environment."

III. Japanese Sea Lion

The Japanese sea lion, formerly considered to be a subspecies of the California sea lion, has now been recognized as a separate species, *Zalophus japonicus* (Rice, 1998). Currently considered extinct by the IUCN, it is possible that a small number of Japanese sea lions may still exist in Korean waters, although the animals reported in Korea may actually be Steller sea lions, *Eumetopias jubatus* (Nishiwaki, 1973). The Japanese sea lion formerly inhabited the southern sea of Japan and coastal waters of Japan from Hokkaido to Kyushu. No individuals of this species have been seen in Japanese waters for over 50 years.

Little is known concerning the species, but it is felt to have been morphologically similar to its counterpart, the California sea lion (*Zalophus californianus*). The Japanese sea lion has probably disappeared due to direct hunting pressure and habitat destruction.

IV. Extinct Population

A. Atlantic Gray Whale

The gray whale (*Eschrichtius robustus*) is best known as a coastal dwelling cetacean that migrates along the western coast of North America from Alaska to Baja California. Almost exterminated by whalers, this population has rebounded as a result of being completely protected, except for aboriginal subsistence hunting (Reilly, 1984). Another population is found in the western North Pacific, where it migrates between the Okhotsk Sea and southern South Korea. This population has been reduced to very low numbers due to overexploitation and is currently highly endangered. A third population in the western North Atlantic appears to have existed until the seventeenth century and was probably rendered extinct by early whaling activity (Mead and Mitchell, 1984). Accounts from this period, although somewhat confusing, describe a whale known as the “scrag” whale, which bears a strong resemblance to the gray whale. Earlier Icelandic accounts describe a “sandloegja,” which is also felt to have been a gray whale (Fraser, 1970). Subfossil remains of gray whales have been found in eastern North America, and radioactive dating has shown the latest to have been from approximately 1675 AD (Mead and Mitchell, 1984). The population went extinct shortly thereafter. Subfossil remains of gray whales have also been found in Europe, but are apparently much older. Therefore, an eastern Atlantic population of gray whales probably also occurred in historical times, apparently going extinct sometime before 500 AD, quite possibly at the hands of early European whalers (van Deirse and Junge, 1937).

V. Prospects for the Future

Even though few species of marine mammals have gone extinct at the hands of humans, many have come very close. Elephant seals, fur seals, monk seals, walruses, and sea otters all have narrowly escaped extinction. Among cetaceans, the great rorquals, the gray whale, and the right whales were all nearly exterminated. Some have rebounded, some appear to be slowly increasing; others apparently are not increasing and may never recover. The history of sealing and whaling makes for depressing reading. Although these industries have mostly disappeared in today's world (with some notable exceptions), some species of marine mammals are still highly endangered. The Mediterranean monk seal is down to less than 1000 individuals and is being forced into tiny pockets of habitat by an explosion of tourism. The vaquita (*Phocoena sinus*), a small porpoise from the northern Gulf of California, exists as a small population under pressure from unintentional destruction from fisheries (Rojas-Bracho and Taylor, 1999). Many other species are also endangered, although they are not in as precarious a state as these. As much as may be desired, it will never again be possible to observe the “sea wolves” of Columbus lounging on the tropical beaches of the Caribbean or Steller's sea cow rising out of the northern mists.

False Killer Whale

Pseudorca crassidens

ROBIN W. BAIRD

I. Characteristics and Taxonomy

The false killer whale is one of the larger members of the family Delphinidae, with adult males reaching lengths of almost 6 m and females reaching up to 5 m. The common name comes from similarity not in external appearance to the killer whale (*Orcinus orca*) but rather in skull morphology of these two species. In fact, the two species do not appear to be closely related; based on genetic similarity, false killer whales appear to be most closely related to the Risso's dolphin (*Grampus griseus*), melon-headed whale (*Peponocephala electra*), pygmy killer whale (*Feresa attenuata*), and pilot whales (*Globicephala* spp.). There is evidence of geographic variation in skull morphology (Kitchener *et al.*, 1990), but no subspecies are currently recognized.

Largely black or dark gray in color (usually with a lighter blaze on the ventral surface between the flippers), it is easily recognizable with its rounded head, gracile shape (Fig. 1), small falcate

Figure 1 The highly acrobatic false killer whale (*Pseudorca crassidens*) leaping while chasing prey. The false killer whale does not resemble the killer whale (*Orcinus orca*) in external appearance, although the skulls of the two species are quite similar. Photograph © Robin W. Baird.

dorsal fin located at the midpoint of the back, and distinctive flippers (with a bulge on the leading edge). Scars from inter- and intra-specific interactions eventually are re-pigmented, unlike in the closely related Risso's dolphin. False killer whales are slightly sexually dimorphic, with the melon of males protruding farther forward than in females. Their teeth are large and conical, with 7–11 in each of the upper jaws and 8–12 in each lower jaw.

II. Distribution and Abundance

False killer whales are found in all tropical and warm temperate oceans of the world, and occasional records of their presence in cold temperate waters have also been documented. Although they are typically characterized as pelagic in habits, they do approach close to shore and utilize shallow waters around oceanic islands. These oceanic habits have hindered the study of this species in the wild, and most of what is known comes from stranded individuals, captive animals, and limited observations of groups around oceanic islands. In the Pacific there is evidence of limited gene flow, and the population around the main Hawaiian Islands is demographically isolated from the rest of the tropical Pacific (Chivers *et al.*, 2007). No estimates of worldwide population size are available, although false killer whales appear to be naturally uncommon throughout their range. Regional estimates for the Hawaiian Islands Exclusive Economic Zone suggest a small population size, in the low hundreds of individuals. No information on population trends is available.

III. Ecology

False killer whales are one of the handful of species that regularly mass strand, with the largest stranding recorded of 835 individuals. The diet appears to be diverse, in terms of both species and size of prey (Fig. 2). In general they feed on a variety of oceanic squid and fish but have also been documented feeding on smaller delphinids being released from tuna purse-seines in the eastern tropical Pacific. One case of predation on a humpback whale (*Megaptera novaeangliae*) calf has also been recorded, and they have been documented attacking sperm whales (*Physeter macrocephalus*). Nonaggressive

Figure 2 A false killer whale attacking a mahi-mahi (*Coryphaena hippurus*). Prey sharing in the wild and in captivity is frequently observed for this species. Photograph © Daniel J. McSweeney.

interspecific associations with bottlenose dolphins (*Tursiops truncatus*) and rough-toothed dolphins (*Steno bredanensis*) have also been reported. No predators of false killer whales have been reported, although large sharks and killer whales likely take some individuals.

IV. Behavior and Physiology

False killer whales are considered to be extremely social, usually traveling in groups of 20 to 100 individuals. Long-term (15 years) associations among individuals have been documented in Hawaiian waters, and analyses of associations of photo-identified individuals indicate strong bonds among individuals (Baird *et al.*, 2008). Such bonds are also evident from their propensity to strand *en masse*, and by the affiliative behavior of stranded animals. False killer whales are active during the day, and food sharing in the wild has been regularly recorded. Little is known about the diving behavior of this species; one tagged animal dove for up to 12 min and to depths of over 230 m.

V. Life History

Life history information comes entirely from stranded individuals. Because the deposition rate of growth layer groups in the teeth has not been calibrated, there is some uncertainty in life history parameters. Both sexes are thought to mature between about 8 and 14 years of age, although there is some suggestion that males may mature later. Maximum longevity has been estimated at 57 years for males and 62 years for females (Kasuya, 1986). Calving interval for one population has been reported as almost 7 years, and calving may occur year-round, with a peak in late winter.

VI. Interactions with Humans

A number of types of interactions between humans and false killer whales have been documented. In Hawaii they are regularly encountered by commercial whale- or dolphin-watching vessels and often bowride. They have been maintained in captivity in a number of aquaria around the world, including in Japan, the United States, the Netherlands, Hong Kong, and Australia. They have been successfully bred in captivity in several locations, and there they have produced viable interspecies hybrids with bottlenose dolphins. False killer whales are one of several species of odontocetes that occasionally steal fish from both commercial and recreational fishermen, with these types of interactions noted in Japan, Hawaii, the Indian Ocean, and the Gulf of Mexico.

Conflicts with fisheries have resulted in direct killing in Japan. Small numbers have been occasionally taken in fisheries, both directly and incidentally as bycatch. In Hawaiian waters the number killed or seriously injured incidentally in the longline fishery is greater than the population is thought to be able to sustain. They are one of a growing list of species that has been recorded ingesting discarded plastic, and high levels of toxins have been documented in tissues collected from stranded animals. It is unknown, however, whether such toxins contribute to immunosuppression in this species.

Feeding Morphology

CHRISTOPHER D. MARSHALL

I. Functional Morphology

Functional morphology is a diverse field of biology that integrates anatomy, biomechanics, and behavior. It is the study of structure, its relationship to function, and organismal adaptation. Marine mammals, and their adaptations to the aquatic environment, have interested functional morphologists for long time. Accordingly, our knowledge of the anatomy of marine mammals is extensive for many species, and new data continues to compile quickly. However, direct experimental investigations are largely lacking relative to terrestrial mammals. This has been due to the difficulty of working with large mammals in an aquatic environment, and the lack of technology that can be taken in the field. As a result morphology has been used extensively to predict function and behavior of marine mammals. However, experimental work regarding functional and behavioral

performance of marine mammals is beginning to flourish as electronics, and other technologies, become smaller, portable, and less expensive. When integrated, morphological inference and direct empirical measurements of function greatly enrich our knowledge of how marine mammals interact with their environment.

A basic necessity for survival of any organism is to feed and forage. The aquatic environment imparts strong selection pressures on feeding adaptations of marine mammals, as well as other life history attributes. Marine mammal adaptations for feeding are especially divergent relative to terrestrial mammals, and this will be the focus of this chapter. As in any comparative study, the phylogenetic history of the organism of interest is of paramount importance. This is particularly true for functional morphology and comparative biomechanics. The fact that “marine mammals” are a diverse collection of nonrelated mammals that have returned to the sea is not only an important consideration for functional studies but also it makes marine mammals an interesting study group regarding convergent evolution of form and function, and phylogenetic constraint.

II. Using Morphology to Predict Behavioral Performance

The skulls of modern cetaceans are among the most derived among mammals. In contrast to the dog (commonly used as a “typical” mammal and a morphological baseline), cetaceans have drastically remodeled the morphology of the rostrum, nares, cranium, ear bones (petrosal bones), and mandible (Fig. 1). The maxilla and premaxilla elongate the facial region but the cranium is shortened because of overlapping (telescoping) of cranial bones. This disparity of facial length vs cranial length is variable among cetaceans (e.g., the short blunt face of *Globicephala* and the long narrow rostra of platanistids). Odontocete jaws can be virtually edentulous (e.g., ziphiids) or filled with several hundred simple homodont teeth (e.g., platanistids). The condylar processes of odontocete mandibles (articulation of the mandible with the skull) are simple (Fig. 1) and allows for only a simple dorsal–ventral motion; most mammals can also move their jaws side-to-side (herbivores excel at this). In general, delphinid muscles of mastication (temporalis, masseter, and pterygoids) are relatively small. The pterygoid muscles are the dominant muscle group. Orcas (*Orcinus orca*) are exceptions to this generalization; these delphinids possess dominant temporalis muscles, perhaps related to the requirements of taking large prey. Compared to the dog, skull attachments for the temporalis and masseter muscles of most delphinids are also reduced (i.e., zygomatic arch, and coronoid and angular processes; Fig. 1). Such comparative anatomical insights are far from esoteric. Functional inferences from skull anatomy and biomechanical measurements, such as simple lever mechanics, can be used to predict feeding behavior, and indirectly trophic ecology.

LEVERAGE—Levers are simple devices that transmit forces from one place to another using a pivot. For example, a person might want to move a large rock that is too heavy to pick up. With the aid of a rigid beam and a smaller rock, one could build a simple Type I lever by placing the tip of the beam under the large rock and pivoting the beam on top of the small rock. The large rock can be moved by imposing force on the beam at the end opposite to the rock. This force is known as the in-force (F_{in}), the small rock is the fulcrum, and the force generated to move the load is the out-force (F_{out}). The distance between the fulcrum and the in-force is the in-lever arm (L_{in}) and the distance between the fulcrum and the load is the out-lever arm (L_{out}). The directions of F_{in} and F_{out} are the lines of action.

In the simplest case, which provides the greatest leverage, the lines of action of F_{in} and F_{out} are parallel to each other and at right angles to the lever arms. Mechanical advantage (MA) is the ratio of the in-lever arm to out-lever arm and also the ratio of the out-force to the in-force ($MA = L_{in}/L_{out} = F_{out}/F_{in}$). A lever system in which an F_{in} of 5N results in an F_{out} of 10N would have a mechanical advantage of 10/5 or 2. Greater mechanical advantage is attained with levers that have a long L_{in} and short L_{out} . Another component to levers is velocity (v). Each lever arm possesses a velocity (v_{in} and v_{out}), and the length of the lever arms influences the velocity such that $v_{in}L_{out} = v_{out}L_{in}$. This relationship is the reciprocal of the force–lever arm relationship ($F_{out}L_{out} = F_{in}L_{in}$). Therefore, there is a trade-off between mechanical advantage and velocity; powerful levers are slow and move only a short distance, whereas fast levers are not powerful, but move over longer distances. This latter type is characteristic of most biological levers.

Biological Levers—The musculoskeletal system of vertebrates is comprised of numerous levers, often in series, that are comprised of muscles, tendons, bones, and joints. Muscles are contractile elements that are attached to bones and cross bony joints by tendons; shortening of muscles produces movement at the joint. Biological levers tend to possess short in-lever arms and long in-lever arms, which impart rapid movement (high v_{out}) with large excursions of distance, but with reduced mechanical advantage. Other lever configurations include Type II and Type III levers. Both of these lever configurations are characterized by having the load and the in-force on the same side of the fulcrum. Type II levers place the load between the fulcrum and the in-force. Type III levers place the in-force between the fulcrum and the load. Mandibles are excellent examples of Type III levers. Lever mechanics of mandibles are useful for predicting feeding behavior. For example, consider the lever mechanics between a dog (*Canis familiaris*) and a bottlenose dolphin (*Tursiops truncatus*; Fig. 2). The temporal mandibular joint (TMJ) forms the fulcrum of the lever. The temporalis, masseter, and pterygoid muscles comprise the F_{in} and the functions to close the lower jaw. For simplicity, only the temporalis muscle will be used in this example. The temporal fossa, the recessed space in which the temporalis muscle resides and attaches, can be used to estimate the muscular line of action. The temporalis muscle originates in this temporal fossa, but crosses the TMJ to insert on the mandible. The in-lever arm is the distance from this muscle insertion on the mandible to the TMJ. The distance from this muscle insertion to the tip of the lower jaw is the out-lever arm. The F_{out} is the bite force produce during jaw closure. Notice that for both the dog and the bottlenose dolphin in Fig. 2, the line of action for the F_{in} is not perpendicular to the out-lever arm. Instead both are angled posteriorly, which has the affect of reducing the F_{in} by the \sin of the angle (θ) from the perpendicular. Note that this angle is much greater for the bottlenose dolphin than for the dog. Also notice that the temporalis fossa, which reflects the size and mass of the temporalis muscle, is smaller in the bottlenose dolphin than in the dog, which again reduces the magnitude of the F_{in} in the bottlenose dolphin. In addition, the proportion of the in-lever arm to the out-lever arm is smaller in the bottlenose dolphin than in the dog, resulting in a lower mechanical advantage. Even qualitatively, and holding body sizes equal, it is obvious that dogs should have a greater bite force than dolphins based on temporalis muscle mechanics alone. However, since force and velocity are inversely proportional, the bottlenose dolphin jaw would be much faster than the dog. Such an arrangement is advantageous to a piscivore, which requires a fast snapping jaw with only enough force

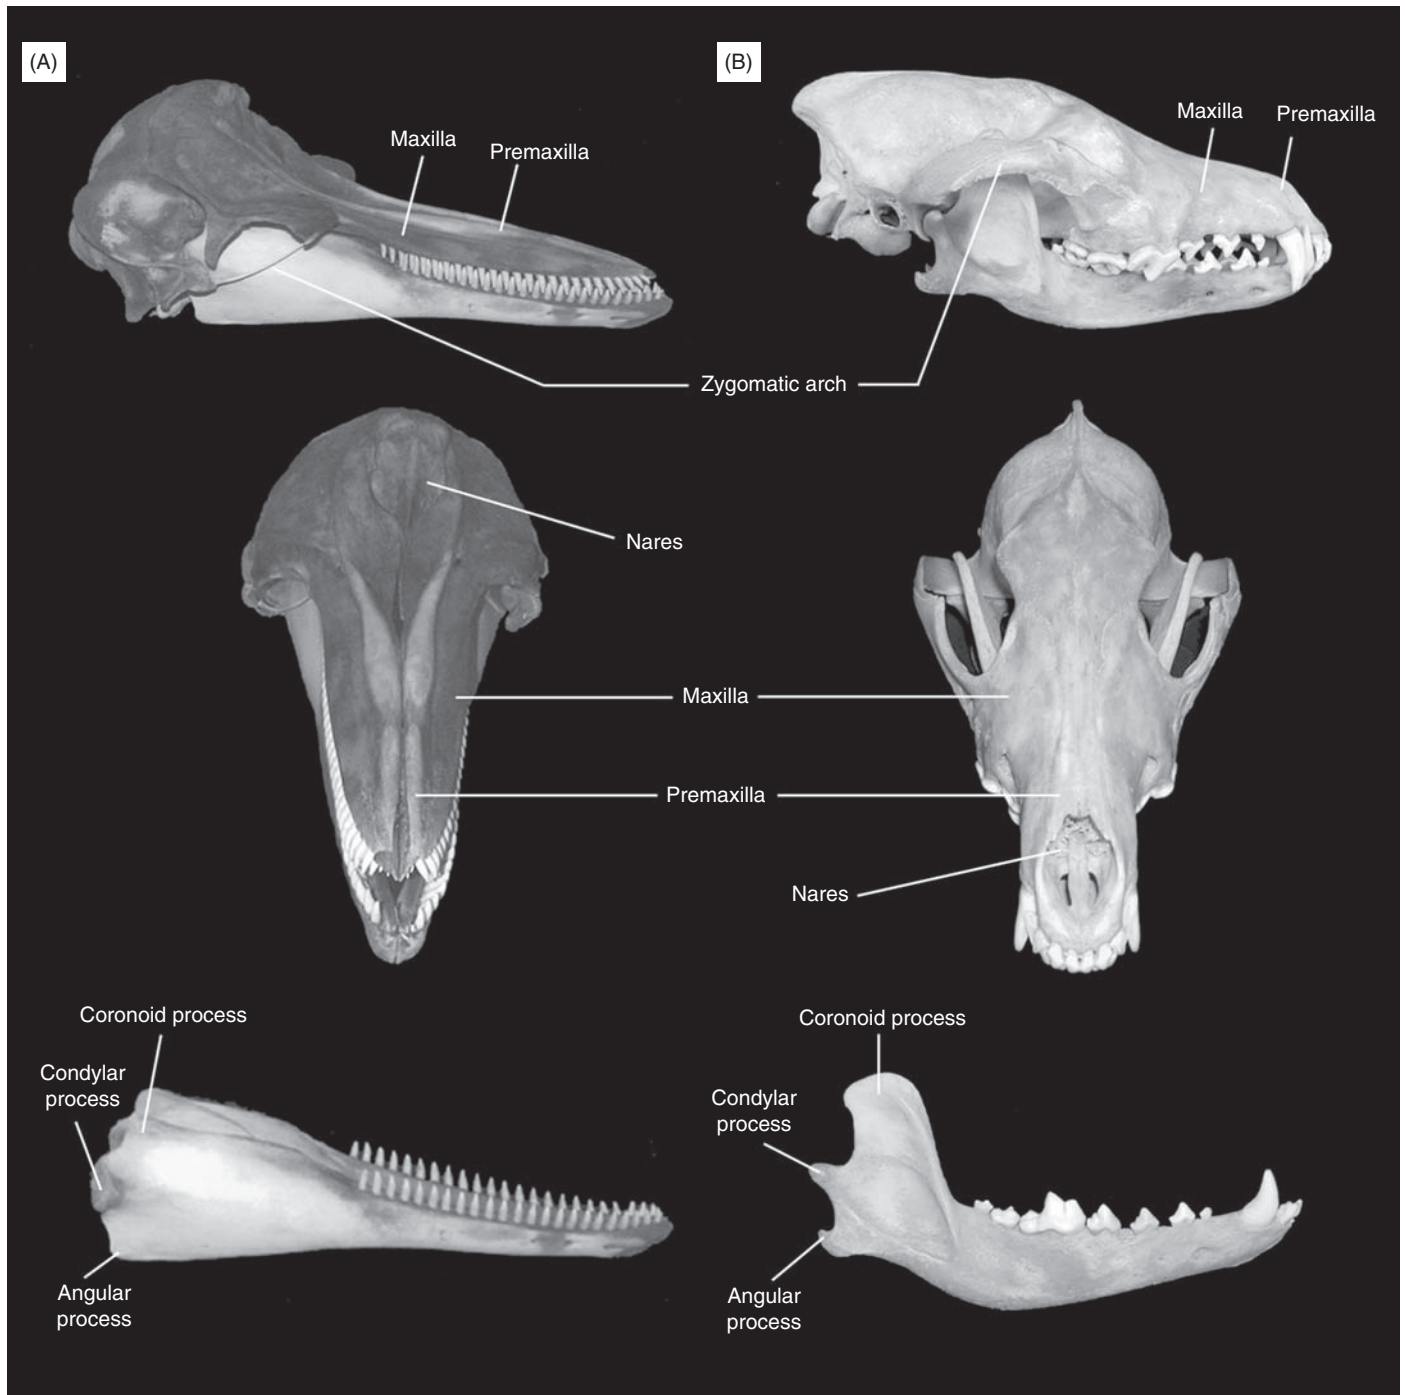

Figure 1 Comparison of the skull morphology of a typical odontocete, (A) a bottlenose dolphin with (B) a dog. Note the elongation of the premaxillary and maxillary bones, thin zygomatic arch, and simple mandible of the bottlenose dolphin relative to the dog.

to grasp and hold onto a fish before it is swallowed whole, without mastication. If muscles were available, a calculation of physiological cross-section of jaw muscles could provide a quantitative calculation of the F_{in} , and therefore bite force. These morphological predictions of behavioral performance of biting can provide meaningful insights in the capability of the feeding apparatus of organisms that are not available for direct studies. The diversity of feeding capabilities

among marine mammals can be appreciated by examining the diversity of marine mammal skulls (Fig. 3). These types of morphological inferences can become more powerful if validated by measuring behavioral performance in live animals. Understanding how morphology constrains behavioral performance can provide indirect inference into an organism's ecology, and its ability to exploit the resources of its environment.

Figure 2 Comparison of Type III jaw levers in (A) a dog and (B) a bottlenose dolphin. White lines indicate limits of lever arms (L), and squares indicate theoretical perpendicular lines of action. Arrows indicate forces (F).

III. Cetacean Functional Feeding Morphology

Cetaceans have developed some of the most specialized and varied feeding mechanisms among mammals. This should not be a surprise since cetaceans exhibit an amazing amount of ecological diversity and inhabit a diverse number of habitats ranging from the tropics to the polar regions. These feeding mechanisms can be generalized to four categories that are specific to the major cetacean groups. The feeding modes of odontocetes range from ram and raptorial feeding to suction feeding, while mysticetes are generally categorized as skimmers and engulfers.

Odontocetes—Although the oral apparatus of odontocetes is not as derived as that of mysticetes, they are still greatly modified compared to terrestrial mammals. One explanation for derived mandibles of odontocetes is that they exhibit dual roles in feeding and sound reception. However, even among odontocetes there is a wide range of morphological and functional diversity. This is reflected in the number of teeth found among odontocetes; some species may possess 200–300 homodont teeth (e.g., river dolphins) within long narrow jaws, whereas other odontocetes are characterized by drastic reduction in tooth number, tooth function, and possess blunt rostra.

The delphinid jaw has often been called a pincer jaw, which refers to a raptorial method of prey capture (Pabst *et al.*, 1999; Werth, 2000a). As demonstrated in the lever example, relatively low mechanical advantage is a modification for quickly grasping and capturing prey, which are then swallowed whole without mastication. River dolphins are exemplary examples of this feeding strategy and are convergent with gharials, specialized crocodilian piscivores. Although “odontocete” often invokes an image of a long snouted dolphin

with a mouthful of teeth, this does not reflect the diversity of the feeding apparatus among this group. In fact, the breadth of morphological diversity is found among the non-delphinid odontocetes. The use of suction to feed is likely common among this group, but has only been demonstrated for a few species. Suction feeding requires a mechanism that rapidly lowers the intraoral pressure relative to the surrounding water. A rapid increase in the volume of the oral cavity can create this pressure difference. Aquatic vertebrates that use suction typically have a suite of anatomical features such as a smooth flat palate, and a robust hyoid apparatus with large lingual and hyoid musculature (e.g., genioglossus, styloglossus, and hyoglossus) which are used to depress a piston-like tongue, or the floor of the mouth. Cetaceans presumed to use suction to feed possess many of these morphologies and may generate negative intraoral pressures in the same way as other aquatic vertebrates. Suction has been observed in live stranded beaked whale (*Mesoplodon carlhubbsi*) calves; investigative palpation suggested that the motion was originating in the region of the throat grooves. Manipulation of ziphiid cadavers demonstrated that the tongue could easily be retracted toward the hyoid apparatus by the extrinsic tongue muscles. Retraction of the tongue by manipulation of these muscles resulted in the distention of the throat grooves. Werth (2000b) provided the first quantitative kinematic investigation of odontocetes using pilot whales (*Globicephala melas*). This study not only validated the use of suction in this species but also demonstrated a four-phase feeding cycle that was divergent from the feeding cycle of terrestrial mammals. Furthermore, experimental work demonstrated varying suction capability in three odontocetes of differing head shape (common dolphin, *Delphinus delphis*; Atlantic white-sided dolphin, *Lagenorhynchus acutus*; and harbor porpoise, *Phocoena phocoena*) using cadavers to directly measure pressure change at three locations in the oral cavity during simulations of hyoid depression (Werth, 2006a). Pressure data was incorporated into a biomechanical model to predict suction capability. Although the largest negative pressures were found within the posterior mouth cavity in all three species, the greatest suction capability was found in harbor porpoises. Such experimental work provides support for a suite of traits associated with presumed suction feeders, which includes a short broad rostrum, reduction or loss of the teeth, adaptations that occlude lateral gape, and a primarily teuthophagous diet. A comparative investigation of feeding kinematics in captive pygmy and dwarf sperm whales (*Kogia breviceps*, and *K. sima*—kogiids), and bottlenose dolphins verified the presumption (based on morphology) that kogiids also use suction as their primary feeding mode and that bottlenose dolphins (in this study) are primarily ram feeders, as long suspected (Bloodworth and Marshall, 2005). A ram-suction index (RSI) calculated for each species verified these observations (*Kogia* = 0.67 ± 0.29 ; *Tursiops* = 0.94 ± 0.11). Overall the feeding cycle duration of kogiids was significantly shorter than bottlenose dolphins (470 ± 139 ms vs 863 ± 337 ms). *Kogia* mean maximum gape angle ($39.8 \pm 18.9^\circ$), and mean maximum opening and closing gape angle velocities (293 ± 261 -deg./sec and 223 ± 121 -deg./sec, respectively) were significantly greater than the mean bottlenose dolphin maximum gape angle ($24.8 \pm 6.6^\circ$) and mean maximum opening and closing gape angle velocities (84 ± 56 -deg./sec and 120 ± 54 -deg./sec, respectively). Negative RSI values in kogiids were correlated with increasing maximum gular depression and retraction, wide gape angle, and rapid opening gape angle velocity. The rapid jaw opening velocity in kogiids likely contributed to suction generation, in addition to hyoid depression. To understand the underlying mechanism of the observed feeding kinematics in kogiids and bottlenose dolphins, a morphological and biomechanical investigation

Figure 3 Diversity of skull morphology among marine mammals. (A) walrus, (B) harbor seal, (C) California sea lion, (D) sea otter, (E) polar bear, (F) gray whale, (G) West Indian manatee, and (H) dugong.

of the hyoid and tongue musculature of both kogiids and bottlenose dolphins was conducted (Bloodworth and Marshall, 2007). The hypothesis that suction feeders possess a more massive hyolingual apparatus that can generate increased maximum theoretical muscle tension contraction, which would presumably result in greater intraoral negative pressures, was tested. Surprisingly, no significant differences in hyolingual maximum theoretical muscle tension were demonstrated between kogiids and bottlenose dolphins. Instead, all evidence pointed to modifications of orofacial morphology, including

increased breadth of the mandible, tongue shape, and lateral gape occlusion, for increased suction feeding performance. A recent morphometric analysis of odontocete mandibles from all living species supports these conclusions; kogiids possess the bluntest mandibles of all odontocetes. (Werth, 2006a)

Mysticetes—All mysticetes possess baleen and feed upon plankton (Slijper, 1962). However the diet of some rorquals, or balaenopterids, is predominately fish and squid, while gray whales (*Eschrichtius robustus*) feed upon marine amphipods and fish in addition to plankton. The

jaws of mysticetes are edentulous; teeth have been replaced by baleen. Baleen are plates of keratinized epidermis (much like hair, nails, and horns) that are used to filter water. They have a straight outer edge, and a rounded inner edge, which is lined by a fringe of hair. The multiple overlapping plates result in the intertwining of the hairs into a woven mat, which separates plankton as water flows into the oral cavity. The differing morphologies of the baleen plates, and the maxilla that suspends the plates, reflect differing feeding mechanics employed by balaenids, balaenopterids, and gray whales.

In general, balaenids are skimmers and balaenopterids are engulfers (Pabst *et al.*, 1999; Werth, 2000a). The maxilla of all mysticetes arch higher above the mandible compared to odontocetes (Figs. 2 and 3). However, the maxilla of balaenids exhibits a markedly distinctive higher arch relative to balaenopterids, which functions to accommodate their taller, narrower, and greater number of baleen plates relative to balaenopterids. This increased number and height of baleen increase the effective surface area for straining plankton from water. Balaenids feed by swimming slowly at the surface with their mouths slightly agape. Water flows into the mouth, through the baleen plates where plankton are filtered, and out the corner of the mouth. Periodically the mouth is closed and plankton are removed from the baleen by the tongue, and ingested. A model of hydrodynamic flow through the oral cavity of bowhead whales (*Balaena mysticetus*) suggests that the unique morphological structures and actions of the oral apparatus, such as the subrostral gap, orolabial sulcus, curvature of baleen, mandibular rotation, and lingual mobility, permit the steady flow of water through the baleen and may improve the efficiency of filtration.

Instead of skimming, balaenopterids lunge and engulf large quantities of water, which is then strained through the shorter, wider, and fewer plates of baleen. This feeding strategy relies on the momentum of the body to operate. Despite their enormous size, rorquals are slender, streamlined, and faster than the relatively bulky and slow swimming balaenids. Although it is likely true for many vertebrates, mysticetes body shape is linked with feeding strategy due to related morphological specializations for hydrodynamic performance. Balaenopterids actively fluke and increase their speed, or lunge, just prior to opening their jaws. High-resolution digital electronic tags attached to free-ranging fin whales (*Balaenoptera physalus*), which included dual-axial accelerometers and hydrophones (to measure fluid flow noise), have verified and characterized this behavior in great detail (Goldbogen *et al.*, 2006). Balaenopterids allow the forward momentum and sudden increase of inertial drag to open the large jaws and cause the throat grooves to expand. Throat grooves in balaenopterids are pleats of blubber which undergo large-scale deformation to provide an expansive cavity (cavum ventrale), which enables these whales to engulf enormous quantities of water. The throat blubber of fin whales can expand to as much as four times its resting length circumferentially, and up to 1.5 times its resting length longitudinally. This extensibility is a direct result of the material properties of the grooved blubber (Orton and Brodie, 1987). The small and weak mandibular articulation with the skull is not capable of preventing the mandible from being detached from the head during the forceful engulfment event. The frontomandibular stay apparatus is a strong ligament extending from the supraorbital process of the frontal bone of the skull to the coronoid process of the mandible. This innovation allows the mouth to open to 90° while protecting the jaw joint from over-extension and damage. The stay apparatus also allows each side of the mandible to rotate ventrodorsally along its long axis (the dorsal surface rotates medially, the ventral surface rotates laterally). This is possible because of the loose articulation of

the mandible with the skull and the unfused and flexible mandibular symphysis. Mandibular rotation further increases the amount of water the whale is able to engulf and may assist in the expansion of the throat grooves. After the mouth is closed, water is forced through the baleen, separating prey items, which are ingested. This water movement is powered by the retraction of the elastic throat grooves, contraction of muscles deep to the grooved blubber, and the return of the tongue to its original position. This behavior is supported by more recent kinematic data of wild feeding rorquals.

The oral apparatus of gray whales possesses characteristics of both balaenids and rorquals (Nerini, 1984). Instead of filtering water, gray whales filter sediment for marine amphipods, creating troughs in the sea floor. Feeding is not completely understood but is thought to be accomplished with the animal swimming on its side, and either using its jaws to excavate long troughs on the sea floor, or using suction to introduce prey laden sediment into the oral cavity. The latter behavior appears more likely and is supported by observations of feeding in a captive gray whale calf. The baleen of gray whales is unusually thick and sturdy, and it is presumed that amphipods are strained through it in a manner similar to balaenids straining plankton from water. Baleen on the right side show considerable more wear than the left side suggesting that this is the preferred side of the mouth to feed. Digital acoustic tags, with 3D accelerometers, attached to gray whales feeding off the central British Columbia Coast demonstrated that feeding occurred on the right side 97.2% of the time and 98.5% of the time at an angle greater than 45° (Woodward and Winn, 2006). Gray whales also skim the surface water for plankton in the same manner as balaenids and are also capable of engulfing prey in a manner similar to balaenopterids. This diversity in feeding modes allows for dietary flexibility so that alternate food sources can be used when prey distribution changes.

IV. Sirenian Functional Feeding Morphology

Sirenians are unusual among marine mammals because of their herbivorous nature, which transcends all aspects of their natural history (Hartman, 1979; Reynolds and Odell, 1991; Reep and Bonde, 2006). The sirenian skull is also derived relative to other mammals. Like cetaceans, the facial region also dominates the skull. Whereas cetaceans have evolved a relatively enlarged maxilla, sirenians exhibit pronounced and expanded premaxillary bones (Fig. 3). This is particularly true of dugongs (*Dugong dugon*). The large anterior bones of both manatees and dugongs increase the surface area for the attachment of large facial muscles that form a muscular hydrostat integral for feeding; the large narial basin allows for greater movement of these facial muscles. Due to their herbivorous diet, sirenians do masticate. The temporalis muscle is well developed, but the masseter muscle is relatively simple (unlike terrestrial herbivores). The coronoid process of the mandible is expanded and modified. The head of the condylar process is small and flat, and the corresponding mandibular fossa is shallow allowing for a great mobility of the TMJ. The mandible is large and heavy; only cheek teeth are present (with the exception of tusks in male dugongs). Unusual skull characters include the massive pterygoid processes, which may provide a second jaw articulation (pterygoid-mandibular) that could allow the lower jaw to rotate and produce transverse (side-to-side) movements during mastication. Such an articulation would displace the fulcrum of the lower jaw from the condyles to the pterygoid processes—an unusual situation among mammals.

Deflection of the rostrum is correlated with sirenian feeding ecology. Dugongs are benthic foraging specialists that target the rhizomes of sea grasses. Their rostrum is accordingly strongly downturned (~70°),

which is advantageous for benthic feeding. Alternatively, Amazonian and West African manatees (*T. inunguis* and *T. senegalensis*) possess the least deflected rostra ($\sim 30^\circ$ and 26° respectively), and this also reflects their trophic ecology. For example, Amazonian manatees are restricted to the freshwater rivers, lakes, and floodplains of the Amazonian basin where they feed upon food high in the water column such as inundated vegetation of the *vârzea*, *igapó*, floating meadows, and emergent grasses (Gramineae; Best, 1981; Rosas, 1994). The diet of West African manatees is not well known, but the murky waters of their habitat do not support extensive submerged aquatic vegetation, and West African manatees most likely rely upon natant, emergent aquatic, and semi-aquatic vegetation (Best, 1981). West Indian manatees (*Trichechus manatus*) exhibit rostral deflections that are intermediate between those of dugongs and other manatees. They are generalist feeders and feed anywhere in the water column. They also feed on a greater diversity of freshwater, brackish, and marine plants.

All manatees possess an unusual form of tooth replacement (Domning and Hayek, 1984). Only cheek teeth, which number 6–8 at any one time, are present. Teeth erupt in the back of the mouth and move anteriorly as they wear. The bony septa between each tooth are reabsorbed in front of a tooth and re-deposited behind it. This allows the teeth to move through the bone of the mandible. Teeth wear as they progress forward. When the teeth reach the anterior-most portion of the tooth row and are completely worn, the roots are absorbed and the tooth is shed. A new tooth erupts in the posterior tooth row that continues the conveyor-like process. Manatees are apparently able to produce an unlimited number of cheek teeth. In contrast, dugongs possess simplified peg-like teeth that are open rooted. Enlarged horny pads on the upper and lower palate play an important role in mechanical reduction and processing of sea grasses rather than teeth (Marsh *et al.*, 1999; Lanyon and Sanson, 2006a, b).

All sirenians possess muscular snouts that are covered by modified vibrissae, or bristles. Vibrissae are specialized hairs that transmit tactile information from the environment to the central nervous system. Although, these bristles are homologous with mystacial and mental vibrissae of the dog, they are short, thick, and robust. The expanded lips of all sirenians move fields of bristles to manipulate vegetation, and introduce it into the mouth (Hartman, 1979; Marshall *et al.*, 2003). The use of vibrissae by sirenians to manipulate objects in their environment is a departure from the classical sensory function of mammalian vibrissae. For example, many other mammals use vibrissae to detect tactile cues. Pinnipeds employ whisking movements for more directed tactile exploration. The sniffing behavior and related vibrissal movement during exploration by rodents involve sweeping of the mystacial vibrissae forward and backward in conjunction with protraction and retraction of the rhinarium and head. The modification of manatee bristles to actively manipulate food and other objects appears to be unique to sirenians. Facial muscles of all mammals, including those that move vibrissae (whisking or manipulative behaviors), are innervated by Cranial Nerve VII, and the cell bodies of the axons of this nerve are located in the facial motor nucleus within the brainstem. The size and morphology of the facial motor nucleus among mammals can be used to infer functional importance of facial muscles and vibrissal use. The facial muscles in Florida manatees are innervated by a large and prominent facial motor nucleus, with clear subdivisions, particularly within the lateral subdivision that is known to innervate the rostral-most facial muscles (Marshall *et al.*, 2007). Such neuroanatomical data supports the important function role that the muscular-vibrissal complex serves in manatees and likely all sirenians. The use of neuroanatomical data is an important tool for predicting function from morphology.

V. Pinniped Functional Feeding Morphology

Pinnipeds (sea lions, seals, and walruses) represent a diverse group of marine mammals with varying life histories. Among marine mammals, their skulls are most similar to that of the dog (Figs. 1 and 3), with notable exceptions such as walruses (*Odobenus rosmarus*; Fig. 3). Pinnipeds are characterized by a large rounded cranium, short snout, large orbits, and narrow interorbital distance. In general, the skulls of otariids (sea lions) are less variable than those of phocids (seals), although some species show sexually dimorphic characteristics. The orbits in small phocids (and therefore the eyes) encompass a greater proportion of the skull than that in larger phocids. The nasal basin of elephant seals (*Mirounga angustirostris*) and hooded seal skulls (*Cystophora cristata*) are enlarged; as in sirenians it is presumed that this allows greater movement of their mobile proboscises. It is presumed that the use of suction feeding is more prevalent among pinnipeds (King, 1983). Pinnipeds that are presumed, or known, to employ suction feeding (e.g., walruses, bearded, crabeater, ringed, and harp seals) tend to have short, wide rostra with jaws that have scoop-like anterior ends, and a long mandibular symphysis, or a mandible in which the ventral borders are angled toward the oral cavity.

Relative to the dog, tooth number in pinnipeds is reduced, and the cheek teeth are relatively uniform in cusp number and shape—virtually homodont. These changes in the cheek teeth are likely adaptations related to eating fish. At least two species, the leopard seal (*Hydrurga leptonyx*) and crabeater seal (*Lobodon carcinophagus*), have specialized teeth. The leopard seal primarily feeds on large vertebrates, such as penguins and other seals. The distinctive cheek teeth possess three long shearing cusps (King, 1983). Crabeater seals actually feed on krill, not crabs. The cusps of their cheek teeth are complicated and modified to form a sieve. These seals swim into a krill patch with mouth open, sucking in water. When the mouth is closed, water is strained through the sieve, and the krill are consumed.

The skull of walruses differs significantly from other pinnipeds (Fig. 3), which is related to the presence of tusks (the dominant feature of the skull), and their specialized feeding behavior (Fay, 1982). The maxillary bones are enlarged to accommodate and anchor the tusks to the skull. The short, wide rostrum is advantageous for benthic feeding, and increases the surface area for their numerous and highly mobile whiskers used to detect infaunal prey. The posterior head is flat and broad, providing a large surface area for attachment of neck flexor muscles. The enlargement of the maxillary bones to anchor the tusks to the skull and large regions for attachment of neck muscles are important for hauling out behavior. Walruses commonly use their tusks to pull and lift their bodies from the water. Hence the derivation of their Latin name *Odobenus* (tooth walker); the tusks are not used for feeding. Walruses excel at suction feeding (Fay, 1982; Kastelein *et al.*, 1994). Powerful intraoral pressures are generated by the piston-like tongue and design of the oral cavity. Suction is used alternatively with hydraulic jetting (the forceful ejection of water from the mouth and the opposite behavior of suction) to excavate bivalve prey and then remove them from their shells. Recent direct observations of feeding walruses in Greenland demonstrate that some populations use their flippers to assist in excavation of prey.

Prey capture by pinnipeds has not been widely investigated (King, 1983; Reidman, 1999). However, kinematic investigations of bearded seal feeding demonstrated that these benthic foraging specialists employ an excavation behavior similar to walruses. Direct measurements of suction generation in bearded seals demonstrated that their suction capability is comparable to that of walruses. In general,

vibrissae appear to be important for prey capture and discrimination. Vibrissal tactile discrimination by harbor seals has been shown to be as sensitive as the hands of monkeys. The vibrissae in harbor seals form a hydrodynamic receptor system that is tuned to the frequency of water movement made by swimming fish (Dehnhardt, 1998; Dehnhardt *et al.*, 2001). It is presumed that peripheral nerves within the vibrissae that terminate on mechanoreceptors are involved; however, the mechanism is still unknown. Compared to terrestrial mammals the number of nerves innervating mystacial vibrissae of pinnipeds is much higher. The number of axons in ringed (*Pusa hispida*) and bearded seals (*Erignathus barbatus*) are around 1500 and around 1650, respectively (Hyvärinen, 1989; Marshall *et al.*, 2006), whereas most mammals possess approximately 200 axons per whisker.

VI. Sea Otter and Polar Bear Functional Feeding Morphology

The functional morphology of sea otters and polar bears has not received much attention. Sea otters forage on the bottom, in waters as deep as 40 m (Kenyon, 1969; VanBlaricom and Estes, 1988; Reidman and Estes, 1990). Their diet is varied but shellfish and urchins comprise a large portion. Otters use their forepaws to excavate clams, and to pry shellfish and urchins from the rocky substrate, sometimes using tools. Food is usually consumed at the surface, and behavioral observations suggest that otters do not use their teeth underwater, even when feeding on fish. Upon surfacing, fish are killed by a bite to the head. A rock or some other tool is usually carried in a flap of skin in the axilla region (under the arm) and is used to pound open shellfish. The spines of urchins are simply bitten off, and the test (shell) of the urchin is crushed with the cheek teeth. Their cheek teeth are broad, flat, and covered with thick enamel. The shearing cusps of the carnassial teeth have been lost; sea otters are adapted for crushing their food (Kenyon, 1969). Polar bears grasp their prey with their mouths and break the neck or skull of their prey with their large masticatory muscles and robust dentition. Their masticatory apparatus appears to resemble a robust version found in other bears.

Feeding Strategies and Tactics

MICHAEL R. HEITHAUS AND LAWRENCE M. DILL

I. Introduction

F Marine mammals are found in a wide range of habitats including the open ocean, coastal waters, rivers, lakes, and even on ice floes and land. They feed on a variety of prey species from aquatic plants to microscopic zooplankton to the largest marine mammals, and a diverse array of strategies and tactics is used to locate and capture these prey. Some marine mammals consume huge numbers of prey items at a time (batch feeding) while others attack and consume prey items singly (raptorial feeding). Many marine mammals forage in large groups while others feed alone. In this chapter, we will consider the wide range of marine mammal foraging behaviors and the circumstances and habitats that led to the adoption of particular feeding strategies and tactics.

Before embarking upon a review of marine mammal foraging, it is important to make a distinction between a strategy and a tactic, terms which have specific meanings in the field of Behavioral Ecology. To put simply, a strategy is a genetically based decision rule (or set of rules) that results in the use of particular tactics. Tactics are used to pursue a strategy and include behaviors (Gross, 1996). Tactics may be fixed or flexible, in the latter case they depend on the condition of the individual or characteristics of the prey or environment. For example, a humpback whale's (*Megaptera novaeangliae*) strategy may be to use that tactic which will maximize energy intake at any particular time. The whale may pursue this strategy by switching between the tactics used to capture fish and those used to catch krill, depending upon the relative abundance of these two prey types.

Our understanding of marine mammal foraging is hampered by the difficulty of studying these animals. They live in an environment where observations are difficult (often beneath the surface), our presence can disturb their foraging behavior, and feeding events often occur quickly and are easy to miss. Despite this, and thanks to many emerging technologies, much is known. We will begin our review by considering ways that marine mammals find and capture their prey, continue with a discussion of group foraging, then conclude with a discussion of the causes of variation in feeding strategies and tactics.

II. Finding Prey

The first step in foraging is locating prey. This may be done over many temporal and spatial scales and can involve migrations of thousands of kilometers or switching between habitats separated by only a few meters to forage in prey-rich locations. Then, once a marine mammal is in a prey-rich area it still must locate prey.

A. Habitat Use

One way that marine mammals can increase their chances of encountering prey is to spend time foraging in those habitats with high prey abundance. There is evidence that a variety of marine mammals

tend to aggregate in areas with high food concentrations. For example, the highest densities of polar bears (*Ursus maritimus*) are found along floe-edges and on moving ice, habitats that contain the highest density of seals; resident killer whales (*Orcinus orca*) are most abundant in Johnston Strait, British Columbia when salmon migrate through the strait. Also, the distribution of humpback whales in the Gulf of Maine appears to reflect the availability of fish prey, and humpback whale distribution in southeast Alaska may partially be determined by krill abundance. When there are a variety of habitats available to marine mammals in a restricted area (such as nearshore environments), a theoretical model predicts that, if the main concern of the animals is to maximize energy intake, they should be distributed proportional to the amount of food available in each habitat (Tregenza, 1995). Testing this hypothesis is difficult since marine mammal prey availability is often hard to quantify. However, the distribution of bottlenose dolphins (*Tursiops* spp.) in Shark Bay, Western Australia, conforms to this hypothesis and matches that of their fish prey in winter months at scales of 100s of meters to kilometers. Similarly, Hawaiian spinner dolphins (*Stenella longirostris*) appear to match the availability of their vertically migrating prey at scales of 20 m to kilometers. Humpback and minke (*Balaenoptera acutostrata*) whales do not appear to conform to this hypothesis. Instead, they appear to show a threshold response to prey availability, only using a habitat once prey density has reached a particular level, but above this threshold there is a tight relationship between zooplankton abundance and whale abundance. Of course, prey availability is not the only factor that might influence habitat use of marine mammals, and this will be considered in detail later.

Many marine mammals forage over great distances, and they may have limited knowledge of the distribution of prey patches, especially in pelagic habitats. In these situations, marine mammals, including pinnipeds and cetaceans, may adopt movement tactics that should maximize the probability of encountering prey. Displacement rates are relatively high, and movements relatively linear, in areas of low prey abundance, but animals exhibit low displacement rates and high turning rates ("area restricted searches") when they encounter rich patches.

B. Migration

When suitable habitats for a marine mammal are widely spaced, movements between them are considered migrations. There is thus a continuum between habitat use decisions and migrations. Some migrations appear to be driven primarily by variation in food availability. Unlike baleen whales, sperm whales (*Physeter macrocephalus*) cannot fast for long periods of time, and female groups use migrations up to 1100 km as part of a strategy for surviving in a variable habitat with low local food abundance and poor foraging success. In fact, this tactic may be the reason that female sperm whales are found in permanent social groups as they may benefit from the experience of old females during migrations.

Migration frequently involves trade-offs between feeding and another factor, like reproduction. Baleen whales and some pinnipeds feed only for a relatively short period of time in high productivity high latitude waters, then fast during the rest of the year while moving to, and spending time at, low latitude breeding grounds. For example, northern elephant seals (*Mirounga angustirostris*) forage along the entire North Pacific, then migrate to a few beaches on the California coast to breed and molt. Also, some humpback whales in the Pacific Ocean reproduce in warm, low productivity, Hawaiian waters, then move to the more productive waters of the north Pacific to feed during the summer months. However, some humpback whales remain in the southeast Alaska feeding grounds yearround, and individuals that

do not consume enough prey during the feeding season may forego migration to continue feeding.

C. Searching and Diving

The way in which an animal moves through its environment can influence its encounter rate with prey, and many animals exhibit stereotyped search patterns. Marine mammals that forage on concentrated prey may continually patrol through areas where they expect to encounter concentrations. For example, leopard seals (*Hydrurga leptonyx*) will patrol along ice edges where departing and returning penguins congregate and killer whales patrol nearshore areas in search of seals. When groups of marine mammals forage, they often spread out into widely spaced subgroups and/or move forward in a line abreast formation (e.g., dusky dolphins [*Lagenorhynchus obscurus*], pilot whales [*Globicephala* spp.], Risso's dolphins [*Grampus griseus*], bottlenose dolphins, killer whales). Spreading out in such fronts may either reduce foraging competition among individuals or increase the probability that prey is detected so the subgroups can converge to feed.

Once a marine mammal has selected a habitat for foraging, it must execute a strategy that will optimize its net energy intake rate, often with respect to trade-offs and constraints. For a diving animal this means that it must balance the energetic costs of diving with the energetic gains of foraging. The costs of diving vary greatly among marine mammals. Polar bears, sea otters (*Enhydra lutris*), and most pinnipeds are divers—they spend most of their time above water or have long surface intervals between food gathering dives. In contrast, most cetaceans and sirenians can best be thought of as surfacers—they spend the majority of their time submerged, and make trips to the surface only to breathe (see Boyd, 1997).

Theoretical studies of optimal diving suggest that as the depth at which prey are located increases, both dive times and surface times should increase (Kramer, 1988), and the type of dive a marine mammal executes will depend on the depth and the distribution of prey. Some predictions of optimal diving theory are supported by several studies of marine mammals, and both dive times and surface times increase with dive depth in pinnipeds, cetaceans, and sirenians. Because a diving individual should behave in a manner that optimizes its net energy intake, marine mammals may exceed aerobic limits when the energetic pay-off is sufficient. In addition to energetic considerations, predation risk may influence the diving behavior of marine mammals, and therefore result in deviations from optimal diving predictions, based on energetic currencies alone (Frid *et al.*, 2006).

There is a great deal of variation in the depths to which marine mammals dive. Some, like sea otters, nearshore odontocetes, and otariids, tend to be shallow divers. Others, including sperm whales, elephant seals (*Mirounga* spp.), and beaked whales are extremely deep-divers, sometimes foraging over 1000 m from the surface. Some species minimize the depths to which they must dive, and thus the costs, by modifying their diel pattern of foraging. For example, some dolphins and pinnipeds are nocturnal foragers on prey whose daily movements bring them closer to the surface at night (e.g., spinner dolphins, northern fur seals [*Callorhinus ursinus*], Antarctic fur seal [*Arctocephalus gazella*]). The diving tactics of beluga whales (*Delphinapterus leucas*) may be influenced by competition with pinnipeds, which are superior divers. The belugas generally forage over the deepest waters and, because of their body size, are able to gain access to benthic areas that the smaller pinnipeds cannot. Although the time spent at the bottom decreases with increasing depth, belugas compensate by increasing their ascent and descent rates as dive depth increases, a result also found in narwhals (*Monodon monoceros*).

D. Prey Detection

Marine mammals have many ways to detect their prey including vision, various types of mechanoreception, echolocation, and hearing. Most marine mammals appear to rely on vision to at least some extent. The large, forward pointing eyes of pinnipeds suggest that vision is an important method for detecting prey. Even species that dive to extreme depths, like the elephant seal, are capable of using vision to find prey in dark waters at their foraging depth. Vision may be less important in other taxa. For example, river dolphins (*Platanista gangetica*) of the Indian subcontinent have eyes that are greatly reduced and may be mostly blind. Sea otters can use their forepaws to find food and discriminate prey items without the aid of vision, and many pinnipeds are found in turbid waters, making vision a poor method of prey detection. However, they are able to use their vibrissae (whiskers) to detect prey through active touch or through minute water movements caused by their prey.

Odontocete cetaceans have a method of prey detection not available to other marine mammals—echolocation. In controlled situations, odontocetes can detect relatively small objects at a considerable distance. For example, a bottlenose dolphin can detect a 7.62-cm diameter sphere from over 100 m. However, it is still unclear how efficient echolocation is under natural conditions. It is likely to be less efficient than suggested by laboratory and controlled experiments (as has been shown for bats), and may vary greatly depending on environmental conditions such as noise.

Echolocation is not always an effective way to detect prey. While most fish cannot hear echolocation calls, clupeid fish and other marine mammals can. Therefore, odontocetes foraging on prey that can detect their echolocation may have to use tactics other than echolocation for detecting prey. This difference in the ability of potential prey to detect echolocation is reflected in the foraging behavior of fish-eating (“resident”) and mammal-eating (“transient”) killer whales off British Columbia. While resident whales commonly use echolocation during foraging, transients do not. Also, when transients echolocate; their pulses are of low intensity and are irregular in timing, frequency, and structure; a pattern that may be difficult for prey to detect. Instead of echolocation, mammal-eating killer whales appear to use passive listening to detect their prey. Other marine mammals probably use passive listening opportunistically, especially bottlenose dolphins that feed on a variety of noisy fish species. Elephant seals and other pinnipeds also have good hearing abilities in water and may use passive listening to find prey.

III. Capturing and Consuming Prey

A diverse array of tactics is used by marine mammals to capture and consume their prey once they have located it (Fig. 1). The most widespread tactic of raptorial predators is to simply chase down individual prey items that they have encountered. However, there are many other, more unique tactics employed by marine mammals.

A. Stalking and Ambushing

Marine mammals often hunt prey that are non-sessile, fast-moving, and have good sensory abilities and, thus, could avoid predators if their approach were too obvious. For example, seals can avoid polar bears by diving back through the ice, and penguins can avoid leopard seals by hauling out, as can pinnipeds approached by killer whales near land. When hunting elusive prey, a predator must rely on either stalking or ambushing. A stalking predator attempts to conceal its identity or presence until it approaches its prey close enough

Figure 1 Whales employ a diverse array of foraging tactics. Art by Pieter A. Folkens/Higher Porpoise DG.

for a sudden, successful attack. In contrast, an ambush predator conceals itself and lies in wait, leaving the approach to the prey.

Polar bears use both stalking and ambush methods when hunting seals hauled out on the ice near breathing holes. In terrestrial stalking, bears creep forward and use ice for cover to closely approach their intended prey. Bears also stalk seals by swimming circuitously through interconnected channels or even under the ice, occasionally surfacing through holes to breathe and monitor their prey. However, an ambushing tactic, where a bear lies, sits, or stands next to a breathing hole waiting for a seal to surface, is the most energy-efficient and most commonly used foraging tactic.

Leopard seals also use both stalking and ambush tactics when foraging. Stalking leopard seals may swim under the ice below a penguin, then break through to capture the bird, or they may swim submerged near a fur seal beach and lunge at pups when they get close enough. Alternatively, leopard seals may ambush their prey by hiding between ice flows near a penguin landing beach. Sea otters will stalk birds by swimming underwater and grabbing them from below, a tactic similar to that used by Steller sea lions (*Eumetopias jubatus*) hunting northern fur seal pups and leopard seals stalking Adelie penguins (*Pygoscelis adeliae*).

Another behavior that could be considered stalking is wave riding and intentional beaching used to capture young pinnipeds and

penguins near the water's edge. This tactic is commonly used by killer whales and occasionally by Steller sea lions and leopard seals. This may be a particularly dangerous foraging tactic, especially for young killer whales that may not be able to return to the water if they strand too high on the beach.

Some stalking predators make detours that involve moving away from the prey and potentially losing visual contact temporarily before making another approach. Polar bears will make detours from their prey while stalking aquatically, and dolphin subgroups may detour away from a school of fish to attack it from opposing sides. Weddell seals (*Leptonychotes weddellii*) have also been observed making detours when stalking cod under fast ice. These detours allow the seal to remain out of the fish's view and to attack from very close range below the fish.

B. Prey Herding and Manipulation

To capture them more efficiently, marine mammals may actively manipulate the behavior of their prey. In other words, marine mammals take advantage of normal prey behaviors to enhance their ability to capture them. These manipulations may help a marine mammal flush prey from hiding, capture an individual prey item, or increase the density of prey aggregations so as to increase the forager's

energetic intake rate. Prey herding is a common tactic used by dolphins, porpoises, whales, and pinnipeds and may be considered prey manipulation when they take advantage of natural schooling and flight behavior of their prey. Dolphin and porpoise groups and individuals have been observed herding prey against shorelines or other barriers, reducing the number of escape routes. Dolphins use shorelines for more than herding fish. Bottlenose dolphins inhabiting salt marshes sometimes form small groups that rush at fish trapped against a mudbank. The wave created by the rapid swim causes fish to strand on the mudbank, and the dolphins slide up the bank and pick fish off the mud before sliding back into the water. A similar behavior is performed by both individuals and groups of humpback dolphins (*Sousa* spp.) foraging around sandbanks off Mozambique.

Marine mammals also herd fish in open waters. When schools are at the surface, dolphins may split into groups to attack from different directions, herding the fish into a ball between subgroups. Other times, fish may be herded up from deeper waters, and trapped between circling individuals and the surface. During a herding event, individuals swim around the fish school, and below it, preventing its escape. Fish herding in open waters has been reported in many dolphin species, porpoises, and sea lions. Sea lions are also found feeding on schools of fish that are herded to the surface by dusky dolphins, but it is unclear if the sea lions aid in fish herding. The tactic of herding fish is found in a variety of marine predators. Although there are no reports of prey herding for many species of pelagic dolphins, it is probably a wide-spread tactic employed by marine mammals feeding on schooling fish.

During a prey-herding event, many different tactics may be used to cause the fish to move into a tight ball and to capture fish in these balls. Splashing at the surface causes fish schools to compact. Dusky dolphins perform leaps at the edge of fish schools that they are herding, and spotted dolphins (*Stenella* spp.) have been observed tail-slapping and splashing at the edge of a fish school when it started to break apart or move in a different direction, but the function of these behaviors is still unclear. Killer whales in Norway and humpback whales in the northwest Atlantic also use tail-slaps when they near schools of prey. Tail-flicks by humpbacks may also be used to concentrate schooling euphausiid prey in southeast Alaska, though this may simply be a hydro-mechanical effect.

Another tactic that marine mammals can use to herd prey is flashing light-pigmented areas of their body toward a fish school. Killer whales herding herring swim under the school and flash their white undersides to keep the school from diving, and a similar behavior has been noted in spotted dolphins. Humpback whales in southeast Alaska may also use flashes to help concentrate prey by rotating their elongated pectoral flippers while they herd herring, thereby showing the highly visible white undersides.

Fish show strong avoidance responses to bubbles and are reluctant to cross barriers composed of them. Not surprisingly, marine mammals take advantage of this response. The use of bubbles during foraging has been observed in many odontocetes, mysticetes, and pinnipeds. Spotted dolphins use bubbles to isolate individual fish, pulling them away from the school with the water disturbance created by the passing bubble, so they can be consumed, and Weddell seals blow bubbles into ice crevices where fish are hiding to flush them out. Killer whales also use bubbles to flush prey, and blow large bubbles toward rays buried in the sediment, causing them to move. However, bubbles are primarily used to concentrate and contain schools of fish. For example, killer whales blow large bubbles near the surface to keep fish in a tight ball. Humpback whales are the best-known bubble users and bubble feeding may be conducted by individual whales

or in large groups. Whales deploy bubbles in a variety of formations including columns, curtains, nets, and clouds, with the tactic used dependent on the characteristics of the prey aggregations.

Sound and pressure waves may also be used to manipulate prey behavior. For example, bubble-netting humpback whales in southeast Alaska produce loud “feeding calls” as they rise to the surface, presumably herding prey up into bubble nets which are meters above the herding schools. Similarly, Icelandic killer whales may use low-frequency calls to herd herring schools into tighter groups. Bottlenose dolphins off Australia and Florida use tail-slaps known as “kerplunks” while foraging in shallow seagrass habitats. The kerplunk displaces a significant amount of water, creates a plume of bubbles, and causes a low-frequency sound. Kerplunks may cause startle responses in fish and help the dolphin locate and flush their prey, while the bubbles may provide a barrier to contain the fish. Humpback whales in the western Atlantic may flush burrowing fish (sand lance) from the bottom by scraping the substrate with their head, then feed on the fish once they have entered the water column.

C. Prey Debilitation

Marine mammals sometimes debilitate their prey before they consume it. Killer whales attacking mysticetes often swim onto their backs when the prey tries to surface, and in some cases the victim may drown instead of dying from its wounds. While killer whales are herding herring, individuals thrash their tail through the school, stunning fish with the physical impact of their flukes; they then feed on the stunned and injured fish. The whales probably use this tactic because it is energetically more efficient than whole body attacks. Bottlenose dolphins strike fish with their tails (“fish whacking”) when foraging alone or in groups, sometimes knocking the fish through the air. Also, there is evidence that walrus (*Odobenus rosmarus*) may use their tusks to kill or stun intended seal prey. Recent studies suggest that the hypothesis that odontocetes use sound to debilitate prey cannot be supported at this time.

D. Tool Use

“Tool use is the external employment of an unattached environmental object to alter more efficiently the form, position or condition of another object, another organism, or the user itself when the user holds or carries the tool during or just prior to use and is responsible for the proper and effective orientation of the tool” (Beck, 1980). Tool use by marine mammals is reviewed in detail elsewhere in this volume, but more marine mammals use tools during foraging than is generally appreciated, so this behavior deserves brief mention here.

Sea otters are the best-known marine mammal tool users and will pick up rocks from the bottom and place them on their chest to use as an anvil for crushing mussels, crabs, or urchins, or use them to smash or dislodge abalone (*Haliotis* spp.) off rocks. In some cases, the rocks are retained between foraging dives to be reused. Certain bottlenose dolphins carry sponges on their rostra, apparently as a tool to aid foraging (Fig. 2). Also, there are popular accounts of polar bears throwing blocks of ice at basking seals to injure or trap them, and polar bears in captivity are often observed throwing large objects, raising the possibility of tool use in the wild. Another behavior that might be considered tool use involves killer whales creating waves to wash hauled out seals into the water. Finally, the use of bubbles to concentrate schooling fish or aid in flushing fish from hiding or a school (discussed earlier) fits Beck's definition of tool use.

E. Benthic Foraging

While most marine mammals pursue their prey in the water column, several species forage on benthic organisms. There are three basic methods that marine mammals use to obtain prey from the bottom: collecting, extracting, and engulfing. Epibenthic prey is simply collected by foraging marine mammals. Sea otters collect echinoderms (mostly sea urchins), crabs, and other benthic organisms with their forepaws.

Infaunal prey items must be extracted from the substrate and require the predator to excavate in some manner. Sea otters use their forepaws to dig for clams in soft-sediment areas and may produce large pits over the course of several dives, occasionally surfacing with a clam. Harbor seals (*Phoca vitulina*) dig for prey in sandy habitats with their foreflippers or snouts while narwhals and belugas use water jets to dislodge mollusks buried in the sea floor. Walrus use a combination of tactics to obtain buried bivalves including digging with their snouts (not tusks) and hydraulic jetting. Walrus make multiple excavations on each dive and have been recorded consuming at least 34 clams on a single dive. Killer whales, in New Zealand, engage in benthic foraging on rays and have been observed pinning them to the bottom and may also be digging for them. Bottlenose dolphins in the Bahamas also dig for infaunal prey (“crater feeding”), and once a burrowing fish has been located, the dolphin will dive into the soft sand and use its flukes to drive deeper, almost up to the flippers, to catch the fish.

If many small infaunal prey items are consumed in a single feeding event, they may be engulfed while still in the sediment. Gray whales (*Eschrichtius robustus*) feeding near the bottom use suction to pull sediment and prey into their mouths, then filter the sediment and water out through their baleen.

F. Batch Feeding

Batch feeding is a tactic employed to consume a large number of prey items in a single feeding event. While mysticetes are obligate batch feeders, some pinnipeds facultatively use this tactic. There are two basic types of batch feeding: skimming and engulfing. Skimmers, most notably the right whales (*Eubalaena* spp.) and bowhead whale (*Balaena mysticetus*), swim through concentrations of zooplankton, either at the surface or in the water column, with their mouths open, filtering water through their fine baleen plates which traps prey.

Engulfers include the rorqual whales and several pinnipeds. These species engulf large amounts of water and prey, then filter the water back through their baleen plates or teeth. Rorquals have a suite of adaptations, including expandable gular pleats and a lower

jaw that can disarticulate from the upper jaw, that allow them to engulf huge volumes of water, and fish or crustacean prey, in each feeding attempt. “Lunge feeding” is one of the most common tactics of rorqual whales feeding near the surface and may take several forms. During a typical lunge, a whale surfaces with its mouth open to capture prey near the surface. Lunge feeding may be done singly or in groups, and in combination with many of the prey concentration tactics.

All Antarctic seals (crabeater [*Lobodon carcinophaga*], Weddell, Ross [*Ommatophoca rossii*], leopard seals) include zooplankton in their diet, as do some Arctic seals (ringed [*Pusa hispida*], ribbon [*Histiophoca fasciata*], harp [*Pagophilus groenlandicus*], largha [*Phoca largha*], and harbor seals). Of these, the crabeater seal is the most specialized batch feeder and zooplankton may comprise up to 94% of its diet. The cheek teeth of crabeater and some other seals are modified for straining krill, which are probably sucked into the mouth when the seal depresses its tongue, then trapped against the cheek teeth as the water is expelled.

G. Ectoparasitism, Kleptoparasitism, and Scavenging

Predators kill their prey in the course of consuming it (Ricklefs, 1990). While most marine mammal foraging is predatory, there are several ways that animals may forage which do not involve killing their own prey. For example, an animal may gouge mouthfuls of flesh from a “host” without killing it (sometimes referred to as ectoparasitism). Although marine mammals fall victim to such ectoparasites (small sharks), there are no concrete examples of marine mammals using this tactic. However, killer whales may effectively ectoparasitize large whales as some attacks do not kill the victim. Kleptoparasitism (food stealing) has been observed only in otters and polar bears but may occur in other species. For example, pilot whales were observed harassing sperm whales until they regurgitated and the pilot whales consumed the regurgitated food. Scavenging is a common foraging tactic, but it does not appear to be widespread among marine mammals. However, it may be an important tactic for polar bears and some pinnipeds. Also, several odontocete species that feed on trawler discards or longline catches could be considered facultative scavengers.

H. Herbivory

Sirenians (manatees [*Trichechus* spp.] and dugongs [*Dugong dugon*]) are the only marine mammals that routinely feed on plants, and both manatees and dugongs may be found foraging individually or in large groups. Manatee feeding appears to be more flexible than that of dugongs as the former will consume either floating or rooted vegetation and sometimes leaves from overhanging branches or vegetation along banks. Dugongs feed almost exclusively on seagrasses but may also intentionally consume benthic invertebrates. While manatees tend to crop vegetation, dugongs often dig up rhizomes and leave large feeding trails through seagrass beds, which can have a large impact on seagrass biomass, both above and in the sediment (Fig. 3), and even on invertebrate communities of the seagrass.

I. Prey Preparation and Consumption

While some marine mammal prey can be consumed immediately after capture, others require extensive handling before they are eaten, and some are only partially consumed. Sea otters remove the heads of birds that they capture and strip the muscle from the breast,

Figure 3 *Dugongs* (*Dugong dugon*) preferentially forage on below-ground portions of many seagrass species, creating a cloud of sediment during foraging activity. Photograph by Michael R. Heithaus.

neck, and legs. Many dolphins and sea lions remove the heads from large fish before consuming them, and bottlenose dolphins will strip flesh from spiny fish. Head and spine removal may reduce the probability that a predator is injured while consuming prey, but it may also be a mechanism to reduce the intake of bony material that provides no nutritional value. Dolphins do not always consume their prey correctly, and sharp spines have been implicated in deaths of bottlenose dolphins stranded in Texas and Florida.

Odontocetes cannot chew prey and must spend considerable time handling large prey items. For example, bottlenose dolphins will drag large fish along sandy bottoms until pieces that are small enough to swallow are broken off. Killer whales are well known for their extensive handling of prey, especially pinnipeds, after capture. Killer whales often breach upon sea lion and seal prey as well as slap them with their tails. The function of these behaviors is unclear, but they may tenderize the prey, aid in training calves in hunting techniques, or even debilitate dangerous prey. Selective feeding on energy-rich portions of prey is common in both killer whales and polar bears. Killer whales will selectively eat the blubber and tongue of whales that they kill and polar bears prefer the blubber and muscle of seals and narwhals over the internal organs. Finally, harbor seals will regurgitate after feeding on sandlance to remove sand from their stomachs. The regurgitated fish are re-swallowed before they sink to the bottom.

IV. Group Foraging

Many foraging tactics are executed by groups of marine mammals. Sometimes these groups are merely aggregations of animals attracted to the same resource, and there appears to be little interaction among individuals as they pursue prey individually. Other group foraging behaviors, like herding of prey, appear to be highly coordinated efforts and may involve animals cooperating with each other to increase their net energy intake rate. It is not always easy to determine whether group foraging marine mammals are cooperative or not. For example, the echolocation rate of an individual resident killer whale decreases as group size increases, suggesting that there may be information transfer. While this could represent cooperative information sharing, it is also possible that individual whales are parasitizing the information of others, as shown in bats. In many cases it is difficult to assess whether marine mammals are foraging cooperatively because group-living may be selected for by factors other than food, and group-foraging, whether cooperative or non-cooperative, is therefore simply a necessary epiphenomenon. One important consideration in studies of cooperation is whether groups are kin based as individuals in kin groups are more likely to engage in cooperative behavior to increase their inclusive fitness.

A. Cooperative Foraging, Food Sharing, and Cultivation

Cooperation can be defined as “an outcome that—despite individual costs—is “good” in some appropriate sense for the members of the group ... and whose achievement requires collective action” (Mesterson-Gibbons and Dugatkin, 1992). Most cooperation is achieved through a mechanism of by-product mutualism, in which an individual acts selfishly to benefit itself, and its actions incidentally benefit other individuals, but not all by-product mutualisms are cooperative. A possible example of by-product mutualism involves bowhead whales skim-feeding in groups with whales staggered in an inverse “V” formation. This formation may aid a whale in prey capture by using adjacent whales as a wall to trap prey or to catch prey that have escaped from the whale in front. These groups sometimes appear to be coordinated, with whales changing direction and leadership. All individuals probably act selfishly, but their presence may benefit other whales.

The above definition of cooperation requires three things be shown to support the hypothesis that a group is cooperative. First, individuals acting cooperatively must realize a short-term cost. This cost may include having to share food with other individuals or an opportunity cost by not attacking prey immediately while herding. Next, energy intake rate of individuals benefiting from cooperation must be higher than what they would have gained without cooperation. Finally, collective action must be required for the hunt to be successful. It is worth noting that in cooperative groups not all group members are required to receive equal benefits, and in groups that appear to be cooperative, a number of individuals may be non-cooperative (Packer and Rutten, 1988).

There are many possible examples of cooperative foraging in the marine mammal literature involving mysticetes, odontocetes, pinnipeds, and sirenians. However, most anecdotal accounts of possible cooperative foraging behavior do not provide enough detail to determine whether these groups were truly cooperative. For example, many dolphin species are known to break into subgroups that spread out across a large front when foraging or to travel in line abreast formation. Generally, when one subgroup finds fish, other subgroups join to feed. This behavior has often been considered

cooperative foraging. However, none of the three criteria for cooperation outlined previously have been shown to apply to these cases. Furthermore, although some authors have assumed that joining subgroups were recruited, they may simply be converging once they determine that another group located food. Fish herdings by dolphins, porpoises, whales, and sea lions have all been cited as examples of cooperative foraging. In these cases, there does appear to be a cost involved as individuals do not start foraging immediately but wait until the school has been herded to the surface (“temporary restraint”). Larger groups of dusky dolphins forage on a single fish school for longer periods of time than do small groups. Some authors have suggested that this indicates an increase in individual intake and that herding requires collective action. However, it is important to measure individual intake rates because longer foraging durations of large groups may simply be the result of larger schools being herded (and increased time until school depletion) or of increased foraging interference in large groups. More studies are required to support the hypothesis that such groups are cooperative.

Deliberate prey sharing provides strong evidence for cooperative hunting but must be viewed with caution as some apparent food sharing may represent intense competition for large prey items or kleptoparasitism (Packer and Ruttan, 1988). Prey-sharing has been observed in few marine mammal species but has been documented in both mammal-eating and fish-eating killer whale populations. Also, an apparent case of prey-sharing has been documented in leopard seals when two seals killed penguins, but one individual released its penguin to be consumed by the other. Prey sharing also has been documented in false killer whales (*Pseudorca crassidens*).

There are a few other examples of marine mammal foraging which appear to represent cooperative foraging. Leopard seals have been observed hunting in a coordinated fashion, with one seal driving penguins toward a second seal hiding behind an ice flow. The process was repeated several times, and both seals caught penguins each time, sharing prey in one instance. Collective action is required if killer whales are to capture large or swift prey and, in general, larger groups are seen when transient killer whales attack such prey.

There may even be a division of labor during their hunts. Also, there is a cost as prey are divided among group members. Bubble-netting humpback whales feeding on herring in southeast Alaska represent another potential example of cooperative foraging. In these groups, one whale deploys a bubble net, starting at a depth shallower than the herring schools. The whales then apparently drive the prey up into the bubble net and simultaneously lunge through the herring trapped against the surface (Fig. 4). Although there are apparently costs to this behavior and coordination is probably required, no data exists on intake rates in these groups. Finally, it is possible that large groups of synchronously diving crabeater seals cooperatively herd krill, but future studies are needed to verify this possibility.

One study has suggested that dugongs cultivate seagrass as they forage in large groups moving among seagrass banks. Although dugong grazing changes seagrass communities to stands of more profitable species, for deliberate cultivation to occur, cooperation among dugongs would be required. In general, true cultivation (gardening) is favored to evolve only when the individual that cultivates an area realizes the benefits of that action (Branch *et al.*, 1992). This implies both a fixed and a defendable feeding site (Branch *et al.*, 1992). Cooperative cultivation by dugongs is unlikely since individual dugongs that moved to a previously cultivated area, before the cultivating individuals, would benefit from reduced foraging competition. Also, there do not appear to be any mechanisms to prevent such cheating. A more likely explanation for the observed pattern of dugong foraging is “traplining” where dugong groups rotate among the most profitable seagrass meadows, and the changes in seagrass communities are an incidental by-product of dugong foraging on rhizomes.

B. Optimal Group Size

The question of why particular group sizes are observed has been raised several times. For some species, group size has been suggested to be that which maximizes the intake rate of individuals in the group (optimal group size). However, this may not generally be the case. When it is difficult for a group to exclude joiners (e.g., when foraging

Figure 4 Humpback whales (*Megaptera novaeangliae*) in southeast Alaska cooperate to catch herring. They use a variety of tactics to manipulate the behaviour of herring, including the use of bubbles as tools. Photograph by Michael R. Heithaus.

on a large fish school), the observed group size will often be greater than that which maximizes intake of each group member, since individuals will continue to join a foraging group until the average energy intake in the group approaches that of a solitary forager (stable group size; Giraldeau, 1988). Also, the benefits of defending resources may be low in large groups since individuals that do not defend the resource will realize higher intake rates than those individuals that try to defend against joining individuals. Finally, group size is likely to be larger than that which is optimal for foraging considerations if there are other benefits of being in a group (e.g., mating opportunities, protection from predators). Therefore, it is likely that most dolphins feeding on large schools of fish are in groups larger than those that would maximize energy intake of each group member. However, some marine mammals may be found in groups that are of optimal size for maximizing energy intake. For example, killer whales feeding on marine mammals may be able to regulate group size as individual prey items are easily defended, and groups (which are kin based) may be able to exclude other individuals before foraging commences. This may explain why the modal group size of three individuals observed in foraging transient killer whales is the group size that maximizes its members' energy intake.

V. Variation in Feeding Strategies and Tactics

Marine mammals show a high degree of variability and flexibility in their foraging tactics. Individuals may be flexible in their foraging tactics depending on their state or circumstances, and this flexibility may lead to variation in foraging tactics among populations, individuals, and age/sex classes. Variation in feeding tactics may also arise from differences in the ways individuals solve cost-benefit trade-offs. Some of these differences among individuals may be genetically based and thus considered strategic variation.

A. Trade-offs

Evolution favors strategies that maximize fitness (usually by maximizing lifetime reproductive success). For example, animals may pursue a strategy that maximizes their expected lifetime energy intake, which may involve a trade-off between maximizing short-term energy intake and minimizing predation risk because habitats that are prey rich are often the most dangerous (Lima and Dill, 1990, Fig. 5). Therefore, marine mammals may sometimes accept lower energetic returns to forage in safe habitats (see Wirsing *et al.*, 2008). For example, bottlenose dolphins in Shark Bay, Western Australia, match the distribution of their prey when their primary predator, the tiger shark (*Galeocerdo cuvier*), is absent but shift to forage mostly in low-risk, low-food areas when sharks are abundant. Dugongs in Shark Bay also reduce their use of food-rich but dangerous shallow habitats as tiger shark abundance increases. In addition, dugongs primarily excavate seagrass rhizomes when tiger sharks are scarce but switch almost exclusively to cropping seagrass leaves, which allows greater vigilance, when sharks are abundant. Finally, female polar bears with cubs often select habitats with lower food abundance to avoid potentially infanticidal adult males, and trade-offs between predation risk to calves and food availability at high latitudes may have led to the evolution of seasonal migrations in baleen whales.

Trade-offs between feeding and predation may also result in habitat use patterns that vary with behavior. For example, spinner dolphins rest in shallow nearshore coves with sandy bottoms during the day, possibly to reduce the probability of shark attack, then

move offshore to feed on deep scattering layer organisms at night. Similarly, bottlenose dolphins in Shark Bay rest almost exclusively in safer, relatively deep waters, but will sometimes move into higher risk but more productive shallow habitats to feed.

Trade-offs between feeding and reproduction also may influence foraging patterns. For example, most phocid females fast during lactation and must consume sufficient food before the breeding season while female otariids make foraging trips of variable duration throughout lactation (see Wells *et al.*, 1999 for a review).

Prey selection can be viewed as the result of another type of trade-off. Each potential prey item differs in the energy required to capture it and the amount of energy the predator will gain from eating it. This trade-off sometimes results in selective foraging where one prey type is favored over others irrespective of its relative abundance. For example, harp seals always preferentially feed on capelin (*Mallotus villosus*) and select Arctic cod (*Arctogadus glacialis*) only in nearshore waters. Prey preferences have also been shown in resident killer whales. Off Alaska, resident killer whales prefer coho salmon (*Oncorhynchus kisutch*), while those off British Columbia prefer chinook salmon (*O. tshawytscha*) that are energy rich but relatively scarce. Prey-selection may also take the form of capturing a particular size of prey. For example, harbor seals in Scotland feed primarily on the most abundant fish species but prefer fish of 10–16 cm in length. Changes in the relative costs and benefits of particular prey items may lead to prey switching, which has been observed in some marine mammals.

B. Ontogenetic Variation

There are often distinct differences in the foraging behaviors of marine mammals of different ages. Such differences may be the result of changing physiological or foraging abilities, the relative importance of energy intake and survival at different life history stages, or differences in experience if a learning period is required for the successful use of a particular foraging tactic. Diving by young seals and sea lions is constrained by physiological development, and they typically make shorter and shallower dives than do adults (e.g., Steller and Australian [*Neophoca cinerea*] sea lions, Weddell and elephant seals). During their first trip to sea, elephant seal pups make a transition from short, shallow dives to a pattern similar to adult seals, with longer deeper

Figure 5 Foraging decisions made by individuals can be influenced by the presence of predators. Some individuals may forage in areas where they are more likely to be attacked by predators if the energy gain in these habitats is sufficient. Photograph by Michael R. Heithaus.

dives that show diel fluctuations. This transition appears to be related to both changes in the physiology of young seals and possibly prey distribution. Young seals of different sizes may adopt different diving tactics. For example, larger yearling Weddell seals engage in relatively shallower dives to forage on benthic prey compared to small yearlings which make deeper dives to forage on energy rich prey. However, the cause of this variation is unclear.

Learning and cultural transmission of foraging tactics play important roles in the acquisition of foraging tactics in cetaceans. For example, there is a long period of practice required for young killer whales to become adept at using the intentional stranding tactic to capture pinnipeds. This period of learning may involve calves preferentially associating with the female pod-members (not necessarily their mother) that engage in this tactic most frequently. Similarly, it appears that sponge-carrying by bottlenose dolphins is socially passed within matriline, especially to female offspring. Finally, sea otters tend to display the diet preferences of their mothers.

C. Inter-Individual Variation

Within many marine mammal populations substantial differences exist among individuals in the foraging tactics that they employ. Northern fur seal females perform two distinct types of foraging dives: shallow dives, which seem to be directed towards vertically migrating prey, and deep dives to feed near the bottom. Shallow dives are made only between dusk and dawn while deep dives occur both at night and during daylight hours. Some individual seals specialize in one dive type or the other while other individuals use a mix of tactics. Southern sea lion (*Otaria flavescens*) individuals differ in their propensity to hunt fur seal pups. In Alaska, only juvenile male Steller sea lions prey upon fur seal pups while in Peru, most hunting is done by just a few adult males, and there are large differences in the success rates of different individuals. Similarly, sea otter predation on birds appears to be largely restricted to a few individuals, and a few individual sea lions have learned to wait at fish ladders and at the mouths of freshwater streams to take advantage of spawning steelhead. Leopard seals also vary in their hunting tactics. For example, a single individual was responsible for all ambushing attacks on Adelie penguins observed in Prydz Bay, Antarctica. In gray seals (*Halichoerus grypus*), there are distinct differences between sexes in diet and foraging behavior (Beck *et al.*, 2007). Finally, individual variation in the prey species consumed by sea otters may be a result of differences in diving tactics as juvenile males forage further offshore and make longer dives than other age/sex classes.

Cetaceans also show individual variation in feeding tactics. In Shark Bay, many unique tactics including kerplunking, sponge-carrying, and extreme shallow water foraging are restricted to a small number of individual bottlenose dolphins. Adult female killer whales perform most of the intentional strandings to catch elephant seals, and within a pod individual females differ in their use of this tactic. Most individual minke whales around the San Juan Islands specialize in either lunge feeding or feeding in association with birds. These two tactics are usually observed in different regions with individual whales showing inter- and intra-seasonal site fidelity. Individual humpback whales differ in their use of various types of lunge-feeding and bubble-netting tactics that may relate to dietary specializations on either krill or herring (*Clupea* spp.) and to the distribution of these prey items. Finally, reproductive state may influence the foraging tactics of cetaceans as lactating female bottlenose, common (*Delphinus* spp.), and pantropical spotted dolphins (*S. attenuata*) consume different prey items than do other dolphins.

D. Intra-Individual Variation

Individual marine mammals can switch among foraging locations and tactics depending on their age, body condition, group size, and prey distribution and abundance. For example, pinnipeds can change their diving behavior in response to increased foraging costs as seals make shallower dives and dive at a steeper angle to maximize their time at a foraging depth. Individuals that encounter different habitats often switch among tactics depending on their location. For example, humpback whales may switch between foraging in large bubble-netting groups and engaging in individual lunges to capture krill. Sperm whale foraging behavior is linked to foraging success, and foraging is more common when prey availability is high or the energetic cost of capturing prey is relatively low. Also, sea otters change the number of prey items they collect on each foraging dive depending on the average prey size available. Offshore of Sable Island, Nova Scotia, harbor seals switch between pursuit and benthic foraging tactics depending on prey type, and Baikal seals (*Pusa sibirica*) shift their foraging tactics between day and night. They use visual cues to feed on pelagic fishes during the day but move to shallow waters, likely to feed on crustaceans using tactile cues, at night.

The flexibility of marine mammals is highlighted by their ability to take advantage of human activities. Many odontocetes, pinnipeds, and sea otters have learned to steal fish from nets. Seal lions will even jump into encircling nets to feed or will follow fishing vessels for days to take advantage of the abundant food resources offered by fishing operations. Bottlenose dolphins are well known for foraging behind trawlers and feeding on discarded fish or fish in nets. Some individual bottlenose dolphins also have learned to take advantage of direct handouts of fish offered by people, and many species of odontocetes remove either bait or fish from fishing lines. In the Bering Sea and off Southern Brazil, killer whales may damage over 20% of the fish captured by longline fisheries.

Both the diversity of habitats in which marine mammals live and the flexibility of individuals has led to the wide variety of foraging tactics exhibited by the group. However, further studies of these tactics are still of great interest, especially systematic investigations of the function and use of particular tactics and the circumstances in which they are employed. For example, current studies are beginning to use a multivariate approach to teasing apart the roles of cultural transmission, genetics, and environmental factors on inter-individual variation in the use of foraging tactics within a population. Such detailed studies will improve the ability to predict influences of anthropogenic changes to marine habitats and prey availability on marine mammals and aid in efforts to conserve them.

mesovarium, which attaches to the dorsal side of the broad ligament. Dugong (*Dugong dugon*) ovaries are also attached to the diaphragm by peritoneal folds that form pouches in the dorsal abdominal wall.

The ovaries are surrounded by the ovarian bursa, a fold of mesosalpinx which forms a peritoneal capsule. There is considerable variation in development and in the extent to which the bursa communicates with the celomic cavity. The ovarian bursa of odontocetes develops *in utero* whereas in mysticetes it develops after birth. In polar bears (*Ursus maritimus*) and other carnivores, the periovarian space between the ovary and peritoneal lining of the bursa communicates with the peritoneal cavity by a narrow passage which may become distended at estrus with fluid of unknown origins. In all marine mammals, and mammals in general, the function of the bursa is to ensure that the ova pass into the oviduct where fertilization occurs.

Marine mammal ovaries vary in size and shape. Quiescent dugong ovaries are small, flattened ovoids or spheres. Ovaries in the Amazonian manatee (*Trichechus inunguis*) are broad and flattened against a short mesovarium. Sea otters (*Enhydra lutris*) have lenticulate, compressed oval ovaries. The odontocete ovary is more or less spherical to ovoid in shape, with a smooth surface in the resting condition whereas in mysticetes ovaries are flat and elongated. Phocid ovaries are ovoid and smooth in the resting state. In some species of phocids, (e.g., gray seals, *Halichoerus grypus*), fetal hypertrophy of the ovaries exists through hormonal influence of the pregnant female. This condition may be less pronounced in otariids.

Typically, eggs ripen and ovulate alternately between the ovaries in successive reproductive cycles and the ovaries are of similar size. However, in some odontocetes there is a prevalence of activity in the left ovary (e.g., 70% in pilot whales, *Globicephala*) and the left ovary is larger than the right (Slijper, 1966). The right ovary may become active later in life.

The mammalian ovary is covered by germinal epithelium (Fig. 1) below which lies connective tissue (*tunica albuginea*) of varying thickness. Germinal epithelium is often invaginated into the *tunica albuginea*, forming small folds, pits, or subsurface crypts. These invaginations are particularly well developed in pinnipeds and form surface fissures in sea otter ovaries. Below the *tunica albuginea* is a layer of follicles and *corpora* that are derived from them. The ovary also contains stromal and connective tissue, interstitial tissue, vascular, nervous and lymphatic tissues, and embryological remnants. The interstitial cells of cetaceans are less numerous and less prominent than those in some other mammalian orders, such as rodents. Understanding the maturation process of the follicles, and development and subsequent regression of the luteal bodies for each species allows researchers to assess the reproductive status of females (immature, ovulating, etc.).

Follicular maturation (Fig. 1) proceeds through a series of changes characterized by two phases. In the first phase, there is a rapid increase in the size of the oocyte and a slow increase in the size of the follicle. Second, there is slow growth of the oocyte and a rapid increase in the size of the follicle which can be seen macroscopically. In dugongs, mature follicles may be just visible as translucent bodies or they may protrude from the ovarian surface. In West Indian manatees (*Trichechus manatus*) the mature follicles appear as large masses of bead-like spherules in the ovary. Similarly, mysticete ovaries may appear grape-like with protruding follicles. Maturing follicles of odontocetes and pinnipeds tend to be more widely dispersed in the ovary.

Oocytes develop within the ovary during fetal development but are dormant until puberty is reached. After puberty, and partly in

Female Reproductive Systems

R.E.A. STEWART AND B.E. STEWART

I. Introduction

The female reproductive system in marine mammals is composed of the basic mammalian reproductive organs: ovary, oviduct, uterus, cervix, vagina, clitoris, and vaginal vestibule. Under the control of endocrine system, these organs are engaged in the reproductive cycle of ovulation, fertilization, implantation, fetal growth, and parturition. Ancillary to reproduction are the mammary glands and lactation. Some variation in anatomy, morphology, and physiology of the reproductive organs, and in reproductive cycles, exists among orders of marine mammals. Species-specific differences within orders also exist, reflecting both phylogeny and the variety of environments inhabited by marine mammals. Variation also exists in how marine mammals use their basic mammalian anatomy in different marine habitats. This is discussed in other articles such as those on reproductive strategies, life history, lactation, and behavior. Here the gross anatomical and morphological characteristics of female reproductive systems are described and the functional adaptations are noted.

II. Anatomy and Morphology

The ovary is the organ where eggs or ova mature and are released during ovulation. Usually, there are two functional ovaries suspended from the abdominal or pelvic cavity by a short mesentery, the

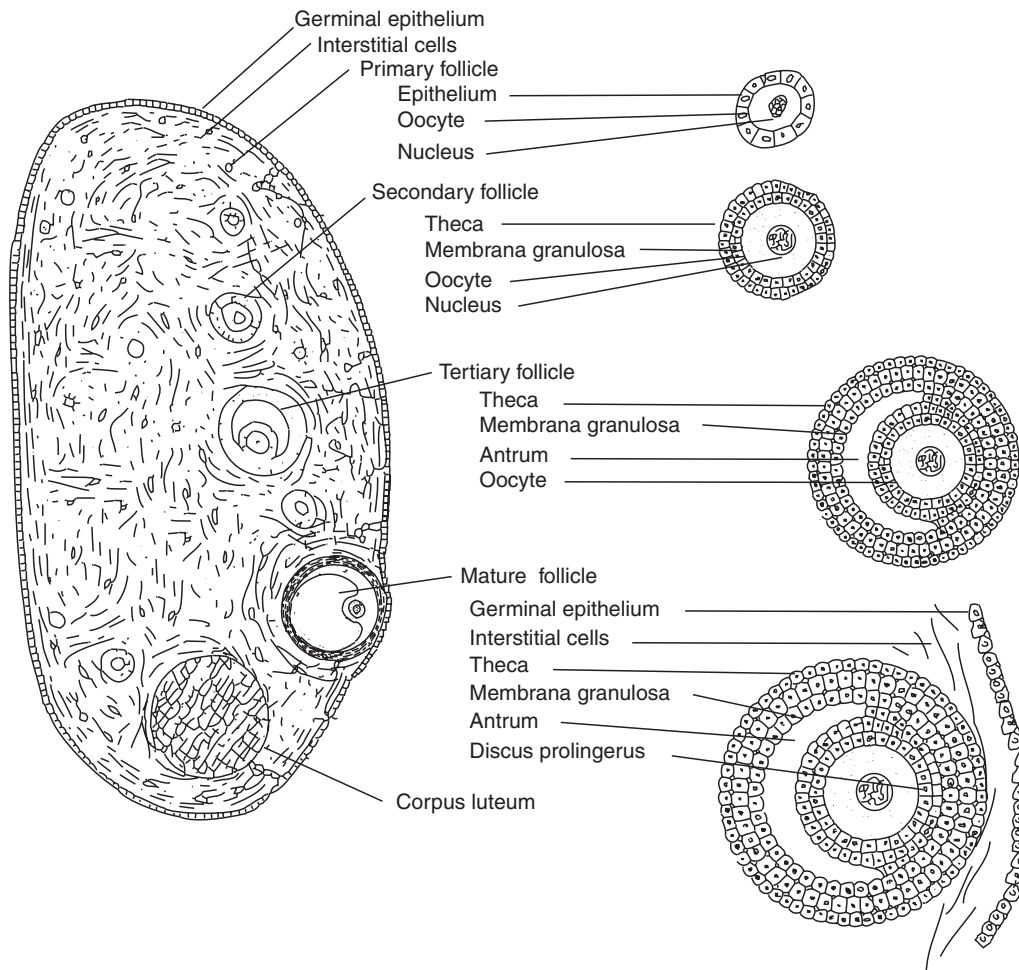

Figure 1 The main structures of a marine mammal ovary showing stages of follicular development. Modified from Penny and Waern (1965).

concert with the annual reproductive cycle, they become primary follicles (Fig. 1) with a single layer of flattened epithelial cells surrounding each oocyte. These follicles lack connective tissue or thecal investment. As primary follicles increase in size they sink deeper into the cortex of the ovary toward the medulla or central area.

Secondary follicles are formed as the single layer of flattened epithelial cells around the oocyte thickens and becomes cuboidal or columnar, forming a distinct *membrana granulosa* (granular membrane or layer). This granulosa layer quickly becomes several layers thick while being encapsulated in an outer sheath or *theca* derived from the *stroma*. The *theca* divides into two layers. The inner layer, the *theca interna*, is glandular and well vascularized while the outer layer, the *theca externa*, is composed of connective tissue. The oocyte is now surrounded by a membrane, the *zona pellucida*, which is jelly-like, contains large amounts of polysaccharides, and lies between the plasma membrane of the oocyte and the granulosa cells.

Tertiary follicles rapidly increase in size because of an increased number of granulosa and thecal cells. Then, one or more cavities form in the granulosa and as the cavities enlarge they coalesce into an antrum which fills with follicular fluid (*liquor folliculi*). The fluid-filled follicle is now surrounded by a wall except at the point of attachment of the oocyte.

Mature or Graafian follicles (Fig. 1) contain an oocyte which is surrounded by an irregular cluster of granulosa cells. These granulosa cells eventually form the *corona radiata* which in turn is attached to cells forming the *discus prolingerus* or *cumulus oophorus*. There is mortality among developing follicles such that only a fraction of those primary follicles that start to develop will ever mature.

Under endocrine control, the mature follicle releases the ovum (ovulation). After ovulation, the *corpus luteum* (yellow body) develops from cellular components of the follicle. Luteinization is the process of transformation of follicular granulosa cells into luteal cells which contain carotenoid luteins (yellow pigments). There is a significant increase in cell size during luteinization. This volumetric growth is in contrast with the accretional growth of thecal cells in tertiary follicles. The *corpus luteum* (CL) is considered to be a gland and several types exist, the nomenclature being based on the morphology or function of the CL. For example, a CL of pregnancy develops when ovulation is followed by fertilization; accessory *corpora lutea* (plural) develop by luteinization of unruptured follicles (common in cetaceans) (Perrin *et al.*, 1984).

If fertilization of the ovum occurs, the CL of pregnancy persists through gestation. There are several phases of development in

this *corpus luteum gravidatilis*: a short post-ovulatory phase when the CL is small, poorly vascularized, and minor changes occur in the luteal cells; a phase during delayed implantation when the CL is smaller than its initial size, vascularization is still poor, and the luteal cells show marked cytoplasmic vacuolation; a short phase related to implantation when vacuoles disappear, the CL enlarges with resumed glandular activity, and vascularization increases; a phase post-implantation and during early pregnancy characterized by minor cell adjustments such as fluid accumulation, more obvious intercellular spaces, appearance of small vacuoles, increase of connective tissue, and thickened walls of blood vessels; the phase of the duration of pregnancy when the *corpus luteum* size is maintained; and the post-parturient phase as a *corpus albicans* (CA). In cetaceans, accessory CLs may also form in the ovary of pregnancy.

In beluga, the *corpora lutea gravidatilis* were about 3–4 cm in diameter and weighed approximately 22 g. CL diameters in blue whales (*Balaenoptera musculus*) average approximately 14 cm; in minke whales (*B. acutorostrata*) they averaged about 7 cm and 160 g. In some odontocetes, such as bottlenosed dolphins (*Tursiops truncatus*), the CL *gravidatilis* may protrude far out from the general outline of the ovary and is connected by a stalk (pedunculated).

The process of degeneration of the *corpus luteum* into the *corpus albicans* is similar regardless of the type of *corpus luteum* (CL of ovulation, pregnancy, pseudopregnancy, or lactation) that is regressing. There are four patterns of degeneration: fibrohyalin invasion, lipid degeneration, slow necrobiosis, and fast necrobiosis. Regardless of the regression pattern, glandular elements are lost, lutein granules vanish, and the size of the body diminishes until the white or gray scar-like *corpus albicans* (CA) is formed.

In most mammals, *corpora albicantia* are assimilated either relatively quickly post-partum or after one or two reproductive cycles, as in the sea otter. In marine mammals that cycle every 2 or 3 years, such as the walrus (*Odobenus rosmarus*), the CA may persist for some time. In cetaceans, *corpora albicantia* are thought to persist throughout a female's lifetime (Perrin *et al.*, 1984), a consequence of the large amount of connective tissue present and its poor vascularization, leading to a slow rate of regression. Some attempts have been made to characterize various types of cetacean *corpora albicantia*, but a definitive way to distinguish those bodies derived from ovulation from those of pregnancy has not been established.

An ovarian structure that appears in at least some pinnipeds is the *hilar rete* (Boyd, 1984). These glandular cells are most abundant during delayed implantation but their function is not clear. They also occur in a number of terrestrial mammals including carnivores, primates, rodents, and hyraxes.

The oviduct, uterus, and vagina are all derivatives of the Müllerian duct system. The oviduct, fallopian tube, or uterine tube is generally highly convoluted and is enclosed in the ovarian bursa. The anterior end forms a funnel or infundibulum near the ovary and the posterior end of the oviduct enters the uterus. In eutherian mammals with a bicornuate uterus (e.g., cetaceans), the isthmus can be straight or convoluted but it has a thick wall and a narrow lumen. Dugong uterine tubes lack a mesosalpinx and exist as a 4-cm long cord-like convoluted tube which lies dorsal to the peritoneum. Generally, the oviduct is lined by simple columnar epithelium that are ciliated, and have occasional goblet cells. There is an inner circular layer and an outer longitudinal layer.

The uterus classification scheme in mammals is based on progressive fusion of the caudal ends of the oviducts. Four major types are recognized (Table I, Fig. 2) of which three types are represented in marine mammals; no marine mammal has a simplex uterus. All types

TABLE I
Uterine Types

Type of uterus	Uterine horns	Cervix	Example
Duplex	Two completely separate horns	2	Walrus
Bipartite	Two horns separated internally by a septum but sharing a small common area near the cervix	1	Phocids
Bicornuate	Two horns with no internal septum, forming a single body of the uterus	1	Cetaceans, sirenians, mustelids, ursids
Simplex	No horns, one uterine body without compartments	1	Humans

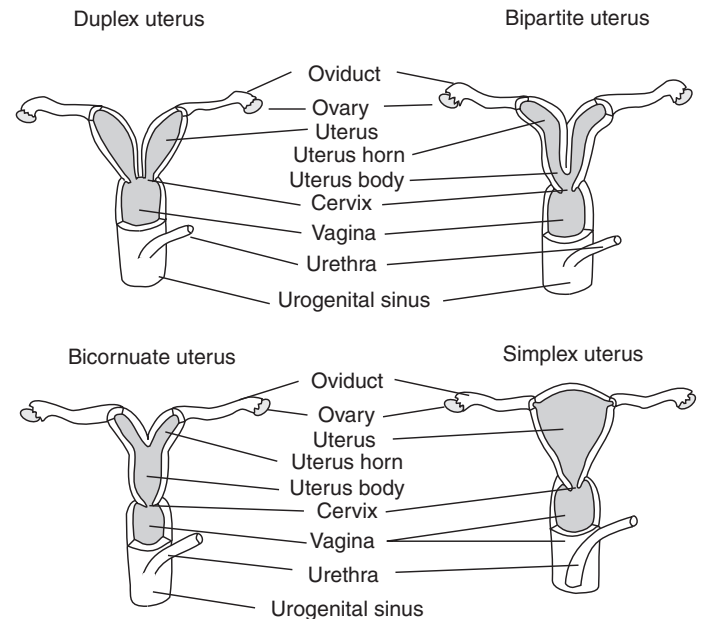

Figure 2 Uterus types found in placental mammals. The simplex type is not found in marine mammals. Modified from Romer (1962).

of uteri are supported by broad ligaments, have two oviducts and deliver into a single vagina.

The uterine wall has three layers: on the outside, the serous membrane; in the middle, the myometrium, which contains the internal circular muscle and the external longitudinal muscle separated by the vascular layer; and the inner lining of the uterus, the endometrium, composed of an epithelial lining of the lumen, a glandular layer, and some connective tissue. All uterine types exhibit changes in the layers of the uterine wall that precede implantation and development of the placenta. During the luteal phase of the follicle (post-ovulatory) the endometrium increases in thickness and the glands become extremely branched and convoluted.

Figure 3 (A) Zonary and (B) diffuse placentas found in marine mammals (B modified from Slijper, 1966).

Embryonic membranes develop before the embryo implants. The yolk sac forms first as endoderm surrounds the nutrient uterine fluid. The chorion and amnion develop as a double layer, originating from embryonic ectoderm. The innermost layer is the amnion which forms the fluid-filled amniotic sac encompassing the fetus. The outer layer of cells of this sac wall is the chorion. The allantois develops as an extension of the embryonic hind gut and forms the allantoic cavity. The allantois fuses with the chorion forming a small round area, the allanto-chorion. This region becomes the placenta (Fig. 3).

The embryonic membranes persist after the placenta is fully developed. In whales, the amniotic sac and allantois extend into the contralateral uterine horn. The chorion has many folds that mesh with the uterine mucosa. In pinnipeds, the chorion extends beyond the zonary placenta. The large allantois almost completely surrounds the amnion. In sirenians, the allantois is also large and nearly fills the chorionic sac.

The placenta is comprised of maternal and embryonic tissue in close union. It allows nutritional, respiratory, and excretory exchange between the maternal and fetal circulatory systems by diffusion across the placental membranes. Additionally, the placenta functions as a protective barrier to bacteria and other large molecules, produces some food materials, and synthesizes hormones required to maintain the pregnancy. The umbilical cord connects the placenta to the ventral surface of the embryo, and is formed of mesoderm and blood vessels. This connection is broken at birth.

There are three types of placentas seen in mammals, defined by the fetal tissue that adheres to the uterine wall. They are the chorionic placenta, the yolk-sac placenta, and the chorio-allantoic placenta which are found in all marine mammals. The chorio-allantoic placenta is the most advanced placenta type in its ability to provide rapid diffusion between the uterine and fetal circulatory systems. As the blastocyst implants and sinks into the uterine endometrium, chorionic villi grow quickly and push further into the endometrium. This process is accompanied by a breakdown of uterine tissue. The degraded debris is called embryotroph. The blastocyst absorbs the nourishing embryotroph until the villi are fully developed and the embryonic vascular system becomes functional.

Although all placentas are derived from both maternal and fetal tissues, the degree of separation of maternal and fetal circulatory

systems is variable and is a function of the type of placenta that has developed. Chorio-allantoic placentas can be further subdivided based on the fetal and maternal cell layers that are in contact. In epitheliochorial placentas (cetaceans), the epithelium of the chorion is in contact with the uterine epithelium. The villi rest in endometrial pockets. In endotheliochorial placentas, (pinnipeds, mustelids, ursids), degradation of the maternal endometrium is more pronounced and the epithelium of the chorion is in contact with the endothelial lining of the uterine capillaries. Hemochorial placentation (sirenians), is characterized by destruction of the endothelium of the uterine blood vessels, allowing blood sinuses to develop in the endometrium. There is direct contact, therefore, between the chorionic villi and maternal blood. Hemoendothelial placentas are not found in marine mammals but occur in some rodents and in lagomorphs.

Placenta shape is characterized by the pattern in which villi are distributed over the chorion. Two shapes occur in marine mammals—diffuse and zonary (Fig. 3). In the diffuse placenta (cetaceans), the villi occur over the entire chorion providing a large surface area for exchange. In a zonary placenta (all other marine mammals), there is a continuous band of villi covering the equator of the chorion. In walrus and sirenians, the zonary placenta leaves detectable scars on the uterus. Both diffuse and zonary placentas are also found in terrestrial mammals.

When the placenta is expelled from the uterus postpartum as afterbirth, a maternal component may or may not be lost in this process. Epitheliochorial placentas have villi which pull out of the uterine pits easily and no endometrium is pulled away. Therefore, no bleeding occurs at birth and this placenta is referred to as non-deciduous. The other types of placentas allow for closer association of maternal and fetal circulatory systems through degradation of the endometrium and extensive intermingling of uterine and chorionic tissue. At birth then, part of the uterine component of the placenta is torn away and bleeding occurs. These are termed deciduous placentas. Bleeding is arrested quickly by collapse of the uterus, contractions of the myometrium constricting blood vessels, and blood clotting. The subsequent development of uterine scars at the bleeding site can result in persistent features that can be used in the interpretation of reproductive history in a female (e.g., walrus, Fay, 1982), although their persistence is variable among species.

The cervix is a well-muscled sphincter that marks the transition between the uterus and the vagina. The West Indian manatee has a rounded cervix. In the dugong, the long, thin-walled vagina has a keratinized shield originating in the vault region. This shield surrounds the cervix and extends along with the ventral wall of the vagina. In cetaceans, the cervix is long with a thick wall and a narrow, sinuous lumen. The portion of the cervix projecting into the vagina (*portio vaginalis uteri*) is species specific in length, e.g., very short in narwhal (*Monodon monoceros*) but long in common porpoise (*Phocoena phocoena*). Vagina length in pinnipeds equals or slightly exceeds the urogenital canal in length.

Many cetaceans have several folds in the upper part of the vagina which are not found in any other mammal. There is a valve-like arrangement to these 4–12 circular folds which project distally and look like a chain of funnels with their mouths directed toward the cervix. This configuration may act to retain sperm but the function of these folds is unclear. Harrison (1969) noted the folds appeared capable, anatomically, of a pumping action and speculated that they may relate to the formation of vaginal plugs. Vaginal plugs are congealed masses of semen that occur in some mammalian orders. They are thought to assist sperm retention and discourage subsequent matings by competing males. There is some suggestion of vaginal plugs in *Tursiops* and *Delphinus* but little other evidence. Vaginal calculi are masses of organic and inorganic material that have been found in *Delphinus*, *Stenella*, and *Lagenorhynchus*. Calculi contain material identical in composition to mammalian bone and some contained recognizable embryonic bones (Perrin *et al.*, 1984). “Vaginal plugs” therefore may represent small or deteriorating vaginal calculi.

The remainder of the female reproductive system consists of the clitoris, urethra, and vaginal vestibule. For all pinnipeds, the presence of the *os clitoridis* has been recorded but it is generally small (<1 cm) and its appearance is irregular. In cetaceans, the clitoris projects from a strand of fibrous connective tissue on the anterior border of the vulva. Dugongs possess a clitoris with a large conical glans which has prominent fissures dividing it into lobes.

The urethra also opens into the vaginal vestibule, draining the bladder which lies ventral to the vagina. The urethra in pinnipeds opens by a large urinary papilla just caudal to the hymen. Pinnipeds have long urogenital canals compared to other mammals and there is a prominent hymenal fold which is smaller in otariids. Dugongs have a urethra which is surrounded by prostate-like tissue which also surrounds the narrow distal portion of the vagina.

In pinnipeds, the vaginal vestibule opens to the exterior just ventral to the anus in a common furrow. In cetaceans, the vulva is a slit-like aperture with *labia majora* and *labia minora* which may be poorly developed. The slit is positioned just anterior to the anus.

Considerable variation exists in mammary gland configuration and nipple location in marine mammals. Phocids have distinct mammary glands enclosed in connective sheaths lying under the blubber layer. In otariids, the mammary glands coalesce to form a sheet-like layer under the blubber over most of the ventral surface of the body. Cetacean mammary glands are elongate, narrow, flat organs that extend in the subcutaneous connective tissue at both sides of the ventromedial line. They extend from a little posterior of the umbilicus to slightly anterior to the anus.

Cetaceans have two nipples in elongated recesses, one on either side of the midline in the urogenital slit. Sireniacs have two pectoral nipples. Sea otters have only two functional teats on the lower abdomen, compared to six or more in most other mustelids. Polar bears have four teats, two on either side of the midline of the belly slightly

posterior of the axillae and two about 15 cm posterior to the anterior pair. Otariids, odobenids, and two genera of phocids (*Erignathus* and *Monachus*) have four teats while the other phocids have two that correspond to the posterior pair of those in otariids. Pinniped nipples are retracted beneath the level of the body surface when a pup is not nursing and become erect during suckling.

III. Reproductive Cycle

In marine mammals, ovulation can be either spontaneous or induced. Spontaneous ovulators release an egg even in the absence of breeding (phocids, cetaceans). Induced ovulators release an egg only in response to coital stimulation (polar bear, sea otter).

The ova normally are fertilized in the oviduct within 24 h of breeding and the zygote's first cell divisions occur there. At the 8–16 cell stage movement to the uterus occurs with assistance of muscle contractions in the oviduct. There, further differentiation into the blastocyst and subsequent implantation takes place.

Implantation of the blastocyst may be immediate (within 1–2 weeks) or after some protracted delay of several months. This delay, also known as embryonic diapause, occurs in the carnivores and pinnipeds and is considered to be obligate. Its duration is species-specific. Facultative delayed implantation can occur in other species of mammals if a female is nursing a large litter at the time of insemination (e.g., some marsupials, some insectivores). The length of active gestation is generally related to the body size of the female and a delay in implantation is thought to allow the young to be born at an advantageous time. For example, harp seals (*Phoca groenlandica*) have a delay of about 3 months followed by an active gestation of about 8.5 months. The delay produces a cycle that is nearly 1 year long, allowing births and breeding to occur during large spring aggregations when pack-ice conditions are suitable. There may be some flexibility in the duration of the delay, and in sea otters, this flexibility may lead to the variation seen in estimates of total gestation, ranging from 6 to 8 months.

Obligate delayed implantation is characterized by ovulation, fertilization, and differentiation up to the blastocyst stage which creates a hollow ball of 100–400 cells surrounding a fluid-filled cavity. Further differentiation of the blastocyst then stops and implantation in the endometrium does not occur. The blastocyst is free-floating in the uterus and is covered by a *zona pellucida*, a noncellular protective layer, for the period of dormancy. Resumption of blastocyst differentiation occurs prior to implantation. During delayed implantation, pregnancy is indicated, macroscopically, by the presence of a *corpus luteum*, and increased diameter of a uterine horn which shows marked surface vascularization, smoothening of the endometrial folds, and development of a nidation chamber where implantation will occur.

Usually, implantation of the blastocyst occurs in the uterine horn corresponding to the active ovary (ipsilateral). However, in odontocetes with only one active ovary, there is a tendency for transuterine migration of the blastocyst which will implant in the other (contralateral) horn. The fetal membranes project into the horn opposite the implantation site. In mysticetes, and most other mammals, there is a slight prevalence (60%) of implanted fetuses in the right horn, reflecting a similar rate of ovarian activity in the right ovary (60%) (Slijper, 1966).

Once implanted, the blastocyst begins to differentiate tissues and organs, and remains in the uterus for the duration of its fetal phase. Nourishment and protection in utero allows for relatively high survival rates of the fetus.

At birth, powerful and rhythmic contractions of the uterine myometrium aided by the abdominal muscles expel the fetus. Continued contractions force the placenta from the uterus and vagina. In cetaceans, birth underwater must be rapid to prevent drowning of the neonate. The newborn swims unaided or is pushed to the surface by its mother or attendants to breath for the first time. Other birthing platforms include land fast ice (ring seal—*Phoca hispida*, Weddell seal—*Leptonychotes weddellii*), pack ice (harp seal, crabeater seal—*Lobodon carcinophagus*), and terrestrial sites (harbor seal—*Phoca vitulina*, polar bears, otariids). Few births have been observed in sea otters and may take place both on shore and in the water. Sirenian births are also rarely seen but are thought to occur in shallow water, although there is some evidence they may also calve on low sand bars.

Cetacean and pinniped neonates have relatively large body sizes, approximately 8–10% maternal weight, compared to mammals in general (Slijper, 1966, Kovacs and Lavigne, 1992) a benefit to these animals that need to swim at birth or shortly afterward, and to maintain homeothermy in cold water. Most marine mammals usually give birth to a single offspring. Twin live births are exceedingly rare in pinnipeds and the sea otter and have never been documented in cetaceans, although multiple fetuses have been observed. Some twins have been reported among sirenians. It is thought that multiple births are incompatible with the production of newborns that are large relative to maternal body size, as is found in these animals. It may also be difficult for a marine mammal mother to properly tend more than one offspring in the marine environment.

Multiple births are the norm in polar bears, however ursids have extremely small young, relative to adult female body weight, that are born in dens and emerge with mother after considerable time when substantial postnatal growth has occurred. Most ringed seals and Baikal seals (*Phoca siberica*) are also born in dens, excavated in snow drifts from a hole scratched in the sea ice by the mother.

All marine mammals suckle their young with milk exclusively before a transition to solid food items and complete weaning is made. The period of lactation is again species-specific and can be relatively short (4 days in hooded seals—*Cystophora cristata*, 10–12 days in harp seals), or more protracted (up to 2 years in sirenians, some cetaceans, walrus), although the young may start to eat solid food before weaning is completed. Marine mammal milk is typically high in fat (40–50%), high in protein (7–19%), and low in lactose (trace 5%) compared to terrestrial mammals.

Milk may be forcefully ejected from the teats or may be sucked from the teats by the neonate. In cetaceans, forceful ejection of milk is required because neonates cannot suck with their lips and must hold their breath during underwater nursing bouts. Indeed, young *Tursiops* can only remain underwater for less than a minute, so they nurse two or three times an hour over an entire 24-h period. Cetacean nipples become protruded during nursing and the milk is expelled under pressure, likely due to contraction of either the cutaneous muscles or the myoepithelial cells surrounding the alveoli. Walrus may suckle young in water and the teats are surrounded by sphincter-like folds of skin which suggest that milk may be squirted into the calves' mouth. Young sea otter pups nurse while lying on the female's chest while older ones lie in the water perpendicular to her. Sirenian calves nurse at the surface with their nostrils in the air or just below the surface. All other marine mammals nurse their young on ice or on land and neonates actively suck milk.

Weaning can be abrupt by abandonment (most phocids and otariids) or extend over some time (walrus, sirenians). The extended care of the young during lactation, and sometimes beyond in a period of learning, further increases survivorship of the offspring beyond the high rate of fetal survival. It also increases the efficiency of

reproduction in that maternal energy expended towards young results in a high rate of offspring that reach reproductive maturity, consistent with other K-selected life history traits.

Age of maturation varies by species and, within a species, can be influenced by environmental factors that affect growth and fattening. Breeding success is often lower in younger breeders, but lifetime reproductive success, the number of descendants produced, of those that breed young and survive, can be high. Diminished reproductive frequency (reproductive senescence) has been described for some marine mammals (walrus, polar bear, some fur seals, and some cetaceans). Although short-finned pilot whales (*Globicephala macrorhynchus*) of advancing age become senescent with no follicular activity, they may still lactate, nursing not only their own previous young but also other young in the pod.

Filter Feeding

DONALD A. CROLL, BERNIE R. TERSHY AND
KELLY M. NEWTON

I. Filter Feeding and the Marine Environment

A fundamental necessity for any organism is acquiring sufficient food for maintenance, growth, and reproduction. This search for food likely drove the return of mammals to the ocean where they were able to exploit highly productive coastal waters. With their return to the sea, marine mammals evolved a number of foraging techniques. Filter feeding, found in the mysticete whales and three species of pinnipeds (crabeater seals, *Lobodon carcinophaga*; leopard seals, *Hydrurga leptonyx*; and Antarctic fur seals, *Arctocephalus gazella*) is the most unique of these adaptations for feeding, and is not found in any terrestrial mammals.

Filter feeding allows these marine mammals to exploit extremely abundant, but small schooling fish and crustaceans by taking many individual prey items in a single feeding event. This adaptation arose in response to the unique patterns of productivity and prey availability in marine ecosystems. Low standing biomass and high turnover of small-sized primary producers that respond rapidly to nutrient availability characterize marine food webs. Due to spatial differences in the physical dynamics of marine ecosystems, productivity tends to be more patchy and ephemeral than in terrestrial systems. Consequently, marine grazers (e.g., schooling crustaceans and fish) often occur in extremely high densities near these patches of high primary production. Most marine mammals are primary carnivores and feed on these dense, patchily distributed aggregations of schooling prey. The spatial and temporal patchiness of this prey means that marine mammals must often travel long distances to locate prey, and the larger body size of marine mammals likely plays an important role (Croll *et al.*, 2005).

Initially, thermoregulatory requirements selected for larger body sizes as mammals returned to the ocean. However, once dependent upon marine prey, large body size also provided a buffer for the patchy and ephemeral distribution of marine prey. Thus, larger individuals could endure longer periods and travel longer distances between periodic feeding events on patchy prey. While adaptive for exploiting patchy prey resources, a consequence of larger body size is a higher average daily prey requirement. For marine mammals that feed on patchy and ephemeral resources, this requires individuals to take in large quantities of prey during the short periods of time it is available (Berta and Sumich, 1999; Bowen and Siniff, 1999).

Filter feeding is a foraging strategy that allows individuals to capture and process large quantities of prey in single mouth full, thus allowing them to acquire energy at high rates when small prey are aggregated. Indeed, for mysticetes, large body size is probably a prerequisite for attaining a sufficiently large surface area for filter feeding. Thus, the interaction of availability of prey resources, high concentrations of prey in schools, and selection for large body size likely led to the evolution of filter feeding. Ultimately, large body size and filter feeding allowed some marine mammals to exploit the extremely high densities of schooling prey that develop at high latitudes during the spring and summer, but fast during the winter when these resources disappear. Large body size provided an energy store for wintering and long distance migration without feeding (Berta and Sumich, 1999).

Due to this dependency on patchy but extremely productive food resources, it is not surprising that filter-feeding whales are believed to have first evolved and radiated in the southern hemisphere during the Oligocene at the initiation of the Antarctic Circumpolar Current (ACC). It is generally agreed that the initiation of the ACC led to cooling of the southern oceans, increased nutrient availability and thus increased productivity. This increased productivity provided a rich resource of zooplankton that could be effectively exploited through filter feeding (Berta and Sumich, 1999). Recently, the discovery of a late Oligocene fossil archaic mysticete that was a macrophagous predator casts doubt on the suggestion that the initial radiation of mysticetes was linked to the evolution of filter feeding (Fitzgerald, 2006).

Present-day filter-feeding marine mammals concentrate their foraging in polar regions and highly productive coastal upwelling regions. The southern ocean is still the most important foraging area for filter-feeding marine mammals. Prior to their exploitation by humans, the highest densities of mysticetes occurred in highly productive southern waters. Crabeater seals, Antarctic fur seals, and leopard seals are found primarily in the southern oceans where seasonally dense aggregations of krill develop (Berta and Sumich, 1999).

II. Diet, Filter-Feeding Structures, and Prey Capture

All filter-feeding species feed on prey that form dense aggregations (primarily pelagic schooling fish and crustaceans or densely aggregated benthic amphipods). Two feeding adaptations have evolved to allow the exploitation of these dense aggregations: baleen (mysticete whales) and modified dentition (seals).

A. Seals—Diet, Feeding Morphology, and Behavior

Unlike mysticetes, pinnipeds evolved in the Northern Hemisphere where krill was not likely an important component of their diet, and adaptations for filter feeding are not nearly as extensive in pinnipeds as in mysticetes.

Only three pinniped species regularly filter feed: crabeater seals, leopard seals, and Antarctic fur seals (Riedman, 1990). When filter feeding, all the three species feed almost exclusively on Antarctic krill, *Euphausia superba* in the Southern Ocean where it is large in size, abundant, and forms extremely dense aggregations. Of the three species, crabeater seals are most highly specialized with krill comprising up to 94% of their diet, while krill comprises approximately 33% of the diet of leopard seals and Antarctic fur seals. The most remarkable adaptation for filter feeding in pinnipeds is found in the dentition of crabeater and leopard seals. In both species elaborate cusps have developed on the postcanines in both the upper and lower jaws (Fig. 1) (Berta and Sumich, 1999). Once the mouth closes around a small group of krill, water is filtered out through the cusps, trapping krill in the modified teeth. Little detailed information is available on the behavior used by filter-feeding pinnipeds to capture prey. However, data from Antarctic fur seals and crabeater seals indicate that they track the diel migration of krill: shallow dives are performed during the night and deeper dives during the day (Boyd and Croxall, 1992).

B. Mysticetes—Diet and Feeding Morphology

Most mysticetes feed primarily on planktonic or micronectonic crustaceans (copepods and krill) and pelagic schooling fish found in shallow waters. Gray whale, *Eschrichtius robustus*, diet consists primarily of benthic gammarid amphipods, although they can forage

Figure 1 Dentition patterns in pinnipeds. Note modified cusps in postcanine teeth in filter-feeding crabeater and leopard seals. From Berta and Sumich (1999).

on a wide variety of prey, including schooling mysids in some areas. Right, *Eubalaena* spp., and bowhead, *Balaena mysticetus*, whales primarily feed on copepod crustaceans of the genus *Calanus*. All of the rorquals feed on euphausiids (krill) to some extent, and blue whales, *Balaenoptera musculus*, feed almost exclusively upon euphausiids (see section on krill). The other rorquals have a more varied diet that includes copepods (sei whales, *Balaenoptera borealis*), and schooling fish (minke, *B. acutorostrata*, Bryde's; *B. edeni*, humpback; *Megaptera novaeangliae*; and fin whales, *B. physalus*) (Berta and Sumich, 1999).

All present-day mysticetes lack teeth and instead have rows of baleen plates made of keratin that project ventrally from the outer edges of the palate. Similar to fingernails, the plates grow continuously from the base, but are worn by the movements of the tongue. As the edges of the plates wear, hair-like fibrous strands emerge as fringes. The outer fibers of these fringes are coarser while the inner fibers form a tangled fringe that overlaps with fringes on adjacent baleen plates. Rows of baleen plates form an extended filtering surface along each side of the palate.

The coarseness of the hair-like fibrous fringes, the density of fibers (number of fibers/cm²), number of baleen plates, and length of baleen plates varies between species, and is related to the prey species captured in the filtering mechanism. Because gray whales feed primarily upon sediment-dwelling benthic amphipods, they have the coarsest filtering mechanism, made up of about 100, 1-m long individual plates with very coarse fibers. This coarse filtering structure allows them to separate amphipods from bottom sediments. In contrast, right whales that feed on small copepods have a fine filtering mechanism composed of more than 350 baleen plates that can

exceed 3 m in length. The fibers of right whale baleen are very fine, forming a dense mat capable of capturing copepods that are less than 5 mm (Berta and Sumich, 1999). The strong, flexible, and light characteristics of baleen plates made them commercially important in the nineteenth century where they served some of the roles of today's plastics.

Mysticetes have evolved three types of filter feeding: sediment-straining (gray whales), skimming (right and bowhead whales), and lunging or gulping (rorquals). The morphology of mysticetes reflects these different strategies. Gray whale heads are straight and relatively short, contain short, coarse baleen, and their throat regions possess only a few grooves (3–5) in the gular region that allows limited distension for taking in bottom sediment, water, and amphipods. Right and bowhead whale's heads have a strongly arched rostrum that allows them to have very long- and fine-textured baleen within a relatively blunt mouth. They have no throat grooves for distension and instead feed by swimming slowly (3–9 km/h) with their jaws held open for long periods while skimming prey from the water. The shape of their baleen minimizes the pressure wave in front of the whale that develops while swimming slowly through prey and enhances prey entry into the mouth (Werth, 2004; Lambertsen *et al.*, 2005). Rorqual heads are large and contain enormous mouths that extend posteriorly nearly half of the total body length. Their mouths contain relatively short baleen that ranges from fine (sei whales) to medium texture (blue, fin, humpback, and minke whales). The heads and bodies of rorquals are much more streamlined than the other mysticetes, allowing them to swim rapidly into a prey school to gulp large quantities of water and schooling prey. One of the most remarkable adaptations for feeding is the presence, in rorquals, of

Figure 2 Skim-feeding in right and bowhead whales. From Berta and Sumich (1999).

70–80 external throat grooves. During gulping, these grooves open like pleats to allow the mouth cavity to expand up to 4 times in circumference, taking in a volume of water equivalent to about 70% of the animals' body weight or greater (Croll *et al.*, 2001; Acevedo-Gutierrez *et al.*, 2002; Goldbogen *et al.*, 2006; Goldbogen *et al.*, 2007). The filter-feeding strategy of Baleenids appears to focus upon enhanced filter area whereas Baleenopterid strategy allows for greater filter pressure.

C. Mysticetes—Feeding Behavior

Observations of feeding gray whales in the Arctic and Bering Sea have shown that the whales roll to one side and suck benthic invertebrate prey and bottom sediments, with some distension of the mouth cavity through the expansion of the throat grooves. Water and mud are expelled through the side of the mouth (Berta and Sumich, 1999). A similar behavior is used by gray whales that do not migrate as far north where they feed on a variety of benthic invertebrates and schooling mysids. This benthic foraging behavior creates scrapes of 1–5-m deep in the ocean floor, and several studies have shown that the disturbance is an important factor in the ecology of soft-bottom benthic communities of the Arctic and Bering Seas. Observational and direct measurement studies have shown that most gray whales and rorquals exhibit a strong right-side rolling preference while filter feeding (Woodward and Winn, 2006). For gray whales this right-side preference has been identified by shorter baleen and fewer parasitic barnacles on the right side.

Right and bowhead whales forage by skimming with their mouths open through concentrations of crustaceans near the surface and deeper in the water column. As the whale swims, water and prey enter through a gap between the two baleen plates in the front of the mouth and water exits along the sides of the mouth. Prey are swept into the back of the mouth by the dynamically controlled flow of water through the mouth and the side-to-side sweeping action of the large muscular tongue (Fig. 2). When the mouth is opened, the large lower lip abducts to create a gutter-like channel to direct water flow along the outside of the baleen to draw water out via negative hydrodynamic pressure through the baleen (Werth, 2004; Lambertsen *et al.*, 2005). While right and bowhead whales generally feed singly, at times they may feed alongside one another—a V-formation of 14 bowhead whales has been observed.

Rorqual lunge feeding has been described as the largest biomechanical event that has ever existed on earth (Croll *et al.*, 2001). Rorquals capture food by initially swimming rapidly (3–5 m/s in fin whales) at a prey school and then decelerating while opening the mouth to gulp vast quantities of water and schooling prey (Fig. 3). To maximize the opening, the lower jaw opens to almost 90° of the body axis. This is possible because the lower jaw has a well-developed

coronoid process. This process is where the large temporalis muscle inserts, and provides an anchor and mechanical advantage for control of the lower jaw while maximizing the gape for prey capture. It is not developed in other whale species, and a tendinous part of the temporalis muscle, the frontomandibular stay, enhances and strengthens the mechanical linkage between the skull and the lower jaw (Lambertsen *et al.*, 1995). The expansion of the mouth during each lunge greatly increases drag and brings the body of the whale almost to a stop. As a result, it appears that filter feeding in rorquals is an energetically costly behavior (Croll *et al.*, 2001; Goldbogen *et al.*, 2006; Goldbogen *et al.*, 2007).

With the mouth open, the onrush of water and prey are accommodated by the distending ventral pleats. The tongue invaginates to form a hollow sac-like structure (cavum ventrale) which lines the inside of the gular region and the ventral pleats distend fully. After engulfing entire schools of prey, the lower jaw is closed. The tongue and the elastic properties of the ventral walls of the throat act in concert to force water out through the baleen (Fig. 3) (Lambertsen *et al.*, 1995; Goldbogen *et al.*, 2006).

Although the process described above is fundamentally the same in all rorquals, some species exhibit modifications and additional adaptations. Sei whales skim-feed in a manner similar to right whales, as well as feeding by lunging. Fin and blue whales often feed in pairs or trios that have a consistent echelon configuration. Humpback whales have a diverse diet and a wider variety of feeding behaviors. They have been observed bottom feeding, and while feeding on schooling fishes have been observed to produce a cloud of bubbles and feed cooperatively to assist in prey capture.

Laboratory experiments have shown schooling fish to react to bubbles by aggregating more densely. Humpback whales appear to take advantage of this as one member of a group of foraging whales that form long-term associations produce a net of bubbles. The bubble cloud serves to aggregate and confuse the prey. Members of the group dive below the bubble cloud and surface together—one whale immediately adjacent to another. The location of the whales in the surfacing group appears to be fairly constant through time. Humpbacks thus likely enhance prey capture success by both using bubbles and foraging cooperatively. A variation of bubble cloud feeding has been observed in humpback whales feeding on sand lance off New England. Here the bubble-cloud feeding is followed by a tail slap—believed to cause the sand lance to aggregate more densely.

D. Mysticetes—Feeding Ecology

All filter-feeding whales exhibit distinct migration patterns linked to seasonal patterns in prey abundance. Seasonally dense aggregations of prey are probably necessary for successful filter feeding. For example,

Figure 3 Lunge feeding in rorqual whales, demonstrating expansion of the throat pleats in invagination of the tongue. From Berta and Sumich (1998).

gray whales undergo the longest migration of any mammal—foraging during the summer and fall in the Bering Sea and Arctic Ocean when dense aggregations of benthic amphipods become available with the seasonal increase in productivity. Humpback whales seasonally migrate from breeding areas to higher latitude foraging areas where schooling fish and krill become seasonally abundant (Berta and Sumich, 1999). The timing of coastal migration patterns of the California blue whale appears to be linked to annual patterns in coastal upwelling and krill development patterns (Croll *et al.*, 2005).

Studies of the diving behavior and daily movement patterns of right whales has shown that they track dense aggregations of copepods that in turn track oceanographic features such as fronts. Zooplankton densities in regions where right whales foraged in the southwestern Gulf of Maine were approximately three times the mean densities in the region (whale feeding densities averaged $3.1\text{--}5.9\text{ g/m}^3$, compared to $1.1\text{--}3.6\text{ g/m}^3$ where whales were not foraging). In a related study using hydroacoustic surveys, zooplankton densities where right whales were foraging were $18\text{--}25\text{ g/m}^3$ (compared to $1\text{--}5\text{ g/m}^3$ where whales were not foraging). Whale diving behavior is related to the depth of prey aggregations. In a year where copepods did not undergo diel migrations, dive depths averaged 12 m, with no dives exceeding 30 m throughout the day and night. In contrast, in a year where copepods showed strong diel shifts in depth (near the surface at night, deeper during the day), whale dive depths were significantly longer during the day (Mayo and Marx, 1990; Baumgartner and Mate, 2003; Baumgartner *et al.*, 2003).

Rorquals also track seasonal and diel patterns in the abundance and behavior of their prey. In general, the distribution and movement

patterns of most rorquals consist of a seasonal migration from high latitudes where foraging takes place to low latitudes where they mate and give birth. However, data from blue whales in the Pacific indicate that feeding also takes place at low latitude, “upwelling-modified” waters, and data from both the Pacific and the Indian Oceans indicate that some blue whales may remain at low latitudes year-round. Fin and blue whales foraging on krill off the coast of North America concentrate their foraging effort on dense aggregations of krill deep (150–300 m) in the water column during the day, and may cease feeding when krill becomes more dispersed near the surface at night (Croll *et al.*, 1998; Croll *et al.*, 2005).

Rorqual foraging appears to only occur in regions of exceptionally high productivity, often associated with fronts, upwelling centers, and steep topography. It has been estimated that fin whales require prey concentrations of at least 17.5 g/m^3 to meet daily energy requirements. Krill densities where humpback whales were foraging in southeast Alaska have been estimated at $910\text{ individuals/m}^3$, and minimum required prey densities for humpbacks were about $50\text{ individuals/m}^3$ (Dolphin, 1987a, b). Krill densities in schools where blue whales were foraging in Monterey Bay, California were estimated at 145.3 g/m^3 compared to an overall mean density of zooplankton of 1.3 g/m^3 in the area (Croll *et al.*, 2005).

III. Summary

Filter feeding in marine mammals is an adaptation that allows individuals to take in large quantities of prey in one mouth full. This is particularly adaptive in marine ecosystems where prey are relatively

small and often densely aggregated, but patchy and ephemeral in space and time. Most filter-feeding species feed on schooling fish and crustaceans. The large body size of marine mammals and particularly mysticetes facilitates filter feeding by providing the ability to have a large filtering area relative to body volume. In addition, large body size likely provides an energetic buffer for animals that must move long distances between dense prey patches and endure long periods of fasting between foraging events.

Fin Whale

Balaenoptera physalus

ALEX AGUILAR

I. Characters and Taxonomic Relationships

Fin whales were initially described by Frederik Martens in 1675 and then by Paul Dudley in 1725. From these descriptions, Linnaeus created his *Balaena physalus* in 1758, which was later designated by Lacépède as *Balaenoptera physalus*.

The fin whale is very close to the other balaenopterids, particularly its congeners and shares with them the same chromosome number of $2n = 44$. It appears to be particularly close to the blue whale (*B. musculus*), from which it diverged between 3.5 and 5 million years ago and with which several hybrids have been described. Although the hybridization rate between these two species has not been properly assessed, it may be in the range of one for every 500–1000 fin whales. At least in one case, a female hybrid was pregnant (Béribé and Aguilar, 1998).

The fin whale (Fig. 1) is **SEXUALLY DIMORPHIC**, with females being about 5–10% longer than males (Gambell, 1985). In the Southern Hemisphere, the average body length of adults is about 26 m for females and 25 m for males; in the Northern Hemisphere the corresponding lengths are 22.5 and 21 m. The fin whale is a slender balaenopterid, its maximum girth being between 40% and 50% of the total length. The rostrum is narrow, with a single, well-developed longitudinal ridge. **BALEEN** plates number 350–400 in each row and their maximum length is up to 70 cm. The dorsal fin is falcate and located at 75% of the total length; it is higher than that of blue whales, but lower than in sei whales (*B. borealis*) or Bryde’s whales (*B. edeni*). The ventral grooves are numerous and extend from the chin to the umbilicus. The pigmentation of the cephalic region is strikingly asymmetrical, whereas the left side, both dorsally and ventrally, is dark slate, the right dorsal cephalic side is light gray and the right ventral side is white. This asymmetry also affects the baleen plates: those on the whole left side and the rear two-thirds of the right side are gray, whereas those on the front third of the right maxilla are yellowish. Particularly in adults, the skin of the flanks in the rear trunk is often covered by small round scars and stripes attributed to the attachment of lampreys and remoras. The white ventral region of whales inhabiting cold waters may have a yellowish layer produced by an infestation of diatoms.

The body mass of adult individuals typically ranges from 40 to 50 metric tons in the Northern Hemisphere and from 60 to 80 metric tons in the Southern Hemisphere. A general formula for estimating body weight (W) from body length (L) is $W = 0.0015 L^{3.46}$. If the

Figure 1 Fin whales feeding in the North Atlantic (Photo by Brenda Rone, courtesy of Northeast Fisheries Science Center).

girth at the level of the navel (G) is available, a more precise formula is $W = 0.0469 G^{1.23} L^{1.45}$.

The relative mass of body tissues varies seasonally according to nutritive condition (Lockyer and Waters, 1986). Average mass relative to total body weight is $18.4 \pm 3.3\%$ for blubber, $45.3 \pm 4.4\%$ for muscle, $15.5 \pm 2.4\%$ for bone, and $9.8 \pm 2.1\%$ for viscera. The liver is large, usually weighing 230–600 kg. The heart is similar in relative size to that of terrestrial mammals but larger than in odontocetes and weighs 130–290 kg. Kidneys are large and weigh 50–110 kg. The right lung is about 10% heavier than the left, with each one weighing 100–160 kg. The spleen weighs 2–7 kg and sometimes has accessory bodies of smaller size.

The rostrum of the fin whale is sharply pointed, without the lateral curvature typical of blue whales. The zygomatic width is about 50–55% of the condylo-premaxillary length, the width of the rostrum at midlength is approximately 30–35% of its basal width, and the whole skull measures about 20–25% of the total body length. Ribs usually number 16 pairs, with the last pair being smaller and not attached to the vertebral column. The number of vertebrae ranges from 60 to 63, with a typical formula of C, 7; D, 15 (16); L, 14 (13–16); and Ca, 25 (24–27). The sternum is broad and variable in shape, usually in the form of a cross or a trefoil. As in other balaenopterids, the scapulae are fan shaped with a convex upper margin. The flippers lack a third digit. The typical digit formula is I, 3–4; II, 6; IV, 5–6; and V, 3–4.

Because the fin whale makes seasonal migrations (see later), which follow alternate schedules in each hemisphere, the northern

and southern populations do not appear to come into contact. This has led to genetic isolation and, as a consequence, two forms, sometimes accepted as subspecies, are recognized: *B. physalus physalus* inhabiting the Northern Hemisphere and *B. physalus quoyi* in the Southern Hemisphere. In addition to the difference in body size mentioned earlier, the flippers of whales from the Northern Hemisphere are shorter and broader than those of their southern counterparts. Small variations in body proportions and coloration between fin whales from different locations in the Northern Hemisphere have also been described. The occurrence off the western coast of South America of a pygmy form, dark in color, and possibly with black baleen, has been proposed though not demonstrated to be genetically distinct (Clarke, 2004).

II. Distribution and Abundance

The fin whale is a cosmopolitan cetacean. It is found in most large water masses of the world, from the Equator to the polar regions (Fig. 2). However, in the most extreme latitudes it may be absent near the ice limit; thus, it has not been reported off northern Novaya Zemlya or Franz Josef Land in the Northern Hemisphere or in the Weddell or Bellinghousen Seas in the Antarctic. It is also absent from the Black Sea and is very rare in the eastern Mediterranean, the Baltic Sea, the Persian Gulf, the Red Sea, and most equatorial regions. The largest concentrations are usually located in temperate and cold waters. Within these, fin whales are thought to segregate

Figure 2 Distribution of fin whales (dark-shaded area).

into independent breeding units, the identity of which is often a matter of discussion (Bérubé *et al.*, 1998). Overall, the fin whale density tends to be higher outside the continental slope than inside it.

The estimated population numbers in recent years are 15,200 in the Antarctic, south of 307°S; 25,800 in the central North Atlantic (East Greenland-Iceland, Jan Mayen and the Faeroes); 4100 in the northeastern North Atlantic (North and West Norway); 17,400 in the Spain-Portugal-British Isles area; 1700 off West Greenland; 1000 off Newfoundland; 2800 off the east coast of North America south of the Gulf of St Lawrence; 5700 in the Bering Sea, Aleutian Islands, and Gulf of Alaska; and 3300 off the west coast of the United States.

III. Ecology

The fin whale feeds on a wide variety of organisms, depending on availability (Kawamura, 1980). Possibly, diet varies with season and locality. Preferred prey in the Northern Hemisphere seems to be krill composed of the euphausiid *Meganyctiphanes norvegica*, although other species of planktonic crustaceans (*Thysanoessa inermis*, *Calanus finmarchicus*), schooling fishes such as capelin (*Mallotus villosus*), herring (*Clupea harengus*), mackerel (*Scomber scombrus*), and blue whiting (*Micromesistius poutassou*), and even small squids are also consumed. In the Southern Hemisphere, the diet is almost exclusively krill, mostly the euphausiid *Euphausia vallentini* but also other planktonic crustaceans such as *Euphausia superba*, *Parathemisto gaudichaudii*, or *Calanus tonsus* in smaller

proportions. Similar to other balaenopterids, the fin whale feeds in summer, when an adult whale is estimated to consume up to 1 ton of euphausiids per day, and fasts in winter (see later).

Because the distribution range and the DIET of fin whales overlap with those of other balaenopterid whales, interspecific competition is likely to occur. This is especially likely in the case of the blue whale, which is often found forming mixed schools with fin whales. This association, together with the evolutionary proximity of the two species, makes blue fin hybrids relatively common (see earlier discussion).

Because they are large and swim fast, fin whales do not have significant predators, with the exception of the killer whale (*Orcinus orca*). In certain regions where this odontocete is abundant, signs of past attacks of killer whales can often be seen on the flippers, flukes, and flanks of fin whales.

IV. Behavior and Physiology

In the Southern Hemisphere, fin whales engage in north-south seasonal migration, feeding in the summer and breeding and fasting in the winter. A similar latitudinal movement has been generally proposed for the Northern Hemisphere, although in many areas this pattern is not clear. For example, in the North Atlantic, although several summer grounds have been identified in medium to high latitudes (northern Morocco, Gibraltar Straits, northeastern Spain, Scotland, northern and western Norway, Newfoundland, the Faroe Islands, and Iceland), no definite wintering grounds are known.

It has been suggested that in this ocean the latitudinal movements of the species are short because of the influence of the Gulf Stream, which would make the higher latitudes suitable as wintering grounds. An alternative explanation is that individuals that concentrate near the coast in the feeding season tend to disperse into open waters during the winter, therefore being more difficult to detect. Indeed, there is evidence that some whales remain in higher latitudes during the coldest months of the year. Also, fin whales may remain at lower latitudes year-round if food is available, as shown by the lack of seasonality of historical catches in the Gibraltar Straits (36°N).

The migration route apparently follows areas of low geomagnetic intensity and gradient and, similarly to other balaenopterids, not all components of the population move together (Walker *et al.*, 1992). Pregnant females are usually the first to initiate the seasonal movement and are soon followed by adult males and resting females. Lactating females and juvenile individuals of both sexes are the last to migrate.

Compared to other large cetaceans, fin whales are relatively fast swimmers. Normal cruising speed is 5–8 knots but may increase up to 15 knots for short bursts. The SWIMMING is usually smooth, and breaching is very rare, except when the whale is harassed. Dives are limited to 100–200 m and usually last 3–10 min. The species is not gregarious and its only social bond appears to be that of cows with their nursing calves, a link that vanishes at weaning. School size is small; the fin whale usually swims single or in groups of two to seven, but transitory large aggregations may occur in highly productive areas.

The sounds of fin whales are simple and mostly consist of low-frequency moans and grunts and high-frequency pulses, apparently with a social function. Regional differences have been found between the Gulf of California and several Atlantic and Pacific Ocean regions. Fin whale moans are loud and can be heard for at least tens, probably hundreds of kilometers.

V. Life History

Growth during the postnatal period is rapid, and 95% of the maximum body size is reached when whales are 9–13 years old (Aguilar and Lockyer, 1987). Males grow faster than females but stop growing sooner. Physical maturity, as determined by the degree of ossification of the vertebral column, is reached at about the age of 25 in both sexes. Longevity has not been determined precisely, but individuals of up to 80–90 years old are known.

Reproductive behavior is poorly known (Lockyer, 1984), but taking into account the reduced mass of their testes, their mating system probably relies on competition between males for monopolizing females and reduced sperm competition. In the Northern Hemisphere, sexual maturity is attained at an approximate length of 17.5 m in males and 18.5 m in females; corresponding figures for the Southern Hemisphere are 19 m in males and 20 m in females. These lengths typically correspond to an age of about 6–7 years in males and 7–8 years in females.

In the Northern Hemisphere, the mating period is December–February, whereas in the Southern Hemisphere it is May–July. Gestation lasts about 11 months, at the end of which a calf about 6–7 m long and weighing 1–1.5 metric tons is born. Only one calf is usually produced per pregnancy, although twinning has been reported. Weaning occurs when the calf is about 6–7 months old and measures 11- to 13-m long.

Weaning is followed by a 6-month resting period, at the end of which mating takes place. Therefore, the reproductive cycle is completed in

about 2 years. Gross pregnancy rates (number of pregnant females in relation to that of adult females) are typically estimated at 38–49%.

VI. Interaction with Humans

Second in size after the blue whale, the fin whale has been much sought after by whalers; it was one of the target species when modern operations started in the early 1870s, and its exploitation continued until the moratorium on commercial whaling came into force in 1985. At the beginning, it was taken in large numbers off northern Norway where catches were recorded as early as 1876; overexploited, this population soon decreased in abundance and the whaling stations had to close in 1904 because of insufficient catches (Tønnessen and Johnsen, 1982). The fishery then extended to other areas of the North Atlantic and from there to the Antarctic, the Pacific, and the Indian Oceans. Captures peaked during the period of 1935–1970, when the fin whale formed the largest part of worldwide catches, with about 30,000 individuals taken annually. In most localities, such a level of exploitation far exceeded the sustainable yield of the populations, and one after another the operations collapsed.

Fortunately, however, management measures introduced by the INTERNATIONAL WHALING COMMISSION in the 1960s and 1970s (IWC, 2007) prevented populations from being reduced to such a low level as its predecessor in the whale exploitation history, the blue whale. In the 1980s, when the moratorium was approved, large-scale commercial fishing of fin whales was only taking place off northwestern Spain and Iceland. Both operations were discontinued, the first in 1985 and the second in 1989. Today, the species is exploited in West Greenland, where about 19 individuals are struck per year by the “aboriginal” whale fishery; in the Antarctic Ocean, where since 2005, 3–10 individuals are taken per year under the Japanese Special Permit Research Program; and off Iceland, where in 2006 commercial whaling was reinitiated with a take of seven individuals. After discontinuation of whaling, populations have either stopped their decline or slowly recovered from losses.

Apart from exploitation, no other severe conservation threats have been identified (Klinowska, 1991). Collisions of fin whales with vessels sometimes occur in locations where boat traffic is very intense, but their frequency does not appear to be significant at the population level. Incidental catches in fishing gear do occur but are uncommon. Given the oceanic distribution of fin whales and their lower position in the food chain, pollution or reduction of food supply by overfishing do not have a significant impact. Overall levels of contaminants are low or extremely low as compared to other marine mammals (O’Shea and Brownell, 1994; Law, 1996). In the North Atlantic and the Mediterranean Sea, where the highest levels of organochlorine compounds have been detected, average concentrations of DDTs in blubber ranged from 0.2 to 12 ppm and those of PCBs ranged from 0.5 to 8 ppm. In fin whales off Chile and South Africa, concentrations were much lower, often below analytical detection limits. A number of heavy metals have also been found in tissues of fin whales, although usually at low concentrations. Levels in the muscle of North Atlantic individuals are in the range of 10–90 ppb of zinc, 0.2–2 ppb of copper, 0.1–2 ppb of cadmium, and 2–3 ppm of mercury.

Figure 1 Mother and calf pair of Yangtze finless porpoises. Photo courtesy of the Institute of Hydrobiology, the Chinese Academy of Sciences.

The finless porpoise was originally described by G. Cuvier as *Delphinus phocaenoides* based on a skull supposedly from the Cape of Good Hope. However, there have been no further records of this species from the southwest coast of Africa, and the true type locality is now considered to be the Indian coast. The genus names *Neomeris*, which is not valid since preoccupied by a polychaete, and *Meomeris*, which is a misspelled name and not available, were formerly used for the finless porpoise (Rice, 1998). Other English common names are finless black porpoise and Indian black porpoise.

Currently, three subspecies are generally recognized: *Neophocaena phocaenoides phocaenoides* from the Indian Ocean to the South China Sea, *N. p. asiaorientalis* in the Yangtze River, and *N. p. sunameri* from the East China Sea and coasts of Japan. *N. p. phocaenoides* has a broader (3–10 cm) and lower dorsal ridge, and *N. p. asiaorientalis* and *N. p. sunameri* have a narrower (0.2–1.2 cm) and higher dorsal ridge. *N. p. asiaorientalis* has the narrowest (<0.8 cm) dorsal ridge. Differences among three subspecies exist in external skull and postcranial morphology (Gao and Zhou, 1995a, b, c; Jefferson, 2002). The darkness and ontogenetic change of color pattern vary among subspecies. *N. p. phocaenoides* is born with lighter color and darkens with growth to be almost black in adults. However, neonates of *N. p. asiaorientalis* and *N. p. sunameri* are black to dark gray and get lighter with age (Kasuya, 1999; Jefferson and Hung, 2004). The border between the range of *N. p. phocaenoides* and *N. p. sunameri* seems to be around the Taiwan Strait, where both the subspecies have been observed, but there is still no evidence of genetic isolation (Jefferson, 2002). The border between the less differentiated *N. p. asiaorientalis* and *N. p. sunameri* may be around the mouth of the Yangtze River, but this is less certain.

Five local populations are clearly identified in Japanese waters based on skull morphology and mtDNA variability (Yoshida, 2002). mtDNA analysis also revealed population differentiation in the Yangtze River (Zheng et al., 2005). Similarly, finless porpoises are considered to likely live in relatively small isolated local populations in other areas.

The only known fossil of *Neophocaena* is a skull from the bottom of the Seto Inland Sea, Japan. It is considered to be from the late Pleistocene and resembles the skull of recent *N. p. sunameri* (Kimura and Hasegawa, 2005). There are conflicting views of whether the finless porpoise is the most primitive or derived member among the phocoenids. A genetic study suggested the species is the oldest lineage in the family (Jefferson and Hung, 2004).

Finless Porpoise

Neophocaena phocaenoides

MASAO AMANO

I. Characteristics and Taxonomy

The finless porpoise is a small phocoenid cetacean lacking a dorsal fin (Fig. 1). Instead of the dorsal fin, a ridge sprinkled with horny tubercles runs down the middle of the back. Although these tubercles seem to be homologous to tubercles on the leading edge of the dorsal fin of other phocoenids, their function is not obvious. It is plausible that they serve as a sensory organ or organ for mutual contact, as many nerve endings occur in the tubercles (Kasuya, 1999). The species has a rounded head without an apparent beak. Its color is uniformly dark to pale gray and somewhat lighter on the ventral side. The teeth are spatulate in shape like those of most other porpoises of the family phocoenidae.

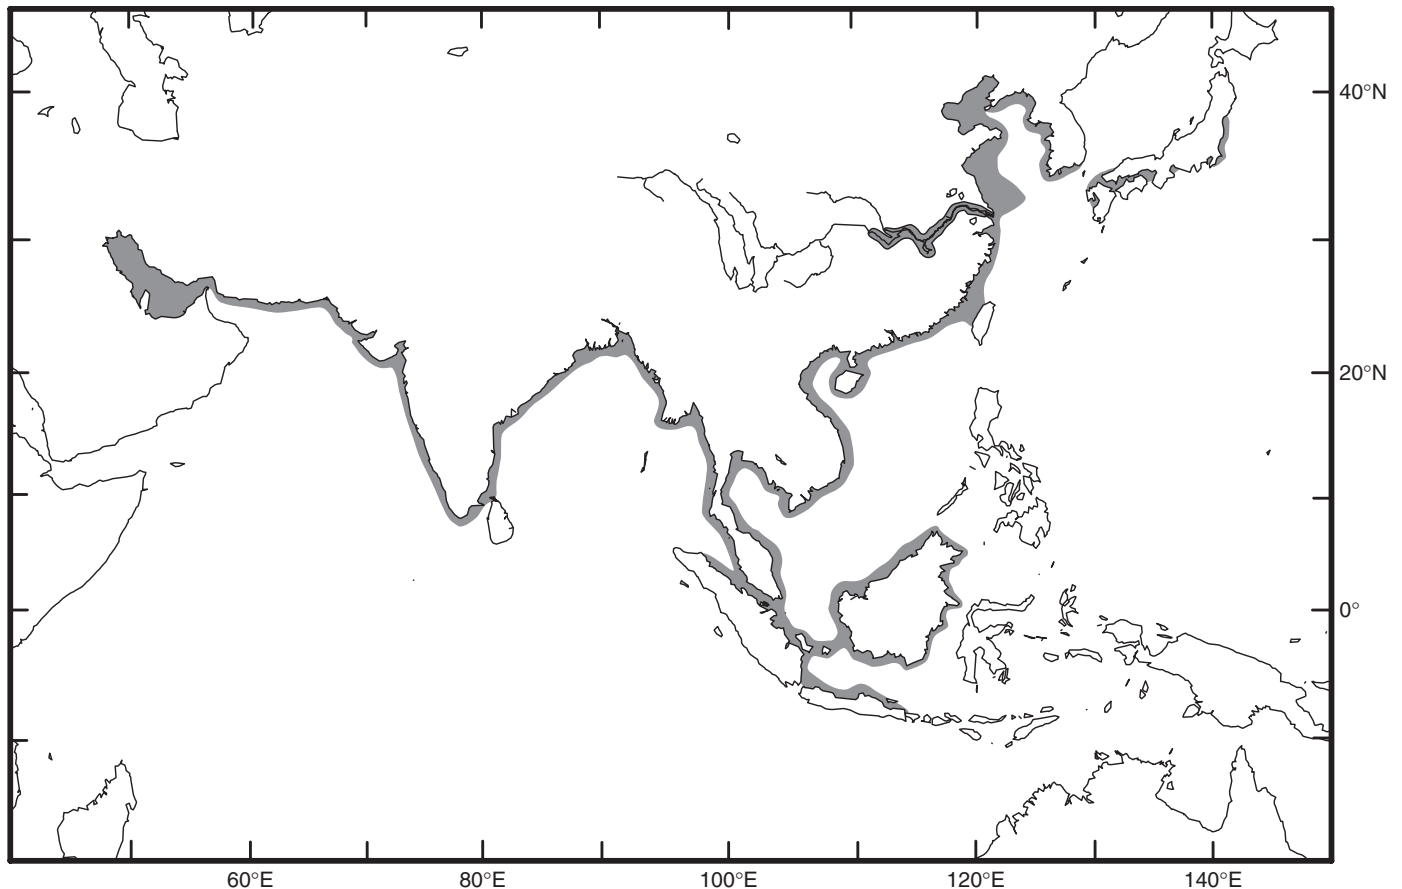

Figure 2 Distributional range of the finless porpoise.

II. Distribution and Abundance

Finless porpoises inhabit shallow coastal waters and some rivers in the Indo-Pacific region (Fig. 2). Their range is from the Persian Gulf in the west and along the coasts of India, Indochina Peninsula, China, and Korea to northern Japan. The southernmost limit of the range is the northern coast of Java. In the Yangtze River, finless porpoises are found to about 1600 km upstream from the sea (Jefferson and Hung, 2004).

Total abundance of the finless porpoise is unknown. There are some estimates for several local populations (Biodiversity Center, 2002; IWC, 2006): about 19,000 in Japanese waters (total of 5 populations), about 27,000 off the western coast of South Korea (IWC, 2006), and at least 220 in Hong Kong and adjacent waters. The number inhabiting the Yangtze River is considered to be less than 2000 (Xia *et al.*, 2005).

III. Ecology

Finless porpoises prefer the mangrove zone in tropical waters. They are also found in estuaries and large river systems such as the Indus, Ganges, and Yangtze Rivers. In Japan, habitat of the finless porpoise is strictly defined by depth (<50 m) and sandy or soft bottom (Shirakihara *et al.*, 1992).

Finless porpoises feed on various prey species from surface to bottom dwellers, including schooling fishes, squids, octopuses, shrimps, and prawns, and they are considered to be opportunistic feeders (Jefferson and Hung, 2004). The known predators apart from

humans are killer whales (*Orcinus orca*) and large sharks, including the great white shark (Jefferson and Hung, 2004).

IV. Behavior and Physiology

Finless porpoises are observed year-round in most localities, but seasonal fluctuation in density suggesting some movements has been reported in some areas.

Finless porpoises rarely form large schools and are usually found in pairs. Kasuya (1999) concluded that a mother and calf or an adult pair is the basic social unit. Finless porpoises usually swim quietly and do not leap or make splashes. They tend to avoid vessels and do not bow ride. However, they can be easily observed in some areas, and commercial porpoise-watching trips are conducted in a few places in Japan.

V. Life History

Finless porpoises grow to around 170 cm in length and 70 kg in weight, but animals over 200 cm and 100 kg have been reported. Males grow slightly larger than females. Size seems to be different geographically and generally greater in the northern population.

Information on reproduction is limited to that of porpoises from Chinese and Japanese waters (Kasuya, 1999; Jefferson *et al.*, 2002). The oldest specimen was a 33-year-old female from the South China Sea, but most aged specimens were younger than 25 years in all areas. Age at sexual maturation is similar among areas and ranged from 4 to 6 years in both sexes. The gestation period is estimated at around 11

months. The peak of the calving season is different among localities: October–January in the South China Sea, April–May in the Yangtze River, November–December and March in western Kyushu, and April–June in the Seto Inland Sea and on the Pacific coast of Japan. Females are thought to calve every 2 years. The lactation period is estimated to be about 7 months, which is short as in other phocoenids.

VI. Interaction with Humans

Because of its nearshore habitat, the finless porpoise tends to be threatened by many human activities. Although there is no fishery that takes finless porpoises directly, incidental catches mainly by gill-nets occur throughout its range (Jefferson and Hung, 2004; IWC, 2006). Habitat degradation by land reclamation and deforestation of mangrove areas are also serious problems. It has been suggested that intensive sand dredging is responsible for severe decline of the species in the central-eastern Seto Inland Sea, Japan (Kasuya *et al.*, 2002; Shirakihara *et al.*, 2007). Moreover, very high levels of toxic contaminants, including organochlorine and butyltin compounds and heavy metals, have been reported in finless porpoises from eastern Asia (Jefferson and Hung, 2004; Ramu *et al.*, 2005). In the Yangtze, the combined threats of bycatches, habitat degradation including heavy traffic and construction, and pollution, which in concert caused extinction of the baiji, are also suspected to have contributed to the recent significant decline of the finless porpoise in the river (Wang *et al.*, 2005).

The distribution seems to be separated into relatively small local subpopulations by unsuitable habitats of deep water or rocky bottoms. Such local subpopulations are easily depleted, contributing to the decline of genetic diversity of the larger regional metapopulations.

Despite these concerns, our ability to assess the current status and population trends of the species is still very limited, especially for the populations in the Indian Ocean and the southeast Asia.

Fisheries, Interference With

DAGMAR FERTL

Marine mammal interactions with fisheries may be characterized as biological (ecological) or operational (IUCN, 1981). This section focuses on operational interactions. “Operational” interactions are those in which marine mammals take fish from fishing operations (depredation), disturb fishing, or damage fishing gear. Interference with fisheries might negatively affect fisheries by resulting in loss of bait, damage to fishing gear, decreased catches, reduced fish weight (in the case of fish farms), or increased time spent during fishing operations. Difficult to assess is hidden damage, i.e., the amount of fish wholly removed from nets without a trace and the catch losses due to the presence of marine mammals.

I. Depredation

Evidence from some fisheries shows that cetaceans, pinnipeds, sirenians, and even the sea otter (*Enhydra lutris*) are attracted to fishing gear and attempt to remove bait and catches during

commercial and recreational fisheries. Read (2005) noted that more information is needed about depredation in artisanal fisheries. Marine mammals also feed at mariculture (i.e., fish farm) enclosures and fish aggregated at natural and artificial constraints in river systems, such as falls or fish ladders. Gear likely to have the most interactions with (and interference from) marine mammals are purse seines, trawls, gill nets, traps, and hooks and lines. In fact, baited longlines have been described as “loaded lunchboxes” and shrimp trawlers as “smorgasbords”.

Fishing operations concentrate food of interest, decreasing energy expenditure associated with foraging by marine mammals. Nursing females may especially benefit from this feeding technique. Fishing operations may permit marine mammals to select food of higher caloric value. Some food niches, not otherwise available to some marine mammals, may be opened up, making prey easier to access that might be normally more difficult (e.g., because of depth required to dive).

Feeding in association with fisheries is likely a learned behavior, with increasingly more individual marine mammals seeking out fishing gear for an easy meal. Very often, acoustic aspects of the fishing activity (e.g., cavitation noise from changes in the propeller speed of ship engines) act as a “dinner bell.” As noted by Königson *et al.* (2006), an earlier foraging experience could encourage individuals to return to feeding grounds that were previously successful. It has been suggested that this type of feeding behavior is also passed from generation to generation by observation and participation (Fertl and Leatherwood, 1997).

Marine mammals may cause abrasions and wounds to fish during unsuccessful capture attempts or while “playing” with fish during fishing operations, even when they are satiated. It is not known how the number of injured fish relates to the total number killed. Marine mammals may take portions of fish or the entire fish, rendering them nonmarketable. Most estimates of loss vary between <1% and 8% of the total catch. There are exceptions, such as in some longline and salmon gill net fisheries. Various species of cetaceans (e.g., killer whale [*Orcinus orca*], false killer whale [*Pseudorca crassidens*], sperm whale [*Physeter macrocephalus*], pilot whale [*Globicephala* spp.]) and pinnipeds (e.g., South American sea lion [*Otaria flavescens*] and California sea lion [*Zalophus californianus*]) depredate longline-caught fish (Gilman *et al.*, 2006). Flesh may be torn from hooked fishes or fish may be removed completely (often leaving only the head or lips) as lines are hauled back to the fishing vessel. Estimates of lost catch per attack by killer whales on longlines off Alaska range from 25% to 100%; of the catch (Yano and Dahleim, 1995), while world-wide catch rate reductions of only 1–3% are reported for sperm whales with longline fisheries (Sigler *et al.*, 2008). Depredation rates may be related to a variety of factors, including low availability of fish in the area at the time or presence of particular individual marine mammals causing problems. Longline fishermen off Alaska report that sperm whale depredation is more common when fishery offal (discarded heads and internal organs) is unavailable (Sigler *et al.*, 2008).

II. Disturbance

When the mere presence (i.e., attendance) of a marine mammal(s) can cause catches to be reduced and time wasted, fishing operations are disturbed. Cetaceans and pinnipeds may disturb fishing activity by causing fish shoals to disperse or sound (dive rapidly); and thus escape being trapped by the net. Marine mammals might also cause a large decrease in prey abundance in a fishing area; e.g., during acoustic surveys of Spanish sardine (*Sardinella aurita*) in

Venezuela, Fréon and Misund (1999) observed that fish disappeared when dolphins arrived in the area. In the case of fish farms, predators may attack and harass fish through the pen walls, thus stressing, scarring, and wounding the fish and resulting in lower product quality through reduced value or reduced fish weight.

Disturbance of fishing activities even occurs in dolphin–human fishing cooperatives, such as one in Brazil, with “bad” dolphins (*ruim* in Portuguese) occasionally interfering with the fishing by dispersing fish and damaging nets and netted fish (Pryor *et al.*, 1990).

Once a marine mammal has located fishing gear, fishermen might have to move to another site or the marine mammal would continue to take substantial amounts of the catch. This disturbance results in cost to the fishermen because they have to move and relocate to fish.

Fishing operations may be impeded in other ways. Seals may be caught in the fish pump (used to remove fish from the net) and die. Fishing operations may be disrupted if live seals are brought aboard in nets or otherwise make their way onto fishing boats, especially if they manage to get below deck. Crew injuries may result from direct interactions with seals, including people being bitten and nylon burns or cut fingers from tug-of-wars between a fisherman and a seal.

III. Gear Damage

When a marine mammal attempts to remove fishery catches entangled in a net’s mesh or hooked on a line, holes may be torn or hooks removed. Marine mammals may become incidentally entangled during these encounters; netting and rope may be lost in trying to free live or dead animals. Damaged gear may not fish as efficiently, and a loss of catch may result. The visible gear damage such as holes and tears in the nets is only a small part of the total economic losses. Indirect expenses include costs for new material, time for repairing fishing gear and reduction in gear durability, increased time and fuel consumption due to emptying the gear more often should also be considered. Further, repairs may be costly, and the time spent repairing fishing gear may be significant in a seasonal fishery where most of the catch is taken in a period of a few weeks. Additionally, animals become injured, with fish hooks in their mouths or dorsal fin disfigurements that occur during the struggle by the animal to free itself (Baird and Gorgone, 2005).

There are numerous examples of marine mammals (particularly pinnipeds) damaging fishing gear; there are more reports of damage to static gear (e.g., fish traps, gill nets, longlines) than moving gear (e.g., trawls, purse seines). Gear damage may also result from accidental collision with fishing gear. For example, humpback whales (*Megaptera novaeangliae*) in Newfoundland in the 1970s caused several hundred thousand dollars of damage annually as a result of colliding with cod traps while feeding on capelin (*Mallosus villosus*).

Cetaceans and pinnipeds are often blamed for damage to gear or catches that should actually sometimes be attributed to other predators. For example, bottlenose dolphins (*Tursiops truncatus*) often are blamed for damage to trawl and gill nets when sharks are often the real culprits. Killer whales and sharks are both known to feed on longline catches off Brazil (Dalla Rossa and Secchi, 2007). Although South African fur seals (*Arctocephalus australis*) are blamed for taking lobsters from traps, clear evidence shows that octopus are to be blamed (Wickens, 1996). Birds may also be seen taking bait off hooks as they are cast into the water during line fishing.

A. Pinniped Interference with Fisheries

Seals, sea lions, and fur seals take caught fish from nets, hooks, trawls, seines (Fig. 1), or traps, and attack fish that are being raised

Figure 1 A gray seal (*Halichoerus grypus*) raiding a gillnet with caught herring (*Clupea spp.*) in the northern Baltic Sea. About 200 herring were set on the net, and 20 min later the net was empty. Photo by Sara Königson.

in aquaculture pens. Pinnipeds may also be attracted by discarded bycatch; e.g., Nitta and Henderson (1993) observed a Hawaiian monk seal (*Monachus schauinslandi*) feeding on discarded fish. The impact of pinnipeds on fisheries is of particular concern through depredation and gear damage during gill netting on the west coasts of North America, Japan, Britain, Scandinavia, and Chile; through depredation, net damage, and disturbance at fish farms on the west coast of North America, Chile, and the United Kingdom (Nash *et al.*, 2000), and depredation from trawls, depredation and gear loss from hand lines (Mejyer *et al.*, 1992), and disturbance of purse seining in South Africa (Wickens, 1995). Estimates of the consumption by seals from fishing operations in South Africa show it to be a minimal percentage of fishery catches and a small proportion of the total predation by seals (Mejyer *et al.*, 1992). Preliminary calculations of overall economic losses resulting from these seals' interference show this to be small (0.3%) in comparison with the wholesale value of the catches.

Some pinnipeds converge on areas where anadromous fish stocks aggregate or where the movements of fish are constrained naturally or artificially (bottleneck or "choke points" where salmonids aggregate in response to human-made structures or natural river physiography, such as fish ladders or below falls, respectively). Seals may be attracted to a farm by escaped fish and oil slicks from feed, or increased wild fish outside the pens. The most thoroughly studied pinniped/salmonid conflict is California sea lion predation on winter steelhead (*Oncorhynchus mykiss*) at Washington State's Ballard Locks. The severe decline in salmon is considered primarily a direct result of human activities (Fraker and Mate, 1999); however, much concern has been voiced that the expanding populations of seals and sea lions may be causing a further decline (or impeding the recovery) of various salmon runs in the Pacific Northwest.

B. Cetacean Interference with Fisheries

The following is not meant to serve as a comprehensive list, but illustrates some of the better known cetacean–fishery interactions. Bottlenose dolphins and “blackfish” (e.g., killer whales, false killer whales, pilot whales) are notorious fish stealers, and there are widespread reports of catch and gear damage by these species. Cetaceans may feed directly on a fishery's target species, such as killer whales and sperm whales feeding on sablefish (black cod, *Anoplopoma fimbria*) in the North Pacific longline fishery (Yano and Dahlheim, 1995). Interactions between sperm whales and killer whales with longline fisheries (Fig. 2) also have been well documented in the Southern Ocean (in particular, South Georgia, the Kerguelen Islands, and Southern Chile). Such interactions include entanglement in gear, following vessels for days, and observed feeding off gear. Killer whales also feed in association with bottom set fisheries off eastern Russia, interfere with the tuna fishery in the Strait of Gibraltar, and even take salmon off lines in recreational fisheries. Zollett and Read (2006) documented depredation by bottlenose dolphins in the Florida king mackerel (*Scomberomorus cavalla*) troll fishery. Long-finned pilot whales (*Globicephala melas*) in Newfoundland frequent traps to remove the target species squid. Bottlenose dolphins in Belize have been observed retrieving fish from local, homemade fish traps. Even baleen whales are known to interact with fisheries, following boats and taking fish from nets; an example is fin whales (*Balaenoptera physalus*) off Archipelago Campano feeding in association with trawls and encircling nets (Mussi *et al.*, 1999). Cetaceans also prey on fish confined in mariculture (i.e., fish farm) enclosures (Kemper *et al.*, 2003; Díaz López, 2006).

Cetaceans may also feed on fish that are ancillary to the catch, as in the case of bottlenose dolphins feeding on bycatch from trawl fisheries for shrimp and prawn (Fertl and Leatherwood, 1997). Whales and dolphins may interfere with traps or pots (Fig. 3), such as bottlenose dolphins in the Indian River Lagoon in Florida interacting with the crab pot fishery, apparently to steal bait fish (Noke and Odell, 2002).

C. Sirenian Interference with Fisheries

Fishermen in Jamaica and Sierra Leone have complained about damage caused to gill nets by “net robbing” West Indian and West

Figure 3 Bottlenose dolphin (*Tursiops truncatus*) investigating fish trap utilized by the Haitian fishermen, in 70ft of water at the Northwest Point of Navassa National Wildlife Refuge. The trap is an Antillean Z-trap constructed of meshed/woven bamboo (3–4cm mesh size) with wooden cross supports and corners and opposing funnel entrances. Photo by Amy V. Uhrin, NOAA Center for Coastal Fisheries and Habitat Research, Beaufort, North Carolina.

African manatees (*Trichechus manatus* and *T. senegalensis*) (Powell, 1978, Reeves *et al.*, 1988). Manatees have been described as stripping the flesh off fish entangled in gill nets and leaving the bones. Fishermen in Puerto Rico have noticed manatees circling gill nets, picking out fish.

D. Sea Otter Interference with Fisheries

When a sea otter investigates a lobster pot, Dungeness crab trap, or live-fish trap, the individual itself can become trapped and die (Newby, 1975).

E. Toward Solutions

In response to presumed or real interference with fishing operations, fishermen use various means to deter marine mammals in an attempt to safeguard their catches and gear. Lethal methods have been attempted, including shooting at or killing the marine mammal with a variety of objects and methods, sometimes involving poison. Sometimes these practices are illegal. Seals have been persecuted much more intensely than cetaceans. Lethal methods have not been found to be a consistently effective means of keeping pinnipeds from interacting with fishing operations. The idea is that if problems are caused by a few rogue seals, then removal of these animals should eliminate the problem. However, this method removes individuals that are then often replaced by others.

A diversity of nonlethal methods has been attempted (Werner *et al.*, 2006). At the most basic level, fishermen throw stones or bait to distract the predator. Other methods used include firing gunshots (nonlethal and lethal), using explosives (such as firecrackers and seal bombs), acoustic deterrent devices (ADDs), gear modifications, gear switching, physical barriers (nets), vessel chase (hazing), tactile

harassment (e.g., rubber bullets), visual signals, and taste aversion (baiting fish using a chemical to induce vomiting).

The most commonly used deterrents are ADDs that have been widely used to attempt to reduce depredation on fish. These include pingers, acoustic harassment devices (AHDs), passive acoustic devices, predator sounds, and banging pipes. Marine mammals are difficult to deter by acoustic methods, and the acoustic signal of the AHDs over time can be a “dinner bell” effect, alerting animals to the presence of a fish pen or trap. New high-intensity AHDs appear to be more effective but have a greater potential for causing hearing damage, as well as affecting nontarget species. In some cases, a problem may be eased by changing the location of the fishing effort.

The most successful mitigation measures appear to be changes to fishing gears or fishing methods where a particular change may reduce or exclude problems, thereby resulting in a permanent solution. Implementation of anti-predator cages around fish farms, physical barriers at the entrance of fish ladders, and the change to synthetic twine in gill nets are some examples. Other measures include exclusion devices in nets to mitigate bycatch (Suuronen *et al.*, 2006). The Southeast Alaska Sperm Whale Avoidance Project (SEASWAP) is testing changes to the longline fishery, such as circle hauls that minimize engine cycling (which as noted earlier, appears to attract whales), and changing the time of year the fishermen deploy their gear.

Capture and relocation of “problem” pinnipeds has proven ineffective, with the animals returning to the problem area. California sea lions have been captured at the Ballard Locks and placed in temporary captivity and released after the steelhead run. This proved ineffective in the long term, as did permanent captivity, which eliminates the “problem” sea lions without having to kill them but is limited by the availability of facilities that can hold the sea lions and the costs involved in capturing and holding the animals.

Past efforts have been unsuccessful in finding effective, long-term, nonlethal approaches to eliminating or reducing marine mammal–fishery conflicts. Some nonlethal deterrence measures appear to be effective initially or effective on “new” animals but become ineffective over time or when used on “new” animals in the presence of “repeat” animals that do not react to deterrence. Further research on the development of new technologies and techniques is needed.

Fishing Industry, Effects Of

SIMON NORTHRIDGE

The fishing industry probably represents the single area of human activity that has the most profound effects on marine mammals. These effects can be categorized broadly as "operational effects" and "biological effects." Operational effects include the accidental capture of marine mammals in fishing gear, a problem that has brought about the extinction of one cetacean species in recent years, and threatens several other populations too. Although accidental capture usually results in the death of the animal concerned, there are also instances where marine mammals are injured or affected in some way during fishing operations so that their survival probability or reproductive potential is compromised. Not all operational interactions have a negative effect on marine mammals. In some cases the effect of the fishing operations may be positive for the marine mammal where, e.g., they feed on discarded fish or take fish that have been caught before these can be retrieved onto the fishing vessel. In a few cases there are even mutually beneficial collaborative efforts between fishermen and marine mammals, with marine mammals assisting in fish capture and being rewarded with a portion of the catch.

Biological effects encompass all the consequences of the large-scale removal of animal biomass from the marine ecosystem through fishing activities, including, although not limited to, possible competition for resources between fisheries and marine mammals. Competitive interactions can be direct or indirect. Direct competition occurs where the mammal and the fishery are both taking the same kind of fish. Indirect competition includes situations where the fishery and the marine mammal population are taking two different types of fish, but where the removal of one of these fish influences the availability of the other through some competitive or predatory link. Indirect interactions need not be competitive, and sometimes the effect of the fishing industry may be to increase the abundance of marine mammal prey items through indirect ecological interactions. Sometimes fisheries may physically alter a habitat and so change the composition and abundance of the fish community to the detriment or advantage of marine mammals and other predators.

Operational effects cover interactions between fisheries and marine mammals that relate to the mechanical process of fishing. Several fisheries have well-documented problems with unwanted entrapment of marine mammals. In some cases the numbers of animals involved are large enough to seriously endanger the marine mammal populations concerned; in one case (baiji, *Lipotes vexillifer*) a species has been driven to extinction, largely due to fishery interactions, while it is feared the same fate awaits the vaquita (*Phocoena sinus*). Examples considered cover gill net fisheries, pelagic trawls, and purse seine fisheries.

Gill nets are a widely used fishing gear with a long history of use in many parts of the world. Their use has become more widespread since the 1950s or 1960s with the introduction of nylon as a netting material during the 1950s. They represent a fuel-efficient means of fishing and, when set on the seabed, provide a fishing method that can be used to exploit areas of rough ground that cannot be fished easily by towed gear. When used in surface waters, they are usually left to drift with the wind and tide and are effective in targeting

dispersed fish schools. They are usually left to fish unattended, and fishing times may range from a few hours to several weeks, but 24h would be a typical soak time. It has been suggested that in contrast to the traditional nets that were made of cotton and other natural fibers, the use of stronger nylon twines has contributed to an increased rate of marine mammal entanglement. This, coupled with a dramatic increase in their usage since the 1950s, has led to some serious conservation and animal welfare problems with respect to marine mammals.

Small cetaceans, such as porpoises (Phocoenidae), and some species of seals seem especially prone to becoming entangled in gill nets. In some instances, this does not present a conservation problem. In Britain, e.g., gray seals *Halichoerus grypus* are frequently caught and drowned accidentally in gill net and tangle net fisheries (Fig. 1). In a seal tagging program run by the Sea Mammal Research Unit in the North Sea, over 20,000 gray seals have been tagged soon after birth since the 1950s. Returns of tags by fishermen indicate that at least 10% of known subsequent deaths are because of net entanglement, and at least 1.5% of all pups tagged were recovered dead in fishing nets. Tag loss over the months and years after tagging and failure to return tags from entangled seals are two reasons why this latter figure must be an underestimate of total mortality rates due to entanglement. Despite such mortality in fishing gear, gray seal numbers have more than doubled in British waters in the past 30 years.

In other cases, accidental catches in fishing gear *can* lead to conservation problems. An isolated population of Hector's dolphin (*Cephalorhynchus hectori*) that lives off the west coast of the North Island of New Zealand now numbers around 100 individuals, and bycatches in gillnets continue to occur despite a ban on gillnetting in part of the range of these animals. There are concerns that this population may be driven to extinction before long (Slooten *et al.*, 2006; Slooten, 2007)

A porpoise species that is endemic to Mexico, the vaquita, is threatened with extinction through accidental catches in gill nets. In this case, the species has a restricted range, in the upper Gulf

of California in Mexico, where there are large numbers of small boats using gill nets and tangle nets to catch a wide variety of fishes. Although the population is thought to be less than 200, one estimate suggests that at least 40 animals drown in gill nets every year. This is clearly an unsustainable rate of mortality and this species' future therefore seems bleak (Rojas-Bracho, Reeves & Jaramillo-Legorreta, 2006).

The North Atlantic right whale (*Eubalaena glacialis*), once one of the more commonly seen whales in the North Atlantic, is now reduced to a population of around 300 animals in that area. The population is declining and it is estimated that at current rates it will be extinct within 200 years (Caswell, Fujiwara & Brault, 1999). Most of this population migrate along the eastern seaboard of the United States every year, where they too are vulnerable to entanglement in gill nets and also in lobster pot lines. Lobster pots are usually set in "strings" of several pots joined by ropes, with each end of the string marked by a surface-floating buoy attached by a rope to the pot string on the seabed. Although only three right whale deaths have been attributed directly to this cause since 1970, evidence of entanglement-related scars on live animals has been identified in around 60% of the population. It has been suggested that some entangled whales die and are dragged to the seabed without being recovered. Others may suffer injuries that lead to subsequent death by other causes, while at least two right whales, encumbered with fishing gear, have been fatally wounded in collisions with ships. These high levels of entanglement may therefore be a major factor of the decline in this population of right whales, even though the vast majority of the entanglements are not immediately fatal.

Marine mammal entanglements in gill nets may occur for a variety of possible reasons. Some people maintain that the animals do not detect the netting and swim into it before realizing it is there. It may be that the animals do detect the netting but that they do not recognize it as something dangerous and attempt to swim through it as though it were some natural obstacle, such as seaweed. Another possibility is that the animals are fully aware of the netting, and the danger it poses, but they simply make mistakes and become entangled while feeding close to the net due to inattention.

There has been much attention given to means of reducing the numbers of marine mammals that become caught in gill nets and tangle nets because of the conservation problems that such entanglements represent. So far, the only effective means of reducing bycatch that has been found is the use of pingers. Pingers are small battery-powered devices that emit a brief high-pitched noise every few seconds. They are attached to the float line or lead line of the gill net and are of similar size and shape as a net float so as to avoid tangling the net when it is being set or hauled. They are effective in reducing the entanglement rates of several marine mammal species in gill nets, although exactly why they work is not clear. They have been developed in collaboration with the fishing industry and are currently being used in several major gill net fisheries around the world.

Pelagic trawling is another fishing method that has increased in recent decades. Trawling dates back for more than a century and initially performed with low-opening nets dragged along the seabed. As various aspects of technology have improved, so trawling techniques have been refined, and trawls have been used to catch fish above the seabed and even near the surface of the water. The development in the 1950s of acoustic fish finders and net sounders that enable the skipper to control the position of the net with respect to that of a fish school has been a key technological development.

Initially, during the 1950s, pelagic trawls were used to catch fish like herring that form dense schools. Typical nets might have had an

opening of around 2000 m², perhaps 50-m wide and 40-m high. Since then, both nets and trawlers have grown in size, as other pelagic fish species have been targeted, some of which may form much more dispersed schools. Net openings at least 10 times as great are now common, with horizontal and vertical openings of up to 200 m. There are numerous records of marine mammals becoming caught in pelagic trawls, sometimes in large enough numbers to present a conservation problem, although the nature and scale of the problem remain obscure in most fishing areas.

Hooker's sea lion (*Phocarctos hookeri*) is endemic to the sub-Antarctic islands of New Zealand, around which a pelagic trawl fishery for squid developed in the 1980s. Observations of fishing activity between 1988 and 1995 suggested annual mortality of between 20 and 140 Hooker's sea lions, at a rate of about 1 animal every 340 trawl tows. The total population of this species was only around 13,000 animals in the mid-1990s, and the accidental catches were therefore considered significant. There is currently a quota system in operation in this fishery to limit accidental catches (Wilkinson, Burgess & Cawthorn, 2003).

Dolphins have also been reported caught in pelagic trawl fisheries in several areas, including the United States, Europe, and New Zealand. The capture of dolphins in pelagic trawls appears to be very variable, depending on the area and probably the type of trawl being used. In one US pair-trawl fishery, common bottlenose (*Tursiops truncatus*), short-beaked common (*Delphinus delphis*), and Risso's (*Grampus griseus*) dolphins were observed accidentally caught in an average of one in every five trawl tows, although this fishery has subsequently been closed. In one New Zealand midwater trawl fishery, rates of common and bottlenose dolphin catches averaged about one animal in every nine trawl tows observed. In European Atlantic waters, one study recorded common and Atlantic white-sided dolphins (*Lagenorhynchus acutus*) caught in sea bass (*Dicentrarchus labrax*) and albacore tuna (*Thunnus alalunga*) pelagic trawl fisheries at rates of one in every trawl tow to 1 in every 15 trawl tows. In other pelagic trawl fisheries for anchovy (*Engraulus encrasicolus*), pilchard (*Sardina pilchardus*), and mackerel (*Scomber scombrus*) in the same area, no dolphin deaths were recorded.

The reasons why some pelagic trawl fisheries have relatively high levels of accidental dolphin catches and others have low or zero levels are not yet clear. It is possible that such factors as the dimensions of the net, the towing speed and duration, and the foraging activity of dolphins around the nets could all be important. There are several accounts of dolphins taking advantage of trawling activity by feeding on fish escaping through the meshes of the trawl. Such behavior may increase chances of dolphin entanglement, but these interactions remain relatively poorly investigated.

As with gill nets and pelagic trawls, technical innovations during the 1950s enabled the development and expansion of purse seine fisheries around the world. Purse seines are used to catch pelagic fish and work by first encircling a school of fish with a long net, hanging from the surface down to depths sometimes of several hundred meters. The bottom edge of the net can be pursed so as to prevent any escape under the netting once it has been set in a circle. The major technical innovations that allowed this fishery to develop globally were the introduction of nylon as a netting material, enabling much larger and stronger nets to be constructed, and the development of the power block, with which large amounts of netting could be hoisted up out of the water.

American fishermen working in the eastern tropical Pacific Ocean during the late 1950s worked out a way of using dolphin schools in conjunction with purse seine nets to catch yellowfin tuna (*Thunnus*

albacares). They discovered that tuna would aggregate under dolphin schools, even if the dolphins were chased. This meant that by using speedboats to corral dolphins they could exploit this behavioral characteristic of the fish to round up tuna schools that would otherwise be invisible below the surface. By corralling a dolphin school and setting a purse seine net around it, a school of tuna would normally also be encircled. The dolphins were not intentionally killed in this activity, but many died as nets were being hauled in and fish were being brought on board. The scale of the fishery meant that in some years hundreds of thousands of dolphins drowned as a result of this fishing activity.

The eastern spinner dolphin subspecies (*Stenella longirostris orientalis*) was depleted to 44% of its original pre-1959 level, whereas the northeastern offshore stock of the pantropical spotted dolphin stock (*Stenella attenuata*) was reduced to about 20% of its pre-exploitation level. From the 1970s onward, in the face of public concerns over the issue, the fishery developed and implemented means of reducing this toll. By encouraging the dolphins out of the net before trying to remove the fish, annual mortality was reduced to a few thousand per year. Despite this, populations of these two species do not appear to have recovered, and it has been suggested that there may be additional, sublethal, impacts of the fishing technique that might be hampering population recovery (Wade *et al.*, 2007).

Normally, interactions between marine mammals and hook and line fisheries have few negative impacts on the marine mammals. In the case of the baiji or Chinese river dolphin (*Lipotes vexillifer*), however, the situation was different. The baiji was endemic to the Yangtze River system in China and is now thought to be extinct after years in which the population was in decline. One of the most important causes of mortality is animals becoming ensnared in "rolling hooks." This type of fishing involves using many sharp unbaited hooks on a line set on the bottom of the river to snag bottom-dwelling fish. Dolphins foraging near such hooks sometimes become snagged too, occasionally causing death. Among the recovered river dolphin carcasses, over 50% of the dolphins had died as a result of such entanglements or other fishing-related injuries (Turvey *et al.*, 2007).

Not all operational interactions have a negative impact on marine mammals. In some cases marine mammals are able to exploit fishing activities to their own advantage. In several parts of the world cetaceans, often killer whales (*Orcinus orca*) and false killer whales (*Pseudorca crassidens*), have been reported to remove fish from hooks during longline fishing operations. This can make fishing in certain areas with longlines unprofitable, and many methods have been tried to eliminate such behavior (Donoghue *et al.*, 2003). There has been remarkably little success reported in trying to prevent such predation, and sometimes the boats involved have had to switch gear or move to other areas.

Other types of fishery where marine mammals actively benefit from fishing activities include trawling, purse seining, and lobster potting. Several species, including bottlenose and white-beaked dolphins (*Lagenorhynchus albirostris*), gray seals, and South African fur seals (*Arctocephalus pusillus*), have been reported to remove fish from fishing gear (Fertl and Leatherwood, 1997). Dolphins typically take undersized fish as they come through the cod end of a trawl. Fur seals swim into purse seine nets by climbing over the float line once a school of fish has been encircled and make a meal of the trapped fish. Gray seals have been observed removing bait from baited lobster pots. There are numerous other examples of marine mammals taking advantage of fishing activities in similar ways, often taking marketable fish, which may provoke considerable resentment on the part of the fishing crews.

In a few places in the world, including Burma (Myanmar), Mauritania, and Brazil, fishermen and dolphins have learned to collaborate in the capture of fish, usually by dolphins driving fish toward fishermen waiting with nets. Some of the catch is then given back to the dolphins as a reward (Busnel, 1973; Thien, 1977; Pryor *et al.*, 1990).

The more widespread but less well-understood interactions between fisheries and marine mammals are ecosystem-level effects, where fisheries may cause fundamental changes to the species composition of the marine environment (see Competition with Fisheries).

Every year the fishing industry removes about 80–90 million tons of fish and other marine organisms from the world's oceans. Another 7–8 million tons of unwanted animal biomass may be caught but discarded prior to landing every year. It has been suggested that fisheries may account for 8% of the global primary productivity of the oceans, and in some of the more heavily exploited areas as much as 35% of local primary productivity may be required to sustain fishery catch levels. It is clear that such levels of fishing activity are likely to have profound effects on marine ecosystems, especially on the top predators, such as marine mammals, as fish populations are reduced and restructured on a very large scale. Therefore in theory, fisheries may compete with marine mammals by depleting their food.

There is of course another side to this concern. Whereas fisheries may cause a depletion of the food resource for marine mammals, marine mammals are also accused of consuming large amounts of fish, thereby reducing the amount of food available for people to eat (Tamura, 2003). As a result of this latter concern, in some parts of the world there are frequent calls for marine mammals to be culled as unwanted competitors.

In both cases, however, it has proved extremely difficult to demonstrate any clear competitive interaction between marine mammals and fisheries. This is mainly because of the complexities of the marine ecosystem, which make it very hard to predict how changes in one fish stock will affect either their predators or their prey. Some brief examples will illustrate this point.

The North Sea and adjacent areas are among the most heavily fished sea areas of the world, with annual landings of all species of over 2 million metric tons. One of the most numerous marine mammals in this region is the gray seal (*Halichoerus grypus*), which feeds on a range of fish species, including Atlantic cod, haddock, whiting, saithe, sand eels, sole, plaice, Atlantic herring, and sprats (*Gadus morhua*, *Melanogrammus aeglefinus*, *Merlangius merlangus*, *Pollachius virens*, *Ammodytes* spp., *Solea solea*, *Pleuronectes platessa*, *Clupea harengus*, and *Sprattus sprattus*). Fisheries also target all of these species, and most of the fish stocks concerned are designated as fully exploited or overexploited. Despite these facts, the gray seal population has more than doubled in size since the early 1980s to somewhere between 130,000 and 200,000 individuals during which time fishing pressure in the region has been intense. There are at least two good reasons for this apparent paradox. First, the most important food of the gray seal is the sand eel (primarily *Ammodytes marinus*) or “sand lance” in the United States. The sand eel fishery was taking over 1 million metric tons of sand eels per year in the late 1990s and was the single largest fishery in terms of the amount landed in the North Sea. Despite this fishing pressure, sand eels were extremely abundant and appeared to have increased in abundance since the 1950s. The proposed reason for this is that sand eel numbers have increased in response to massive declines in the abundance of Atlantic herring and mackerel as a result of intense herring and mackerel fishing in the 1960s and 1970s. Paradoxically,

therefore, heavy fishing pressure may have led to an increase in a less commercially valuable species that is a major food of gray seals.

Alongside this, although gray seals and fisheries consume other more marketable species in common, gray seals typically consume smaller-sized individuals of around 15–20 cm in length, whereas commercial fisheries generally concentrate on fish of 30 cm and larger. As commercial fishing pressure intensifies, larger fish have become scarcer, but smaller fish of the same species may not be affected or at least not until there are two few large fish left to generate sufficient eggs to replenish the stock. Indeed, in many of the commercially useful gadid cod family fishes, small fish are consumed in large numbers by bigger fish of the same species. Thus, reduction of the numbers of larger fish may actually boost the numbers of smaller fish (Daan *et al.*, 2005).

It would seem that although gray seals are feeding in an area that is very heavily fished because they exploit a niche that is not directly in competition with fisheries, they are able to thrive. Indeed their population expansion may have been assisted by fishery-induced changes to the species and size structure of the system they inhabit.

Although pinniped numbers may have increased with increasing fishing pressure in one area, this is by no means the norm. In the Gulf of Alaska and the Bering Sea, several pinniped populations have undergone dramatic declines over periods when fishing activity has been increasing. The Pribilof population of Northern fur seals (*Callorhinus ursinus*) declined from 1.25 million animals in 1974 to around 877,000 animals in 1983. At around the same time, harbor seal (*Phoca vitulina richardii*) numbers in the Gulf of Alaska and southeastern Bering Sea declined, with one major haul-out site at Tugidak Island recording an 85% reduction in numbers between 1976 and 1988. Populations of both of these species now seem to be stable or increasing, but numbers of Steller sea lions *Eumetopias jubatus* in western Alaska started to decline in the 1970s and numbers declined until at least 2000. Declines of up to 80% have been recorded in some areas.

The reasons for the declines of these three species over much the same time period are not known, but there is some agreement that food availability, especially for younger animals, seems to be a key issue. For all of these three species, Alaska pollock (*Theragra chalcogramma*) is an important prey item. Alaska pollock is also the target of one of the largest single-species fisheries in the world. The fishery for Alaska pollock increased greatly during the 1970s with over a million tons being landed annually from the eastern Bering Sea alone throughout most of the 1980s and 1990s.

An obvious explanation is that the fishery has deprived the pinnipeds of their food. A closer inspection, however, reveals that the situation is more complex. Overall, the pollock biomass has stayed remarkably buoyant throughout this time period. Numbers of pollock, especially numbers of the larger or older age classes that are the target of the fishery, have not declined until relatively recently. Smaller pollock are consumed by the pinnipeds and are not targeted by the fishery but are cannibalized by the larger fish. Numbers of smaller pollock have declined. Furthermore, for Steller sea lions at least, pollock does not appear to be a favored food item. In other parts of the Steller sea lion's range, such as southeastern Alaska, where the population is not in decline, pollock makes a smaller contribution to the diet, after oily fish such as herring.

It may be that the three pinniped species have all suffered from some change in the relative abundance of their preferred diet items. It has not yet been possible to determine whether such

ecosystem-level changes have been the result of long-term oscillations in oceanographic conditions or whether the pollock fishery has in some way altered the abundance of the pinniped's preferred prey items through the cascading effects of restructuring the pollock population. Controversy still surrounds the issue (Fritz & Hinckley, 2005; Trites *et al.*, 2007), but it serves to illustrate that indirect or competitive interactions between fisheries and marine mammals are always difficult to interpret or understand.

The effects of fisheries on marine mammals do not necessarily have to be mediated through changes in their food supply. Changes to predation on marine mammals could also arise through the effects of fishing. On the Atlantic coast of Canada, also a heavily fished region, gray seal numbers have also been increasing steadily for more than two decades for unknown reasons. One suggested reason has been that fisheries may have greatly reduced the number of large sharks in coastal waters of Atlantic Canada, and as gray seals are known to be subject to predation by certain sharks, such a reduction might be one of the factors contributing to the increase in gray seal numbers (Brodie & Beck, 1983).

Conversely, recent increases in predation on sea otters (*Enhydra lutris*) in the Aleutian Islands have been attributed to behavior changes in killer whales in the region, some of which now seem to be preying more heavily on sea otters than in previous decades. The possibility has been raised that this change in behavior has been caused by a decline in other more favored food items, including sea lions (Springer *et al.*, 2003). Such declines could, as has been suggested earlier, be at least partly due to the effects of fishing on sea lion food items.

All of these hypotheses demonstrate the complex ways in which fishery-induced changes to the marine ecosystem may affect marine mammals, although none has yet proved testable. In almost all cases where some form of competition is perceived, any closer scrutiny of the situation reveals that the complex predatory interrelations of the marine ecosystem make it extremely difficult to predict the results of any proposed management action. The extent to which the fishing industry competes with marine mammals is therefore still very much an open question.

Folklore and Legends

ROCHELLE CONSTANTINE

Folklore and legends are usually traditional stories popularly regarded as the telling of historical events. When in the form of myths, they often involve some form of the supernatural.

They have been with us for thousands of years and, because of this, folklore and legends form the basis of many religious beliefs, value systems, and the way we perceive our place in the world and our interaction with other animals. Man has long revered whales and dolphins in legends. For thousands of years they have been aligned with the gods, mythologized, and celebrated in art.

Some of the earliest legends about dolphins were told in Greek mythology, where it was believed that the sun god Apollo assumed the form of a dolphin when he founded his oracle at Delphi on the edge of Mount Parnassus. The ancient Greeks also believed Orion was carried into the sky riding on the back of a dolphin and was gifted three stars by the gods. This constellation is now known as Orion's Belt.

Many cultures, both ancient and recent, revered dolphins and believed them to be messengers from the gods. The pre-Hellenic Cretans appeared to have honored dolphins, and the ancient Greek, Oppian (*ca.* ad 180), wrote of godly intervention in the dolphins' move to the sea. It was believed that by the devising of Dionysus, the Greek god of wine, dolphins exchanged their life on land for life at sea and took on the form of fishes. Even though they changed form, it was believed that they retained the righteous spirit of man and, because of this, they preserved their human thoughts and deeds. Oppian also wrote of dolphins stranding themselves to die, so mortals could bury them and thereby remember the dolphins' gentle friendship. This was seen as an example of how magnificent dolphins were (McIntyre, 1974). The close alignment with man meant that ancient Greeks held dolphins in extremely high regard and that killing a dolphin was tantamount to killing a person. Both crimes were punishable by death.

Pliny the Elder (AD 23–79), a Roman philosopher, told the story of a peasant boy in the Mediterranean Sea who developed a relationship with a solitary dolphin he named Simo. The legend tells that the boy fed the dolphin and, in return, the dolphin gave him rides across the bay on its back. The boy became ill and died and, according to local knowledge, the dolphin returned to their meeting place for many days until it was believed that it died of a broken heart. Many of the Roman legends involved close human/dolphin contact and may seem fanciful, but in more recent times these bonds between solitary dolphins and humans have been well documented.

Drawings carved into rocks in northern Norway of killer whales (*Orcinus orca*) and other local animals are the earliest known artwork portraying dolphins. These drawings have been estimated at 9000 years old. The most detailed and colorful ancient art work was done by the ancient Greek and Minoan (Crete 3000–1500 BC) people. Dolphins were portrayed on frescoes, mosaic floors, coins, vases, and in sculpture. One of the earliest known pieces is a dolphin fresco painted *ca.* 1600 BC on the wall of the queen's bathroom in the Minoan palace of Knossos. The Dionysus cup dated 540 BC shows the Greek wine god with dolphins and grapes. Coins portraying dolphins have been found in Syracuse, Greece, *ca.* 480 BC, and the Romans also had dolphin coins in Second century BC.

It appears in many legends that the great whales were not necessarily held with such high regard as the dolphins. Whales were typically described as monsters of the sea, their great size to be feared by all. Oppian (*ca.* AD 180) told of the hunt of a whale—its monstrous size and unapproachable limbs a terrible sight to behold. In biblical times, the story of Jonah and the whale was well known, and it is popular even today. The story tells of Jonah who fled from the lord by boat to Tarshish. When the ship was underway, the lord caused a great storm. In fear of their lives, Jonah asked the mariners to cast him into the sea so the lord would again make the sea calm and spare the mariners' lives. Once Jonah was in the sea, however, the lord prepared a "great fish" to swallow him. He was in the belly of the whale for 3 days and 3 nights where he prayed and vowed salvation to the

lord. Upon his vow the lord spoke to the whale and it vomited Jonah onto dry land and spared his life. Although today we know that it is unlikely that this event truly occurred, the story displayed the power of the lord and what he was capable of doing to those who defied him (Unsworth, 1996).

In his novel "Moby Dick" (1851), Herman Melville described a white sperm whale (*Physeter macrocephalus*) of uncommon magnitude, capable of great ferocity, cunning, and malice. Melville's novel summarized the fears of Yankee whalers that the tables would be turned and the whale would become the attacker (Melville, 1851).

Not all folklore portrays whales as fearsome beasts. Maori folklore of the Ngati Porou people tells of their ancestors being carried safely across the Pacific to New Zealand on the back of a whale (Ihimaera, 1987). The Ngai Tahu people consider the sperm whales off the coast of the South Island as taonga (treasures). If a whale strands, prayers are said to return its spirit to Tangaroa, the Maori god of the sea. After this, the lower jawbone is removed for ceremonial carving and placement on the marae, the tribes' traditional meeting grounds.

The north Alaska Inuit people have for over 1000 years relied on whale products for their survival. As with many traditional hunting societies, ceremonies accompany the hunt to ensure good luck, and many hunters take charms or amulets to ensure their luck and safety. Some believe the skull of the dead whale must be returned to the sea to assure the immortality and reincarnation of the whale, thereby protecting future hunting success (Lowenstein, 1994).

The Haida people of northwestern North America tell of an evil ocean people who used killer whales as canoes. The Haida turned a chief into a killer whale, and they believe that this whale now protects them from attacks by the ocean people.

The Tlingit (pronounced "Kling-kit") people of southeastern Alaska immortalize killer whales in their beliefs and folklore. Images of killer whales appear in many of their masks, carvings, totems, and blankets. At gatherings, the Tlingit tell stories, including one about the origin of killer whales. They believe a man from the Seal people carved many killer whales from wood but only the one carved from yellow cedar would swim. The legend says he carved many more from cedar and they swam up the inlet where he taught them how to hunt and what to hunt for. He also taught them not to hurt people. The Tlingit in return do not hunt killer whales and they believe that because of this the killer whales look after them (Fig. 1).

On Mornington Island in the Gulf of Carpentaria, northern Australia, a tribe of Aborigines have been in direct communication with Indian Ocean bottlenose dolphins (*Tursiops aduncus*) for thousands of years. They have a medicine man who calls the dolphins and "speaks" to them telepathically. By these communications he assures that the tribes' fortunes and happiness are maintained.

Many people who live on the banks of the Amazon River believe that river dolphins or botos (*Inia geoffrensis*) have the ability to transform themselves into handsome young men to woo women during fiestas and times of ceremony. So strong is this belief that some children are believed to have been fathered by these dolphins (Sangama de Beaver and Beaver, 1989).

A Japanese legend tells of a gigantic whale that challenges a sea slug to a race after boasting that he is the greatest animal in the sea. The sea slug accepts and arranges for his friends to wait at different beaches along the chosen course. On the day of the race, the whale surges ahead, but when he arrives at the first beach he is astonished to find the sea slug already there. So he challenges it to another race, only to have the sea slug win again. This happens many times until the whale admits defeat. This legend is analogous to the European legend of the tortoise and the hare but shows the Japanese peoples' close relation to the sea and its inhabitants and their use in teaching moral lessons.

Perhaps such legends and folklore serve the purpose of helping people understand their past or to help society learn valuable lessons. In many societies today we revere whales and dolphins, and this will continue to develop our folklore into the future.

Forelimb Anatomy

LISA NOELLE COOPER

Marine mammals are descended from terrestrial mammals whose forelimbs were weight-bearing appendages specialized for terrestrial locomotion. In the transition to an

aquatic lifestyle, most marine mammals evolved a flipper by encasing the forelimb in soft tissue (Fig. 1). Most living marine mammals have a flipper, and flipper shape and the morphology of the underlying bony structures greatly affect the function of marine mammal forelimbs.

I. Cetaceans

From the gracile and crescent-shaped flippers of a pilot whale, to the thick and door-like flippers of right whales, cetacean flippers come in lots of shapes and sizes (Figs. 2 and 3) (Howell, 1930; Benke, 1993). Most delphinids have small and thin flippers, except the broad and thick flippers of the killer whale (*Orcinus orca*). Killer whales display sexual dimorphism in that the male flippers are larger compared to female flippers. Beaked whales and the pygmy sperm whale can tuck the flippers into an indentation in the body wall during deep dives. Bowhead and right whales have large, broad flippers, while pygmy right whales and rorqual whales have elongated and very thin flippers. Intermediate between the forelimb morphologies seen in right whales and rorqual whales, the gray whale has a broad and elongated flipper. The most unusual flipper shape is seen in humpback whales as they have longest flippers of any cetacean and the leading edge of the flipper is scallop shaped by the presence of large tubercles.

Cetacean flippers function to stabilize the body and aid in turns (Woodward *et al.*, 2006). Large bowhead and right whale flippers are useful when the whale is turning at slow speeds. Gray whales make long migrations and breed in shallow lagoons, and as such their flippers have a broad surface area useful for turning at slow speeds, but the elongate flipper is also useful for generating lift while migrating. Most rorqual whales use their tiny flippers to stabilize and aid in turns. The humpback whale flipper is the exception among rorquals. The flipper is slapped on the water surface during mate displays and social touching. While swimming, the flipper moves in alternating dorsal–ventral strokes, and deforms into concave and convex arc shapes. Leading edge tubercles increase flipper area to maintain laminar flow, hinder generation of tip vortices, and allow a greater generation of lift.

All modern cetaceans have a remarkably shortened humerus, and the radius and ulna are flattened (Fig. 1A) (Howell, 1930). In most small-sized odontocetes, the carpal bones of the wrist have distinct bony articular facets, but almost all mysticetes and large-bodied odontocetes have burr-shaped carpal bones that lack articular facets and these carpals are immersed in a block of cartilage (Fig. 1A).

Cetacean metacarpals and phalanges, the bones of the digits, have unique characteristics compared to other mammals. These bones are hourglass shaped and lack all articular facets such that the dorsal and palmar, and proximal and distal surfaces are unidentifiable. Differentiating characteristics between metacarpals and phalanges are lacking, and identification of these elements can only be certain in articulated limbs. Cetaceans also have epiphyses on both the proximal and distal surfaces of the metacarpals and phalanges. Cetaceans are the only mammals to have a greater number of phalanges per digit (hyperphalangy) than the standard mammalian condition of two phalanges in the thumb, followed by three phalanges in the other digits (Table I). Odontocetes have the greatest number of phalanges in digits II and III, while mysticetes display the greatest number of phalanges in digits III and IV. Most cetaceans have five digits, but three families of mysticetes (Neobalaenidae, Eschrichtiidae, and Balaenopteridae) lack metacarpal I and all the phalanges of digit I (Fig. 1A).

Compared to other marine mammals, the cetacean flipper has a distinct lack of muscular and soft tissue structures (Howell, 1930). The triceps muscle complex is reduced with only the heads originating from the scapula being functional. The elbow is locked and the triceps

humeral heads are reduced. Flexor and extensor muscles are prominent in most mysticetes (except *Megaptera*), and sperm whales and beaked whales (physeterids, kogiids, and ziphiids), but are lacking in other families of odontocetes (monodontids, phocoenids, and delphinids). Intrinsic manus muscles (interossei, lumbricals, abductors, adductors) are absent in most cetaceans, with exceptions found in physeterids and kogiids.

Figure 3 Flipper shapes of some cetaceans. Top row representative mysticetes, bottom row representative odontocetes. The leading edge of the flipper is to the left.

Fossil evidence indicates cetaceans increased surface area for muscles acting on the shoulder joint, immobilized the elbow and wrist, and elongated the manus (Uhen, 2004). The earliest Eocene archaeocetes used their forelimbs for terrestrial locomotion and their limbs appeared similar to those of Eocene artiodactyls. In the late Eocene, basilosaurid archaeocetes were fully aquatic and developed a wider

scapula, allowing for greater areas of origin for the infraspinatus and supraspinatus muscles. Basilosaurids also developed a strong deltopectoral crest on the humerus for insertion of the deltoid muscle. This crest was lost in Oligocene cetaceans as the insertion of the deltoid muscle shifted to the distal and dorsal surface of the humerus. The elbow joint lost mobility as the distal end of the humerus evolved a v-shaped articular surface that locked the radius and ulna in place. Fossil evidence indicates elbow mobility was lost about 29 million years ago. It is currently unknown when wrist mobility was lost. Fossil evidence indicates the process of digital elongation, indicated by hyperphalangy, began at least 7–8 million years ago, although it may have started much earlier during the Oligocene.

II. Sirenians

Manatees do not use their flippers as control surfaces while the animal is swimming; instead forelimbs mostly function to orient the animal and make small corrective movements during feeding, rest, or socializing. The forelimbs are the main sources of propulsion while the animal is in contact with the sea floor, in which manatees may “walk” on the sea floor by placing flippers one in front of another, or propel themselves by paddling (Hartman, 1979). Forelimb movements are supported by abundant musculature and large, rounded tendons throughout the proximal and distal limb (Murie, 1872). Manatee digits are immersed in thick connective tissue and lack the ability to abduct and adduct, but retain intrinsic muscles of the manus (abductors and interossei).

Modern sirenians (dugongs and manatees) have a slightly modified mammalian forelimb (Howell, 1930). The elbow is mobile in sirenians, and this joint motion is stabilized by a proximally fused radius and ulna. The wrist is highly mobile and lacks a pisiform carpal bone. Dugongs have three carpal elements in the wrist, while manatees have six. The manatee manus is slightly modified as digit I lacks one phalanx, digit IV is the longest and most robust, and phalanges on the ends of the digits are irregularly shaped and flattened (Fig. 1AB). Manatees also have a number of broad and flat nails on the surface of the flipper (Fig. 1b), and some captive manatees increase the number of nails.

III Marine Carnivores

A. Pinnipeds

Pinnipeds, unlike other marine mammals, have pairs of flippers on both the forelimbs and hindlimbs. This discussion will only address the foreflippers.

Pinnipeds are unique in that their flippers are utilized mostly in aquatic locomotion and have limited utility on land. Odobenid (walrus) forelimbs act as paddles or rudders for steering (Gordon, 1981) and are used to remove sediment when searching for prey. While on land, walrus forelimbs support the trunk by placing the digits flat and bending the wrist at a right angle. This bent forelimb morphology makes terrestrial locomotion awkward. Otariid pinnipeds (English, 1976, 1977) have elongated and thin flippers that flap like

a bird wing to produce thrust underwater, and are used to support the trunk on land. Phocid forelimbs function solely in steering while underwater but are usually held flush with the body wall, and are not a significant source of propulsion. On land, most phocids do not use their forelimbs as a weight-bearing appendage.

Walrus (*Odobenus*) flippers are short compared to other pinnipeds, but are very broad and have tiny nails on the dorsal surface. Otariids have elongate and thin flippers with a slight crescent of skin at the ends of each digit. Phocid flippers are divided between some of the digits, and long thin nails extend beyond the dorsal surface of all five digits.

The digits of pinnipeds also have unique characteristics (Howell, 1930). All pinnipeds have elongated the digits by developing bars of cartilage at the ends of each digit. These cartilaginous extensions are longest in otariids, slightly shorter in the walrus and shortest in some phocids. Metacarpal I is longer and thicker than metacarpal II in all pinnipeds except phocines.

Pinnipeds also display large and complex forelimb muscles. The walrus has large and powerful muscles, with relatively the same sized muscle bellies as otariids.

Otariids isolate more than half of the forelimb musculature in the proximal portion of the forelimb. The triceps muscle complex is relatively large, and allows for elbow retraction. Muscles acting on the otariids wrist create palmar flexion, which is the main source of propulsion. Otariids also have muscles acting on the digits: interossei, digital abductors and adductors, and in some specimens a single lumbrical. Phocids have an enlarged triceps muscle complex.

The earliest fossil pinniped, *Enaliarctos mealsi*, already had forelimbs modified as flippers. No fossils indicate the transition between terrestrial carnivores and aquatic pinnipeds (Berta *et al.*, 1989).

B. Sea Otters

Sea otters (*Enhydra*) do not use their forelimbs while swimming. The forelimbs are specialized in movements requiring great dexterity: prey manipulation, grooming, and caring for young (Howard, 1973).

Sea otter forelimbs are small and retractable claws extend from each of the digits (Fig. 4). The digits cannot act individually as they are connected by soft tissue webbing. Thick pads line the palmar surfaces of digits. Forelimb musculature is well developed.

Figure 4 Sea otter foreflipper (Howard, 1973).

The giant extinct sea otter *Enhydritherium* was propelled by its forelimbs, but all modern sea otters are pelvic paddlers with enlarged hindlimbs.

C. Polar Bears

Polar bears are powerful swimmers but also walk on ice or land. The forelimbs are incredibly strong and are the main sources of propulsion while swimming, killing prey, fighting, and hauling out of the water. Alternating strokes of forelimb flexion generate propulsion while swimming and the hindlimbs trail and remain motionless. While fighting another, polar bears will stand on their hind limbs, wrap forelimbs around another and bite. To haul out of the water, the polar bear pulls itself mostly out of the water with its strong forelimbs, and uses the hindlimbs after most of the body mass is out of the water. While walking on ice or land, polar bears place the whole hand flat on the substrate.

Polar bear forelimbs are similar to other bears, except that the scapula has a narrow postscapular fossa. This fossa gives origin to the subscapularis muscle.

Forensic Genetics

C. SCOTT BAKER AND MEREL L. DALEBOUT

I. Introduction

Molecular genetics provide a powerful tool for the conservation and management of cetaceans and other marine mammals—the identification of products derived from hunting, strandings, and fisheries bycatch (Baker and Palumbi, 1994; Cipriano and Palumbi, 1999; Dalebout *et al.*, 2002a). Such products include soft tissue such as meat, organs, blubber, skin, and blood, as well as teeth, bone, baleen, and hair. The examples given here are for cetaceans, but the approaches can be applied to carnivores and sirenians. Although the species origins of these products may be impossible to determine on the basis of appearance, they contain DNA that can be amplified, sequenced, and compared to sequences from known specimens. With advances in molecular methods over the last decade, DNA can now be recovered from almost any biological source, even products that have been preserved, cooked, or canned (Asensio Gil, 2007). With a comprehensive reference library of homologous sequences, such as the control region or cytochrome *b* gene of the mitochondrial (mt) DNA, a product of unknown origin can be attributed in most cases to one of the approximately 90 accepted or proposed species of cetaceans (Baker *et al.*, 2003). If a comprehensive archive of tissue is maintained as part of a regulated hunt or documented fisheries bycatch, it is also possible to trace the origins of a product to a specific individual by matching of nuclear DNA genotypes (Cipriano and Palumbi, 1999; Dalebout *et al.*, 2002b; Palsbøll *et al.*, 2006). Although many of the applications of these methods are not intended for criminal prosecution, they share the common methodology of wildlife forensic genetics (US Fish and Wildlife Service, 2001) and the broader objectives of improving controls over trade and exploitation of protected species.

The forensic use of molecular genetic methods is of particular interest to the International Whaling Commission (IWC), as it attempts to develop a Revised Management Scheme (RMS) for the regulation of any future commercial whaling, and to the Convention on International Trade in Endangered Species of Wild Fauna and Flora (CITES), as it attempts to implement a verifiable system for controlling trade in cetacean products. An important application of forensic genetics has been to identify the species and, in some cases, geographic origins of whale, dolphin, and porpoise products sold in two countries with active commercial markets: Japan and the Republic of (South) Korea (Baker and Palumbi, 1994; Baker *et al.*, 1996; Grohman *et al.*, 1999; Simmonds *et al.*, 2002). Of particular concern has been the sale of protected species or populations (stocks) derived from illegal, unreported, and unregulated (IUU) exploitation (Baker *et al.*, 2000b, c; Baker *et al.*, 2002). Other applications include identifying stranded individuals and fisheries bycatch, particularly for poorly described species such as beaked whales (Henshaw *et al.*, 1997; Dalebout *et al.*, 1998; Dalebout *et al.*, 2004), and monitoring of trade in pinniped penises sold as aphrodisiacs (Malik *et al.*, 1997). Most recently, molecular identification of species and capture–recapture analysis of DNA genotyping from individual products have been used to estimate the true level of bycatch for some species sold in commercial markets (Baker *et al.*, 2006; Baker *et al.*, 2007).

II. Molecular Taxonomy and Identification of Cetacean Species

The methods for molecular identification of species in trade developed initially from basic research on species-level phylogenetic relationships and the genetic structure of populations (Baker and Palumbi, 1994; Baker *et al.*, 1996, 1994; DeSalle and Birstein, 1996; Malik *et al.*, 1997; Roman and Bowen, 2000; Shivji *et al.*, 2002). More recently, there has been an explosion of interest in the systematic application of these techniques to basic organismal taxonomy (Hebert *et al.*, 2003; Tautz *et al.*, 2003; Blaxter, 2004), including cetaceans (Baker *et al.*, 2003; Ross *et al.*, 2003; Dalebout *et al.*, 2004). Now referred to as “molecular taxonomy” or “DNA taxonomy,” the objective of identifying known species from a designated homologous gene sequence differs from the usual goal of molecular phylogenetics, which is more concerned with hierarchical relationships above the species level. For species identification of cetaceans and other animal species, the molecular marker of choice has usually been mitochondrial DNA (mtDNA). In general, mtDNA offers two important advantages over nuclear genetic markers. First, because of its maternal inheritance and absence of recombination, the phylogenetic relationship of mtDNA sequences reflects the history of maternal lineages within a population or species. (If hybridization is encountered, nuclear markers are required to identify the paternal species; discussed later). Second, all else being equal, the effective population size of mtDNA genomes is one-fourth that of autosomal nuclear genes and their rate of random genetic drift is proportionately greater. This results in more rapid differentiation of mtDNA lineages among populations, compared to nuclear genes, and consequently greater sensitivity in the detection of recent historical demographic or speciation events. The ability to detect population differentiation is also enhanced by the rapid pace of mtDNA evolution, which is generally estimated to be five to ten times faster than nuclear coding DNA in most species of mammals.

Although one approach to molecular taxonomy has advocated a universal “DNA barcode of life” for all animal species based on the mtDNA cytochrome *c* oxidase I gene (COI) (Hebert *et al.*, 2003), it is not clear that this locus is the most sensitive or reliable for identification of cetaceans (Amaral *et al.*, 2007). Instead, species-level identification of marine mammals has relied primarily on the phylogenetic reconstruction of sequences from the mtDNA control region (sometimes referred to as the D-loop) or the cytochrome *b* gene. The control region of the mtDNA does not code for a protein or RNA and, in the absence of these constraints, accumulates mutational substitutions more rapidly than other regions. For this reason, it has become the marker of choice for most studies of the population structure of cetaceans and pinnipeds. The cytochrome *b* gene, a protein region of the mtDNA, has also been used widely for species-level phylogenetics (Arnason and Gullberg, 1996; LeDuc *et al.*, 1999) and in some cases, for population structure of marine mammals (Lento *et al.*, 1997). Because of the large number of reference sequences available on public databases such as *GenBank* and *EMBL*, both loci have been used for species-level identification of marine mammals.

The basic steps involved in the phylogenetic identification of an unknown specimen or market product are illustrated in Fig. 1. First, mtDNA is extracted from the product in question, such as a flensed piece of skin and blubber from a commercial market. Second, a fragment of the mtDNA control region is amplified from the product via PCR (Saiki *et al.*, 1988)—a cyclic, *in vitro* enzymatic reaction that results in the exponential replication of a small targeted fragment

Figure 1 The basic steps involved in species identification of an unknown cetacean product using of nucleotide sequences amplified, by PCR, from the mtDNA control region. The “test sequence” derived from an unknown species origin is aligned and compared to a comprehensive reference database of sequences from specimens of known provenance, such as that available on the web-based program, www.DNA-surveillance.

of mtDNA (usually <1000 base pairs). Third, the exact nucleotide sequence of the amplified fragment is determined using a dideoxy-terminator sequencing reaction, followed by electrophoresis through an acrylamide gel. In most laboratories, this step is now automated with a computer-assisted laser scanner. Fourth, the sequence of the product, now referred to as the “test sequence,” is aligned to and compared with the sequences from reference samples. For protein coding regions, such as cytochrome *b* or COI, alignment is unambiguous among cetaceans (or other mammals) because of the absence of insertions or deletions (indels) in the codon sequences. For the noncoding CR, however, the presence of numerous single- and multiple-base indels often requires an automated alignment procedure and manual confirmation to optimize identification.

Finally, the “test sequence” is grouped with the most closely related reference sequences in the reference database using phylogenetic reconstruction methods, such as minimum evolution (neighbor joining), maximum parsimony, or maximum likelihood. The reconstruction is usually represented as a “tree,” with closely related sequences forming neighboring branches. This approach allows a hierarchical comparison to establish first the suborder and family derivation using a small number of reference sequences from each of a large number of species. Once the family or subfamily is established, the phylogenetic reconstruction of the test sequence can be repeated using a larger number of reference sequences to better represent the diversity within each of the smaller number of species at this taxonomic level. A close relationship or match with a “reference” sequence provides evidence for identification of the species origin of the product. One or more “out-groups” (i.e., distantly related species) are used to protect

against a misclassification error. The strength of support for an identification or phylogenetic grouping is evaluated by “bootstrap” resampling of the sequence data. The relative support for a grouping or branch in the tree is shown as the percentage agreement from a large number (>1000) of bootstrap simulations.

As a conservative approach to forensic identification, a species identification should be considered “confirmed” only if the test sequence is “nested” within the range of reference sequences for a given species. This is necessary because the molecular systematics of some marine mammals, particularly the cetaceans, are not fully described (Reeves *et al.*, 2004; discussed later). If a test sequence is intermediate between two groups of reference sequences, rather than nested within one or the other, it could be a related species or subspecies not included in the reference database. Where a reference database is considered to be comprehensive in regards to known species, the finding of a particularly divergent sequence could be evidence of an unknown or unrecognized species or subspecies (Baker *et al.*, 1996; Dalebout *et al.*, 2004; Dalebout *et al.*, 2007).

When a large set of reference sequences is available from the range of a single species, it is possible to use intraspecific variation to evaluate the geographic origin of a sample (Baker *et al.*, 2000a). In many cases, the management of marine mammals is based on geographic populations or stocks (Dizon *et al.*, 1992). Catch quotas and limits of incidental mortality from fisheries bycatch are usually set according to such stock definitions, as well as according to species. Hunting may be allowed in an abundant stock but prohibited in another stock of the same species that is depleted from past exploitation. However, the ability to identify or estimate the geographic

origin of a specimen or product is determined by the genetic distinctiveness of the recognized stocks, as well as by the comprehensiveness of the reference samples.

III. Web-Based Species Identification with www.DNA-surveillance

To assist in the genetic identification of whales, dolphins, and porpoises, an interactive application for phylogenetic identification has been developed and is accessible through the website, <http://www.DNA-surveillance> (Ross *et al.*, 2003). *DNA Surveillance* (2008) implements phylogenetic methods for identification of species within a particular taxonomic group, such as the currently available datasets for whales, dolphins, and porpoises. The application automates the procedure of species identification by aligning a user-submitted gene sequence of unknown origin against a set of validated reference sequences. The evolutionary distances between the unknown or “test” sequence and each of the reference sequences is computed and a phylogenetic tree displays the affinity of the unknown sequence to the reference sequences.

DNA Surveillance differs in several important ways from the blast search options available on the website of the international genetic database, *GenBank* (Ross and Murugan, 2006). The problems associated with using *GenBank* for species identification are particularly relevant to cetaceans, where the primary taxonomic identification of the voucher specimen can be ambiguous or incorrect (Henshaw *et al.*, 1997; Dalebout *et al.*, 1998). Sequences entered in *GenBank* are not curated and often are not associated with identifiable reference or voucher specimen material. The taxonomic representation of a BLAST search is difficult to judge because of the large number of redundant gene sequences for some species, the absence of sequences from other closely related species and the nature of the pair-wise alignment and search algorithm. BLAST and related search engines seek only locally maximal matches in pair-wise comparisons. The extreme (E) value associated with each sequence hit in a BLAST search is not a rigorous measure of evolutionary distance or genetic similarity and is dependent on the size of the database being searched (Karlin and Altschul, 1990). Inconsistent application of keywords also reduces the power of searching *GenBank* by fields, impeding effective data mining. By contrast, *DNA Surveillance* is designed specifically for species identification of selected taxonomic groups. The reference sequences in *DNA Surveillance* are prealigned at each hierarchical level of the database, using a mixture of algorithmic and manual methods, to create an optimized alignment. The sequences in *DNA Surveillance* were chosen to reflect known phylogenetic diversity at the species and population level (where available). The genetic distances and trees in *DNA Surveillance* are calculated using standard phylogenetic algorithms, as implemented in the Phylogenetic Algorithms Library (Drummond and Strimmer, 2001).

The reference data sets mounted on *DNA-surveillance* comprise sequences from both the mtDNA control region and cytochrome *b* gene. Reference sequences were selected to reflect the generic, specific, or geographic diversity observed at a taxonomic level and to maximize the discriminatory power of the analysis. In an effort to validate the dataset, most sequences were derived from specimens that had been identified by experts and for which diagnostic skeletal material or photographic records were collected (Dizon *et al.*, 2000). Data sets are arranged hierarchically, allowing initial family-level identification of cetaceans and subsequently more detailed analysis within the suborders Mysticeti (baleen whales) and Odontoceti (toothed whales). The datasets currently mounted on *DNA-surveillance* at this

writing are taxonomically comprehensive, with a total of 399 control region sequences and 264 cytochrome *b* sequences representing 88 species (DNA-surveillance, 2008). Sequences from documented specimens represent all of the 83 species recognized by Rice (Rice, 1998), with two exceptions: the Atlantic hump-backed dolphin, *Sousa teuszii*, and the Indian hump-backed dolphin *S. plumbea* (the latter of which has not been accepted by IWC). The datasets also includes one species found in an alternate species listings, *Platanista minor* (IUCN Red Book), and seven species accepted, revised, or proposed in publications since Rice (1998): *Balaenoptera omurai* (Wada *et al.*, 2003), *Eubalaena australis* and *E. japonicus* (Rosenbaum *et al.*, 2000), *Mesoplodon perrini* (Dalebout *et al.*, 2002b), *M. traversii* (van Helden *et al.*, 2002), *Orcaella heinsohni* (Beasley *et al.*, 2005), and *Sotalia guianensis* (Caballero *et al.*, 2007). Both the control region and cytochrome *b* datasets include sequences from multiple specimens for most species.

In a typical analysis, the user copies a DNA sequence (in FASTA or text format) into a data input window and chooses the appropriate reference data set. The test sequence is aligned by a simple profile alignment against the pre-aligned data set of reference sequences. The user can also choose that a computationally more intensive full alignment of the test and reference sequences be performed as part of the analyses. A neighbor-joining (NJ) tree is built from the table of evolutionary distances (Saitou and Nei, 1987) and rooted using an out-group appropriate for each data set. The phylogenetic tree, in both graphic and text format, and a table of distances are displayed and can be downloaded to the user. An optional bootstrap analysis (Felsenstein, 1985) can be performed to assess the robustness of the resulting phylogenetic tree.

IV. Taxonomic Uncertainties and Species Identification

Problems in molecular identification of cetacean species can occur if taxonomic sampling is incomplete (missing species) or within-species sampling is not sufficiently representative of diversity. In cases of deep intraspecific diversity or shallow interspecific divergence, an unknown test sequence could group with the next most closely related species as a result of such sampling error. For this reason, it is important that levels of genetic diversity within, and divergence between species in a group of interest are assessed as part of the development of a molecular taxonomy (Dalebout *et al.*, 2007). As a conservative approach, Baker *et al.* (1996) suggested that identification of a test sequence should be considered conclusive only if it nests within the diversity of reference sequences for a given species. In practice, this is less crucial if phylogenetic support for the species-level grouping is strong and the taxonomic sampling is known to be complete.

More problematic are cases where the phylogenetic reconstruction of mtDNA sequences is not concordant with accepted species taxonomy described from morphological characteristics. Instead of the expected pattern of species-specific monophyly, where all mtDNA lineages (sequences) from a given species group with each other, some lineages group with another species (paraphyly) or fail to form species-specific groups (polyphyly). The reasons for species-level paraphyly or polyphyly of mtDNA are varied and include recent hybridization as well as incomplete lineage sorting due to recent speciation (Funk and Omland, 2003). If species or species complexes are truly paraphyletic, it is unlikely that a phylogenetic approach to “species” identification will be successful. Instead, molecular identification can only to be made with confidence to a higher taxonomic

rank within which mtDNA lineages are monophyletic (e.g., genus or subfamily). Although species-level monophyly of mtDNA has been demonstrated for many species of cetaceans, including the beaked whales (Dalebout *et al.*, 2004; Dalebout *et al.*, 2007) and baleen whales (Baker *et al.*, 1993; Rosenbaum *et al.*, 2000; Wada *et al.*, 2003), apparent paraphyly is reported for some species of the family Delphininae, particularly in the genera *Stenella*, *Tursiops*, and *Delphinus* (Dizon *et al.*, 2000; Reeves *et al.*, 2004).

V. Individual Identification and a Diagnostic “DNA Register”

F An alternative to the species identification of an unknown specimen or product is individual identification by DNA genotyping or “profiling” using variable nuclear markers. As in human forensic genetics, a combination of variable nuclear markers (such as microsatellites, Single Nucleotide Polymorphisms (SNPs), or nuclear introns) can be used to establish individual identity with high probability (or to exclude identity with certainty, barring experimental error). The DNA profile of the market product can be compared to that from archived tissue collected in a regulated hunt or documented bycatch for verification of trade records. One of the first efforts to track the individual identity of a whale in trade involved a product from the Japanese market, identified initially as a blue whale, *Balaenoptera musculus*. The mtDNA sequence from this product matched closely with the published sequence of a blue/fin (*B. physalus*) hybrid killed during a scientific whaling program by Iceland. Because mtDNA is maternally inherited, it cannot, by itself, identify a product as a hybrid. Subsequent comparison of variable nuclear DNA introns from tissue archived during the Icelandic whaling program supported the assumption that this product was derived from this hybrid individual (Cipriano and Palumbi, 1999).

In response to concerns about the continued sale of protected species and the poor control of whale-meat markets, the Government of Norway initiated a program to DNA-profile all whales taken in its commercial hunt (IWC, 1998). The DNA profiles of each individual whale are stored on an electronic database, forming a “DNA register” of all products intended for the market. If the register is comprehensive or “diagnostic,” a match with a market product would confirm the legality of the product (Dizon *et al.*, 2000). A product that did not have a match in the register would be illegal. Further genetic investigation would then be required to determine the species and geographic origin of illegal products. The Governments of Japan has also committed to the development of DNA registers as part of its ongoing programs of scientific whaling and intends to include the bycatch of baleen whales destined for sale in commercial markets (IWC, 2005b). The effectiveness of the Norwegian DNA register was tested recently with products from North Atlantic common minke whales (*Balaenoptera acutorostrata*) purchased at Norwegian markets. The results demonstrate the matching of the test profiles to the register, confirming the potential power of the DNA registers, but highlighted a number of methodological problems that need to be addressed to ensure successful implementation for control of trade (Palsbøll *et al.*, 2006).

Individual identification of market products can also be a powerful tool for describing market dynamics even in the absence of a DNA register or official tissue archive. Dalebout *et al.* (2002b) used mtDNA sequences to identify minke whale products sold in Japanese and Korean markets and subsequent DNA profiling to identify replicate products derived from the same individual. Many of these products in both countries were derived from whales taken as unregulated bycatch (discussed later). Individual identification provided information

on distribution of products and a minimum “census” of the true number of takes in this bycatch. More recently, Baker *et al.* (2007) expanded on this work in the Korean market, using a modified capture–recapture model based on DNA profiles, to estimate the true number of whales in trade (reflecting the true number killed) over a 5-year period from 1999 to 2003 (discussed later).

VI. Monitoring of Commercial Markets in Whale, Dolphin and Porpoise Products

In recognition of historic patterns of over-exploitation, the International Whaling Commission (IWC) voted in 1982 to impose a global moratorium on commercial whaling. Although the moratorium took effect in 1986, whaling never actually stopped. IWC member nations continue to hunt some species of whales for scientific research or for aboriginal and subsistence use. Whales killed for scientific research can be sold legally to domestic consumers and traded to other member nations of the IWC (subject to CITES permits), thereby sustaining a commercial market for meat, skin, blubber, and other whale products. Small cetaceans are also hunted or taken as fisheries bycatch and sold for consumption in many parts of the world (Clapham and Van Waerebeek, 2007). Although the IWC regulates only hunting of large whales, international trade in all cetaceans is subject to CITES. When some species are protected by an international prohibition against hunting or trade but similar species are not, it is crucial to identify the origin of products that are actually sold in retail markets.

In an effort to monitor the sale and trade of cetaceans products, molecular methods have been used to identify the species and geographic derivation of products sold in two countries with active commercial markets: Japan and the Republic of (South) Korea. Whale meat is widely available in retail markets of both countries despite the international moratorium on commercial whaling (Chan *et al.*, 1995; Mills *et al.*, 1997; Kang and Phipps, 2000). Japan sustains a legal market for whale products through its growing scientific whaling programs in the Southern Hemisphere and the North Pacific Ocean (Gales *et al.*, 2005). South Korea has no program for scientific hunting but reports a substantial fisheries bycatch of cetaceans each year, including minke and other baleen whales (Mills *et al.*, 1997). Products from this unregulated incidental mortality are sold in local markets but their international trade is prohibited by CITES.

Surveys of whale-meat markets conducted, since 1993 in Japan and 1994 in Korea, have employed both species identification and individual identification to detect the sale of protected species and assess the true take of species in unregulated bycatch or by illegal hunting. As summarized in the year 2000 (Baker *et al.*, 2000b), surveys of Japanese markets have revealed numerous cases of protected species of large whales including sperm whales (*Physeter macrocephalus*), fin whales, blue/fin whale hybrids, two species of Bryde’s whales (*B. edeni* and *B. brydei*, following the taxonomy of Wada *et al.*, 2003), sei whales (*B. borealis*), humpback whales (*Megaptera novaeangliae*), and gray whales (*Eschrichtius robustus*). With the expansion of the Japanese scientific programs since 2000, however, some formerly protected species are now included in this hunt and regularly available on commercial markets.

Market surveys have also provided information on the diversity of small cetacean products available for sale. In Japan (Endo *et al.*, 2005), a total of 160 “small cetacean” products sold for human consumption in markets from 2000 to 2003 were identified as originating from seven species of the family Delphinidae, one species of beaked whale (*Berardius bairdii*) and one species of porpoise

(*Phocoenoides dalli*). In Korea (Baker *et al.*, 2006), a total of 357 whale-meat products, purchased from late 2003 to early 2005, were identified as originating from 15 species of cetaceans: three baleen whales (North Pacific minke, common form Bryde's and humpback), three beaked whales (Stejneger's beaked whale, *Mesoplodon stejnegeri*; Cuvier's beaked whale, *Ziphius cavirostris*; and Blainville's beaked whale, *Mesoplodon densirostris*), seven species of the family Delphinidae (bottlenose dolphin, *Tursiops truncatus*; Risso's dolphin, *Grampus griseus*; short-beaked common dolphin, *Delphinus delphis*; Pacific white-sided dolphin, *Lagenorhynchus obliquidens*; false killer whale, *Pseudorca crassidens*; killer whale, *Orcinus orca*; short-finned pilot whale, *Globicephala macrorhynchus*), and two porpoises (harbour porpoise, *Phocoena phocoena*; finless porpoise, *Neophocaena phocaenoides*).

Detailed comparisons of mtDNA sequences and individual identification by DNA profiling have provided information on high levels of unregulated exploitation of minke whales in coastal water of Japan and Korea. The North Pacific minke whale forms at least two stocks with marked differences in frequencies of mtDNA haplotypes (Goto and Pastene, 1997): the "J" stock found in the Sea of Japan/East Sea, and the "O" stock found in the North Pacific to the east of Japan. Although the "O" stock is subject to legal scientific hunting by Japan and is reported to be relatively abundant, the "J" stock was depleted by commercial hunting before 1986 and is considered a "Protection Stock" by the IWC. Using molecular methods and mixed-stock analysis, market surveys from 1993 to 1999 showed a large proportion of products from Japan were derived from the protected "J" stock despite relatively low numbers in official reports of fisheries bycatch (Baker *et al.*, 2000a).

Surveys of Korean markets have raised similar concerns about exploitation of the "J" stock minke whales. The sale of minke whales reportedly taken as incidental bycatch supports a thriving trade in whale products concentrated in three coastal cities along the southeastern coast of the Korean peninsula: Busan, Ulsan, and Pohang (Kang and Phipps, 2000). As trade in whale products is unregulated, the dynamics of market distribution are not well described (IWC, 2006a). Available information suggests that fishermen negotiate the sale of bycatch informally through a network of perhaps 10 wholesalers operating in these three cities. Whale products are sold in numerous small shops and restaurants in or around Busan, Ulsan, and Pohang, including speciality whale-meat restaurants and large fisheries markets (IWC, 2006). Given the high commercial value of whale and dolphin products (reportedly up to US\$100,000 wholesale for an adult minke whale), there is considerable incentive to enhance the potential for bycatch through modified fishing practices, similar to that of traditional "net whaling". Although the Government of South Korea reports relatively large numbers of minke whale as bycatch in its annual progress report to the IWC, market surveys indicate that these records are incomplete, perhaps due to substantial levels of illegal hunting (IWC, 2005a). A capture-recapture analysis of individual market products purchased during market surveys from 1999 to 2003 (discussed earlier, Baker *et al.*, 2007) estimated that the true number of whales entering trade across the 5-year survey period was 827 individuals (CV = 0.24), significantly greater than the officially reported bycatch of 458 whales for this period. Considering results from surveys of both Japanese and Korean markets, the estimated true levels of illegal, unreported, or unregulated exploitation has serious implications for the survival of this genetically distinct coastal population.

VII. Conclusions

Molecular methods have great power to detect trade in protected species and to monitor or estimate unregulated or undocumented

trade in whales, dolphins, and porpoises. Efforts to improve monitoring and detection of IUU exploitation of cetaceans and control trade in cetacean products would be enhanced greatly by the establishment of diagnostic "DNA registers" (Dizon *et al.*, 2000). The Governments of Japan and Norway have both committed to the development of DNA registers as part of their ongoing programs of scientific or commercial whaling, and in the case of Japan, the effort is intended to include the bycatch of baleen whales destined for sale in commercial markets (IWC, 2005b). Korea has made efforts to improve the collection of biological samples from the bycatch of baleen whales (IWC, 2006), although it has not committed to develop a DNA register. No country has yet committed to develop a register for small cetaceans, even though products from directed hunting and bycatch of these species are often destined for commercial markets (Clapham and Van Waerebeek 2007).

Given the commitment to DNA registers by Japan and Norway, it is puzzling that the governments of both countries oppose implementation of market surveys as a component of any system of observation and monitoring of future whaling. Formal statements by both countries claim that the IWC has no competency in market monitoring (IWC, 2001a, b), although methods for market surveys to estimate bycatch and other human induced mortality have been under discussion at the IWC for several years (IWC, 2003). Assuming a continuation of this political opposition, it is likely the future market surveys will have to follow an "empirical" approach, similar to that advocated for surveys of wild-meat markets (Fa *et al.*, 2004) and including methods of estimation typically used in the molecular ecology of living populations Baker (2008). For countries that regulate hunting or keep official records of bycatch, an empirical approach is likely to require more effort and to yield less precise estimates than combining market surveys with a diagnostic DNA register (IWC, 2006). For countries such as China, Taiwan, Indonesia, and the Philippines, where trade in whale and dolphin products is known or suspected (Barnes, 1991; Dolar *et al.*, 1994; Mills *et al.*, 1997) but which keep few records of hunting or bycatch, an empirical approach will be the only option available for monitoring exploitation in the foreseeable future.

Fossil Sites, Noted

R. EWAN FORDYCE

I. Introduction

Fossil marine mammals—Cetacea, Sirenia, Desmostylia, Pinnipedia and other aquatic carnivores—are known from hundreds of sites worldwide (Fig. 1). Localities span from modern tropics to poles, in both north and south and on all major continents, but with most in northern temperate regions. Usually, sites preserve marine sedimentary rocks, which have been exposed on land through sea level fall and/or uplift, followed by erosion. There are a few records (dredgings) from the deep ocean, and there are some important fresh water sites for secondarily nonmarine species. Fossils give only a general guide to former distributions in ancient oceans. Sites vary from rich localized concentrations at sites a few tens of meters across, to scattered occurrences across many kilometer which become significant at the regional level, and they range in age from Eocene to Pleistocene (Fig. 2). The case studies below, given in sequence from oldest to youngest, span all the major time intervals and oceans.

II. The Role of Geological Processes

Marine mammal history has been affected by geological changes in oceans and climates over millions (M) of years (Fordyce and Muizon, 2001). These changes ultimately reflect global tectonic processes: continental drift and the rearrangement of land and sea. Continents are now relatively more emergent than for much of the past 50 million years, with less continental shelf and less extensive shallow continental sea than in the past. Most continents preserve coast-parallel strips of ancient marine rock now exposed on land. These may be extensive and a notable source of fossils (e.g., Atlantic Coastal Plain, eastern USA), or limited (e.g., most of Africa). Sometimes extensive shallow epicontinental seas overlapped the continents, as in northern Europe and the Paratethys. Major drops in sea level occurred about 30 million years ago (Ma) and, associated with widespread glaciation and global cooling, since 2 Ma (major fluctuations; Ma, million years).

When the first cetaceans and sirenians appeared, beyond 50 Ma, the extensive shallow Tethys Sea stretched from the Pacific to about the modern Mediterranean. By the end of the Eocene, India had moved northwards to collide with Asia, closing much of the Tethys. More-western remnants of the Tethys, through what is now southern Eurasia, were eliminated in the Miocene, when Africa collided with Eurasia. Later, the Mediterranean dried out completely about 6 Ma, with dramatic consequences for the biota.

In the south, Australia moved north away from Antarctica opening part of the Southern Ocean by the end of Eocene time (34 Ma). Later, Antarctica and South America separated in the Oligocene about 30–23 Ma, to open the Drake Passage, allowing west-to-east flow of a newly developed Antarctic Circumpolar Current. This current isolated Antarctica thermally, and probably allowed the Antarctic icecap to expand, global climates to cool, and global oceans to become more heterogeneous. Australia continued to drift north, so that in about Middle Miocene (~15 Ma) it closed the Indopacific seaway between Australia and Asia and restricted equatorial circulation between the Indian and Pacific Oceans. In the middle Pliocene (~3–4 Ma), the Panama Seaway closed, cutting Caribbean–Pacific

links. The closure of the Panama Seaway correlates closely with the start of Northern Hemisphere continental glaciation.

III. A Global Summary of Localities

Important localities occur in marine sequences around the modern Mediterranean, which is a remnant of the formerly extensive Tethys sea and its now-vanished northeast arm, the Paratethys. Cetaceans, pinnipeds, and sirenians are notable. Italy has many sites of Pliocene to Oligocene age, while the most significant localities along the southern Mediterranean are in the Egyptian Eocene (discussed later). Paratethyan localities to the northeast include some in Austria, Hungary, Slovakia, Croatia, Romania, Ukraine, and several in the Caucasus mountains and borders of the Caspian Sea including Georgia, Azerbaijan, and Kazakhstan.

Eastern North Atlantic cetaceans and pinnipeds have come from Miocene–Pleistocene and, rarely, Eocene–Oligocene sequences bordering the North Sea, in Denmark, northern Germany, Poland, Sweden, Netherlands, Belgium, Britain, and North Sea dredgings. Eocene to Pliocene fossils from the western North Atlantic include many from the Atlantic Coastal Plain (Delaware to Florida) and Gulf Coast. The Caribbean–tropical Atlantic has few reported sites, but southwest Atlantic fossils from Argentina include latest Oligocene, and Miocene–Pleistocene, with some from Miocene–Pliocene non-marine strata. A few sites in the eastern tropical Atlantic have produced Eocene cetaceans (Nigeria, Senegal, Togo), the tip of South Africa has rich Pliocene bone-beds including cetaceans and pinnipeds, and abundant cetacean bones dredged from offshore.

Eocene basal Cetacea from Pakistan and India lived in the now-obiterated Tethys Sea. Otherwise, there are sparse reports of fossil Neoceti from around the Indian Ocean. From Kenya comes a Miocene apparent freshwater beaked whale (Ziphiidae), and ziphiid rostra have been dredged from off Western Australia.

A few regions around the Pacific, which was the largest ocean during cetacean history, have received concentrated attention. Japanese Mio–Pliocene cetaceans and pinnipeds are well documented, and studies of Oligocene cetaceans are underway. There are only sporadic records of fossil marine mammals from further north in the Pacific (Sakhalin and the Aleutian chain). From the Eastern North Pacific (Mexico to British Columbia) come notable Miocene–Pleistocene assemblages; of hundreds of known Oligocene fossils, only a few species are described. Significant assemblages of Mio–Pliocene cetaceans and pinnipeds come from Peru, and, largely unstudied, northern Chile. New Zealand assemblages, from the Southern Ocean margin, span from the Eocene to Quaternary, including important Oligocene material; most fossils are cetacean but for a few geologically young pinnipeds. A scattered Oligocene to Neogene record of cetaceans and pinnipeds and fragmentary sirenians from Australia also hints at the composition of Southern Ocean faunas. One Eocene and one Pliocene site are reported from Antarctica.

IV. Eocene: Mediterranean/Tethys (Northern Egypt)

Eocene strata in northern Egypt, near Cairo and southwards at Fayum, have produced fundamentally important archaeocete cetaceans and sirenians. For nearly a century, the cetaceans were the most archaic known (Kellogg, 1936). Assemblages have modest diversity, involving a few species of sometimes excellent preservation; fossils are locally abundant. The Cairo sequence, at Gebel Mokattam, is slightly older than that of Fayum. Patterns of fossiliferous strata reflect changing sea levels and shallow marine deposition at a passive continental margin (Gingerich, 1992). Marked unconformities,

or breaks in the record, were caused by lowered sea level. Paleoenvironments range from riverine (with sirenians) through estuarine, active shoreface, barrier bar, and shallow shelf.

At Gebel Mokattam, Cairo, the Mokattam Formation comprises limestones deposited in a shallowing marine shelf setting from approximately 48–41 Ma. Key fossils are the protocetid archaeocete *Protocetus atavus* and early sirenians such as *Eotheroides aegyptiacum* (Dugongidae; named by famous anatomist Richard Owen), *Eosiren abeli*, and *Protosiren fraasi* (Protosirenidae)—all about 46 Ma. Another protocetid, *Eocetus schweinfurthi*, is younger (~41–37 Ma), from the overlying shallow marine Gushi Formation.

To the south, Fayum marine strata span the Middle and Late Eocene (~43–35 Ma). Gehannam Formation limestone has yielded fossils of the sirenians *Eotheroides* and *Protosiren*, and associated skeletons of archaeocetes: the 4.5- to 5-m long *Dorudon* (formerly *Prozeuglodon atrox* and larger ~16-m *Basilosaurus isis*, the latter known to have hind limbs (Uhen, 2004; Gingerich, 2005). Archaeocete skeletons are abundant at horizons that probably represent low-stands of sea level. *Moeritherium*, a pig-sized estuarine stem-proboscidean, is present. The top of the Gehannam Formation varies in age according to locality. It is succeeded in places by barrier beach sands of the Birket Qarun Formation, a unit with many archaeocete skeletons in the base, including the dorudontine *Ancalcetetus simonsi*. The youngest marine rocks at Fayum are lagoonal strata of the Qasr el Sagha Formation (~35–37 Ma), a unit that has produced the sirenian *Eosiren libyca*, two dorudontine archaeocetes—the small *Saghacetus osiris* and larger *Dorudon atrox*—and *Moeritherium*. Above this marine sequence, the sirenian *Eosiren imenti* occurs in Oligocene riverine strata of the Gebel Qatrani Formation.

The Egyptian localities are important sources of early archaic cetaceans and sirenians, including significant type specimens (basic standards of reference). The geologically youngest Egyptian archaeocetes, from the latest Eocene, were contemporaneous with the oldest crown-group Cetacea, Neoceti.

V. Oligocene: Southwest Pacific (Waitaki Valley, New Zealand)

Thin marine Oligocene strata (34–23 Ma) in the Waitaki Valley area of New Zealand, at 45°S, are a source of early Neoceti, or “modern” Cetacea (Fordyce and Muizon, 2001; Fordyce, 2006). Important localities include those near Oamaru, Duntroon, Wharekuri, and Hakataramea Valley, spanning some tens of kilometer. Field studies started in the 1880s; Benham and Marples were notable researchers, both on archaic mysticetes referred to *Mauicetus*. Many specimens represent unnamed new species.

The Wharekuri Greensand and Ototara Limestone have produced some of the few Early Oligocene (~33 to ~30 Ma) cetaceans reported worldwide. The strata are truncated above by a major unconformity probably caused by sea level fall at approximately 30 Ma, and are succeeded by the Kokoamu Greensand, a thin (usually <5 m), burrowed, shelly, sediment-starved unit. Greensand grades up over several meter into the massive Otekaike Limestone (up to 50-m thick), which spans the later Late Oligocene (~25 Ma) and earliest Miocene (~23 Ma). Sediments accumulated in a quiet setting below storm wave base, in mid-to-outer shelf depths. Associated vertebrates include penguins, sharks, and bony fish, but no other marine mammals. International correlation is based on planktic foraminifera, coccoliths, and strontium dating. Cetaceans occur both as isolated bones and as skeletons. The source units are often cemented, producing resistant outcrops so that excavations need pneumatic tools and saws, are limited in scope, and mostly recover partial rather than whole skeletons.

Basal Oligocene cetaceans from the Wharekuri Greensand include two presumed mysticetes: a large species with severe vertebral pathology, and a neonate. Elsewhere, fragments from the Ototara Limestone include a small *Llanocetus*-like toothed archaic mysticete. The overlying Kokoamu Greensand has produced baleen-bearing whales including Marples' widely cited "*Mauicetus*" *lophocephalus* and other unnamed eomysticetids, presumed stem-balaenopterids, and a stem-balaenid. There are no definite records of toothed basal mysticetes. Sparse odontocetes from the lower to middle Kokoamu Greensand are mostly Platanistoidea, including species of Squalodontidae, and provisionally identified Waipatiidae and Dalpiazinidae, but no true dolphins (Delphinida) are reported. In the early 2000s, enigmatic toothed cetaceans, long known from fragments, were finally identified as late persisting archaeocetes. A pivotal specimen is a skull, which is placed cladistically between Neoceti and the archaeocete group Basilosauridae; the fragmentary and enigmatic *Kekenodon onamata* is probably related.

Cetaceans are better preserved in the upper Kokoamu Greensand and overlying Otekaikē Limestone. Mysticetes include the stem balaenopterid *Mauicetus parki* and relatives, and eomysticetids. Odontocetes are mainly rare but well-preserved platanistoids, including Squalodontidae, the small *Waipatia* (Waipatiidae), "*Microcetus*" and *Notocetus* (both Squalodelphinidae), and undescribed Dalpiazinidae. Tantalizing fragments of an archaic species of Delphinida and a sperm whale are known. There are notable absences, including the mysticete groups Aetiocetidae, Mammalodontidae and Janjucetidae. In contrast to South Carolina, there are no archaic odontocetes comparable to *Agorophius* and *Xenorophus*.

Small-to-medium-sized mysticetes dominate assemblages, with small odontocetes also conspicuous. The shallow broad seas could have been a breeding ground for mysticetes from the recently developed Southern Ocean ecosystem to the south. Why platanistoids are common but delphinoids and sperm whales are rare is not clear. Perhaps the shallow seaway suited neritic rather than more-pelagic species. The assemblages give the impression that the Oligocene was a time of structural/ecological experiment. Species were spread fairly evenly amongst diverse family-level taxa, whereas, for extant cetaceans, a few families account for most species diversity. Some of the better preserved fossils will help resolve cladistic relationships of extant Cetacea, thus providing an independent standard against which to compare molecular classifications.

VI. Miocene: Southwest Atlantic (Patagonia)

Strata of the "Patagonian" marine stage in southern Argentina have produced Early Miocene Cetacea, which include basal (stem) members of modern families. These fossils are from the Gaiman and Monte Leon Formations of Santa Cruz, Chubut, and Rio Negro Provinces, and represent the Leonian local stage, Early Miocene and possibly latest Oligocene. Other marine mammals—pinnipeds, sirenians—have not been reported. The strata represent shallow-water settings, in which age-diagnostic microfossils are uncommon, and exact international correlations are uncertain. The Chubut River region has provided the main described material. More than a century of basic taxonomy includes work by Moreno, Lydekker, True, and Muizon. Cabrera (1926) and Cozzuol (1996) summarized the fossils.

Amongst the Early Miocene Cetacea, the small *Morenocetus* is an early right whale. The rostrum is not known, but other skull features are consistent with balaenid affinities. Some studies, surprisingly, place this whale in the crown Balaenidae, rather than in the stem. Of less certain relationships are the stem-balaenopterids *Aglacetus* and "*Plesiocetus*," also known from variably complete skulls. Skull form is quite different between these mysticetes, indicating quite different habits and affinities.

Odontocetes are notably more diverse, and include some of the best-known early sperm whales: the small *Diaphorocetus*, and the much larger *Idiorophus*. Both are archaic in appearance, retaining upper teeth with obvious enamel and a narrow anterior on the rostrum. Archaic platanistoid odontocetes include the large and long-beaked shark-toothed dolphin *Phoberodon* (Squalodontidae) and the short-beaked *Prosqualodon*. *Prosqualodon* is also present in New Zealand and Australia; it has been placed variously in the Squalodontidae or its own group Prosqualodontidae, in turn dubiously allied with the true dolphins (Delphinida). A third group of platanistoids, the Squalodelphinidae, is represented by *Notocetus*, in turn important in refining the higher classification of the Platanistoidea. *Notocetus*-like odontocetes also occur in New Zealand pointing, as for *Prosqualodon*, to a Southern Ocean distribution. *Notocetus* and other squalodelphinids range into the North Atlantic and Mediterranean. The eurhinodelphinid *Argyrozetes* shows extreme lengthening of the rostrum, particularly the toothless premaxillae; another Early Miocene species in this genus has been reported from California. True dolphins (Delphinida) are rare, represented by the kentriodontid *Kentriodon*.

The Patagonian cetaceans indicate that "modern" ecological structuring (e.g., deep-diving sperm whales, skim-feeding balaenids) was established by the Early Miocene. Some species probably had circum-Southern Ocean distributions as also seen amongst living cetaceans.

VII. Miocene: NorthWest Atlantic (Chesapeake Bay)

Shallow-dipping strata of the Chesapeake Group exposed around the western shores of Chesapeake Bay, in Maryland and Virginia, have been an important source of Miocene and Pliocene marine mammals for over 150 years (Gottfried *et al.*, 1994). Fossil cetaceans, sirenians, and phocid seals are present, along with land mammals, other vertebrates, and rich assemblages of marine invertebrates. Early studies on these fossils were made in the 1800s by the pioneering vertebrate paleontologists Harlan, Leidy, and Cope. Later, True (early 1900s) and Kellogg (1920s–1960s) produced such detailed descriptions of taxa such as *Delphinodon* and *Parietobalaena* that the Chesapeake fossils have become international standards of comparison. Significant collections are held in the Smithsonian Institution.

Marine mammals occur in five formations of the Chesapeake Group: Calvert (Early to early Middle Miocene), Choptank (Middle Miocene), St. Mary's (later Middle Miocene), Eastover (Late Miocene) and Yorktown (Pliocene). These are mainly fine grained, shallow water strata deposited in climate regimes ranging from subtropical (early Miocene, ~19Ma) to near-modern (Pliocene, ~4.5Ma) (Weems and Edwards, 2007). Strata are soft, so that fossils can be collected easily. The fossils are often preserved well, with fine sutural detail present and only limited crushing. Material ranges from single worn bones to nearly-complete skeletons.

Fossils from the Calvert Formation are important in revealing faunal composition around the Early to Middle Miocene boundary, approximately 16Ma. Amongst the diverse cetaceans, odontocetes include species in three families of Platanistoidea: the shark-toothed dolphins, Squalodontidae (*Squalodon*), Squalodelphinidae (e.g., *Phocageneus*), and stem-Platanistidae (*Zarhachis*, possibly *Pomatodelphis*, and the long-enigmatic *Araeodelphis*). The extinct long-snouted Eurhinodelphinidae include two Calvert species of *Schizodelphis*, and two of *Xiphiacetus* including the former "*Eurhinodelphis*" *bossi*. True dolphins, Delphinoidea, are placed in the archaic grade family Kentriodontidae (e.g., *Kentriodon*, *Hadrodelphis*). There is a small sperm whale, Physeteridae (*Aulophyseter*; =*Orycterocetus* of older accounts), and extinct dolphins of uncertain affinities (*Tretosphyx*, *Pelodelphis*).

Mysticetes represent stem balaenopterids or balaenopteroids (e.g., *Aglaocetus*, *Diorocetus*, *Parietobalaena*; Steeman, 2007); there are no firm reports for the Cetotheriidae or Balaenidae, groups that appear higher in the Chesapeake Group. Other marine mammals are markedly rarer in the Calvert Formation. Phocid seals, known mostly from isolated elements but also from rare partial skeletons, form the basis for the phocine *Leptophoca*, and a species of the monachine *Monotherium*. Sea cows include the extinct dugong *Metaxytherium crataegense* which also occurs in the Pacific (Montera Formation, Peru), indicating movement presumably through the Central American Seaway.

Marine mammal assemblages from the Chesapeake Group reveal marked faunal change over time. Archaic cetaceans from the Calvert Formation, such as the eurhinodelphinids, squalodontids, and squalodelphinids, are rare or absent in overlying (younger) units, while extant families such as the Delphinidae and Balaenopteridae become significant by the Pliocene. Concurrently, species-level diversity dropped. Ecological shifts are indicated by the absence of squalodontids and long-snouted eurhinodelphinid and stem-platanistid/platanistoid dolphins.

South of Chesapeake Bay, strata of the lower Yorktown Formation (Early Pliocene, ~4.5 Ma) at Lee Creek Mine, North Carolina, have produced thousands of isolated marine mammal bones (Whitmore, 1994), expanding the fauna beyond the Yorktown at Chesapeake Bay. Fossils include ziphiids, physeterids, kogiids, delphinids, balaenopterids, balaenids, and phocid seals. Unusual elements include monodontids (now found only at high latitudes) and pontoporiids (now restricted to the South Atlantic). Similar assemblages occur in the San Diego and Pisco Formations.

Strata of the Chesapeake Group, especially the Calvert Formation, are one of the world's richest sources of fossil marine mammals, particularly Cetacea. The abundance of young animals could reflect favorable conditions for calving, or, equally, a high mortality for young individuals.

VIII. Miocene: Northeast Pacific (Sharktooth Hill, California)

The Sharktooth Hill Bonebed of Kern County, in the foothills of the Sierra Nevada, California, is a key horizon for marine mammal fossils in the Pacific Basin. The assemblage includes more than 100 marine vertebrates (Kellogg, 1931, Barnes, 1977). Cetaceans, pinnipeds, rare desmostylians, turtles, marine birds, chondrichthyans, teleosts, and terrestrial vertebrates occur abundantly in, and less commonly above, a thin (10–30 cm) dense and geographically widespread layer in the Round Mountain Silt (Temblor Formation, Middle Miocene). This bone-bed formed probably over hundreds to thousands of years about 16 Ma, a little after a peak time of global warmth; it represents a mix of organisms from pelagic, neritic, and terrestrial environments. Such a deposit containing spectacularly concentrated fossils is termed a lagerstätte (fossil deposit of exceptional abundance or quality). Most of the fossils are isolated elements dominated by mammalian postcrania and by shark teeth, but sometimes there are natural associations of bones from one individual. Preservation varies; bones may be finely preserved, or eroded, and sometimes carry marks caused by scavengers or predators. The deposit has been studied extensively, mainly by research groups from Los Angeles, San Diego, and Berkeley.

Cetaceans dominate the marine mammals (Barnes, 1977). Mysticetes include presumed stem balaenopteroids *Aglaocetus*, *Parietobalaena*, *Peripolocetus* and *Tiphycetus*, known from partial skulls, and previously regarded as Cetotheriidae. A possible right whale is reported, but Cetotheriidae in the strict sense appear absent. Amongst odontocetes, archaic sperm whales include the moderate-sized

Aulophyseter. The taxonomy of the smaller odontocetes is less certain, for Kellogg, who named most of the species, based on several new species and genera on isolated periotics which, in a few cases, have been linked to later-discovered skulls. Of note are a long-beaked allodelphinid dolphin ("*Squalodon*" *errabundus*; Platanistoidea), and species in the archaic delphinoid group Kentriodontidae (e.g., *Kentriodon*). Several named odontocetes are still enigmatic (e.g., *Oedolithax*, *Lamprolithax*). In terms of ecological composition, the cetaceans are comparable to faunas in Californian waters today.

Otariid (or otarioid) pinnipeds are significant and include the types for some species or genera. They are the small archaic inogatariene *Neotherium*, three species of the large *Allodesmus* (including the rare type-species *A. kernensis* and more common *A. gracilis*), the large rare *Pelagiartcos*, and two unnamed "desmatophocines." No phocids have been described. Of other marine mammals, sirenians have not been reported, but fragmentary desmostylians occur.

There are conspicuous faunal similarities with the slightly older assemblage from the Calvert Formation of Maryland and Virginia, western North Atlantic; e.g., *Parietobalaena* and *Kentriodon* are reported for both places. Differences are also marked; e.g., phocoid seals, sirenians, and squalodontid and eurhinodelphinid odontocetes are absent from the Sharktooth Hill Bonebed, while otarioid seals and desmostylians are absent from the Calvert.

IX. Mio-Pliocene: Southeast Pacific (Peru)

Since the early 1980s, Muizon and others have documented diverse later Miocene and Pliocene marine mammals, including some quite surprising ecotypes, from the sandy Pisco Formation of southern Peru. Rich localities are around Sacaco, near Lomas, where well-preserved skeletons of cetaceans and pinnipeds occur, and Ica, to the north. Pisco strata include diatomite, sandstone, siltstone, and occasional conglomerate, sometimes volcanic-rich, with marine invertebrates and bone-rich horizons. Settings are intertidal, barrier bar, lagoonal, and shallow embayment; these environments were probably protected from the open Pacific, perhaps by rocky promontories. The sequence of vertebrate faunas involves: Cerro la Bruja (base), El Jahuay, Aguada de Lomas, Montemar, Sud-Sacaco, and Sacaco (top). The exact age for each horizon is uncertain because the Pisco Formation mostly lacks fossils useful in international correlation.

Odontocete cetaceans are the most diverse marine mammals (Muizon, 1988). The oldest productive Pisco horizon, Cerro la Bruja, is probably Middle Miocene, approximately 15–12 Ma; taxa include kentriodontids (e.g., *Atocetus*) and an early record for stem Pontoporiidae (the peculiarly short-beaked *Brachydelphis*). Other younger Miocene horizons at El Jahuay (~9 Ma) and Aguada de Lomas (8–7 Ma) yield early porpoises (stem Phocoenidae, e.g., *Australithax*), archaic sperm whales (narrow-skulled *Scaphokogia*), archaic dolphins (Kentriodontidae, e.g., *Atocetus*), beaked whales (stem Ziphiidae), and sperm whales (stem Physeteridae) (Muizon, 1988). Younger assemblages, from the latest Miocene Montemar (~6 Ma), and Pliocene Sud-Sacaco (4–5 Ma) and Sacaco (3–4 Ma) localities for the Pisco Formation, are similar in content. Of note are stem pontoporiids (*Pliopontos*), porpoises (*Piscolithax*), ziphiids (*Ninoziphius*), sperm whales, and kentriodontids, but also more-modern dolphins (Delphinidae) and an unnamed beluga (Delphinapterinae). The most peculiar Pliocene odontocetes are two species of the extinct tusked walrus-mimic *Odobenocetops*. These animals, reported only from the Pisco Formation, have secondarily lost many of the distinctive facial features of odontocetes (Muizon and Domning, 2002).

Mysticeti from the Pisco Formation include cetotheres and up to six balaenopterids: a small cetother, *Piscobalaena*, the larger *Piscocetus* (a possible Cetotheriid) and an extinct *Balaenoptera* (Balaenopteridae). *Piscobalaena* includes excellent specimens important in understanding the Cetotheriidae (Bouetel and De Muizon, 2006). Some of the mysticetes preserve baleen plates *in situ* on the skull (Brand *et al.*, 2004).

Up to nine species of phocid seals are present. Two lobodontines, the *Monachus*-like *Piscophoca pacifica* and long-skulled *Acrophoca longirostris*, are known from articulated skeletons. From the relatively barren upper Pisco Formation comes the unique specimen of an extinct fur seal, *Hydrarctos* (Otariidae: Arctocephalinae) which is probably Late Pliocene. A sirenian, probably close to *Dugong*, is from Early Pliocene lagoonal deposits. Despite the unexpected occurrence, it seems certain that the extinct species of Pisco sloth *Thalassocnus* really were marine mammals. Marine sloths range from 7–8 Ma to 4–3 Ma and possibly 3–1.5 Ma at Sacaco (Muizon *et al.*, 2003), they are abundant, there are no other putative land mammals in the vertebrate assemblage, and the adjacent coast was a desert.

Pliocene assemblages from the Pisco Formation include some cetaceans and pinnipeds similar to those from the Yorktown Formation of the Chesapeake Group, North Atlantic, indicating contact through the Central American Seaway before the uplift of Panama. Several genera also occur at Isla Cedros, Baja California Sur. When considered with roughly contemporaneous assemblages from elsewhere in the eastern Pacific (Isla Cedros and San Diego), and contrasted with modern communities, it seems that there must have been considerable faunal turnover late in the Pliocene or in the Pleistocene.

X. Plio-Pleistocene: Northeast Pacific (San Diego, California)

Well-preserved geologically young marine mammals—from the later Pliocene and earlier Pleistocene—are rare, but important in revealing marine mammal ecology before the dramatic climate shifts and sea level change of the Pleistocene glaciations. One notable sequence is the ~84 m of San Diego Formation at and near San Diego, Southern California (Deméré, 1994). This sandy to gravelly unit was deposited late in the Pliocene (3–2 Ma) and possibly Pleistocene (>1.5 Ma), in settings mostly from shoreface to mid- and outer shelf. The lower finer strata with abundant fossils are marine, while the coarser and sparsely fossiliferous upper strata are partly nonmarine. The formation contains many marine mammals that are now extinct, including some whose descendants live in quite different settings today.

Pinnipeds, Cetacea, and Sirenia are present (Barnes, 1977, Deméré, 1994), including many complete enough to identify to species level. The pinnipeds include Otariidae, e.g., an extinct species of *Callorhinus*, and Odobenidae, e.g., the extinct long-tusked walrus *Valenictus* and *Dusignathus*. There are no phocids.

Three families of mysticetes include two species of the cetother *Herpetocetus*, providing one of the last records of Cetotheriidae *sensu stricto*. The extinct minke whale *Balaenoptera davidsonii* is one of five rorquals (Balaenopteridae), and there are two right whales (Balaenidae). Notable amongst odontocetes are the long-beaked *Parapontoporia* (a marine stem Lipotidae), two porpoises (Phocoenidae), a beluga-like animal (Delphinapterinae), and two dolphins (Delphinidae), including *Stenella* or *Delphinus*). The huge sirenian *Hydrodamalis cuestae* appears to be a direct ancestor to the recently exterminated *Hydrodamalis gigas*, Steller's sea cow, of the cold North Pacific.

These fossils imply major shift in geographic range and/or ecology in geologically recent times: walrus (now only one species, of *Odobenus*)

and belugas currently live in cold northern waters, as *Hydrodamalis* also did until a few 100 years ago. Descendants of *Parapontoporia* have left the eastern Pacific, and cetotheres are extinct.

Franciscana Dolphin

Pontoporia blainvillei

ENRIQUE A. CRESPO

I. Characteristics and Taxonomy

Franciscana (*Pontoporia blainvillei*) is also known as the La Plata River dolphin. In Uruguay and Argentina it is called *franciscana*, whereas in Brazil it is called *toninha* or *cachimbo*. Although both this species and the Yangtze river dolphin, *Lipotes vexillifer*, were until recently regarded as of the family **Pontoporiidae**, the franciscana is now the sole member of this family. The franciscana is the only one of the five river dolphins living in the marine environment. It is one of the smallest dolphins and has an extremely long and narrow beak and a bulky head. The franciscana is brownish to dark gray above, turning lighter to the flanks and belly (Fig. 1). The number of teeth in the upper and lower jaws ranges from 53 to 58 and from 51 to 56, respectively.

A. Fossil Record

Three records have been related to the franciscana and assigned to the Family **Pontoporiidae**: *Brachidelphis mazeasi*, a middle

miocene fossil from the Pisco Formation (Perú), *Pontistes rectifrons*, a late miocene fossil found in the Paraná Formation (Argentina), and *Pliopontos littoralis*, a pliocene fossil closely related to the living species described from the Pisco Formation (Perú).

B. Geographic Variation

Skull morphology, genetic markers and parasites have been used to identify stocks. The existence of two potential populations was tested by means of the differences in skull morphology. A northern (smaller) form was proposed between Rio de Janeiro and Santa Catarina and a southern (larger) form for Rio Grande do Sul, Uruguay, and Argentina. The existence of differences between populations was confirmed some years later, using mtDNA from samples collected at Rio de Janeiro and Rio Grande do Sul (Secchi *et al.*, 1998). It was found that six exclusive haplotypes were present in the northern population and five in the southern one, indicating some degree of segregation between the stocks. Recent work on mtDNA and radio tracking carried out at Bahía Samborombón and Bahía Anegada (Argentina) reveal significant genetic division at the regional level, fine-scale structure within the study area, limited movement patterns, a small home range, and a high degree of isolation (Bordino *et al.*, 2007). Gastrointestinal parasites were also used as bioindicators to study the existence of stocks. The parasites seem to indicate segregation into two functional or ecological stocks between southern Brazil–Uruguay and Argentina. Three species of parasites were recommended as biological tags (*Hadwenius pontoporiae*, *Polymorphus cetaceum*, and *Anisakis typica*). On the base of the present information, at least three stocks or populations could exist.

II. Distribution and Abundance

The species is endemic in southwestern Atlantic waters. Based on the distribution of sightings and catches, the franciscana lives in a narrow strip of coastal waters beyond the surf to the 30-m isobath

Figure 1 A live-stranded franciscana in a tank. Photo by R. Bastida.

(Fig. 2). The complete range known for the franciscana extends from Itaúnas (18°25'S, 39°42'W) in Espírito Santo, Brazil, to the northern coast of Golfo San Matías (41°10'S) in northern Patagonia, Argentina. Recent surveys carried out in Argentina showed that franciscana is also found up to the 50-m isobath. However, density declines with distance from the coast. In the strip between the 30- and the 50-m isobaths, density is half that between the coast and the 30-m isobath. With regard to abundance estimates, only two surveys were carried out for franciscanas. One survey was at Rio Grande do Sul State coast, southern Brazil, a region where there are current data on annual incidental mortality. At Rio Grande, the density was estimated to be 0.657 dolphins per km², with a population estimation of 42,000 individuals in 64,000 km² between the coast and the 30-m isobath. In Argentina, the second area where the franciscanas were surveyed, density was lower than in southern Brazil (0.304–0.377 dolphins per km²) and abundance was estimated to be 15,000 individuals between the coast and the 50-m isobath in 50,000 km².

III. Ecology

Little is known about the northern stock or population between Espírito Santo and Santa Catarina, a region that is under the influence of the Brazil tropical current. Between southern Brazil and Golfo San Matías, the franciscana lives in a transition zone in which

the surface circulation of the southwestern Atlantic is dominated by the opposing flows of subtropical and subantarctic water masses. The coastal marine ecosystem is characterized by continental runoffs with a high discharge of high-nutrient river flows (e.g., Lagoa dos Patos, Río de la Plata). Juvenile sciaenids, the most important prey of the franciscana, are typically associated with those continental runoffs and the influence of subtropical shelf waters. The franciscana feeds mostly near the bottom on fishes of several families, such as sciaenids, engraulids, batrachoidids, gadids, carangids, and atherinids. However, sciaenids account for most of the fish species. The diet also includes squids, octopus, and shrimps. The franciscana feeds on the most abundant species in the region and seems to change its diet according to seasonal prey fluctuations. A comparison of results between two studies carried out 15 years apart in Rio Grande do Sul showed shifts in prey composition in which important prey of the former period were depleted in artisanal fisheries. Among predators, remains of franciscanas were found in stomach contents of killer whales (*Orcinus orca*) and several species of sharks.

IV. Behavior and Physiology

Very little is known about behavior of free-ranging franciscanas, in part because they are difficult to observe in the wild and in part as a consequence of low sighting effort. The franciscana is thought to be

Figure 2 Distribution range of the franciscana dolphin (*Pontoporia blainvillei*) in the Southwestern Atlantic Ocean. The shaded area represents approximately the 30-m isobath.

solitary or not gregarious. Herd size may range from 2 to 15 individuals. In aerial surveys carried out in southern Brazil with the objective of estimating abundance, 37 sightings gave a mean herd size of 1.19 (SD: 0.47, range: 1–3). In aerial surveys conducted in Argentina, 101 franciscanas were observed in 71 sightings with an average of 1.43 (SD = 0.85, range: 1–5) individuals per group. A study of wild behavior at Bahía Anegada in southern Buenos Aires Province showed a seasonal pattern with cooperative feeding, with traveling activities increasing during winter and high tide. The mean swimming speed was estimated in 1.3m/sec (+/- 0.09) with a maximum of 1.8m/sec, and mean dive duration was estimated in 21.7sec (+/- 19.2) (range from 3 to 82sec). The average at the surface was estimated to be 1.2sec.

V. Life History

Females are larger than males. Adult females range between 137 and 177 cm in total length, whereas males range between 121 and 158 cm. The weight of the mature females range between 34 and 53 kg and that of males range between 29 and 43 kg. Neonates in Uruguay range in size between 75 and 80 cm, whereas in southern Brazil they range between 59 and 77 cm (some of the smaller neonates could be near term fetuses). Neonates weigh around 7.3–8.5 kg. Age at sexual maturity is estimated to be 2.7 years, and the gestation period is between 10.5 and 11.1 months. Females give birth around November and lactation lasts for 9 months. However, calves take solid food around the third month, sizing between 77 and 83 cm. Mating seems to occur in January and February. The calving interval is around 2 years; nevertheless, few females are lactating and pregnant at the same time. Reproductive capacities and life span are low for the species, which is a problem for the population to sustain the mortality rates caused by fisheries. Longevity has been estimated to be close to 15 years for males and 21 for females, fairly low when compared to most of the small cetaceans. Few individuals attain ages over 10 years. Three types of acoustic signals have been recorded, including low, high, and ultra high frequency clicks.

VI. Interactions with Humans

Incidental catches in gillnets, mostly of juvenile individuals, became a serious problem for the species throughout its distribution range, probably since the end of World War II. At that time, many artisanal fisheries for sharks developed in the region for Vitamin A production, which was exported to Europe. During the 1970s, gillnet mortality in Uruguay was estimated at above 400 individuals/year and fell to around 100 individuals/year in the last few years for economic reasons. Nevertheless, minimum mortality rates were always estimated at several thousands of individuals throughout the distribution range. At present, higher mortality rates are shown by the fisheries at Rio Grande do Sul and Buenos Aires Province, where no less than 700–1000 and 500–800 are, respectively, incidentally taken. The estimated mortality for the whole distribution range could be around 1200–1800 individuals per year. Due to the variability found in mortality rates and abundance estimates, it is not known if those mortality rates are sustainable. In gross numbers, the upper limits of abundance estimations cannot account for the lowest estimates of mortality. Therefore, more precise estimates are needed along with conservation measures to preserve the species. Other threats to the franciscana include habitat degradation. A large proportion of the distribution range is subject to pollution from several sources, especially the agricultural use of land and heavy industries between São Paulo in Brazil and Bahía Blanca in Argentina. The coastal zone is

also intensely used for boat traffic, tourism, and artisanal and industrial fishing operations.

Fraser's Dolphin *Lagenodelphis hosei*

M. LOUELLA L. DOLAR

I. Characteristics and Taxonomy

Fraser's dolphin was described in 1956 based on a skeleton collected by E. Hose from a beach in Sarawak, Borneo in 1895. F.C. Fraser gave it the genus name *Lagenodelphis*, due to what appeared to him a similarity of the skull to those of *Lagenorhynchus* spp. and *Delphinus delphis*. The external appearance of this species was not known until 1971 when specimens were found in widely separated areas: near Cocos Island in the eastern tropical Pacific, South Africa, and southeastern Australia (Perrin *et al.*, 1973).

Fraser's dolphin is easily identified by its stocky body, short but distinct beak, and small, triangular, or slightly falcate dorsal fin; the flippers and flukes are also small (Fig. 1; Jefferson *et al.*, 1993; Jefferson and Leatherwood, 1994; Perrin *et al.*, 1994). The color pattern is striking and varies with age and sex (Jefferson *et al.*, 1997). For example, a distinct black head stripe or "bridle" is absent in calves, variable in females, and extensive in adult males, where it merges with the eye-to-anus stripe to form a "bandit mask." Color pattern in the genital region may also be sexually dimorphic. The back is brownish gray, the lower side of the body is cream colored, and the belly is white or pink. Other features that appear to vary with age and sex are dorsal fin shape and the post-anal hump. With some variability, the dorsal fin is slightly falcate in calves and females and more erect or forward canted in adult males. Similarly, the post-anal hump is either absent or slight in females and young of both sexes and well developed in adult males. From a distance,

Figure 1 Fraser's dolphins in Verde Island Passage, Philippines. (A) Group of females and calves and (B) an adult male, showing the "bandit mask." Photographs by M.L.L. Dolar.

the eye-to-anus stripe makes Fraser's dolphin look similar to the striped dolphin, *Stenella coeruleoalba*. However, the distinctive body shape of Fraser's dolphin rules out confusion with other species. The largest male recorded was 2.7 m long and the largest female 2.6 m with males over 10 years old significantly larger than females. Large males could weigh up to 210 kg. Based on a limited number examined, it is tentatively proposed that Fraser's dolphins in the Atlantic are larger than those in the Pacific.

Fraser's dolphin belongs to the subfamily Delphininae. Based on cytochrome *b* mtDNA sequences, it is more closely related to *Stenella*, *Tursiops*, *Delphinus*, and *Sousa* than it is to *Lagenorhynchus* (LeDuc *et al.*, 1999). Morphologically, the skull (Fig. 2) structure shows close similarity with that of the common dolphin, *D. delphis*, in terms of the presence of deep palatal grooves, and with those of *S. longirostris*, *S. coeruleoalba*, and the Clymene dolphin, *Stenella clymene*, in several other characteristics.

II. Distribution and Abundance

Fraser's dolphin is a tropical species, distributed between 30°N and 30°S. Strandings outside this limit, such as in southeastern Australia, Brittany, United Kingdom and Uruguay, are considered unusual and are probably influenced by temporary oceanographic events. Density and abundance are known only for a few areas: eastern tropical Pacific, 289,300 with CV 0.34 (Wade and Gerrodette, 1993); eastern Sulu Sea, 13,518 with CV 0.26 and density 0.58/km² (Dolar *et al.*, 2006); Hawaii,

Figure 2 Skull of Fraser's dolphin. Photograph by W. F. Perrin.

10,226 with CV 1.16 and density 0.0042/km² (Barlow, 2006). Populations in Japan and the Philippines differ morphologically (Perrin *et al.*, 2003).

III. Ecology

Fraser's dolphins are typically an oceanic species, except in places where deep water approaches the coast such as the Philippines, Indonesia, and Lesser Antilles, where Fraser's dolphins can be observed within 100 m from shore (Balance and Pitman, 1998; Dolar *et al.*, 2006). In the eastern tropical Pacific, they were observed to occur at least 15 km from the coast where water depth was between 1500 and 2500 m. In the Sulu Sea, Philippines, high sighting rates and large school sizes were in waters 700 to 3,500 m, peaking at about 1000 m, although some animals were observed in shallower waters adjacent to the continental shelf. In the Gulf of Mexico, sightings have been in waters around 1000 m deep, and the animals appear to be more common in the Gulf than anywhere else in the North Atlantic (Würsig *et al.*, 2000). Affinity to deep waters can be explained by the type of prey eaten by Fraser's dolphins, which is composed of mesopelagic fish, crustaceans, and cephalopods (Robison and Craddock, 1983; Dos Santos and Haimovici, 2001; Dolar *et al.*, 2003). It is also suggested that compared to other pelagic dolphins, Fraser's dolphins feed selectively on larger prey that inhabit deeper waters. In the eastern tropical Pacific and the Sulu Sea, the most common fishes in the diet are the Myctophidae and the Chauliodontidae, and the most common crustaceans are the Ophrophoridae. Mesopelagic cephalopods also comprised a significant amount of the DIET in the Sulu Sea animals, i.e., about 30% by volume.

In southern Brazil, cephalopods, fishes, and crustaceans were found in the stomachs of four stranded Fraser's dolphins. Based on prey composition, it was hypothesized that Fraser's dolphins in the eastern tropical Pacific feed at two depth horizons: the shallowest level of no less than 250 m and the deepest no less than 500 m. In the Sulu Sea, Fraser's dolphins appear to feed from near surface to deeper than 600 m. Myoglobin (Mb) concentrations in the skeletal muscles of Fraser's dolphin support the distribution and feeding habits of this species (Dolar *et al.*, 1999). However, in South Africa and in the Caribbean, Fraser's dolphins were observed FEEDING near the surface (Sekiguchi *et al.*, 1992; Watkins *et al.*, 1994).

Although no PREDATION has been reported, Fraser's dolphins may be preyed upon by killer whales (*Orcinus orca*), false killer whale (*Pseudorca crassidens*), and large sharks. Cookie cutter sharks (*Isistius brasiliensis*) are thought to inflict circular wounds.

An external PARASITE, *Xenobalanus* sp., and internal parasites (*Phyllobothrium delphini*, *Monorhynchus grimaldi*, *Anisakis simplex*, *Tetrabothrius* sp., *Bolbosoma* sp., *Strobicephalus triangularis*, *Campula* sp., and *Stenurus ovatus*) have been observed in Fraser's dolphins.

Dolphin morbillivirus was found present in samples of Fraser's dolphins from the southwest Atlantic with an indication that the virus might be endemic to these animals (Van Bressem *et al.*, 2001).

IV. Behavior and Physiology

Fraser's dolphins often swim in tight fast-moving schools of 100 to 1000 individuals with the members of the school "porpoising in low-angle, splashy leaps" and have been reported to swim away from

vessels in the eastern tropical Pacific. In the Philippines, they were observed to ride the bow at boat speed less than three knots but were often displaced by melon-headed whales (*Peponocephala electra*).

In the eastern tropical Pacific and in the Gulf of Mexico, Fraser's dolphins are often found together with melon-headed whales (Perryman *et al.*, 1994; Würsig *et al.*, 2000). Although also sometimes seen with melon-headed whales (when in relatively shallow waters), Fraser's dolphins in the Sulu Sea are often seen with short-finned pilot whales, *Globicephala macrorhynchus* (Dolar *et al.*, 2006). Other species Fraser's dolphins have not been seen with are the false killer whale, Risso's dolphin (*Grampus griseus*), spinner dolphin, pantropical spotted dolphin (*S. attenuata*), bottlenose dolphin (*Tursiops truncatus*), and sperm whale (*Physeter macrocephalus*). In the western tropical Indian Ocean, Fraser's dolphins have not been seen with any other species.

Fraser's dolphins are deep divers. Based on the vertical distribution of the prey they eat, they could dive down to 600 m or deeper. Mb concentration in epaxial muscles averages at 7.1 g Mb/100^g muscle and is comparable to those of the very best divers such as the Weddell seal (*Leptonychotes weddellii*), northern bottlenose whale (*Hyperoodon ampullatus*), and sperm whale.

V. Life History

The oldest specimen recorded from a sample of 16 dolphins from southeastern Brazil (Siciliano *et al.*, 2007) was 19 years old. An asymptotic length of 231.2 cm predicted for this group using the Gompertz model occurred at about 7–8 years old. In Japan, the oldest specimen from a sample of 108 dolphins was estimated to be 17.5 years old with the males reaching sexual maturity at about 7–10 years at 220–230 cm and the females at 5–8 years at 210–220 cm (Amano *et al.*, 1996). The school showed a mixed-age group and a ratio of 1:1 between males and females. Mating may be promiscuous. The annual ovulation rate is about 0.49, and the gestation period is about 12.5 months. The calving interval is approximately 2 years. In Japanese waters, calving appears to peak in spring and fall. Limited samples from South African waters suggest that calving occurs in summer. Length at birth is estimated to be about 100–110 cm.

VI. Interaction with Humans

Fraser's dolphins are caught in drive nets in Japan and by harpoon in the Lesser Antilles, Indonesia, and (before they became protected) in the Philippines (Dolar, 1994; Dolar *et al.*, 1994). They are also caught incidentally in purse seines in the eastern tropical Pacific and the Philippines, in trap nets in Japan, in gill nets in South Africa and Sri Lanka, in anti-shark nets in South Africa, and in drift nets in the Philippines.

Gastrointestinal Tract

JAMES G. MEAD

The gastrointestinal tract consists of all structures derived from the primitive gut tube and distal to the esophagus. As such, the gastrointestinal tract includes the stomach, small intestine, large intestine, and those accessory structures that have formed from that part of the gut (liver, gall bladder, pancreas,

hepatopancreatic duct, anal tonsils). The posterior boundary is the lower part of the anal canal where the mucous membrane of the gut ends and the epidermis begins.

The anatomy of the gastrointestinal tract has long fascinated workers. Grew (1681) is the earliest worker who dealt with that topic exclusively. Tyson (1680), in his marvelous treatment of the anatomy of the harbor porpoise (*Phocoena phocoena*), went extensively into the gastrointestinal tract. Owen dissected the dugong (*Dugong dugon*) (1838) and then summarized the information on the digestive system of mammals in his magnum opus on comparative anatomy (1868). William Turner (1912) did extensive studies of the stomach of cetaceans which are summarized in his catalog of the specimens of marine mammals in the Anatomical Museum of the University of Edinburgh. Langer (1988) and Reynolds and Rommel (1996) discussed the gastrointestinal tract of the Sirenia in some detail.

The parts of the gastrointestinal tract are described starting with the stomach and progressing distally, using the terminology of Chivers and Langer (1994). The major features of the gastrointestinal tract are summarized in Table I. Some dimensions are presented in this chapter but taking consistent measurements of the gastrointestinal tract, both length and volume, is difficult due to the elasticity of the organs. At death, the muscles lose their tonus and the length and volume can double or triple (Slijper 1962).

I. Major Organs

A. Stomach

The stomach is a series of compartments starting with the cardiac, fundic and ending with the pyloric. The boundary of the stomach with the esophagus is determined by the epithelial type; stratified squamous for the esophagus, columnar for the stomach. The distal boundary is marked by the pyloric sphincter.

1. *Pinnipedia* The stomach in pinnipeds is relatively uncomplicated when compared to the rest of marine mammals. The stomach in the California sea lion (*Zalophus californianus*) (Green, 1972, p. 286) consists of a simple cardiac chamber into which the esophagus enters, followed by a narrowing into the pyloric chamber. There is a prominent pyloric sphincter. The pyloric end of the stomach is strongly recurved of the cardiac portion. The stomach in the walrus, southern sea lion (*Otaria flavescens*) and Weddell seal (*Leptonychotes weddellii*) do not differ from the California sea lion. The stomach of the walrus (*Odobenus rosmarus*), although it is not described in any detail, does not appear to differ markedly from that of the other pinnipeds. Pinnipeds follow the carnivore plan of a relatively simple single-chambered (monocular) nonspecialized stomach.

2. *Sirenia* The stomach in the dugong is moderately complex. Externally it is a simple oval organ with the esophageal opening in the center. Internally there is a ridge (gastric ridge) that divides the

stomach into two compartments, the cardiac and the pyloric portions. There is a development of a powerful sphincter up to 4-cm thick at the esophageal/gastric junction (Owen, 1868). The stomach wall is highly muscular. There is a cardiac gland that is roughly spherical and about 15cm in diameter in adults. The cardiac gland opens into the first compartment, where the esophagus also opens. The mucosa in the cardiac gland is packed with the gastric glands that are distinguishable from the glands in the main stomach compartment. The glands consist of chief and parietal cells in a ratio of about 10:1. The mucosa in the cardiac glands is arranged in a complex plicate structure. The pyloric aperture is in the second compartment. The cardiac region of the stomach extends for several centimeters from the esophageal junction. The stomach is lined by gastric glandular epithelium with a particular abundance of goblet cells and mucus-secreting gastric glands.

The stomach of the dugong appears to be modified to secrete mucus to aid in lubricating the ingested material and prevent abrasion to the mucosa. It is interesting that the salt content of the dugong diet is high; the sodium is about 30 times and the chloride about 15 times that of terrestrial pasture plants.

The stomach in the recently extinct *Hydrodamalis* (Steller's sea cow) was apparently very large. According to Steller it was 6-ft long and 5-ft wide when distended with masticated sea-weed. The stomach in the manatees (*Trichechus* spp.) is very similar to that in the dugong. The stomach is divided by a muscular ridge into cardiac and pyloric regions. A single cardiac gland opens into the cardiac region of the stomach.

3. *Cetacea* The cetacean stomach is a diverticulated composite stomach, consisting of regions of stratified squamous epithelium, fundic mucosa, and pyloric mucosa. The stomach, as typified by a delphinids, consists of four chambers. These have been referred to by various anatomical terms: forestomach (first, esophageal compartment, paunch) main stomach (second, cardiac, fundus glandular, proximal), connecting chamber (third, fourth, “narrow tunneled passage,” “conduit étroit,” intermediate, connecting channel, connecting division), and pyloric stomach (third, fourth, fifth, pyloric glandular, distal).

A. FORESTOMACH There is no full consensus about the homology of the forestomach in *Cetacea*. It is lined with stratified squamous epithelium, such as the esophagus, and there was reason to believe that it was just an esophageal sacculation. Embryological work in the minke whale (*Balaenoptera acutorostrata*) demonstrated that the forestomach was formed from the stomach bud, but that the esophagus was not. This indicates that the cetacean esophagus is homologous to the forestomach of ruminants.

The forestomach of delphinoids (also called paunch) is lined with stratified squamous non-keratinized epithelium. The epithelial lining is white in freshly dead animals and is thrown into a series of longitudinal folds when empty. Similar to the other chambers in the stomach it is variable in size. It is pyriform and on the order of 30-cm long in an adult *Tursiops truncatus* (280cm total length). The forestomach is highly muscular but has no glandular functions. The forestomach/main stomach aperture is a wide opening (3–5cm in adult *Tursiops*) in the wall of the forestomach near the esophageal end. The forestomach functions as a holding cavity analogous to the crop of birds or the forestomach of ungulates. Because the communication with the main stomach is so wide, there is a reflux of digestive fluids from the main stomach and some digestion takes place in the forestomach. The same general relationships hold in *Phocoena*, *Delphinapterus*, and *Monodon*.

The forestomach of platanistoids is unusual in *Inia geoffrensis* and *Platanista gangetica* in that the esophagus runs directly into the main stomach and the forestomach branches off the esophagus. In the two other genera of platanistids the forestomach is lacking entirely.

The forestomach is present in *Physeter catodon*, where it was approximately 140 by 140cm and lined with yellowish-white epithelium in a 15.6m male. The forestomach is absent in all ziphiids, and present in all species of mysticetes.

B. MAIN STOMACH The main stomach has a highly vascular, glandular epithelium which is grossly trabeculate. The epithelium of the main stomach is dark pink to purple. The main stomach is the compartment which secretes most of the digestive enzymes and acids and in which place digestion commences. It has also been known as the fundic stomach. It is present in all cetaceans.

In delphinoids, the main stomach is approximately spherical and on the order of 10–15cm in adult *Tursiops*. The same general relationships hold in *Phocoena*, *Delphinapterus*, and *Monodon*. In *Platanista* there is a constricting septum of the main stomach which forms a small distal chamber, through which the digesta must pass. *Lipotes vexillifer* presents an unusual situation in having three serially arranged main stomach compartments. The second and third compartments are very much smaller than the first and are topographically homologous with the connecting chambers. However they are lined by epithelium that has fundic glands, typical of the main stomach.

There is nothing remarkable about the main stomach of physeteroids, but in some ziphiids there is a subdivision in their main

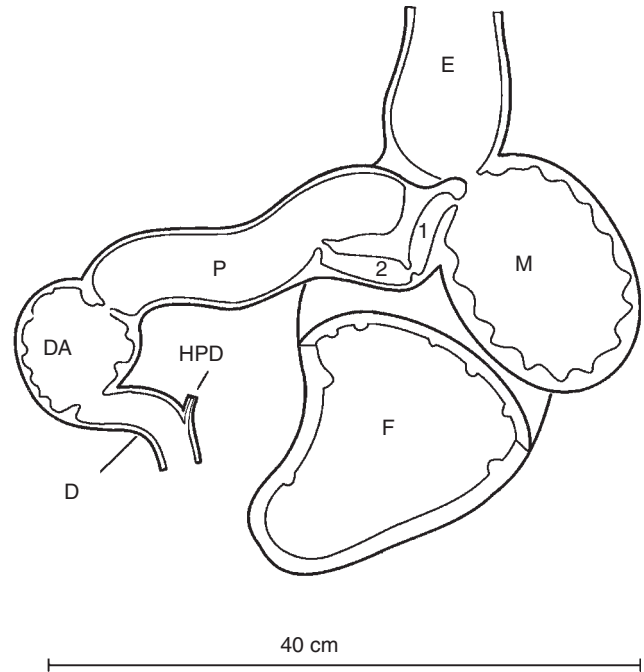

Figure 1 Stomach of a spinner dolphin, *Stenella longirostris*, in ventral view. D, duodenum; DA, duodenal ampulla; E, esophagus; F, forestomach; HPD, hepatopancreatic duct; M, main stomach; P, pyloric stomach; 1, 2, compartments of connecting chambers. After Harrison et al. (1970).

stomach. There is an incipient constriction in the main stomach of *Berardius bairdii* and *Mesoplodon bidens* that divides the stomach into two compartments. The connecting chambers exit off the second compartment. Another type of stomach modification has occurred in *Mesoplodon europaeus* and *M. mirus*, where a large septum has developed forming a blind diverticulum in the main stomach. An additional septum has developed in the diverticulum in *Mesoplodon europaeus* subdividing it Fig. 2. There is nothing remarkable about the main stomach in mysticetes.

C. CONNECTING CHAMBERS The connecting chambers, also called the connecting channel, the intermediate stomach, or the third stomach, are present in all *Cetacea*. They are lined with pyloric epithelium and are easily overlooked in dissections. They are small in most cetaceans but have been greatly developed in ziphiids. Because of their proliferation in ziphiids, where they seem to function as something more than channels between the main and pyloric stomachs, their name was changed from connecting channels to connecting chambers.

The connecting chambers in a typical delphinoid consist of two narrow compartments lying between the main stomach and the pyloric stomach. The diameter of the connecting chambers is 0.8cm in adult *Tursiops* and the combined length is 7–9cm. The epithelial lining is very similar to the pyloric stomachs. In some species the compartments are simple, serially arranged; in others they may have diverticulae. The same general relationships hold in *Phocoena*, *Delphinapterus*, and *Monodon*.

Connecting chambers occur in all the species of platanistids, with the exception of *Lipotes*. In that species, the compartments lying between the main stomach and the pyloric stomach (second and third compartments of the main stomach) are lined with epithelium containing fundic and mucous glands in the first compartment and

fundic glands in the second compartment. This would make them subdivisions of the main stomach.

The connecting chambers in ziphiids are globular compartments, ranging in number from 3 to 11. They are separated by septa and communicate by openings in the septa. The openings are sometimes central in the septa, sometimes peripheral. The connecting chambers are lined with pyloric epithelium. The connecting chambers in specimens of adult *Mesoplodon* (~5 m long) are about 10 cm in diameter.

Many workers have described the connecting chambers in a number of species of *Balaenoptera* (blue, *B. musculus*; fin, *B. physalus*; sei, *B. borealis*; minke, *B. acutorostrata* and *B. bonaerensis*). The connecting chambers in common minke whales were 10–30 cm in length. The inflated connecting chambers in an 8.5-m female *Balaena mysticetus* were 5 cm in diameter and 17 cm combined length. The presence of connecting chambers was not mentioned in dissections of right whales. The connecting chambers are relatively large in a newborn *Eschrichtius*.

D. PYLORIC STOMACH The pyloric stomach in delphinoids is a simple tubular cavity lined by typical mucous producing pyloric glands. The epithelium is in many ways similar to the epithelium of the small intestine. The pyloric stomach is about 20-cm long and 4 cm in flat diameter in an adult *Tursiops*. The same general relationships hold in *Phocoena*, *Delphinapterus*, and *Monodon*.

The pyloric stomach in *P. gangetica* is a single chamber about 12-cm long and contains abundant large tubular pyloric glands. The pyloric stomach is comparable in *Inia* and *Pontoporia* but differs markedly in *Lipotes*. In that species it is differentiated into a proximal bulbous compartment and a smaller distal compartment. The epithelial lining in *Lipotes* is similar to all other Cetacea.

The available data on the pyloric stomach of physeteroids is scanty. The pyloric compartment is present and there is no reason to assume that it is different from the rest of the cetaceans. The pyloric stomach in a newborn *Ziphius* was a simple spherical compartment that measured about 10 cm in diameter. It was lined with smooth pyloric epithelium and communicated with the duodenum through a strong pyloric sphincter. This is also the case in *Hyperoodon*, *Tasmacetus*, and some species of *Mesoplodon* (*M. densirostris*, *M. hectori*, and *M. stejnegeri*). In *B. bairdii* the main pyloric compartment has expanded in volume to where it is nearly the size of the main stomach, and has developed a small distal accessory chamber. The pyloric compartments are in series, accessory chamber lies between it and the duodenum. In all other species of *Mesoplodon* examined to date (*M. bidens*, *M. europaeus*, and *M. mirus*), a blind diverticulum has developed. The diverticulum comes off the proximal side of the pyloric stomach and lies along the distal connecting chambers. The accessory pyloric stomach communicates with the pyloric stomach through a wide opening.

In all of the balaenopterid species examined (*B. acutorostrata*, *B. borealis*, *B. musculus*, and *B. physalus*), the pyloric stomach is smaller than the main stomach. The pyloric stomach contained 8.5–12.1% of the total inflated stomach volume (18–39). It is lined with smooth pyloric epithelium. In balaenids and newborn *Eschrichtius*, the pyloric stomach appears to be similar to that of balaenopterids.

B. Small Intestine

The small intestine starts at the pyloric sphincter. Digestion continues in the small intestine and absorption of the nutrients takes

place here via absorptive villi in the mucosa. The small intestine consists of duodenum, ileum, and jejunum. The hepatic and pancreatic ducts open into the duodenum. The duodenum is short and has longitudinal folds. In the jejunum, the folds are circular (plicae circulares). Circular folds gradually disappear and are replaced by longitudinal folds toward the end of the ileum. The diameter of the intestine increases where it ends at the ileocolic orifice, opening into the colon. The ileocolic orifice is usually provided with a sphincter permitting partial closure.

1. Pinnipedia The demarcation between pylorus and duodenum is sharply marked by position of the duodenal (Brunner's) glands in *Leptonychotes weddelli*. The duodenum is 1 or 2 ft in length. Small plicae circulares and short irregular villi were present in the duodenum. Jejunum and ileum are hard to differentiate. *Phoca vitulina* has a small intestine of "great length," 40 ft in a seal 3 ft long (snout → end of flippers). An adult male *Mirounga leonina* (4.80 m length) had a small intestine length of 202 m. *Otaria byronia* lacks plicae circulares, villi being arranged on delicate transverse linear folds. *Eumetopias* has small intestine length of 264 ft (~80 m). Owen (1853) described the intestine in passing in his description of a young walrus. The small intestine was 75 feet (~23 m) long, the cecum was 1.5 in. (3.8 cm), and the large intestine was 1 foot (~30 cm) in length.

2. Sirenia The duodenum of the dugong and manatee has two duodenal diverticula that are crescentic in shape and about 10–15 cm long, measured in the curve. They communicate via a common connecting channel with the duodenum. The lining of the diverticulae is similar to the pyloric region of the stomach and contains mucous glands. The duodenum is about 30 cm in length, similar to other medium-sized mammals. Both the duodenum and the diverticulae contain prominent plicae circulares. There is a weak sphincter at the distal end of the duodenal ampulla. The length of the small intestine is from 5.4 to 15.5 m, 4–7 times the body length of the animal. Brunner's glands are present in the duodenum and the diverticulae. Paneth cells are absent in contrast to most domestic terrestrial herbivores. The diverticulae appear to enlarge the surface of the proximal duodenum which would allow a larger volume of digesta to pass from the stomach at one time.

3. Cetacea In delphinoids, there is no cecum and no marked differentiation between large and small intestine. Intestine length ranged between 8.85 and 16.80 m in specimens of *Tursiops*, *Delphinus*, and *Stenella* (total lengths from 160 to 230 cm). There is a duodenum about 30-cm long but they lack differentiation between jejunum and ileum. Examination of the small intestines by light microscopy revealed a lack of well-developed villi in delphinids.

The length of the small intestine in a 204-cm *I. geoffrensis* was 4.15 m and the duodenum is approximately 20-cm long, with the jejunum not differentiated from the ileum. A prominent longitudinal fold begins at the opening of the hepatopancreatic duct in the duodenum and continues throughout the small intestine. The small intestine varies in diameter from 0.7 to 0.8 cm. The small intestine grades into a "smooth-walled portion" which is 1 cm in diameter. The boundary between small and large intestine is indistinct, with the "smooth-walled portion" was 80 cm in length and graded into the colon distally.

There are no plicae circulares or typical villi in the intestine of *Pontoporia*. A distinct continuous longitudinal fold occurs in the small intestine. There are abundant plicae circulares in the proximal part of the intestine in *P. gangetica*, which change to longitudinal

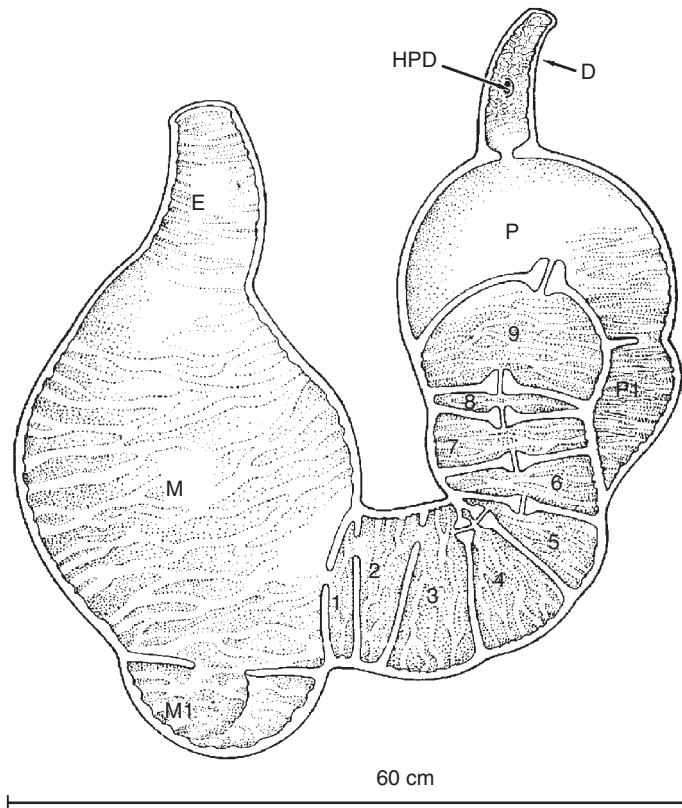

Figure 2 Stomach of a Gervais' beaked whale, *Mesoplodon europaeus*, in dorsal view. Drawing by Trudy Nicholson.

folds in the last meter or two. There is a prominent cecum and an ileocolic sphincter. The small intestine in most platanistids is extremely long. The ratio of small to large intestine length is between 50% and 60% in *Pontoporia*, 50% in *Inia* but only around 9% in *Platanista*.

The total intestinal length in *Physeter* adults can range up to 250 m. The plicae circulares are unusual in that they appeared to be spiral. There is no cecum and the transition between the small and the large intestine is gradual. In beaked whales, the intestine is also long, and may reach 6-times body length in *Hyperoodon*. There is a unique vascular rete (*mirabile*) intestinale associated with the large and small intestine in at least *Ziphius* and *Berardius* and there is no cecum.

The mean ratio of the length of the small intestine to body length in minke whales (*B. acutorostrata*) was rather small (3.92) and averaged 36 m in length. The minke whale possessed a duodenal ampulla, but there was no indication of differentiation of the jejunum and the ileum.

C. Large Intestine

The large intestine consists of the colon (ascending, transverse and descending), cecum, vermiform appendix, rectum, anal canal and anus. The cecum is a diverticulum of the proximal end of the colon, near the ileocolic juncture. The vermiform appendix is the narrowed apex

of the cecum. The colon functions to absorb water and consolidate the fecal material. Most mammalian colons have their longitudinal muscle fibers arranged in groups into bands called taenia coli. The colon has a series of lateral bulges called haustra, and fatty projections (appendices epiploicae). The rectum is the straight portion of the large intestine that transverse the pelvis. The anal canal is the specialized terminal portion of the large intestine. The anal canal has many lymph nodes and glands and the anal sphincter controls excretion of fecal wastes.

1. *Pinnipedia* In pinnipeds the cecum is short and blunt or round and an appendix is not present. The large intestine is relatively short and not much larger in diameter than the small intestine. No taenia coli, plicae semilunares, haustra, and appendices epiploicae are present.

The colon is about 6-ft long (183 cm) in an adult *Leptonychotes*. The colon grades into the rectum, which begins at the pelvic inlet and ends at the anal canal. Throughout the length of the rectum the lining is thrown into large irregular transverse rectal plicae. Toward the distal portion of the rectum, the plicae become organized into five longitudinal anal columns that continue into the anal canal. The anal canal is much smaller in diameter than the rectum. Small coiled tubular rectal glands were present. The anal canal ends where the mucosa changes into a pigmented cornified stratified squamous epithelium (epidermis). There are circumanal glands, which are coiled tubular structures, representing modified sweat glands, and these are confined exclusively to this region. In *Leptonychotes* there is no evidence of other anal glands, sacs, or scent glands.

2. *Sirenia* The cecum in the dugong is conical and was about 6-in. long and 4-in. wide at the base in the half-grown specimen that Owen dissected (Owen 1838, 1868). A sphincter is present in the ileocecal juncture. There is no constriction between the cecum and the colon. The epithelia lining of the cecum is smooth and its walls are muscular. Owen (1868, p.457) hypothesizes that the cecum acts as a pump, "giving a first powerful impulse to the long column of vegetable 'magma' usually distending the colon."

The colon in the dugong is thinner-walled than the small intestine and is between 4 and 11 times the total body length (5.8–30.0 m). There are no taeniae coli (Hill, 1945). The lining of the colon is smooth, with the exception of irregular folds that are present at the wider terminal portion. The lining of the rectum is provided with longitudinal folds which become finer and more numerous in the anal canal. The lining of the anus is grayer and harder than the lining in the rectum. The anal canal is about 5-cm long. At the distal end of the canal the longitudinal folds become higher and terminate in globular swelling which occlude the lumen and which has termed "anal valves."

3. *Cetacea* In delphinoids, there is no cecum and no marked differentiation between large and small intestines in delphinoids. The colon in *I. geoffrensis* is 40-cm long, followed by a 5-cm rectum and a 3-cm anal canal. The proximal and distal portions of the colon are 1 cm and 1.5 cm respectively. There is a pronounced cecum that is 5–9 cm (2–3.5 in.) long in *P. gangetica*. The large intestine is short, 60 cm in adults. The lengths of the large intestine (cecum, colon, rectum, and anus) in 4 specimens that ranged between 76 and 127 cm total length, ranged from 25.5 to over 58 cm (the 127 cm specimen was lacking the cecum). There was no trace of taeniae coli. There is no cecum in *Pontoporia*. The longitudinal fold in the small intestine of *Pontoporia* divides to become two distinct longitudinal folds. Taeniae and haustra coli were not found.

In large adult *Physeter* the large intestine can be up to 26-m long. The mucosa of the large intestine in *Physeter* is not folded, and there is no cecum. The diameter of the descending colon is markedly increased in *Kogia* spp. There is no cecum and the transition between large and small intestines is gradual in ziphiids.

Mysticetes have a very short cecum except in right whales where it is absent altogether. There is a marked difference between the diameter of the large and small intestines in right whales (*Eubalaena* spp.). In the blue whale (*Balaenoptera musculus*), the taeniae consists of three longitudinal muscular bands. The mean ratio of the large intestine to body length in minke whales (*B. acutorostrata*) is 40%. The mean ratio of cecum length to body length is 4%; the cecum varies between 30 and 50 cm.

II. Accessory Organs

The liver is derived from a diverticulum of the embryonic duodenum. As it grows, the liver expands to become the largest internal organ. The liver functions in storage and filtration of blood, in the secretion of bile, which aids in the digestion of fats, and is concerned with the majority of the metabolic systems of the body.

The liver is multilobed in pinnipeds, and has 7 or 8 lobes in *Otaria*. In Sirenia, the diaphragm is oriented in the dorsal plane instead of the transverse plane. The liver in the dugong and manatee are flattened against the dorsally oriented diaphragm. The liver is comprised of four lobes, the normal central, left and right, and the fourth, Spigelian lobe that lies on the dorsal border of the liver and is closely associated with the vena cava.

The liver in cetaceans is divided into two lobes by a shallow indentation. Occasionally, there is a third intermediate lobe. The cetacean liver is greater than would be expected for a mammal of its size.

The gallbladder is located on the posterior side of the liver where the hepatic duct issues, it forms in embryology from the same diverticulum as the liver. The gall bladder stores and concentrates the bile that is secreted by the liver. The gall bladder is universally present in pinnipeds and tends to be pyriform and located in a fossa of one of the subdivisions of the right lobe of the liver. The gall bladder is small in the dugong and is strongly sigmoid in shape. It lies on the ventral surface of the central lobe where the falciform and round ligaments attach. The gall bladder is absent in all members of the order Cetacea. The duct systems for bile produced in the liver are increased in diameter, suggesting that bile is stored here.

The pancreas also develops out of outgrowths of the embryonic duodenum. It consists of two developmental bodies, the dorsal and ventral pancreas, which may empty into either the hepatic duct or directly into the duodenum. The pancreas secretes enzymes that are discharged into the duodenum and insulin that is discharged directly into the blood. The pancreas in marine mammals appears to have no remarkable differences from other mammals.

Tonsils are bodies of organized lymphatic tissues around crypts which they use to communicate to the lumen of whatever system they are in. In some cetaceans, but not in pinnipeds and sirenians, clusters of lymphatic tissue that can be called tonsils occur in the anal canal.

Anal tonsils have not been reported in most delphinoids, balaeonids, eschrichtiids, and neobalaenids, and *Pontoporia*. Anal tonsils were found in the anal canal of *P. gangetica* and *Stenella coeruleoalba*, and lymphoid tissue also occurred in the anal canal of *I. geoffrensis*. Anal tonsils also occur in sperm whales. In the gray whale,

anal tonsils consist of masses of lymphatic tissue that communicated with the anal canal via crypts. They lie near the boundary of the anal canal with the rectum, 30–40 cm from the anal orifice.

Genetics for Management

PHILLIP A. MORIN AND ANDREW E. DIZON

Certain kinds of genetic information are particularly well suited to assist in designing strategies to protect human-impacted marine mammals. What sort of genetic information is required depends on the particular conservation goals wildlife

managers seek to achieve when protecting specific species, or populations within species. For example, is the goal to prevent extinction of the species as a whole or to prevent extirpation of local, but not necessarily genetically unique, populations? For most developed nations, these goals are codified in laws presumably reflecting, at least in democratic societies, the will of the public. To achieve these goals, managers often choose between controversial and conflicting strategies, such as various limits on the species and numbers of marine mammals that can be incidentally killed during certain fishing operations. Relaxed limits favor the fishermen but may put a population of marine mammals at risk; stringent limits are less risky but may put an unupportable burden on fishermen by restricting their fishing options. Obviously, the kind and the quality of biological data, genetic or otherwise, informing this choice are critical. Decisions have to be based on the current scientific information available, or they will be challenged in the courts. Although most scientific information on impacted populations is of value, certain kinds of information are much more important for the management process. If only limited data are available (molecular or other), biased or misleading conclusions can result in inappropriate decisions being made, eventually imperiling the population needing protection in the first place. Biological data on marine mammals, especially cetaceans, are difficult and consequently expensive to obtain. By consuming limited conservation funds, even good but irrelevant studies can impede the conservation effort. To insure that genetic studies proposed are relevant for management needs requires an understanding of the policy (the conservation goals) before doing the science (the information gathering) (Taylor and Dizon, 1999).

One advantage that genetic analyses have over “whole animal” studies is that data are easier to collect and few constraints are put on the quality of a sample or its origin. DNA is a relatively tough molecule, and adequate samples can be obtained from tiny amounts of a variety of tissues such as skin, blood or blood stains, hair follicles, placenta, excrement, baleen, modern or ancient bone, or, in some circumstances, formalin-preserved tissues. For instance, adequate amounts of mtDNA from *ca.* 1000-year-old bowhead whale (*Balaena mysticetus*) bones have been obtained. More recent historical samples of bone and baleen from St Lawrence Island in the Bering Sea have been used for both mtDNA and SNP analysis (Morin and McCarthy, 2007). For live animals, projectile biopsy (crossbow, firearm, or lance) has been used successfully for all but the smallest and shyest cetaceans (see chapter on Genetics, Overview).

I. The “Conservation Unit”

Today, defining the population segment on which to focus conservation efforts is the primary use of genetic information. The US Marine Mammal Protection Act of 1972 (MMPA), the US Endangered Species Act of 1973 (ESA), the relevant legislation of some other nations, and the Revised Management Procedure of the International Whaling Commission (IWC) all direct that management efforts must be focused on populations below the species level. Although most other countries have not necessarily established laws codifying the conservation unit, biologists are generally in agreement that species comprise a collection of semi-isolated populations (i.e., species-wide panmixia is the exception) and that those semi-isolated populations should be the focus of management. However, the devil is in the details, and there is much controversy on the precise definition of these units. Besides having obvious biological consequences

for getting the groupings correct, there can be economic ones as well. For instance, quotas on harvest or incidental take are calculated as some allowable fraction of the overall abundance within the chosen conservation unit. A small conservation unit is the most *biologically* risk-averse because quotas are then necessarily small, and there is a greater likelihood that removals will be equally distributed over the whole unit. However, a large conservation unit is the most *economically* risk-averse because the quotas are larger, and there is the potential that excessive removals in one part of the range (the sink) will be compensated for by immigration from outside of the exploited region (the source).

Policy tries to provide managers with guidance to balance conservation and economic issues by defining the management unit (MU). For instance, the US ESA seeks to prevent the extinction of distinct population segments that are evolutionarily unique. The policy addresses last-ditch efforts to rescue populations whose abundances are so low, or whose abundances will become so low in the near future, that if something is not done immediately, they will likely go extinct. These so-called evolutionarily significant units (ESUs) are defined in the statutes as (1) being “substantially” reproductively isolated from other population segments of the same species and (2) representing an important component in the evolutionary legacy of the species. The first criterion speaks to the rate of exchange between the population segment and other segments. The second speaks to the time the population segment has been isolated. In contrast, the US MMPA seeks to maintain viable populations across their historical ranges at 50% of their historical population size. This act addresses maintenance of abundance. The MMPA conservation units could be characterized as demographically independent populations (DIPs) to contrast them with ESUs. Some use the term “management unit” to refer to a DIP, but because both DIPs and ESUs are MUs in the strict sense, it is important to distinguish them. Genetic data are useful for defining both. However, the policy goals are different and, consequently, the details of genetic studies directed toward either must take slightly different approaches.

A. The Evolutionarily Significant Unit

Because the ESA is concerned with conservation units that are characterized as being “evolutionarily” different, the genetic methodology employed must be sensitive to evolutionary distances between taxa. Indeed, the traditional academic use of genetic data is employed to reconstruct common ancestry and to group taxa based on common ancestry. No restriction is based on the taxon level examined (subspecies, species, genus, family, etc.), except that the taxa are assumed to be reproductively isolated and that sufficient time has passed so that measurable genetic differences have accrued between every individual in one taxa and every individual in another. For higher level taxonomic relationships, the grouping derives *a priori* from a particular classification based on morphological distinctiveness. For groupings below the species level, the grouping often derives *a priori* from geographical clustering; some have termed this phylogeography to contrast it to traditional phylogenetics.

Regardless, the key to ESU status is still reproductive isolation and time. Using DNA sequence data to test these *a priori* groupings to see if they are genetically accurate, an investigator demonstrates that all the individuals of each *a priori* stratum fall into exclusive genetic clusters (Waples, 1991; Hillis *et al.*, 1996; Ross *et al.*, 2003). If so, ESU status can be presumed for the groupings. The evidence addresses the policy that protection should be offered to a population

segment that is first of all “substantially” reproductively isolated. If they were not isolated, it would be impossible to demonstrate the presence of exclusive genetic clustering. The genetic evidence is usually presented in the form of a branching diagram representing the evolutionary pathways leading to mutually exclusive genetic clusters (Fig. 1A). In cetaceans, several species have been defined almost exclusively on the basis of genetic evidence for reproductive isolation, in the form of substantial genetic differentiation from other animals previously thought to be of the same species (Kingston and Rosel, 2004; Dalebout *et al.*, 2007).

If animals are commonly moving between groups and interbreeding, the groups would not be reproductively isolated from one another and would share genetic material. As a result, the genetic analysis would not find unique groupings of individuals corresponding to each population, and no ESUs could be defined.

B. The Demographically Independent Population

Consider, however, if the individuals in the sample fail to fall into exclusive genetic clusters that are congruent with the *a priori* classification. For example, what is happening if some of the individuals sampled in the Northern Hemisphere cluster genetically with those in the South (Fig. 1B)? This situation can be the result of (1) insufficient time having elapsed from when the populations were split to purge ancestral shared alleles or haplotypes from the populations, (2) a degree of gene flow that exists or has existed recently (e.g., a few adventuresome individuals immigrated to the south or vice versa to breed), or (3) a combination of the two. It also means that the populations under consideration do not meet ESU criteria. Nevertheless, the populations may be genetically distinguishable if there are significant frequency differences in alleles or haplotypes between the groups. These populations would be characterized as DIPs and the definition would pertain to an intermediate situation between complete, long-term isolation of the ESUs and free gene flow between geographically distinct populations (panmixia).

It is in the range of dispersal rates between the virtual isolation of the ESU and complete panmixia where the interpretation of genetic information requires an understanding of policy. The logical thread goes as follows: e.g., the US MMPA establishes, albeit somewhat obliquely, that populations be maintained at 50% of their historical capacity as functioning elements of their ecosystems. This is interpreted to mean that adequate population levels shall be maintained across their historical ranges. It would forbid management action that resulted in extirpation in one portion of the range, even if such extirpation would not reduce the overall species abundance to below 50% of historical levels.

What happens if anthropogenic mortality occurs at different levels in different parts of the range, e.g., there is heavy incidental take in the southern part of the range because it overlaps with a gill net fishery, but none at all in the central and the northern part of the range? For example, consider a temperate, coastal species that inhabits waters from northern California through Canada, the Aleutian Peninsula, to Japan. Due to the large distances involved, distinct habitat differences, and the coastal behavior of this species, complete panmixia is not very likely and some population structure, i.e., dispersal between certain population segments, is reduced. Say samples are available from each of five putative population groupings (defined *a priori*) in the US Pacific northwest waters. An extensive genetic analysis using both mtDNA and microsatellites is performed, and initial analyses using phylogenetic methods demonstrate no

Figure 1 Hypothetical genetic evidence representing two different evolutionary histories presented in the form of branching diagrams representing the evolutionary pathways leading to mtDNA haplotypes observed in a sample of marine mammals. The size of circles is proportional to the number of individuals in the sample exhibiting the particular haplotype, and each haplotype differs from a connected neighbor by a 1-bp difference. (A) North Atlantic and South Atlantic stocks have been isolated for a sufficient amount of time so that there are no haplotypes common to both. Geographic strata are concordant with genetic ones. (B) The isolation of the two stocks is (1) recent so that common haplotypes (C, F, G, and I) have not yet been purged via genetic drift from the North Atlantic, the South Atlantic, or both or (2) the isolation is incomplete, and there is a degree of continual interchange between the stocks. Even though the geography and the genetics are not strictly concordant, the distribution of haplotypes within each of the two stocks in this example is modally different.

striking genetic clustering concordant with the geographic groupings. However, proximal populations were observed to share haplotypes and microsatellite alleles, and statistical analysis showed that significant frequency differences for the mtDNA haplotypes and for many of the microsatellite loci distinguish the populations. The inference here is that dispersal is sufficiently limited among the five populations so that some genetic differentiation has occurred among them. The populations are isolated but cannot be considered ESUs because the “evolutionary legacy” criterion is not met. They should be considered DIPs because dispersal between them is sufficiently reduced to warrant managing them separately [e.g., establishing individual quotas for incidental kills (“take”) for each population]. Moritz described

such populations as MUs, representing “populations connected by such low levels of gene flow that they are functionally independent” (Moritz, 1994).

This recommendation can actually be made with confidence because of the shape of the curve that relates genetic differentiation and dispersal (Fig. 2). The strength of the result is reflected in the left-hand portion of the graph, genetic differentiation is detectable only when exchange rates between the putative populations are virtually nonexistent from a demographic or management point of view. This is in the range of a few dispersers per generation. However, the weakness of genetic analyses comes from how rapidly genetic differentiation declines as dispersal increases only slightly. Genetic differentiation disappears at dispersal rates that still might be considered insignificant from a demographic point of view, say a few percent per year. In other words, it is very difficult to demonstrate statistically significant genetic differentiation if dispersal between strata is more than a few dispersers per year.

So by demonstrating genetic differentiation, the geneticist has confidently demonstrated demographically insignificant exchange rates. The management consequences are that any anthropogenic mortality within the strata must be compensated for by production from within rather than dispersal from adjacent, perhaps less impacted, units. Under this circumstance, which is actually common in coastal populations, mistakenly assuming that adjacent populations will serve as a source for the losses within the impacted population can result in destruction of the impacted population and failure to maintain it as a functioning element of its ecosystem. Disregarding

Figure 2 The idealized relationship between the degree of genetic differentiation (fixation index), dispersal rate expressed as the average dispersal rate per year, and population size expressed as the number of breeding animals, or breeding females in the case of mtDNA analyses (effective population size). The fixation index ranges between 1 (no common alleles or haplotypes) and 0 (no differences in allelic or haplotypic distribution). Demographically insignificant rates of exchange (e.g., 1% per year) in anything but the smallest effective population sizes probably result in an inability to subdivide populations with any degree of statistical confidence. Perhaps more importantly, because the curve is so flat at this point and higher, genetic data have little resolution to accurately estimate dispersal rate in this range.

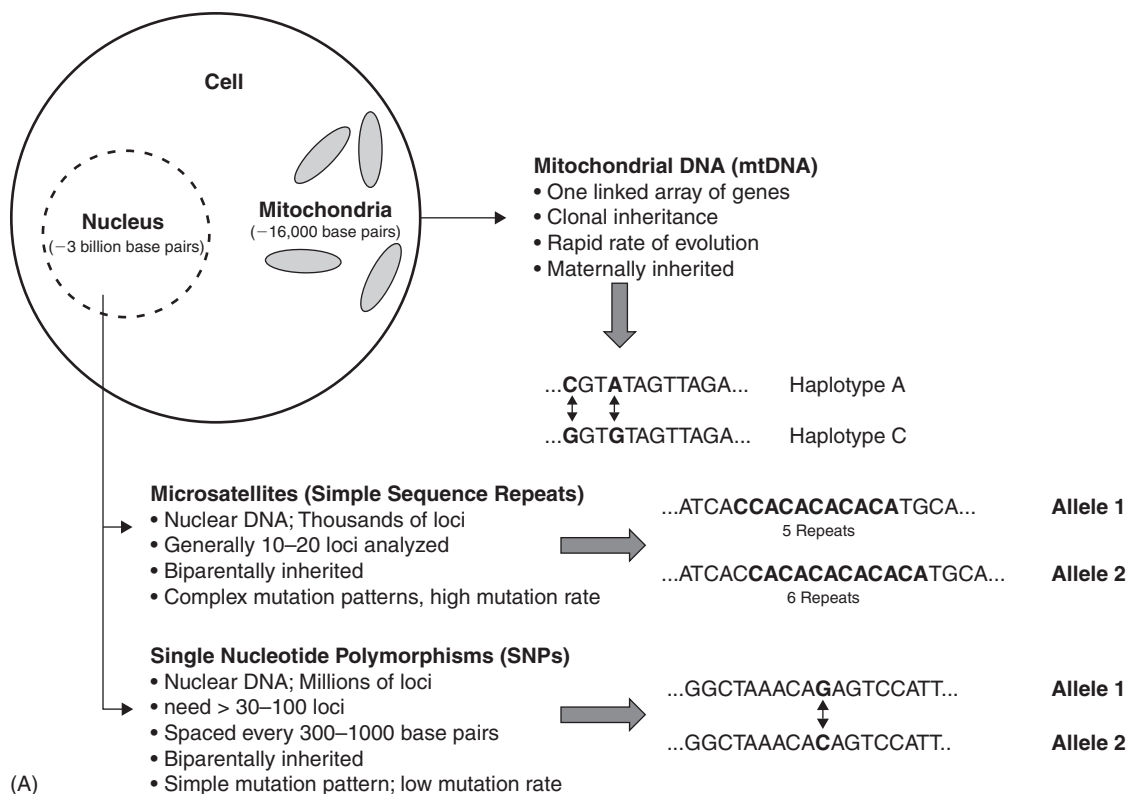

the geneticist’s recommendation may mean that the manager will have failed to meet a policy goal stipulated in the US MMPA.

However, it is not a “symmetrical” situation. What happens when genetic evidence fails to establish significant demographic isolation between units? Because there was no evidence of population subdivision and hence restricted dispersal, a manager may be tempted to use this negative evidence to infer that the putative populations could be coalesced into one larger MU. Coalescence of two or more small populations into one larger MU would allow the manager to establish a larger incidental take quota and avoid the inevitable economic and political consequences of restricting fishing effort to reduce the incidental fishing mortality. The manager argues that high levels of take in one localized portion of the range (the sink) will be compensated for by production in and dispersal from less exploited portions of the range (the source).

This would turn out to be an appropriate decision if the failure to find evidence of population subdivision was due to demographically high levels of exchange between the exploited and the unexploited regions. However, the decision may have serious biological consequences if the failure to find genetic differences was simply because the experimental design of the genetic study lacked statistical power to discriminate subdivision (e.g., too few samples tested, too little portion of the genome tested, or an insufficiently variable portion of the genome tested), or if genetic isolation of populations is recent. In reality, although undetected, in this case the populations were demographically isolated, and it would be unlikely that adjacent populations could replenish losses due to incidental take in the exploited region. Because exchange between populations may be high enough to prevent detection genetically but not high enough for demographic replenishment, failure to discriminate the subdivision genetically should not at present be used as a scientific rationale for coalescing smaller populations into larger MUs in the absence of sufficient evidence for statistical power to detect such subdivision. Such evidence can be obtained from simulations of the populations and genetic data, as in the program POWSIM (Ryman and Palm, 2006).

II. Molecular Markers

Currently, management-oriented genetic studies use primarily (1) genotypes from microsatellite loci within the 3×10^9 or so base pairs (bp) of the mammalian nuclear genome or (2) DNA sequence data from a portion of the 1.6×10^4 bp of the mitochondrial genome; the subsequence is also known as a haplotype (Fig. 3). Mitochondrial (mt)DNA is a multicopy, circular, cytoplasmic DNA that in marine mammals is inherited intact from the mother. In contrast, microsatellites are part of the nuclear genome and are inherited biparentally. They are short stretches of repeated DNA that are distributed abundantly in the nuclear genome and show exceptional variability in most species. Newer markers that are rapidly gaining ground in molecular ecology studies of marine mammals include single nucleotide polymorphisms (SNPs) (Morin *et al.*, 2004), amplified fragment length polymorphisms (AFLPs) (Kingston and Rosel, 2004), and sequencing of nuclear genes (Palumbi and Cipriano, 1998). These are all methods for assessing sequence variation primarily in nuclear DNA, and primarily at the level of individual nucleotide changes (though insertions/deletions may also be assessed). Because single nucleotide changes are the most common type of variation in the genome, methods for assessing large numbers of polymorphic sites, such as SNP and AFLP genotyping, provide good statistical

(B)

	Microsatellite locus A	SNP locus A	Mitochondrial haplotypes
Sample 1	5 6	C T	A = CGTATAGTTAGA
Sample 2	5 8	C C	B = CGTATACTTAGA
Sample 3	8 8	C T	C = CGTGTAGTTAGA
Sample 4	8 6	T T	A = CGTATAGTTAGA
Sample n	5 5	C C	D = CACATACTTAGA

Figure 3 Currently, data for most management genetic studies primarily consist of microsatellite DNA, mitochondrial DNA, or both, but SNPs are becoming more common. (A) Microsatellites are short tandem repeats (two, three, or four base repeats) of nucleotides, e.g., CACACACACA . . . , ATGATGATG . . . , or GATAGATAGATA Microsatellite data consist of n pairs of alleles for each individual at m number of microsatellite loci within the 3×10^9 or so base pairs (bp) of the mammalian nuclear genome. There is estimated to be a microsatellite region every 3000 or so base pairs. Microsatellites are part of the nuclear genome and are inherited biparentally. Mitochondrial data consist of n DNA subsequences (haplotypes) at some locus within the 1.6×10^4 bp of the mitochondrial DNA genome. mtDNA is a multicopy cytoplasmic DNA that, in vertebrates, is inherited intact from the mother. Each mitochondrion may have 5–10 DNA molecules, and there may be from 100 to 1000 mitochondria per cell. For mitochondrial DNA, a sequenced portion of 12 bp of the 16,000-bp molecule is shown. (B) Sample 1 is heterozygous at microsatellite locus A having a pair of alleles that have five and six CA repeats, and nucleotides C and T at SNP locus A. Sample 1 also possesses an “A”-type mitochondrial haplotype that, e.g., differs by 2 bp from the “C”-type. For actual studies, the number of microsatellite loci examined might typically range from 8 to 20, and the size of the mitochondrial sequence examined might range from 350 to 1200 bp.

power for genetic assessment of populations, while also assaying more of the genome. With SNPs, the possibility for looking at patterns of variation in individual genes opens the possibility of directly or indirectly assessing genetic variation under selection, or variation associated with known phenotypes. One often-used example of this is genetic determination of sex.

III. Focusing on the Individual

In the previous sections, the focus was on a population of animals united by some characteristic, e.g., geographic locale. In this section, the focus is on the individual and what information genetic studies can provide to management.

A. Illegal Traffic and Trade

Two sorts of questions are usually asked

1. Did sample X come from the same individual as sample Y? Nuclear marker analysis is used to establish an individual's genetic fingerprint; this is also known as genotyping.
2. What is the provenance of sample X, i.e., what species or geographic population characterizes the sample? For this, sequence analyses are generally employed at higher levels of differentiation, and genotypes are used for assignment to a group or population.

Question 1 is much like placing crime suspects at the crime scene via something the suspect has left behind (e.g., clothing fibers, fingerprints, hair, DNA), and genotyping is a highly reliable means of answering it. The genetic profile of a piece of meat in a market of unknown provenance could be compared with the genetic profiles in a database of "legally" harvested whales or, alternatively, the sample could be compared with the genetic profiles in a database of biopsied, protected ones.

Question 2 is more general and deals with establishing that the sample came from an animal that belonged to a certain group or taxon. Genetic analyses can help determine whether a given market sample came from a proscribed or a permitted taxon. For example, a particular market sample is humpback whale (*Megaptera novaeangliae*). The unknown sample is compared genetically with samples whose taxon identity is known. Because the genetic differences between taxa above the species level are so large, assignment analyses are almost infallible (e.g., did the sample come from a whale or a cow?). In most situations, assignment is accurate at the species level (e.g., did the sample come from a minke whale *Balaenoptera acutorostrata/bonaerensis*, or a blue whale *B. musculus*?). However, there are exceptions, such as discriminating species among the genera *Delphinus*, *Stenella*, and *Tursiops* using only mtDNA control-region sequence. Accurate assignment of an individual sample to its geographic origin is more difficult [e.g., did the sample come from a gray whale (*Eschrichtius robustus*) harvested off the eastern Pacific Ocean or from the Okhotsk Sea?]. Although there are exceptions to this rule, in general the lower the taxonomic division the greater the difficulty in distinguishing provenance of an individual sample. At these lower levels, relatively large numbers of microsatellites or SNPs may provide sufficient power for statistical assignment tests. An example of this was the use by Kingston and Rosel (2004) of hundreds of variable AFLP loci to identify clear genetic differentiation of coastal and pelagic *Tursiops truncatus* populations in the western North Atlantic and differentiation between two sympatric species of *Delphinus* with relatively low mtDNA sequence divergence.

B. Other Uses of Individual-Oriented Genetic Information

Genetic mark-recapture and monitoring methods based on genotyping can be substituted for traditional tagging methods, i.e., Discovery tags, for estimating population size, dispersal rate, and migration pathways (Palsbøll, 1999; Schwartz *et al.*, 2007). The management value of such data is obvious. However, if populations are large, the number of "recaptures" is likely to be small, and the cost of genetic analysis of many samples can be high. Nevertheless, such methods have been used to estimate population size and level of reproductive isolation (Garrigue *et al.*, 2004) and to complement ongoing photographic identification projects. Besides re-identification of individuals, genotyping can be used to reliably identify parent-offspring relationships, although large numbers of microsatellite loci must be examined to do this accurately. It is probably worth the effort because by doing so, dispersal can be measured over two generations rather than over the lifetime of single individuals. For conservation decisions, inter- rather than intragenerational movement (i.e., gene flow) is probably a more important parameter than movements of a single individual. Another important demographic parameter that emerges from a study of parent-offspring relationships is the fraction of mature animals enjoying reproductive success. In other words, what is the particular breeding structure of the population, and how does that influence effective population size, inbreeding, and gene flow between populations (e.g., if a small proportion of males actually reproduce, dispersal does not accurately reflect gene flow)?

Finally, determining sex provides a means to examine geographical segregation by sex and whether males or females are the dispersers. It is a common situation with many marine mammal species that females tend to be strongly philopatric, returning year after year to specific feeding or breeding sites. Female philopatry can be demonstrated by examining genetic population subdivision separately in males and in females. If only females are strongly philopatric, mtDNA subdivision should be apparent among the females but not the males. When males are the dispersers but not females, nuclear marker subdivision should be nonexistent because the males of breeding age serve as a "conduit" to homogenize the alleles between populations. If there are data on age, it is sometimes possible to demonstrate that the likelihood of dispersal increases with age of the males. There are policy implications in demonstrating female philopatry. Although this sort of population structuring would not qualify the population as an ESU, it does qualify it as a DIP worthy of management. If the animals from a particular feeding or breeding area are extirpated (males and females), recolonization will not likely take place. The strongly philopatric females from other breeding or feeding grounds would not recolonize the depopulated region, and the dispersing males would not likely return to an area with no females. Thus, if policy deliberately excluded populations based on female philopatry, there could likely arise a situation where take could reduce or fragment ranges.

C. The Hidden Power of Molecular Genetics

In addition to providing answers to population subdivision, dispersal, individual identities, and breeding behavior, molecular genetic analyses present a previously unexploited opportunity for gaining understanding of marine mammals via remote, nonlethal sampling. Some of these data can have direct relevance for management. Consider that a skin sample contains the entirety of the individual's genetic blueprint. The ability to read this blueprint is progressing at an astounding rate, and although most of the progress is within the

human genome, around 70% of the cetacean genes are homologous, and tools developed for medical research can be utilized for marine mammals. For example, DNA sequence information extracted from the genes of skin cells can provide data about expressed characteristics of other tissues or organs. Sequencing visual pigment genes from skin is a good example. Levenson *et al.* (2006) have shown that, with collateral data about visual performance of particular photoreceptors via behavioral or physiological testing, it is possible to extrapolate from the DNA sequence to the spectral sensitivity. Understanding the visual abilities of cetacean could aid in the design of fishing nets with increased color contrast, making them more visible to marine mammals, thereby reducing entanglement rates while sustaining the catch rate of the target species.

IV. Conclusion

Although examination of genetic material offers unparalleled insights into many biological aspects of an animal's life, certain sorts of genetic information provide data that are directly relevant to the management process. The most important is the definition of the conservation unit. By common sense and by law in many countries, this unit is created out of the understanding that the vast majority of species (marine mammal or otherwise) are not panmictic. Species are subdivided geographically into isolated and semi-isolated groupings. Genetic analyses can measure this directly and provide the main avenue whereby the geneticist can provide information to facilitate management decision-making. Other genetic information on impacted populations is certainly of high value. This chapter has provided some examples. Regardless of the sort of genetic information collected, to insure that genetic studies and information will be useful for management requires a clear understanding of the conservation policy that the studies are designed to help implement.

Genetics, Overview

PER J. PALSBØLL

I. Introduction

Genetics is the study of the transmission of and variation in hereditary traits. In the case of genetic analyses of natural animal populations at the level of organisms or above (e.g., populations or phyla), most studies draw their inferences from the relative degree of difference in consanguinity (i.e., kinship or relatedness) among individuals, populations, and species. The confidence with which such inferences can be relied upon depends on the accuracy of the genetic estimates derived from the collected genetic data, which in turn is linked to the amount of genetic data as well as the underlying assumptions made during the analysis of the data.

In principle, the relative degree of relatedness among organisms is estimated from, and positively correlated with, the proportion of shared inherited characters. It is possible to use any hereditary trait in an organism toward this end; however, the farther removed from the locus that encodes the trait under study (i.e., the DNA itself), the higher the chance that external factors may have altered the phenotypic expression of the hereditary trait. Consequently, while relatedness may be estimated from morphological characters, and a single morphological character might represent the expression of many loci, the phenotypic expression might have been altered by extrinsic factors, such as environmental or physiological variables, to an unknown extent, thereby masking the genetic underpinnings of the morphological trait. In contrast, the composition of most cellular components is usually not susceptible to such extrinsic variation, and thus the interpretation of the observed variation of such cellular components may be directly linked to the state of the encoding locus, the genotype. This observation explains why biochemical/molecular

methods were so readily adopted in place of morphological methods to estimate genetic and phylogenetic relationships when efficient methods to detect biochemical changes emerged in the mid-1960s. Until the 1980s, the biochemical/molecular methods applied to natural populations were mainly indirect in the sense that they did not detect differences in the DNA sequence of the encoding locus itself. For instance, the most widely employed biochemical method, allozyme electrophoresis, detects differences in the overall electric charge of enzymes caused by amino acid replacements. An important limitation of allozyme electrophoresis is that only a small part of the genome consists of genes encoding enzymes, and only a small subset of the possible amino acid substitutions result in a change of the overall electrical charge of the enzyme. In addition, homoiothermic organisms (birds and mammals) have reduced level of isozyme variation compared to poikilothermic animals and plants.

Despite these limitations, a large number of studies have been conducted based upon allozyme electrophoresis, providing novel and valuable insights. Interested readers should consult the works of Wada and Danielsdóttir, both of whom have undertaken extensive allozyme-based studies of various cetacean species.

The most basic level of genetic organization is the DNA sequence of the genome itself, which became accessible in a practical manner due to a series of technical advances during the 1980s culminating with the development of the polymerase chain reaction (PCR) by Mullis and coworkers in 1987. The PCR technique permits simple and robust *in vitro* amplification of any specific nucleotide sequence if the nucleotide sequence of the flanking regions is known. Once amplified, the exact nucleotide sequence of the locus is readily determined. PCR-based analysis of DNA sequences has become the predominant method used in genetic studies of marine mammals. For this reason I will rely upon examples based upon analysis of DNA sequences rather than allozymes or morphological characters in this chapter.

II. Obtaining Tissue Samples

A prerequisite for DNA-based methods is, naturally, DNA. The most common source of genomic DNA is from soft tissue samples. Soft tissue samples are readily available from dead animals, e.g., stranded or killed specimens. However, it is often scientifically or ethically desirable to obtain samples from free-ranging, live animals. The advantage of PCR-based techniques is that only a minute amount of target DNA is required, and hence adequate amounts of DNA are readily obtained from skin biopsies, sloughed skin, hair, and even feces, which can be collected from free-ranging marine mammals with relative ease.

The high sensitivity of PCR-based methods also enables the use of historical samples, such as hair from old furs, baleen or even dried blood obtained from old logbooks. However, the quality of DNA extracted from such historical samples is usually inferior and obtained in much lower concentrations than DNA extracted from fresh tissue samples. The same is usually true for DNA extracted from fecal or similar degraded samples. The low concentration and often highly degraded DNA obtained from historical samples necessitates additional precautionary measures to prevent cross-contamination among samples as well as repeated analyses to insure that a correct genotype is obtained due to various artifacts potentially occurring during PCR, such as allelic dropout and spurious alleles.

Tissue samples can be collected from free-ranging animals by invasive and noninvasive techniques, each with respective advantages and disadvantages. Invasive techniques, such as the collection of skin biopsies, enable a directed sampling scheme. This implies that, conditions permitting, skin biopsies can be collected from those individuals relevant to the specific objective of the study and a biopsy can usually be linked to a specific individual. Multiple biopsy systems have been developed to collect skin biopsies from marine mammals, all principally consisting of a delivery unit, such as a crossbow or gun, and a projectile unit, usually an arrow (called a bolt in the case of a crossbow). The projectile unit carries the biopsy tip and a stop to limit the depth of penetration, which may act as a float as well. The biopsy tip is typically a simple hollow tube of stainless steel with one or more barbs retaining the sample when the projectile unit is retracted after hitting the target animal. Systems of various kinds and ranges have been developed; the currently most powerful system was developed by Finn Larsen with which a skin biopsy was collected from a blue whale (*Balaenoptera musculus*) at a distance of approximately 70 m (~210 ft, Fig. 1). Skin biopsies from pinnipeds or smaller odontocetes are usually collected when the animals haul out on land or bow-ride using a hand pole on which a biopsy tip is mounted. Invasive sampling techniques are under some circumstances viewed as intrusive and thus undesirable. In order to investigate such concerns, data have been collected during biopsy sampling to assess possible adverse effects. To date the only discernable effects appear to be short term and may be equally attributable to the multiple close approaches of the boat toward the target animal while attempting to collect a sample. Although the resolution of such studies is typically low, given the pervasive use of skin biopsy sampling today in e.g., baleen whales, any substantial side effects would likely have been detected by now.

The alternative, noninvasive sampling methods are typically of a more opportunistic and random nature, which may prohibit the

pursuit of some research objectives. For cetaceans, the most common kind of noninvasive samples are from sloughed skin. The outer epidermis in cetaceans differs from that of most other mammals by the lack of dead keratinized cells and consists mostly of live cells complete with nuclei and mitochondria, the two cellular compartments with genomes in mammals. There is considerable variation among cetacean species in terms of the amount and how often the skin is sloughed. Sperm whales (*Physeter macrocephalus*) have been observed to slough massive amounts of skin, whereas other species, such as fin (*Balaenoptera physalus*) and minke (*B. acutorostrata* and *B. bonaerensis*) whales rarely slough any skin. The main disadvantage when collecting samples such as sloughed skin in a noninvasive manner is the opportunistic nature of the samples and the difficulty in linking a specific sample to a particular individual during multi-individual sightings, which may influence the pursuit of some research objectives. In addition, the quality and quantity of DNA extracted from such samples are more variable than those of samples from skin biopsies.

Some projects have used skin swabs, where skin is scraped off the target individual without penetrating the epidermis. Such methods also require multiple close encounters, just as is the case when collecting skin biopsies, and may thus be equally invasive in terms of the degree of disturbance to the target individual.

Genomic DNA has also been successfully extracted from samples collected from fecal plumes in the water column, from dugongs, dolphins, or baleen whales, which contain epithelial cells from the intestinal tract. Among pinnipeds, the most common noninvasive samples are fecal samples (scats), typically collected from haul-out sites on land. In bears, hair has proven an excellent source of noninvasive samples, where the DNA is extracted from the root cells. In order to insure that hair samples contain the root (which is where most of the DNA is contained), the hair must be pulled out of the skin. In the case of bears (and other terrestrial animals with fur), a simple, highly effective sampling scheme has been utilized based upon “hair-traps” with scent lures to attract bears and barbed wire that passively collect hair samples.

Samples are usually preserved by freezing with or without some conservation buffer. Commonly used conservation solutions are 70–96% ethanol or distilled water saturated with sodium chloride and 20% DMSO, both of which enable storage at ambient temperatures, although it is usually recommended to freeze samples at -18°C or below.

III. Commonly Analyzed Genetic Markers

As mentioned earlier, genetic analyses of different taxa, e.g., individuals, populations, or species, are in essence about estimating the relative degrees of consanguinity among the included taxa. Put simply, the higher the proportion of shared traits/characters between

two entities, the higher the degree of relatedness, or, in the case of nucleotide sequences, the more mutations (i.e., differences in the nucleotide sequence) at the same locus separating two different entities the less related they are inferred to be.

In principle, there are two kinds of mutations in nucleotide sequences, substitutions or insertions/deletions of one or more nucleotides. The latter kind of mutations is commonly observed at microsatellite and minisatellite loci and short interspersed elements (SINEs), all of which have been employed in genetic analyses of marine mammals. The most commonly analyzed loci of this kind, at this time, are microsatellite loci. Most DNA sequence changes at microsatellite loci consist of additions or deletions of one or more DNA sequence repeats. These kinds of mutations are likely due to single-strand slippage when the parental template and the new native DNA strand misalign in the repeated DNA sequence during DNA replication. This mode of mutation is termed a step-wise mutation model (Fig. 2). Mutation rates at microsatellite loci are often high and have been estimated at 10^{-4} – 10^{-5} , which is several-fold higher compared to single-nucleotide substitutions. The high mutation rate often results in multiple alleles at each locus and consequently high levels of heterozygosity. Microsatellite loci are therefore well suited as genetic markers for the estimation of close relationships, such as parent–offspring relations. In contrast, microsatellite loci are less well suited to estimate more distant relationships due to high levels of allozygosity due to the high rate and step-wise mode of mutation. Alleles at a microsatellite locus will differ solely by the number of repeats, and two copies of the same allele (i.e., the same number of repeats) may be allozygous or autozygous (Fig. 2). This aspect has to be taken into account during the data analysis, and several estimators of genetic distance have been developed specifically for microsatellite loci. However, accounting for the step-wise mutation model in the estimation also introduces additional variance in the estimation of the degree of genetic divergence, which in turn reduces the precision of the estimate. Although the probability of allozygosity is low among closely related individuals, such as members of the same population, it increases with the degree of genetic divergence and becomes an issue as individuals, populations, and species become more genetically divergent. Many assessments have also demonstrated that a simple step-wise mutation model is inadequate because of additional mutational constraints acting upon microsatellite loci, such as limits on the number of repeats, rare multi-repeat mutations, and microvariants (mutations involving partial repeats), all of which affect the usability of microsatellite loci for the estimation of distant evolutionary relationships.

Similar to microsatellite loci, minisatellite loci are composed of tandem repeated DNA sequences but with a larger repeat size (>30 nucleotides long). Alleles are discriminated based upon the number of repeats as for microsatellite loci, but the individual fragments

Figure 2 The step-wise mutation mode at microsatellite loci. $+/- (GT)$ denotes a mutation by single-strand slippage, i.e., addition or deletion of a single GT repeat unit.

are much longer. The process of altering the number of repeats at minisatellite loci is known as unequal crossover, when recombination occurs during meiosis. Analyses based upon minisatellite loci became popular in the late 1980s but have since largely been replaced by microsatellite analysis, which are technically simpler and more readily standardized within and among laboratories.

SINEs are irreversible insertions into the genomic DNA of reverse-transcribed RNA probably of viral origin. The random and irreversible nature of these insertions implies low or no reversal of “mutations” making these kinds of these genetic markers ideal for estimating more distant genetic relationships. Not surprisingly they have been used successfully in resolving the phylogenetic relationships within Cetacea and the placement of cetaceans within Artiodactyla.

The rate of nucleotide substitutions is typically several-fold lower compared to insertion and deletions at microsatellite loci. Substitutions are detected either by whole-sequence analysis or as single nucleotide polymorphisms (SNPs), and in some cases as amplified fragment length polymorphisms (AFLPs). The two latter methods are more efficient compared to whole-sequence analysis, but each method has important drawbacks relative to whole-sequence analyses.

In a SNP analysis, the detection method typically targets only a single polymorphic nucleotide position and detects only the two different bases (e.g., guanine or cytosine) that have been characterized previously at that specific position. Such an analytical system results in a biallelic locus, with very low mutation rates. This in turn yields low statistical power and low accuracy compared to whole-sequence and microsatellite analysis. The chief advantages of SNP analyses are the ability to fully and easily automate data generation, and that data are readily comparable among laboratories. SNP analyses also target very small DNA fragments and are therefore ideally suited for old samples or samples of poor quality. To date the application of dedicated SNP analysis in marine mammals has been limited, but the use will likely increase (Morin *et al.*, 2004).

AFLP analyses are somewhat similar to the use of minisatellites in terms of the nature of the final data and the associated difficulties in standardization of data, thereby hampering comparisons between laboratories (and even among analyses within the same laboratory). The main advantages of AFLPs are the large amount of data (loci) generated in a single analysis, and that generic PCR primers are used to generate the data. In contrast, SNP, SINE, whole-sequence, and microsatellite analysis requires the development of PCR primers that target a specific locus, which is both cost- and time-consuming to develop. AFLP data are treated as dominant alleles, prohibiting the use of more traditional population genetic assessments, which may be critical for some studies.

The lower rate of single-nucleotide substitutions implies lower autozygosity, and single-nucleotide substitutions are therefore in many ways better suited to estimate more distant evolutionary relationships than microsatellite loci. However, the rate of single-nucleotide substitutions differs among and within loci due to varying (often unknown) selective pressures. An example is codons in exons. In most cases a single amino acid is encoded by at least four different codons. The different codon sequences encoding for the same amino acid typically differ at the third position, at times at the first and only rarely at the second codon position. Hence, nucleotide substitutions at the third position are usually synonymous and not subject to selective constraints. In contrast, the majority of nucleotide substitutions at the first and the second codon positions are nonsynonymous. The selective constraints are thus higher at the first and the second codon positions, and the substitution rate is usually lower than that at the third codon position.

Because of the different selective pressures relative to codon position, phylogenetic analyses usually stratify nucleotide sequence data according to codon position. There are, however, multiple exceptions to this rule of thumb, such as MHC genes, which evolve primarily by amino acid substitutions.

In mammals, the vast majority of the genome does not encode enzymes and was thus presumed to be under little or no selection pressure. However, as more and more genomic data becomes available, the large variations in mutation rates observed among such putatively noncoding DNA sequences indicate the existence of selective constraints acting on these DNA sequences as well. Possible explanations are aspects such as chromosome pairing during meiosis, replication and transcription rates, chromosomal stability, and numerous other phenomena.

A prerequisite for the estimation of the relative degree of genetic divergence among taxa is a model that adequately captures the underlying mutational mechanisms. One important assumption in most evolutionary models is the absence of homoplasy. The commonly employed infinite-site mutation model assumes that new mutations always occur at a new site in the nucleotide sequence that has not previously been subject to a mutation. The infinite-allele model differs slightly in that multiple mutations at the same position can occur, but no allozygous alleles have identical nucleotide sequences. The consequence of either model is that identical nucleotide sequences are all assumed to be autozygous. Although these idealized models probably are applicable to closely related taxa, multiple mutations do occur, especially at fast evolving nucleotide sequences such as the mitochondrial control region, which need to be accounted for as taxa become genetically divergent.

The earlier mentioned variance in mutation rates among loci is in fact an advantage, as it enables the researcher to pick loci with mutation rates that are appropriate for the level of genetic divergence of the taxa under study. Usually the goal is to uncover sufficient amounts of variation to facilitate accurate estimations, while keeping the amount of homoplasy as low as possible.

Mammalian cells contain two different genomes. The cell nucleus harbors two full complements of chromosomes, one paternally and the other maternally inherited. Secondly, the mitochondria, in the cell cytoplasm, possess a small genome, consisting of a circular DNA molecule of approximately 16,500 nucleotides in length in mammals. During the formation of the zygote, the sperm cells appear not to contribute any mitochondria to the resulting zygote in mammals, although rare cases of paternal leakage of mitochondrial DNA have been reported. Thus in principle and for all practical purposes, the offspring inherits only the maternal mitochondrial genome.

IV. Analyses of Individuals

In the case of marine mammals, genetic methods have been applied to identify individuals and parent–offspring relations as well as full-siblings for a number of different purposes.

Identifying marine mammals by traditional tagging methods is often not feasible. In many instances, marine mammals are simply too large, have too-wide ranges, and live in a too-dense medium to make traditional tagging practical. Tag attachments are usually relatively short-lived (although this is changing), in part because of the significant drag caused by the water, unless the tag is attached to solid structures, such as the tusk of a male narwhal. Although individual identification from natural markings has been applied successfully to a number of marine mammal species, this approach is limited to species with sufficient levels of natural variation among individuals.

In contrast, individuals from most species are readily identified by “genetic fingerprinting,” even species with much reduced levels of genetic variation such as northern elephant seals (*Mirounga angustirostris*). Coworkers and I set out to verify if “genetic tagging” was feasible for a wide-ranging cetacean species. Our study included 3068 skin biopsy samples collected over a period of 8 years (from 1988 to 1995) from humpback whales (*Megaptera novaeangliae*) across the North Atlantic (Palsbøll *et al.*, 1997). Each humpback whale was identified by its composite genotype collected from six hypervariable microsatellite loci. The main issue in individual identification from a genetic profile is the probability of identity. The probability of identity is readily estimated from the population allele frequencies for all degrees of relationship ranging from unrelated individuals to first-order relatives, such as parent–offspring pairs, and decreases rapidly with the number of loci. The difficulty lies in determining the proportion of each degree of relationship in a sample, which in turn determines the expected number of individuals that have identical genetic profiles by chance; these different animals may be mistakenly be assumed to represent the same individual. Although the probability of identity is positively correlated with the degree of relatedness, the proportion of pairs of a specific degree of relation decreases with as the degree of relatedness increases. In the case of the humpback whale study mentioned earlier, the probability of identity and expected numbers of different individuals with identical composite genotypes were estimated assuming that all samples came from unrelated individuals only, first for each maternally related feeding aggregation and subsequently for the entire population. The expected number of pairs of different individuals with identical genetic profiles by chance in the total sample of 3068 was estimated to be less than one. Consequently, skin biopsy samples with identical genetic profiles were inferred as originating from the same individual. In total, 698 such samples with duplicate genetic profiles were detected. In all cases samples inferred as originating from the same individual had the same sex and mitochondrial control region sequence.

In a few cases, samples had been collected from the same individual humpback whale as far apart as 7500 km. The overall pattern of re-sightings within and among sampling areas was in agreement with two decades of sighting records of individual humpback whales identified by their natural markings. The genetic “tags” were also used to estimate the abundance of humpback whales on the breeding grounds in the West Indies using mark-recapture techniques. Since the sex of each individual whale had been determined by genetic analysis as well, separate estimates of male and female abundance were calculated. Unexpectedly, the study yielded a significantly higher estimate of males at 4894 (95% confidence interval, 3374–7123) relative to that of females at 2804 (95% confidence interval, 1776–4463). The reason for this apparent underrepresentation of females on the breeding range (the sex ratio among the calves and all whales on the feeding grounds has previously been estimated at 1:1) could not be resolved on the basis of the data collected during the study. However, the authors suggested either spatial or temporal segregation among females as the source of the difference between the two abundance estimates.

Pomilla and Rosenbaum (2005) identified the same single female humpback whale by genetic tagging first in the Indian Ocean off Madagascar in 2000 and later again in the South Atlantic off Gabon (i.e., on the other side of the African continent) in 2002, demonstrating the tremendous migration potential migrating whales possess.

An aspect of marine mammal biology where genetic methods are especially useful is determination of parentage, e.g., to study breeding strategies and to assign individual reproductive fitness. Paternal reproductive success can be assessed in several ways, either by

determination of specific parentage or by the level of paternal variation among the offspring. The former approach is relatively straightforward, as individuals that are related as parent and offspring will have at least one allele in common at each locus. However, as is the case for individual identification (as discussed earlier), two individuals that are not related as parent and offspring may also share the minimum of one allele at each locus by chance. The probability that two individuals not related in parent–offspring manner share one or two alleles at each locus by chance decreases with the number and variability of loci genotyped. Hence, confident assignment of parentage requires that a relatively large number of variable loci are genotyped. In addition to a sufficient number of genetic markers, an adequate set of samples is required in order to insure that parent and offspring pairs are among the collected samples. To date only a few studies have attempted assignment of paternity in marine mammals, e.g., in gray seals, (*Halichoerus grypus*) or harbor seals (*Phoca vitulina*) either by analysis of microsatellite loci or “multi-locus” DNA fingerprinting, as in the case of the northern elephant seal where genetic diversity is exceptionally low.

Hoelzel *et al.* (1999) compared reproductive success of northern and southern (*M. leonina*) male elephant seals estimated as the proportion of pups fathered by the α -male in his own harem. Previous behavioral observations indicated a higher level of competition for matings among male northern elephant seal compared to male southern elephant seals, leading to the hypothesis that northern elephant seal α -males on average are less successful than their southern conspecifics. The genetic analysis corroborated this hypothesis, finding that southern elephant seal α -males sired a significantly higher proportion of pups in their own harem than did northern elephant seal α -males.

Multi-locus DNA fingerprinting differs from microsatellite analysis mainly by the fact that the alleles from multiple loci are detected simultaneously and is in essence similar to AFLP methods. The simultaneous detection of multiple loci prevents assignment of individual alleles to loci, which is why the degree of relatedness usually is estimated from the proportion of bands shared between individuals. However, the relationship between the degree of band sharing and relatedness is not straightforward, which is why the degree of band sharing is usually calibrated with a sample of individuals of known relationship, i.e., parent–offspring pairs.

Amos *et al.* (1993) employed multi-locus fingerprinting as well as microsatellite loci to study the pod structure of long-finned pilot whales (*Globicephala melas*). The whales are found in groups known as pods. Pilot whale pods appear to consist of mature animals as well as immature animals, presumably calves of the mature females. However, the genetic analyses revealed that also the adult males within a pod were closely related to the mature females in the same pod, indicating that males stay within their natal pod even after they become mature. The genetic analyses revealed that mature males had not sired the calves in their own pod. Curiously, calves of the same cohort in a pod shared paternal alleles, indicating that a single or few closely related males sired calves of the same age. The authors proposed that mature males leave their natal pod briefly and mate with receptive females when pods meet during the breeding season. This hypothesis would explain why no males appeared to have sired calves within their own pod. Mature males of different ages within a pod would then also be maternally related and in fact live “with Mom” for their entire life!

Cerchio *et al.* (2005) used microsatellite loci to assess the reproductive skew among male humpback whales. Humpback whales congregate on tropical breeding grounds where groups of males of up to 25–30 individuals compete intensely for access to mate a single

female that presumably is in estrus. The studies detected an unexpected low degree of skew in reproductive success among males.

Individual-based analyses such as the above examples have the potential to address new issues with genetic methods that previously were infeasible. Traditional population genetic analyses (see later) yield evolutionary estimates of genetic divergence/diversity and may thus be of limited relevance to contemporary management and conservation issues. However, identifying individuals and parent–offspring relations provides a “real-time” insight into population structure and dispersal at a time scale relevant to management and conservation purposes.

The collection of multi-locus genotypes at highly variable loci, such as microsatellite loci, from each individual enables so-called assignment tests. If one assumes panmixia, then the probability of observing an individual’s multi-locus genotype may be estimated from the population allele frequencies. If the probability is substantially higher for one population compared to the remainder candidate populations, the individual is assigned to that population. By this approach it is also possible to estimate “real-time” gene flow and recent events. Gaggiotti *et al.* (2002) used such an approach to determine the origin of individuals in newly established gray seal rookeries off the British Isles, demonstrating density-dependent dispersal in this species from the older established rookeries.

V. Analyses of Populations

A large number of genetic studies of marine mammals have been undertaken for the purpose of identifying population structure and mechanisms of intra-specific evolution. In practical terms, the aim is to determine if individuals belonging to the same partition are more closely related to each other than with individuals from other partitions, which is expected if partitions represent different entities (e.g., pods, population, or species). In numerical terms this objective translates into estimation of the degree of genetic heterogeneity among subpopulations, traditionally estimated as the relative increase in homozygosity due to population subdivision, e.g., Wright’s F statistics. The increase in homozygosity due to population structure is a product of random genetic drift. Random genetic drift denotes the random changes in allele frequencies resulting from the sampling of alleles for each new generation from the parental generation. If one assumes panmixia within each subpopulation with respect to the locus under study (which is likely to be the case in most instances) and the absence of any selection, the offspring generation can then be viewed as a random sample of the parental alleles. As with any random sampling process, such sampling is subject to stochastic variation, i.e., alleles are not resampled in exactly the same proportions as those found in the parental generation, and the allele frequencies will thus oscillate between generations unless the population is very large. The long-term consequence of random genetic drift in a finite-sized population is that all but one allele will be lost from the population in the absence of introduction of new alleles by gene flow and mutation. In other words, due to random genetic drift, alleles are lost from a population (thereby increasing the homozygosity) at a rate depending on the population size as well as the rate of introduction of new alleles either by mutation or gene flow from other subpopulations. Since the process is random, it follows that different alleles will increase/decrease in frequency due to random genetic drift in different populations. Overall the effect of random genetic drift is that we find more homozygotes among the sampled individuals than expected from the overall allele frequencies estimated from all populations combined. Gene flow homogenizes allele frequencies among populations by transferring alleles from one

population to other populations. If there are no major fluctuations in effective population size, gene flow, or mutation rates, an equilibrium state is reached where the rate of divergence in allele frequencies due to random genetic drift and mutation is equivalent to the rate of homogenization due to gene flow. Even very low levels of gene flow (e.g., 10 individuals per generation) among populations will homogenize allele frequencies among populations to an extent that no effect of random genetic drift and mutation can be detected. Neither the mutation rate nor the effective population size is usually known in natural populations. For instance, two populations may have a similar level of genetic variation (e.g., estimated as the heterozygosity) but differ in terms of population sizes and mutation rates. For instance, the degree of heterozygosity estimated among samples collected from a small population at loci with high mutation rates may be similar to that estimated from a large population at loci with low mutation rates. As the level of genetic variation depends upon the combination of effective population size and mutation rate (and these are typically unknown), it is common to simply combine both in the composite parameter θ (called theta), where $\theta = 4N_e\mu$ (for a diploid locus). N_e denotes the effective population size and μ the mutation rate. The advantage of this approach is that θ can be estimated from population genetic data, i.e., from the number of alleles, heterozygosity, polymorphic nucleotide positions, and the variance in allele size (for microsatellite loci). Comparisons of estimates of θ are used to draw inferences regarding differences in mutation rates among loci within single populations or differences in effective population size among populations as well as estimates of genetic divergence.

Several recent studies (Roman and Palumbi, 2003; Alter *et al.* 2007) have utilized population-specific estimates of θ from both haploid mitochondrial and nuclear autosomal DNA sequences to infer the effective population size in North Pacific gray whales (*Eschrichtius robustus*), as well as North Atlantic minke, fin, and humpback whales. The genetic estimates of effective population sizes in these populations, inferred from the amount of current degree of genetic diversity, were then equated to census population sizes, which in all cases were much higher than the abundance estimated in these populations today by use of other methods. For instance, the estimate of abundance arrived at in this manner for North Atlantic humpback whales was 240,000 individuals, much more than the best estimate of 10,600 individuals derived from mark-recapture data. The authors argued that their estimates reflect historical, pre-whaling abundance in these populations, as there is a time lag between the reduction in abundance (e.g., caused by whaling) and the corresponding decrease in genetic diversity in a population. These genetically derived estimates of abundance are subject to a number of assumptions about gene flow, sampling of all relevant populations, demographic changes, unknown mutation rates, and finally whether evolutionary estimators may be readily applied to contemporary populations (i.e., what is the effect of whaling, which for these species began some 250 years ago or later). The conservation and management implications of these findings are substantial; not only would conservation targets need be raised considerably, but the results also question our fundamental understanding of the “natural” state of our oceans. Given the many underlying assumptions and the large effects of violations of these assumptions, it remains open whether, for instance, these genetic estimates of abundance reflect local (e.g., North Atlantic) humpback whales, or global abundance.

As mentioned earlier, many population genetic studies of marine mammals have employed analysis of microsatellite loci. In addition, the nucleotide sequence of the maternally inherited mitochondrial control region is usually determined as well. The mitochondrial control

region constitutes the only major noncoding region of the mitochondrial genome, with mutation rates well above those for the remainder of the mitochondrial genome. Usually the sequence of the first 300–500 nucleotides in the mitochondrial control region is determined, which constitutes the most variable part of the mitochondrial control region. Because the mitochondrial genome is maternally inherited, any results from this locus estimate only the degree of maternal relation among samples. Most microsatellite loci, however, are of autosomal origin and thus inherited in a Mendelian manner.

The different modes of transmission of the mitochondrial and nuclear genome imply that each may reflect a different evolutionary relationship for the same set of samples. Palumbi and Baker (1994) investigated this aspect in 1994 in a study of humpback whales. In addition to mitochondrial control region sequences, the study also included data collected from the first intron in the nuclear protein-encoding locus actin. A phylogenetic analysis of the actin intron *I* allele nucleotide sequences revealed the existence of two main evolutionary lineages with no apparent geographic distribution. The two lineages could be distinguished by a SNP, which was detected by digestion with the restriction endonuclease *MnII* to yield a biallelic locus. This detection method was subsequently employed in the analysis of samples collected off Hawaii and western Mexico, both winter breeding grounds for eastern North Pacific humpback whales. Although the distribution of mitochondrial control region alleles was highly heterogeneous between the same two population samples (the Hawaiian sample being almost entirely monomorphic), no significant level of heterogeneity was detected in the distribution of the two actin intron *I* alleles. These “contrasting” results, i.e., little or no gene flow at the mitochondrial locus but indications of high levels of gene flow at the nuclear actin intron *I* locus, were interpreted as the result of male-mediated gene flow, different rates of random genetic drift at each of the two genomes or a combination of both. A subsequent study (Baker *et al.*, 1998) revealed significant levels of heterogeneity also at nuclear loci (mainly microsatellite loci) among samples collected from humpback whales off California and Alaska, which winter off Mexico and Hawaii, respectively. The simplest explanation for the seemingly discrepant outcome of the two studies is likely an increase in statistical power due to larger sample sizes and the inclusion of additional nuclear loci in the analysis (actin intron *I* as well as four microsatellite loci). However, the results do not eliminate the possibility of some contribution from male biased gene flow to the level of heterogeneity; more work is required to reach an affirmative conclusion.

The issue mentioned earlier, i.e., different degrees of male and female gene flow, is highly relevant when studying marine mammals. This has been clearly demonstrated in several population genetic analyses of species such as the North Atlantic humpback whales as well as northern right whales (*Eubalaena glacialis*) and belugas (*Delphinapterus leucas*). North Atlantic humpback whales summer at several high-latitude feeding grounds off the eastern sea border of North America, West Greenland, Iceland, Jan Mayen, and Bear Island in the Barents Sea. Whales from these distinct feeding grounds all appear to congregate on common winter grounds in the West Indies. The winter constitutes the breeding and the mating season. Calves are born during the winter and follow the mother during the spring migration to a high-latitude feeding ground and later on during the autumn migration back to the West Indies. At the end of their first year the calves separate from their mother. The calf will, however, continue to migrate back to the same high-latitude feeding ground in subsequent summers to which it went with its mother during the first summer. The population genetic consequence of this maternally directed

migration pattern is that North Atlantic humpback whale summer feeding grounds can be viewed as a single panmictic population with respect to nuclear loci, but structured in terms of mitochondrial loci. The latter is due to the maternal transmission of the mitochondrial genome in combination with the maternally directed site-fidelity to the high-latitude summer feeding grounds. Nuclear alleles are exchanged when humpback whales from different summer feeding grounds mate in the West Indies. However, the calves only inherit their maternal mitochondrial genome, and thus there is in principle no exchange of mitochondrial DNA among summer feeding grounds, if calves keep returning to their maternal high-latitude summer feeding ground. Several population genetic studies have analyzed North Atlantic humpback whales and in conclusion found what was expected from the earlier work (Palsbøll *et al.*, 1995). However, low levels of heterogeneity have also been detected at nuclear loci when comparing western and eastern North Atlantic high-latitude summer feeding grounds, indicating that some eastern North Atlantic humpback whales may winter and breed elsewhere than in the West Indies.

On a much more detailed scale, (Hoelzel *et al.*, 1998; Hoelzel *et al.*, 2007) determined the genotype at multiple microsatellite loci and the nucleotide sequence in the variable part of the mitochondrial control region in samples collected from pods of killer whale (*Orcinus orca*) observed in Puget Sound in the northeastern Pacific. Two kinds of killer whale pods are found in Puget Sound, resident and transient pods. The latter pods spend only part of the year in Puget Sound. Although the resident pods seem to feed almost exclusively on fish, the diet of transient pods is mainly composed of marine mammals. The two kinds of pods also differ in average number of individuals and vocalizations. The genetic analysis revealed significant levels of heterogeneity between resident and transient killer whales not only at the mitochondrial locus but also at the nuclear loci as well. This result was interpreted as evidence of a highly restricted degree of gene flow between two different kinds of foraging specialists, and in fact it might be that this feeding specialization drives the genetic divergence between the two sympatric groups of killer whales.

All the above-mentioned examples assume the absence of selection on the marker, but one could well envision natural selection affecting the degree and distribution of genetic variation among and within subpopulations.

One such possibility is the sperm whale (*P. macrocephalus*) for which very low levels of variation have been detected in the mitochondrial control region on a worldwide scale. This observation prompted Whitehead (1998) to propose cultural transmission of adaptive traits in matrilineal whale species as the cause of the low levels of variation at maternally inherited mitochondrial loci. The basic principle proposed by Whitehead is that long-term association between females and their offspring facilitates an efficient cultural transmission of behavioral traits, e.g., feeding behaviors. If a maternal lineage adapts more efficient behaviors, which in turn increases that lineage's reproductive success, such maternal lineage will eventually increase in proportion within the population. The model is similar to genetic inheritance of adaptive traits, i.e., natural selection, the only difference being that transmission across generations is culturally mediated as opposed to genetically. Since the mitochondrial genome is maternally transmitted it will thus “hitchhike” along with maternal cultural transmission of advantageous behavioral traits. The study reported low levels of genetic variation at mitochondrial loci in species which were classified as matrilineal by the author, i.e., species with pods presumably consisting of females and their offspring, such as pilot whales and sperm whales. In contrast, the nucleotide

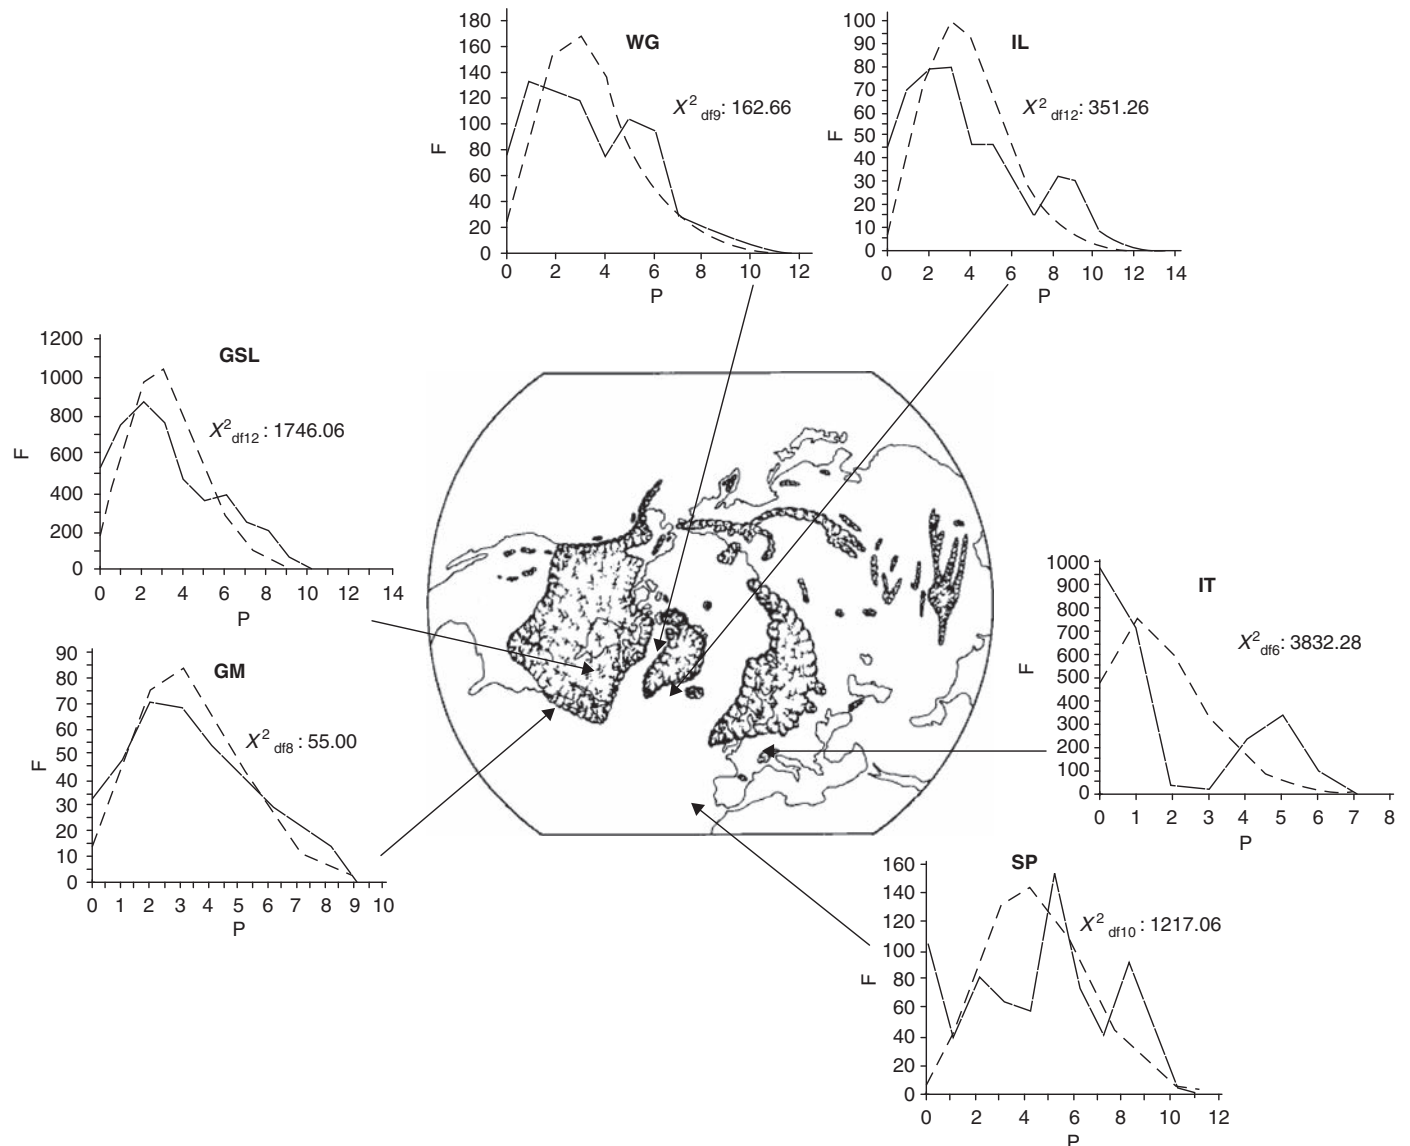

Figure 3 Indication of postglacial expansions on western North Atlantic fin whale, *Balaenoptera physalus*, populations from genetic data. Observed (solid line) and expected (dashed line) frequency distributions of pair-wise differences among mitochondrial control region nucleotide sequences in North Atlantic fin whale populations under a model of exponential expansion (see text for details). A close match between the observed and the expected distribution suggests that the samples were obtained from an exponentially expanding population. The marked areas on the map of the Northern Hemisphere indicate the presence of solid ice sheets during the last Pleistocene glaciation. diversity was on average 10-fold higher in species classified in the study as nonmatrilineal. The author demonstrated, by use of computer simulations, that maternal cultural transmission of advantageous behavioral traits could indeed reduce the nucleotide sequence variation at mitochondrial loci significantly if the cultural transmission was efficient and the selective advantage relatively high (~ 0.1). Although there have been no objections to the hypothesis of cultural transmission of adaptive behavioral traits occurring in cetaceans, others have pointed toward other evolutionary models, such as continued selection and fluctuating population sizes, as equally compatible with the observed data.

The environment inhabited by marine mammals is relatively devoid of physical barriers in comparison to the terrestrial

environment. In addition, many marine mammal species have wide ranges, and thus there is a high potential for dispersal. In spite of this, most genetic studies of marine mammals have detected population structure in the distribution of genetic variation within as well as between ocean basins. The lack of physical barriers to dispersal indicates that intrinsic factors may play a role in generating population structure, such as foraging specialization and maternally directed site-fidelity. Even for species where no obvious behaviors limiting dispersal have been observed, population genetic structure was detected, such as in the case of polar bears (*Ursus maritimus*) and fin whales (*Balaenoptera physalus*). In these two instances, it appears that the availability of prey is, at least in part, responsible for generating population genetic structure. In the case of polar bears,

Figure 4 The changes to the traditional artiodactyl phylogeny suggested by the findings of Shimamura *et al.* (1997) (see text for details). Reprinted by permission from Nature (Milinkovitch and Thewissen, 1997). Copyright © (1997) Macmillan Magazines Ltd.

Paetkau *et al.* (1999) analyzed 16 different microsatellite loci in a total of 473 polar bears collected from all areas of the Arctic. The study detected a pattern of genetic divergence among subpopulations that was consistent with the distribution of active annual sea-ice, which in turn relates to the abundance of ringed seals, which is their main prey. A study of North Atlantic and Mediterranean Sea fin whales (Bérubé *et al.*, 1998) was based upon analyses of mitochondrial control region sequences as well as six microsatellite loci in 309 specimens. The population structure revealed from the genetic analyses was consistent with an isolation-by-distance model, which could be explained by a distribution described as a “patchy-continuum” previously suggested by Sergeant and based upon the overall distribution of prey. Interestingly the fin whale study also revealed the possible effect of major geological events, in this case glaciations, upon the present day levels and distribution of genetic variation. The frequency distribution of mitochondrial nucleotide sequences suggested that fin whale population in the western North Atlantic had undergone rapid expansion in abundance most probably from a small postglacial founder population (Fig. 3).

VI. Analyses of Interspecific Relationships

A well-founded phylogenetic description of marine mammals is fundamental to our understanding of the unique evolution and adaptations observed in this group of mammals. Phylogenetic studies have been conducted at several levels, e.g., among cetaceans as well as at higher levels, such as the relation of cetaceans to ungulates.

The latter question has attracted much attention, as molecular data is emerging complementing earlier morphological estimates of the phylogenetic affinities of marine mammals. The results emerging from the molecular data are, at the moment, inconsistent with the morphological findings as well as among the different molecular data

sets themselves with regard to the branching order in several parts of the evolutionary tree. There are multiple possible explanations for such incongruence, such as incomplete taxonomic sampling, inadequate model of change (molecular and morphological), insufficient choice, and number of out-groups as well as incomplete fossil records. As mentioned earlier, the level of homoplasy increases with genetic divergence, which complicates the interpretation of nucleotide sequence data. Instead of DNA nucleotide sequences, the more common sort of data employed in phylogenetic analyses, Shimamura and coworkers (1997) used SINEs. The random and irreversible nature of SINEs make these loci ideal loci for phylogenetic analyses, with a very simple mutation model that is devoid of many of the problems, such as homoplasy, codon position, transition/transversion ratio, and the like, which introduce variability in analyses of single-nucleotide substitutions. The SINE-based study found support for the notion that Artiodactyla is a paraphyletic group, in that cetaceans did not constitute a sister group but originated within Artiodactyla (Fig. 4). Earlier studies, based upon a sequence analysis of nuclear loci encoding milk proteins by Gatesy and coworkers also arrived at the same conclusion, i.e., artiodactyls are a paraphyletic group, also from the position of the cetacean branch. The paraphyly of Artiodactyla was subsequently supported in a comprehensive phylogenetic estimation conducted by involving data from several nuclear and mitochondrial loci. Given the highly specialized cetacean morphology, comparisons of morphological characters with terrestrial mammals is not a trivial matter, making molecular-based phylogenies attractive.

A perhaps more controversial study is an early phylogenetic analysis that estimated the phylogenetic position of the sperm whales within Cetacea from mitochondrial nucleotide sequences. Conventional taxonomy based upon morphological characters places this distinct and old lineage of cetaceans among the odontocetes, as sperm whales share many morphological characters with other

odontocetes, the presence of teeth and echolocation being the most obvious traits. In contrast, the new study found that sperm whales were significantly more closely related to the baleen whales than to the remainder of the odontocetes (Milinkovitch *et al.*, 1993). The result of this study has since been the subject of numerous additional analyses and reanalyses and in many ways become a case study of phylogenetic estimation from genetic characters and revealed many different (problematic) aspects of single-locus phylogenetic estimation. Such studies have shown that estimation of taxonomic relationships from nucleotide sequences is sensitive to such factors as choice of out-groups, taxonomic sampling, sequence alignment, and long branches. Subsequent analyses based upon nuclear and mitochondrial loci showed a strong support among nuclear genes for the traditional odontocete affinity of the sperm whales and less strong support for the alternate view among the mitochondrial nucleotide sequences. Later studies based upon Y-chromosome specific sequences have also confirmed the “traditional” cetacean phylogeny (Nishida *et al.*, 2007).

The same studies have also illuminated rapid radiation events leading to the extant baleen whales and within the toothed whales, in particular the dolphins, which explains why phylogenetic estimates based upon mitochondrial genes (all belonging to the same locus) have proven inadequate to resolve the phylogenetic relationships or yielded erroneous results.

In several instances interspecific analyses of DNA sequences have revealed “cryptic” species in cetaceans. Initial work on mitochondrial DNA sequences, which was later confirmed by analyses of 13 nuclear loci, suggested three species of right whales; a North Atlantic (*E. glacialis*), a southern right whale (*E. australis*), and a North Pacific (*E. japonica*) (Rosenbaum *et al.*, 2000).

The above examples illustrate that our understanding is still far from satisfactory and that additional work is necessary before we have a more thorough and definitive understanding of the evolution of this highly specialized group of mammals and the underlying molecular mechanisms which we employ in our inferences.

Geographic Variation

WILLIAM F. PERRIN

I. The Nature of Geographic Variation

Mammals vary from place to place, in size, shape, coloration, osteology, and genetic features, including chromosomes, enzymes, and DNA sequences. They also vary in sounds produced, other behavior, life history, breeding system, parasites, contaminant loads, biochemical features such as fatty acids, and other characters. This chapter focuses on geographic variation in morphology. When morphological variation and range are discontinuous, i.e., the populations or metapopulations are allopatric and can be diagnosed from one or, more commonly, a few characters, they are usually recognized as species, with the inference that they have diverged irrevocably in their evolutionary paths. When this is not true and groups differ from each other on average (modally) rather than absolutely, the variation is considered to be *geographic variation* within a species, and the form is recognized as a *subspecies*, *race*, or *geographic form*.

Figure 1 Geographic variation in the number of teeth in spinner dolphins from five regions. Average and frequency distribution are shown; sample sizes are shown in parentheses. By permission from Perrin et al. (1999).

Mammal species tend to vary geographically most in those features that vary most within a population. If, as for most mammals, body size varies broadly within a population, then geographic variants will usually differ in average body size. In another example, odontocete cetaceans are unusual among mammals in that they vary greatly in the number of teeth and vertebrae within a species, and, as expected, these features differ sharply between geographic forms (Fig. 1).

Geographic variation may be *discordant*, i.e., the geographic pattern may differ among characters. For example, spinner dolphins (*Stenella longirostris*) in the eastern tropical Pacific vary differentially in color pattern, dorsal fin shape, fluke shape, and skull features (Perrin et al., 1991), creating a complex mosaic of subspecies (see later) and varying zones of intergradation, depending on what feature is being looked at.

It is likely that most geographic variation in morphology (and the underlying genetic basis) in marine mammals is due to differential

selection (ecological divergence) rather than genetic drift. By saying that two populations belong to the same species, we are implying that there is, or recently has been, gene flow between them. Populations can diverge sharply morphologically in the presence of even substantial gene flow if the ecologically engendered differential selection is strong enough (Orr and Smith, 1998). However, modeling studies have indicated that social behavioral characteristics, such as female philopatry and polygynous breeding systems, both common in marine mammals, can lead to the sequestering of variation due to drift within populations; this may accelerate evolutionary divergence (Storz, 1999).

Neutral genetic differences can accumulate across populations due to drift, and markers for this geographic variation are used extensively in defining marine mammal populations for purposes of assessment and management.

II. Subspecies

Subspecies are formally named or otherwise recognized geographic variants within a species. Subspecies are currently recognized for 29 of the 127 or so marine mammal species (Table I).

The situation for subspecies is not as tidy as might be implied from Table I. Many of these subspecies were poorly described and may prove to be invalid; others may turn out to be full species. Some probably include multiple distinctive populations that deserve subspecific status but are as yet poorly understood. As indicated, some geographic forms have been recognized but not yet named. Some workers would disagree with certain of these subspecific designations and perhaps recognize others. Many additional subspecies were described in the past but have since been discounted (Rice, 1998). As for all of taxonomy, progress in classification at this level (*beta taxonomy*) is uneven and iterative.

In a recent workshop on cetacean taxonomy (Reeves et al., 2004), participants agreed that the subspecies concept may be construed as broad enough to contain two types of entities, populations that are not quite far enough along the continuum toward full specieshood to be judged as species, and populations that may well be species but for which not quite enough evidence is available to justify their designation as such. They also agreed that while the subspecies concept has been largely based on morphology, it should be extended to include genetic evidence, especially as many marine species are more susceptible to genetic sampling than to collection of full osteological specimens. The workshop arrived at the following criteria advised to be applied in defining subspecies:

The subspecies concept should be understood to embrace groups of organisms that appear to have been on independent evolutionary trajectories (with minor continuing gene flow), as demonstrated by morphological evidence or at least one line of appropriate genetic evidence. Geographical or behavioral differences can complement morphological and genetic evidence for establishing subspecies. As such, subspecies could be geographical forms or incipient species.

III. Cetaceans

For the odontocetes, in every case where adequate samples of specimens from different regions have been available for examination, geographic variation has been found (Amano and Miyazaki, 1992; Perrin and Brownell, 1994; Archer and Perrin, 1999; Perrin et al., 2003; Jefferson and Van Waerebeek, 2004; Lazaro et al., 2004), so it can be expected to be universal.

Body size tends to be larger in open waters than in closed seas. For example, in the contiguous eastern North Atlantic, Mediterranean, and Black Sea, the short-beaked common dolphin, *Delphinus delphis*, is largest in the North Atlantic, smallest in the Black Sea, and intermediate

^dCombines “subsp. A” and “subsp. B.”

in average size in the Mediterranean (Perrin, 1984). The common bottlenose dolphin, *Tursiops truncatus*, shows the same pattern, being largest in the open Atlantic and smallest in the Black Sea, as does the beluga, *Delphinapterus leucas*, in the Canadian Arctic (Stewart and Stewart, 1989; Doidge, 1990). Body size also varies inshore/offshore. In the eastern tropical Pacific, the coastal subspecies of the pantropical spotted dolphin, *Stenella attenuata graffmani*, is on average larger than the offshore form, *S. a. attenuata*. It also has larger teeth; it may prey on larger tougher, benthic fish species, whereas the offshore form feeds primarily on small epipelagic fishes and squids. The pattern is repeated in the Atlantic spotted dolphin; the coastal form is larger than the offshore form in the Gulfstream (Perrin *et al.*, 1987). However, in the bottlenose dolphin in the western North Atlantic, the pattern is reversed; the offshore form is larger than the coastal form (Hoelzel *et al.*, 1998), in correlation with different stomach contents and parasite loads. Variation in size can also be latitudinal; short-beaked common dolphins in the eastern Pacific are longest in the Central Stock off Central America and shorter to the north and south (Perryman and Lynn, 1993). Although it has been suggested that some of this variation in body size could be ecophenotypic (due, e.g., to differential nutrition across areas of varying productivity), it is thought to most likely be determined genetically.

The dorsal fin is another feature that varies markedly with region in some odontocetes. A dramatic example of this can be seen in the tropical Pacific; whereas the fin in spinner dolphins in the Hawaii and the South Pacific is slightly falcate and subtriangular, typical of the species around the world, in large adult males in the far eastern Pacific (*Stenella longirostris orientalis* and *S. l. centroamericana*) the fin is canted forward, with a convex posterior margin (Fig. 2). Animals in a broad zone of HYBRIDIZATION or intergradation are intermediate. A similar variation is present in short-beaked common dolphins; large adult males from the equatorial offshore eastern Pacific have more erect, triangular dorsal fins than in other regions. In both species the more erect (or forward-canted) dorsal fin is correlated with the development of a post-anal ventral hump (of unknown function).

Color pattern also varies within a species. In the *truei* form of Dall's porpoise (*Phocoenoides dalli truei*) in the western Pacific the ventrolateral white field is greatly enlarged from that in *P. d. dalli*. The just-described geographic variation in dorsal fin shape in the spinner dolphin is correlated with variation in color pattern; the dorsal overlay in the eastern spinner is extensive and dark, obscuring the cape and giving the animal a monochromatic rather than a tricolor appearance. In killer whales in the Antarctic, the cape is visible; in

Figure 2 Geographic variation in shape and color pattern in spinner dolphins from the eastern and central Pacific: (A) Hawaii, (C) far eastern Pacific, and (B) intermediate form from region far offshore in eastern Pacific. By permission from Perrin (1990).

other areas of the world it is not (Evans *et al.*, 1982). The degree of spotting in the Atlantic spotted dolphin (*Stenella frontalis*) varies from intense along the US east coast to slight or none in animals in the offshore Gulf Stream to the northeast (Perrin *et al.*, 1987).

The most extensive studies of geographic variation in odontocetes have dealt with cranial features, characters that can be measured in collections of museum specimens. Within a species, variation has been found to be greatest in elements involved in feeding: size and number of teeth, length and breadth of the rostrum, and size of the temporal fossa. This implies that much geographic variation must be associated with factors in trophic ecology such as available forage, foraging techniques, and competition. Cranial variation in the offshore spotted dolphin has been shown to be correlated with environmental parameters such as water depth, solar insolation, sea-surface temperature, surface salinity, and thermocline depth (Perrin *et al.*, 1994), and the distribution of two forms of the spinner dolphin in the eastern Pacific is associated with different water masses (Fiedler and Reilly, 1993). Different geographic forms or subspecies may also exhibit different patterns in life history parameters, such as age and size at attainment of sexual maturity, fecundity, and survival, but these differences can be due to differential population status as well as genetic factors (Chivers and DeMaster, 1994).

Mysticetes have not been as well studied because of their large size and a paucity of museum series of specimens (Reeves *et al.*, 2004). Subspecies and populations have been recognized mainly on the basis of DISTRIBUTION and, more recently, genetic differences. No adequate morphological comparisons of the recognized populations of bowhead whales, *Balaena mysticetus*, have been carried out; the same is true for the two extant populations of the gray whale, *Eschrichtius robustus*, and the several populations of humpback whales, *Megaptera novaeangliae* (apart from fluke coloration). It is only in the rorquals that progress has been made in documenting geographic variation in morphology; this has been due to the availability of large series of specimens in factory-ship whaling operations. A dwarf form of the minke whale, *Balaenoptera acutorostrata*, exists in the Southern Hemisphere. Minke whales from the Sea of Japan ("J Stock") and Pacific coast of Japan ("O Stock") may differ modally in body proportions and baleen and flipper coloration (Kato *et al.*, 1992). Small coastal and large offshore forms of Bryde's whales, *B. eden/brydei*, have been described from South Africa and Japan. The pygmy blue whale, *B. musculus brevicauda*, is shorter (by 2 m in the North Pacific; Gilpatrick *et al.*, 1997) and heavier than other blue whales. (Thus the heaviest animal on earth is called "pygmy.")

IV. Carnivores

Similar to cetaceans, pinnipeds can vary geographically in body size (e.g., *Arctocephalus tropicalis* among Amsterdam, Gough, and Marion Islands; *Odobenus rosmarus* between the Atlantic and the Pacific Arctic; *Mirounga leonina* between Macquarie Island and South Georgia; *Pusa hispida* between the Baltic and the Sea of Okhotsk; Rice, 1998), coloration (*Phoca vitulina* between different islands off California; Yochem *et al.*, 1990), and cranial features (*Phoca vitulina* among several subspecies; *P. hispida* between pack ice and shore-fast ice and between the freshwater populations; *Halichoerus grypus* between the two sides of the Atlantic and the Baltic; *Histriophoca fasciata* between the western and the eastern parts of the Bering Sea; and *Monachus monachus* between the Mediterranean and the Atlantic; Rice, 1998).

The three subspecies of sea otter are distinguished on the basis of body size and cranial characters (Wilson *et al.*, 1991) and the two subspecies of polar bears on the basis of skull size (Rice, 1998).

Although for some small cetaceans efforts to find genetic markers concordant with geographic morphological variation have failed (see Dizon *et al.*, 1991 for *Stenella longirostris*), the reverse is true for pinnipeds; genetic differences or reproductive isolation have been found between populations that cannot be distinguished morphologically in *Arctocephalus forsteri*, *Zalophus californianus*, *Eumetopias jubatus*, and *P. hispida* (Hoelzel, 1997; Loughlin, 1997; Rice, 1998). Factors causing this may be polygyny and strong phyloptry (promoting accumulation of neutral variation due to drift) combined with relatively uniform ecological selection promoting morphological homogeneity over the range of the species.

V. Sirenians

A molecular study of *Trichechus manatus* (García-Rodríguez *et al.*, 1998) found variation not in accordance with the presently recognized subspecies based on cranial characters; *T. m. latirostris* is closely linked to the Caribbean population of *T. m. manatus*, whereas the phylogenetic distances among the Caribbean, Gulf of Mexico, and South American populations of *T. m. manatus* are comparable to that between *T. manatus* and the Amazonian manatee, *T. inunguis*. These results were supported by further genetic investigations (Vianna *et al.*, 2006). As for many other marine mammal taxa, the taxonomy is ripe for revision based on both morphological and molecular characters.

Geographic variation in cranial morphology has been found within *Dugong d. dugon*, between Australia and Tanzania and between the Gulf of Carpentaria and Queensland in Australia (Rice, 1998).

A specimen of similar characters found in the Bering Sea was the basis for another species, Baird's beaked whale, *B. bairdii* Stejneger, 1883. Due to uncertainty in morphological difference, the validity of the two species has long been questioned (Balcomb, 1989), but they are now considered to represent distinct species based on mitochondrial DNA (Dalebout et al., 2004).

Currently recognized morphological differences between the two species are slight and limited to smaller adult size in Arnoux's beaked whale (8.5–9.75 m vs 9.1–11.1 m) and possible differences in flipper size and in the shape of nasal bones and vomer. Condylbasal lengths of skulls of adult Arnoux's beaked whales range 1174–1420 mm, and those of Baird's beaked whale are 1343–1524 mm. Other measurements in percentage of condylbasal length are (both species combined), length of rostrum 60.7–69.5%, width of rostrum at base 64.4–82.3%, and breadth across zygomatic processes of squamosals 47.1–56.5%. Nasal bones are large but do not overhang the superior nares. Among Ziphiidae, their skulls show the least bilateral asymmetry and are distinguished by the greatest nasal area on the vertex of skull, followed by frontals and premaxillae in decreasing order (Dalebout et al., 2003). A pair of large teeth erupt on the anterior end of the lower jaw at around sexual maturity and abrade rapidly. The tooth is flat, triangular in shape (about 8 × 8 × 3 cm), and has elements of rudimentary enamel, thin dentine, massive secondary dentine filling the pulp cavity, and thick cementum that covers the root.

The vertebral formula of 3 Arnoux's beaked whales was C7, T10–11, L12–13, Cd17–19, total 47–49, and that of 49 Baird's beaked whales off Wadoura, Japan, C7, T9–11, L12–14, Cd17–22, total 47–52 (mean 48.9); most (41) had either 48 or 49 vertebrae (Kasuya unpublished). There are five phalanges in the manus.

The stomach lacks an esophageal compartment, and the glandular stomach has up to nine segments. The cecum is absent. The nasal tract has three pairs of sacs.

The entire body is dark brown. The ventral side is paler and has irregular white patches. Tooth marks of conspecifics are numerous on the back, particularly on adult males.

These are the least sexually dimorphic species in the Ziphiidae. The body is slender with a small head, a low falcate dorsal fin, and small flippers that fit into depressions on the body. A pair of throat grooves and some accessory ones contribute to expand the oral cavity at suction feeding. The equation $W = (6.339 \times 10^{-6})L^{3.081}$ expresses the relationship between body weight (W , in kg); and body length (L , in cm) off Japan. The blowhole is crescent shaped with the concavity directing anteriorly. The melon is small and its front surface is almost vertical, with a slender projecting rostrum.

Giant Beaked Whales

Berardius bairdii and *B. arnuxii*

TOSHIO KASUYA

I. Characteristics and Taxonomy

These two species are the largest members of the family Ziphiidae (Fig. 1). Arnoux's beaked whale, *Berardius arnuxii* Duvernoy, 1851, was described based on a skull from New Zealand.

II. Distribution and Abundance

Arnoux's beaked whales inhabit vast areas of the Southern Hemisphere outside of the tropics, from the Ross Sea at 78°S to Sao

Figure 1 Baird's beaked whale (C. Brett Jarrett).

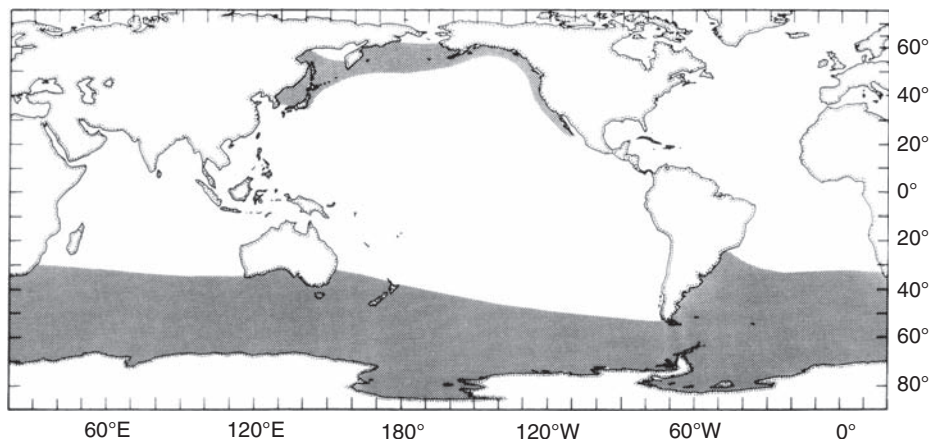

Figure 2 Giant beaked whales in the genus *Berardius* are distributed disjunctly. *B. arnuxii* occurs in waters around the Antarctic, reaching northward to the shores of the Southern Hemisphere continents. *B. bairdii* ranges across the northern Pacific from Japan, throughout the Aleutians, and southward along the coast to the southern tip of Baja California.

Paulo (24°S), northern New Zealand (37°S), South Africa (31°S), and southeastern Australia (29°S) (Fig. 2). Baird's beaked whales inhabit the temperate North Pacific and adjacent seas, mainly deep waters over the continental slope. The northern limits are at Cape Navarin (62°N) in the Bering Sea and in the central Okhotsk Sea (57°N), where they occur even in shallow waters of 200–1000 m. On the American side they usually occur north of northern Baja California (30°N), but there are records from La Paz (24°) in the southern Gulf of California. The southern limits on the Asian side are at 36°N on the Japanese coast in the Sea of Japan and at 34°N on the Pacific coast. They occur year-round in the Okhotsk Sea and the Sea of Japan, including the drift ice area of the former. A vagrant was taken off the Chinese coast (30°N) (Wang, 1999).

Off the Pacific coast of Japan, the whales appear in May in waters over the continental slope at depths of 1000–3000 m. Their numbers increase toward summer when hunting commences and then decrease toward October. During this period they are almost absent in waters farther offshore. Factors determining the range are unknown and their wintering ground has not been identified (Kasuya and Miyashita, 1997).

Abundance has been estimated only for Japanese waters, 5029 for the Pacific coast, 1260 for the eastern Sea of Japan, and 660 for the southern Okhotsk Sea, with 95% confidence intervals of about 50% on both sides of the mean (International Whaling Commission, 1992, 1994).

III. Ecology

For Baird's beaked whales off the Pacific coast of Japan (35°N), 81.8% of the food in number of individuals eaten was benthopelagic fish (Moridae and Macrouridae comprised 81.3%) and 18.0% various cephalopods (Gonatidae and Cranchiidae comprised 11.7%), but among individuals in the southern Okhotsk Sea (44–45°N) fish made up only 12.9% (Moridae and Macrouridae comprised 9.2%) and most of their food was cephalopods (87.1%) (Gonatidae and Cranchiidae comprised 86.7%) (Walker *et al.*, 2002). These data agree with earlier studies of Baird's beaked whales off California, that ate mainly Moridae, Macrouridae, and cephalopods with occasional ingestion of pelagic fish, and of an Arnoux's beaked whale that had squid beaks in the stomach, and suggest that they are opportunistic feeders.

Cyamids attach on teeth and skin, stalked barnacles on teeth, and diatoms on skin. Wounds attributable to the cookie-cutter shark,

Isistius brasiliensis, are common in Japan. Scars from killer whale teeth are common on flippers and tail flukes, suggesting predation. Internally, they are heavily parasitized in the stomach, liver, blubber, and kidney, with extensive kidney pathology due to the nematode *Crassicauda giliakiana*.

IV. Behavior and Physiology

Information comes from observation of Baird's beaked whales off Japan (Kasuya, 1986; Kasuya and Miyashita, 1997; Kasuya *et al.*, 1997). When traveling, they form tight schools of 1–30 individuals (mean 5.9) (Fig. 3). Schools of 2–9 individuals constitute 64% of the encounters and singletons 14%. Diving lasts up to 67 min (mean 18.2), 39% last less than 11 min, 27% 11–20 min, and 18% 21–30 min. Time at the surface is 1–14 min (mean 3.9) and tends to be greater after a longer dive. During surface schooling, individuals blow continuously while swimming slowly and are easily identifiable from vessels.

V. Life History

Age is determined using growth layers in the tooth cementum. The gestation time is unknown, although 17 months is suggested from interspecies relationship among toothed whales. Neonates are about 4.6 m long. Females first ovulate at age 10–15 years when they are 9.8–10.7 m and live to about 54 years.

The testis is histologically mature when it weighs 1.5 kg, which corresponds to age 6–11 years or a body length of 9.1–9.8 m, but continues growing until age 30, when it reaches 3–9 kg. Males live to about 84 years. Lack of behavioral data inhibits judgment of the age at which males begin to participate in reproduction.

Physical maturity, determined from the fusion of vertebral epiphyses to the centrum, is attained before 15 years and within 5 years after attainment of sexual maturity. Mean body lengths of whales 15 years or older are 10.45 m (SD = 0.31, $n = 22$) in females and 10.10 m in males (SD = 0.35, $n = 66$).

The sex ratio is about 1:1 before sexual maturity (44% males at age 3–9 years), after which males increase with age to reach 100% at 55 years and over. Seventeen percent of 170 individuals taken off Japan were males at ages 55–84 years, which were older than the oldest females (54 years). This explains the high male proportion (67.6%)

Figure 3 A school of Baird's beaked whales in the southern Okhotsk Sea ($44^{\circ} 15'N$, $145^{\circ} 30'$) on 26 September 1994. Copyright Asahi Shinbun.

in the sample. Such a sex ratio imbalance is common among whaling samples from Japan (Sea of Japan, Okhotsk Sea, and Pacific), Russia (Kuril and Aleutian Islands), and Canada (off Vancouver Island) and is believed to reflect a lower natural mortality rate of males.

The proportion of females among sexually mature individuals was 23%. This is increased to 37% with the assumption that males attain reproductive capacity at 30 years when testicular growth ceases. Ovulation occurs throughout life at an approximate rate of once every 2 years. The apparent high fecundity and shorter longevity of females combined with greater male longevity have invited speculations on their social structure including a possible male contribution in rearing calves.

IV. Interactions with Humans

Exploitation has not been reported for the Arnoux's beaked whale. Past hunting of Baird's beaked whales by the USSR, Canada, and the United States was at low levels. Only Japan currently hunts them. This started in the early seventeenth century at the entrance of Tokyo Bay. The annual catch was less than 25 before 1840 and then declined. In 1891, whaling cannons were introduced and

the operation moved to outer seas. After World War II the fishery expanded to the entire northern Pacific, reported a maximum annual catch of over 300, and subsequently declined. A question exists about the reliability of the statistics (Balcomb and Goebel, 1977). In 2007 the industry operated with a quota of 10 for the Sea of Japan, 4 for the southern Okhotsk Sea, and 52 for the Pacific coasts.

There are no identified threats to the species except for takes by Japanese whaling from three putative stocks off Japan (Okhotsk Sea, Sea of Japan, and Pacific). Effect of the present catch should be evaluated together with consideration of effects of the past whaling operations on the stocks, using newer abundance estimates.

Gray Seal

Halichoerus grypus

AILSA HALL AND DAVID THOMPSON

I. Characteristics and Taxonomy

The gray seal is the only member of the genus *Halichoerus* a member of the family of the true seals or Phocidae. Its species name, *grypus*, means hook nosed, referring to the Roman nose profile of the adult male. *Halichoerus* means sea pig in Greek. This species exhibits SEXUAL DIMORPHISM with the mature males

Figure 1 Female gray seal, *Halichoerus grypus*.

Figure 2 Male gray seal, *Halichoerus grypus*.

weighing between 170 and 310 kg and adult females between 100 and 190 kg. Individuals from the population in the western Atlantic are significantly larger than those from the eastern Atlantic; males can weigh over 400 kg and females over 250 kg. Genetic studies suggest that the western and the eastern Atlantic populations are distinct and diverged approximately 1 million years ago (Boskovic *et al.*, 1996).

Morphological differences between the sexes can be seen in Figs. 1 and 2. The neck and chest of the male are wrinkled and often scarred, whereas females are much sleeker. Both have the convex nose and wide muzzle, which are very pronounced in the male. Pelage patterns are highly variable, but many of the females are slate gray in color with a distinctive cream/off-white underside, particularly around the neck, spotted with black blotches. Males are usually more uniformly dark when mature, but subadults can have similar cream-colored patches on the neck and the side of the face. Females mature at between 3 and 5 years old and males around 6 years, although they are probably not socially mature until 8 years old.

II. Distribution and Abundance

Figure 3 shows the geographic range of the gray seal. Breeding rookeries are usually on remote beaches and uninhabited islands but they also breed on fast ice in the Baltic and the Gulf of St Lawrence. Table I shows the relative size of the various gray seal populations worldwide. Because the relationship between the number of pups

born each year (pup production) and the total population size is not well known, the pup production estimates for each population are given. The total population will probably lie somewhere between 3 and 4.5 times the pup production depending on the local survival and fecundity patterns.

III. Ecology

Gray seals are highly successful predators of the North Atlantic. They feed on a variety of fish species and cephalopods (Hammond *et al.*, 1994a, b). However, a large proportion of their diet is sand eels or sand lance (*Ammodytidae*), which can make up over 70% of the diet at some locations and in some seasons. Other prey include whiting, cod, haddock, saithe, and flatfish (plaice and flounder). They are largely demersal or benthic feeders, and foraging trips lasting between 1 and 5 days away from a haul-out site are frequently focused on discrete areas that are within 40 km of a haul-out site (McConnell *et al.*, 1999).

IV. Behavior and Physiology

The females give birth, on land or on ice, to a single white-coated pup between September and March. The earliest breeding colonies are those in the south of the United Kingdom and Ireland. Further north around the British Isles the breeding season is later, between October and November. In Canada, peak pupping is not until January and in the Baltic it occurs in late February–early March.

At birth the pup weighs between 11 and 20 kg and, over the lactation period, lasting an average of 18 days, can quadruple in weight to over 40 kg. The mothers' milk is very fat rich (around 50–60% lipid) and is mobilized from her blubber stores. The pup's white coat, known as the lanugo, is shed at weaning. The pup then undergoes a postweaning fast on land for a period lasting, on average, approximately 25 days (Bennett *et al.*, 2007), during which it loses approximately 0.5 kg per day. The reason for this fasting period is not fully understood, but physiological changes during this time suggest that it is related to the development of diving ability.

Toward the end of lactation the female comes into estrus and mates. On some colonies there may be as many as 10 females to 1 male, whereas on rookeries, where access is not restricted by narrow gullies, the sex ratio may be 2 females to 1 male. Males compete for access to females but do not defend discrete territories, and matings may occur in the water as females return to the sea, as well as on land. Females fast during the breeding season and may lose up to 40% of their initial body weight as they do not feed during this time. The gestation period is 8 months, and to achieve a 12-month breeding cycle the fertilized egg is not planted until 4 months after conception. This occurs around the time of the annual molt when animals spend longer time hauled out on land. Gray seals generally return to their natal site to breed and show a high degree of site fidelity, often returning to within meters of their previous pupping sites (Pomeroy *et al.*, 1994).

On average, gray seal dives are generally short, lasting between 4 and 10 min with a maximum recorded duration of about 30 min. Gray seal foraging is mainly confined to the shallow continental shelf waters. Typically, animals dive down to the sea bed, in relatively shallow waters 60–100 m in depth but are capable of routinely diving to 200 m in some areas. Dives to more than 300 m have been recorded.

V. Interactions with Humans

Hunted throughout much of its range until the mid twentieth century it is now protected under national and international legislation. Small scale controlled hunting continues in parts of its range and

- and Varola (2006) propose an age of divergence for Eschrichtiidae of about 10 Ma and the Mediterranean Basin as the center of origin of the family.
- Questions remain regarding the phylogenetic position of Eschrichtiidae among baleen whales. Recent phylogenetic reconstructions of extant mysticetes based on morphology indicate Eschrichtiidae + Balaenopteroidae (6 rorquals and the humpback, *Megaptera novaeangliae*) are included within a monophyletic Balaenopteroidea (Geisler and Sanders, 2003). However, analyses based on molecular characters (Rychel *et al.*, 2004) and “total evidence” support two competing hypotheses concerning relationships within the Balaenopteroidea (1) the eschrichtiids and balaenopterids as sister taxa, and (2) eschrichtiids nested within a paraphyletic Balaenopteridae (Deméré *et al.*, 2005).

The gray whale (Fig. 1) is a slow-moving sturdy mysticete, slimmer than right whales and stockier than most rorquals. It attains a maximum length of 15.3 m (50 ft). The skin is a mottled light to dark gray with whitish blotches and heavily infested with barnacles and cyamids, or “whale lice,” especially on the head (Fig. 2). Instead of a dorsal fin, the back has a hump followed by a series of fleshy knobs, or “knuckles,” along the tailstock. The baleen is cream to pale yellow, the shortest (5–40 cm), coarsest, and with fewest plates (130–180 per side) of any whale. There are typically 2–7 short, deep, longitudinal creases on the throat rather than the numerous long ventral pleats of balaenopterids. The narrow triangular head (seen from above) is moderately arched downward (seen from the side) and relatively small (~20% of skeletal length) (Fig. 3). The overall skull structure is less telescoped than in other extant mysticetes. Unique to grays is a bulging “tailstock cyst” (10–25 cm wide) of unknown function on the ventral surface of the caudal peduncle. The flukes are 3–3.6 m across and frequently lifted before a deep dive. The blow is 3–4 m high, heart-shaped, bushy, or columnar. The behavioral ecology of the gray whale is unique among mysticetes, it is the most coastal; makes the longest migration; calves in warm bays, lagoons, and coastal areas; and is an intermittent suction feeder that regularly forages on benthos (organisms living within, at, or near to the sea floor), but also feeds opportunistically on plankton and nekton by gulping and skimming.

Gray Whale

Eschrichtius robustus

MARY LOU JONES AND STEVEN L. SWARTZ

I. Characteristics and Taxonomy

The gray whale (*Eschrichtius robustus*, Lilljeborg, 1861) is the only living species in the family Eschrichtiidae (Ellerman and Morrison-Scott, 1951) (=Rhachianectidae; Weber, 1904). The genus name honors Danish zoologist Daniel Eschricht; *robustus* means strong or oaken in Latin. The evolutionary history of the modern genus is not well known. The fossil record of *E. robustus* includes recent and Pleistocene subfossils from both sides of the North Atlantic and a Pleistocene fossil (200–300 Ka) from California (Deméré *et al.*, 2005). A specimen from Japan that Ichishima *et al.* (2006) assigned to *Eschrichtius* sp. extends the earliest fossil record of the modern genus to the late Pliocene (1.8–3.5 Ma).

Recently the content of the family Eschrichtiidae has expanded to include two extinct genera based on specimens from Italy. “*Balaenoptera*” *gastaldii* † (Strobel, 1875), formerly assigned to *Balaenoptera* by Portis (1885), instead appears to be a new genus of basal eschrichtiid from the late Pliocene (1.8–3.5 Ma) (Deméré *et al.*, 2005). The new genus (and species) *Archaeschrichtius ruggieri* † (Bisconti and Varola, 2006) was formally described based on a specimen (7.5–11 Ma) from the late Miocene and represents the oldest eschrichtiid identified to date. The two new taxa are characterized as intermittent suction feeders like the living gray whale. Bisconti

II. Distribution and Abundance

Once found throughout the Northern Hemisphere, the gray whale became extinct in the Atlantic and now is a relict species confined to the productive neritic and estuarine waters of the North Pacific Ocean and adjacent waters of the Arctic Ocean (Fig. 4). Mixing between Atlantic and Pacific populations was possible during warm interglacial periods (such as 1–12 Ka). Whales could have moved between the Beaufort Sea and the Hudson Bay until the Little Ice Age when temperatures cooled enough for ice to form across most of the Northwest passage of the Arctic (1400–1850) isolating the populations. There are two extant Pacific populations of gray whales. The eastern population (also called the *American*, *California*, or *Chukchi* stock) occurs in the eastern North Pacific and Amerasian Arctic Oceans (between North America and Asia). The remnant western population (also called the *Asian*, *Korean*, or *Okhotsk* stock) occurs in the western North Pacific (off Asia). Genetic studies show the groups are differentiated at the population level.

A. North Atlantic Population(s) (Extinct)

The modern gray whale once existed in the North Atlantic in the coastal waters of Europe, Iceland, and North America. Subfossils from Europe have been found off the Baltic coast of Sweden,

Figure 1 The head of the gray whale is typically covered with patches of barnacles and whale lice (A). The blow is heart-shaped if viewed from directly in front or behind (B). Instead of a dorsal fin, grays have a low hump followed by a series of bumps (C). The flukes often are lifted above the surface before a deep dive (D).

Figure 2 Dense clusters of barnacles surrounded by whale lice (cyamids) develop shortly after birth. Barnacles leave white scars on the skin, which slowly re-pigment over time.

Belgium, the Netherlands, and England (the most recent dated 1650), and along the coast of the United States from New Jersey to Florida (the most recent from colonial times about 1675). Based on written accounts, the last few gray whales in the North Atlantic were killed in the late seventeenth or the early eighteenth century by early Basque, Icelandic, and Yankee whalers. Whether coastal whaling was solely responsible for or only hastened the extinction

of an already generally moribund North Atlantic population(s) is unknown (Fig. 4).

B. Western North Pacific Population (Critically Endangered)

The western gray whale is now a remnant population close to extinction that occurs off Russia, Japan, Korea, and China. Although it once utilized coastal feeding sites throughout the northern Sea of Okhotsk, today the core of the population feeds primarily from June to November off the northeastern coast of Sakhalin Island, Russia. During 2004–2006, six western gray whales (~5% of the population) that were sighted in feeding areas off Sakhalin Island also fed along the eastern coast of Kamchatka Peninsula, Russia. The Sakhalin Island foraging habitat, which is vital especially for pregnant and lactating females, lies within a region that is undergoing massive oil and gas development (Fig. 4; Reeves, 2005). The known parts of the population's current north–south migratory route include eastern Kamchatka, the eastern shores of Sakhalin Island and mainland Russia, possibly the Korean Peninsula, and the east and west coast of Japan. The mating and winter calving areas have yet to be determined. Speculation that they winter off the south coast of Korea is not supported with any observations. Evidence suggests whales traverse the East China Sea into the South China Sea to tropical waters off southeastern China (18–20°N) at least as far south as Hainan Island in winter. Before the twentieth century, offshoots of the population migrated off eastern and western Japan (Omura, 1984), but today sightings are rare.

The western north Pacific gray whale is one of the most critically endangered populations of whales (CR in IUCN Red List), and its

Figure 3 Gray whales commonly spy hop.

Figure 4 Distribution of the extant populations of gray whale.

survival is in jeopardy (<http://www.iucnredlist.org>). This stock was reduced to such low numbers by heavy international exploitation off Russia, Korea, and Japan from the 1840s to the mid-1960s that it was nearly extinct. Estimates of prior abundance are highly speculative, from 1500 to 10,000 whales. In 2007, the population size was estimated to be only 121 whales (90% CI = 112–130) (Cooke *et al.*, 2007). Constraints affecting population recovery include the low estimated number of reproductive females (28; 90% CI = 24–33), low juvenile survival, a male-biased sex ratio, the alarming advent of

thin and emaciated whales (~5–51% from 1999–2007), and genetic isolation from the eastern gray whale population. Of great concern is the number of females that have recently died along the coast of Japan. During 2005–2007, four female gray whales were entrapped and died in net fisheries (three off northeastern Honshu and one in Tokyo Bay; Cooke *et al.*, 2007). Surviving whales continue to be threatened by occasional exploitation by Japanese fishermen, entanglement in fishing gear, collisions with ships, and oil and gas exploration/development. Even the loss of one additional female per year

(about the death rates in recent years) would be sufficient to drive the population to extinction. Killer whales also at times prey on western gray whales, especially calves.

C. Eastern North Pacific Population

From late May to early October, the core of the eastern population is on its feeding range in the shallow coastal and shelf waters between Alaska and Russia and along their northern coastlines. Until the late 1990s, the northern Bering Sea, especially the Chirikov Basin, as well as the southern Chukchi Sea were the primary feeding grounds and supported high biomass of benthic amphipod prey and large numbers of feeding gray whales. However, in recent years a major ecosystem shift has been underway in the northern Bering Sea. A warming trend from arctic to subarctic conditions is resulting in higher air temperatures, lower winter ice cover, and increases in seawater temperature. Primary productivity has declined by about 70% from 1988–2004, reducing food supply to benthic communities in the Chirikov Basin. The ice-dominated, shallow ecosystem favoring benthic amphipod communities is being replaced by one dominated by pelagic fish. The ecosystem reorganization no longer favors benthic predators. Gray whales have responded by shifting their foraging distribution northward from the Chirikov Basin into the southern Chukchi Sea. Today, the primary feeding grounds are located only in the Chukchi Sea. Ongoing environmental changes should be expected to affect a much larger portion of the Pacific-influenced sector of the Arctic Ocean.

Secondary feeding sites are located in the western Bering Sea (off the Koryak coast), the southeastern Bering Sea (primarily along the eastern Alaska Peninsula and mainland coast), and in the Beaufort Sea (east to 130°W off northern Canada). Since 1980, there has been a westward opening of the range into the East Siberian Sea (179°E in 2007) as the pack ice and Arctic ice cap recede due to global warming. The northern boundary of the range is the Arctic ice-edge (72–75°N as of 2007). The foraging limits, however, are thought to be determined by ocean currents (originating with the Green Belt in the Bering Sea) that deliver high nutrient concentrations and high primary production biomass at broad frontal zones to benthic communities with resultant high secondary production which gray whales exploit (Highsmith *et al.*, 2006). The southern limit of the range along the Asiatic coast of the Bering Sea is approximately 60°N. Since 1979, a few whales have foraged annually off southeastern Kamchatka Peninsula (51–55°N). During 2004–2006, six were identified as western gray whales indicating the feeding ranges of both populations overlap in this area. The first ever winter-long acoustic study in 2003–2004 detected gray whale calls in the Beaufort Sea, suggesting whales are extending residence times in the Arctic as the region warms, although it cannot be certain they have not wintered in the Arctic previously.

This population makes the longest annual migration of any mysticete, 15,000–20,000 km (roundtrip). Spanning up to 55° of latitude, the migration connects Arctic feeding grounds with southern mating regions, calving, and assembling grounds in temperate and in subtropical coastal waters in winter, which are presumably safer from killer whale predation. In the fall, whales start the southward migration with females in late pregnancy going first, followed by adults and immature females, then immature males. They exit the Bering Sea via Unimak Pass, Alaska, with approximately 90% filing through from mid-November to late December, and mainly follow the coast to Mexico. The trip averages 2 months. Mating occurs mainly during the middle of the migration, but courtship/mating also happens in the winter assembly area.

Winter grounds extend from central California south along Baja California, the Gulf of California, and mainland coast of Mexico south to Bahía de Banderas, Jalisco (20°45'N, 105°34'W). Pregnant females carrying near-term fetuses begin to arrive by late December to early January. By mid-February, the bulk of the population has arrived. The calving areas are coastal California and the west coast of the Baja California Peninsula—San Diego Bay (possibly occupied historically, but no longer used), Laguna Ojo de Liebre (Scammon's Lagoon), Laguna Guerrero Negro (no longer used), Laguna San Ignacio, and Bahía Magdalena and adjacent waters (from Estero Las Animas to Bahía Almejas), and eastern shore of the Gulf of California—the open coast of Yavaros (Sonora) and Bahía Reforma (Sinaloa) (Rice and Wolman, 1971). Most calves are born near to or within the lagoons and Bahía Magdalena region. The majority of whales, except most mothers with newborns, occur outside of the lagoons and estuaries in the waters of Bahía Sebastián Vizcaíno, Bahía de Ballenas, and elsewhere along the coastline. El Niño (warm) and La Niña (cold) events cause variability in the Mexican Pacific, which influences gray whale distribution. During El Niño, the migration of whales to Bahía Magdalena diminishes, while it increases during La Niña.

The north migration to the feeding grounds occurs as two phases. The first phase (late January through March) consists of newly pregnant females who go first to maximize feeding time in the Arctic, followed by adult females and males, then juveniles. The second phase (April through May) consists primarily of mothers and calves. They remain in the breeding area 1–1.5 months longer, allowing calves to strengthen and rapidly increase in size before the north migration. Cows and calves travel very close to shore (90% are within 200 m) mostly alone or in pairs.

The north migration culminates in the dispersal of the population throughout the Arctic feeding grounds. An exception is pockets of whales that feed opportunistically south of the Bering Sea during summer, or perhaps much of the year. Roughly, 1000 whales (~0.5% of the population of ~18,000 in 2007) forage along Kodiak Island, southeast Alaska, British Columbia, and areas southward to Baja California. Many may migrate through these areas, but some stop to feed for the summer, perhaps longer (Darling, *et al.*, 1998; Moore *et al.*, 2007). In Mexico, a few occur year-round in Bahía San Quintín and Cabo San Lorenzo, on the Pacific coast of Baja California, and Bahía de Los Angeles in the Gulf of California.

Commercial whaling of eastern gray whales began in 1846. Estimates of historic pre-whaling abundance differ widely. Those derived from whaling statistics range from 15,000–20,000 whales (Henderson, 1972) to 30,000–40,000 (Scammon, 1874), while a recent genetic analysis of DNA variables suggests a much larger pre-whaling population averaging approximately 96,000 individuals (76,000–118,000), but this estimate likely measures the eastern and western stocks together (Alter *et al.*, 2007). The population was hunted to very low numbers by 1939 (models suggest possibly a few thousand). The stock finally received limited protection from commercial whaling in 1937 and full protection in 1946 under international treaty, except for a small aboriginal hunt. It is not known how many whales remained. The population made a dramatic comeback to 21,000 whales, and was removed from the US government's endangered species list in 1994. Growth continued through 1997/1998, when abundance reached a high of 29,758 whales (Rugh *et al.*, 2005). At that time, there were indications that the population might be approaching carrying capacity and might begin to level off, but it has since suffered a major mortality event.

In 2000/2001 the abundance estimate dropped alarmingly by 35% to 19,448, and in 2001/2002 it was 39% less at 18,178 whales,

indicating there had been a large die-off of about 11,500 whales over a 4-year period (Rugh *et al.*, 2005). In addition, the number of calves produced annually during 1999–2001 was about 70% lower than during the previous 5-year period. The population die-off was coincident with a spike in the number of stranded dead whales in 1999 (274 whales) and 2000 (368 whales), about 10 times greater than the annual average during the previous decade. The emaciated condition of many indicated they had starved. During this time, many living gray whales were also thin or emaciated.

Food shortage is the likely cause of these events, although contributing factors such as disease cannot be ruled out (Moore *et al.*, 2007). A large downturn in benthic amphipod biomass occurred during the 1990s in the Chirikov Basin, a primary feeding area, due to ecosystem changes in the northern Bering Sea, or overgrazing of the prey base that could no longer sustain the growing population, or both. Since malnourishment was also occurring in the western population, an alternative hypothesis posited that more global or ocean-wide changes are influencing the availability of, or access to, primary prey for the species.

Preliminary analysis of the latest 2006/2007 census suggests that both population size and calf abundance are similar to the low levels observed in 2001/2002, and some of the whales are “skinny.” In San Ignacio Lagoon, a major breeding area, approximately 11–13% of the whales were “skinny” rather than robust during 2007, indicating those whales were nutritionally stressed. The future of the population will hinge on the whales’ ability to adjust quickly to the ongoing ecological transitions associated with global climate warming.

III. Ecology

A. Diet and Feeding

The feeding ecology of gray whales is unique and complex. The diet consists of a wide variety of benthic organisms (infaunal, epibenthic, and hyperbenthic) but also includes planktonic and nektonic organisms (midwater and sea surface) and perhaps some plants. Gray whales use three foraging methods, they typically rely on intermittent suction as their primary mode and also opportunistically employ gulping and skimming to capture midwater and sea surface species. They are able to switch techniques to exploit the most optimum prey species, or assemblage of species at any one location within their summer–fall feeding range and elsewhere in the migratory and the wintering areas. Foraging activity occurs at water depths of 4–120 m, but mostly at 50 m or less. Water is obtained from their food (most fish and invertebrate prey consist of 60–80% water) and metabolically derived water.

Most gray whales concentrate their feeding during 5 months, from about May through October (eastern population) and June through November (western population) when they are in high-latitude high-productivity waters where food resources are patchy but dense. They forage primarily on or near the ocean floor and appear to feed continuously, 24 h a day. Gray whales preferentially forage on aggregations of crustaceans and invertebrates. At least 60 benthic amphipod species, 80–90 other benthic invertebrate species, and small fish occur in the northern diet. Principal prey in soft-bottom habitats include infaunal amphipods (tube-dwelling ampeliscid amphipods and burrowing pontoporeid amphipods dominate), polychaete worms, and bivalves. In some areas eastern gray whales also feed on locally abundant swarming species such as cumaceans, mysids, shrimp, krill, mobile amphipods, and shoals of sardines and anchovy. Energy might also be obtained from plant material (e.g., algae,

kelp, sea grass) which is deliberately ingested in some cases, probably more than has usually been assumed, rendering the gray whale a partial herbivore, but almost nothing is known about the role of plants in their feeding ecology (Nerini, 1984). During the feeding season an adult eastern gray whale might consume approximately 220,800 kg of food (using 1200 kg/day and 184 feeding days).

During most or all of the 6–7 months when gray whales are migrating and on the winter grounds, they primarily fast and rely on stored lipid in body fat and blubber as the prime energy source. When whales return to northern feeding grounds, they will have lost 16–30% of body weight and must single-mindedly forage to replenish fat reserves. Lactation represents the greatest cost of reproduction, and pregnant females put on 25–30% more weight than other whales (exclusive of fetus). Lipids are also a critical source of water essential to maintaining water balance during fasting or greatly reduced food intake. Exceptions are small lactating females, which probably resume feeding on the north migration, and juvenile animals that tend to feed opportunistically throughout the year.

Some eastern gray whales (~1000 or 0.5% of the population) do not complete the annual migration to the feeding grounds and remain south of the Aleutian Islands during summer to forage opportunistically and sporadically in localized areas on infauna, swarming benthic invertebrates, and planktonic preys (e.g., amphipods, isopods, mollusks, cumaceans, shoaling mysids, shrimp, crabs, herring, eggs, and larvae).

To suction feed, the gray whale uses gular muscles and the tongue in a piston-like action to suck prey into the mouth. When foraging on infauna (prey living within sediments), whales roll on their side with the head just above the bottom and swim slowly while suctioning prey and sediment into the side of the mouth in pulses and filtering the prey with their baleen. This creates a series of large excavations, or “feeding pits,” in a single dive (pits are ~3 m long, 1 m wide, and 1/2 m deep), and whales often trail clouds of sediment, or “mud plumes,” in their wake (Fig. 5). This foraging on infauna significantly affects the habitat through sediment disruption and resuspension, and removal of the benthic prey assemblages. Gray whales also commonly use intermittent suction to feed on swarming organisms in near-bottom water and shoaling prey in the water column. In these instances, suction feeding does not result in seafloor excavations or mud plumes. When viewed from above the sea surface, indications of suction feeding in the water column include defecating whales, fecal slicks, whales trailed by seabirds, and animals “working” (diving repeatedly) in an area.

As a feeding generalist and flexible forager, the gray whale is responsive to feeding opportunities along their entire range and varies its foraging method accordingly. This provides insights into gray whale survival over the millennia. During Pleistocene glacial advances, the most recent of which ended 10–12 Ka, sea level was approximately 75 m lower than now. Consequently, areas that are currently major feeding grounds were above sea level, and marine access to the Arctic was blocked by the Bering land bridge. The ability to use alternative prey, feeding modes, and locations may have been critical to the species during periods of glacial maxima when continental shelf areas were above sea level (Highsmith *et al.*, 2006).

B. Predators and Parasites

The killer whale (*Orcinus orca*) is the only predator of gray whales. Tooth rakes often occur on living whales, thus many attacks are not fatal. A reduced risk of calf mortality by killer whales (more

Figure 5 Feeding gray whale.

abundant at high latitudes in colder coastal seas) is proposed as the primary benefit to females migrating to give birth in the subtropics. Even so, calves remain prime targets during the north migration. Gray whales attempt to escape from killer whales by swimming into shallow water, often inside the surf zone.

Gray whales have heavy infestations of external parasites and commensals, more than any other cetacean. A host-specific barnacle, *Cryptolepas rhachianecti*, forms large colonies deeply embedded in the skin. Three species of cyamids (whale lice), *Cyamis scammoni*, *Cyamus kessleri*, and *Cyamus ceti* feed on skin around barnacles, blowholes, skin folds, and swarm into wounds (Fig. 2). These are not known to be harmful and may be more accurately regarded as mutualists or commensals rather than parasites, although whales in poorer nutritional condition tend to have heavier infestations. Apparently, gray whales are less prone to internal parasites than other cetaceans. These include trematodes (liver), nematodes (stomach), and cestodes and acanthocephalans (small intestine). Some require fishes as intermediate hosts (Rice and Wolman, 1971).

C. “Skinny” and “Stinky” Whales

From 1999 to 2007, gray whales in poor body condition, unusually thin or emaciated and referred to as “skinny” whales, have been present in both populations. The proximate cause is nutritional stress, but underlying cause(s) remain unknown. Explanations include natural or human-caused changes in prey availability or habitat quality, physiological changes due to stress, disease, or a combination of these.

Since the 1960s, indigenous Russian whalers have reported east-ern gray whales exhibiting a strong, foul-smelling medicinal odor,

called “stinky” whales. The meat is malodorous and inedible (even village dogs will not eat it), and such whales have severe halitosis. The problem only exists in the region of Chukotka where similar phenomena occur in the meat of seals, walrus, fish, and murre eggs. The odiferous condition may result from altered metabolism due to a limited food supply, new or different foods consumed, disease, biotoxins, or abnormal metabolic pathways resulting from genetic anomalies.

IV. Behavior and Physiology

A. Social Organization

Gray whales form no long-lasting associations and apparently have little social cohesion. The bond between mother and calf stops after weaning. They migrate solo or in transitory pairs and small groups. On the feeding grounds, whales are usually single or in small groups and widely dispersed, not surprising given the large benthic area needed to supply the energy requirement of each whale. Large aggregations can occur on feeding grounds and breeding grounds but are in constant flux. There is no territoriality or aggression toward conspecifics. Care-giving behavior to aid young in the calving areas and joint defense against killer whale attacks occur but are rare. Whalers report standing-by behavior in which whales support or refuse to leave an injured companion, making them easy targets.

B. Sensory Perception

Underwater sound rather than vision is the gray whale’s primary sensory modality. They create a variety of phonations, which are mostly low frequency broadband signals that range from about 100 Hz

to 4 kHz but may go up to 12 kHz. Use of mostly low frequency sounds might be an adaptive strategy for grays to circumvent the high levels of natural background noise prevalent in the coastal environment (e.g., waves, bubbles, currents, ice movement) by producing sounds that are generally at frequencies below it. Unfortunately, manmade noise is a rapidly increasing pollutant in the ocean. Much of it occurs in the lower frequency range and has a high level of output (e.g., high-intensity air guns for seismic exploration, military and civilian sonar systems, ship-shock trials, offshore drilling and construction, industrial activities, supertankers, icebreakers). Anthropogenic noise can interfere with whale communication, reduce ability to hear natural sounds that aid in foraging and navigation, and may damage hearing. Grays try to circumvent this noise by increasing call types, rates, and loudness to enhance signal transmission and reception.

Gray whales see moderately well both in air and in water, but the visual system likely is of inferior importance to that of the auditory system because of functional restrictions in turbid water and darkness. The position of the eyes suggests that they have stereoscopic vision forward and downward permitting efficient estimation of distance. The eyes are adapted for heightened sensitivity to dim light and for improving contrast and resolution underwater. Grays possess a tiny presumably functional olfactory system, but are microsmatic at best. The sense of touch is very well developed. Taste buds occur at the back of the tongue.

C. Swimming, Breathing, and Diving

On migration, eastern gray whales mostly progress in one direction and travel at the same speed day and night. The southward trip to the winter grounds averages 55 days, at approximately 7–9 km/h (144–185 km/day). Northbound grays average approximately 4.5 km/h (88–127 km/day). Mothers and calves travel approximately 96 km/day; speed is about the same as other whales, but they pause to rest and nurse. Calves position themselves in a “drafting” position alongside their mothers, and the hydrodynamic effect is that the calf can gain thrust to swim while saving energy at traveling speed. If pursued, grays reach 13 km/h but can only maintain that speed for a few hours. In extreme duress, speed can surge to 16 km/h for short bursts. Breaching, spyhopping, and lobtailing are common during migration and on the breeding grounds (Fig. 6). Maximum dive depth is approximately 170 m. Maximum duration of breath holding is approximately 26 min., associated with resting and hiding. Blow pattern varies depending on age (calf vs adult) and behavior.

Figure 6 Gray whales breach frequently while migrating and on the winter range. One animal was observed to breach 40 consecutive times.

V. Life History

Gray whales appear to have a promiscuous mating system, where both sexes may copulate with several partners during the breeding season. Multiple inseminations likely occur, suggesting that sperm competition is a feature in reproduction. Sexual maturity is attained from 6 to 12 years (average is 8 for both sexes), at a mean length of 11.7 m in females (called cows) and 11.1 m in males (called bulls). Mating and calving are strongly seasonal and synchronized with the migratory cycle. Bulls have a peak of spermatogenesis in late autumn or in early winter correlated with the time cows come into estrus. Thus mating occurs mainly during the middle of the south migration, but courtship/mating activity also continues during January and February as whales travel into and socialize throughout the winter assembly range where most females calve (eastern population).

Bulls can mate annually. Females usually have one estrous cycle per 2 years (rarely they may ovulate twice), thus at most only half the reproductive females are available annually for mating. Ovulation usually occurs in late November and December within a 3-week period during the south migration (while the eastern population is still north of central California). Females usually conceive following their first ovulation but may undergo another estrous cycle about 40 days later if they fail to conceive (Rice and Wolman, 1971).

Copulation is belly to belly. Pairs or trios of whales sometimes court and mate quite gently. However, in larger groups of up to 20 consorting adults, there is a high level of activity marked by rolling, splashing, and energetic cavorting (Fig. 7). Estimates of the gestation period vary from 11 to 13 months. Cows bear one calf at intervals of 2 years, but longer intervals of three or more years occur. Birth season for the eastern population lasts from late December to early March (median birth date is January 27) when near-term cows are in or near the Mexican calving grounds, although some are born off California.

A mother's bond with her calf is very close; they are unusually affectionate, protective, and will fight fiercely, even to the death, to defend young from danger (Fig. 7). Calves consume about 189 l of rich milk per day (53% fat, greater than any other cetacean, 6% protein). Weaning occurs at 7–8 months around August when calves are 7.6–9.5 m long. Cows then have a 3–4 month resting period until November–December when estrus begins anew.

Figure 7 Gray whales mate with multiple partners, often in large, energetic courting groups (A). Newborn calves have more uniformly dark skin and are supported on their mothers' backs for their first few breaths (B).

Most neonates are 4.6–4.9 m long and weigh about 680–920 kg. Adults weigh 16,000–45,000 kg and stop growing at about 40 years, when the average female is 14.1 m long and the average male is 13.0 m. The largest female recorded was 15.3 m and the largest male 14.6 m long. After birth, females are slightly bigger than males at all ages, but there is no significant difference in their appearance (the distance from the genital slit to the anus is longer in males). Longevity is unknown (age is calculated from growth layers in the waxy earplugs that fill the auditory canal), but estimates vary from at least 40 to over 80 years.

IV. Interactions with Humans

A. Whaling

Although the International Whaling Commission (IWC) banned commercial whaling of gray whales in 1946, it allows aboriginal whaling of the eastern population for cultural and subsistence purposes. For the years 2008–2012, the quota for aboriginal kills off the Chukotka Peninsula (Russian Federation) is set at 620 whales, with a maximum of 140 in any year. Whale oil, meat, bones, hide, and baleen are used.

There has been illegal hunting of gray whales in violation of the IWC moratorium on whaling, by its member nations as well as pirate whaling by fleets acting beyond national jurisdiction. In 2000 it was revealed that this prohibited species was killed “at every sighting” by the former Soviet Union from 1961–1979. Occasionally a western gray is taken incidentally by Japanese fishermen (e.g., in 2005, three females were killed in fishing nets). The IWC prohibits killing them deliberately, but sale as “bycatch” occurs in markets in Korea, Japan, and elsewhere. DNA profiling of whale meat suggests the true magnitude of intentional “net whaling” (deliberate entanglement in fishing nets and gear) of western gray whales sold as bycatch in Asia is larger than reported. If this mortality continues in such a small population, the population is projected to decline toward extirpation.

B. Whale-Watching Industry and Friendly Whales

The eastern population of gray whales supports a major whale-watching industry. Whalers dubbed the gray whale the “devil fish” for its ferocity when harpooned, yet it is a gentle species if unmolested. Known today for approaching boats curiously and letting whale watchers pet it, the gray is popularly called the “friendly whale” (Fig. 8). From a conservation perspective, tourism poses both

Figure 8 A “friendly” gray whale calf and mother allow whale watchers to pet them (note the tip of the cow’s rostrum in the foreground).

risks and benefits to gray whales. Risks arise from the potential for vital behavior patterns and essential habitat to be degraded by too much attention. Benefits come from a better-educated public more likely to highly value gray whales and to provide support for their protection and conservation of their habitats.

C. Oil and Gas Development and Exploration

Discovery of extensive oil and gas resources on the Sakhalin Shelf has placed the Critically Endangered western gray whales in peril. The feeding ground off Sakhalin Island lies within the region which is now the site of ongoing large-scale oil and gas development by several consortia of Russian and multinational companies. Although some measures are being taken to mitigate deleterious effects, the oil and gas production, in addition to associated extensive shipping and aircraft traffic, may damage the habitat, stress or disturb the whales, or displace the population, which is dependent on the Sakhalin Shelf for its primary feeding ground (Fig. 9).

D. International and National Protection

Gray whales received protection from commercial whaling under the 1937 *International Agreement for the Regulation of Whaling*, to which most whaling nations concurred, and more comprehensive protection under the 1946 *International Convention for the Regulation of Whaling*, to which the Soviet Union and Japan also adhered. In the United States, two statutes provide legal protection, the *Marine Mammal Protection Act*, passed in 1972; and the *Endangered Species Act*, which became law in 1973. The eastern population recovered and in 1994 the US Department of Interior removed it from the *List of Endangered and Threatened Wildlife and Plants* (under the US Endangered Species Act). The World Conservation Union (IUCN) reclassified it from *Endangered* to *Lower Risk: conservation dependent* in the 1996 *IUCN Red List of Threatened Animals*. However, these actions had no bearing on the status of the western gray whale population, which remained *Endangered* throughout its range. It was reclassified in the 2000 IUCN Red List from *Endangered* to *Critically Endangered* (under 1996 categories and criteria) (<http://www.iucnredlist.org>). The gray whale is listed in Appendix 1 of CITES.

Figure 9 The critically endangered western gray whale’s core feeding ground off Sakhalin Island, Russian Federation, in the Okhotsk Sea is located within a multi-national oil and gas development area.

Mexico recognized the importance of the breeding lagoons to the recovery of the gray whale and it is the only nation to provide important habitat protection for the eastern population. In 1972, it established Ojo de Liebre Lagoon (the principle calving and nursery area) as the world's first whale refuge. In 1979, San Ignacio Lagoon became a *Whale Refuge and Maritime Attraction Zone*. In 1980, reserve status extended to Laguna Manuela and Laguna Guerrero Negro. All lie within the *El Vizcaíno Biosphere Reserve*, created in 1988. In 1993, the United Nations Educational, Scientific, and Cultural Organization (UNESCO) made Ojo de Liebre and San Ignacio Lagoons World Heritage Sites. Lastly, in 2002, all Mexican territorial seas and EEZ were declared a refuge to protect large whales.

Group Behavior

ALEJANDRO ACEVEDO-GUTIÉRREZ

Many animals spend part or all of their lives in groups. Their size and composition have diverse effects on morphology and behavior including relative brain size and extent of sexual dimorphism. A group may be viewed as any set of individuals, belonging to the same species, which remain together for a period of time interacting with one another to a distinctly greater degree than with other conspecifics. Thus, the study of group-living is the study of social behavior, and marine mammal societies can be remarkably diverse (Fig. 1).

Groups can be classified based both on the amount of time individuals interact with each other and on the benefits that individuals receive. Schools last for periods of minutes to hours while groups last for months to decades. Aggregations (or non-mutualistic groups) do not provide a larger benefit to individuals than if they were alone, while groups (or mutualistic groups) do provide such benefit to their members. Aggregations are formed because a nonsocial factor, e.g., food, attracts individuals to the same place; groups are formed because they provide a benefit to their members.

Recent studies have highlighted the challenges of defining marine mammal groups in nature, particularly those of cetaceans. For instance, most scientists determine whether individual dolphins belong to the same group based on the distance separating individuals (usually ≤ 10 m) or the radius comprised by the group (usually ≤ 100 m), and/or by whether individuals are engaging in the same behavior or not. However, a study of bottlenose dolphins (*Tursiops truncatus*) in Sarasota Bay, Florida, indicates that the communication range of social sounds between females and dependent calves could be at a minimum 487 m and reach up to 2 km or more (Quintana-Rizzo *et al.*, 2006). Hence, the traditional distinctions of a group—practical, replicable, and undoubtedly useful in advancing our understanding of group behavior—are likely not meaningful to a cetacean. Because cetaceans rely on acoustic communication to maintain group cohesion, the study

Figure 1 (A) Blue whales (*Balaenoptera musculus*) are usually found alone or in small numbers. (B) South American sea lions (*Otaria flavescens*) aggregate in large numbers during the breeding season. Photos by A. Acevedo-Gutierrez.

highlights the importance of understanding communication range to define cetacean groups.

To describe the social structure of a population, it is essential to measure how much time individuals spend together (association patterns) and the rate at which individual associations changes over time (lagged association rates). However, the amount of time that animals spend together depends both on genuine social affiliations and on how much individual home ranges overlap. For instance, two individuals may be observed together because they have a similar home range, forming then an aggregation, rather than because they are genuinely affiliated, which would then be a group. Employing network analyses, association analyses, and estimates of lagged association rates at different spatial scales, a study of coastal bottlenose dolphins in eastern Scotland shows that the population is composed of two social units with restricted interactions as a result of social affiliation (Lusseau *et al.*, 2006). The study highlights the importance of network analyses and the use of different temporal (lagged association rates) and spatial scales to understand the organization of social marine mammals.

I. Theory of Group-Living

There appear to be three conditions under which group-living will evolve, the benefits to the individual outweigh the costs, the

costs outweigh the benefits but strong ecological constraints prevent dispersal from the natal territory (for instance, lack of high-quality breeding openings explains within-population dispersal decisions and family groups in birds), and the area where the group lives can accommodate additional individuals at no cost.

A. Benefits and Costs of Group-Living

Group-living is usually explained in terms of benefits to the individual group members via direct or indirect fitness. Increases in direct fitness include mechanisms such as direct benefits of group-living, direct and indirect reciprocity, and mutualism. Increases in indirect fitness are achieved via kin selection. It has been argued that when competition occurs at the level of groups rather than individuals, group-living is best explained in terms of benefits to the groups themselves, group selection. However, many scientists consider that whenever interactions occur at a local spatial scale, and dispersal is limited, then interactions occur among genetic relatives, and thus kin selection rather than group selection is operating (Nowak, 2006).

Kin selection is perhaps the most frequently employed argument to explain benefits of group-living. For instance, kin selection explains the generalities of cooperative breeding in mammals and birds (Brown, 1987; Jennions and Macdonald, 1994), and the evolution of cooperation among male chimpanzees (*Pan troglodytes*) (Morin *et al.*, 1994). Further, mammalian female kin (including several odontocete species) spend more time in close proximity and are more likely to help each other. Females may allosuckle or gain higher reproductive success by forming coalitions with kin. However, explanations based on kin selection are in some cases inadequate and some behaviors are best explained in terms of direct fitness via diverse mechanisms. Direct benefits from early detection of danger explain the sentinel behavior of meerkats (*Suricata suricatta*) (Clutton-Brock *et al.*, 1999) and delayed direct benefits to the subordinate male explain the occurrence of dual-male courtship displays in long-tailed manakins (*Chiroxiphia linearis*) (McDonald and Potts, 1994). By-product mutualism explains territorial coalitions in Australian fiddler crabs (*Uca mjoebergi*), which assist other crabs in defending their neighboring territories; in this manner, the neighbor keeps its territory and the ally pays to retain an established neighbor rather than renegotiate boundaries with a new neighbor (Backwell and Jennions, 2004).

Benefits to increase foraging efficiency and reduce predation, and the number of individuals that can be supported by the available local resources have been typically viewed as important factors shaping group-living. These benefits apparently apply to all social organisms; for instance, the ability to disperse and exploit new food patches appears to favor the aggregation of solitary slime mold into a multicellular organism known as a slug (Kuzdzal-Fick *et al.*, 2007). However, increased foraging efficiency and reduction of predation can be accomplished through a myriad of different mechanisms (Table I). In addition, increased foraging and reduce predation are sometimes inadequate to explain group-living, in African lions (*Panthera leo*), female-grouping patterns are best explained as facilitating cooperative defense of cubs against infanticidal males and defense of territory against other females, not as increasing foraging efficiency (Packer *et al.*, 1990). Group-living can also impose several costs to individuals, including increased competition over access to resources and mating opportunities, exposure to infection, and conspicuousness to predators (Table II). In general, it is believed that for mammals the main benefit of sociality is protection against predators whereas the main cost is increased competition for resources.

TABLE I
Benefits of Group Living

Reduction of predation[°]

- Enhanced ability to detect predators: sensory integration.
- Enhanced ability to deter predators, even larger than group members.[°]
- Enhanced ability to escape, including predator confusion and coordinated evasion behavior.[°]
- Reduced individual probability of being selected as prey:
 - By associating with conspecifics: dilution effect.[°]
 - By hiding behind conspecifics: selfish herd.[°]

Allocation of time to other activities

- Reduced individual vigilance time
 - Because of group vigilance (many eyes).[°]
 - Because of decreased individual predation risk.[°]
- Increased foraging time for mothers by having babysitters.[°]

Enhanced detection and capture of prey

- Foraging in risky, but profitable, areas.
- Finding prey or reducing variation in food intake through cooperative searching: sensory integration.[°]
- Following more knowledgeable animals in the group to a food source: information transfer.[°]
- Following other species with more specialized senses to a food source.[°]
- Joining resources uncovered by others, also known as conspecific attraction, kleptoparasitism, area copying, scrounging, or tolerated theft.[°]
- Acquisition of innovative feeding behaviors from another group member:
 - Social learning through social facilitation (contagion of motivational states).
 - Directing attention to particular locations or objects: local enhancement.
 - Imitation of knowledgeable tutors.[°]
 - Information sharing and cultural transmission.[°]
- Increased diversity and size of prey that is captured:
 - Due to more individuals foraging.[°]
 - Due to prey flushed by movements of group members.[°]
 - Due to individuals with different skills or abilities foraging together: skill pool effect.
- Increased food intake as a result of communal foraging.[°]
- Lower risks of injury while hunting.[°]

Acquisition or defense of resources

- Large groups defend, occupy, or displace small groups from better territories.
- Large groups acquire or defend localized food sources, including carcasses, from conspecifics or other species.[°]

Improved reproduction

- Caring and protection of offspring.[°]
- Learning to be a parent.[°]
- Finding mates in isolated or vast areas.[°]
- Enhanced reproductive synchrony.[°]
- Enhanced survival when there is prevention of dispersal to neighboring territories.
- Males benefit from cooperative displays, subdominant males receive the payoff later in time.
- Males in large groups gain access to females.[°]

Reduction of parasitism

- When number of hosts in a group increases more rapidly than the number of mobile parasites, reduced individual probability of being parasitized by associating with conspecifics: dilution effect.

Other

- Huddling to survive cold temperatures.[°]

[°]Suggested or documented costs in marine mammals.

The magnitude of the costs of sociality may be important in shaping group-living. It has been suggested that in some species differences in group size may be related to the differences in their costs of locomotion. Under this ecological-constraints model, large group sizes must travel farther each day because they deplete food patches more rapidly or require searching larger areas. Supporting the model, day range, and group size are positively correlated in various primate and carnivore species (Wrangham *et al.*, 1993). Animals that travel further spend more energy and reproduce less efficiently, hence a negative relationship between group size and reproductive performance is predicted within species. However, marine mammals

reduce the costs of locomotion by developing energy-conserving swimming behaviors such as routine transit speeds, wave-riding, porpoising, and gliding. Hence, one would expect that group size in marine mammals is unrelated with distance traveled. Although I am unaware if such correlative study has been conducted, it has been hypothesized that reduced cost of locomotion coupled with a lack of restriction to a particular territory has allowed some populations of killer whales (*Orcinus orca*), and possibly long-finned pilot whales (*Globicephala melas*), to develop societies in which females and males remain with their natal group for life (Fig. 2). In this manner, males traveling with their mothers can have large home ranges and thus find potential mates.

TABLE II
Costs of Group Living

Increased predation

- Large groups more attractive to predators.
- Larger groups more likely to be detected by a predator: encounter effect.

Reduced foraging efficiency

- Increased amount of food needed for group.[°]
- Increased energy spent, distance traveled, or area covered to find food for group.[°]
- Increased conspicuousness: prey able to detect predators sooner than if predators are alone.
- Reduction in food intake due to sharing of prey, scramble competition, scrounging, and individual discrepancies in foraging success.
- Reduction in food intake due to interference by the behavior of other individuals.[°]
- Reduce ability to learn innovative foraging skills due to scroungers in the group.

Increased conflicts for resources due to presence of more conspecifics or other species

- Individuals from other groups or species following social parasitism.[°]
- Individuals from other groups or species attracted to feeding parties: local enhancement.[°]

Reduced reproduction, increased competition for mates, or other limited resources

- Individual discrepancies in number or quality of mates obtained.[°]
- Extrapair copulations and loss of fertilizations to other members of group.[°]
- Increased intra-specific competition for limited resources.[°]
- Increased infant mortality.[°]
- Increased risk of exploitation of parental care by conspecifics.
- Theft of nest material.

Increased risk of infection

- Increased contagious parasitism.
- Increased disease transmission.

[°]Suggested or documented costs in marine mammals.

Figure 2 In certain populations male and female killer whales (*Orcinus orca*) remain with their natal groups throughout their lifetime. Photo by Christopher Pearson

Recent studies have documented novel strategies followed by individuals living in groups, including the complexity of intragroup and intergroup interactions. Female African lions cooperate to defend their territory from intruders; however, some individuals consistently lead the approach whereas other individuals lag behind without being punished by the leaders (Heinsohn and Packer, 1995). One potential

explanation for this tolerance is that females need to defend their territories against other groups and their success depends in part on the number of defending females even if some individuals never lead the charge. Pinyon jays (*Gymnorhinus cyanocephalus*) draw sophisticated inferences about their own dominance status relative to that of strangers that they have observed interacting with known individuals (Pazy-Miño *et al.*, 2004). That is, they make judgments about relationships on the basis of indirect evidence rather than by learning through direct interactions with other individuals. The study is the first experimental demonstration of transitive inference in animals and implies that such cognitive capabilities are widespread among social species.

Complex social behaviors have also been reported in marine mammals. In a breeding colony of gray seals (*Halichoerus grypus*) at the island of North Rona, Scotland, a few large males monopolize matings on the breeding beaches, however females over the years give birth to full siblings not sired by the dominant male (Amos *et al.*, 1995). The fathers of the pups are nondominant males that mate with the same females in different seasons. Thus behavioral polygyny and genetic fidelity seem to operate simultaneously in this colony. It has been suggested that this strategy of partner fidelity is maintained in the population because it may diminish aggressive interactions between dominant males and thus reduce the pup mortality originated by these clashes.

Perhaps one of the most complex behaviors described in marine mammals is the formation of alliances among male Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) in Shark Bay, Australia, in which complexity is only matched by humans (Connor *et al.*, 1999; Connor, 2007). Males form strong and stable bonds for over 10 years with one or two other males, males in these first-order alliances cooperate to form aggressively maintained consortships with individual females.

Each first-order alliance forms moderately strong bonds with one or two other alliances, these second-order alliances do not endure for more than a few years and males cooperate to take or defend females from other alliances. Recently, it has been described that some second-order alliances associate regularly and cordially with other groups, suggesting a third level of alliance formation. A different strategy is for males to form a large but loose superalliance that competes with the smaller and more stable first-order or second-order alliances. Members of the superalliance split into smaller alliances of pairs and trios that are constantly changing but are always comprised of males from the superalliance. These pairs and trios join conflicts involving members of the superalliance and are always victorious. It is hypothesized that the large size of the superalliance allows individuals to compete with the smaller alliances and that the fluidity of individual associations within the superalliance allows males to maintain affiliative bonds. Because alliance formation is a strategy to obtain access to females, it has been hypothesized that alliances increase male reproductive success. Supporting this hypothesis, a recent study suggests that the vast majority of paternities are achieved by males involved in some form of alliance. However, within first-order alliances a few males dominate fertilizations, indicating skew in reproductive success among males in stable alliances (Krützen *et al.*, 2004). Given that males in stable first-order alliances formed small second-order alliances are more related to their allies than expected by chance, the reproductive skew among males may be explained in terms of kin selection (Krützen *et al.*, 2003). Interestingly, superalliances, where no reproductive skew has been described, are not formed by closely related males. Finally, the observation that some juvenile males without an alliance may achieve paternities suggests that alternative male tactics other than alliance formation exist in the population. What favors alliance formation among males? A recent model predicts that males will form alliances except when the number of males competing for a receptive female is very few, when there are substantial costs to being in an alliance, or when alliances do not out-compete single males.

B. Female Social Behavior

One previously neglected area of research is the study of female social behavior. Females and males frequently have different interests, as a result female relationships are important in understanding social evolution independently of the behavior of males. For instance, dominant female chimpanzees have a higher reproductive success than subordinate ones, apparently because they are able to establish and maintain access to good foraging areas, competing in extreme cases as intensely as males (Pusey *et al.*, 1997). Females may also influence behaviors that affect the interests of males, female bird song appears to have evolved in part to compete for males, however this behavior has the potential consequence of preventing polygyny by deterring rival females (Langmore, 1998). In mammals, most females remain within their natal area or group throughout their lives. This female philopatry facilitates the formation of social groups through kin selection. Hence, understanding social behavior in many mammal species requires studying female social behavior. For instance, theoretical and empirical evidence indicates that females live in groups that often exceed the optimal group size (Silk, 2007). This discrepancy is associated with mechanisms regulating group size, such as trying to oust other group members or exclude immigrants, actions that are costly to the individuals performing them.

The study of females is also essential to understand group-living in marine mammals. Captive female bottlenose dolphins

Figure 3 *Alloparenting behavior apparently allows sperm whale (*Physeter macrocephalus*) mothers to make deep foraging dives. Photo by A. Acevedo-Gutierrez.*

maintain dominance hierarchies and also compete aggressively against each other. However, unlike chimpanzees, it is unknown if female dominance hierarchies in free-ranging dolphins translate into differences in reproductive success. The preference and fidelity of female gray seals at North Rona toward nondominant males undermines the polygynous strategy of dominant males and results in a different mating system from that inferred by behavioral observations (Amos *et al.*, 1995). The large number of females in colonies of certain pinnipeds, such as northern elephant seals (*Mirounga angustirostris*), has permitted the existence of alloparenting and the appearance of a distinct suckling strategy by calves, milk-stealing. Male and female sperm whales (*Physeter macrocephalus*) have different grouping strategies, females appear to spend their entire lives within their natal group, forming strong matrilineal societies. Adult males are less social, leaving their nursing group when they reach puberty and after they have reached their late 20s roam among nursery groups looking for mates. The function of the female groups is to provide care for calves that are too young to follow their mothers during their deep foraging dives (Fig. 3). It has been suggested that this alloparenting reduces the period in which the calf is unaccompanied and thus provides protection from predators and also perhaps provides communal nursing (Whitehead, 1996; Mann *et al.*, 2000a). Thus key features of the sperm whale society are explained solely by the behavior of females.

II. Social Behavior of Marine Mammals

There are several differences between terrestrial and marine environments that have allowed the evolution of distinctive strategies in marine mammals. Drag, heat loss, and density of the water generate differences in scaling and costs of locomotion, allowing many marine mammals to have large body sizes and large home ranges. Sound is the form of energy that best propagates in water, not surprisingly marine mammals employ it for social communication and many species navigate via echolocation. Marine mammals must find food that is for the most part dispersed and patchy, thus they appear to have no territories outside of the breeding season. Due to the global effects of the atmosphere and the ocean in the marine environment, marine mammals are affected by both global and local processes as

Figure 4 In certain species, pinniped females cluster during the breeding season and males are able to monopolize access to them. Photo by A. Acevedo-Gutierrez.

exemplified by the impact of El Niño Southern Oscillation events on different populations.

A. General Strategies

Sirenians, sea otters (*Enhydra lutris*), and polar bears (*Ursus maritimus*) are solitary animals that have few social interactions beyond mating and mother/offspring pairs. The time that these pairs remain together is 1–1.5 years in sirenians, 5–7 months in sea otters, and 2.5 years in polar bears. When a female becomes receptive sirenians form aggregations that have as many as 17 males physically competing for access to the female or defending display territories. During the breeding season male sea otters establish territories that include the areas occupied by several females, whereas male polar bears mate with only one partner because females have a dispersed distribution.

Most pinnipeds aggregate in colonies during the breeding season, a major factor influencing the size of these colonies is the distribution of habitat available for parturition. Pinnipeds give birth out of the water and thus the areas favored for parturition are oceanic islands, ice, or isolated mainland regions not easily accessible to terrestrial predators. When available space is limited, females become densely aggregated in large colonies that favor mating systems in which males defend either aggregations of females or areas occupied by females, or aggregate and display before aggregations of females (Fig. 4). However, when parturition space is dispersed, females are isolated, males usually have access to only one female, and no colonies are formed. At small spatial scales (within colonies), lack of suitable habitat might also explain high density of females in many cases; however, in various populations there is plenty of unoccupied space and females are still clustered. Hence, other factors need to be invoked to explain this clustering. For instance, females reduce the individual probability of being harassed by less competitive males by clustering (Trillmich and Trillmich, 1984). Female Galápagos sea lions (*Zalophus wollebaeki*) avoid overheating by clustering along the wet shoreline, which in turns determines the distribution of dominant and subdominant males (Wolf *et al.*, 2005). The strongest association found in pinnipeds is formed by a mother and her offspring, and lasts for less than 1 week to almost 3 years, depending on the species. Pinnipeds haul out together outside of the breeding season.

Although this non-reproductive social behavior is poorly known, there is evidence that it increases vigilance for predators in harbor seals (*Phoca vitulina*). It is believed that hauling out together also allows pinnipeds to rest, avoid predators, molt or warm themselves. For instance, walrus (*Odobenus rosmarus*) in large numbers may decrease the rate of body heat loss, particularly in calves, when on land or on ice.

The complexity of cetacean societies appears to be related to amount of time invested in lactating and in rearing their calf after weaning. Baleen whales are found in schools of varying size, from single individuals to more than 20 whales. Pairs of mothers and their offspring form stable associations that last less than 1 year. It is currently unclear if long-term associations exist among adult whales. Most females give birth every 2–3 years, and have the potential to produce more than 20 calves throughout their lifetime. Schools of baleen whales have been observed in both feeding and breeding grounds. For instance, feeding humpback whales (*Megaptera novaeangliae*) forage alone, in aggregations, or as a group, depending on prey type, while aggregations of breeding males display acoustically or compete directly for access to females. Odontocetes are the most social marine mammals and have different types of societies as suggested by the large variation in school size between species (Table III). Short-term associations between adults characterize porpoises. Associations between mothers and their offspring last for 8–12 months. Females breed every 1 or 2 years and may give birth to 15 calves or more during their life span.

It is believed that medium-sized dolphin species live in fission–fusion societies with fluid group membership. Yet, a recent study indicates that spinner dolphins (*Stenella longirostris*) around Midway Atoll live in stable bisexually bonded societies of long-term associates with strong geographic fidelity, no obvious fission–fusion, and limited contacts with other populations (Karczmarski *et al.*, 2005). It is hypothesized that the geographic isolation and small size of the remote atoll favor long-term group fidelity and social stability over the fluidity of the fission–fusion society is replaced. Bottlenose dolphins live in fission–fusion societies that are believed to reduce feeding competition by allowing individuals to disperse. Associations between adults are varied, they last a short amount of time in some individuals and several years in others. In certain populations males form relatively stable groups and rove among female groups. Females give birth at least every 3 years and may produce close to 10 calves throughout their lifetime. Calves remain with their mothers 2–11 years (Fig. 5). Adult females form strong bonds with their calves as well as stable, moderate-level associations with other females within social clusters named bands. Bands tend to be composed of female relatives, but they can also include unrelated females. It has been hypothesized that reproductive condition (e.g., females with same-aged calves) determines associations within bands while kinship determines band membership. Why do female bottlenose dolphins form groups? Two leading hypothesis are protection from predators and defense against sexual coercion by males.

Little is known about the social structure of beaked whales (Ziphiidae) given their pelagic and deep-diving behavior. However, the northern bottlenose whale (*Hyperoodon ampullatus*) society in the northwestern Atlantic appears to comprise roving strong male–male bonds and weaker female–female bonds (Gowans *et al.*, 2001). Female and immature whales form a loose network of associations, showing neither preferential associations with particular individuals nor long-term bonds. Although males form many short-term associations, associations between some males last for several years. This social organization is reminiscent of that observed in some bottlenose

TABLE III
School Sizes of Odontocetes

Species ^a	Average school size	Maximum school size
<i>Phocoenoides dalli</i> (7)	2.3–7.4	5–500
<i>Neophoca phocaenoides</i> (1)	2.0	13
<i>Phocoena phocoena</i> (6)	1.2–5.7	15–100

dolphin populations foraging in shallow, enclosed bays rather than that of sperm whale populations, which forage in deep water canyons as northern bottlenose whales do. Baird's beaked whales (*Berardius bairdii*) apparently employ a novel social strategy. Males live longer than females and thus there is an excess of mature males over

Figure 5 Bottlenose dolphin (*Tursiops truncatus*) calves remain with their mother for up to 8 years.

females (Kasuya, 1995). It has been hypothesized that these traits indicate a society in which males provide significant parental care by rearing weaned calves, protecting them from predators and teaching them foraging skills.

In the case of the sperm whale and large-sized delphinids (pilot whales and some populations of killer whales), females appear to spend their entire lives within their natal group, forming strong matrilineal societies. Females usually breed every 3–6 years and may give birth to about 5 calves throughout their lifetime, more in the case of long-finned pilot whales. Females may live over 20 years past their post-reproductive years. It has been suggested that this strategy allows old females to transmit and store cultural information, and provide alloparental behavior. In the case of short-finned pilot whales (*Globicephala macrorhynchus*), it is possible that non-reproductive females even provide alloparental nursing (Kasuya, 1985). Male sperm whales and perhaps male short-finned pilot whales leave their nursing group when they reach puberty. However the former, after they have reached their late 20s, roam among nursery groups looking for mates; the latter appear to join a different nursery group and remain in it, engaging in few clashes with other males, apparently because they are able to engage in non-reproductive mating with old females, as it apparently occurs in bonobos (*Pan paniscus*). Male killer whales in some populations, and perhaps male long-finned pilot whales, remain in their natal group for life but mate with females from other groups when they meet, hence avoiding inbreeding. It is important to explain the absence of male dispersal because in the majority of social mammals males disperse from their natal group and do not interact with relatives (in a few species it is the females who disperse). The accepted explanation is that this sexually dimorphic dispersal and lack of interaction with relatives avoids inbreeding in mammals. The lack of male dispersal in killer whales has been explained in terms of the benefits that male apparently provide to the offspring of related females, such as assistance in hunting and teaching (Mann *et al.*, 2000a).

Among vertebrates, female killer whales, short-finned pilot whales, humans (*Homo sapiens*), and probably sperm whales, spend a substantial part of their adult life reproductively sterile and helping their close relatives. As such, the females undergo menopause and the species can be viewed as eusocial (McAuliffe and Whitehead, 2005). Cetacean menopause is believed to be adaptive, where the benefits of assisting kin outweigh the costs of reproductive cessation. Similar to human grandmothers, cetacean grandmothers appear to help by

storing and providing information to the other members of their matriline. This informative role of grandmothers might be the primary motor of eusociality and also supports the growing evidence of culture among cetaceans (Whitehead, 1998, 2007; Whitehead *et al.*, 2004). An important impact of culture can be found in social learning among matrilineal odontocetes, whereby learned behaviors passed on to family members are being conserved within matriline and affecting the course of genetic evolution. For instance, it has been suggested that the division of sympatric resident and transient killer whales off the west coast of Washington State and Canada was originally cultural; however, they show enough differences in feeding behavior, vocalizations, social systems, morphology, and genetics that they may be incipient species. In another example, indirect measures of the reproductive success of groups of sperm whales vary according to differences in culture between the groups. Although modification of the course of genetic evolution through culture has only been demonstrated in humans, further studies in more species and longer datasets on well-studied species will shed more light into the impact of culture on cetacean evolution. Why do some cetacean species engage in social learning? Apparently the prevalence of social learning and culture in cetaceans is related to patterns of environmental variation (Whitehead, 2007). Under this scenario, social learning is advantageous in environments where variation in biotic and abiotic factors is large over long time scales, such as marine ecosystems.

B. Foraging

Increased foraging efficiency is considered to be one of the principal roles of group-living in cetaceans. However thus far transient killer whales provide the only clear example supporting the argument that marine mammals live in groups because of foraging benefits (Baird and Dill, 1996). Transient killer whales live in the Pacific Northwest and prey on harbor seals and other small marine mammals. Individuals maximize their caloric intake if they feed in groups of three, which is the size of the group in which they live. The small size of these groups is apparently maintained by the departure of all female offspring and all but one male offspring from their natal group.

Two benefits of group-living through foraging efficiency are the ability to search for prey as a group and to forage communally (Fig. 6). Searching for prey as a group allows individuals to combine their sensory efforts, which should be an advantage when prey has a dispersed and a patchy distribution. Communal foraging allows individuals to combine efforts to pursue and capture prey. This behavior has been reported in dolphins, baleen whales, including blue whales (*Balaenoptera musculus*) and bowhead whales (*Balaena mysticetus*), and pinnipeds, such as fur seals and sea lions. However, in some instances it is unclear whether individuals combine efforts to pursue and capture prey, or merely aggregate in an area where food is concentrated. A particular type of communal foraging behavior, termed prey herding, has been observed when feeding on shoaling fish. Individuals encircle shoals of fish and thus create a tight, motionless ball of prey from which they can grab individual fish with their mouths, in some cases individuals release bubbles to further tighten the ball of prey. This herding of prey has been well described in humpback whales, dusky dolphins (*Lagenorhynchus obscurus*), and killer whales. However, it has also been reported in other species, such as bottlenose dolphins, common dolphins (*Delphinus* spp.), clymene dolphins (*Stenella clymene*), and Atlantic spotted dolphins (*S. frontalis*). It is difficult to document this behavior, and no study has yet quantified the success of cetaceans in herding prey.

Figure 6 Communal foraging allows dolphins to combine pursuing efforts.

C. Predation

Reduction of predation is considered to be another principal function of group-living in cetaceans, certain shark species and some large delphinids attack cetaceans, and calves suffer higher mortality than adults do. However, pinnipeds apparently also form groups in response to predation. Walrus sometimes form groups lasting throughout the year in the water and on haul-out sites. It has been suggested that this may be a female strategy for pup defense against predation by polar bears.

Thus far no conclusive evidence shows that group-living in cetaceans is driven because of benefits in reduction of predation, although it has been suggested that this could be the case in sperm whales. Nonetheless group-living may provide several benefits to reduce predation. Groups are able to mob and chase away predators, as has been observed in hump-backed dolphins (*Sousa* spp.) when attacked by a shark. It is believed that other dolphins also employ this antipredatory strategy. Sperm whales, and perhaps humpback whales, employ the marguerite formation, in which adults surround young individuals by having their heads toward the center (horizontal formation) or toward the surface (vertical formation). Adults have their flukes toward the periphery and employ them to slap at the predators, which in the majority of observations have been killer whales.

Group-living appears to be mostly related to food and predation in terrestrial and marine mammals. Thus it has been argued that the variation of group sizes among dolphin species is related to food availability, related to prey habitat, or to the need to defend from predators. For instance, the reproductive success of female Indo-Pacific bottlenose dolphins is highest in shallow waters, either because calves and their mothers are able to detect and avoid predators or because prey density is highest (Mann *et al.*, 2000b).

I compiled data on the average school size from 24 species of the family Delphinidae (Table III). Because definitions of school vary among researchers, I attempted to make values comparable by selecting only studies with at least 30 observations throughout a season and that defined schools as the number of individuals engaged in similar activities regardless of distance between them. I averaged the values from species belonging to the same genus and related them to crude measures of predation pressure and prey habitat, measures that were obtained from the literature. Results indicate that regardless of the body weight of the genus, average school sizes are larger when predation pressure is high rather than low, and when prey

Figure 7 Relationship between predation pressure, prey habitat, and average school size of 16 genera of the family Delphinidae. Open circles indicate small genera (females weigh less than 150 kg), solid circles indicate large species (females weigh more than 150 kg).

is found in open rather than enclosed waters (Fig. 7). School sizes are largest when both predation pressure is high and prey lives at depth in oceanic waters. Thus it appears that the average school size of dolphin genera is related both to the predation they experience and the habitat where their prey lives. However, comparative research of group size in Delphinoidea (Delphinidae, Phocoenidae, Monodontidae)—including phylogeny, physical environment, diet, predation pressure, and life history—indicated that phylogeny explained most of the observed variation in group size (Gygax, 2002a, b). Although group size also increased with openness of the habitat and showed a U-shaped relationship with temperature, the simplest interpretation of the study is that group size resulted from a random process and has been marginally shaped by direct selection.

D. Resource Defense

Interspecific contests over food are thought to also influence the group size and the group composition of predators. In the case of marine mammals, one study has documented the influence of competitive interactions with sharks on dolphin food intake and apparently on group size (Acevedo-Gutiérrez, 2002). As Isla del Coco, an oceanic island off Costa Rica, underwater observations indicate that bottlenose dolphins eat less food if there are many silky sharks (*Carcharhinus falciformis*) converging on the same fish school. The observations also indicate that the interactions between sharks and dolphins represent contests over food between these two similarly sized species, and not predation on the dolphins by the sharks. Dolphin groups of moderate size (around 10 individuals) are able to chase sharks away from the shoal and monopolize it. However, dolphins are not always found in such numbers when feeding because individual dolphins eat less as the number of dolphins increases. (There are fewer cookies available per person the more people are at the party.) As such, dolphins appear to increase group size when sharks are present but not when they are absent by leaping and/or by producing sounds to attract other dolphins. Dolphins leap out of the water and slap the water

Figure 8 Leaps and slaps at the water may attract other dolphins to feeding events.

with their flukes and body more often while feeding than while engaged in any other type of behavior (Fig. 8). They also increase whistle production in the presence of sharks but not when sharks are absent. Given the patchy and ephemeral nature of food resources in the open ocean, it is expected that further observations from species living in pelagic zones will indicate that interspecific contest over food are relatively common and are more important than currently viewed in influencing group-living in marine mammals.

III. Conclusion

Group-living involves benefits and costs, and the resultant society represents a balance between the different interests of all group members. The aquatic environment has allowed marine mammals to pursue complex and sometimes unique social strategies. At the same time, the basic needs of finding food, insuring reproduction and evading predators are also found in terrestrial environments. This convergence provides interesting parallels between the social strategies of marine mammals and those of terrestrial mammals, chimpanzees and bottlenose dolphins, elephants and sperm whales. Not surprisingly, much insight on group-living in marine mammals is gained by examining the societies of other taxa, most notably birds and terrestrial mammals. Of particular usefulness are comparative studies examining traits that are both consistent across taxa and common in some groups but not in others. These comparisons will allow us to examine specific hypotheses and test predictions regarding sociality as well as assist us in identifying data gaps and research needs.

It is clear that many questions about the group behavior of marine mammals remain unanswered and that much work remains to be done. For instance, the relationship between group-living and fitness remains to be described. However, studies on previously neglected topics such as female social behavior have increased in the last years and have improved our understanding of marine mammal societies.

As is the case of studies on terrestrial mammals, long-term studies of free-ranging populations have provided the most critical information to understand the evolution of group-living of marine mammals. Examples include bottlenose dolphins in Florida, Australia and, recently, Scotland; killer whales in the Pacific Northwest; sperm whales in the Galapagos Islands; humpback whales in their breeding and foraging grounds; northern elephant seals in California;

Antarctic fur seals (*Arctocephalus gazella*) and, recently, southern elephant seals (*Mirounga leonina*), and gray seals in the United Kingdom and Canada. A cursory review of the literature indicates that many more such studies are being started in other populations and, most importantly, on other taxa. It seems certain that our understanding of marine mammal group-living in the next 10 years will be not only more thorough but more inclusive.

Habitat Pressures

PETER G. H. EVANS

Like other animals, marine mammals may have preferred locations in which they spend the majority of time or where they engage in particular important life history activities such as giving birth, calf rearing, or feeding. The array of physical and oceanographic features that typify those locations forms the habitat of a species or local population. Often these are difficult to define. An ice-breeding seal clearly depends on pack ice upon which to give birth and that constitutes its breeding habitat, and a gray whale (*Eschrichtius robustus*) may seek out a sheltered tropical lagoon to calve, but for a large open-ocean baleen whale like a fin whale (*Balaenoptera physalus*) or blue whale (*B. musculus*), identifying its habitat requirements for breeding can be a difficult task. The same applies to feeding habitats: manatees (*Trichechus* spp.) and dugongs (*Dugong dugon*), e.g., require specific habitats such as shallow seagrass beds for feeding, but oceanic dolphins may range the high seas in pursuit of shoaling (schooling) fishes, making it difficult to identify whether they have specific habitat requirements. Human activities impinge upon the lives of marine mammals if they damage or destroy those habitats which may be important to them. Our knowledge of habitat pressures facing marine mammals is therefore limited to particular species, and especially to locations nearshore where animals have been studied more intensively and their ecological requirements are better defined.

Habitats formed by eddies, thermoclines, and fronts, particularly if they are driven by currents or wind, may shift from one locality to another during the life span of a marine mammal, leading to shifts in their geographic distributions. Habitats determined by geomorphological features such as depth, topography, available haulout, or den sites [in the case of pinnipeds and polar bears (*Ursus maritimus*), respectively], are relatively stable over time in relation to location. Strong site fidelity may lead a population to have difficulty in adjusting to changes in local food availability.

Habitat pressures upon marine mammals from anthropogenic influences may be grouped into five categories: (1) physical damage to their environment: a river or seabed and its constituent communities; (2) contamination from chemical pollutants; (3) direct removal of important prey through fisheries; (4) disturbance from human activities either by the introduction of sound into the environment or through ship strikes; and (5) physical and oceanographic effects from global climate change.

I. Physical Damage

Human population pressures frequently lead to direct changes to coastal and riverine environments. Estuaries are turned into industrial

harbors, wetlands are drained for agricultural purposes or for tourism, and coastal waters are modified often irreversibly by dredging of the seabed and input of a wide variety of pollutants. Some of the most obvious detrimental changes to a habitat come from alteration of rivers inhabited by particular dolphin species (Reeves and Smith, 1999). Water is often taken out of rivers for other uses, such as for drinking, flood control, or irrigation agriculture. In Pakistan, e.g., most of the annual flow of the Indus River is diverted into canals, and this, along with dam construction, has resulted in the Indus river dolphin (*Platanista gangetica minor*) losing probably at least half of its historical range (Reeves *et al.*, 1991). Dams modify water flow and affect the sedimentation of rivers; they also block traditional movement patterns of marine mammals that can lead to population fragmentation. The construction of large dams (such as the Ghezouba Dam and the Three Gorges Dam) along the Yangtze River system had serious consequences upon the already endangered baiji (*Lipotes vexillifer*) (Reeves and Leatherwood, 1994), which is now believed to be extinct. It may also restrict movements of more widespread species such as the Amazonian manatee (*Trichechus inunguis*) in Brazil (Rosas, 1994).

On land, one of the greatest habitat pressures leading to mass extinctions of fauna and flora is that of deforestation, particularly in the tropics. In the 1980s, Latin American countries are estimated to have eliminated 7.4 million hectares of tropical forests annually, with Brazil sustaining the greatest annual loss with 3.2 million hectares per year. This deforestation directly affects the fresh water habitats of the boto or Amazon river dolphin (*Inia geoffrensis*), as well as the Amazonian manatee (Rosas, 1994; Reeves and Smith, 1999; Reynolds, 1999).

After centuries of direct exploitation, pinnipeds have largely sought sites remote from human activities to give birth to their pups. They, therefore, are less likely to experience direct physical damage to those breeding habitats.

II. Chemical Pollution

Nearshore environments in particular are exposed to a potential wide range of pollutants as a result of industrial and agricultural activities. Those pollutants may concentrate in the food web, and either degrade the habitat by removing important prey populations or cause health deficiencies in the local populations of marine mammal species. Although high levels of potentially damaging pollutants have frequently been detected in marine mammals, particularly seals and coastal small cetaceans inhabiting nearshore environments, direct causal links with health status have rarely been demonstrated. Baltic ringed (*Pusa hispida*) and gray (*Halichoerus grypus*) seals during the 1970s had lesions of the reproductive system attributed to high PCB and DDT levels in their tissues. By the late 1980s and through the 1990s, as levels in those pollutants declined, the proportion with lesions had declined substantially, along with an increase in their pregnancy rate (O'Shea, 1999; Reijnders *et al.*, 1999). In an experimental study with harbor seals (*Phoca vitulina*), females fed with fish from the heavily polluted Dutch Wadden Sea had poorer reproductive success than those fed less contaminated fish from the North Atlantic. The effects were attributed to PCBs or their metabolites, and seals with the highest PCB intake were found to have reduced blood levels of thyroid hormones and vitamin A, both of which are known to be important in reproduction, including spermatogenesis.

Belugas (*Delphinapterus leucas*) in the highly polluted St. Lawrence Estuary in North America had a high prevalence of tumors which had been attributed to carcinogenic compounds such

as polycyclic aromatic hydrocarbons (PAHs) and other toxic compounds such as PCBs (Martineau *et al.*, 1999; Michaud and Béland, 2001). These were thought to account for low reproductive success in this population. However, although both sets of compounds occurred at high levels in this population, a direct link has not been clearly demonstrated, and the population in fact appeared to have increased since hunting ceased in 1979 (Kingsley, 2001).

Stranded harbor porpoises (*Phocoena phocoena*) from around the British Isles had PCB concentrations sufficiently high to cause adverse physiological effects, and mortality identified as from infectious diseases was considered to be associated with chronic exposure to these chemicals (Jepson *et al.*, 2005). Mass mortalities of striped dolphins (*Stenella coeruleoalba*) in the Mediterranean, bottlenose dolphins (*Tursiops truncatus*) in the eastern United States, harbor seals in the North and Baltic Seas, and Baikal seals (*Pusa sibirica*) in Lake Baikal also have showed significantly high concentrations of PCBs, which were thought to have reduced resistance to disease, thus making these populations more susceptible to virus infection.

Despite examples like these of apparent links between contamination and health status, the biological significance and nature of effects generally remains uncertain, and it has been impossible to demonstrate conclusively that demographic changes to a population can be attributed to pollution. The only exceptions are where pollution can be shown to lead directly to mortality. After the Exxon Valdez tanker went aground in Prince William Sound, Alaska, in 1989, releasing large volumes of crude oil, several thousand sea otters (*Enhydra lutris*) and about 300 harbor seals died as a result of the oiled pelts losing their vital insulation properties (Loughlin, 1994).

III. Competition with Fisheries

Habitats compromise animal and plant communities in an often complex web of interaction. When one or more members of the community are removed in large numbers, this can have repercussions throughout the food web, altering predator-prey relationships and competition for resources. Following the intense exploitation of large baleen whales in the Southern Ocean during the first half of the twentieth century, it was estimated that their overall biomass was reduced from 43 million tons to about 6.6 million tons, and that this made available a “surplus” of about 153 million tons of krill (Laws, 1985). These massive changes to the food web of the Southern Ocean had important effects on the remaining members with individual whales growing faster, reaching sexual maturity at an earlier age, and exhibiting increased pregnancy rates. Similar changes in life history parameters were seen in other marine species like the Antarctic crabeater seal (*Lobodon carcinophaga*) and several seabird species.

During the twentieth century, fisheries around the world intensified to such an extent that major changes in fish stocks were observed for many species. Rarely, however, has it been possible to show that prey depletion had reduced the numbers of a particular marine mammal species. Many marine mammals have catholic (broad or species rich) diets, and appear to respond by switching prey. The relative ease of capture and nutritive contents of different prey species may vary, but it has scarcely ever been possible to demonstrate that these have affected reproductive or survival rates, and hence led to a decline in that population. More often than not, the species appears to respond by shifting its distribution.

On both sides of the North Atlantic, fishing activities have markedly reduced the stocks of Atlantic mackerel and herring (*Clupea* spp.), resulting in other fish (upon which they prey) such as sand lance, sprat, and gadoid species becoming locally very abundant. Not only did some cetacean species like harbor porpoises and humpback whales (*Megaptera novaeangliae*) switch their diets to include those prey in greater amounts, but some also showed geographic shifts in distribution. Gray seals, feeding largely on sand lance, increased in number in the North Sea at around 7% per year, while right whales (spp.), feeding largely on plankton (the prey of sand lance) in the North-west Atlantic showed local declines. When some local sand lance and sprat populations crashed a few years later, further changes were witnessed. In the Gulf of Maine, e.g., fish-eating humpback and fin whales were replaced by plankton-eating right and sei (*Balaenoptera borealis*) whales, harbor porpoises moved nearer shore, and Atlantic white-sided dolphins (*Lagenorhynchus acutus*) became abundant and white-beaked dolphins rare (*L. albirostris*) (Kenney *et al.*, 1996).

In the Bering Sea and Gulf of Alaska, substantial declines in the numbers of Steller sea lions (*Eumetopias jubatus*), harbor seals, and northern fur seals (*Callorhinus ursinus*), as well as several species of fish-eating birds, have occurred since the 1970s. Although other factors may also be involved, most of these declines have been attributed to a decline in food availability resulting from the development of the Walleye pollock (*Pollachius pollachius*) fishery, a key prey species for many of these marine mammals following the demise of local herring stocks (Reeves and Reijnders, 2002). Similarly, the collapse of productivity of the Barents Sea ecosystem, brought on partly from excessive fishing mortality, has had far-reaching effects on a range of species from seabirds through to marine mammals (Bjørge, 2002).

IV. Disturbance

Sounds are introduced into marine and fresh water environments from a wide variety of sources: motor-powered vessel traffic of various sizes; active sonar for object detection including fish-finding and submarines; seismic exploration and subsequent drilling and production for oil and gas; explosions from military exercises and ocean science studies; and marine dredging and construction (Richardson *et al.*, 1995; Würsig and Evans, 2002; Nowacek *et al.*, 2007). Most of the sounds produced are concentrated between 10 and 500 Hz frequency. However, speedcraft of various types generate noise mainly between 2 and 20 kHz by cavitation of the propeller, and sidescan and military sonar generate sounds between 2 and 500 kHz (particularly in the lower-frequency range) (Evans, 1996).

Among cetaceans, baleen whales have rather different hearing sensitivities to those of toothed whales and dolphins. The former are most sensitive at low frequencies below 5 kHz and the latter above 1 kHz. Thus, baleen whales are likely to be most vulnerable to large vessels, oil and gas activities, marine dredging and construction, whereas toothed whales and dolphins may be more susceptible to recreational speedboats and most forms of active sonar.

Changes in behavior (e.g., movement away from the sound, increased dive times, clustering behavior) are often recorded in the vicinity of loud sounds. Few experimental studies have been conducted to test the nature and duration of negative responses. One such study in relation to low-frequency regular ATOC (Acoustic Thermometry of Ocean Climate project) sound pulses was conducted west of California (Calambokidis *et al.*, 1998). Aerial surveys showed no significant differences in numbers of marine mammals of any species between control and experimental surveys, but humpback and

sperm whales (*Physeter macrocephalus*) were on average further from the sound source during the experimental periods. Although many other studies have reported negative reactions, there is very little information concerning the long-term impact of sound disturbance. In Hawaii, humpback whale mothers with their calves are thought to have shifted their distribution offshore in response to the high volume of recreational traffic. Whale and seal watching itself can impose pressures upon marine mammals, disturbing seals from haulout or breeding sites, and whales (and dolphins) from favored feeding areas. These have even been found to have long-term consequences upon reproductive success, as in one bottlenose dolphin population from Australia (Bejder *et al.*, 2006).

Besides those indirect effects where sound disturbance may interfere with or frighten marine mammals, there is some evidence that loud sounds can cause physical damage. Temporary or permanent shifts in hearing thresholds may occur which could affect auditory acuity, and post-mortem examination of humpback whales found dead in the vicinity of drilling operations has revealed ear damage. Most notably, mid-frequency sonar (mainly between 2 and 10 kHz) used in military activities has been linked to mass strandings of beaked whales, and there have been a number of recent such events (e.g., in the Bahamas and the Canaries) (Evans and Miller, 2004; Cox *et al.*, 2006). In those cases, however, it has not been entirely clear whether the strandings have resulted from direct acoustic trauma or some behavioral change leading to gas bubble formation.

A new concern has arisen within Europe with the rapid expansion of offshore wind farms, mainly in shallow areas where harbor porpoises and harbor seals occur. Pile-driving activities during the construction phase in particular situations appear to have negative impacts on harbor porpoises, which can be relatively long-lasting (Carstensen *et al.*, 2006).

Powered vessels pose an obvious threat to marine and fresh water mammals through direct damage. Collisions have been reported in a wide variety of species, and in some, such as the Florida manatee (*Trichechus manatus*) and the North Atlantic (*Eubalaena glacialis*) and North Pacific (*E. japonica*) right whale, they are regarded as the major threat to their survival. With the advent of high-speed ferries in many parts of the world, ship strikes are being reported with increasing frequency, especially affecting some of the larger baleen whales like fin whales and the slower swimming toothed whale species like sperm whales and pilot whales (*Globicephala* spp.).

V. Climate Change

As a result of emissions by humans of substances which deplete the ozone layer, our increasing use of hydrocarbons for energy and fuel, and large-scale deforestation and desertification, the world is experiencing climate change such that it is predicted that, in the next hundred years, temperatures will rise by 1.0–3.5°C and overall sea level will rise by anywhere from 15 to 95 cm. Obvious consequences will be the melting of polar ice, drowning of coastal plains, and changes to shallow seas. Other less direct implications include an increase in the frequency and velocity of storms, and more extreme seasonal fluctuations in local climate (including, e.g., El Niño Southern Oscillation events). Shifts in areas of primary productivity may lead to distributional changes for many marine mammal species, but some such as the polar bear, land-breeding pinnipeds, and coastal cetaceans and sirenians may find it difficult to adjust to the loss of important feeding or breeding habitat (Würsig *et al.*, 2002). Already there is concern that less stable ice in some parts of the Arctic has reduced the availability of ringed seals to polar bears,

thus reducing the breeding success of the bears, which in those areas depend upon this species for food (Tynan and DeMaster, 1997).

During recent El Niño events, there has been reproductive failure in many seabird populations and some colonies of fur seals. During the 1982 El Niño, e.g., all Galapagos fur seal (*Arctocephalus galapagoensis*) females lost their pups due to starvation (Trillmich and Dellinger, 1991). However, many pelagic toothed whales and dolphins, being less tied to a particular locality, simply shifted their distributions: short-finned pilot whales (*Globicephala macrorhynchus*), e.g., left southern Californian waters following the departure of a species of squid, their main prey. Such changes can affect other members of the ecosystem. When the squid returned some years later, the temporarily vacant niche became occupied by another cetacean species, the Risso's dolphin (*Grampus griseus*) (Shane, 1995).

Despite the many pressures upon their habitats, marine mammals appear to be remarkably resilient, often living in highly modified coastal and riverine environments. Of course, because demographic changes may be slow and difficult to detect, we rarely know whether these are nonetheless having negative effects. In the case of small local populations of endangered species like the northern right whales, vaquita (*Phocoena sinus*), various river dolphins, monk seals (*Monachus* spp.), and manatee populations, the dangers of habitat pressures are all too obvious. However, even for other species, a precautionary approach would be prudent, and there is scope for the establishment of protective areas where human activities can be zoned.

Habitat Use

ALEJANDRO ACEVEDO-GUTIÉRREZ

I. Introduction

A. Temporal and Spatial Scales in Ecology

Ecology is the study of interactions between organisms and their environment, and the distribution and abundance of organisms resulting from these interactions. The environment of any organism includes abiotic factors—non-living chemical and physical factors such as temperature and light—and biotic factors—living organisms with which any individual interacts. For instance, other organisms may compete with an individual for food and resources, prey upon it, or change its physical and chemical environment. At the core of both ecology and conservation biology are questions that examine the relative importance of various environmental components in determining the distribution and abundance of organisms.

Habitat use studies attempt to describe, explain, and predict the distribution and abundance of organisms. In these studies, identifying the factors that influence distribution and abundance at different spatial and temporal scales is fundamental. This concept can be illustrated by examining the distribution and abundance of blue whales (*Balaenoptera musculus*) from the California/Mexico populations and fin whales (*B. physalus*) from the Gulf of California population. Blue whales and to a lesser extent fin whales depend on krill (Euphausiacea) as a prey item. Krill form large, dense swarms during the day and have their largest concentrations below 100 m in depth. At night, krill come near the surface but are scattered over large areas. During winter in Bahía de Loreto, Gulf of California, México, blue and fin whales engage in deep foraging dives during the day while at night they perform shallow dives, very few of which appear to be foraging dives. During the day, krill swarms are found around underwater edges, where depth diminishes rapidly, and blue and fin whales concentrate their movements and feeding in those areas. Both blue and fin whales move out of Loreto around early spring. Bahía de Loreto is thus a short-term feeding site for both whales, which behavior and movements closely match those of krill.

By combining the information from Loreto to that from other studies, the following general picture of the California/Mexico population of blue whales emerges: In late spring, blue whales move north to feed during summer and early fall along the California coast in the Farallones Islands, Cordell Banks, and Monterey Bay, on large swarms of krill. The whales move back south in fall, feeding around the Channel Islands and perhaps off Bahía Magdalena, Mexico. During winter, whales are back in the Gulf of California, including Bahía de Loreto. However, there is a large degree of variation, and many whales may winter in the Costa Rica Dome, an oceanographic feature in the Pacific Ocean. Although the picture of the Gulf of California population of fin whales is less complete, we know that they feed during the spring in the southern region of the Gulf of California, including Loreto. During the summer, a time of year in which krill are less abundant in the gulf, they move further north into the gulf to prey on schooling fish.

This example illustrates the importance of defining temporal and spatial scales in an ecological study, and documents how the distribution of marine mammals is influenced by the environment at different spatial and temporal scales. At scales of days and tens of kilometers, blue whales are found during the day along canyon edges, feeding on

krill swarms. At scales of months and hundreds to thousands of kilometers, blue whales move to different coastal areas to exploit krill swarms. In the case of fin whales, at scales of days and tens of kilometers, they are also found during the day along canyon edges feeding on krill swarms. However, at scales of months and hundreds to thousands of kilometers, they move within the same oceanographic area (the Gulf of California) and switch prey items, from krill to schooling fish. Even closely related species of marine mammals can make different decisions regarding their distribution: blue whales move out of the Gulf of California and look for the same prey item; fin whales remain in the Gulf of California and switch prey items. Given that marine mammals are generally long lived and that their cost of locomotion in the water is relatively low, understanding their distribution and abundance at multiple temporal and spatial scales is even more crucial than for shorter-lived or less mobile organisms.

B. Research on Marine Mammal Habitat Use

Marine mammals are highly mobile, tend to cover large areas, move in three spatial dimensions, and spend the vast majority of their lives under water. Hence, controlled experiments are next to impossible to conduct, and describing, explaining, and predicting distribution and abundance present unusual challenges to researchers. In general, studies are unable to show a causal explanation between a factor or factors and the observed distribution and abundance of a marine mammal population; rather, scientists rely on quantitative correlations that are indicative of potential causal factors. For instance, several studies document that during the summer belugas (*Delphinapterus leucas*) in Alaska are distributed near coastal mud flats and river mouths; however, it is unclear whether the observed distribution is caused by prey availability, breeding, calving, molting, or shelter from predators (Goetz *et al.*, 2007).

Our understanding of marine mammal habitat use has been improved by employing remote-sensing techniques and sophisticated statistical analyses. Remote-sensing techniques allow scientists to correlate marine mammal distribution with dynamic environmental variables that take into account spatial or temporal scales. For example, in the Gulf of St. Lawrence, the distribution of blue whales, fin whales, minke whales (*Balaenoptera acutorostrata*), and humpback whales (*Megaptera novaeangliae*) is highly correlated with thermal fronts, which were described from sea-surface-temperature satellite images (Doniol-Valcroze *et al.*, 2007). Remote-sensing techniques also allow scientists to describe the three-dimensional space distribution of marine mammals and correlate it with environmental factors. For instance, the amount of time that Weddell seals (*Leptonychotes weddellii*) in Antarctica spend at the bottom phase of a dive correlates with an index of prey abundance (Mitani *et al.*, 2003; Watanabe *et al.*, 2003; Mitani *et al.*, 2004). These results were obtained by attaching recorders to individual seals, which recorded dive behavior, acceleration, geomagnetic intensity, and digital still pictures. This methodology allows scientists to describe three-dimensional spatial use of seals, which spent their time under water on a small region with a steep bottom contour, apparently searching for benthic-pelagic prey throughout the water column (Mitani *et al.*, 2004).

Sophisticated statistical analyses allow scientists to simultaneously correlate the distribution and abundance of marine mammals with many different environmental factors. In the Bahamas, the occurrence of Blainville's beaked whales (*Mesoplodon densirostris*) is correlated in decreasing order of importance with seabed aspect (facing direction), seabed gradient (slope), and water depth, an analysis conducted with generalized additive modeling (GAM). Blainville's

whales occur in areas with a northeast aspect, intermediate gradients, and depths between 200 and 1000m where bottom topography forces the Deep Western Boundary Current toward the surface (MacLeod and Zuur, 2005). The authors hypothesize that prey are concentrated in these same areas. In the Faroe-Shetland Channel north of the United Kingdom, a GAM analysis of dolphin sounds indicates that dolphin distribution is best predicted by a combination of water noise level, time of day, month, and water depth (Hastie *et al.*, 2005).

Despite our inability to determine causality and hence fully explain the relationship between marine mammal distribution and abundance, and several biotic and abiotic factors, several tools such as remote-sensing techniques and GAM analysis allow scientists to describe, predict, and partially explain the determinants of such relationships.

C. Habitat Use and Evolution

Understanding the distribution and abundance of marine mammals is important not only to ecologists, conservation biologists, environmentalists, managers, and tour operators, but also to evolutionary biologists. This is because the interactions of organisms with their environment that occur over a long period of time are important causes of evolutionary change. Lake Apoyo, a volcanic crater lake in Nicaragua, was seeded only once by the ancestral benthic species *Amphilophus citrinellus* from which the new limnetic species *A. zalius* evolved within less than 10,000 years by exploiting a different habitat (Barluenga *et al.*, 2006). These two species are both reproductively isolated and eco-morphologically distinct; thus providing a convincing example of habitat use as an agent of evolutionary change via sympatric speciation. Sympatric speciation is a contentious concept in evolutionary biology, for which few convincing examples exist worldwide. Hence, documenting evolutionary change in marine mammals due to habitat use has been extremely difficult. The apparent incipient speciation of sympatric resident and transient killer whales (*Orcinus orca*) off the west coast of Washington State and Canada may be such an example (Baird *et al.*, 1992). However, it has been suggested that the division was originally cultural (Whitehead *et al.*, 2004).

II. Intrinsic Factors in Habitat Use

Most explanations on habitat use by marine mammals refer to environmental factors, such as prey availability, predation, or temperature, which are extrinsic to the organisms. However, traits intrinsic to the organisms themselves may affect their ability to exploit certain habitats and hence determine their distribution and abundance.

A. Body Size

Body size affects many important traits in organisms, including morphology, metabolic rate, and reproductive costs. Species with large body size and large amounts of fat stored in blubber are able to travel far or to exploit very patchy resources. An example of the relationship between habitat use and large body size is the northern elephant seal (*Mirounga angustirostris*). This species makes a double migration each year: one after molting and one after breeding, with individual annual movements of 18,000–21,000km (Stewart and DeLong, 1993, 1995). Adults stay at sea for 8–9 months of the year to forage, using the California Current as a corridor to foraging areas further north that are related to water masses and the distribution of squid. While at sea, both sexes dive almost continuously, remaining submerged for about

90% of the total time. Large body size has also predisposed marine mammals to long dives, because body size augments oxygen stores and diminishes specific metabolic rate (use of oxygen per unit of mass) (Hoelzel, 2002). Because deep dives require longer dives than shallow dives, large marine mammals such as the sperm whale (*Physeter macrocephalus*) are able to exploit deep-water habitats. However, given the many different physiological adaptations for diving found in marine mammals, body size alone cannot predict the vertical distribution of marine mammals.

B. Age

Given that marine mammals are long-lived predators, the habitat that they are able to exploit may change over time to reflect increased physiological capabilities as body size increases and by increased learning. Dive and depth duration in Australian sea lions (*Neophoca cinerea*) increase with age; however, such development is slow (Fowler *et al.*, 2006). Pups at 6 months of age show minimal diving activity, they are weaned at about 17 months of age, and as 23-month-old juveniles they tend to dive to 40–50m depths (62% the depth of adults). Pup and juveniles do not reach adult depth or durations and hence occupy shallower habitats than those exploited by adults. Adult New Zealand fur seals (*Arctocephalus forsteri*) utilize continental shelf waters and deep waters over the shelf break, where presumably high densities of fishes and cephalopods are found, while juveniles use pelagic waters up to 1000km from the habitats used by adults (Page *et al.*, 2006). It is hypothesized that due to their small body size, juveniles cannot efficiently utilize prey in the same habitats as adults because they do not have the capacity to spend enough time under water at the greater depths. Hence, adult male and female New Zealand fur seals are large enough to engage in benthic feeding in shelf breaks, whereas the smaller-sized juveniles are constrained to epipelagic feeding at night.

C. Sex

Many marine mammal species segregate by sex. The harbor seal (*Phoca vitulina*) provides a good example of such segregation (Boness *et al.*, 1994; Coltman *et al.*, 1997). Females and males have similar body sizes (females weigh about 85kg; males about 110kg) and mate at sea. Females nurse their pups for about 24 days, fasting for about 1 week and then having to take regular foraging trips while lactating. Most males forage early in the season and in doing so most individuals maintain or increase body mass during this period. During the latter part of the breeding season, males rarely forage and spend time reproducing when females are receptive. Hence, the habitat occupied by both sexes is different: during the first 10 days after birth, females are on land while males are at sea diving to depths exceeding 60m; between 10 and 20 days after birth, females make trips at sea and dive to 50–60m while males are also at sea in areas where females move but diving to only 20m. It appears that the different habitat use in which females and males engage represents a balance between foraging and reproduction to maximize reproductive success.

The relationship between habitat use and sex is also related to body size in sexually dimorphic marine mammal species. Such body size differences may require the sexes to use different habitats. For instance, gray seals (*Halichoerus grypus*) are sexually dimorphic in size (Breed *et al.*, 2006). At Sable Island, Nova Scotia, males and females utilized different habitats, differences that were most pronounced just before and immediately after breeding. Females mainly used mid-shelf regions whereas males primarily used areas along the continental shelf break. It is hypothesized that these differences maximize fitness

by reducing intersexual foraging competition. Southern elephant seals (*Mirounga leonina*) from Kerguelen Island travel to the Antarctic shelf (Bailleul *et al.*, 2007). As the ice expands during winter, females appear to shift from benthic to pelagic foraging, while males continue to forage almost exclusively benthically over the continental shelf. It is hypothesized that this difference in habitat use is related to the different energetic requirements between the two sexes, or to the need for females to return to Kerguelen in the spring to give birth, whereas males can remain in the ice.

D. Individual Variability

Differences in habitat use may also be related to individual variability. For instance, there is significant variation between individual female Antarctic fur seals (*Arctocephalus gazella*) in trip durations and the maximum distance reached from the breeding beach (Staniland *et al.*, 2004). Apparently, there is a strong individual component to where a seal forages, especially in terms of the distance traveled. The authors suggest that once the foraging area is selected by an individual seal, the dive behavior within that area is determined by the area itself, perhaps related to the spatial and temporal distribution of the prey within it, and not by the individual seal.

E. Life History

Life history refers to the patterns of resource allocation to maintenance (survival), growth, and reproduction. Life history traits appear also to influence habitat use in marine mammals. As described earlier, blue whales migrate from the Gulf of California to the California coast searching for krill aggregations, while fin whales remain in the Gulf of California and switch prey items. In this case, the blue whale pattern is to move to another body of water and feed on the same prey; the fin whale pattern is to remain in the same body of water and feed on different prey. Along the Scandinavian coast, harbor porpoises (*Phocoena phocoena*) experience different ecological regimes during the year and shift from pelagic prey species in deep waters to more coastal and/or demersal prey in relatively shallow waters (Fontaine *et al.*, 2007). In this case, the harbor porpoise pattern is similar to that of fin whales: they both adapt their foraging to local oceanographic conditions rather than perform an extensive migration.

Larger body size implies a longer dive time. However, whales of the family Balaenopteridae (rorquals) dive less than expected based on body size because their foraging strategy of lunging is costly (Acevedo-Gutiérrez *et al.*, 2002). Apparently, the effort needed to accelerate a large mass increases the costs of feeding and reduces time under water. Despite engaging in behaviors to reduce such costs—such as gliding gaits during dive descent, accelerating at the beginning of a lunge and gliding throughout the rest of the lunge—rorquals do not exploit the deep waters that smaller species use. In this case, the rorqual pattern is to exploit relatively shallow habitats due to the constraints imposed by their foraging behavior.

III. Extrinsic Factors in Habitat Use

Most habitat use studies attempt to explain the distribution and abundance of marine mammals in relationship to external biotic and abiotic factors. Two important extrinsic factors influencing the distribution of a species are food availability and predation risk. In general, marine mammals should exploit areas of high prey density and avoid areas of high predator density. However, it is also important to understand the temporal and spatial scales, given that the predictability of prey distribution tends to decrease with the spatial scale.

A. Prey Availability

Prey availability is the most frequently factor invoked to explain the distribution and abundance of marine mammals, regardless of the spatial and temporal scale of the study. However, understanding the mechanism influencing prey availability itself has proved as challenging as determining the causality of marine mammal distributions. Croll *et al.* (2005) took advantage of a relatively straightforward system: blue whales feed exclusively upon dense but patchy schools of pelagic krill; hence, understanding krill distribution will assist in understanding blue whale distribution. By employing remote-sensing techniques and concurrent measurements, they examined the temporal and spatial linkages between intensity of upwelling, primary production, distribution of krill, and distribution and abundance of blue whales in Monterey Bay, California. The study indicated that seasonally high primary production supported by coastal upwelling combined with topographic breaks off California maintained high densities to allow exploitation by blue whales. Blue whales appeared in the area in late summer and early fall and fed exclusively upon adult krill *Thysanoessa spinifera* and *Euphausia pacifica* aggregations, diving to depths between 150 and 200 m on the edge of the Monterey Bay Submarine Canyon. High krill densities were supported by high primary production between April and August and a submarine canyon that provided deep water down-current from an upwelling region. Peak krill densities occurred in late summer and early fall, lagging the seasonal increase in primary production by 3–4 months, due to the growth to adulthood of krill spawned around the spring-increase in primary production, and to decreased upwelling in late summer. It is predicted that the annual migratory movements of the California blue whale population reflect seasonal patterns in productivity in other foraging areas in the Northeast Pacific. The annual increase in the abundance of blue whales was linked to wind-driven upwelling, but these linkages occurred through a sequence of bottom-up biological processes that lagged in time. Consequently, models that attempt to predict the distribution and abundance of marine mammals need to include bottom-up processes and temporal scales.

Another example of the importance of understanding the spatial and temporal distribution of prey to describe, explain, and predict marine mammal distribution is found in dugongs (*Dugong dugon*). Like other herbivores, dugongs must select quality food plants to optimize their nutrient intake. Across multiple spatial scales, they appear to prefer some seagrass pastures and avoid others. At medium spatial scale remote sensing, it was confirmed that a 24 km² seagrass meadow in Hervey Bay, Australia, is an important dugong habitat due to the presence of five species of seagrasses, which covered 91% of the total habitat area (Sheppard *et al.*, 2007). However, at a small spatial scale, dugong use within the meadow is still not well understood because the influence of seagrass food quality on dugong grazing patterns and nutritional ecology is poorly understood. Consequently, understanding the dynamics of seagrass communities is essential for predicting patterns of habitat use by dugongs.

B. Predation Risk

Predation risk is an important factor explaining the distribution and abundance of marine mammals regardless of the spatial and temporal scale of the study. For instance, tiger shark (*Galeocerdo cuvier*) predation risk correlates well with the habitat use of Indo-Pacific bottlenose dolphins (*Tursiops aduncus*) in Shark Bay, Western Australia (Heithaus and Dill, 2002, 2006). The biomass of dolphin prey is greater in shallow habitats than in deeper ones; however, when tiger sharks are present in the area, their density is highest in shallow

habitats. It is believed that shallow habitats are also inherently risky because shark detection apparently decreases as dolphin echolocation efficiency and visual detection of sharks camouflaged over seagrass diminish in shallow habitats. Hence, shallow habitats are the best places to forage for dolphins, but are also the most risky. As a result, in seasons of high shark abundance, dolphins foraged much less in the productive but risky shallow habitats than expected if food was the only relevant factor. These results suggest that dolphin habitat use reflects a trade-off between predation risk and prey availability. Besides showcasing the importance of predation risk in explaining habitat use, this study also indicates that the distribution and abundance of marine mammals is simultaneously affected by more than one factor. Further, because the distribution and abundance of tiger sharks are influenced by species other than dolphins, the distribution of the primary prey of the sharks may indirectly influence dolphin habitat use. Hence, as also exemplified by the studies described in the section on prey availability, it is important to consider the community context in studies of habitat use.

C. Intraspecific Competition

In many species, differences in habitat use between sexes are apparently a consequence of social interactions. A recent study of the Galápagos sea lion (*Zalophus wollebaeki*) indicates that sexual segregation on land was high both during the reproductive and non-reproductive periods (Wolf *et al.*, 2005). A generalized linear model of habitat use showed that adult males frequented habitat types that adult females used much less, with males being most abundant in suboptimal inland habitats. It is hypothesized that this habitat segregation resulted as a by-product of social processes, primarily intra-sexual competition and female avoidance of male harassment.

D. Human Influence

Human activities, also termed anthropogenic influences, are an important extrinsic factor affecting the distribution and abundance of marine mammals. Boat traffic is an activity with many documented cases of impact on marine mammal habitat use. In the short term, this activity may cause marine mammals to temporarily abandon or avoid a particular site. For instance, the number of harbor seals hauled out in a particular site may diminish dramatically in relation to boat traffic (Suryan and Harvey, 1999; Johnson and Acevedo-Gutiérrez, 2007). In New Zealand, the frequency of bottlenose dolphin (*Tursiops truncatus*) visits to Milford Sound has diminished as a result of boat traffic; additionally, when dolphins visit the fjord they remain at the entrance, away from tour boats (Lusseau, 2005). In the long term, boat traffic may create a permanent abandonment of areas visited by marine mammals and hence creating a permanent shift in distribution. For example, boat traffic may cause harbor seals to abandon haulout sites where alternative haulout locations are limited (Suryan and Harvey, 1999). In Shark Bay, Australia, the abundance of Indo-Pacific bottlenose dolphins has declined in areas operated by two or more dolphin-watching boats compared to areas with no boats or with only one boat (Bejder *et al.*, 2006).

Human activities may also cause marine mammals to visit rather than leave a particular area. For instance, two sympatric communities of Indo-Pacific bottlenose dolphins are found in Moreton Bay, Australia (Chilvers *et al.*, 2007). The non-trawler community does not associate with trawler vessels, whereas the trawler community associates with trawlers to feed on flushed prey. While the distribution of the non-trawler community is explained by season and tide,

the distribution of the trawler community is explained by the distribution of trawler boats.

IV. Conclusion

The habitat use of marine mammals is affected by abiotic and biotic factors, including intrinsic and extrinsic factors. The scientists' goal is to describe, explain, and understand the relative importance of each factor in the distribution and abundance of marine mammals. To reach this goal, the temporal and spatial scales of the study system need to be clearly defined. Given the challenges inherent in studying marine mammals, the use of sophisticated remote-sensing technologies and statistical models has been very successful in gathering and integrating data on habitat use. Long-term studies and studies in new regions are fundamental to answering questions on habitat use. However, the most promising line of work is to conduct integrative studies that consider community and ecosystem structure at different spatial and temporal scales, such as the study on the California/Mexico population of blue whales described throughout this chapter.

Hair and Fur

PAMELA K. YOICHEM AND BRENT S. STEWART

I. Structure and Function

The presence of hair is one of the characteristics that distinguishes mammals from other vertebrates. Hair consists of keratinized epidermal cells, formed in hair follicles located in the dermal layer of the skin. Adaptations to an aquatic or amphibious lifestyle are apparent in marine mammal skin and hair (Ling, 1974; Williams *et al.*, 1992; Pabst *et al.*, 1999; Reeves *et al.*, 2002). Pinniped and sea otter (*Enhydra lutris*) hairs are flattened in cross-section rather than round as in other carnivores. This is evidently an adaptation for enhancing streamlining of the body and reducing drag during swimming. Pinnipeds and sea otters have diffuse smooth muscle in their dermis, but they lack true arrector pili muscles. Pinnipeds, sea otters, and polar bears (*Ursus maritimus*) possess sebaceous glands and sweat glands, but these are absent in cetaceans and sirenians. Cetacean skin is hairless except for a few vibrissae or bristles occurring mostly on the rostrum or around the mouth. These are usually lost before or soon after birth. Sirenians have widely scattered hairs. The integument of pinnipeds, sea otters, and polar bears generally has two layers of hair. The outer protective layer consists of long, coarse guard hairs and the inner layer is composed of softer intermediate hairs or underfur. Polar bear, sea otter, and otarid guard hairs are medullated (having a sheath), whereas phocid and walrus hairs (*Odobenus rosmarus*) are not. The hairs typically grow in groups or clumps, with a single guard hair emerging cranial to one or more underfur hairs. Each hair grows from a separate follicle, but the underfur follicles feed into the guard hair canal so that all hairs in a particular clump emerge from a single opening in the skin. Some pinnipeds have a relatively sparse hair coat [walrus, elephant seals (*Mirounga* spp.), and monk seals (*Monachus* spp.) with a single guard hair per canal], whereas others have a lush, thick coat (fur seals, with dozens of underhair or fur follicles feeding into each guard hair canal). Sea otters have the densest fur of any mammal, with approximately 130,000 hairs/cm², about twice as dense as that of northern fur seals (*Callorhinus ursinus*). Albinism and other skin and hair color anomalies have been reported in pinnipeds and cetaceans (Fertl *et al.*, 1999; Bried and Haubrex, 2000).

The appendages of some pinnipeds and the pads of sea otters are hairless, allowing these species to readily lose excess body heat by conduction to the environment. Although most marine mammals rely on blubber for insulation, a layer of air trapped within the hair or fur serves as the primary insulator in fur seals and sea otters and keeps the skin dry when the animals are submerged. Sea otter pelage is coated with squalene, a hydrophobic lipid that aids in waterproofing the fur. Skin secretions in pinnipeds also assist in waterproofing, and provide defense against microbial infections (Meyer *et al.*, 2003).

Figure 1 Catastrophic-type molt in the northern elephant seal (*Mirounga angustirostris*), where the upper epidermis and hairs are shed in large patches within a few weeks. Photograph by B. S. Stewart.

II. Molt

Many phocid seals possess a white lanugo coat *in utero*; this may be lost before birth, or may persist for several weeks (as in some arctic and antarctic species). This pelage provides insulation for neonates of ice-breeding seals until they develop a blubber layer and also may serve as camouflage or protective coloration. Other examples of distinct neonatal pelage include the woolly black coat of elephant seals, which is replaced by a silvery hair coat after the pup is weaned, and the fluffy buff-colored pelage of sea otter pups, which persists for several months. The signals for initiation and control of the annual pelage cycle are not known for most species but are thought to include endocrine (thyroid, adrenal, and gonadal hormones), thermal, and nutritional influences (Ling, 1970; Ashwell-Erickson *et al.*, 1986). Molt is generally seasonal, beginning shortly after breeding. Sea otters may molt year-round, although more hairs are generally replaced in summer than in winter. The duration of molt in pinnipeds ranges from a very rapid and “catastrophic” shedding of large patches of superficial epidermis and associated hairs (elephant seals, monk seals) (Fig. 1) to the more gradual pattern seen in otariids, with hairs replaced over several months. A disruption of the molt process, resulting in breakdown of the protective skin barrier, appears to underlie Northern Elephant Seal Skin Disease (Beckmen *et al.*, 1997; Yochem, 2008), an ulcerative dermatopathy affecting primarily yearling northern elephant seals (*Mirounga angustirostris*).

Figure 1 *The harbor porpoise.*

shape is a characteristic that distinguishes porpoises from the dolphin family, which have conical teeth. Another characteristic feature of harbor porpoises is the presence of tubercles or small hard bumps on the leading edge of the dorsal fin. The function of these is not yet known.

Although the fossil record containing porpoises is poor, recent genetic investigations have made it possible to reconstruct the most probable relationships among the porpoises. Early morphological studies suggested that harbor porpoises were related to Burmeister’s porpoise (*Phocoena spinipinnis*) and the vaquita (*Phocoena sinus*), and therefore these three species have been placed in the same genus. However, genetic information suggests close relation to the Dall’s porpoise (*Phocoenoides dalli*), a species endemic to the Pacific Ocean (Rosel *et al.*, 1995).

II. Distribution and Abundance

Harbor porpoises are distributed throughout the coastal waters of the North Pacific, the North Atlantic, and the Black Sea (Fig. 2). The porpoises in each of these ocean basins are reproductively isolated, resulting in division of the species into subspecies: *Phocoena phocoena phocoena* in the Atlantic Ocean and *Phocoena phocoena vomerina* in the Pacific Ocean. Most likely there is an additional, yet unnamed subspecies in the western North Pacific. The harbor porpoises of the Black Sea are classified as a separate subspecies *Phocoena phocoena relicta*. These subspecies differ from each other morphologically and genetically. Atlantic harbor porpoises have larger skulls but shorter jaws than Pacific harbor porpoises. Some morphological differences and variation in pigmentation are observed within the Atlantic Ocean porpoises.

Within the ocean basins the subspecies are divided into several genetically distinct population units. Thirteen population units have been suggested for the North Atlantic. Recent genetic studies indicate that the population structure might be more complex and that the current population units should be revised (Andersen, 2003). Several population units are described from the North Pacific.

The global population size of harbor porpoises is at least 700,000. The North Sea is a particularly important porpoise habitat housing about 335,000 porpoises (Hammond *et al.*, 2002). Other important harbor porpoise habitats are the Gulf of Maine—Bay of Fundy area, the US west coast, and Alaska (Bjørge and Donovan, 1995). The abundance is declining in some areas, mainly due to human-induced factors. The entire subspecies in the Black Sea numbers only about 10,000 porpoises and is possibly declining. Baltic Sea porpoises number a few hundred and are critically endangered.

Harbor Porpoise

Phocoena phocoena

ARNE BJØRGE AND KRISTAL A. TOLLEY

I. Characteristics and Taxonomy

The harbor porpoise is a small odontocete inhabiting coastal temperate and boreal waters of the Northern Hemisphere (Bjørge and Donovan, 1995). It derives its common English name from the Latin for pig (*porcus*) and is sometimes referred to as the “puffing pig” in parts of Atlantic Canada. The Norwegian common name “nise” is derived from an old Norse word for sneeze and refers to the sound the porpoises make when they surface to breathe.

Harbor porpoises have a short, stocky body (Fig. 1) resulting in a rotund shape, an adaptation that helps them limit heat loss in the cold northern climes (McLellan *et al.*, 2002). The dorsal side of the harbor porpoise and the tail flukes are dark gray, almost black. The chin and underbelly are contrasting light gray, almost white. The head and sides are shaded gray, and darker gray stripes originate near the back of the mouth and run back toward the flippers, which are dark gray. Individual differences in the shading patterns occur. The triangular-shaped dorsal fin makes this species easily recognizable at sea, as does its characteristic forward rolling behavior when it surfaces.

Harbor porpoises have small spade-shaped teeth, about 22–28 pairs in the upper jaw and 21–25 pairs in the lower jaw. The spade

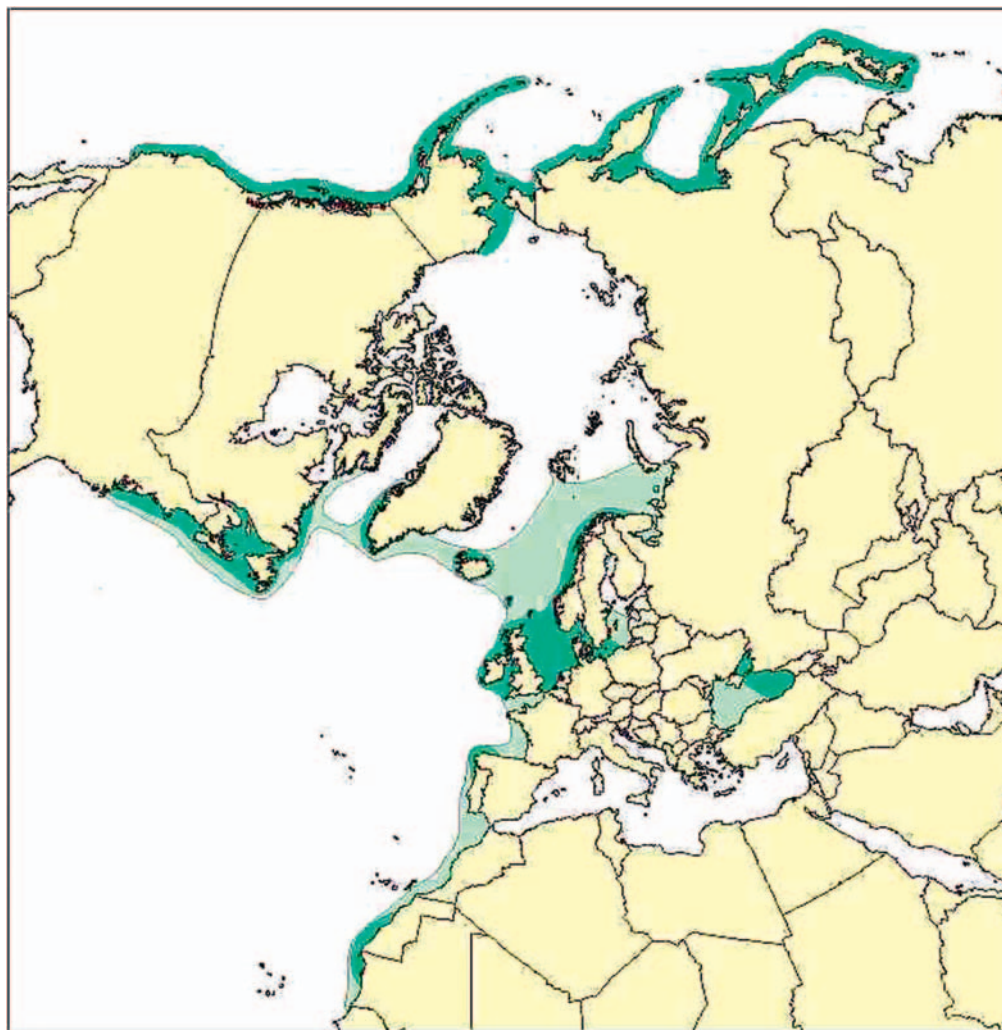

Figure 2 The regular worldwide distribution of the harbor porpoise is shown in dark green. The distribution where harbor porpoises occasionally occur is shown in light green.

III. Ecology

Harbor porpoises are primarily fish feeders, but in some areas they prey on squid and crustaceans. Small pelagic schooling fishes with high lipid content such as herring, sprat, and anchovy and a range of bottom-dwelling fishes are common prey species. Harbor porpoises usually forage near the sea bottom in waters less than 200m depth. They also are known to forage close to the surface, e.g., on sprat. When harbor porpoises occur in deeper waters their diet may include mid-water species such as pearlsheds. These mid-water fishes become available to the harbor porpoises when they migrate toward the surface at night. Although they generally feed independently, groups of porpoises have been observed collaborating to keep schools of fish closely together and herding them to the surface. The harbor porpoises possibly use the sea bottom and the sea surface as back walls when they are chasing fish.

IV. Behavior and Physiology

Some studies have demonstrated that harbor porpoises may reside within an area for an extended period of time. However,

onshore/offshore migrations and movements parallel to the coast are known to occur. Two large-scale surveys in the North Sea and adjacent waters in 1994 and 2005 showed a stable population size but a shift in distribution from north to south within the North Sea over this period. Such shifts may mirror changes in distribution and availability of important prey species. In some coastal areas, harbor porpoises migrate offshore to avoid ice during winter. In the long and narrow fjords of Norway, where porpoises live year-round, input from rivers form a fresh water top layer, which may freeze within a few hours. Under such circumstances, porpoises can be fatally trapped. The water input from rivers during winter has increased in recent decades due to climate change, and increased risk of ice entrapment of porpoises may be an unexpected effect of higher winter temperatures.

Dive telemetry data have shown that porpoises can dive to at least 220 m. The majority of extended dives are about a minute long, but dives of over 5 min have been recorded (Westgate *et al.*, 1995). The most cost-effective swim speed of harbor porpoises is estimated to about 1.4 m/sec (Otani *et al.*, 1998, 2001). The aerobic dive limit (ADL) depends on swim speed and for porpoises swimming at about 1.5 m/sec or less is about 4 min. Free ranging porpoises usually swim

at a speed of slightly less than 1 m/sec and most of their dives are less than 4 min. They, therefore, spend most of their time working aerobically.

Harbor porpoises have extremely thick blubber compared to body size, an adaptation that aids in thermoregulation of the relatively small body in cold waters. Calves have thicker blubber and are more rotund than adults, providing them with an excellent capacity to conserve heat. It is the outer blubber layer that is most stable and important for conserving heat. The inner layer is more metabolically active and serves as an efficient energy store.

Harbor porpoises are normally found in small groups of 1–3 animals often consisting of a mother–calf pair. Larger groups of 6–8 animals are not uncommon and on rare occasions they may form much larger aggregations. Their swimming and surfacing movements are quick, but they rarely leap out of the water. When surfacing, their dorsal side is exposed for a few seconds in the characteristic forward roll movement. When the porpoises occasionally rest at the surface for extended periods, the body is tilted slightly backward with the blowhole as the most elevated part of the body.

V. Life History

Harbor porpoises at birth are usually about 70–75 cm long and weigh 5 kg (Lockyer, 2003). The calving season varies from region to region, but in most areas calving takes place from May to August. Mating takes place approximately a month and a half after the calving season. The gestation period is approximately 10.5 months. The calves are weaned before they are 1-year old but may begin to catch small solid food items (e.g., euphausiids) when they are just a few months old. Calves grow rapidly, with males reaching about 120 cm and females 125 cm in length at the end of their first year. On average, adult females reach 160 cm in length and weigh around 60 kg. Males are smaller than females, growing only to about 145 cm and 50 kg. The largest recorded size for this species was from a female which was over 200 cm and 70 kg. They become sexually mature between 3 and 4 years of age but are not physically mature until they are about 5 (males) and 7 (females) years old. Harbor porpoises have an average life span of about 8–10 years, although some have been documented to live longer than 20 years. The oldest documented harbor porpoise was 23 years old.

In the Atlantic, most sexually mature females produce a new calf every year, but in the Pacific it appears that the calving interval may be 2 years. Harbor porpoises likely have a promiscuous mating system, whereby each individual mates with several other individuals. Further, they are thought to be “sperm competitors” because males produce large quantities of sperm, presumably in order to mate with several females. The testes undergo large seasonal change in size: they increase up to 800 g just prior to the mating season but regress in winter to a total weight of about 200 g.

VI. Interactions with Humans

The harbor porpoise as a species is not threatened and IUCN has listed it as LC (least concern). However, the populations in the Baltic Sea and in the Black Sea are listed as CR (critically endangered) and EN (endangered), respectively. Harbor porpoises inhabit coastal waters and are therefore exposed to many negative environmental effects of modern society; eutrophication, chemical pollution, noise, ship traffic, and overfishing of prey are just a few of the

human-induced disturbances of this species (Jepson *et al.*, 1999; Beineke *et al.*, 2007; Lahaye *et al.*, 2007).

In the past, harbor porpoises were harvested for their meat and blubber in many areas, e.g., in Puget Sound, the Bay of Fundy, Gulf of St. Lawrence, Labrador, Newfoundland, Greenland, Iceland, Black Sea, the Danish Belt Seas, and the Baltic Sea. Most of these fisheries are now closed, but hunting still occurs and is increasing in Greenland, where the annual take now exceeds 2000. However, legal protection of the species in most areas does not protect the porpoises against accidental deaths in fishing nets. Throughout its range there are high incidental bycatches of harbor porpoises in fishing gear, and in many areas the bycatch is above sustainable levels. Entanglement in fishing nets is currently the most significant human-induced threat to the porpoises. Modifications in fishing practices are urgently needed to ensure the long-term survival of some porpoise population units. Harbor porpoises spend time close to the surface when they breathe and close to the sea bottom when they forage in shallow waters. Porpoises are therefore exposed both to driftnets hanging from the surface (e.g., driftnets set for salmon) and to bottom-set gill nets. The porpoises emit click trains and use echoes of their own sound to find fish and navigate. Therefore, they are able to detect nets before they are in physical contact with the nets. However, the range within which they can detect the netting of gill nets is less than 10 m. Mean click-train interval of about 12 sec is common in harbor porpoises. However, about 4% of all click-train intervals are longer than 50 sec. Therefore, a swim speed of slightly less than 1 m/sec makes porpoises very susceptible to entanglement in fishing gear during periods of prolonged click-train intervals. The use of modified, more detectable nets, or the use of “pingers” (devices that emit warning sounds) on gill nets may assist in mitigating bycatches. In some areas, knowledge of porpoise movements and habits has aided in setting fishing regulations designed to help protect the species.

The harbor porpoise is a high-trophic-level predator exposed to bio-accumulated pollutants. Some of the bio-accumulated pollutants (e.g., PCBs) suppress the immune system when they enter mammals in elevated concentrations. It can be assumed that chronic PCB exposure predisposes harbor porpoises to infectious disease mortality. Baltic Sea porpoises have about 250% higher levels of PCBs than North Sea porpoises.

North Sea harbor porpoises have a high burden of mercury, and it appears that mercury burden is associated with prevalence of parasitic infection and certain pathological diseases such as pneumonia. About 15% of stranded porpoises died from pneumonia.

The recent development of offshore windmill parks in shallow waters is a possible new threat that could displace harbor porpoises from their preferred habitat. These windmills emit sounds with yet unknown long-term effect on porpoises. The number of offshore windmill parks is currently growing in the North Sea region in an attempt to generate renewable, environment-friendly energy.

Harbor Seal and Spotted Seal

Phoca vitulina and *P. largha*

JOHN J. BURNS

The harbor seal (*Phoca vitulina*) is also widely known as the common seal. It occurs over a great latitudinal range and in many different coastal and insular habitats around the rims of both the North Atlantic and North Pacific regions (King, 1983). Spotted seals (*P. largha*), in contrast, occur only in seasonally ice-covered seas of the Western Hemisphere (Burns, 1986). The name “larga seal” is sometimes used for the spotted seal and is derived from *largha*, which is part of the scientific name. These two sibling species are the most closely related members of the subfamily *Phocinae* and are fascinating examples of adaptations to vastly different environments. Most harbor seals occur in habitats that are sea ice free throughout the year, or at least where their coastal haulout and rookery sites are clear of sea ice during the breeding season. Spotted seals, conversely, utilize sea ice during the breeding season. In this context, it is important to distinguish between sea ice and fresh water icebergs calved from tidewater glaciers. Both species are of medium size. In some areas of the North Pacific their distributions overlap.

I. Characteristics and Taxonomy

A. Appearance

Based on external appearances, harbor and spotted seals older than weaned pups are not readily distinguishable from each other. Body size of spotted seals falls within the range of that for all but the largest harbor seals.

The pelage pattern and coloration of harbor seals is variable (Fig. 1). Background color ranges from yellowish or yellowish-gray (light phase) to blackish (dark phase). Light phase seals are usually paler on the flanks and belly than on the back, are covered with small black spots, and often show small pale rings, usually on the slightly darker dorsum. Dark phase harbor seals also have dark spots that are largely masked by the background coloration. Usually the dark seals show obvious light rings, especially on the dorsum. Seals of intermediate coloration are common. Throughout their broad range there are regions within which a particular pelage type predominates. Ungava seals (*P. v. mel-lonae*) are of the dark phase, as are most western Pacific harbor seals. Spotted seals are more uniform in color and pattern (Fig. 2). They tend to resemble light-phase harbor seals, which has contributed to the confusion about these two species.

B. Size

The average length of harbor seals varies among populations. The smallest and largest seals occur in the North Pacific region and therefore they bracket the size of animals from other regions. Those from the northern Gulf of Alaska are the smallest. The average standard length and weight of adult males from that area is about 160 cm and 87 kg, while that of adult females is about 148 cm and 65 kg. Newborn pups average 82 cm and 10 kg (Pitcher and Calkins, 1979). The largest seals are from the Aleutian Islands and northern Japan. Length and weight of adult males ranges from 174 to 186 cm and 87 to 170 kg and

Figure 1 Adult harbor seals (*Phoca vitulina*) on Año Nuevo Island, CA.

Figure 2 An adult female spotted seal (*Phoca largha*) (right) with her lanugo-clad pup (center, partially concealed), and an attending male (left), in the Bering Sea.

that of adult females from 160 to 169 cm and 60 to 142 kg. Newborn pups were up to 98 cm and 19 kg (Naito and Nishiwaki, 1972; Burns and Gol'tsev, 1984).

Spotted seals are about the same size as most harbor seals and there are slight differences among populations. Adult males from the Bering Sea range from 161 to 176 cm and 85 to 110 kg. Adult females are 151 to 169 cm and 65 to 115 kg (Burns, 1986). Near-term fetuses and newborn pups from the Okhotsk Sea are 78 to 92 cm long and 7 to 12 kg (Trukhin, 2005). Healthy pups usually double and sometimes triple their birth weight during the 3- to 4-week nursing period.

C. Diagnostic Characters

There are genetic (O'Corry-Crowe and Westlake, 1997), morphological, ecological, and behavioral differences between harbor and spotted seals. The breeding habitat of harbor seals is coastal and insular.

They give birth mainly on shore rookeries, although in some parts of Alaska they utilize icebergs calved from tidewater glaciers in protected fjords. Spotted seals use seasonal sea ice, mostly far from shore. During the breeding season, harbor seals occur in herds with no obvious social organization. Spotted seals occur as widely scattered adult pairs, usually with a pup (triads). In the areas where they occur together, harbor seals breed about 2 months later than spotted seals (reproductive separation). The pelage of newborn harbor seals is like that of adults because the lanugo is shed before birth (*in utero*). Occasionally, especially in the northern parts of their range, or in the case of premature pups, the lanugo is retained for up to a few days after birth. The pups usually enter the water shortly after birth, often within an hour. Spotted seal pups retain their whitish wooly lanugo, which is important for thermoregulation, for about 4 weeks. After the lanugo is shed the pelage resembles that of adult animals (Figs. 3 and 4). They remain on the ice during the nursing period and are abruptly weaned (abandoned).

Figure 3 Partially molted, weaned, spotted seal pup (*Phoca largha*).

Figure 4 Completely molted spotted seal pup (*Phoca largha*). Note the adult-like pelage.

There are no individual cranial measurements that consistently separate harbor from spotted seals. As with body size, skull measurements are within the range of those in harbor seals. The ratios of some measurements are useful for differentiating between the two species (Chapksii, 1969; Shaughnessy and Fay, 1977, Burns *et al.*, 1984). Those ratios include jugal length/condylobasal length; nasal length from maxillo-frontal suture/condylobasal length; and interorbital width/mastoid width. Several non-metrical characters, used in combination, do permit differentiation. In harbor seals the skull is more massive, the bullae are more flattened and angular, the premolar teeth of adults are mostly obliquely set (straight in spotted seals), the posterior margin of the jugal bone is mostly angular (as opposed to rounded), the glenoid fossa is more flattened and angular, the bony process of the external auditory meatus is mostly straight and blade like (as opposed to mostly blunt and rounded), the shape of the posterior edge of the bony palate is mostly acute (as opposed to mostly rounded), and the hyoid arch is incomplete, having abbreviated stylohyals that are not attached to the bullae (as opposed to complete and attached in spotted seals). Unfortunately, none of these diagnostic characteristics are useful for differentiating live seals under field conditions.

Very experienced observers can distinguish between these two seals, even those with similar pelage, based on behavior when hauled

out together on land, on general facial features of adults, and on behavior when frightened into the water.

D. Nomenclature

There are five presently recognized subspecies of harbor seals: *P. v. vitulina* (Linnaeus, 1758); *P. v. concolor* (DeKay, 1842); *P. v. mellonae* (Doutt, 1942); *P. v. richardii*¹ (Grey, 1864); and *P. v. stejnegeri* (Allen, 1902). The spotted seal (Pallas, 1811) is considered to be a monotypic species. The different subspecies of harbor seal were originally recognized on the basis of geographical separation and skeletal morphology. Recent studies of their genetics sustain those conclusions. Boundaries between the eastern and western subspecies within both the North Atlantic and North Pacific Oceans are not known with certainty.

II. Distribution and Movements

The distribution of harbor and spotted seals is shown in Fig. 5. Harbor seals occur over a latitudinal range from about 30°N to 80°N in the eastern Atlantic region and about 28°N to 62°N in the eastern Pacific region. They have the broadest distribution and occur in most different habitats of any other pinniped. Although the centers of abundance (greatest numbers of breeding animals) are in the northern temperate zone, breeding colonies of these seals occur north or south of that zone, depending on the presence of required environmental conditions created by regional oceanographic and climatic conditions. The high-latitude distribution in the Atlantic region is due to relatively warm oceanographic features, including the so-called North Water in Baffin Bay (eastern Canada–west Greenland) and the strong influence of warm water carried across the Atlantic to northern Europe by the Gulf Stream and associated gyres.

In the eastern Atlantic, *P. v. vitulina* normally occurs from the French coast bordering the English Channel, throughout the North Sea and northward to Finmark on the Barents Sea; including into the southern Baltic Sea and waters of Ireland and Great Britain. Stragglers occur to Portugal in the south and to the eastern Barents Sea in the northeast. The northernmost breeding population (here assumed to be *P. v. vitulina*) is in western Svalbard (Spitsbergen) at 78°30'N.

The boundary between *P. v. vitulina* of the eastern Atlantic and *P. v. concolor* of the western Atlantic is not known. However, harbor seals extend across the North Atlantic as a series of widely separated populations that occur at Svalbard, the Faeroe Islands (uncertain), Iceland, southern East Greenland, and West Greenland northward to about Upernavik (72°N). In Greenland the seals are considered to be *P. v. concolor*, as are those in most of eastern North America.

In the western Atlantic region the normal range of *P. v. concolor* extends from about 40°N (New Jersey) to about 73°N (northern Baffin Island, Canada); including into Hudson Bay and southern Foxe Basin. Stragglers have occurred as far south as Florida. The resident fresh water seal of the Ungava Peninsula in eastern Canada, *P. v. mellonae*, was first described and recognized as a separate subspecies by Doutt (1942), mainly on the basis of skull features and apparent isolation. It occurs in several drainage systems that empty into eastern Hudson Bay, where *P. v. concolor* is found. The subspecific designation of the

¹Editorial protocol for this book requires the nomenclature of Rice (1998), which is *P. v. richardii*. The correct nomenclature, in my opinion, is *P. v. richardsi* in accordance with the explanations in Shaughnessy and Fay (1977). The person in whose honor this subspecies of seal was named was Capt. Richards, not Capt. Richard.

Figure 5 The distribution of harbor seals (*Phoca vitulina*) (five subspecies) and spotted seals (*Phoca largha*).

Ungava seals was in doubt for several reasons, including their close proximity to salt water harbor seals; the fact that in general harbor seals occur frequently in rivers and lakes; and because the fresh water drainages in which it occurs flow into Hudson Bay. However, passage to and from salt water is blocked by numerous obstacles resulting from isostatic uplifting (rebound) of the peninsula since the last Pleistocene glaciation. The distinct status of this rare fresh water seal has been upheld on the basis of genetic differences (Smith, 1999).

In the North Pacific region the distribution of harbor seals extends from Cedros Island near the west-central coast of Baja California, Mexico (about 28°N), northward to the Gulf of Alaska and southeastern Bering Sea including the Pribilof Islands, across the entire Aleutian Ridge (the Aleutian and Commander islands) to the Kamchatka Peninsula of eastern Russia, southward in the Kuril Islands and beyond to Hokkaido Island in northern Japan. *P. v. richardii* is the subspecies of the eastern North Pacific region and *P. v. stejnegeri* occurs in the western Pacific. The boundary between these two subspecies is currently thought to be in the western Alaska Peninsula–eastern Aleutian Islands, although uncertainty about that question still exists. The northernmost pupping colonies in the Pacific region are in Prince William Sound, Alaska, at about 61°13'N. That is some 1920 km farther south than the northernmost breeding group in the Atlantic region.

Great distances separate the Atlantic and Pacific forms. There are no breeding colonies between Baffin Island in northeastern Canada and the Pribilof Islands of southeastern Bering Sea, nor between northern Norway and the Pribilof Islands.

Seasonal and annual movements of harbor seals are quite varied depending on the environments in which they occur. They are usually considered to be relatively sedentary, with a high degree of fidelity to one or a few haulout sites. This view, although perhaps applicable to some populations, is a gross oversimplification. It is now recognized that they move, in some cases quite extensively. Generalizations are inappropriate in view of this seals' wide distribution and differences in stock sizes, population dynamics, and the varied environments they occupy. In most instances, some individuals are likely more sedentary and show stronger site fidelity than others. Kinds of movement include migrations, juvenile dispersal, seasonal shifts, shifts related to breeding activity, responses to seasonal habitat exclusion, responses to acute or chronic disturbance, and immigration/emigration, occasionally on a relatively large scale.

The spotted seal was, until recently, considered to be a subspecies of harbor seal. It is now recognized as a distinct species (Shaughnessy and Fay, 1977), that includes several widely separated breeding populations. The centers of abundance during the breeding season are mainly in the temperate/subarctic boundary regions. The seal is well adapted to exploit the "front" and broken ice zones of seasonal sea ice that overlies continental shelves during winter and spring. Spotted seals resort to haulouts on land during ice-free seasons of the year. There are great seasonal expansions and contractions of range, commensurate with the annual cycle of sea ice advance and retreat. Their distribution in all areas is most restricted during the period of maximum ice cover. They occur in the Bering, Chukchi (in summer), Beaufort (in summer), and Okhotsk seas, Tartar Strait, the Sea of Japan, and the northern Yellow Sea/Bo Hai (Bohai Sea), and adjacent embayments that border China, and in summer the eastern Korean Peninsula. The most southern breeding populations (about 38°N) are in the Sea of Japan and the Yellow Sea. Their occurrence at these southern latitudes is because of a cold winter climate, dominated by the so-called Siberian High Pressure system that results in a limited sea ice cover during mid-winter.

In all areas, as the seasonal ice cover recedes and disintegrates, spotted seals expand their range and haulout on land. Some animals of the population that winters and pups on ice in the Bering Sea migrate northward into the Chukchi and Beaufort seas during the ice-free months. Their summer-early autumn distribution extends as far north as 71°30'N near Point Barrow, Alaska, and to about 70°N on the northern shores of Chukotka, Russia. Thus, the total range of the Bering Sea population extends over 15° of latitude or about 1665 km.

Spotted and harbor seals are sympatric (have overlapping ranges) in the southeastern and southwestern Bering Sea, on the Kamchatka Peninsula, in the Kuril Islands, and northern Japan. Similarities in general appearance and occurrence on land (sometimes in close proximity) have long contributed to the confusion about these two different species.

A. Abundance

Population sizes of harbor and spotted seals have fluctuated due to both natural and anthropogenic causes, including hunting, incidental taking, competition with commercial fishers for food, habitat alteration,

disturbance, protective measures, diseases, climate regime shifts, and other factors. Some populations are small and isolated; persisting in what may be marginal habitat. These may be the ones most vulnerable to changes in environmental factors and to direct exploitation. In general, direct exploitation has now been reduced greatly. Most populations are currently protected from hunting except under terms of special licenses or in areas where they are taken by indigenous peoples for subsistence purposes. Population estimates for some regions are fragmentary and in several cases outdated. For others, they are compilations of surveys in different subregions, on changing populations, sometimes several years apart. Nonetheless, they provide useful indications of regional abundance, and further illustrate this seals' coastal and insular distribution, primarily in the northern temperate zone.

In the middle 1980s there were perhaps 98,000 eastern Atlantic harbor seals (*P. v. vitulina*) (Reijnders *et al.*, 1993). By then populations had recovered after prolonged and sometimes intensive hunting and control programs. The largest numbers were and still are around the rim of the North Sea and Iceland. Areas of greatest abundance were in Great Britain (up to 47,000), Iceland (28,000), the Wadden Sea (10,000), and Kattegat/Skagerrak (6000). The smallest known populations are in the Baltic Sea (perhaps 200) and around Svalbard (500–600 in 1990). In 1988 a large proportion of some populations died from a viral epidemic: up to 48% in parts of southeastern Great Britain and an estimated 60% in the Wadden Sea and Kattegat/Skagerrak (Dietz *et al.*, 1989). These affected populations recovered rapidly and by 1992 there were an estimated 7250 seals in the Wadden Sea and perhaps 5200 in Kattegat/Skagerrak (Reijnders, *et al.*, 1993).

The current number of all western Atlantic harbor seals (*P. v. concolor*) is not known with certainty, but may be around 115,000. Data for Canadian waters are fragmentary and based largely on information from Sable Island, reported in Boulva and McLaren (1979). That population has declined. Baird (2001) summarized available information and suggested that perhaps 12,700 harbor seals, not including those of the Ungava Peninsula, may be in Canadian waters. In parts of eastern Canada, as well as in Greenland these seals are harvested for meat and for their beautiful hides, which are made into traditional clothing and other articles of Native handicraft (Teilmann and Dietz, 1994). About 100,000 seals occur in US waters (Waring *et al.*, 2007). Almost all are in Maine. That population has been increasing and, in 2001, was estimated to be about 99,300 (Gilbert *et al.*, 2005). There is no population estimate for Greenland. They were never abundant, and have apparently undergone a long-term decline. In the past they were more widely distributed, mainly in West Greenland. Fewer than 40 a year were harvested in Greenland in the late 1980s (Teilmann and Dietz, 1994).

The number of fresh water seals of the Ungava Peninsula is low and the estimate of 120 to perhaps 600 animals is uncertain (Reijnders *et al.*, 1993). The actual number is probably closer to the lower value. This includes the entire subspecies. Ungava seals are considered to be possibly endangered, vulnerable, and rare. That designation is based on a lack of information, a very limited range, low numbers, and potential threats from proposed development in the region. This subspecies may well be a relict, persisting in habitat that has been altered drastically and unfavorably by the natural geological processes of post-glacial land rebound (uplift) during Holocene and Recent times (Smith, 1999).

In the eastern Pacific region, harbor seals are abundant although as elsewhere numbers have fluctuated greatly. There is no estimate for the number in Mexican waters. In waters from California to Alaska the total may approach 350,000 of which 74,000 occur from California to Washington State (Carretta *et al.*, 2007), 75,000–88,000

in British Columbia in 1988 (Olesiuk *et al.*, 1990; Baird, 2001), and about 180,000 in Alaska (Angliss and Outlaw, 2007). The reported breakdown of those estimates for US waters is: 34,283 in California in 2005; 24,732 in Oregon and coastal Washington in 2003; 14,612 in inland waters of Washington in 2003 (Jeffries *et al.*, 2003); 112,391 in southeastern Alaska in 2006; 45,000 in the Gulf of Alaska including the Aleutian Islands in 2006; and 20,109 in southeastern Bering Sea in 2006. From California to southeastern Alaska they have increased over many years. In recent years the rate of increase has slowed or stopped, perhaps as these populations approach or reach an equilibrium level. In the Gulf of Alaska region the trend has been the opposite of that farther south, with an 85% decline between 1976 and 1988. These opposite trends in the southern and northern parts of their range are apparently mainly responses to a major shift in Pacific climate that began about 1976 (Ebbesmeyer *et al.*, 1991).

The range of the western Pacific harbor seal extends across the Aleutian Ridge to Asia. These seals are predominately of the dark color phase, they tend to occur in very small groups (as opposed to large aggregations), and they mainly occupy rocky islands and shorelines. Regional estimates of numbers are: Aleutian Islands, about 3400 in 1994 (Withrow and Loughlin, 1995); Commander Islands, 1500; Kamchatka Peninsula, 200; Kuril Islands, 1900; and northern Japan, 300. Estimates for the latter four areas are from the early 1990s (Reijnders *et al.*, 1993). They are classified as rare in Japanese and Russian waters, and are now protected from hunting.

There are no reliable estimates of the present size of spotted seal populations, except perhaps in the Bohai Sea. They are, however, common within all parts of their known normal range in the Okhotsk, Bering, and Chukchi seas. Various estimates, all of which have high levels of uncertainty, are noted by Trukhin (2005), including that of 290,000 in the 1990s, inclusive of all populations combined. Indirect and anecdotal information from Native subsistence hunters suggests that over the past two decades spotted seals of the Bering Sea may have slowly declined. If the perceived decline is real, it may be a response to changed food-web dynamics, and a greater frequency of less favorable sea ice conditions during late winter/early spring. This would be in accord with the numerical trend for harbor seals in the Gulf of Alaska and parts of the southeastern Bering Sea. Spotted seals are an important resource to American-Native subsistence hunters in coastal areas of the Bering and Chukchi seas, where an estimated 5265 a year may be taken (Angliss and Outlaw, 2007). There is no confidence interval associated with that estimate and it is questionably high. There is essentially no subsistence hunting in the Okhotsk Sea. Ship-based commercial hunting in both the Okhotsk and Bering seas was reduced during the late 1980s and finally ceased in 1995. The size of populations in the Yellow Sea, and the Sea of Japan, noted in Trukhin (2003), were 4000–4500 and perhaps up to 8000+, respectively. According to Dong and Shen (1991), in the Bohai Sea, including Liaodong Bay, there were an estimated 4000–4500 in 1990; the estimate subsequently included in Trukhin (2005). This compares with estimates of >7000 in the 1930s, >8100 in 1940, and 2269 in 1979, after a period of intensive harvesting. There is a report of as few as 1000 at the present time (Bo, 2006), although no substantiating information was included. In China, these seals were accorded protection from hunting in the 1980s.

III. Ecology

A. Foods and Feeding

Feeding forays of harbor seals can be close to haulout sites, or many miles distant, either along the coast (including rivers) or

seaward. They are capable of feeding at considerable depths (to 500+ m) and are generalists that prey mainly on abundant and easily available foods, with diets varying by season and region. There are long-term changes in foods that are associated with environmental changes, and therefore dynamic changes in the abundance of different prey species. Primary food items are small- to medium-size fishes (or age classes), such as various members of the codfish family, hake, mackerel, herring (*Clupea* spp.), sardines, smelts, shad (*Alosa* spp.), capelin (*Mallotus villosus*), sand lance, sculpins, a variety of flatfishes, salmonids, and many others. Their propensity for cod, salmon, and other commercially important species has resulted in long-standing conflicts with fishermen in many areas. Cephalopods (squid and octopus) are usually reported as being next important after fishes, followed by crustaceans including mainly shrimps and crabs. Several studies have reported that shrimp may be particularly important to recently weaned pups.

Although there is great diversity in foods, a few items usually comprise the majority of seasonal diets in an area. As examples, in Atlantic Canada, 23 different food items were identified but 4 accounted for 84% of the estimated biomass of prey consumed (Boulva and McLaren, 1979). In the Gulf of Alaska, fishes comprised 73.8% of the diet and 27 different species were eaten. The four most important foods were walleye pollock (*Theragra chalcogramma*), cephalopods, capelin, and flatfishes (Pitcher, 1980). In the western Aleutian Islands the main food items, at least in 1958 and 1962, were Atka mackerel (*Pleurogrammus monopterygius*) and octopus (Kenyon, 1965). The main foods of the Ungava seals are thought to be resident brook (*Salvelinus fontinalis*) and lake (*S. namaycush*) trout Smith, 1999). Seals in Lake Iliamna, Alaska, feed on the variety of salmonids [charr (*Salvelinus* spp.), trout, and salmon] that occur there in large numbers (traditional local knowledge).

The food habits of spotted seals are noted in several publications including Tikhomirov (1966); Lowry and Frost (1981); and Trukhin (2005). These seals are also generalist feeders, although in continental shelf waters, they primarily utilize similar types of abundant fishes, crustaceans, and cephalopods. Because they have a pelagic distribution in winter–spring and a different coastal and pelagic distribution during ice-free months, there are major seasonal and regional differences in food habits. Additionally, there are age-related differences. Most reports about food habits are based on seals examined during spring (mainly April and May) when they are associated with sea ice. A few samples are from animals collected in the coastal zone during autumn, and there are anecdotal observations of summer feeding, especially in areas where subsistence and commercial fishing activities occur. There are few data from the late autumn and winter months, although in the Bering and Okhotsk seas these seals occur where pollock, herring, eelpout, flounders, shrimp, and crabs are abundant.

Independent feeding by spotted seal pups begins after they are abruptly weaned. During the time of fasting and early independent feeding they live on their accumulated fat reserves and lose between 18% and 25% (sometimes up to 30%) of their weight (Burns, 1986). The first food consumed is frequently small amphipods or euphausiids. Abundant schooling fishes are the main foods of older seals and, in the Okhotsk Sea, occurred in 89% of seals 1–4 years old and 70% of seals >5 years old. Cephalopods were next in importance, followed by decapods. Amphipods were still consumed by the 1- to 4-year olds but were not found in older animals. The frequency of occurrence of cephalopods was higher in older age animals. Spotted seals were reported to feed more in the morning and evening than at other times of the day. During spring the main food items in the Bering Sea, depending on the region, were pollock,

arctic cod (*Boreogadus saida*), sand lance, and capelin. In the Okhotsk Sea, pollock were most important. In Peter the Great Bay (Sea of Japan) the dominant fishes were saffron cod (*Eleginus gracilis*), flounders, and rockfish, and in Tartar Strait (between mainland Russia and Sakhalin Island) they were saffron cod, flounders, and salmon. In all areas, crustaceans and cephalopods were also important. There has been little sampling in coastal habitats during summer when anadromous and coastal spawning fishes such as charr, salmon, capelin, smelt, herring, flounders, saffron cod, and other species are abundant. According to traditional local knowledge, those foods are utilized intensively by the seals.

B. Haulouts

As already noted, harbor and spotted seals are superficially quite similar in appearance. Harbor seals haul out mainly on land, although in some areas of mainland Alaska they use icebergs calved from tidewater glaciers. Also, in the northern parts of their range, where labile sea ice occurs to or very near shore, they haul out on it until the land sites are accessible, usually long before the pupping season. They use haulouts throughout the year, although most frequently and in greatest numbers during the pupping and molting seasons. Regardless of season, haulout activity is strongly affected by the stage of the tide, air temperature, wind speed, precipitation, and time of day. They lie close to the water when hauled out, and usually flee when disturbed. Habituation is not uncommon where regular and continuous, non-threatening, human activities occur, and they are not unduly harassed. The substrate at natural haulouts on land is diverse and includes mud flats, sand and gravel bars and beaches, rocks, glacial icebergs, and occasionally sea ice. Depending on the region, haulouts can be on lakes, rivers, estuaries, bays, ocean shorelines, islands, islets, ledges, and any other setting where the seals can rest, undisturbed, with immediate access to deep water. They may, on occasion, haul out on man-made structures such as docks, floats, and log rafts.

Spotted seals use sea ice starting with its formation in autumn (Burns, 1970). They often concentrate in large numbers on the early ice that forms near river mouths and estuaries (fresh water freezes at a higher temperature than seawater) and feed on autumn spawning fishes. As the ice thickens, becomes attached to land, and extends farther from shore, spotted seals move seaward into the drifting ice. Their association is mainly with the highly labile marginal areas and they move (southward in the Chukchi/Bering sea region) to maintain an association with that habitat. During the cold weather of winter they rarely haul out. Peak haulout on the ice is during the pupping and molting season.

As the sea ice cover retreats and disintegrates in late spring–early summer, spotted seals again move shoreward and, in the Bering Sea, northward. Again, large aggregations can often be seen close to shore on the last remnants of former shore-fast ice and on ice flushed from rivers and estuaries. At this time of year they feed extensively on the dense schools of spawning herring and smelt. They haul out on shore when the ice is gone. Between haulout bouts on land, some seals travel long distances in the open sea, even between Alaska and Siberia, and use multiple haulouts (Lowry *et al.*, 1998). Shore haulouts are mostly on isolated mud, sand, or gravel beaches, or on rocks close to shore. They are often on river bars, tidal flats, and barrier islands. Spotted seals are especially vigilant on land, where they are subjected to attack from a variety of predators. Their association with sea ice starts again as soon as it begins to form in the autumn.

IV. Behavior and Physiology

A. Mating System

In both harbor and spotted seals, mating occurs in the water at about the time that pups are weaned, although females mating for the first time or that have not given birth in a specific year may breed outside of the peak period of the post-parturient animals. There is intermale competition for females.

Harbor seal males use vocal behavior and display dives, within aquatic territories, for mate attraction and for male–male competition (Hayes *et al.*, 2004), that often involves vigorous fighting (Burns and Gol'tsev, 1984). The territories are near haulouts or along female traffic corridors, to maximize their exposure to estrous females, and they are polygynous. Thus, the locations are often fairly fixed over time. Males exhibit interannual fidelity to their acoustic display stations, which are within their larger territories (Hayes *et al.*, 2004).

The mating system of spotted seals is quite different than that of harbor seals (Burns, 1970, 1986). They begin to form pairs prior to or early in the pupping season, before females obtain estrus. They are considered to be annually monogamous and territorial. Triads consisting of a female, her pup, and an attending male can be seen on the ice, or with the attending male close by (Fig. 6). These triads are widely spaced, although there are regions of high abundance. In an environment of drifting and shifting ice floes the spacing suggests that aquatic vocal behavior by males is important, both to initially attract a mate and to maintain a shifting territory around her. Interestingly, adult male spotted seals do not have the assorted types of aggression wounds that are common on harbor seals during the mating season. Females attend their pups on the ice, especially during the early nursing period, and the males stay with the females. Pairs that include an adult female that did not pup are also formed. In the Bering and Okhotsk Seas, such pairs are seldom seen on the ice in early April (prior to the molt in adults), probably because there is no pup for the female to attend.

B. Molt

In harbor seals, the molt generally occurs during mid-summer to early autumn, within 2 or 3 months of the pupping season (Bigg, 1981). During the molt, seals haul out more frequently than at any other time of the year except for the pupping season. There are differences in timing among age and sex cohorts. Usually yearlings begin and end the molt earliest, followed by subadults, then adult females, and last, adult males. There is overlap among these general age groups. Throughout their extensive range the molt occurs after cessation of the breeding season. Accordingly, it occurs later in the year in the late breeding populations such as those in Europe, British Columbia, and Puget Sound.

Spotted seals of the Okhotsk and Bering seas molt mainly in late spring (Burns, 1970; Trukhin, 2005). Pups, as mentioned, have the color and pelage pattern of adults after their lanugo is shed. Older seals begin the molt immediately after the breeding season and show an overlapping age-related sequence similar to that of harbor seals. The period of intensive molt is during May and June, during which time the sea ice is retreating rapidly and deteriorating. In areas where the ice disappears early, or in minimal ice years, the molt is completed on shore haulouts and at sea.

V. Life History

A. Mortality Factors

Seal control programs, commercial hunting (now discontinued), large-scale die-offs due to epizootic diseases, and natural long-term population changes are known to occur in harbor seals. As examples, in late 1979 and 1980 an estimated 500 seals died along the New England coast, from an influenza virus of avian origin. Another less severe disease-caused die-off occurred in the same area in 1982 (Geraci *et al.*, 1982). The largest known incident of mass deaths occurred in northern Europe, during 1988–1989, when an estimated

Figure 6 A triad of spotted seals (*Phoca largha*) during breeding season, in Bering Sea: lanugo clad pup (right), the mother (center), and attending adult male (left, in the water).

18,000 harbor seals died due to a viral infection that rapidly spread among some colonies in the North Sea region. In all areas the populations had previously reached high levels after cessation of control programs (Dietz *et al.*, 1989). In the eastern North Pacific, south of the northern Gulf of Alaska, there has been a sustained long-term increase in numbers. Farther north they declined about 85% between 1976 and 1988 (Baird, 2001; Angliss and Outlaw, 2007). These changes in the eastern Pacific are probably mainly related to natural large-scale ocean regime shifts now known to have occurred. Nothing is known about natural fluctuations in spotted seals, although it is probable that they have also been affected by climate change and therefore changes in carrying capacity of their more remote environment.

The reported predators of harbor seals include killer whales (*Orcinus orca*), sharks, Steller sea lions (*Eumetopias jubatus*), eagles, ravens (*Corvus* spp.), and gulls. Spotted seals are preyed on by those same animals and also by walrus (*Odobenus rosmarus*), polar bears (*Ursus maritimus*), and arctic foxes (*Alopex lagopus*), as well as by shore-based predators such as brown bears (*Ursus arctos*), wolves (*Canis lupus*), wolverines (*Gulo gulo*), and red foxes (*Vulpes vulpes*). Indigenous peoples still harvest small numbers of both species of seals for subsistence uses. They are also occasionally taken incidentally in the course of other activities, particularly in commercial gill net fisheries for salmon.

B. Reproduction

In both harbor and spotted seals, mating occurs at about the time that pups are weaned (Bigg, 1969; Boulva and McLaren, 1979; Burns, 1986). As with all other pinnipeds, fertilization is followed by a prolonged period of delayed implantation (embryonic diapause) that lasts up to about 2.5 months, after which the embryo implants and resumes development. The total gestation period, from fertilization to birth, is about 10.5 months. In most populations, pregnancy rates exceed 85%; in other words, most sexually mature females bear a pup every year.

In general, female harbor seals reach sexual maturity at ages 3–4 years, and physical maturity by age 6 or 7 years. Males obtain sexual maturity at 4–5 years and physical maturity by 7–9 years. The maximum life span is around 35 years, although few animals live that long in the wild. They are reproductively active throughout their lives. All harbor seal populations have a similar reproductive cycle. However, over their very broad range the specific timing of events varies. Depending on the region in question, births occur in late winter to summer. Within a specific population the peak of pupping can shift slightly over time, apparently in response to significant environmental change. Additionally, there is some interannual variability. In general, the pupping season extends over a period of up to about 10 weeks, within which there is about a 2-week peak. Females bear a single pup although twinning has been recorded. In most regions, pups are born on land, usually between the high- and low-tide water lines. In some parts of Alaska pups are born on floating icebergs calved from tidewater glaciers in protected fjords.

Newborn pups can and do enter the water, often being forced to do so by tidal inundation of birth sites or because of disturbance by birds scavenging afterbirth. Mother–pup bonding is a critical phase of behavior within the first hour of birth, as mutual recognition is required to locate and/or remain with each other on rookeries and in the water. Young pups often cling to their mothers' backs in the water. Mothers feed during the approximately 4-week nursing period (some reports indicate as long as 6 weeks). Pups start to catch their

own food during the late stages of the nursing period, and some maintain an association with their mothers after weaning.

To put timing of the generalized reproductive cycle into a regional context, the peak period of pupping can be used as the benchmark event. For harbor seals of the European coast, most pupping occurs during late June and early July. In most of eastern Canada and Greenland, births are mainly during mid-May to mid-June, slightly later at higher latitudes (Boulva and McLaren, 1979; Gjertz and Børset, 1992). However, the Ungava seals reportedly pup during late April or early May (Smith, 1999). There are considerable differences among populations of the Pacific region (Temte *et al.*, 1991). Births occur during early February in Mexican waters; in March–April in southern California; in May along the outer Washington coast; between late June and September in Puget Sound and southern British Columbia; during May to late June in northern British Columbia, most of Alaska and Japan; and early June to late July (peak around July 1) in the Aleutian, Pribilof, and Kuril islands.

Spotted seals have the same basic reproductive cycle as harbor seals, although timing of events is directly related to the most favorable sea ice conditions at the time of birth through weaning (Burns, 1970). Those events have evolved to coincide with the average period of greatest extent and stability of seasonal ice (births), and the subsequent onset of its seasonal disintegration (weaning). The timing of these conditions varies by region.

Pups are born exposed on the ice and, during the first 2 or 3 weeks, are more like land mammals. They spend most of the time on ice floes, without benefit of snow lairs, until weaned (*cf.* Fig. 2). Their only protection from wind is that provided by their mothers or the shelter of ice ridges. The exposed and relatively immobile pups are not subjected to significant predation by polar bears or arctic foxes because the labile marginal ice in which they occur during spring is well south of the normal range of those predators. Polar bears and arctic foxes do not occur in the Okhotsk Sea or farther south.

Unseasonably early destruction and disintegration of the ice front zone, caused occasionally by severe southerly storms, probably results in a high mortality of nursing pups. During early life the dense coat of lanugo provides the required insulation for maintaining body heat, although that important function is assumed by the rapidly increasing blubber layer acquired during the 4-week nursing period. At weaning, most pups are heavier than at any other time during their first year of life. They are so fat and buoyant that they are poor divers. This large energy store provides sustenance during the early stages of adjustment to independent life.

Weaning, which is abrupt, coincides with the normal seasonal onset of ameliorating spring weather and disintegration of the seasonal ice cover. The use of sea ice as a platform on which to bear and nurture pups is central to the ecology of spotted seals. These events (birth, dependence during the nursing period, weaning, and early independence) are more restricted in time than is the case with harbor seals. Pups are born earlier in the more southerly parts of this species' range. In the Yellow Sea the peak period is during late January (Dong and Shen, 1991); in the Sea of Japan it occurs during February and March, and in both the Okhotsk and Bering seas the peak is during the first half of April. Mothers feed during the nursing period, although the pups remain on the ice, sometimes wriggling over brash ice to move between closely adjacent ice floes.

Pupping on land has been reported to occur on shores of the Bohai Sea and occasionally elsewhere. It occurs during years when, or in regions where, suitable sea ice is insufficient or absent (Trukhin, 2005; Bo, 2006). It may become more frequent as a result of global

warming. Spotted seal pups born and nurtured on land might sustain a higher incidence of mortality, due to their relatively long period of dependence, and slow development of aquatic capabilities.

VI. Interactions with Humans

A. Conservation Concerns

There are similar conservation concerns relevant to both harbor and spotted seals. The general problem of pollution from military, agricultural, and/or industrial activities (including coastal and offshore oil and gas development) is of particular concern because of its direct and indirect effects on seals and the foods they eat. Oil spills are and will continue to be a chronic problem. Major disease outbreaks may have been intensified because of suppressed immune responses caused by a variety of pollutants. The role of increased density dependent disease-caused mortality is not understood, but it may become more evident in populations that achieve or exceed the carrying capacity of available habitat. Hunting may still be an important factor in limiting or reducing some of the small breeding populations of harbor seals in Greenland and northeastern Canada. Fishing activities can affect both species adversely by causing incidental mortalities, and by competing for fish the seals depend upon for food. Fishery interactions are probably limiting any increase of the small populations of harbor seals in northern Japan and parts of Greenland. Development projects can alter or eliminate important habitat or displace seals by increased disturbance near haulouts. This would be most likely for spotted seals, as there are no known instances of habituation. Disturbance at shore haulouts, together with a low level of illegal hunting, are considered to be problems for small population of spotted seals in the Bohai Sea. They use summer haulouts in increasingly industrialized coastal areas of China and the eastern Korean Peninsula. The small relict population of Ungava seals may be particularly vulnerable to proposed hydroelectric projects within their limited range.

B. Climate Change

Climate change, specifically warming, will have major impacts on harbor and spotted seals. The contentious aspect of that important issue is the extent to which natural change is being exacerbated by anthropogenic effects. Climate has changed many times in the past and has been an important force affecting zoogeography, population fluctuations, extirpation, and extinction. Global warming is definitely causing later formation and earlier breakup, and reducing the extent and thickness of seasonal sea ice. It might well result in an increase of suitable habitat for harbor seals in the north, and an overall decrease of spotted seal habitat, especially in the southern parts of its range.

Harp Seal

Pagophilus groenlandicus

DAVID M. LAVIGNE

I. Characteristics and Taxonomy

The harp seal is one of the most abundant and best known of all pinniped species. Referred to by most scientists by the Latin name, *Pagophilus groenlandicus* (Erxleben, 1777), which means the ice-lover from Greenland, it is still sometimes called *Phoca groenlandica*, the Greenland seal. Its common names, the harp or saddleback seal, come from the black wish-bone or harp-shaped marking found on the backs of adults (Fig. 1). The faces of adults are also black, whereas the remainder of the body appears silvery-gray when dry. Young pups, which have a characteristic white pelt at birth, are known as "whitecoats" (Fig. 1).

Adult harp seals are about 1.7 m (5.6 ft) in length, with females being marginally smaller than males. Adults weigh about 130 kg (288 lbs) early in the pupping season, but their mass varies considerably throughout the year and from one year to the next. The adult dental formula is: I 3/2, C 1/1, PC 5/5 = 34.

II. Distribution and Abundance

The harp seal inhabits the North Atlantic and Arctic Oceans from northern Russia in the east to Newfoundland and the Gulf of St. Lawrence (Canada) in the west (Fig. 2). Its annual range is essentially tied to the southern and northern limits of pack ice and is largely coincident with the subarctic region of the North Atlantic.

Although some scientists recognize two subspecies, it is more common to refer to three distinct populations or stocks, based on geographic distribution and small morphological, genetic and behavioral differences. One population, found largely in the Barents Sea, reproduces on the "East Ice" in the White Sea off the coast of Russia. This population is designated by some Russian scientists as *P. g. oceanis* (Rice, 1998). A second population lives off the east coast of Greenland and breeds on the "West Ice" in the Greenland Sea near the island of Jan Mayen. The third lives in the Northwest Atlantic off the east coast of Canada and breeds in two locations: on the "Front" off the coast of Newfoundland and Labrador, and in the Gulf of St. Lawrence. The latter two populations are assigned to *P. g. groenlandicus* by some scientists (Rice, 1998).

Figure 1 Adult female harp seal with “whitecoat” pup. Photograph by N. Lightfoot.

Figure 2 Harp seal distribution in the North Atlantic Ocean. The four red circles indicate major pupping areas (see text for details).

The Northwest Atlantic harp seal population is the largest of the three. Population size was estimated to be 5.5 million in 2007 (95% CI = 3.8–7.1 million), not significantly different from the 2005 population estimate of 5.8 million (95% CI = 4.1–7.6 million)

(Department of Fisheries and Oceans, 2007). The most recent estimate of population size for the West Ice population is 634,960 (95% CI = 425,140–844,860) animals aged 1 year and older (1+) and 106,710 ($\pm 35,041$) pups in 2005 (ICES, 2006).

Population size for the White Sea population was estimated at 2,064,600 (95% CI = 1,496,520–2,633,480) 1+ animals, and 360,880 ($\pm 62,279$) pups, also in 2005 (ICES, 2006).

III. Ecology

Harp seals exhibit catholic feeding habits, which vary with age, season, location, and year. While at least 67 species of fin fish and 70 species of invertebrates have been recorded in their stomachs (Wallace and Lawson, 1997), harp seals tend to concentrate on smaller fishes such as capelin (*Mallotus villosus*), arctic cod (*Boreogadus saida*), and polar cod (*Arctogadus glacialis*), and a variety of invertebrates, including euphausiids (*Thysanoessa* sp.). Harp seals rarely eat Atlantic cod, *Gadus morhua*, the biomass of which has been reduced by more than 99% in the Northwest Atlantic since the early 1960s, largely due to overfishing (Hutchings, 2006).

Before the collapse of cod, predation by harp seals in the northern Gulf of St. Lawrence accounted for 1% of large cod mortality, whereas fishing accounted for 46%. Morissette *et al.* (2006) concluded that seals play an important role in maintaining the structure of the ecosystem and, overall, have a positive impact on marine ecosystems.

Harp seals are prey for polar bears (*Ursus maritimus*), killer whales (*Orcinus orca*), and sharks (e.g., *Somniosus microcephalus*). Their major predator, however, is *Homo sapiens*.

IV. Behavior and Physiology

Harp seals are highly migratory animals that spend most of the year at sea, traveling and feeding, sometimes in groups (Fig. 3), sometimes alone. They are particularly gregarious during the breeding season, when most adult females haul out on ice to give birth and nurse their pups. Adult males congregate nearby, waiting to participate in mating once the pups are weaned. Harp seals exhibit little sexual dimorphism and appear to have a promiscuous breeding system.

Harp seals maintain a thick blubber layer that not only provides insulation against the heat-draining properties of cold water but supplies a rich source of energy that can be used during fasts and when food is scarce. Blubber also rounds out the body contours to streamline the seal's body and reduce drag when swimming. In addition to providing propulsion in water, the flippers serve to regulate heat loss by means of countercurrent heat exchangers. Harp seals also have brown fat that can be used to warm cool blood returning from the periphery, just as neonatal harp seals use brown fat for rapid heat production. Among the behavioral means of reducing heat loss, harp seals on ice can keep their fore flippers held against their bodies and their hind flippers pressed together to reduce the exposed surface area and thereby conserve heat.

Such adaptations seem adequate for maintaining homeothermy, even in cold climates. The evidence is that harp seals, like other marine mammals, do not need (or have) elevated metabolic rates or huge appetites to meet their energy demands, either on land or in water (Lavigne *et al.*, 1986; Innes *et al.*, 1987).

Harp seals are modest divers. Average maximum dive depth is 370 m (1214 ft) and mean dive duration is about 16 min (Schreer and Kovacs, 1997).

Vision is the harp seal's primary sense. The harp seal eye is relatively large, covered by a cornea that is constantly lubricated by tears

Figure 3 A group of harp seals moving northward in the Gulf of St. Lawrence. Photograph by IFAW/S. Cook.

produced by lacrimal glands to protect it from salt water. Unlike the eyes of terrestrial mammals, the seal's eye lacks tear ducts to drain away the tears, which explains why harp seals often appear to be crying. The harp seal eye has a large spherical lens to provide additional focusing power under water and a highly mobile pupil which contracts in bright light to produce a reasonably focused image, even when the animal is on land or ice. Visual sensitivity in dim light is enhanced by the harp seal's rod-dominated retina, backed by a reflective tapetum lucidum, reminiscent of that found in cats. The rod visual pigment exhibits maximum sensitivity in the blue-green region of the spectrum, consistent with Lythgoe and Dartnall's "sensitivity hypothesis" (Lavigne and Ronald, 1975). Harp seals also have cone photoreceptors (Nagy and Ronald, 1970) for vision in bright light, which possibly allow some form of color vision. Like other ice-dependent seals, the harp seal cornea tolerates the high levels of ultraviolet radiation found in bright, snowy environments, thereby avoiding "snow-blindness" (ultraviolet damage to the cornea), an affliction that plagues humans in such environments.

Harp seal hearing is also adapted to function both in air and under water. In air, the seal's hearing range is similar to that of humans although not quite as sensitive. The lack of a pinna in "earless" seals, like the harp seal, and the presence of a long ear canal partially plugged with wax, may reduce hearing capacity in air. Under water, the hearing range is extended to more than 60,000 Hz and, over those frequencies heard in both air and water, the harp seal actually hears better under water. Even more remarkably, seals possess good directional hearing both in air and under water.

Harp seals are known for their varied vocalizations during the breeding season. While their vocalizations on ice are relatively few (e.g., "bawling" vocalizations of hungry pups calling for their moms, "mumbling" sounds observed in playing pups, and threatening growls and "warbling" associated with agonistic behaviors in older animals; Kovacs, 1987), at least 19 call types have been identified in wild harp seals under water during courtship and mating (Perry and Terhune, 1999). The extent to which wild harp seals vocalize outside the breeding season remains unknown. Despite their "high-frequency" hearing under water, there is no evidence that harp seals are capable of echolocation.

Figure 4 A female harp seal identifies her pup. Photograph by IFAW/S. Cook.

Harp seal females often use their sense of smell to identify their own offspring during the nursing period (Fig. 4). Their sense of smell may also allow harp seals to detect approaching predators when on ice. In water, however, seals keep their nostrils tightly closed and their sense of smell is of no use.

Harp seals also have well developed, beaded whiskers, called vibrissae, arranged in horizontal rows on both sides of the snout. There is some evidence that the vibrissae provide tactile information, as they do in other carnivores, including cats. Their vibrissae are also sensitive to low frequency, waterborne vibrations and may function to detect the movement of fish and other aquatic organisms.

V. Life History

Female harp seals congregate near the southern limits of their range (Fig. 2) from late February to mid-March (depending on location) to give birth to their white-coated pups. Each female gives birth

Figure 5 Molted harp seal pup or “beater,” aged about 4 weeks. Photograph by IFAW/S. Cook.

to a single pup, although twin fetuses have been reported. Newborn pups weigh about 11 kg (24 lbs) at birth and lack the thick insulating layer of blubber found in older seals. Pups are nursed on a fat-rich milk for about 12 days, during which time they deposit a thick (ca. 5 cm or 2 in.) blubber layer and grow at about 2.2 kg (5 lbs) per day. During this time they pass quickly through a number of recognizable developmental stages. At weaning the pups weigh, on average, 36 kg (80 lbs). At this stage they are known as “graycoats” because their spotted, gray juvenile pelage has grown in and can be seen beneath the white neonatal coat. Shortly thereafter, the white coat becomes loose and, within a few days, it begins to fall out. Once the white coat is completely molted, exposing the black-spotted, silvery-gray pelt of the young harp seal, the animal is called a “beater” (Fig. 5).

At the age of about 13–14 months, young harp seals undergo their second molt; the “beater” pelt is replaced by a similar spotted pelt and the animals are renamed “bedlamers.” Bedlamers retain the spotted pelt through successive annual molts until the spots begin to disappear and the dark, harp-shaped pattern of the adult coat begins to emerge. Older harp seals with a combination of the spotted bedlamer pelt and the distinct adult “harp” are called “spotted harps.”

The transition from the bedlamer pelt to the adult pelage begins with the onset of sexual maturity. In 2001, the mean age of sexual maturity for females was about 5.3 years (Sjare *et al.*, 2004). Most male harp seals, which possibly mature later than females, develop the black “harp” marking abruptly, whereas in females the transition is more gradual and may take many years. Some female harp seals never lose all their spots or develop a complete “harp” (Lavigne and Kovacs, 1988). Any seal with a complete harp and black face may be aged anywhere from about 5 to 30+ years—the life expectancy of the species.

Weaning in harp seals is abrupt. The adult females simply leave their pups on the ice and turn their attention to mating. Mating usually occurs in the water (Lavigne and Kovacs, 1988) but has also been photographed on the ice. The fertilized egg divides several times, forming a spherical embryo that floats freely in the womb for more than 3 months before implanting in the wall of the uterus. This type of suspended development—known as delayed implantation—ensures that all females give birth to their pups at the same time each year when the short-lived pack ice is available as a whelping platform.

Meanwhile, the weaned pups remain on the ice and undergo a post-weaning fast. This fast may last upward of 6 weeks, during which the weaned seals may lose up to half of their body mass as they draw on their thick blubber layer for sustenance. Eventually,

they enter the water, or the ice melts beneath them, and they begin swimming and feeding on their own.

After mating, older harp seals congregate once again on pack ice farther north to undergo the annual molt. Following the molt, in which the pelt and surface layers of skin are replaced, the seals continue their migration to summer feeding areas in subarctic and arctic waters to the north. All three populations exhibit similar patterns of annual migration, although the timing of specific events, such as pupping, mating, and molting, varies slightly among populations.

VI. Interactions with Humans

All three harp seal populations have been hunted by humans for centuries, and all three have undergone documented declines in numbers as a result of over-exploitation. And all three continue to be hunted today.

The commercial hunt for Northwest Atlantic harp seals, which occurs mainly after the spring whelping season, remains the largest hunt for any marine mammal population in the world. Over 1 million seals were killed between 2004 and 2007, inclusive, of which more than 95% were pups under the age of 3 months. The Total Allowable Catch (TAC) for Canada’s 2007 commercial seal hunt was 270,000, which was higher than the estimated replacement yield (the number of seals that can be removed from the population without causing it to decline from one year to the next) of 165,000. This population is also hunted in the eastern Canadian Arctic (some 800 animals per year) and off the west coast of Greenland (currently about 70,000–90,000 animals per year) during the summer months.

For harp seals breeding on the West Ice, the TAC for 2004 was set at 15,000 1+ animals, or an equivalent number of pups (where one 1+ animal = two pups), almost double the estimated sustainable catch level for this population of 8200 1+ animals. Catches in 2004 and 2005 were 9895 (including 8288 pups) and 5808 (including 4680 pups), respectively (ICES, 2006).

For the White Sea population, the 2004 TAC was set at 45,000 1+ animals (or an equivalent number of pups, where one 1+ animal = 2.5 pups). The reported catch for this population in 2005 was 22,474 (including 15,420 pups) (ICES, 2006).

Over-exploitation, particularly in the Northwest Atlantic, and the largely unregulated trade in seal products (especially seal skins, seal oil, and penises) in the absence of a precautionary management approach (e.g., Johnston *et al.*, 2000; but see Hammill and Stenson, 2007), remain potential threats to the species. Other frequently cited threats involve proposals to cull harp seal populations ostensibly to benefit commercial fisheries, including recently proposed “seal exclusion zones;” incidental catches in fishing gear; environmental contaminants; and reduced food availability due to overfishing.

Today, the most serious threat is global warming and its potential effects on ice-breeding harp seals (Johnston *et al.*, 2005). In 10 of the 12 years between 1996 and 2007, there has been below average ice cover off Canada’s east coast. The lack of suitable ice, combined with violent storms, and early ice break-up, disrupts the harp seals’ normal pupping season. This can result in increased abortions if female seals do not find ice upon which to give birth, or increased mortality of newborns if the ice breaks up before the end of nursing. In 2002, Canadian government scientists estimated that 75% of pups born in the southern Gulf of St. Lawrence died even before the annual seal hunt began; in 2007, almost all the pups born in that region may have suffered a similar fate. Such effects, in any given year, result in reduced cohort (year-class) size and have longer-term implications for population size and trends.

If warm years with reduced ice coverage become the norm, as appears to be happening, there will be additional effects. These include effects on timing of reproduction and the loss of critical breeding habitat. They also include effects on the distribution and abundance of fish and invertebrates, leading to further changes in availability of prey for harp seals, and ripple effects on seal condition, growth, reproductive success, and survival.

Health

JOSEPH R. GERACI AND VALERIE J. LOUNSBURY

The health of an animal is linked to age, behavior, and environment. Like terrestrial species, marine mammals are subject to infection, injury, and metabolic disturbances. Our understanding of marine mammal health is impeded not only by the difficulties inherent in studying these species in the wild, but also by their unique biology. Today, the challenge is compounded by human impacts on the health of marine mammals and their environment.

I. Adaptations to Life at Sea

Cetaceans, sirenians, pinnipeds, and sea otters (*Enhydra lutris*), all taxonomically distant, have evolved similar biological mechanisms to cope with a marine existence (Elsner, 1999). These include biological and behavioral strategies for controlling body temperature, diving, maintaining salt and water balance, and promoting reproductive success—adaptations vital to health and survival.

A. Temperature Balance

Other than tropical waters, the sea is always colder than a mammal’s body temperature. Water conducts thermal energy about 20 times faster than air, so even a few degrees difference can be enough to drain vital heat reserves. To counter this, marine mammals have evolved numerous mechanisms, of which blubber arguably tops the list. More or less a fatty envelope, blubber in cetaceans and certain pinnipeds offers mechanical protection, warmth, buoyancy, nutrients when food is scarce, and fresh water in reserve. Otariid pinnipeds, having thinner blubber and less body fat than phocids or the walrus (*Odobenus rosmarus*), are thus less tolerant of cold and depend to a certain extent on their pelage for insulation. This is especially true for otariid pups, which may not acquire an adult coat or adequate fat until they are about 3 months old and, in the meantime, are prone to hypothermia when they become wet. Species with less blubber rely on other strategies. The sea otter depends entirely on a high metabolic rate (and high caloric intake) to generate heat and on its dense, well-groomed fur to prevent heat loss. The living sirenians, with low metabolic rates and little ability to control surface heat loss, are narrowly restricted to tropical and subtropical waters.

Environmental temperature has more than a subtle bearing on health. To survive in a cold climate, a marine mammal must be robust, appropriately insulated, and have all surface heat control mechanisms operating. If not, the only recourse is to increase metabolic rate and either eat more or borrow fat from vital fat reserves. Ironically, as a last measure to conserve heat, pinnipeds and sea otters may haul out on land where the prospect of feeding is hopeless.

Can a marine mammal be too warm? Not if it is healthy and in the right place. In a warming environment, a whale may eat less and metabolize blubber, which effectively reduces insulation, and shed excess heat by increasing blood flow to the skin, particularly of the extremities. On land a wet seal or sea otter may get some comfort from evaporative cooling, and to avoid overheating when dry, it relies mostly on circulatory and behavioral adaptations (e.g., seeking shade, sleeping, moving to the surf zone). These strategies work to a point. A sea otter out of water can become distressed at air temperatures as low as 10°C and die within hours at 21°C. A cetacean stranded on a sunny beach can literally cook inside its own blubber.

B. Breathing and Diving

Marine mammals forage at all depths. Sea otters and sirenians, which feed in relatively shallow waters, have little need to dive deeply or for more than just a few minutes. Some species of phocids and odontocete cetaceans, however, make sustained dives to 600–1000 m or more, where they must cope with extraordinary pressures, periods of a half hour or more without oxygen, and the potential accumulation of deadly nitrogen. How do they adapt?

During a prolonged dive, circulation to the skin and viscera may almost cease, allowing oxygen to be channeled to organs that need it most, such as the heart and brain. A long, deep dive—whether to feed, explore, or escape—requires a shift to anaerobic metabolism, which is physiologically exhausting and therefore needs to be highly managed. So for the most part, marine mammals are adapted to feed within the depth and time limit of their aerobic diving capacity. That, in turn, is governed by the size, age, and health of the individual. Because of their relatively greater capacity to store oxygen, large animals tend to be better divers. It is not surprising that juveniles may find it difficult to reach prey that is easily accessible to adults.

C. Salt and Water Balance

The osmotic concentration of the sea is nearly 4 times greater than that of mammalian body fluids. Chemical equilibrium thus favors both loss of body fluids into the sea and encroachment of salts into the animal. Marine mammals have strategies that stop this from happening: (1) external surfaces are impermeable to seawater; (2) body water is highly conserved—sweat glands are either reduced or absent and the kidneys efficiently concentrate urine; (3) they drink little seawater and acquire most of their fresh water from food (water makes up about 70% of a fish, 80% of a squid, and over 90% of aquatic plants, and each gram of dietary fat or blubber they metabolize yields close to its weight in fresh water). In pinnipeds and cetaceans, the physiological response to stress is also designed to conserve water. During stress, the adrenal gland produces aldosterone, a hormone that induces the kidney to draw salt and water from what would otherwise form urine, back into the body. Maintaining this delicate salt and water balance depends, among other factors, on adequate blubber, well-functioning kidneys, proper hormonal balance, an intact epidermis, and—above all—good health.

D. Strategies for Rearing Young

The social, physical, and biological conditions that together create a healthy environment are especially critical during the period of an animal's life when it depends entirely on its mother. Just how critical that period is depends on the species, location, patterns of maternal care, and environmental conditions, and can be quite predictable. For example, pinnipeds that disperse for much of the year

regroup to give birth and mate again at a certain time and place. While obviously effective for the population, the resulting crowding on the rookery poses a risk of serious injury, super-infection by parasites, and disease transmission—ironically more often in the pups than the adults.

II. What Can Go Wrong?

Body systems work together, all complementing one another. Impairment of one system can disturb the entire equilibrium, leading to secondary problems, which then threaten the animal's health (Gulland *et al.*, 2001; Geraci and Lounsbury, 2005). For example, blubber is a protecting blanket, hydrodynamic shield, and a source of energy, insulation, water reserves, and buoyancy. In the simple case where food is scarce and blubber depletion the outcome, all its benefits are under attack. To name a few, the animal gradually becomes less able to rest at the surface, maintain body heat, forage, escape predators, or keep up with a group. The ensuing stress may open the door to disease, further weakening the animal. The situation naturally exacerbates if blubber loss was caused by illness in the first place.

Injuries and illnesses are not always apparent and are often detected only after analyzing blood or tissue samples from a living animal or dissecting a dead one. Even careful study might not reveal serious biochemical and physiological conditions. Stress is poorly understood and its effects difficult to quantify. What little is known about the process in marine mammals shows that it can disrupt thyroid and adrenal gland function, water and electrolyte balance, and metabolism and reproduction, and can lower the number of certain blood cells that support an animal's immune system and protect it against parasitic infection (St. Aubin and Dierauf, 2001).

A. Reproductive Failure and Death of the Newborn

Reproduction in animals is an orderly, coordinated progression of biological and behavioral dynamics. Weakness or disruption at any point can lead to failure, evident as abortion, stillbirth, premature birth, or weakness or death of the newborn. The causes of reproductive failure are often obscure, particularly in species that cannot be studied from shore.

In some species, the risk of abortion or stillbirth appears to be greater for first-time mothers. Young mothers are usually smaller and may give birth to smaller offspring that are more vulnerable to hypothermia and injury. The health and nutritional condition of any mother, regardless of age or size, affects the fetus. In some pinnipeds, decrease in prey abundance associated with El Niño events has been linked with decreased fertility, increased abortions, and reduced pup production (Trillmich *et al.*, 1991). The same outcome befell harbor seals (*Phoca vitulina*) in Europe that were swept by a morbillivirus epidemic. Using history as a guide, when launching any study of a population experiencing serious reproductive failure, the compass swings toward environmental disruption, epidemic disease, reduced prey stocks, or high levels of certain anthropogenic contaminants (Geraci *et al.*, 1999).

B. Starvation

Marine mammals spend much of their time searching for food of the appropriate type, size, and quality to satisfy needs that vary seasonally and with age. Some animals, e.g., dependent young, the sick, and the very old, can starve even when prey are plentiful. Many factors determine how long an animal can survive without food: its age,

fat reserves, metabolic rate, energy demands, and general health. Large animals with low metabolic rates survive longer than those with high energy demands, such as small species, newborn, and growing pups. Baleen whales may feed very little for 6–8 months of the year, but a sea otter without food for even 2 days can die from the complications of starvation. Put into perspective, starvation is a major cause of death in pinniped and sea otter pups.

Throughout the period of dependency, a young animal's survival hinges on the health of its mother. Before giving birth, a phocid seal or baleen whale must develop ample fat reserves to carry it through a period of fasting or reduced feeding during lactation. The pup or calf born of a malnourished mother is at risk from the moment of birth and its longevity is compromised early in its development.

The young of species in which females feed continuously during lactation face a different threat. A bottlenose dolphin (*Tursiops truncatus*) calf depends on the state of its mother's nourishment throughout what may be a year or more of nursing. More subtle is an otariid pup's risk of starvation if a shift in prey abundance forces its mother to spend longer periods away from the rookery.

Weaning frees a young animal from dependence to face the challenge of providing for itself. Manatees (*Trichechus* spp.) and some cetaceans and otariids remain with their mothers long enough to learn foraging skills. Not so for all sea otters. Newly independent juveniles, handicapped by their high need for food and inexperience gathering it, often starve. Females are singularly vulnerable because they tend to remain within a prescribed range, even when prey there becomes depleted.

Depletion of food stocks, whether from overgrazing, overfishing, or climatic or oceanographic fluctuation, can affect entire populations. Food scarcity in one area may cause some animals to move elsewhere. When food abundance changed during the El Niño of 1982–1983, California sea lions (*Zalophus californianus*) moved northward, and many northern fur seals (*Callorhinus ursinus*) may have emigrated from San Miguel Island to rookeries in the Bering Sea. Some animals are unable or unwilling to make such excursions, e.g., females with pups, territorial males, or populations in remote ranges. When fish disappeared from surface waters around the Galapagos Islands during the 1982–1983 El Niño, widespread starvation of the islands' fur seals (*Arctocephalus galapagoensis*) soon followed (Trillmich *et al.*, 1991).

Starving animals eventually die—some quickly, as would a pup deprived of milk or a sea otter overcome with hypothermia and exhaustion. Others die after a period of illness triggered by malnutrition and mediated by factors such as hypothermia, dehydration and electrolyte imbalance, hormonal disturbances, and infection by parasites and opportunistic pathogens (Geraci and Lounsbury, 2002). Some starving seal pups may ingest whatever is nearby—gravel, stones, or grass—and consequently die of an impacted stomach.

While a sudden shortage of prey may cause outright, widespread starvation, the more subtle effects of nutritional stress, including low productivity and decreased juvenile survival, may prove equally damaging to a population.

C. Direct Environmental Effects

Extreme weather conditions can take a toll on all age classes. Intensely cold winters have killed up to 2% of the Florida manatee (*Trichechus manatus latirostris*) population, mostly juveniles. Storms hitting a crowded pinniped rookery during breeding season can leave pups hypothermic, battered on rocks or drowned, separated from their mothers and starving, or victims of adult aggression. Unusual ice conditions can be hazardous even for cold-water species. Sea otters

trapped out of water by heavy ice die of starvation, stress, and shock. An untimely freeze in polar waters can trap cetaceans in ice where they may ultimately suffocate or starve. Severe storms and unseasonable warm weather can fracture ice floes that crush large numbers of breeding seals and their pups, sometimes affecting the entire year's production. The early retreat of Arctic sea ice observed in recent years may force nutritionally stressed Pacific walrus mothers—deprived of the platform essential for rearing young and reaching vital feeding grounds—to abandon their calves (Cooper *et al.*, 2006).

D. Trauma

For most marine mammals, the risk of injury is continual, whether from natural sources, such as storms, predators, and aggressive encounters, or human activities, such as fishery operations and recreational boating. For example, injuries are common on pinniped rookeries where pups often are trampled accidentally or attacked by adults, fall into gullies or crevices, or wash off unprotected beaches into pounding surf. Adults can be victims as well, as bulls compete for territories and females, and females compete for space.

Historically, commercial hunting had serious impacts on certain species or stocks of marine mammals. Today, more animals die in accidents. Interaction with fishers is a leading cause of death and injury: pelagic odontocetes die in purse seines and drift nets, coastal cetaceans and pinnipeds in gill net and trawl fisheries, and some river dolphins from fishing methods that use electricity and explosives. Marine mammals thought to compete with commercial operations may be deliberately shot.

Discarded net fragments, ropes, packing bands, monofilament line, and other debris also put animals at risk (Laist *et al.*, 1999). The effects of entanglement on populations vary: some suffer significant impact, others do not. For the individual victim, the problem is always serious. An animal that does not drown immediately may escape with fractures and internal injuries or may carry net fragments, ropes, or bands that increase drag, impede swimming ability, or become snagged. A seal pup growing into its packing-band “collar” will eventually die, either from suffocation or from deep cuts and infection.

Coastal dwellers are especially prone to certain injuries from human activities. For example, dugongs (*Dugong dugon*) in Queensland (Australia) waters have died in shark nets set to protect public beaches. Right whales (*Eubalaena glacialis*) in the Northwest Atlantic and manatees in Florida are injured or killed by collisions with vessels in coastal channels at rates that jeopardize their populations. Cetaceans—especially beaked whales—may be injured and strand after exposure to high-intensity underwater sound, such as that associated with naval sonar operations. Studies of cetaceans involved in such events show evidence consistent with acute decompression sickness, or “the bends” (Jepson *et al.*, 2003)—a condition previously thought to have dropped out of the cetacean gene pool.

E. Predation

There are times in a marine mammal's life when it draws the attention of predators. Probably the easiest meal is a small, inexperienced animal that can be found in a particular place on schedule—criteria often met by young pinnipeds, whether on land or ice or at sea. As some examples, arctic foxes (*Alopex lagopus*) and polar bears (*Ursus maritimus*) break into ringed seal (*Pusa hispida*) birth lairs to take pups and, sometimes, their mothers. Steller sea lions (*Eumetopias jubatus*) on the Pribilof Islands eat young northern fur seals (*Callorhinus ursinus*) that venture into the water. Southern sea lions (*Otaria flavescens*) raid South American fur seal (*Arctocephalus*

australis) rookeries, driving away the adults and killing pups. Leopard seals (*Hydrurga leptonyx*) consume large numbers of crab-eater seals (*Lobodon carcinophaga*) from the time the weaned pups leave the safety of the ice until they are several months old and large enough to escape attack. Killer whales (*Orcinus orca*), working in teams, patrol pinniped rookeries, washing seals into the water or even chasing them onto a beach; other pods may attack baleen or sperm (*Physeter macrocephalus*) whales. In the Aleutian Islands, killer whales facing reduced abundance of pinniped prey may have turned to sea otters, perhaps contributing to the dramatic decline in local sea otter populations over the past few decades. Sharks pose a danger to many species or populations, including the Hawaiian monk seal (*Monachus schauinslandi*).

The impact of a predator can extend beyond its effect on the individual prey. Killing a pregnant mother with a dependent young removes not one, but three animals from the population. A female northern elephant seal (*Mirounga angustirostris*) may recover rapidly from a shark attack, as many seem to do, but may be less able to nurse her pup and is unlikely to mate in the compressed breeding season. In this case, a single attack, while only injuring the mother, may have cost the population two pups.

F. Parasites

Almost all marine mammals are infected by parasites by the time they are weaned or shortly afterward. Most of these parasites have evolved with their hosts and, under normal circumstances, cause little damage to otherwise healthy animals. Among these are the amphipods and copepods that eat bits of whale skin, seal lice that normally occur in small numbers and consume insignificant amounts of blood, and gastrointestinal helminths (“stomach worms”). Others are harmful enough to affect the well-being of individuals and even segments of a population. For pinnipeds, these include heartworms, some lungworms, and the hookworm *Uncinaria lucasi*; and in cetaceans, the nematodes *Crassicauda* spp. (in the mammary glands, cranial sinuses, and kidneys) and the trematodes *Nasitrema* spp. (in the cranial sinuses) and *Campyla* spp. (in the liver and pancreas).

Consequences can be unexpectedly serious when individuals are exposed to parasites for which they have evolved no tolerance. Two such parasites have been implicated in about 40% of California sea otter deaths in recent years (Kreuder *et al.*, 2003). Marine mammal infections with the protozoan *Toxoplasma gondii*, a parasite of cats, may be one example of “pathogen pollution,” as oocysts shed in cat feces enter coastal waters in runoff and sewage. In sea otters, infection may have little apparent effect or may lead to encephalitis, heart disease, or abnormal behavior that increases the risk of shark attack. Infection with the acanthocephalan *Proflicollis* spp. is acquired through ingestion of infected mole crabs (*Emerita* spp. and *Blepharipoda* spp.), items traditionally not included among the sea otter’s preferred prey. This parasite actively penetrates the intestinal wall, causing fatal peritonitis.

Any parasite can become destructive when the mechanisms that maintain the host–parasite balance break down, as they do when an animal is ill or starving. Prolonged stress, by retarding wound healing and destroying protective blood cells, can set the stage for a parasite to do real harm. It is no surprise that debilitated animals that strand ashore often suffer from serious parasitic conditions.

An animal’s parasite burden can offer clues to its overall health and to changes in its environment, such as alterations in prey abundance. Certain seal lice that transmit heartworm feed and proliferate on the animal only on land. Any illness that causes the seal to spend

more time ashore assures that both the lice and the heartworms will flourish by sapping what is left of the animal’s energy. To find the cause of the animal’s original illness, one must go deeper than the tempting diagnosis of louse and heartworm infestation. A fast-swimming odontocete offers barnacles little opportunity to attach; the presence of species such as *Lepas* spp. or *Xenobalanus* spp. on a dolphin’s flukes or dorsal fin suggests that the animal has been moving unusually slowly, a common sign of illness. Differences in parasite fauna can indicate differences in feeding habits or prey availability: walruses feeding on benthic invertebrates have few if any nematodes in their stomachs, whereas those that eat fish have more. The relationship between diet and parasitism is predictable enough that variations in parasite burden are used to distinguish populations and help identify segregated social groups.

G. Microorganisms

Microorganisms of all kinds—bacteria, fungi, and viruses among them—abound in the sea. Some are of the types found on land and in land dwellers; others, including certain *Vibrio* bacteria, thrive only in aquatic habitats. Like terrestrial mammals, marine mammals harbor many organisms that are considered normal. Few of these are necessarily pathogenic, meaning they do not always cause infectious disease, but some are more threatening than others (Dunn *et al.*, 2001; Kennedy-Stoskopf, 2001). The fine line between infection and infectious disease depends on both the aggressiveness of the organism and the susceptibility of the host, that is determined by the condition of its immune system. Age is also a factor. A very young animal may benefit from maternal antibodies, that protect it against organisms with which the mother has earlier come into contact. The pup or calf then develops its own active immune capability, which affords increasing protection until its declining years, when immune function once again weakens. For these reasons the very young and the very old are more likely to acquire infections. Of course, natural and human-related stresses may compromise immune function in animals of all ages.

1. Bacteria The nature and severity of bacterial infections can be influenced by the animal’s behavior and age, and environmental conditions. Habitat also plays a determining role. A phocid pup born on clean sand is less likely to acquire a serious navel infection as it drags its unhealed umbilicus across the rookery than a pup born in areas fouled by feces, stagnant water, or decaying vegetation. For pups in fouled environments, bite wounds provide another route for infection by bacteria such as *Streptococcus* and *Corynebacterium* (Baker, 1984).

Infections are sometimes predictable. During molt, seals slough skin and hair. In northern elephant seals the process is exaggerated and large sheets of epidermis are lost; many animals, particularly yearlings, come ashore with skin infections during this time. Weddell seals (*Leptonychotes weddellii*), which use their teeth to maintain breathing holes in ice, and sea otters that feed on hard-shelled prey grind down their teeth to such an extent that they develop abscesses and bone infection.

A few bacteria are inherently pathogenic (Geraci *et al.*, 1999). Leptospirosis, caused by the spirochete *Leptospira* spp., occurs in domestic and wild animals worldwide. Infection in California sea lions has caused kidney disease in juvenile and subadult males and abortion in females. A concern for human health arose with the discovery of disease outbreaks associated with *Mycobacteria* of the complex associated with tuberculosis (*M. bovis*, *M. tuberculosis*) in captive New Zealand fur seals (*Arctocephalus forsteri*) and Australian sea lions (*Neophoca cinerea*) in the early 1990s. The disease has since been found in

free-ranging otariids from Australia, New Zealand, and South America and may be endemic in certain wild populations. Bacteria representing an apparently new strain or species of *Brucella* have been found in many marine mammal populations. The implications for the animals and the persons who work with them are as yet unknown. To date, infection has been linked to brain lesions in striped dolphins (*Stenella coeruleoalba*) and abortion in dolphins and possibly pinnipeds.

The impact of bacterial infection on animal health depends on the organ involved. An isolated abscess in a muscle may have little apparent effect, while a similar infection in the lung can be seriously debilitating. Bacterial pneumonia, often associated with lungworms, can be serious enough to cause death or stranding. The same is true of a condition like gastroenteritis that can quickly alter water and electrolyte balance and lead to a host of secondary problems.

2. Mycotic Infections Fungal organisms rank low on the list of primary pathogens of marine mammals. They tend to infect animals that are weakened, perhaps by other chronic debilitating disease. After a long, terminal illness, an animal can be literally riddled with systemic fungi. The usual source is soil, dust, or water. The wide variety of fungi found in marine mammals includes *Candida*, *Aspergillus*, *Coccidioides*, *Blastomyces*, *Histoplasma*, *Fusarium*, *Nocardia*, and *Lacazia*.

Lobomycosis, a skin infection caused by the yeast *Lacazia loboi*, has an unusual range. The disease occurs in bottlenose dolphins from Florida waters and in tucuxi (*Sotalia fluviatili*) in South America. Curiously, other than in cetaceans, Lobo's disease occurs only in people inhabiting low-lying wetlands of Central and South America.

Coccidioidomycosis, caused by the soil fungus *Coccidioides immitis* and generally associated with terrestrial animals, was historically considered rare in marine mammals. What might be described as outbreaks of infection in California sea lions and sea otters between 1986 and 1994 coincided with a rise in human infections, attributed to unusual environmental conditions. The sea lions and otters presumably inhaled fungal spores transported from land by offshore winds.

3. Viruses First recognized in the late 1960s, viral infections in marine mammals have emerged as the greatest cause of large-scale mortality (Geraci *et al.*, 1999). To spread rapidly, a virus requires a naive host population of a minimum density, which can arise either through population growth or changes in social behavior. Once infected, a migrating or wandering animal may carry the virus to new habitats.

More than 450 harbor seals died in a disease outbreak in New England during the winter of 1979–1980. The cause was found to be an influenza virus of avian origin that had infected the seals, probably as they hauled out on the rookeries of Cape Cod, Massachusetts. Seals of all ages developed pneumonia, which forced many out of the water and onto crowded beaches where the virus could spread easily from seal to seal by aerosol transmission. This was the first marine mammal die-off of demonstrated viral origin.

Morbilliviruses—a group that includes human measles virus and canine distemper virus (CDV)—have since proved to be an ominous threat to marine mammals (Van Bresse *et al.*, 2001). Phocine distemper virus (PDV), closely related to CDV, killed more than 18,000 harbor seals and a few hundred gray seals (*Halichoerus grypus*) in the North Sea in 1988; another outbreak of similar scale and pattern occurred in 2002. CDV killed several thousand Baikal seals (*Pusa sibirica*) in 1987 and thousands of Caspian seals (*P. caspica*) in 1997 and 2000. Between 1990 and 1992, another morbillivirus (a cetacean morbillivirus or CeMV) killed thousands of striped dolphins in the

Mediterranean Sea. Infected animals developed pneumonia, fever, and neurological disorders associated with encephalitis. The immunosuppressive effect of these viruses led to the development of secondary, often overwhelming, infections by bacteria, fungi, and other viruses.

Morbillivirus infection, often without recognized illness, is now known to be common in many cetacean and pinniped populations, and present in some long before the European epidemics. Retrospective studies indicate that morbillivirus infection, which was observed in some bottlenose dolphin carcasses examined during a die-off along the US mid-Atlantic coast in 1987–1988, played an important role in that event, and that outbreaks have occurred sporadically in coastal bottlenose dolphins populations along the southeast United States since the early 1980s. Pilot whales (*Globicephala* spp.), pelagic social species with large populations in which the virus may be endemic, may be a vector for CeMV in the North Atlantic. Similarly, harp seals (*Pagophilus groenlandicus*) are a likely reservoir for PDV and may have introduced the virus into immunologically naive European seal populations. Terrestrial carnivores are the likely source of CDV. Serological studies have tentatively linked a 1955 die-off of crabeater seals along the Antarctic Peninsula to CDV, perhaps transmitted from sled dogs (*Canis lupus familiaris*).

A number of viruses are associated with less serious health conditions (Kennedy-Stoskopf, 2001). Poxviruses, e.g., commonly cause skin lesions in pinnipeds and cetaceans; pox disease can appear and disappear in conjunction with other illnesses or stress. Herpesviruses are also common in cetaceans and pinnipeds and, although not usually serious, they have been associated with fatal pneumonia and hepatitis in harbor seal pups and encephalitis in a stranded harbor porpoise (*Phocoena phocoena*). Calicivirus infection is common among many marine mammals in the North Pacific; clinical disease, which in California sea lions appears as vesicular lesions on the skin of the flippers and mouth, may accompany stress, debilitation, or other infectious conditions, particularly leptospirosis.

Numerous other viruses have been found in marine mammals, many without recognized effect. The number of viruses and other pathogens continues to grow. Some may represent new or emerging diseases in marine mammal populations, while other “discoveries” reflect the growing intensity of research and advances in pathogen isolation and identification.

H. Metabolic Disorders

Metabolic processes sometimes break down (St. Aubin and Dierauf, 2001). Environmental and biological factors that control hormonal regulation may fail to become synchronized, demands on the system may be overtaxing, and organ function, under the influence of a genetic clock, deteriorates with age and illness. The animal becomes incapacitated, but the underlying reason may be evident only at the molecular level and therefore difficult to detect. Not surprisingly, little is known about metabolic diseases in aquatic species.

In marine mammals, salt and water balance is regulated in part by the adrenal gland. Aldosterone, secreted from the adrenal cortex, normally acts on the kidney tubules to conserve sodium and thereby maintain salt and water balance. In pinnipeds, conditions that lead to prolonged stress, including molt, malnutrition, and disease, can exhaust the gland of aldosterone, resulting in loss of sodium from the body, a condition known as hyponatremia. Affected animals lose their appetite, become weak and disoriented, and eventually die. Aldosterone features in the stress response of cetaceans as well, only it does not become depleted and the animals do not develop

hyponatremia. Quite the contrary, in severe stress following a stranding, a cetacean may eventually begin to drink seawater and develop a condition of salt overload, or fatal hypernatremia, that dehydrates tissues, including the brain.

I. Tumors

Marine mammals develop all kinds of tumors, from benign lipomas that are little more than fatty lumps in the great whales to highly malignant lymphomas in young seals. As studies on marine mammals have increased, so have the numbers and variety of reported tumors (Gulland *et al.*, 2001).

In other mammals, tumors have been associated with a variety of factors, including hormones, viruses, congenital and hereditary defects, and physical and chemical agents. Establishing these links has generally required years of investigation on large populations and a systematic consideration and elimination of other possible contributors. These requirements are difficult to meet in marine mammal studies (O'Shea *et al.*, 2003). Hence it may never be possible to prove the assumption that environmental contaminants are responsible for the unusually high incidence of tumors in beluga whales (*Delphinapterus leucas*) in the St. Lawrence River, however, plausible or tempting the link. One study has been more fruitful: a herpesvirus, in combination with exposure to PCB contaminants, has been linked to the high rate of urogenital cancer in California sea lions.

J. Biotoxins

Of the thousands of known species of marine phytoplankton, at least 40 can produce toxins that are harmful to humans and other top predators. Only since the late 1980s have we begun to realize the potential impact of such toxins on marine mammal populations (Geraci *et al.*, 1999; Van Dolah *et al.*, 2003). These compounds are difficult to detect and may leave little evidence of their presence. Thus their role in marine mammal mortality is often uncertain and may have gone unrecognized in the past. As one example, ciguatoxin, a dinoflagellate neurotoxin, was implicated in the illness of about 50 Hawaiian monk seals on Laysan Island in 1978; the weak, lethargic seals eventually became emaciated, suffered from severe parasitic infections, and died. Fourteen humpback whales (*Megaptera novaeangliae*) died in Cape Cod Bay (Massachusetts) in the winter of 1987 after eating mackerel containing saxitoxin, a neurotoxin that even in minute quantities causes respiratory paralysis.

In 1988, brevetoxin, a neurotoxin produced by the dinoflagellate *Karenia brevis*, the organism responsible for "red tides," was implicated in a die-off of several hundred Atlantic bottlenose dolphins along the US mid-Atlantic coast. Although the role of brevetoxin in that event remains unclear, this toxin has since been linked to mortality of bottlenose dolphins and Florida manatees in the Gulf of Mexico, where red tides are a recognized threat to the manatee population. Red tide outbreaks in southwest Florida in 1982, 1996, 2003, and 2005 killed about 37, 150, 98, and 81 manatees, respectively; these animals died of acute and chronic poisoning after consuming and inhaling *K. brevis* toxins.

In 1998, California sea lions along central California were poisoned by domoic acid, a neurotoxin produced by the diatom *Pseudonitzschia* sp. It caused convulsions, loss of coordination, and vomiting. While more than half of the stranded sea lions died, others were brought to rehabilitation centers and recovered. This discovery clarified some previously unexplained sea lion strandings and die-offs in this region. Subsequent outbreaks have affected sea lions and other marine mammals from central California to Mexico.

Marine mammals may be particularly susceptible to the neurological action of biotoxins for several reasons: (1) during a dive, blood is channeled to the heart and brain, effectively concentrating toxin there, and away from the liver and kidney where it is normally metabolized and excreted; (2) a short period of disorientation may be enough to impede an animal's ability to reach the surface for a vital breath of air (or to evade an oncoming vessel); and (3) animals that remain in the area of a bloom may be subject to the cumulative effects of toxins ingested or toxic aerosols inhaled over a period of days or weeks.

K. Strandings

Stranding is defined as having run aground. The term here describes any marine mammal that falters ashore ill, weak, or simply lost. Most animals die at sea and only a fraction reach the shore. Those that do come ashore generally reflect the age, sex, and density of the animals in the area (Geraci and Lounsbury, 2005). Any change in the expected profile may be a signal that something unusual is happening, such as a toxic event, a disease outbreak, intensive local fisheries operations, or a change in prey abundance.

Pinnipeds and, to a lesser extent, sea otters normally spend time ashore, but only those unwilling or unable to return to sea are considered stranded. These would include pups that become separated from their mothers prematurely or fail to make a successful transition to independence. Most strand in the vicinity of the rookery, although some may stray far from their normal range. Other than in spring, when pups may come ashore in large numbers, and in the absence of unusual events such as disease outbreaks, pinnipeds normally strand alone.

Many cetaceans that strand singly are debilitated in some way. Some offshore species strand with characteristic illnesses. Short-beaked common dolphins (*Delphinus delphis*) along California, e.g., develop parasite-related brain damage, and dwarf (*Kogia sima*) and pygmy (*K. breviceps*) sperm whales along the southeastern US coast often come ashore with heart disease of uncertain cause and with impacted stomachs after ingesting plastic bags and other debris.

A mass stranding can be defined as two or more cetaceans, excluding mother-calf pairs, that come ashore alive at the same time and place. Highly social species of odontocetes [e.g., sperm whales, pilot whales, false killer whales (*Pseudorca crassidens*), and Atlantic white-sided dolphins (*Lagenorhynchus acutus*)] are the most probable victims. Many explanations have been proposed, but the only common link seems to be the strong social nature of these species. Once one or more animals strand, for whatever reason, the compulsion to stay together brings others ashore.

A stranded animal's chances of surviving diminish by the hour. Sea otters and pinnipeds risk hyperthermia, injury from terrestrial predators, and starvation. A cetacean has difficulty shedding heat even in cold weather, and a larger one may develop respiratory fatigue and distress as the chest cavity is compressed under its own weight. Within a few hours of stranding, some cetaceans begin to show evidence of shock or vascular collapse, which leads to poor circulation and impaired organ function. The onset of shock further impairs the whale's health and may prevent its recovery, even if it is returned to sea in what appears to be good condition.

L. Habitat Alteration and Disturbance

Marine mammals have adapted over millions of years to the often harsh conditions of the marine environment. In the past few decades, environmental change has proceeded at a rate far exceeding

the slow pace of evolution. How well can marine mammals cope with urban and industrial wastes, coastal dredging, undersea construction, vessel traffic, noise, and intense competition from humans for food resources? As with other influences on health, the effects—if they can be determined with any degree of certainty—will vary depending on species, sex, age, individual tolerance and behavior, and a host of other factors.

1. Contaminants As long-lived predators at the top of the food chain, marine mammals accumulate contaminants in their tissues (O'Shea *et al.*, 2003). The concentrations and distribution within tissues depend on the type of contaminant and the animal's age and sex. Because most compounds accumulate over time, older animals generally have more. Fat-soluble substances, such as the persistent DDT, PCBs, and related organochlorines, reside in fatty tissues like blubber, liver, and brain; heavy metals are found in liver but also distribute in muscle, kidney, and other organs. Pregnant and lactating females produce milk using stored fat and the chlorinated hydrocarbons that came with it. While the suckling offspring loads up with contaminated milk, the female depletes her stores and, over time, has proportionally less and less than a male of equivalent size and age. What concentrations are eventually harmful to the male, or to the female as she loads and unloads the compounds with each reproductive cycle, or to the pup that may be even more sensitive? What happens to an animal of any age that becomes ill, stops eating, and uses stored fat, which releases these potentially toxic compounds into the bloodstream where, in increasingly higher concentrations, they are carried to other tissues?

As yet, no clear picture emerges, and broad differences in effects among species continue to invite speculation. In Baltic seals, organochlorine levels seem to be associated with low pregnancy rates and uterine pathology, as well as a disease complex characterized by metabolic disorders, hormonal imbalance, cranial bone lesions, and reduced immune function. The nature of marine mammals and the environment they live in pose serious challenges to conducting investigations that require tight controls and sophisticated technology. Meanwhile, we rely on empirical observations and preliminary studies that offer clues. Experimental studies are, nevertheless, yielding data supporting the link between exposure to certain chlorinated hydrocarbons and impaired immune function—and to tumors—in at least some species. A better understanding of the influence of contaminants on health will likely emerge from continued laboratory investigations.

2. Oil Spills Oil spills are visible and unsightly, and sea otters show us how quickly fatal one can be. The 1989 *Exxon Valdez* incident in Prince William Sound, Alaska, was dramatic and beyond the proportion of other spills that have affected marine mammals (Loughlin, 1994). Until that event, relatively few marine mammals were known to have been killed by oil.

The impact of spilled oil depends on its composition, environmental conditions, and the species involved (Geraci and St. Aubin, 1990). During the first few hours or days after a spill, low molecular weight fractions are the most acutely toxic. They irritate and harm tissues, especially the sensitive membranes of the eyes and mouth; they can be ingested during feeding or when a fouled animal is grooming; or their vapors can be inhaled and damage the lungs. Light fractions are absorbed into the blood where they can attack the liver, nervous system, and blood-forming tissues. Sea otters caught in the *Exxon Valdez* spill showed signs of lethargy, respiratory distress, and diarrhea, and evidence of liver damage, kidney failure, and endocrine imbalance. Between 3500 and 5500 otters were estimated

to have died. Three hundred harbor seals also died; many had brain lesions, probably resulting from inhalation of vapors from fresh oil.

Evaporation of the low molecular weight fractions leaves heavy residues and thick, foamy emulsions called “mousse.” By sticking tenaciously to vital insulating hairs of sea otters, polar bears, and some species of pinnipeds (e.g., fur seals), these substances can destroy the animals' ability to maintain thermal balance. The sea otter is especially vulnerable because its survival depends on a well-groomed hair coat.

Except for the sea otter, there is no real evidence that marine mammals ingest much oil. They may be able to deal with small quantities of fresh oil or that premetabolized by their prey because they, like other mammals, have liver enzymes required to metabolize and excrete such compounds.

3. Ingesting Debris Some marine mammals become entangled in fishing nets and debris. Others are as likely to ingest various types of discarded items and trash that enter the oceans—mostly from land sources—at a rate of over 6 million metric tons each year. Florida manatees, e.g., face increasing risks of ingesting fishing line and hooks, wire, plastic bags, and other rubbish trapped in floating mats of vegetation (O'Shea *et al.*, 2001). Some cetaceans, including pygmy sperm whales and some beaked whales, share a tendency to ingest plastics. Some items are small and inconsequential; others may block or perforate the gastrointestinal tract, leading to slow starvation or sudden death.

4. Other Disturbing Influences Habitat degradation can take many other forms: prey depletion, nutrient enrichment that leads to toxic algal blooms, underwater drilling noise, heavy vessel traffic, and disturbance of pupping or calving areas, to name a few. The potential range of effects is immense. A boat traveling through one of Florida's canals might collide with a manatee and kill it or raise the turbidity and inhibit the growth of water plants that are vital to its diet. Individuals might respond to food shortage or disturbance by moving to marginally suitable environments, e.g., northward to colder waters, where risks of cold stress are increased. A harp seal wandering far from its normal range following a collapse of prey stocks might introduce a pathogenic virus into a susceptible population. A sudden, unusual noise near a crowded pinniped rookery might cause animals to panic and stampede, trampling or abandoning their young. Intense underwater sound offshore might cause deep-diving beaked whales to ascend rapidly to the surface in panic and consequently suffer “the bends.”

Other reactions to disturbances may be more subtle. In terrestrial mammals, intense noise alone can cause disorders ranging from long-term hearing loss to physiological stress, hypertension, hormonal imbalance, and lowered resistance to disease. Such effects are nearly impossible to document in marine mammals. It can be assumed that animals are generally unlikely to become habituated physiologically to any disturbances that are associated with threatening situations.

III. The Future

We have a growing understanding of the range of pathogens in the sea and the mechanisms marine mammals have evolved to counter their effects. However, the expression of illness, whether in an individual or a population, is governed by dynamic environmental conditions, some of which are within our ability to control. For example, reductions in pollution, coastal habitat loss, and harmful fishing practices would have both direct and indirect health benefits for some marine mammal populations. Other environmental conditions are more difficult or impossible to control.

Harmful algal blooms have increased in frequency and distribution in the past few decades. Blooms in some areas are linked to human activities, in others to oceanographic anomalies that may be associated with climate change. There is also growing evidence that changing environmental conditions can influence the prevalence or virulence of pathogens (Harvell *et al.*, 1999). Thus it may be no coincidence that several major outbreaks of viral disease in marine mammals during the past few decades occurred in during periods of unusually warm weather.

If it is true that changes in our environment are occurring at an accelerated pace—and if the few years since the first edition of this encyclopedia are any indication of future trends—the ocean environment and every species dependent upon it, from benthic bacteria to blue whales (*Balaenoptera musculus*), and ourselves, are facing challenging times (Smetacek and Nicol, 2005; Grebmeier *et al.*, 2006). New chapters on health will be written with every technological leap in oceanography, remote sensing, medical diagnostics, and data integration. What pathogens will accompany the increasing traffic across oceans of people, animals, and goods? The effects of global warming on weather patterns, ocean dynamics, nutrient transport, prey distribution and abundance, and the spread of (and emergence of new) toxic organisms and pathogens will dramatically change what we have written here. Adaptation by some marine mammal species or populations may become evident as changes in general distribution, migratory patterns, and feeding areas or prey. Species already pressed to the edge of their “preferred” habitat may not be able to bear much more change. Others on the margin, like bowhead whales (*Balaena mysticetus*), may prosper as retreating sea ice opens the way for greater primary production and prey availability. Barring a catastrophic event, many—if not most—species will, as they have throughout their evolution, muster their pre-adaptive genes to secure a niche that will assure their survival, and their health.

Hearing

SIRPA NUMMELA

Animals use sound and hearing for communication, especially signaling different behaviors related to reproduction, breeding, territory marking, as well as for detection and localization of prey and predators and navigation. Cetaceans have succeeded superbly in aquatic hearing, and have also become crucially dependent

on their hearing while adapting to the aquatic world. Sirenians have not invested so fully to their auditory sense as whales, but their hearing is sufficiently functional even though it does not have a very prominent role among their senses. Pinnipeds are dependent on their audition in both air and water, and their requirement to hear in both media poses demands beyond those on the whales and manatee ear. Good hearing ability in air does not necessarily imply an equally good hearing ability in water, and it is impossible to optimize the auditory functions in both media; compromises are made regarding hearing sensitivity and frequency ranges.

I. Acoustics

A. Sound Velocity

For pure tones sound velocity c is the product of sound frequency f and sound wavelength λ ; $c = f\lambda$, and is nearly 5 times higher in water than in air. This means that for a given sound frequency, the wavelength is nearly 5 times longer in water than in air. Shorter wavelengths have better spatial resolution, and hence high frequencies are better suitable for detecting small objects than are low frequencies, and are thus used in echolocation. However, high frequencies attenuate rapidly and do not carry very far.

B. Impedance

The characteristic acoustic impedance of a medium is $Z = p/v$, where p is the sound pressure, v is the particle velocity. A given sound pressure gives air molecules a larger particle velocity than water molecules, leading to lower impedance of air than of water. In addition, the specific acoustic impedance of the fluid-filled cochlea is approximately one-tenth of the characteristic acoustic impedance of water, $Z_c = 150 \text{ kPas/m}$. Hence in hearing, airborne sounds travel from a medium of low impedance to one with much higher impedance in the ear. Waterborne sounds travel from a medium with higher impedance to one with slightly lower impedance. The impedance mismatch causes a reflection of sounds at the interface, and to overcome this, an impedance matching device is needed. This device adjusts the sound pressure and particle velocity, either by increasing the pressure, and/or decreasing (airborne sound) or increasing (waterborne sound) the particle velocity between the outer medium and the cochlea.

C. Sound Intensity and Sound Pressure

Sound loudness is measured with pressure meters and is given in decibels, generally expressed using sound pressure level: $L_p = 20 \text{ dB} \log p/p_o$. The reference pressure value p_o for sounds in air is $20 \mu\text{Pa}$, and in water $1 \mu\text{Pa}$. For the cochlear sensitivity, the incident sound energy is a relevant parameter, and sound intensity should be used when comparing the hearing of a terrestrial vs an aquatic animal.

For a plane wave, the sound intensity $I = p^2/Z$, where Z is the characteristic acoustic impedance of the medium, Z_{air} or Z_{water} . The ratio $Z_{\text{water}}/Z_{\text{air}}$ is approximately 3700. This means that when plane waves with equal intensities in air and water are compared, the sound pressure in water is larger. With the conventional reference pressure p_o values of $20 \mu\text{Pa}$ (air) and $1 \mu\text{Pa}$ (water), the waves have equal intensities when the sound pressure level L_p of the aquatic wave is 61.8 dB larger than sound pressure level L_p of the wave in air. Hence, for audiograms from different habitats, a terrestrial animal and an aquatic animal have equal sensitivities (equally sensitive hearing) if the threshold L_p value of the aquatic animal is 61.8 dB larger than the threshold L_p of the terrestrial animal.

D. Directional Hearing

Interaural time difference and interaural intensity difference are two methods that are used by mammals to determine the direction of a sound. The interaural time difference is a usable method when the interaural distance (head size) is relatively large when compared to the wavelength of the sound; mostly at lower frequencies. Measuring experimentally the temporal resolution or the minimum audible angle gives indications of the sound localization abilities of an animal.

The interaural intensity difference is caused by the shadowing effect of the head, sound intensity is generally larger in the ear where it arrives first. This means of binaural hearing is important when the interaural time difference is small, usually at higher frequencies. Additionally, the intensity difference between the ears increases with the sound frequency (Fig. 1). Hence, echolocation using high-frequency hearing not only gives better spatial resolution than using low frequencies, but it also improves directional hearing.

Figure 1 (A) Diagram of a mammalian head with sound arriving obliquely from the right, showing that the left ear is in a sound shadow. (B) Approximate sound intensities at left and right ear for mammal in (A). From Nummela and Thewissen (2008), with permission.

II. Ear Anatomy and Hearing Mechanisms

A. Land Mammals

In a land mammal ear, sound is collected by the outer ear pinna, and guided through the external auditory meatus (outer ear canal) to the tympanic membrane, which is set into vibration (Fig. 2A). These vibrations are carried further by the ossicular chain, situated in the middle ear cavity and consisting of three small bones, malleus, incus, and stapes. The malleus is attached to the tympanic membrane with its handle, the manubrium. The middle ear ossicles together form a swing which vibrates between the tympanic membrane and the oval window of the cochlea, setting the inner ear fluid into motion. The tympanic bone and the petrotic bone have several contacts with each other, and are also in close contact with the squamosum and other skull bones. In land mammals, the ear is not acoustically isolated from the skull, and this makes bone conduction a possible hearing mechanism, in addition to the general land mammal mechanism.

While hearing in air, sound energy is transmitted from areas with lower impedance of air to much higher impedance of the inner ear (discussed earlier). In such a case, the pressure should be increased, and the particle velocity should decrease (as $Z = p/v$). This is in fact what happens. The pressure is increased when sound is transmitted from a larger area (tympanic membrane) to a smaller area (oval window), and the particle velocity is decreased when the malleus lever arm is longer than the incus lever arm. These two arrangements together, the area ratio and the lever ratio, contribute to the sound energy transmission in the middle ear, and the middle ear functions as an impedance matching device between the surrounding air and the inner ear fluid, decreasing the reflection of sound at the tympanic membrane. Additionally, the middle ear functions as an intensity amplifier.

The mammalian cochlea is a coiled structure with channels, filled with inner ear fluid (endolymph and perilymph). The basilar membrane supports the organ of Corti which contains the auditory sensory cells,

along with a row of supporting cells. The vibrations of the stapes at the oval window are transferred to the movements of the inner ear fluid, this causes the bending of the auditory hair cells and leads to a nerve impulses in the cochlear nerve. The basilar membrane is tonotopic so that the base of the membrane is most sensitive to high frequencies, and the apex (helicotrema) is most sensitive to low frequencies. The number of turns in the cochlea varies, but is related to the sound frequencies heard by the animal; animals that hear high frequencies have more turns than animals that specialize on hearing low frequencies.

The hearing range is in general determined by the ear structures. In the middle ear, low-frequency transmission is constrained by the elasticity of the system; large tympanic membrane and middle ear volume together with non-stiff ossicular chain improve low-frequency hearing. High-frequency transmission is constrained by the mass of the system, mainly by the middle ear ossicular mass; for high-frequency transmission small middle ear is needed. The inner ear can be a constraining factor too, and this is often seen in the audiogram as a very steep rise at the high-frequency part.

B. Bone Conduction

Bone conduction occurs when sound energy is transmitted from a surrounding medium to the cochlea through vibrations of the soft tissues and bony parts of the head directly, instead of the outer ear and the rotating ear ossicles. Functionally, there are two types of bone conduction: compressional and the inertial. In the compressional type, a pressure differential develops across the cochlear partition of the inner ear. In the inertial type, relative motion between the ossicular chain and the temporal bone leads to cochlear stimulation much the same way as in air-conducted hearing of land mammals. Both of these types lead to displacement of the basilar membrane and (eventually) bursts of neural impulses.

In general, bone conduction is disadvantageous to land-living mammals, as it interferes with airborne sounds entering the ear.

Figure 2 (A) Diagram of the land mammal ear. (B) Diagram of the modern odontocete ear. For technical reasons, the mandibular foramen and the mandibular fat pad are shown on the lateral side of the mandible, although they in reality are situated on the medial side. Coc, cochlea; EAM, external acoustic meatus; FaPa, mandibular fat pad; Inc, incus; Inv, involucrem; Mal, malleus; Man, mandible; MeTy, medial synostosis between petrotic and tympanic bone, in cetaceans this synostosis is absent and is homologous to a gap between these bones ("MeTy"); OvW, oval window; Per, petrotic bone; PeTy, joint between petrotic and tympanic; Sin, air sinuses; Sk, skull; Sta, stapes; TyBo, tympanic bone; TyMe, tympanic membrane; TyPl, tympanic plate. Reprinted by permission from MacMillan Publishers Ltd: *Nature* (Nummela et al., 2004).

Bone conduction can be minimized if the mass center point of the ossicular chain coincides with its rotational axis. However, bone conduction in marine mammals can be useful because the density of water is similar to the density of the body tissues allowing for efficient transfer of energy. A disadvantage of bone conduction is that it does not allow for directional hearing. Marine mammals such as cetaceans avoid bone conduction by inserting air cushions between ears and skull in order to acoustically isolate the ears.

C. Generalized Odontocetes

Odontocetes have excellent hearing; they are able to hear very high frequencies, exceeding even 150kHz, and their hearing sensitivity in water is very acute. Additionally, as an adaptation to the aquatic environment, odontocetes have developed rapid auditory temporal processing which facilitates sound localization and echolocation.

The ears of modern odontocetes are exclusively adapted for underwater hearing (Fig. 2B). Odontocetes lack an outer ear pinna, and their external auditory meatus is very thin and partly occluded and not functional in hearing. In most species, the tympanic and periotic bones are connected to each other through small, usually non-bony contacts, and together these bones form a tympano-periotic complex that houses the middle ear and the inner ear. The tympanic bone is bowl-shaped, and houses the middle ear cavity. The lateral wall of the tympanic bone is thin, like in mammals in general; in odontocetes this wall is called the tympanic plate. The medial part of the tympanic is thick and bulky, a massive counterpart to the thin lateral part. The tympanic membrane has become a long conical structure, sometimes called the tympanic ligament, it attaches with its medial tip to a small process in the malleus. The odontocete tympanic membrane is not functional in hearing, but rather in the pressure regulation of the middle ear cavity. The three middle ear ossicles are situated between the tympanic plate and the oval window. The malleus has lost its manubrium but has a long thin anterior process, processus gracilis, which connects it to the anterior rim of the tympanic ring. The malleus joints the incus, and these two ossicles together form most of the mass of the chain. The incus in turn joints with the stapes. The footplate of the stapes sits at the cochlear oval window (Fig. 3 and 4).

The tympano-periotic complex is surrounded by air sinuses and thus it is acoustically isolated from the skull. The odontocete lower jaw contains fatty tissue called mandibular fat pad in the mandibular canal, and through the large mandibular foramen this fatty structure reaches up to the tympanic plate (Figs. 3 and 4). The mandibular fat pad is composed of triacylglycerols that are known to conduct vibrations efficiently. Experimental evidence has shown that the odontocete lower jaw is very sensitive to sound, and it has been

Figure 3 Medial view of lower jaw showing the mandibular foramen size. (A) Right mandible of deer, *Odocoileus*. (B) Left mandible of dolphin, *Lagenorhynchus*. Scale bar = 5cm. From Nummela et al. (2007).

suggested that the odontocetes use their lower jaw as an outer ear that collects sound energy that is then guided forward by the mandibular fat pad to the tympanic plate. The tympanic plate vibrations are moved forward to the ossicular chain and to the cochlea. It should be noted that in water, ossicles of high mass can transmit high frequencies which in air can only be transmitted by very light ossicles. Killer whales and mice can hear equally high frequencies, but the ossicles differ hugely in their size.

For an odontocete in water, sound energy travels from higher impedance to somewhat lower impedance. Then, to minimize the reflection of sound energy, pressure should be decreased and particle velocity should be increased. However, when the vibration moves from the larger tympanic plate to the smaller oval window, the pressure increase is inevitable. On the one hand it is advantageous; it increases the intensity, resulting in better hearing sensitivity. But the increase of pressure is disadvantageous in an odontocete ear and

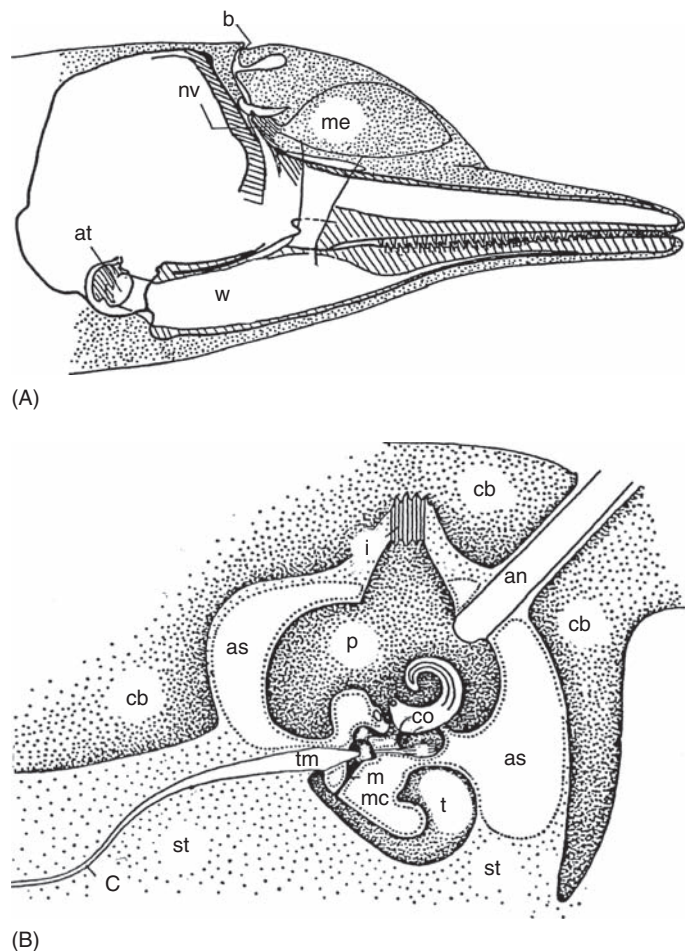

Figure 4 (A) Structures in the odontocete head (modified from Norris, 1968). (B) Odontocete middle ear region (modified from Reysenbach de Haan, 1957). The nasal valve lips, the blowhole and the melon contribute to sound production and focusing. an, auditory nerve; as, air sinuses; at, attachment of the mandibular wave guide onto the tympanic bulla; b, blow hole; c, auditory canal; cb, cranial bones; co, cochlea; l, ligaments; m, malleus; mc, middle ear cavity; me, melon; nv, nasal valve with lips; p, periotic bone; t, tympanic bone; tm, tympanic membrane; st, soft tissues; w, mandibular wave guide.

needs to be compensated by a large increase of particle velocity, hence the lever mechanism (Fig. 5). The lateral wall of the tympanic bone, the tympanic plate, vibrates relatively more than the thick involucrum which stays practically immovable. This structure forms the first of the two middle ear lever mechanisms in the odontocete ear, increasing particle velocity. In the rotation of the ossicular chain the malleus and incus move very little in the epitympanic recess, and the incus long arm moves much more; this forms the second middle ear lever and, again, the particle velocity is increased.

A tympanic plate, made of bone, can be much larger than a tympanic membrane and still vibrate as one single unit. With a large tympanic membrane, when the sound frequency becomes high enough, the vibration of the membrane breaks into several small units, and this may lead to a considerable loss of energy. A bony rigid tympanic plate hence makes it possible for this area to be so large, a condition for the functional success of the odontocete ear. Another factor that helps in rigidity is the increased bone density in the odontocete ear. The tympano-periotic complex together with the ossicles have clearly higher density than the rest of the skull, approximately $2.6\text{--}2.7\text{ g/cm}^3$.

The sound velocity is nearly 5 times larger in water than in air means that the wavelength of a given sound is equally much longer in water, reducing considerably the usefulness of the interaural time difference. However, despite this increase in velocity and wavelength, the wavelength of the high frequencies that marine mammals, especially odontocetes, use are sufficiently short to allow binaural hearing. The high frequencies together with a large head compensate for the increase in sound velocity, resulting in good directional hearing in odontocetes.

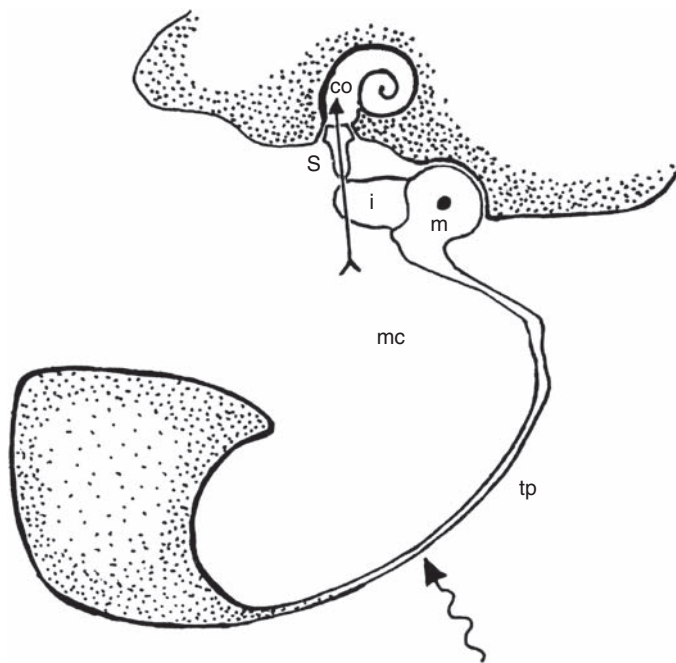

Figure 5 Schematic presentation of the odontocete middle ear structure. The incident sound arriving at the tympanic plate is represented by the wave-formed arrow. The black dot indicates the rotational axis of the ossicular chain, and the straight arrow shows the direction of the stapes movement during increasing sound pressure. *co*, cochlea; *i*, incus; *m*, malleus; *mc*, middle ear cavity; *s*, stapes; *tp*, tympanic plate.

The auditory input area of the dolphin head was studied by Mohl *et al.* (1999), who found that the best auditory sensitivity is at the middle of the lower jaw (see Figure 3 in Echolocation chapter). Recently Popov *et al.* (2008) presented evidence for double acoustic windows in the dolphin: they were able to identify for the *Tursiops truncatus* at least two different sound-receiving areas (acoustic windows) with different frequency sensitivity. One window was situated 22–26 cm caudal of the melon tip, close to the bulla and auditory meatus, and mainly sensitive to frequencies between 16 and 22.5 kHz. The other window was found 9–13 cm caudal of the melon tip, this place corresponding to a proximal part of the lower jaw, and being most sensitive to frequencies between 32 and 128 kHz. The significance of these multi-receiving areas is not clear yet but it is possible that they provide cues for localization of sound sources and sound pattern recognition, because the best-sensitivity axis direction may be frequency dependent.

Audiograms for odontocetes are presented in the chapter on Echolocation. Comparisons of behavioral and evoked electrophysiological measuring techniques for determining hearing thresholds have been carried out to find out how these two techniques could be replaced by each other. Electrophysiological methods give a relative sensitivity, not the absolute thresholds, but are much less time consuming and in many cases the only possible ones (e.g., with stranded animals). Behavioral methods require time for training, being also much more expensive. In general, the thresholds agree relatively well with each other, between auditory evoked potential and behavioral measurements, the AEP had consistently higher thresholds, with the greatest differences at the lowest frequencies. See Supin *et al.* (2001).

D. Physeteroidea/Ziphiidae

Beaked whales such as *Ziphius cavirostris* and *Mesoplodon densirostris* produce high-frequency echolocation clicks, in *Z. cavirostris* clicks the energy is centered on 42 kHz, with energy up to about 80 kHz. The temporal resolution of beaked whales is high, similar to that of other cetaceans.

The ear structures of physeteroids and ziphiids are similar to those of other odontocetes, but some differences do exist. The processus gracilis is short, and sometimes hardly discernible, the malleus has a larger and less elastic contact with the tympanic plate rim. Also, the contacts between the tympanic and periotic are less elastic, as there is real synostosis between the bones, although not wide. The malleus lacks a transversal part, being relatively round, and the incus joint facet is flat. There is also a relatively long mastoid process, especially in ziphiids, and this process stays in contact with the skull in a similar way as in mysticetes, although not that deep. The tympano-periotic complex is relatively smaller than in other odontocetes. These morphological differences have functional consequences; the lack of elasticity is the contacts theoretically improves the transmission of higher frequencies. However, no quantitative models have so far been presented for this type of hearing mechanism, and the odontocete model may be applied to these species.

Very little is known of the hearing of these species. Auditory evoked potentials measured on a stranded juvenile beaked whale (*Mesoplodon europaeus*) showed that the animal was most sensitive to high-frequency signals between 40 and 80 kHz, when the lowest tested frequency was 5 kHz, the highest was 80 kHz. The animal was probably able to detect frequencies much higher than 80 kHz (Cook *et al.*, 2006).

E. Mysticetes

Low frequencies have long wavelengths, and carry over longer distances as they attenuate more slowly than high frequencies; thus low frequencies are more suitable for long-distance communication. Mysticetes specialize in hearing low frequencies that carry very far with little attenuation. These whales can communicate with each other over hundreds, even thousands of kilometers. The frequency range of sounds that whales utilize ranges from a few hundred hertz (Hz) to well over one hundred kilohertz (kHz).

Mysticetes are specialized to produce frequencies in the lower range, mainly <5 kHz, the lowest frequencies used are 10–15 Hz. Hence the hearing frequency range of mysticetes is clearly different than that of odontocetes. Mostly, the ear anatomy is similar to that of odontocetes, Mysticetes have no outer ear pinna, their external auditory meatus is thin, and hardly functional in hearing. At the medial end of the meatus there is a wax plug attached to the tympanic membrane. The tympanic and periotic together form a tympano-periotic complex, but here the connections between the two bones are true ossifications, although they are relatively small. The bone complex is partly isolated from the skull with sinuses, but a long mastoid process extends posteriorly from the periotic and makes large, although loose contact with the skull. The tympanic membrane is a conical structure, and its medial tip is attached to the malleus. The malleus is fused to the anterior rim of the tympanic ring with its anterior process, the processus gracilis, and this rod-like process is long and robust, not thin and elastic like in odontocetes. The three ossicles form a chain between the lateral wall of the tympanic and the oval window. The term “tympanic plate” is a functional term, and is not used for mysticetes, at least as long as it is unclear whether the lateral wall of the tympanic bone functions as an analog to the land mammal tympanic membrane, as it does in odontocetes.

The size of the ear complex and the ossicles is huge, but still the size relations between different parts coincide with those of odontocetes (Nummela 1999b). Hence, when looking for functionally important relations it would seem that the odontocete and the mysticete ears act similarly. However, the sound route to the ear is unclear in mysticetes. They do not have a mandibular canal, and no fat pad that would conveniently guide sound-induced vibrations further. Mysticetes are highly dependent on their low-frequency hearing in their long-distance communication that can span over tens, even hundreds of kilometers. No behavioral measurements on mysticete hearing exist, but their hearing frequency ranges have been predicted, e.g., on the basis of the detailed inner ear morphology (Ketten, 2000; Parks *et al.*, 2007). This can give relative values for frequency ranges, but does not tell anything about the hearing sensitivity or the sound transmission mechanisms of mysticetes as such.

F. Pinnipeds

Stimulation of the cochlea by bone conduction can be even enhanced conveniently by morphological changes in the middle ear structures. The mass center point can be moved further away from the rotational axis by placing extra mass in some part of the ossicular chain. This will increase the different phases of vibration between the stapes and cochlear capsule. This kind of morphological evolution has occurred, e.g., in phocids and odobenids, in which the incus is inflated.

Pinnipeds are amphibious and need to hear both in air and in water. In general, they have better hearing sensitivity than terrestrial mammals have in water, but worse sensitivity than odontocetes have in water. All pinnipeds have retained the land mammal type sound

transmission mechanism, with some modifications though. All otariids, the eared seals, have a small outer ear pinna, whereas phocids and odobenids do not. The tympanic bone in pinnipeds forms large middle ear cavity, typical of carnivores, and the periotic is in close contact with the skull. The otariid middle ear ossicles are of the same size as normal terrestrial carnivore ossicles, but phocid and odobenid ossicles are enlarged and pachyostotic, the most prominent example being the elephant seal ossicles. The mass of the phocid ossicles is further increased by a somewhat higher ossicular density ($2.2\text{--}2.3\text{g/cm}^3$) than the one for land mammals (around 2.0g/cm^3).

Pinnipeds have periotic bones that are fused to the skull, and there may be a fat channel or the enlarged mastoid bone that provides bilateral sound conduction. When diving, the pressure in the middle ear cavity is increased with the help of cavernous tissue in the cavity walls.

For hearing in air, pinnipeds use the normal land mammal hearing mechanism through the tympanic membrane. For hearing in water, no special hearing mechanism is known at least so far, but it is supposed that pinnipeds in water rely on bone conduction. The enlarged ossicular mass of some species limits the high-frequency hearing limit in air, but is apparently advantageous in enhancing the signal in the bone conduction, by creating a larger phase difference between different vibrating structures. As a result, phocids and odobenids have sacrificed part of their high-frequency hearing in air in order to gain better hearing in water.

Both the middle ear and the inner ear can constrain the hearing frequency range, and both may be the main limiting factor in phocids and otariids. As shown in Fig. 6, the high-frequency hearing limits of phocids in air are clearly lower than the limits in water, but for otariids, these limits are similar in air and water (these are experimental results from behavioral audiograms). The mass inertia of the heavy phocid ossicles explains the lower high-frequency hearing limits in air—according to the underwater audiograms the phocid cochlea is sensitive to higher frequencies. The inertia of the normal-sized otariid ossicles should allow the underwater hearing limit to be at higher frequencies than in air. However, their high-frequency hearing limits in air and water are approximately similar, so the limiting factor must be the cochlea alone.

In Fig. 7, the underwater audiogram is shown for walrus, and for two phocids and one otariid. The high-frequency hearing limit is lowest for the walrus, although its middle ear structure is overall similar to that of the elephant seal. Hence, the cochlea is the main limiting factor for the high-frequency hearing of the walrus.

The issue of whether some or all species of pinnipeds possess specialized acoustical abilities for underwater echolocation of the type shown by odontocete cetaceans, has been a controversial issue for decades, and was reviewed by Schusterman *et al.* (2000). The current understanding is that pinnipeds have not developed active biosonar, but rather that their amphibious lifestyle has resulted in relatively non-specialized underwater hearing abilities, which these animals use in combination with alternative senses that are possibly equally prominent, e.g., vision and hydrodynamic reception (see chapters on Vision and Sensory Biology).

In the absence of biosonar, pinnipeds may still have great hearing acuity under water. It has been claimed that due to the amphibious way of life, selection pressures for highly sensitive, acute underwater hearing have not shaped the pinniped auditory system to as great an extent as they have in the dolphins, but instead, pinnipeds would rely largely on other sensory cues (Schusterman *et al.*, 2000). Bodson *et al.* (2006) have shown experimental evidence for underwater auditory localization of *Phoca*, where the seal was able to localize and accurately attain hidden underwater sound sources, and there

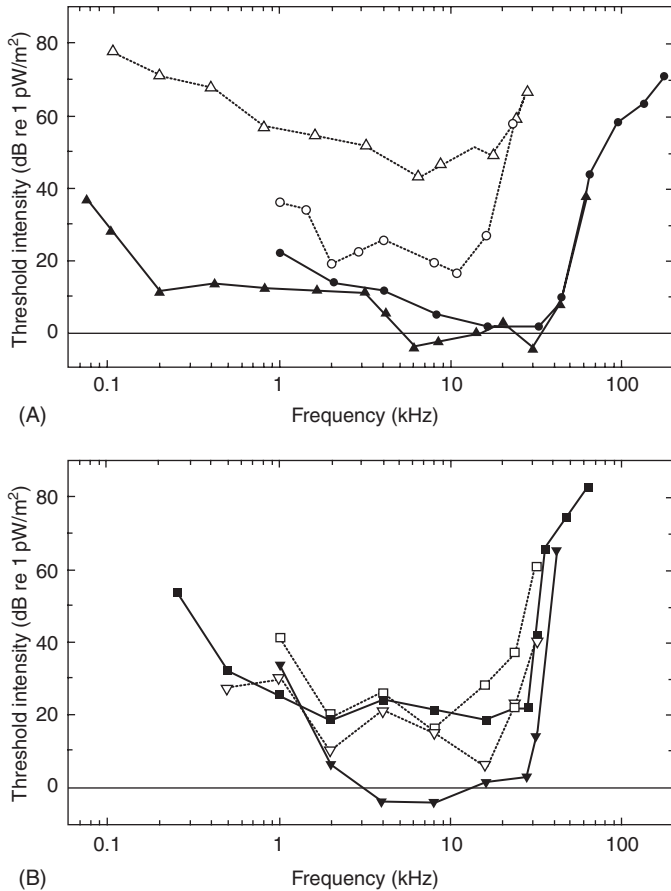

Figure 6 Audiograms for (A) phocids and (B) otariids. All threshold intensities are given in decibels relative to 1 pW/m^2 , for comparison of thresholds in water and air. Open symbols in-air, filled symbols underwater. \circ , \bullet *Phoca vitulina*; Δ , \blacktriangle *Mirounga angustirostris*; \square , \blacksquare *Zalophus californianus*; ∇ , \blacktriangledown *Callorhinus ursinus*. was no indication that the seal was guided by other than acoustical information.

Aerial sound localization abilities of pinnipeds (*Mirounga*, *Phoca*, *Zalophus*) are comparable to the domestic cat and rhesus monkey. Factors such as head size and head movements may also help sound localization in pinnipeds (Holt et al., 2004).

G. Sirenians

Sirenians are obligate herbivores that do not echolocate, but have been reported to have good high-frequency hearing, although their hearing sensitivity is clearly lower than that of odontocetes. Manatees have relatively good localization abilities. The ear anatomy of sirenians is very different from that of any other mammals (Ketten et al., 1992; Chapla et al., 2007), and at the moment it is unclear how the sound reaches the cochlea. No quantitative mechanism for sirenian hearing has yet been presented.

Sirenians have no outer ear pinna, and their external auditory meatus ends in a blind sac. Fatty tissue separates the meatus and the tympanic membrane, this fatty tissue also occurs around the tympanic bone. The tympano-periotic complex is intracranial but is not fused to the skull bones. The tympanic is a ring-shaped bone and does not form a cup-like bulla like in many other mammals, e.g., cetaceans and pinnipeds. The tympanic and periotic are fused to each other at two small locations. The tympanic membrane is large, and thick, and bulges outward, pushed by a cartilaginous keel of the malleus that is an extra structure between the malleus and the tympanic membrane. The middle ear ossicles are massive, and pachyostotic, and their density is the highest known among mammals (ca. 2.9 g/cm^3 ; Chapla et al., 2007). The zygomatic process is very fatty. It has been suggested that the sound path to the inner ear would be through this process so that the fat in the process would help in guiding sound to the ear similar to the mandibular fat of odontocetes. However, although experimental evidence for this is lacking, this is the only hearing mechanism suggested for sirenians so far. It is also possible that sirenians use bone conduction hearing to some degree.

Figure 7 Audiograms for the Pacific walrus, harbor seal, northern elephant seal, and California sea lion. The ambient noise is plotted in $\text{dB re } 1 \mu\text{Pa}/\sqrt{\text{Hz}}$ (note that this is a different unit than the one along the Y-axis). From Kastelein et al. (2002), with permission.

It is assumed that sound waves pass directly through the soft tissues of the head to the ears, but little is known about the properties of the manatee's tissues. The fatty tissue is significantly less dense than other soft tissues of the head and the squamosal bone is significantly less dense than the other bones of the head. In contrast to cetaceans where the relationship of the ossicular mass and the tympano-periotic is constant, the sirenian ossicular chain is overly massive where the periosteum separates the bilobed periotic from the squamosal bone.

Evoked potential studies on West Indian manatee (*T. manatus*) in air response up to 35 kHz with the largest peaks in response to stimuli from 1 to 1.5 kHz. AEP measurements on the Amazonian manatee *T. inunguis* in a water-filled bath gave response to stimuli up to 60 kHz. The first underwater behavioral audiogram for the West Indian manatee is of U-shape, like in mammals in general, and the hearing range extends from 0.4 to 46 kHz, with peak sensitivity at 16 and 18 kHz, the range of best hearing is 6–20 kHz (Fig. 8; Gerstein *et al.*, 1999).

Florida manatees have been found to have surprisingly good temporal resolution (600 Hz), roughly 10 times that of humans (50 Hz) and half that of dolphins (1200 Hz). Amazonian manatee was measured to have much lower temporal resolution, but this much reduced response was perhaps be a result of long-term adaptation (Mann *et al.*, 2005).

Manatee vocalizations range from 4 kHz to above 25 kHz. Many of these vocalizations are harmonic, and it is possible that the high temporal resolution of the auditory system provides a useful system for detecting the harmonics. Selective pressures to localize sound under water might also be responsible for the high-frequency sensitivity of the manatee. Higher-frequency sounds will produce larger interaural intensity differences than low-frequency sounds because they are more effectively shadowed by the head.

H. Polar Bear and Sea Otter

The polar bear (*Ursus maritimus*) and the sea otter (*Enhydra lutris*) are amphibious and apparently have relatively sensitive hearing in their watery habitat. Nachtigall *et al.* (2007) measured auditory evoked potentials for polar bear in air, and made estimations of their hearing sensitivity, based on the background noise. The polar bear hearing was found sensitive over a wide frequency range, with the best sensitivity in the range 11.2–22.5 kHz. No detailed descriptions appear for the ear or hearing mechanisms of these species. Based on their land mammal ear, both these species use the general land mammal hearing mechanism in air, and in water supposedly rely on bone conduction mechanism. Whether these species possess some morphological adaptations that would enhance the bone conduction stimulus, is currently unknown. However, most likely both these amphibious carnivores at least in air hear relatively high frequencies, and have good hearing sensitivity, like carnivores in general.

III. Evolution of the Aquatic Ear in Cetaceans

A. General

Evolutionarily, the odontocete ear is best understood. The evolutionary history of cetacean hearing can be divided into three different phases: (1) the modern generalized whale underwater hearing mechanism evolved already among archaeocetes during the Eocene, within less than 10 million years (Nummela *et al.*, 2004, 2007); (2) echolocation evolved around the time of divergence of odontocetes and mysticetes, or alternatively, within the earliest odontocetes; and (3) mysticete low-frequency hearing evolved most likely within the early mysticetes, perhaps as a consequence of the evolution of their large size.

Figure 8 Best-fit curves of sirenian, pinniped, and odontocete audiograms. Third-order polynomial curves are accompanied by shallow water and noise curves. From Gerstein *et al.* (1999) with permission.

Figure 9 (A) Diagram of the pakicetid ear. The malleus is probably of land mammal type, and its position is shown with a dotted line. (B) Diagram of the remingtonocetid/protocetid ear. Coc, cochlea; Dom, dome-shaped depression for periotic; EAM, external acoustic meatus; FaPa, mandibular fat pad; Inc, incus; Inv, involucrum; Mal, malleus; Man, mandible; OvW, oval window; Per, periotic bone; PeTy, joint between periotic and tympanic; Sk, skull; Sta, stapes; TyMe, tympanic membrane; TyPl, tympanic plate. Adapted by permission from Macmillan Publishers Ltd: *Nature* (Nummela et al., 2004).

The ancestral land mammal ear and the modern odontocete ear represent evolutionarily stable configurations. Characteristic of the whale ear evolution from pakicetids to the modern odontocete ear is that the connections between different bone structures, tympanic, periotic, and the rest of the skull, become more delicate and sophisticated. During the Eocene, the size of the tympanic bone and the tympanic plate relatively diminishes. While it is true that a large tympanic plate (just like a large tympanic membrane in land mammals) collects more energy and hence increases the signal/noise ratio, it also has a larger mass which constrains transmission of high frequencies to the ear. With the disconnection between the typano-periotic and the skull, and the delicate connections between tympanic and periotic themselves, together with a smaller and thinner tympanic plate, the ear became suitable for higher-frequency hearing and in due time, for echolocation.

B. Archaeocetes

Beginning with the earliest whales, pakicetids, the ear changed gradually and the generalized whale underwater hearing mechanism evolved in less than 10 million years. Pakicetids (Fig. 9A) had an outer ear canal leading to the tympanic membrane, and a small mandibular foramen in their lower jaw, indicating that no mandibular fat pad that would guide vibrations from the lower jaw, as happens in modern odontocetes, was yet present. The typano-periotic complex stayed in close contact with the skull, giving no acoustic isolation between the two cochleae. A fossil incus of *Pakicetus*, resembling the incus of artiodactyls, indicates that pakicetids still had a land mammal ear with a malleus and tympanic membrane typical of a land mammal. The tympanic bone of pakicetids resembled an artiodactyl tympanic but was unlike that in land mammals, the tympanic was not connected rostro-medially to the periotic. This enabled the medial wall of the tympanic, which was very thick and pachyostotic, to form

a loosely suspended center of mass that could vibrate independently of the periotic. This kind of arrangement could enhance the transmission of bone-conducted sound to the cochlea, and would be a possible mechanism for underwater hearing. A pachyostotic involucrum was earlier thought to be a unique character of cetaceans, but a similarly pachyostotic involucrum has recently been described for *Indohyus*, a fossil artiodactyl and the closest relative of cetaceans (Theewissen et al., 2007).

Pakicetids had two different hearing mechanisms, one in air, and the other in water. In air, they apparently used the land mammal sound transmission mechanism where sound energy reached the inner ear through the tympanic membrane and the middle ear ossicles. Under water, pakicetids used bone conduction mechanism which is not the most sophisticated hearing mechanism but can be combined with the needs of airborne hearing.

Among archaeocetes, the ambulocetid ear structures and their hearing mechanisms are least well known. Ambulocetids had a massive lower jaw with a large mandibular foramen, indicating the presence of a mandibular fat pad for guiding the vibrations received by the lower jaw. The tympanic bone was large, with a thick involucrum, and stayed in close contact with the lower jaw. It is likely that ambulocetids could mainly hear through bone conduction when keeping their lower jaw attached to the ground, like the modern crocodiles do. In water, the same mechanism could be used, but the sensitivity was obviously poor, and the frequency range of hearing was very low.

Remingtonocetids and protocetids had a large mandibular foramen in the lower jaw, indicating the presence of a mandibular fat pad (Fig. 9B). The contact between the tympanic and periotic was further reduced. The shape of the tympanic bone, the ossicles, and the tympanic membrane (as evidenced by the morphology of the malleus and the tympanic ring) was more modern than in earlier archaeocetes. The tympanic membrane had a conical shape, and the malleus had lost its manubrium, being apparently attached to the tip of the conical

tympanic membrane from its head. This morphology suggests that the modern generalized whale hearing mechanism made its debut in remingtonocetids and protocetids, sound vibrations in water arriving at the lower jaw were carried further with the mandibular fat pad to the tympanic plate, and the vibrations of the plate were transmitted through the ossicles to the cochlea. With the external auditory meatus still present, it was possible for sound in air to reach the tympanic membrane that way. However, with the malleus lacking the manubrium that would attach it to the tympanic membrane, the efficiency of this mechanism was poor. Due to the lack of air sinuses found in modern odontocetes the tympano-periotic complex was still connected to the skull, and hence the ears were not acoustically isolated from each other, providing these animals with poor directional hearing (Fig. 10).

Basilosaurid cetaceans had a functionally modern ear, with the three parts, outer, middle, and inner ear present. The tympano-periotic complex was partly isolated from the skull, with air sinuses around, and the ossicles had the morphology resembling that of dolphins. The large mandibular foramen of *Zygorhiza* indicates that the route for sound to reach the ear was through the mandibular fat pad, and although the external auditory meatus is still present, it was hardly patent.

Hind Limb Anatomy

PETER J. ADAM

With the development of tail flukes for producing propulsion in whales, manatees (*Trichechus* spp.), and dugongs (*Dugong dugon*), the pelvis and hind limbs became vestigial structures that now associate only loosely with the spine. The major role of the pelvic apparatus in these forms, when present, is to serve as attachment points for muscles acting on the genitalia and the abdominal body wall. Marine carnivores, which still maintain close ties with the terrestrial environment, have not had such a dramatic reduction in the pelvis and hind limb structures. Both pinnipeds and the sea otter (*Enhydra lutris*) have united the toes to form flippers. Phocids, which use the hind limbs to generate swimming

thrust and which cannot rotate the hind feet under the body while on land, have highly modified hind limbs. Phocid adaptations include increasing the surface areas available for muscles that flex the leg, modifications of limb muscles to aid in undulatory movements of the spine, and a general increase in the muscle mass operating on the hind limb (in particular the muscles acting to flex the limb).

I. Cetaceans

The known fossil record documenting cetacean evolution shows a progressive reduction and loss of hind limb skeletal elements and disassociation of the pelvic girdle from the vertebral column as whales became less dependent on nearshore environments and developed tail flukes to generate swimming thrust. This trend is most marked with the origin of the basilosaurine whales, in which the tibia and fibula became fused with each other and tarsal elements co-ossified into a single immobile mass. Basilosaurines also mark the point during which the pelvis became disassociated from the vertebral column. Among modern forms, only vestiges of the hind limb skeleton can be found, and these are contained within the body wall. Mysticetes may possess fragments of pelvis, femur, and tibia, whereas the occurrence of hind limb and pelvic elements is more variable among both individuals and species of odontocetes. When present, the pelvis bear little resemblance to those of terrestrial mammals and, when undeveloped, may exist only as a band of connective tissue connecting spinal muscles to those of the genitalia and abdominal wall. If present as a bony element, each pelvis is typically cigar or sickle shaped, with only the pelvic bone proper contributing to its structure (Fig. 1). Atavistic femora and occasional tibiae have been described from numerous (mysticete and odontocete) taxa, although occurrence of these elements is infrequent. Hind limb buds are present during early embryogenesis of all whale species documented so far, although the mesodermal cells that usually form the internal limb structures die or are reallocated to other functions as limb buds are resorbed later in ontogeny (Sedmera *et al.*, 1997; Thewissen *et al.*, 2006). Retention of a rudimentary pelvis is associated with the attachment of numerous muscles acting on the reproductive organs of both sexes. In males, the pelvis is usually larger relative to that of females. It serves as the site of origin for muscles acting on the genitals and anal region (e.g., the penis retractor and levator ani muscles) and may also serve as a site of attachment for posterior fibers of the rectus abdominis muscle. When present, the pelvis is isolated from the spine (sacral vertebrae are absent) but maintains a soft tissue attachment to the hypaxial spinal musculature. Rearrangements of spinal and pelvic

muscles in association with tail-based locomotion have led to considerable controversy over specific identities of muscles in these regions.

II. Sirenians

The evolutionary loss of the hind limb in sirenians closely parallels that of cetaceans (Fig. 1), with modern forms possessing only a vestigial pelvis composed of ischium and ilium bones. In dugongs (Domning, 1991), each pelvis is long and stick-like in appearance, and the ilium and ischium are of subequal length, fusing by 5 years of age in both sexes. In manatees, the pelvis are more plate-like and cross-shaped in lateral view. The ischium is the largest portion of the manatee pelvis, with the ilium forming a small cap on the anterior surface of the bone complex. As in whales, sirenian pelvises lack bony attachment to the vertebral column. In dugongs, the pelvis join with the anterior caudal vertebrae by an aponeurosis thought to be homologous with the coccygeus muscle, as well as by the retractor ischii and ischiococcygeus muscles to caudal chevron bones (small bones underneath each tail vertebra). The pelvis serve as the origin for muscles acting on the genital organs (e.g., in females, the constrictor vulvae, constrictor vestibuli, and urethralis muscles) as well as some muscles inserting into the skin of the abdominal region (e.g., part of the transversus abdominis). The atavistic appearance of femora has been reported for manatees.

III. Marine Carnivores

A. Pinnipeds

The earliest known pinniped, *Enaliarctos* from the late Oligocene of California (Berta and Ray, 1990), possessed a well-developed hind flipper, and intermediate stages in the anatomical progression from a limb used for terrestrial locomotion to one specialized for swimming are undocumented. Anatomical adaptations of the hind limbs of extant pinnipeds largely reflect strategies adopted by each family for swimming and terrestrial locomotion. Phocid seals and walruses (*Odobenus rosmarus*) primarily use the hind limbs to generate thrust while swimming and have relatively more muscle mass in the pelvic region relative to the pectoral region and forelimb. Otariids propel themselves with the forelimbs and have relatively lower pelvic muscle mass. On land, otariids and walruses are able to rotate their hind feet under their body and progress with modified walking motions; phocids lack the ability to rotate their feet under their body and move along the ground with undulatory movements of the body.

Externally, the hind limbs of pinnipeds extend beyond the body contour from the approximate middle or end of the crus. In walruses and phocids the middle digit is the shortest, and digits increase in length both laterally and medially, giving the flipper a crescent shape (more marked in phocids). Thin, extensible interdigital webbing stretches between adjacent digits in these forms. In otariids, the interdigital areas are occupied by thick layers of connective and other tissues, making the hind flipper a much more rigid structure. Emargination of the distal interdigital regions of the flipper confers a scalloped shape to its trailing edge. Claws are reduced in all pinnipeds, although those of the middle three digits tend to be better developed than those of the first and fifth digits. Claws are positioned terminally in phocids and subterminally in walruses, but are located considerably farther proximally in otariids due to the development of distal cartilaginous rods on the ungual phalanges. The presence of these cartilaginous extensions gives the ungual phalanges an hourglass shape and roughened distal ends. The plantar surface of otariid and walrus flippers is hairless, with moderately developed foot pads related to their

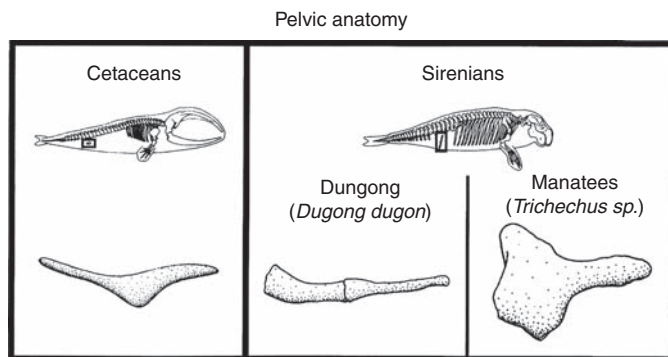

Figure 1 Line drawing of the right pelvis of a cetacean (left) and sirenian (right) in lateral view (anterior toward the right). Position and orientation of the pelvis are indicated by boxes on the skeletal outlines.

ambulatory terrestrial locomotion. Foot pads are lacking on phocids. With the exception of interdigital regions, which are hairless or have only sparse hair, the dorsal pedal surface typically has a hair density subequal or slightly lower than that of the body.

Departures of the skeletomuscular anatomy from the condition observed in typical terrestrial carnivores are most prevalent in phocid seals due to their highly modified (undulatory) terrestrial locomotion and specialized hind limb swimming. The iliac region of the phocid pelvis is expanded laterally, particularly among phocines. This confers a mechanical advantage to the gluteus muscle complex, which inserts onto the greater trochanter of the femur and functions to flex the leg against the water. The ischiopubic region of phocid pelvis, posterior to the acetabulum, is elongate relative to otariids and the walrus. This increases the surface area available for attachment of the strong muscles acting to medially flex the leg during the power stroke of the swimming cycle (e.g., the adductor, gracilis, gemelli, obturatorius, and semimembranosus muscles). The ischial tuberosity, often misidentified as the “ischial spine,” is greatly enlarged in phocids, but undeveloped in otariids and the walrus. It serves as the site of origin for the biceps femoris muscle, which inserts broadly onto the tibia. The orientation and widening of the biceps femoris in phocids indicate that it is primarily responsible for lifting the hind limb off the ground during terrestrial locomotion, as well as medially flexing the limb during swimming. The pinniped femur is short and stout, and the distal condyles are inclined relative to the long axis of the shaft. The fovea capitis of the femoral head is lacking. This indicates the loss of the teres ligament, which normally maintains the femoral head within the acetabulum of the pelvis in terrestrial mammals that have weight-bearing hip joints. In phocids, the lesser femoral trochanter is either reduced or absent, and the two muscles typically inserting onto it have undergone major changes from their usual orientation and function: (1) the iliacus muscle inserts onto the more distal femoral epicondylar crest or proximal tibia and (2) the psoas major muscle, arising from the posterior thoracic, lumbar, and sacral vertebrae, inserts onto the medial surface of the ilium and thus aids in lateral undulation of the spine during swimming rather than acting on the limb. Proximally, the tibia and fibula of most pinniped species become fused prior to maturity. The posterior tibial fossa is deep in phocids, reflecting enlargement of the tibialis caudalis muscle, which originates from this region and inserts onto the tarsus and first metatarsal, acting to plantar flex the pes during the swimming power stroke. The tendon of the flexor hallucis longus muscle passes over a posterior projection of the astragalus that is unique to phocids, limiting dorsal flexion of the pes. This, in combination with the elongated ischiopubis (which limits anteroventral bending of the spine when phocids are on land), limits the ability of phocids to assume a four-legged stance. Additionally, the tibioastragalar joint of phocids is nearly spherical and would unlikely bear the weight of the animal. This is in contrast to the more rigid, hinge-like joint found in other pinnipeds and terrestrial carnivores. Inserting tendons of the large plantar flexing muscles (i.e., the flexor digitorum longus, flexor hallucis longus, and flexor digitorum superficialis muscles) often combine together in a complex manner at the level of the tarsals. A united tendon of these muscles sends branches out to the digits, although slips extending to the first and fifth digits tend to be larger in phocids. The pedal formula of all pinnipeds is 2-3-3-3-3, the primitive condition for all mammals. In phocids and the walrus, metatarsals and phalanges of the first and fifth digits are more robust than those of the middle three digits. This is associated with hind limb swimming, where both digits may act as leading edges of the flipper during the complex power stroke. Metatarsal-phalangeal and

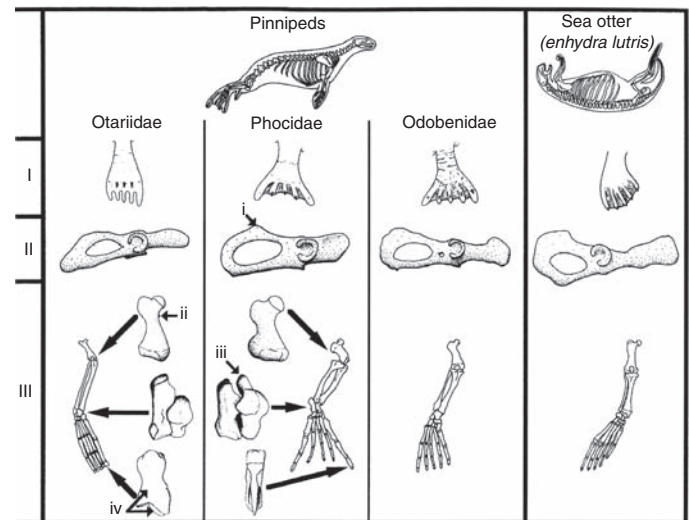

Figure 2 Line drawings of the external flipper morphology (row I), right pelvis (row II, lateral view, anterior is toward the right), and right hindlimb skeleton (row III, anterior, or dorsal, view) of representative species of pinnipeds (otariidae, *Callorhinus*; Phocidae, *Monachus*; and Odobenidae, *Odobenus*) and the sea otter (right). Indicated features of the otariid and phocid hind limbs are as follows: i, enlarged ischial tuberosity of phocids; ii, presence of a lesser femoral trochanter in otariids and walrus (absent or reduced in phocids); iii, posterior projection of the phocid astragalus, over which the tendon of the flexor hallucis longus muscle passes; and iv, first ungual phalanx of the otariid pes showing the lack of a claw and distal roughened surface to which cartilage is attached in life.

interphalangeal joints tend to be of the tongue-and-groove type in phocids and hinge-like in otariids and the walrus. However, all pinnipeds have reduced trochleation of the metatarsals and phalanges (Fig. 2).

Available evidence indicates that blood supplying the crus and pes of phocids passes primarily through the external iliac, femoral, and saphenous arteries. Maintenance of this primitive condition is related to the efficiency of the system for supplying oxygen and nutrients to the heavily used hind limb musculature. In contrast, otariids have adapted the blood vessels such that most of the blood supplying the distal limb regions passes through the internal iliac and gluteal arteries. The passage of blood via this route is believed to enhance heat dissipation. The walrus is intermediate to these conditions, although detailed description of its anatomy is lacking. The presence of a circulatory countercurrent system (*rete mirabile*) in the hind limbs has been reported for several phocid and otariid species. Anatomy of the spinal nerves serving the hind limb of pinnipeds is poorly known. Available evidence suggests that the lumbosacral plexus has shifted posteriorly by one vertebra, being composed of ventral rami arising from the third through fifth lumbar, first through third sacral, and first caudal vertebrae. Division of this plexus into lumbar and sacral plexi is not possible.

B. Polar Bears and Sea Otters

Adequate descriptions of polar bear (*Ursus maritimus*) pelvic and hind limb anatomy have not yet been made, but there is little indication that the morphology of this species has diverged appreciably

from that of other species of *Ursus*. Departures of sea otter hind limb anatomy from that of other terrestrial mustelids (Tarasoff 1972; Tarasoff *et al.*, 1972), however, are seen more readily. Externally, the leg is enclosed within the loose body skin to the approximate level of the ankle. The digits are bound together by interdigital webbing, although the fourth and fifth digits are bound more closely together than other adjacent digital pairs. The sea otter is unusual in that in overall length the digits decrease in size from the fifth to the first: V > IV > III > II > I. While swimming, sea otters use the hind feet to generate thrust and sweep the leg through the water such that the fifth digit forms the leading edge of the pes. The hair densities for the ankle and interdigital webbing have been estimated at 107,000 and 3300 hairs/cm², respectively, compared to a density of 125,000 hairs/cm² for the back. Pads are present on the phalangeal portion of each toe and are variably found ventral to the metatarsals. As with pinnipeds, the fovea capitis is absent from the femur, marking the absence of the teres ligament. The biceps femoris muscle inserts onto the middle of the tibia and maintains the leg in a posterior position. The flexor digit V muscle is very large in the sea otter (relative to other mustelids). This enlargement corresponds to the use of the lateral surface of the pes to lead during the power stroke of the limb. The remaining hind limb anatomy of the sea otter corresponds well with that of terrestrial mustelids (Fig. 2).

History of Marine Mammal Research

BERND WÜRSIG, WILLIAM F. PERRIN AND
J.G.M. THEWISSEN

If research is the gathering of knowledge, then we can think of marine mammal research to have gone on as long as humans have gazed at whales spouting offshore and seals pupping on beaches. But early observations of nature were largely tied up with myths about animals and legends of their capabilities. A common theme appears to have been the changing of humans to dolphins and whales, and the reverse. This theme is recognized in remaining legends of Australian aborigine "dream time," boto (*Inia geoffrensis*) and baiji (*Lipotes vexillifer*) river dolphin folklore (Sangama de Beaver and Beaver, 1989; Zhou and Zhang, 1991, respectively), tales of the god-like killer whales (*Orcinus orca*) of Pacific Northwest indigenous tribes (McIntyre, 1974), and many more.

Some early writings show remarkable insights in marine mammal biology. Well over 2000 years ago, scholars of China's Han Dynasty in the annotated dictionary "Er-Ya," described the baiji as related to marine dolphins, implying that those were known to intellectuals of the time. Even earlier, the Greek philosopher/scientist Aristotle (384–322 BC) differentiated between baleen and toothed whales and described both types in some detail. It is unfortunate but totally understandable in hindsight that he classified cetaceans as fishes, a practice still present in Britain's term "Royal Fishes" under which all whales and dolphins belong by law to the Crown. The Roman writer/lawyer/admiral Pliny the Elder (23–79 AD) published a book on dolphins and whales 400 years after Aristotle's time as part of his 37-volume "Natural History."

Not much scientific inquiry or thought was conducted between Roman times and the western Renaissance, and knowledge, at least written knowledge, of marine mammals languished as well. The modern progression of marine mammal research can perhaps best be

described as occurring in four general (and not mutually exclusive) phases: (1) morphological description from beach-cast specimens and fossils; (2) descriptions of behavior, anatomy, and distribution as gathered during hunting and whaling activities; (3) studies of physiology and behavior in captivity; and (4) studies of ecology, habitat use, numbers, life history patterns, behavior, and physiology in nature. A fifth phase may be thought of as an ever-increasing sophistication in integrating knowledge from terrestrial situations as well as from different fields of marine mammal endeavors.

The phases of research mentioned above follow a rough chronology, with morphology and systematics the main topics pre-1900s; hunting-related habitat, morphological, and behavioral research mainly from the 1850s to the 1970s; scientific captive animal descriptions beginning around 1950; and more ecologically oriented descriptions in nature beginning around the 1970s. All phases are ongoing, with electronic devices helping to elevate in-field research on marine mammal lives to a new level of sophistication. A very readable recent account of the history of marine mammal studies is found in Berta and Sumich (1999). Elsewhere, this volume lists some of the major deceased marine mammal researchers of the past and mentions their classic works in the field (see References).

Pierre Bélon was probably the first “modern” marine mammal author since Pliny’s time. He published accurate descriptions and woodcuts of some whales, dolphins, and seals (Belloni, 1553), and these (and also, unfortunately, the less accurate ones) were much copied by others in the next two centuries.

The real burst of marine mammal knowledge did not come until later, however. And then it came suddenly, in tune with eighteenth century awakening of scientific thought in the western world. While many authors could be mentioned, three early contemporaries did much to advance cetacean descriptions, taxonomy, and systematics. These were the French zoologist La Cépède (1804) and the Cuvier brothers. Georges Cuvier, who arguably founded modern evolutionary theory, wrote on many topics, including cetaceans; whereas his less-famed brother Frederic published two important works on cetaceans (Cuvier, 1829, 1836). These three were followed by the Belgian zoologist Van Beneden in the latter half of the nineteenth century, with work mainly consisting of compilations of information on fossil whales, and by a host of fine morphologists, taxonomists, systematists, and evolutionary historians in the twentieth century (summaries are provided by Rice, 1998; Thewissen, 1998; Pabst *et al.*, 1999; and Reynolds *et al.*, 1999). While much of the earlier work centered on cetaceans, the British zoologist John Edward Gray described both seals and whales in the British Museum (Gray, 1866), and the American zoologist Joel Allen wrote excellent monographs on whales, pinnipeds, and sirenians (Allen, 1880).

Yamase (1760) began the science of marine mammalogy in Japan at about the same time as serious studies began in the west. He presented accurate figures and descriptions of the external morphology of six toothed and seven baleen whale species and distinguished them from fishes. His work was brought to the west in a marine mammal section of “Fauna Japonica” by Siebold (1842). Otsuki began to describe the internal anatomy of cetaceans of Japan in 1808, but his manuscript remains unpublished.

A second major phase of information gathering, often linked intricately with that just described, involved descriptions of animals as related to HUNTING and WHALING. Morphological information was at the core of these descriptions, but behavior and the basic society structure of whales and pinnipeds—of course much of the time affected by the hunting activities themselves—were recorded as well. One of the earliest accurate accounts consisted of German-born

and Russian-naturalized Georg Steller’s descriptions of pinnipeds and the soon-after extinct Steller’s sea cow (*Hydrodamalis gigas*), the largest and only cold-water sirenian known (originally published in Latin in 1751, and republished in English as Steller, 1899). Quite a few books related especially to whaling were produced, but perhaps the most enduring one from the nineteenth century was by the North American whaling captain Charles Scammon, who wrote with feeling and accuracy on behavior and life history habits of marine mammals of the North Pacific (Scammon, 1874). In the twentieth century, one of the most famous works largely relying on whaling-accumulated data consists of Everhard Slijper’s book “Whales and Dolphins” (published in English in 1976). A very readable account of whaling and the literature derived from whaling can be found in “Men and Whales” by Richard Ellis (1991).

Modern factory whaling itself helped to usher in excellent research on numbers, habitat use, life history patterns, and morphology/physiology. This was so especially during the *Discovery* investigations of 1925–1951, a British research program that was responsible for a wealth of new data, especially on large whales of the southern hemisphere. These investigations consisted in part of extensive long-term tagging (“discovery tags,” shot into the blubber and muscle tissues of whales, and later recovered during actual whale kills). In this manner, migrations of great whales were delineated long before modern radio and satellite tags provided such information (e.g., Allen, 1980). Dozens of fine researchers published hundreds of papers that relied on the *Discovery* expeditions, and on other whaling data since then (e.g., Laws, 1959) (see also the section “International Whaling Commission” in this volume). As a counterpoint to early cetacean information, the reader interested in pinniped research from the ancient Greeks to about 1983 can consult an excellent annotated bibliography of over 12,000 publications by Ronald *et al.* (1976, 1983).

While whaling, sealing, and other forms of direct hunting are much abated today as compared to in the 1960s, there are still powerful low-level, oft-indigenous hunts, especially in protein-poor areas of the world (Perrin, 1999). As a result, data are being accumulated and analyzed on morphology, GENETICS, taxonomy, and SYSTEMATICS, life history, prey patterns, and so on. Excellent recent information has become available from results of hunting on, e.g., pilot whales (*Globicephala* spp.), oceanic dolphins (especially of the genus *Stenella*), bowhead whales (*Balaena mysticetus*), sperm whales (*Physeter macrocephalus*), and several seal, fur seal, and sea lion species (summaries in Berta and Sumich, 1999; Reynolds and Rommel, 1999; and Twiss and Reeves, 1999).

A third major research avenue has come about as a result of keeping marine mammals in captivity. Attempts to do so in the early part of the last century usually resulted in the animals’ untimely deaths—due to poor water, incorrect or tainted food, disease, and aggression between individuals in confined spaces. Facilities that housed marine mammals simply replaced dead ones by more captures from nature. However, especially since the 1970s, amazing strides in husbandry have been made for all marine mammals (except large whales), and the better aquaria now keep—and breed—animals very well. Unfortunately, there are still many “primitive” facilities, especially in less-developed parts of the world. At present, there are representatives of all major taxonomic groups in captivity, as show animals and for research: toothed whales and dolphins (only two baleen whales, each time young gray whales, *Eschrichtius robustus*, have been successfully kept); pinnipeds of all types, but especially California sea lions (*Zalophus californianus*); sirenians (mainly the West Indian manatee, *Trichechus manatus* and the dugong, *Dugong dugon*); and polar bears (*Ursus maritimus*) and sea otters (*Enhydra lutris*).

Only through holding animals in controlled situations have researchers learned that dolphins echolocate (Au, 1993); that all marine mammals exhibit reduced heart and general metabolic rates during dives (Ridgway, 1972; Pabst *et al.*, 1999); and that both dolphins and sea lions have remarkably advanced cognitive capabilities (Tyack, 1999). Furthermore, it is now fully appreciated that while pinnipeds and cetaceans are finely tuned underwater swimmers and divers with superbly evolved methods of breath holding, avoiding or reducing lactic acid depth during long submergences, and navigating in dark and cold waters, there is no secret “magic” to their energetic capabilities (Costa and Williams, 1999).

One major misstep from studies in captivity took place: the American John Lilly avowed in the 1960s that his research on bottlenose dolphins (*Tursiops truncatus*) proved that these popular show animals have an intelligence superior even to that of the brightest dogs (*Canis lupus familiaris*) and chimpanzees (*Pan troglodytes*), and likely equal to that of humans (Lilly, 1967). Careful studies by others have shown that dolphins are undeniably “smart” (intelligence is very difficult to define and compare, but has something to do with well-developed flexibilities of behavior and of innovative learning), but that there is no reason to believe that dolphins fare better in this “intelligence/cognition” sphere than many other highly social mammals (Herman, 1980, 1986; Tyack, 1999; Wells *et al.*, 1999).

While the study of marine mammals dead from the sea and live in captivity continues and grows, a relatively new approach has become the major research avenue since the 1970s. This consists of our fourth phase, of researchers going out into nature to observe the animals in their own milieu; as the animals associate with conspecifics; eat and are being eaten; and mate, give birth, and raise their young. We are learning more about the lives of these generally social creatures as they face storms, heavy years of sea ice, seasons of poor food resources (e.g., caused by “El Niño” southern oscillation climatic events), parasite infestations, adoring but noisy boatloads of whale-watching tourists, crowded shipping lanes, and habitat degradation near shore and in mighty rivers. This information on ecology of marine mammals is vital if we are to help protect them and their natural ecosystems from the depredations of overfishing, habitat POLLUTION by chemicals, heavy metals, and noise; and the results of global climate change and whole-scale habitat destruction due to the effects of ozone depletion and global warming (Tynan and DeMaster, 1997; Ferguson *et al.*, 2005).

Studies in nature often rely on visual or photographic recognition of individual whales, dolphins, and pinnipeds, often with the help of tags or color marks but also by natural markings (Hammond *et al.*, 1990). Researchers have described movement patterns by tracking animals with surveyor’s transits from shore, and from shore and vessels by small radio tags placed on their bodies (Würsig *et al.*, 1991). Since the early 1990s, satellite tags that relay position information to earth-orbiting satellites have become smaller, less expensive, and ever more popular. As a result, we know that northern elephant seals (*Mirounga angustirostris*) swim and dive into deep oceanic waters for months at a time, humpback whales (*Megaptera novaeangliae*) take rapid zigzag courses between their mating and feeding grounds, North Atlantic right whales (*Eubalaena glacialis*) undergo previously unsuspected jaunts between Greenland and New England during the feeding summer, and much more (Wells *et al.*, 1999). Tags are being fitted not only with depth-of-dive measuring and telemetering devices, but also with ways to ascertain geographic position, swimming velocity, angles of dives, water and skin temperature, individual sound production, heart rate, and, in the future, other physiological measures. Recent advances in small and low-light capable video camera/record systems are even giving data on SWIMMING, socializing,

and feeding behavior directly from the animals under water (Davis *et al.*, 1999).

Physiological research, previously entirely within the realm of captivity, is more and more possible with innovative or sophisticated techniques in nature. Samples of stool, urine, blood, and even mother’s milk are being collected from pinnipeds resting on land or ice. Trained dolphins have been released at sea, commanded to dive, and then told to exhale into a funnel to ascertain oxygen consumption values and to station themselves so that blood can be drawn. Small darts have been developed that are fired from a crossbow or pneumatic pistol and that obtain skin and blubber samples from free-living cetaceans for analyses of genetics (Dizon *et al.*, 1997), toxin loads, reproductive status, and blubber energy content for relative measurements of health within and between populations. Sloughed skin samples from breaching whales have been successfully collected from the water and genetically sampled for gender, social grouping, and population data. A technique has been developed to harmlessly “skin-swab” bow-riding dolphins, also for genetic analysis (Harlin *et al.*, 1999).

In response to an apparent increase in marine mammal strandings and the emergence of new marine mammal diseases in recent years, studies of wild marine mammal disease and ocean chemical contaminants are on the increase. While studies in nature have yielded data on the presence of deadly viruses and contaminant levels in tissues of beached and dying marine mammals (Aquilar and Borrell, 1997), they have provided little insight into immune defense against disease or the biochemical consequences of contaminants. More recently, e.g., species-specific biomarkers have been developed to assess the dolphin immune system (Romano *et al.*, 1999). Because they are readily available for long-term studies requiring serial sampling of tissues and health and reproductive histories, captive marine mammals afford unique opportunities to provide basic insight into the relationships among contaminants, the immune system, and animal health. Once they are developed and tested on animals in captivity, biomarkers can be used with wild marine mammal populations to assess contaminant exposures and their possible effects on immune systems and neurologic responses (Ridgway and Au, 1999), as well as on reproductive success (Ridgway and Reddy, 1995), growth, and development.

The sensitive hearing of marine mammals has led to concerns that intense sound or noise pollution generated by humans could impede communication, cause physiological stress, or damage hearing. Marine mammal hearing studies currently underway should help to define mitigation criteria for the effects of human-generated sound in the ocean (Schlundt *et al.*, 2000), and ultimately allow us to find a balance between the ecological needs of marine mammals and the role the ocean plays in commerce, exploration, travel, and defense.

Overall, descriptions of marine mammal taxonomy and population biology have shifted from mainly morphological approaches to an increasing reliance on molecular methods. Up through the 1960s, cetologists studied dolphins by harpooning them. For example, the revision of the spotted dolphins (*Stenella attenuata* and *S. frontalis*) by Perrin *et al.* (1987) was based in part on dolphins collected at sea by Francis C. Fraser, Dale W. Rice, William E. Schevill, and Edward D. Mitchell, all eminent scholars and pioneers of modern cetology. Without those specimens, the study would not have been possible; that is the way it was done until protection of marine mammals became the norm in most countries in the 1970s. Another source of specimens has been dolphins that died in oceanaria. The same revision by Perrin *et al.* (1987) included spotted dolphins

retrieved from oceanaria by David K. Caldwell through the 1970s and early 1980s. And at that time, there were still a number of accessible directed dolphin fisheries; the spotted dolphin review also included specimens from directed fisheries in the Caribbean, St. Helena, West Africa, Japan, and the Solomon Islands. Today, dolphins, whales, and pinnipeds are stringently protected in the wild in most places. For oceanaria, restrictions have been placed on species and numbers of animals that can be captured for exhibit and the high monetary value of captive marine mammals has resulted in better husbandry and fewer deaths. As a result of these factors, marine mammal biologists practicing morphological approaches became limited to specimens from strandings and bycatch, greatly decreased opportunities for amassing adequate series of specimens for quantitative analysis. But then along came biopsy sampling and ready techniques of amplifying DNA fragments by a technique termed *polymerase chain reaction (PCR)*. Collection of samples by biopsy is legal and doable, so the balance of taxonomic and population studies has shifted from morphology to genetics. And the traditional morphologists have been scrambling to keep up by re-educating themselves in the new techniques or recruiting collaborators who know their way around genetics.

The study of marine mammals has now matured into a fifth phase, characterized by the obliteration of boundaries that separated the previous phases. New studies on marine mammals are often integrative, combining methods and ways of thinking largely gleaned from terrestrial animals. This comparison of ideas and research techniques holds great promise for the understanding of the biology of marine mammals.

As our understanding of their biology increases, marine mammals become appealing subjects for approaches that are at times laboratory heavy and at times nearly biomedical in scope. In turn, these approaches enrich knowledge of marine mammals. For instance, biochemical analyses of body fats, first championed for humans and other terrestrial animals, give new insights into the functions of different fats in cetaceans (Koopman *et al.*, 2003). Immuno-histochemical staining techniques originally used for non-marine mammal studies allow the identification of genes that significantly affected cetacean evolution, such as those genes responsible for the loss of hind limbs (Thewissen *et al.*, 2006). Our understanding of the social systems of terrestrial mammals, with one major aspect being sperm competition at the physiological level (Kenagy and Trombulak, 1986) has begun to inform us about the relatively non-competitive baleenid whales, gray whales, quite a few species of dolphins, and manatees that have polygynous or polygandrous (multi-mate) societies (Reynolds *et al.*, 2004).

Through sophisticated studies with modern techniques, marine mammalogy is beginning to enrich more broad fields of science such as behavioral ecology, physiological ecology, and evolutionary biology. It was recognized long ago that marine mammals represent amazing natural experiments of evolution, and the maturation of the field of marine mammalogy is allowing for these experiments to be explored, and to inform all of biology.

Sophisticated electronic and biochemical techniques have recently been and are being developed to study the lives of marine mammals. However, the “tried and true” methods of looking at fossil bones, dissecting and describing pathologies of a net-entangled animal or one cast on shore after a storm, safely and carefully experimenting with animals in captivity, and the dogged gathering of behavioral information by binoculars and notebook are by no means passé. The greatest change since about the 1960s is the ever wider availability of information. This means that there is now a wealth of background knowledge

available to anyone anywhere with a computer and an Internet connection. We are, in this new twenty-first century, in a vibrant phase of marine mammal research, and we see a very bright future for evermore exciting discoveries in our field.

Although much of the research landscape looks bright, we would be amiss if we did not cite a note of pessimism as well, as it is undeniable that many populations and some entire species are facing reductions and even extinction due to human-caused habitat degradation, including rapid climate change. For example, the Chinese river dolphin, baiji, is very likely extinct (Turvey *et al.*, 2007), and the vaquita (*Phocoena sinus*) and Mediterranean monk seal (*Monachus monachus*) may not be far behind. No amount of modern and multi-disciplinary research will be able to wrest information from a species that is gone from the face of the Earth.

Hooded Seal

Cystophora cristata

KIT M. KOVACS

I. Characteristics and Taxonomy

The hooded seal is a large phocid that is silver-gray in color with irregular black spots covering most of the body; the face is often completely black (Fig. 1). Adult males are about 2.5 m long and weigh an average of 300 kg; large males can be in excess of 400 kg. Adult females are considerably smaller than males, measuring 2.2 m in length and weighing an average of 200 kg. Hooded seal pups are approximately 1 m long when they are born and weigh about 25 kg. They are blue on their backs and silver-gray on their bellies (Fig. 1). This distinctive "blueback" pelage is maintained for about 2 years (Lavigne and Kovacs, 1988).

The most distinctive physical feature of hooded seals is the prominent nasal ornament borne by adult males (Fig. 1). When relaxed the nasal appendage hangs as a loose, wrinkled sac over the front of males' noses. During the breeding season (in March) males inflate this sac to display to females and to other males, forming a tight, bi-lobed "hood" that covers the front of the face and the top of the head. This structure

Figure 1 (A) Hooded seal mother-pup pair with an attending male in the background. (B) Blueback hooded seal newly weaned, 4 days old. (C) Hooded seal male with the nasal septum extruded and hood partially inflated.

is the source of the species' common name. Males also have the ability to inflate the elastic nasal septum, which when expanded, protrudes through one nostril as a big membranous pink-red balloon; the source of its secondary common name, the bladdernose seal. Both of these secondary sexual characters are used by males to display to females and to other males during the breeding season. The hood is also used as a threat at other times of year.

The taxonomic history of the species is a bit complex. They have been linked with the elephant seals by some authorities (who attributed these animals jointly to the tribe Cystophorini), and the blueback (pups) were actually described originally as a separate species (*Phoca mitrata*, Cuvier) in the early 1800s (Kovacs and Lavigne, 1986). But, for quite some time hooded seals have been classified

within the family Phocidae, subfamily Phocinae, and are the only species in the genus *Cystophora*.

The dentition of hooded seals is I 2/1 C 1/1 PC 5/5. The teeth, other than the canines, are quite small.

II. Distribution and Abundance

Hooded seals are a migratory species with a range that encompasses a large sector of the North Atlantic (Fig. 2). They follow an annual movement cycle that keeps them in close association with drifting pack ice most of the time. During the spring, the adults concentrate for breeding purposes in three locations: one group forms off the east coast of Canada which is split into two whelping (birthing) patches, one in the Gulf of St. Lawrence and the other north of Newfoundland—an area known as the Front; a second group congregates in the Davis Strait; and a third comes together on the West Ice, east of Greenland. Some weeks after breeding the animals move into traditional molting areas on the southeast coast of Greenland, near the Denmark Strait or in a smaller patch that is found along the northeast coast of Greenland, north of Jan Mayen. After the annual molt, hooded seals disperse broadly for the late summer, autumn, and early winter months, preferring areas along the outer edges of pack ice but ranging quite broadly both toward the north and south of the North Atlantic. Records of hooded seals being found outside their normal range are not uncommon; young animals in particular are great wanderers. Juveniles have been found as far south as Portugal and the Caribbean in the Atlantic Ocean and in California on the Pacific side (e.g., Mignucci-Giannoni and Odell, 2001).

The global population of hooded seals is approximately 660,000 animals. Three stocks are recognized for the purposes of setting harvest quotas: in Canadian waters (including the Front and Gulf breeding areas), the Davis Strait, and the West Ice (west of Jan Mayen Island). The West Ice stock declined markedly from the 1940s to the 1980s but has stabilized during the last two decades at levels (70,000) that are as low as 10–15% of the population size 60 years ago. Annual pup production varies considerably from year to year, in part due to prevailing sea ice conditions.

Genetically speaking, hooded seals are reported to be panmictic.

III. Ecology

Hooded seals are pack-ice seals that spend much of the year in association with sea ice. However, they can go on pelagic excursions for many consecutive weeks far from ice-filled waters. During such trips they do not haul out. Hooded seals are deep divers; adult animals can dive to depths of over 1000 m and can remain under water for periods of up to almost an hour (Folkow and Blix, 1999). The diel pattern of diving is quite consistent, but they seem to dive deeper and longer during the day compared to at night. Diving in winter also appears to be deeper and longer than during the summer season. Hooded seals feed pelagically on a variety of deep-water fishes, including Greenland halibut, and a variety of redfish species as well as squid. Herring, capelin, sand eels, and various gadoid fishes including Atlantic cod and Arctic cod can be important seasonally. The hooded seal diet appears to be more varied when they are feeding in inshore waters compared to during their pelagic off-shore periods, when they forage on only a few species (Haug *et al.*, 2007).

Polar bears (*Ursus maritimus*) are natural predators of hooded seals, but human exploitation is likely the greatest source of mortality. Killer whales (*Orcinus orca*) are also a likely predator, although this has never been documented conclusively.

Figure 2 Map showing the distribution of hooded seals (pink-shaded area).

IV. Behavior and Physiology

Hooded seals are for the most part solitary animals outside the breeding and molting seasons. Even during these two annual phases when they do aggregate into loose herds, they are very aggressive with one another and do not tolerate close contact beyond the mother–offspring bond or a short male–female pairing period. But, even at sea multiple hooded seals can be seen together sometimes, perhaps attracted to a common resource such as abundant food rather than their proximity being a social tie. Their vocal repertoire is quite simple, as would be expected for a species that is not highly social (Ballard and Kovacs, 1995).

The breeding season occurs in late March. It is short, lasting only 2–3 weeks in a given area. Females give birth in loose pack ice areas, preferring quite thick first-year ice floes for whelping. They space themselves out within the herd at intervals of 50 m or more when ice conditions permit, but the form of the herd and inter-female distances are highly variable, depending on the ice conditions. Mothers attend their pups continuously during the 4-day long period of lactation (Bowen *et al.*, 1985). Hooded seals are notable for having the shortest lactation period of any mammal. Pups are born in a very advanced developmental state, having already shed their grayish-white embryonic first coat of hair (which appears as tight little disks

of hair when the placenta is passed) while in the uterus, and having already accumulated a thin layer of subdermal blubber (Lydersen and Kovacs, 1999). During the incredibly short nursing period, pups drink up to 10 l of milk per day that contains an average fat content of 60% (Debiez *et al.*, 1999). This energy-rich diet allows pups to more than double their birth mass during the few days that they are cared for by their mothers; they gain approximately 7 kg per day during nursing. Energy assimilation is extremely efficient during lactation; pups store approximately 75% of the energy they ingest (Lydersen *et al.*, 1997). Pups are weaned weighing 50–60 kg. Mothers lose about 10 kg per day during the nursing period; 40 kg are lost over lactation, representing approximately 17% of total maternal body mass (Kovacs and Lavigne, 1992). During the time when mothers are with their pup, a male often attends the pair. Males compete with one another to maintain positions close to a female. The battles are often bloody, and the mating season is energetically costly. Males lose an average of 2.5 kg per day, which represents a seasonal loss of about 44 kg (14% of total body mass; Kovacs *et al.*, 1996). When a mother is ready to leave her offspring, the attending male accompanies her to the water where mating takes place. Males will return to the whelping area after mating with a female, to resume mate searching. Individual males have been recorded with up to eight females in one breeding season; they can be

considered polygynous (serially monogamous; Kovacs, 1990). Like all phocid seals, hooded seals have delayed implantation of the embryo, for 3–4 months, and an active gestation period of about 8 months.

The pups remain alone on the ice following weaning for some days or weeks before going to the water and learning to swim, dive, and forage. During their time on the ice they fast, using body reserves stored in their substantial blubber layer to fuel their energy needs. When they do start to eat, pups feed on krill and other invertebrates initially, until they have sufficient aquatic skills to capture fish. Little is known about juvenile hooded seals. They are only infrequently seen among adult breeding or molting aggregations. It is assumed that they spend a lot of their time at sea and in isolated arctic pack ice areas. They dive to depths in excess of 500 m during their first year of life.

Hooded seals molt annually, in mid to late summer at traditional sites (discussed earlier). Molting herds are usually loose aggregations, similar to breeding concentrations. However, ice conditions dramatically affect the geographic locations and the densities at which the animals concentrate.

Most physiological studies of hooded seals have investigated various aspects of their diving capacity. They have elevated hematocrit, large myoglobin stores, high tolerance to CO₂, large blood volume, and other features that are typical of deep-diving seals. Adult hooded seals have the largest body oxygen stores reported to date (89.5 ml/kg; Burns *et al.*, 2007). Hooded seals have large, frontally facing eyes that are likely important in light detection at depth (possible detection of prey-emitted phosphorescence). They also have well developed though not elaborate vibrissae.

V. Life History

Bluebacks go through a gradual transition, changing slowly over a period of several annual molting periods and becoming increasingly spotted until they have the irregularly blotchy pelt of the adult. Male and female pups are similar in size, but by 1 year of age there are distinct differences in length and mass between the sexes that persist throughout life. The marked sexual dimorphism within this species suggests that the sexes are likely to exhibit different distributions, foraging patterns, etc., but few details regarding at-sea portions of the life cycle are available. Only females and young animals have been satellite-tracked to date. Females reach sexual maturity at an age of three years; males are a little bit older when they mature and are probably significantly older before they can compete at a level that permits them to mate. Hooded seals live to be 25–35 years of age.

VI. Interactions with Humans

Hooded seals have been commercially exploited for centuries; usually in conjunction with hunts whose primary target was the more abundant harp seal. Norway, Russia, Denmark, Greenland, Great Britain, and Canada have taken part in commercial harvesting of hooded seals. Pre-World War II hunting was done for oil and leather, but improved techniques for handling furs meant that the blueback pelt was the most financially lucrative product of the hooded seal harvest following the war. Adults continued to be taken for oil and leather production, but the numbers were reduced because the market demand for these products dropped. Because adult females remain on the ice to defend their pups against hunters, many adult females were killed. Regulations limiting the killing of mothers have become increasingly restrictive and few females are now taken in the whelping patches. Annual catches of hooded seals have always varied dramatically,

depending largely upon ice conditions at the time of breeding. In years of high harvests, up to 150,000 animals have been taken in the North Atlantic. Seal management in international waters has been put under the auspices of the International Commission for the Northwest Atlantic Fisheries (ICNAF), with Canada, Norway, and Denmark being voting members in the early 1960s. Documented population declines of hooded seals lead to the introduction of quota management during the 1970s. A bilateral agreement for East-Atlantic harvesting between Norway and Russia was also formulated. Following Canada's declaration of a 200-mile economic zone in the late 1970s, Norway and Canada also created a bilateral agreement, and ICNAF was transformed into the Northwest Atlantic Fisheries Organization (NAFO). Under this agreement, Canada and Norway cooperate extensively with information exchange regarding hooded seal abundance estimates and quota revisions. The small population of hooded seals breeding in the Gulf of St. Lawrence is protected from harvesting, as is the Denmark Strait molting concentration.

Declines in abundance of West Ice seals have resulted in the termination of hunting in this area since 2005 as a precautionary measure. Subsistence harvesting of hooded seals takes place in Arctic Canada and in Greenland in addition to Canada's commercial harvest. Similar to the case for most pack-ice breeding seals, the most obvious threat to this species is climate change (Kovacs and Lydersen, 2008). Sea-ice predictions suggest that the breeding habitat of hooded seals will decline dramatically in the decades to come, and the precipitous declines in the abundance of the Northeast Atlantic hooded seal stock in recent decades might be linked to changes already taking place in sea-ice conditions and distribution as well as broader ecosystems shifts.

Hooded seals are not a typical aquarium species, but they have been kept in zoological parks and research facilities in Europe and North America.

Figure 1 Hourglass dolphins possess two lateral white areas along the flank that are united by a thin white line that resembles an hourglass. Schools of individuals can swell from the small group of 3 pictured, commonly to around 6 or 7 and rarely up to 60 individuals. Photograph by Robert Pitman.

Hourglass Dolphin

Lagenorhynchus cruciger

R. NATALIE P. GOODALL

I. Characteristics and Taxonomy

The name *Delphinus cruciger* was based on a drawing from a sighting in the South Pacific in 1820. Synonyms include *D. albigena*, *D. bivittatus*, *Electra clancula*, *E. crucigera*, *D. superciliosus*, *Phocoena crucigera*, *P. d'Orbigny*, *Lagenorhynchus wilsoni*, *L. latifrons*, and *L. Fitzroyi* (with *L. australis* and *L. obscurus*). The complicated synonymy of this species has been reviewed by Goodall *et al.* (1997). The accepted combination, *L. cruciger*, was made by Van Beneden and Gervais in 1880. Common names have included the crucigere, the albigena, grindhval, sea skunks, and springers; the name in Spanish is *delfin cruzado*.

The hourglass dolphin is mainly black or dark with two elongated lateral white areas, in some animals joined with a fine white line, that resembles an hourglass, which gives it its common name (Fig. 1). The forward patch extends onto the face above the eye, which is within the black surface but outlined with a large dark eye spot with a point forward and a thin white line. The dark pigment of the lips is of varying shape; a gape to flipper stripe may be gray to tan, beige, or even rose. One animal had a white half-moon mark outlining the blowhole. On the side below the white flank patch, there is a lobe of white projecting forward, which may form a sharp point, a blunt, curved shape, or a hook. The flank patches on some animals almost meet on the upper tail stock. Part of the underside of the flippers is white. The ventral region is generally white, with some dark areas forward from the tail stock to the genital region. The pigmentation of juveniles has not been described.

The hourglass is a rather stocky dolphin with a large, recurved dorsal fin that is variable in shape from erect to hooked. The tail stock is often keeled, especially in large males. Total lengths ($n = 13$) range from 142 to 187 cm. Females ($n = 5$) measured 142–183 cm, males ($n = 8$) 163–187 cm. This is probably not the total range of length

Figure 2 Hourglass dolphin specimen RNP 2366 stranded at Estancia Moat, Tierra del Fuego in January 2005: view of teeth. Photograph by Carolina Navarro.

for the species. Weights are known for only five specimens. Females of 163.5 and 183 cm weighed 73.5 and 88 kg, respectively. A 174-cm male weighed 94 kg, one of 180 cm 93 kg, and one of 178.5 cm about 100 kg (it had been attacked by birds).

The condylobasal lengths of 12 skulls ranged from 316 to 370 mm. Visible teeth numbered 26–34 upper and 27–35 lower in each jaw (Fig. 2). Vertebral count is Cv7, Th12–13, L18–22, and Ca29–33 for a total of 69–72 ($n = 9$). The first two cervicals are fused ($n = 6$). The vertebrae of *L. cruciger* are smaller than those of *L. australis*, but slightly larger than those of *L. obscurus* and are similar to the latter in shape (illustrated in Goodall *et al.*, 1997). There are 12–13 ribs ($n = 9$); one specimen had seven pairs of sternal ribs, another eight. The phalangeal formula ($n = 6$) is: I = 2–3, II = 8–11, III = 6–8, IV = 2–4, and V = 0–2.

The intestine lengths of three specimens were 18, 18.5, and 19.7 m. One specimen had 670 lobes in the left kidney.

II. Distribution and Abundance

The hourglass dolphin is pelagic and circumpolar in the Southern Ocean, in both Antarctic and subantarctic waters, from about 45°S to fairly near the ice pack (Fig. 3). Exceptional northern sightings were at 36°14'S in the South Atlantic and 33°40'S in the South Pacific off Valparaiso, Chile. The southernmost sighting was at 67°38'S in the South Pacific. Most specimens were found between 45°S and 60°S, the northernmost from New Zealand and the southernmost from the South Shetland Islands. Hourglass dolphins are often sighted throughout their range. Abundance for south of the Antarctic Convergence in January, based on sighting surveys from 1976/1977 to 1987/1988, was estimated at 144,300 (CV = 0.17) (Kasamatsu and Joyce, 1995).

III. Ecology

This dolphin is circumpolar in the Southern Hemisphere on both sides of the Antarctic Polar Front and northward in cool currents associated with the West Wind Drift. Recorded water temperatures range from 0.3°C to 13.4°C. Sightings reflect observer effort, with most from the Drake Passage, due to ship traffic between South America and the Antarctic Peninsula, as well as south of New Zealand and Australia.

Although oceanic, this dolphin is often sighted near islands and banks. It is most often seen in areas with turbulent waters. It has been sighted during nearly every cruise in the Southern Ocean, especially in the Drake Passage (A. Walley and others, personal communication) and South Georgia. During dedicated bird and mammal surveys, 480 hourglass dolphins were recorded from September to February over the continental slope or in deep waters to the north, east, and south of the Falkland Islands (Islas Malvinas), but none were seen in July or August (White *et al.*, 1999). Recent sightings have been made in the Beagle Channel (D. Kuntshik, personal communication) and Canals Sarmiento and Ballenero, Chile. On

September 24, 2005, one apparently wounded animal (possibly from a boat strike?) swam for several hours among the catamarans tied up at the tourist pier in Ushuaia, Tierra del Fuego. The hourglass pigmentation was clearly visible.

These dolphins were found so often with fin whales (*Balaenoptera physalus*) that whalers used them as cues for finding whales. They have also been seen with sei and minke whales (*B. borealis* and *B. bonaerensis*), large bottlenose whales (*Hyperoodon* and *Berardius*), pilot whales (*Globicephala melas*), and southern right whale dolphins (*Lissodelphis peronii*) (Goodall, 1997; White *et al.*, 1999). Seabirds, mainly great shearwaters and black-browed albatrosses, feed in association with hourglass dolphins (White *et al.*, 1999).

Hourglass dolphins often feed in large aggregations of seabirds and in plankton slicks. The stomachs of a few specimens from different oceans have been examined. Prey items included unidentified small fish (off Chile), the fish *Krefflichia andersonii* (Myctophidae) of about 2.4 g and a length of 55 mm (east of Cape Horn); small squid, including some from the families Onychoteuthidae and Enoploteuthidae (Indian Ocean); and fish otoliths, squid beaks, and crustaceans (South Pacific) (Goodall *et al.*, 1997). Two males from Chubut, Argentina, contained 10 prey species, including fish, cephalopods, crustaceans, and polychaetes. The most abundant prey in the first dolphin was the lesser shining bobtail squid (*Semirossia tenera*), followed by the small Patagonian squid (*Loligo gahi*) and juvenile Argentine hake (*Merluccius hubbsi*), indicating that the dolphin fed in surface waters. Annelids in the stomachs may have come from prey species. The most abundant prey of the second dolphin was the pelagic fish *Protomyctophum* sp. (Myctophidae); the stomach also contained one Argentine hake and the squid *Illex argentinus* and *L. gahi*.

Recorded parasites include the cestode *Phyllobothrium delphini*, the nematode *Anisakis simplex sensu lato*, and digeneans (Capulidae) of the genera *Hadwenius* and *Oschmariella* (Gasitúa *et al.*, 1999; Fernández *et al.*, 2003).

Figure 3 Distribution of the hourglass dolphin compiled from incidental and dedicated sighting surveys and the location of specimens from 1824 to 2007. Small circles indicate single specimens, and large circles represent three specimens off New Zealand and six at Tierra del Fuego.

The largest animal known, a male from the Falkland (Malvinas) Islands, had long-standing gastric trauma, a penetration of some duration, with extreme peritonitis, as adhesions were forming. One of the animals from northern Patagonia had five ulcers in the main stomach, one with an *A. simplex* larva attached (Fernández *et al.*, 2003).

Concentrations of heavy metals in one animal in the blubber were cadmium 0.0022 µg/g damp weight and lead 0.0013 µg/g damp weight (Gazitúa *et al.*, 1999).

No predators are known, although killer whales and leopard seals are possibilities. One animal had wounds in the abdominal area which may have been made by sharks (Fernández *et al.*, 2003).

IV. Behavior and Physiology

Nothing is known of the migratory movements of this species. Animals of the Antarctic Polar Front zone and the continental shelf break, they may move into subantarctic waters or nearer shore in winter. However, during dedicated surveys, this species was not observed off the Falkland Islands (Las Malvinas) in July and August, where many had been seen in spring and summer (White *et al.*, 1999).

Hourglass dolphins are rapid swimmers with a forward, plunging movement. They commonly bow-ride ships, especially in rough weather. They often leap from the sea, porpoise like penguins, and have been observed to spin. They especially seem to enjoy wave-surfing during very high seas.

During the Southern Hemisphere minke whale assessment cruises conducted by the International Whaling Commission (IWC), school sizes ranged from 1 to 60 animals (mean 7). Other studies reported mean sizes of 4 and 5.7 animals.

During passive acoustic surveys for odontocetes aboard the RV *James Clark Ross* in 1998/1999 and January/February 2000, dolphin-like clicks were confirmed on two occasions when the dolphins were seen near the hydrophone and heard on 22 more in the area north and south of South Georgia and 60°S and southward off the Northwest Antarctic Peninsula, but they could not all be identified with certainty (Leaper *et al.*, 2000).

V. Life History

Very little is known of growth and reproduction in this species. A 163.5-cm female was sexually immature and one of 183 cm was pubescent. Based on fusion of the vertebral epiphyses, the 163.5-cm female was physically immature. The 183-cm female was subadult.

Males of 174 and 187 cm were sexually mature. A male of 163 cm was physically subadult, one of 187 cm was nearly mature, and one of 174 cm was physically mature. Nothing is known of the young, times of birth, and reproduction rates; only three calves, seen in January and February, have been reported.

Three specimens have been aged through sectioning of teeth. A male of 164 cm had eight growth-layer groups (GLGs), and one of 178 cm had nine; both were sexually mature (Fernández *et al.*, 2003). The Strait of Magellan male of 180 cm had eight GLGs.

The testes of sexually mature males are very large in relation to total length. Those of the 180-cm Strait of Magellan male weighed 420 and 400 g (L-R) and measured 25.5 cm in length and 6.5 cm in width. This animal, collected in November, may not have been sexually active. Those of the Falkland animal (187 cm), stranded in January, weighed 2250 and 2200 g and measured 36 × 11 cm. The testes of the Tierra del Fuego animal of 178.5 cm, also in January, weighed 1900 and 1850 g and measured 42.4 × 8 cm and 42.9 × 10.1 cm. The prostate gland of this animal also seemed large, weighing 429 g (17.7 × 10.8 × 3.4 cm).

VI. Interactions with Humans

Hourglass dolphins seem to be attracted to ships. They often approach from considerable distances, changing course to do so, and remain with the ship for up to 30 min (Thiele, 1996).

Several hourglass dolphins have been taken for scientific study (Goodall *et al.*, 1997). No other directed catches are known. At least one stranded animal was probably the result of a ship strike or net capture held against the side of a ship, as there were cuts along the anterior dorsal surface and the skin and blubber had been rubbed off near the dorsal fin, flippers, and flukes.

The only INCIDENTAL CATCHES reported were three females from New Zealand and a drift net catch in the southern Pacific Ocean. Hourglass dolphins were seen several times near ships during longline hauling operations for Patagonian toothfish (*Dissostichus eleginoides*) off South Georgia, but “did not appear to interact with fishing operations” (Ashford *et al.*, 1996). Most of the specimens described here were strandings.

No hourglass dolphins have been kept in CAPTIVITY.

Humpback Dolphins

S. chinensis and *S. teuszii*

GUIDO J. PARRA AND GRAHAM J.B. ROSS

I. Characteristics and Taxonomy

Humpback dolphins (Fig. 1) are medium-sized delphinids found in coastal waters of the eastern Atlantic (West Africa), Indian, and West Pacific Oceans (Fig. 2). Genetic and morphological information indicate that they are delphinids (family Delphinidae). Initially, humpback dolphins were thought to be related to *Sotalia* spp., small delphinids that inhabit coastal and riverine waters of South America and *Steno bredanensis*, an oceanic dolphin species. However, molecular studies indicate that humpback dolphins are more closely related to tropical oceanic species, including those of the genera *Stenella*, *Delphinus*, *Tursiops*, and *Lagenodelphis* (LeDuc *et al.*, 1999). The taxonomy of the genus *Sousa* is not well established and no study to date has resolved the number of species in the genus. Current views range from recognition of only a single, variable species – *S. chinensis* – to three nominal species: *S. chinensis* (Pacific Ocean), *S. plumbea* (Indian Ocean), and *S. teuszii* (Atlantic Ocean). Other nominal species include *S. lentiginosa* (Owen, 1866) and *S. borneensis* (Lydekker, 1901). Studies on skull morphology support the division of the genus into the *chinensis*, *plumbea*, and *teuszii* forms; however, patterns of cranial variation were thought conservative and no taxonomic revisions were recommended (Jefferson, 2004). Recent phylogenetic studies indicate that Australian humpback dolphins are highly divergent from those in Southeast Asia and may represent a distinct species (Frère *et al.*, *in press*). Further morphological and molecular studies are needed to resolve the taxonomy of this highly variable genus. At present, the Scientific Committee of the International Whaling Commission recognizes only two species, *S. teuszii* and *S. chinensis*, the latter comprising all Indo-Pacific populations of *Sousa*.

Humpback dolphins are characterized by a robust and medium-sized body (Jefferson and Karczmarski, 2001; Ross *et al.*, 1994). The melon is moderate in size, slightly depressed and in profile slopes gradually to an indistinct junction with the long, narrow rostrum. Neonates have vibrissae. The gape is straight. The broad flippers are rounded at the tip and the flukes are broad and full, with a deep median caudal notch. Dorsal and ventral ridges on the caudal peduncle are well developed in African and Indian Ocean populations. Overall, humpback dolphins reach a maximum total length of 2.6–2.8 m in different parts of their distribution. A few animals exceeding 3.0 m in length have been recorded in the Arabian and Indian regions. Maximum weights of 250–280 kg have been recorded for humpback dolphins in South Africa and Hong Kong, respectively. Sexual dimorphism in total body length and weight is only apparent in the South African animals where mean lengths and weights

for fully grown males are 2.70 m and 260 kg compared to 2.40 m and 170 kg in females.

Characteristic features of the skull include a long, narrow rostrum strengthened by raised premaxillary bones and increasingly compressed toward the tip, large temporal fossae on which the jaw muscles insert and pterygoid bones that are separated in the midline by up to 11 mm. A broad gap exists between the posterior margin of the maxillary bones and the supraoccipital crest of the skull. The mandibular symphysis is long with each jaw bearing 27–39 teeth, wedge shaped at their base. Skull morphology is similar in all populations, apart from lower tooth counts, a shorter mandibular symphysis and a broader cranium in West African animals (*S. teuszii*). For a thorough review of geographic variation in skull morphology of humpback dolphins, see Jefferson and Van Waerebeek *et al.* (2004). The mean number of teeth per jaw increases eastward from 28 or 29 in West African animals (*teuszii* form) to 35 or 37 teeth in north Indian Ocean populations (*plumbea* form) and 33 or 35 teeth in Southeast Asian and Australian animals (*chinensis* form). The range of vertebral formulae in South African animals was 7 C, 11–12 T, 9–12 L, 20–24 Ca = 49–52. The first and second cervical vertebrae are fused. Vertebral counts in humpback dolphins farther east are similar to those of the South African sample (49–53), while West African humpback dolphins have 52–53 vertebrae.

Regional differences occur in external morphology, especially in coloration and shape and size of dorsal fin and hump (Fig. 1). In Indian humpback dolphins (*plumbea* form), the dorsal fin is smaller, slightly falcate, less triangular in shape and sits atop a prominent and well-developed dorsal hump (Fig. 1A). The dorsal fin of Pacific humpback dolphins (*chinensis* form) is short, triangular in shape, slightly recurved and has a wide base without a basal hump (Fig. 1B). Atlantic humpback dolphins (*S. teuszii*) have a very similar dorsal fin shape and basal hump to Indian humpback dolphins, but the hump tends to be more pronounced and fin more triangular in shape with a rounded tip. Coloration varies greatly according to geographic location and age. Calves throughout the range are mostly dark gray above with a lighter ventral surface. Adults from the western Indian Ocean are usually dark gray; with lighter ventral surface shading to off-white with light spotting sometimes present (Fig. 1A). Atlantic humpback dolphins have a similar appearance to that of Western Indian Ocean animals. Adults from Australia are pale gray in color with flanks shading to off-white and spotted toward the ventral surface (Fig. 1B). Rostrum, melon, and dorsal fin in Australian animals whiten with age. Most adults from Southern China are pure white, often with dark spots on the body and a pinkish tinge resulting from blood flushing during periods of high activity (Fig. 1C).

II. Distribution and Abundance

Humpback dolphins are tropical to subtropical species found mainly in coastal waters of the eastern Atlantic, Indian and western Pacific Oceans (Fig. 2). Atlantic humpback dolphins are endemic to coastal waters of the eastern Atlantic of West Africa from Morocco to Southern Angola (Van Waerebeek *et al.*, 2004). Indo-Pacific humpback dolphins (including the *plumbea* and *chinensis* forms) occur from South Africa to Central China and northern Australia (Jefferson and Karczmarski, 2001). Recent observations suggest that the *plumbea* form ranges from False Bay in South Africa to at least the Bay of Bengal in India. The *chinensis* form extends from the Gulf of Thailand east to central China and northern Australia. The distributions of the *plumbea* and *chinensis* forms may overlap in the Bay of Bengal. At least one humpback dolphin, most likely *S. plumbea*,

Figure 1 Regional differences in the external appearance of humpback dolphins. (A) Humpback dolphin from the east coast of South Africa exhibiting dark gray coloration and well-developed dorsal hump typical of animals from the Eastern Atlantic (*S. teuszii*) and Western Indian Ocean (*Sousa plumbea*). (B) Humpback dolphin from Cleveland Bay, Australia showing lighter coloration and absence of dorsal hump distinctive of animals from the Eastern Indian Ocean and Pacific Ocean (*Sousa chinensis*). (C) External appearance of adult humpback dolphin from Hong Kong showing the brilliant white/pink coloration characteristic of animals in southern China which differs from conspecifics elsewhere. (D) Humpback dolphin from the Bay of Bengal, India. Note the absence of dorsal hump and resemblance to animals from the Pacific Ocean (*S. chinensis*).

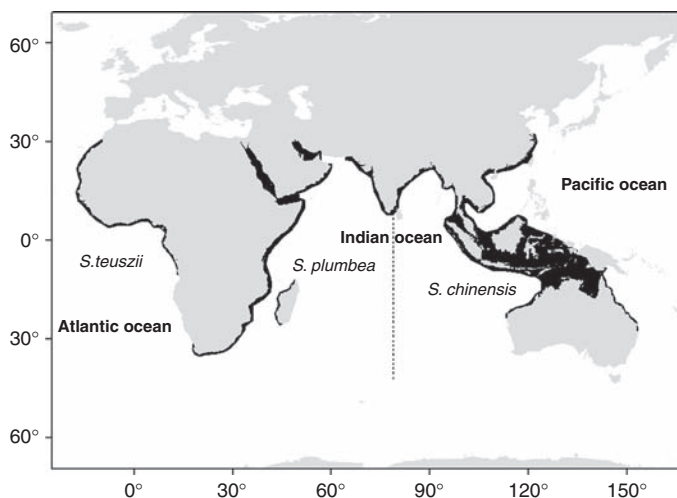

Figure 2 Map showing the distribution of humpback dolphins in the Eastern Atlantic, Indian and west Pacific Oceans.

reached the Mediterranean Sea via the Suez Canal (Kerem *et al.*, 2001). Australian humpback dolphins range from approximately the Queensland–New South Wales border ($31^{\circ}27'S$, $152^{\circ}55'E$) to western Shark Bay, Western Australia ($25^{\circ}51'S$, $E113^{\circ}20'E$).

Estimates of population size are only available for a few selected areas. At least on a local scale, populations of humpback dolphins are small (usually in the low hundreds) with the exception of the Hong Kong/Pearl River estuary population in China which is estimated to be at about 1500 animals (Jefferson, 2000). In contrast, preliminary surveys of the Xiamen Area to the north of Hong Kong indicate a small population of 80 humpback dolphins (Jefferson and Hung, 2004). Population estimates in Australian waters suggest that there are about 100 individuals inhabiting Moreton Bay, southern Queensland and less than 100 animals in Cleveland Bay, northeast Queensland (Corkeron *et al.*, 1997; Parra *et al.*, 2006a). Populations of South Africa were estimated at 466 (95% CI = 447–485) dolphins in Algoa Bay (Karczmarski *et al.*, 1999b) and 74 (95% CI = 60–88) in Richards Bay (Keith *et al.*, 2002). In Maputo Bay, Mozambique, preliminary estimates indicate that about 105 (95% CI = 30.5–150.9) humpback dolphins inhabit this area (Guissamulo and Cockcroft, 2004). Between 58 and 65 humpback

dolphins occur in a small area (26km²) off the south coast of Zanzibar (Stensland *et al.*, 2006). A very small population (<100 individuals) has been identified off central western Taiwan (Wang *et al.*, 2004).

III. Ecology

Though key habitats vary with geographical location, humpback dolphins are typically found in shallow waters of less than 20m, close to the coast and associated with river mouths, mangroves, tidal channels and inshore reefs (Karczmarski *et al.*, 2000a; Atkins *et al.*, 2004; Parra, 2006). In Australia, humpback dolphins occur occasionally offshore but generally in shallow water around islands or reefs as well as in reef lagoons such as Ningaloo Reef, Western Australia (Parra *et al.*, 2004). In Australia, China and India, high-density areas are usually associated with estuarine habitats and deep water channels. In China, dolphins may swim up rivers for tens of kilometers. In the Arabian region, humpback dolphins are mainly found in shallow coastal waters along low-energy sandy shorelines, though in some areas around Oman humpback dolphins are frequently seen along high-energy rocky shorelines in waters over 40m deep (Baldwin *et al.*, 2004).

Limited quantitative data are available on the feeding ecology of humpback dolphins throughout their range. Based on studies in South Africa and Hong Kong (Barros and Cockcroft, 1991; Barros *et al.*, 2004), it appears that humpback dolphins are opportunistic-generalist feeders, eating a wide variety of coastal, estuarine and reef-associated fishes (and occasionally cephalopods and crustaceans) both on the bottom and within the water column (Fig. 4). Fishes in the families Haemulidae, Sciaenidae, Sparidae, Mugilidae and Clupeidae have been identified as important prey items across the South African and Chinese range of *Sousa*. The most common fish prey species eaten by South African animals were *Mugil cephalus*, *Pomadasys olivaceum*, and *Pachymepoton aneum* and by Chinese animals, *Johnius* sp. *Collichthys lucida* and *Thryssa* spp. Prey species reported from Senegal include *Pristipoma jubelini*, *Ethmalosa fimbriata*, and *Mugil* spp. Incidence of scars resulting from interactions with sharks has been observed in South African and Australian animals. Adult tiger (*Galeocerdo cuvier*), great white (*Carcharodon carcharias*), and bull (*Carcharhinus leucas*) sharks are the most likely predators of humpback dolphins. The effects of predation on humpback dolphins' ecology are uncertain.

IV. Behavior and Physiology

Humpback dolphins swim slowly at about 5km/h, surfacing briefly at intervals of up to a minute. Longer dives may last up to 5min. Typically they avoid boats and rarely bow-ride. Nevertheless, animals in Hong Kong appear to be used to the presence of boats and have been observed bow-riding dolphin-watching boats. When approached, humpback dolphins generally dive, split up into small groups or single animals and often change course underwater, re-appearing unexpectedly some distance away. When a humpback dolphin surfaces, the beak or occasionally the whole head is typically raised clear of the water and the body is arched, showing the upper back and dorsal fin while the rest of the body remains underwater. Flukes are usually exposed at the surface before animals go for a deep dive. Humpback dolphins display a wide variety of aerial displays including vertical leaps, side leaps and forward/backward somersaults (Fig. 3).

The observed daytime behaviors of humpback dolphins include foraging/feeding, traveling, socializing and resting (Parsons, 2004a). Daytime behavior in Algoa and Richards Bays (South Africa), Hong Kong and Cleveland Bay (northeast Queensland, Australia) is dominated by foraging activities followed by traveling and socializing.

Figure 3 An adult humpback dolphin doing a somersault in Cleveland Bay, Queensland, Australia.

Figure 4 Humpback dolphin catching a Mullet (*Liza* spp.) at the mouth of the Devi River in Orissa, India.

Foraging activities are usually associated with inshore reefs, tidal channels and river mouths. In Algoa Bay, foraging behavior showed tidal, diurnal and seasonal patterns with increased feeding at high tide in the morning and evening and during the winter season. Cooperative feeding appears to be limited. Individuals in foraging schools are usually widely dispersed (50–100-m apart), move in various directions without an obvious pattern, dive frequently and steeply downward [often preceded by fluke (tail fin) up or peduncle (tail stock) arches] and have extended submersion times of more than 2min. At the surface, individuals often display rapid accelerations and erratic movement while chasing fish. In northeast Queensland, Australia and in the tidal channels of the Bazaruto Archipelago, Mozambique, humpback dolphins have been observed beaching themselves intentionally as they chase fish into shallow waters and sandbanks. Humpback dolphins in Hong Kong are frequently seen feeding in the freshwater/saltwater mixing zone. Schools foraging behind fishing trawlers are common in Australia and Hong Kong and for some individuals this appears to be a major source of food.

Socializing (including mating) in humpback dolphins is characterized by individuals in close proximity showing high levels of physical interaction including body contact (animals touching and biting each other and rubbing their bodies) and frequent aerial behavior such as leaps and somersaults. Fins and flukes often break the surface of the water. Copulation lasting 20–30sec occurs with one dolphin inverted below its partner. Observations of dolphins rising vertically belly to

belly in the Arabian Gulf and the Indus delta have been ascribed to mating behavior. Mating and births occur year round. Allomaternal care of offspring has been suggested for humpback dolphins in Algoa and Plettenberg Bays, South Africa.

Throughout their range, humpback dolphins are most frequently seen in relatively small schools of less than 10 animals. Solitary animals and schools of 2–6 individuals are the most common, although aggregations of 30–100 individuals have been observed along the Arabian Sea coast of Oman. In general, schools consist mainly of adult animals only or combinations of adults, juveniles, and calves. Schools solely composed of juveniles are rare. Little seasonal variation in school size occurs in Australian, Hong Kong, and Mozambique waters. However, significant increases in school size have been documented during summer and winter in Algoa and Plettenberg Bays, South Africa. School size also appears to vary according to behavioral activity. For example, in Cleveland Bay, Australia, socializing schools of humpback dolphins are larger than schools that are foraging or traveling. Additionally, schools foraging behind trawlers are larger than schools foraging independently of trawlers or traveling. Studies in South Africa, Hong Kong, and Australia indicate that humpback dolphins live in a fission–fusion society where individuals associate in schools that change often in size and composition. Long-lasting affiliations among adult animals do occur but are uncommon. Female–calf associations are stable and strong during the first 3–4 years.

Sound production and reception are vital to humpback dolphins in the often murky habitat they occupy. The acoustic repertoire of Pacific humpback dolphins includes a variety of sounds similar to those of other delphinids, ranging in frequency from a minimum of 0.6 kHz to a maximum of at least 200 kHz (Van Parijs and Corkeron, 2001c; Goold and Jefferson, 2004). Sounds produced by Australian humpback dolphins have been classified into five different vocalization categories of variable frequency and length: broad-band clicks (>kHz, 0.1–10 sec); barks (0.6–22 kHz, 0.1–7.4 sec); quacks (0.6–3.7 kHz, 0.08–2.7 sec); and grunts (0.09–1.4 kHz, 0.06–2 sec) (Van Parijs and Corkeron, 2001b, c). High-frequency broadband clicks appear to be used for echolocation and have been recorded mostly during foraging activities and to a lesser extent during socializing and traveling. Barks and quacks are produced predominantly during social and foraging behaviors, while grunts appear to be restricted to social behavior. Additionally, 17 different narrow-band frequency-modulated sounds (whistles) have been described for Australian humpback dolphins. These whistles are mainly heard during social behavior. It has been suggested that humpback dolphins may use their hearing capabilities to locate sound-producing prey by passively listening for the sounds that they make.

Throughout a significant part of their range, humpback dolphins share their coastal habitat with Indo-Pacific bottlenose dolphins (*Tursiops aduncus*), snubfin dolphins (*Orcaella heinsohni*) and finless porpoises (*Neophocaena phocaenoides*). Interactions with bottlenose and snubfin dolphins have been recorded in the wild. Mixed schools of humpback and bottlenose dolphins have been observed in South Africa (Karczmarski *et al.*, 1997), Tanzania (Stensland *et al.*, 2003), Oman (Baldwin *et al.*, 2004) and Australia (Corkeron, 1990). In South Africa, most interactions appear to be non-agonistic, with humpback dolphins remaining in the periphery or at distance of the school of bottlenose dolphins. However, aggressive interactions from bottlenose dolphins toward lone humpback dolphins have been documented in South Africa and Oman. In Tanzania, dolphins in mixed schools are often seen resting, traveling, and socializing, including male bottlenose dolphins herding female humpback dolphins. Mixed schools of bottlenose and humpback dolphins in Moreton Bay, Australia, have only been seen while feeding behind trawlers. During these interactions, bottlenose dolphins were

higher in number and appeared to be dominant over humpback dolphins. Interactions between humpback and snubfin dolphins have only been observed in northeast Queensland, Australia (Parra, 2006). Here, interspecific interactions are mainly of aggressive-sexual nature with humpback dolphins dominating snubfin dolphins. No interactions have been observed between finless porpoises and humpback dolphins. In Hong Kong these species show spatial and temporal differences in their habitat use. Interspecific interactions between humpback dolphins and other dolphins and porpoises within their range appear to be complex and may be the result of anti-predator and foraging strategies, interspecific mating or competition for resources.

Although humpback dolphins do not undergo large-scale seasonal migrations, seasonal changes in their distribution and abundance have been observed in South Africa (Karczmarski *et al.*, 1999a), Mozambique (Guissamulo and Cockcroft, 2004) and in Hong Kong and adjacent waters (Jefferson, 2000). Long-term observations of individual animals in localized areas in Australia, Hong Kong and South Africa indicate varying degrees of site fidelity, with some animals using local study areas seasonally and some others throughout the year. For example, in Cleveland Bay, northeast Queensland, Australia, most humpback dolphins are not permanent residents, but it was found that individuals did use the same areas within the bay regularly from year to year following a movement model of emigration and re-immigration (Parra *et al.*, 2006a). At Lantau Island, Hong Kong, humpback dolphins are present year round in waters to the north but shift their distribution to the south and east during the summer monsoon season (Parsons, 1998a). These seasonal changes in distribution and abundance are presumably associated with changes in prey availability and increase in the outflow of the Pearl River. Individual linear movements vary from only a few tens of kilometers in Hong Kong up to 120 km along the Natal and Eastern Cape coast in South Africa. Large linear movements seem unlikely, as extensive reviews of photo-identification catalogs from areas wide apart (>500 km) have yielded no matches. The home range size of humpback dolphins is unknown mainly because of the localized nature of the studies conducted and the difficulties in tracking individual animals for long periods of time. Individuals in Hong Kong and the Pearl River estuary region showed range sizes from 24 to 304 km², with an average of 99.5 km² (Hung and Jefferson, 2004). In Cleveland Bay, northeast Queensland, Australia, a representative range of 190 km² and a core area of 17 km² were identified at the population level (Parra, 2006).

V. Life History

Most of the information available on the life history of humpback dolphins comes from populations in South Africa and Hong Kong (Cockcroft/Karczmarski and Jefferson references, respectively). Births occur year-round, although there is evidence of seasonality for South Africa and China. In South Africa, calving peaks in spring or summer, the gestation period lasts 10–12 months, lactation may last >2 years, sexual maturity is reached at 10 years of age for females and 12–13 years for males and a 3-year calving interval has been suggested. In Hong Kong, most births occur between January and August, a gestation period of 11 months is presumed, length at birth is assumed to be about 100 cm and females reach sexual maturity at 9–10 years of age.

VI. Interactions with Humans

The conservation status of almost all populations of humpback dolphins throughout their range is uncertain, primarily because monitoring of population sizes and mortality is lacking in most

regions. Humpback dolphins are currently listed as Near-Threatened (*S. chinensis*) and Vulnerable (*S. teuszii*) by the IUCN and are listed in CITES Appendix I the western Taiwan population of *S. chinensis* is listed as Critically Endangered. Population estimates for a few selected areas indicate that the populations are relatively small (with the exception of Hong Kong) and thus vulnerable to anthropogenic mortality and potentially rapid population declines. Humpback dolphins are vulnerable to human impact because of their dependence on coastal and estuarine habitats which are under increasing pressure from expanding human populations. Anthropogenic threats throughout their range include wildlife tourism, direct takes, incidental captures in gill nets and shark nets and habitat degradation and loss.

In Australia, observations and interactions with free-ranging humpback dolphins occur only in Queensland (Parra *et al.*, 2004). In southern Queensland, up to seven free-ranging humpback dolphins visit Tin Can Bay regularly, where they are fed fish by visitors. Dedicated dolphin-watching trips including humpback dolphins are limited to a handful of boat operators in Moreton Bay and in Hervey Bay. In contrast, dozens of dolphin-watching operations involving humpback dolphins occur in Goa (Parsons, 1998b), Zanzibar (Stensland *et al.*, 2006) and in Hong Kong (Ng and Leung, 2003). If properly managed, marine mammal-watching activities can benefit the animals conservation through promoting increased public awareness of their biology and threats. However, dolphin watching is also recognized as a potential threat to the dolphins. Careful management, official dolphin-watching codes and enforcement are needed in order for the industry to be sustainable. Official dolphin-watching codes have been implemented in Australia and Zanzibar, but enforcement is lacking. A voluntary code has been established in Hong Kong, while no regulations exist in India.

Incidental mortality of humpback dolphins in fishing nets has been reported for almost all areas within their range. Though the data on levels of mortality are lacking for most regions, incidental catch in fishing nets is thought to be one of the most direct sources of human-caused mortality of humpback dolphins. Of 28 humpback dolphins stranded in Hong Kong between May 1993 and March 1998, 21% showed signs of net entanglement and 11% of boat collision (Parsons and Jefferson, 2000). Some of the animals photo-identified in Hong Kong show evidence of scars from fisheries interactions (2.6–6.8%) and boat propellers (1.2–1.9%). Humpback dolphins are also incidentally caught in shark nets set for bather protection in South Africa and Australia (Cockcroft, 1990; Parra *et al.*, 2004) (Fig. 5). Along the KwaZulu-Natal coast, South Africa, catches are high and shark nets represent a major threat to the small populations of humpback dolphins inhabiting these waters. A total of 129 humpback dolphins were caught in shark nets along the KwaZulu-Natal coast between 1980 and 1998 with the majority being caught at Richards Bay. Humpback dolphins were among the most commonly caught dolphin species in shark nets off Northeast Queensland, Australia. Net attendance rules and gear modifications have been introduced in Queensland's inshore gillnet fishery and most shark nets have been replaced with drumlines to reduce the incidental take of non-target species. However, enforcement is lacking in remote areas and there is no evidence that any of these measures have provided any benefit to the conservation of humpback dolphins.

At present, directed takes of humpback dolphins are rare and are probably restricted to occasional opportunistic hunting. An estimated 22 humpback dolphins were caught intentionally for human consumption between 1986 and 1999 off the east coast of Madagascar (Razafindrakoto *et al.*, 2004). In Zanzibar, dolphins were hunted for shark bait and for local consumption until 1996 (Stensland *et al.*, 2006). This hunt has now been replaced by dolphin-watching tourism

Figure 5 Humpback dolphin entangled in a shark net in South Africa.

which has become an alternative livelihood for the local communities. A total of 36 individuals were taken in Xiamen, China in the early 1960s to determine if leather could be made from the skin (Jefferson and Hung, 2004).

Very few humpback dolphins have been held in captivity. There are reports of live captures of a large number of Indo-Pacific humpback dolphins from the Gulf of Thailand for the oceanarium trade. At least 13 humpback dolphins, most captured in the Tin Can Bay area, have been held in captivity in Australian oceanariums. Humpback dolphins from South Africa, Australia and Thailand have survived in captivity for periods from 3 months to over 30 years.

Because of increasing pressure from expanding human populations (especially in coastal zones throughout the humpback dolphins range), the major threat to all populations is degradation and destruction of coastal habitats. This degradation is mainly being caused by coastal zone development, overfishing of prey, pollution and vessel traffic. For example, high levels of pollutants – particularly mercury and organochlorine contaminants such as DDT – have been found in Hong Kong's population of humpback dolphins (Parsons, 1998c; Parsons, 1999; Parsons, 2004b; Jefferson *et al.*, 2006). The high level of neonatal mortality (53% of strandings) observed in Hong Kong humpback dolphins may be related to organochlorine contamination. Ingestion of contaminated seabed sediments, prey species and transfer of contaminants via lactation are all part of the problem. Studies in Moreton Bay, Australia, indicated that noise from transiting vessels affects group cohesion in humpback dolphins (Van Parijs and Corkeron, 2001a). Moreover, humpback dolphins in Hong Kong tended to dive for longer periods of time in areas of high vessel traffic (Ng and Leung, 2003). In recognition of the numerous risks humpback dolphins face in Hong Kong waters, the Agriculture, Fisheries and Conservation Department (AFCD) of the Hong Kong Government funded several studies to examine the status of the local humpback dolphins. These studies led to the establishment in 1996 of the Sha Chau and Lung Kwu Chau Marine Park, northwest of Lantau Island, as well as the development of a conservation program in 2000 for the protection of humpback dolphins.

The cumulative effect of anthropogenic threats may result in the loss of populations of humpback dolphins already depleted, restricted to certain types of habitats and with small geographic ranges. However, the lack of baseline ecological data for most populations makes determining the effects of habitat loss difficult. Due to their apparent small population sizes, detection of small and

progressive population declines is extremely difficult. Thus, detection of population trends should not be the trigger for conservation actions. Precautionary measures to maintain viable populations while minimizing the impacts of management decisions on different stakeholder groups are necessary. The much greater challenge of conserving all forms of humpback dolphins will be the maintenance of high-quality habitat throughout the highly populated developing countries that coincide with their coastal distribution. Improved understanding of humpback dolphins' biology, ecology and taxonomy will be a key element toward their successful conservation and management.

Humpback Whale *Megaptera novaeangliae*

PHILLIP J. CLAPHAM

The humpback whale (Fig. 1) is one of the best known and easily recognizable of the large whales. It is known for its frequent acrobatic behavior and its occasional tendency to approach vessels. In the last 30 years, thousands of humpback whales have been identified individually from natural markings (notably the pattern on the ventral surface of the tail flukes), and as a result much has been learned about the biology and behavior of this species.

I. Characteristics and Taxonomy

At close range, humpback whales are easily distinguished from any other large whale by their remarkably long flippers, which are approximately one-third the length of the body. The flippers are ventrally white and can be either white or black dorsally depending on the population and the individual; the flippers of North Atlantic humpbacks tend to be white, while those in the North Pacific are usually black (Fig. 1). The body color is black dorsally, with variable pigmentation on the underside (black, white, or mottled). The head and jaws have numerous knobs called tubercles, which are also diagnostic of the species. The dorsal fin is small but highly variable in shape ranging from low (almost absent) to high and falcate. Like all rorquals, humpbacks have a series of pleats running from the tip of the lower jaw to the umbilicus. The tail is usually raised during a dive; the underside exhibits a pattern that is unique to each individual and which ranges from all white to all black. The presence of white on the ventral surface, and the prominent serration of the trailing edge, distinguishes humpbacks from other whales that “fluke” while diving, such as right, bowhead, blue, gray, and sperm whales.

Adult female humpback whales are typically 1–1.5 m longer than males. Maximum reliably recorded adult lengths are in the 16–17 m range, although 14–15 m is more typical (Clapham and Mead, 1999). Calves are 3.96–4.57 m at birth, and approximately 8–10 m at independence (Clapham *et al.*, 1999), which occurs at the end of the calf's natal year. There are no easily observable differences between male and female humpbacks. Females possess a grapefruit-sized lobe at the rear of the genital slit; this lobe is absent in males (Glockner-Ferrari and Ferrari, 1990). In addition, the spacing between the genital slit and the anus is considerably greater in males.

The skull of the humpback whale is easily distinguished from that of other baleen whales by the narrowness of the rostrum relative to the zygomatic width. The humpback has between 270 and 400 baleen plates on each side of the mouth. The plates are usually black, although those close to the tip of the jaw are sometimes white or partly white.

The genus *Megaptera* is monotypic and is one of two genera in the family Balaenopteridae (the “rorquals”). No subspecies are recognized. The binomial *Megaptera novaeangliae* derives from the Greek for “big wing” (*mega* + *pteron*) and the Latin for “New England” which was the origin of the specimen used by Borowski in his description of the species in 1781.

II. Distribution and Abundance

Humpback whales are found in all oceans of the world. They are a highly migratory species, spending spring through fall on feeding

Figure 1 Humpback whale (C. Brett Jarrett).

grounds in mid- or high-latitude waters, and wintering on calving grounds in the tropics, where they do not eat (Dawbin, 1966). They are typically found in coastal or shelf waters in summer and close to islands or reef systems in winter. Some documented migratory movements of this species represent the longest-known migration of any mammal, being almost 5000 miles one way (Palsbøll *et al.*, 1997). It is possible that some humpbacks do not migrate every year, although the number and sex/age class of these animals remains unclear. Remarkably, the purpose of the migration remains unknown; it may reflect a need to maximize energetic gain by exploiting pulses of productivity in high latitudes in summer, then gaining thermodynamic advantages by over-wintering in warm water. The only non-migratory population is that residing in the Arabian Sea, where monsoon-driven productivity in summer permits the whales to remain in tropical waters year-round (Mikhalev, 1997).

In the North Atlantic, humpbacks return each spring to specific feeding grounds in the Gulf of Maine, Gulf of St. Lawrence, Newfoundland, Labrador, Greenland, Iceland, and Norway. Fidelity to these areas is strong and is determined by where a calf was taken by its mother in the former's natal year. Genetic analysis has indicated that this fidelity is maintained on an evolutionary timescale in at least Iceland and Norway (Palsbøll *et al.*, 1995; Larsen *et al.*, 1996). Despite this fidelity, whales from all feeding grounds migrate to a common breeding area in the West Indies, where they mate and calve (Katona and Beard, 1990). However, genetic data indicate the existence of a second breeding population composed of many of the animals from Iceland and Norway, whose migratory destination is unknown. Historically important breeding areas in the Cape Verde Islands and the southeastern Caribbean appear to be utilized by relatively few whales today.

In the North Pacific, there are at least four separate breeding grounds in Hawaii, coastal Mexico, offshore Mexico (the Revillagigedo Islands), and Japan/Philippines (Calambokidis *et al.*, 1997). Whales from these wintering areas migrate primarily to Alaska, California, possibly the Bering Sea/western Gulf of Alaska, and the western North Pacific, respectively. However, crossover is not unknown and some trans-oceanic movements have been recorded (e.g., British Columbia to Japan and back).

In the Southern Hemisphere, humpbacks feed in circumpolar waters around the Antarctic and migrate to relatively discrete breeding grounds in tropical waters to the north. Seven breeding populations or "management areas" are recognized by the International Whaling Commission (IWC) in the Southern Hemisphere, and these are linked with varying confidence to six feeding areas in the Antarctic. Some movement between these regions is very likely, but the extent of such exchange remains largely unquantified.

III. Ecology

The humpback whale has a generalist diet, feeding on euphausiids and various species of small schooling fish. The latter include herring (*Clupea* spp.), capelin (*Mallotus villosus*), sand lance (*Ammodytes* spp.), and mackerel (*Scomber scombrus*). Humpbacks appear to be unique among large whales in their use of bubbles to corral or trap schooling fish. Whales blow nets, clouds, or curtains of bubbles around or below schools of fish, then lunge with mouths open into the center of the bubble structure (Jurasz and Jurasz, 1979; Hain *et al.*, 1982). As with other balaenopterids, the ventral pleats expand when a humpback is feeding, allowing the animal to greatly increase the capacity of its mouth.

Rake-mark scars from teeth attest to the fact that humpbacks are commonly attacked by killer whales (*Orcinus orca*). However, it seems likely that fatal attacks are largely confined to young calves (Mehta *et al.*, 2007), and predation does not appear to be a significant factor in the social organization of the humpback (Clapham, 2000).

IV. Behavior and Physiology

The social organization of the humpback is characterized by small unstable groups, and individuals typically associate with many companions on both feeding and breeding grounds (Clapham, 2000). Longer-term associations (those lasting days or weeks) are occasionally recorded, but their basis is unclear. There appears to be no territoriality in this species.

In winter, male humpback whales sing long, complex songs, the primary function of which is presumably to attract females, although a role in dominance sorting or cooperative behavior among males has also been suggested (Darling *et al.*, 2006). All whales in a given population sing essentially the same song, and although the form and content of all songs change over time, the whales somehow coordinate these changes. Males also compete very aggressively for access to females (Tyack and Whitehead, 1983), and the resulting "competitive groups" can last for hours and involve tail slashing, ramming, or head butting. Males may also form coalitions, but further research is required to assess the significance and composition of such alliances.

In part because of the prominent male display aspect (i.e., singing behavior), the mating system has been compared to a lek (Mobley and Herman, 1985; Clapham, 2000), although it does not possess the rigid territoriality common to such systems. Males almost certainly remain in breeding areas longer than females and attempt to obtain repeated matings, while newly pregnant females return quickly to higher latitudes (Chittleborough, 1965; Dawbin, 1966) where they will feed for many months in order to prepare for the considerable energetic cost of lactation.

Humpbacks are well known for their often spectacular aerial behaviors. These include breaching, lobtailing, and flipping. Such behaviors occur at all times of year and in a variety of contexts, and it is clear that they perform a range of functions. These may include play, communication, parasite removal, and expression of excitement or annoyance.

How humpback whales find their food remains largely a mystery. Baleen whales do not appear to possess echolocation, though it is possible that they retain a useful sense of smell which could be used to detect prey patches at the surface. Similarly, we have little understanding of how humpbacks navigate across thousands of miles on their annual migrations, though biomagnetic orientation has been suggested (on little direct evidence) as a component of this ability.

V. Life History

Breeding in humpback whales is strongly seasonal. Females come into estrus in winter, at which time testosterone production and spermatogenesis also peaks in males (Chittleborough, 1965). The gestation period is about 11.5 months, with the great majority of calves born in mid-winter. Calves probably begin to feed independently at about 6 months of age, but nursing likely continues in many animals until shortly before independence at about a year of age. The age at which sexual maturity is reached appears to vary among populations from 5 to 10 years. Interbirth intervals in females are most commonly 2 years, although annual calving is not unknown (Clapham and Mayo, 1990; Glockner-Ferrari and Ferrari, 1990). Although multiple fetuses have been recorded in dead pregnant females, living twins or multiplets are unknown.

VI. Interactions with Humans

The humpback whale was heavily exploited by the whaling industry for several centuries. Because of its coastal distribution, it was often the first species to be hunted in a newly discovered area. Last century, more than 213,000 humpbacks were slaughtered in the Southern Hemisphere alone; of these, more than 48,000 were taken illegally by the Soviet Union (Yablokov *et al.*, 1998). Indeed, the USSR killed 25,000 humpbacks in just two Antarctic whaling seasons (1959/1960 and 1960/1961), resulting in the crash of the populations concerned. It is quite likely that more than 90% of the animals in some populations were killed during the most intensive periods of exploitation. As a result, the humpback was long considered an endangered species. Despite this, most studied populations appear to be making a strong recovery, and the species is now rated Least Concern (LC) by the IUCN. However, some populations are still listed as Endangered (Oceania and Arabian Sea) and others may be in similar trouble. The North Atlantic population was most recently estimated at 11,570 animals (Stevick *et al.*, 2003). An estimate of 6000–8000 for the North Pacific (Calambokidis *et al.*, 1997) is widely regarded as conservative, and new estimates will shortly be available from a major international collaborative study in this ocean. Strong population growth rates have been reported for many areas, ranging from 6.5% in the Gulf of Maine to more than 10% in some Southern Hemisphere populations; however, the IWC recently agreed that annual increase rates above 10.6% are biologically unrealistic for this species (IWC, 2007). Commercial whaling for humpbacks officially ended worldwide in 1966; however, the Soviets continued to hunt this species for some years afterwards, and Japan has recently added a catch quota for humpback whales to its scientific whaling program

in the Antarctic. Small aboriginal hunts for humpbacks still occur in a couple of locations, and many more whales die from entanglement in fishing gear or collisions with ships. However, none of these impacts appears to be significant at the population level, and the outlook for this once-overexploited species appears good in most areas.

Hunting of Marine Mammals

RANDALL R. REEVES

Ancient middens testify to the importance of marine mammals in the lives of early maritime people around the world. Many of the bones and bone fragments found in such sites probably came from animals that were scavenged from beaches. However, ingenious methods of capturing pinnipeds, sirenians, and cetaceans eventually were developed, and the archaeological refuse came to signify past hunting. The rewards were tempting—large amounts of nutritious meat and fat, hides, ivory, sinews for sewing, and bones for making household implements or weapons. These products eventually came to have high commercial value, fueling the modern global whaling and sealing industries.

No taxonomic group of marine mammals has been spared from hunting pressure. However, some species have been hunted more intensively than others. The great whales (the sperm whale *Physeter macrocephalus* and the baleen whales) have been sought for their oil, meat, and baleen; pinnipeds for their oil and pelts; sea otters (*Enhydra lutris*) for their furs; and sirenians mainly for their flesh and skins. In contrast, some dolphin and porpoise populations have hardly been hunted at all, and they remained secure until the advent and proliferation of unselective fishing methods, which result in the incidental killing of non-target organisms. Marine mammals have also been hunted with the intention of reducing their predation on valued resources such as fish, crustaceans, or mollusks (Bearzi *et al.*, 2004). This culling, often implemented through government-sponsored bounty programs, is similar to that directed at wolves (*Canis lupus*), mountain lions (*Puma concolor*), and other predators in parts of North America, with the outspoken support of ranchers and sport hunters.

I. Hunting of Whales, Dolphins, and Porpoises

People in the Arctic were hunting bowhead whales (*Balaena mysticetus*) as long ago as the middle of the first millennium, and western Europeans were taking right whales (*Eubalaena glacialis*) by the beginning of the second (Ellis, 1991; McCartney, 1995). The technology and culture of subsistence whaling spread within the Arctic and subarctic from the Bering Strait region, whereas the development and spread of commercial whaling were driven by the Basques of western Europe (Du Pasquier, 2000). From its beginnings in the Bay of Biscay, this whaling eventually reached all of the world's oceans and involved people of many nationalities. Modern whaling, characterized by engine-driven catcher boats and deck-mounted harpoon cannons firing explosive grenades, began in Norway in the 1860s (Tønnessen and Johnsen, 1982). A key feature of modern whaling was that it

made possible the routine capture of any species, including the blue whale (*Balaenoptera musculus*), fin whale (*B. physalus*), and other fast-swimming balaenopterines. In the first three-quarters of the twentieth century, factory ships from several nations (e.g., Norway, the United Kingdom, Germany, Japan, the United States, and the Soviet Union) operated in the Antarctic, the richest whaling ground on the planet. At its pre-War peak in 1937–1938, the industry's 356 catcher boats, associated with 35 shore stations and as many floating factories, killed nearly 55,000 whales, 84% of them in the Antarctic.

Commercial whaling declined in the 1970s as a result of conservationist pressure and depletion of whale stocks. The last whaling stations in the United States and Canada were closed in 1972, and the last station in Australia ceased operations following the 1978 season. By the end of the 1970s, only Japan, the Soviet Union, Norway, and Iceland were still engaged in commercial whaling. With the decision by the International Whaling Commission (IWC) in 1982 to implement a global moratorium on commercial whaling, Japan and the Soviet Union made their final large-scale factory-ship expeditions to the Antarctic in 1986–1987, and Japan stopped its coastal hunt for sperm whales and Bryde's whales (*Balaenoptera edeni*) in 1988. Iceland closed its whaling station in 1990 and shortly thereafter withdrew its membership in the IWC (only to rejoin in 2002). Contrary to the widespread belief that commercial whaling ended in the 1980s, however, Norway and Japan continued hunting common (*Balaenoptera acutorostrata*) and southern (*B. bonaerensis*) minke whales. By formally objecting to the moratorium decision, Norway reserved its right to carry on commercial whaling. Thus, Norwegian whalers killed hundreds of common minke whales in the North Atlantic annually throughout the 1990s and early 2000s, their self-assigned quota increasing to well over 1000 by 2006. Using a provision in the whaling treaty that allows member states to issue permits to hunt protected species for scientific research, Japan has continued taking hundreds of southern minke whales in the Antarctic and common minke whales in the western North Pacific each year. They now also include in their annual "scientific" sample sei whales (*B. borealis*), Bryde's whales, sperm whales, and fin whales. In 1999, the Icelandic parliament approved the resumption of a shore-based commercial hunt, and whaling for common minke whales resumed in Iceland in 2003. Iceland also has announced plans to follow Japan's lead and expand its efforts to include "scientific" catches of fin whales. Because the main incentive for commercial whaling nowadays is the Japanese demand for whale meat, Norway and Iceland have been eager to reopen the international trade in whale products.

The hunting of smaller cetaceans has generally been confined to coastal waters and conducted on a smaller, or at least localized, scale (Mitchell, 1975). There are, however, some examples of large, well-organized hunts. Fishermen in the Faroe Islands have continued to kill hundreds, and in some years well over a thousand, long-finned pilot whales (*Globicephala melas*) and Atlantic white-sided dolphins (*Lagenorhynchus acutus*) in a centuries-old drive fishery. The method involves a number of small boats that herd the animals into shallow water where they can be killed with lances, long knives, or firearms. There also has been a long-standing drive fishery in Japan, taking a variety of delphinid species, most notably striped dolphins (*Stenella coeruleoalba*) and bottlenose dolphins (*Tursiops* spp.). The Japanese hunt involves other methods as well, including the use of hand-thrown harpoons to take dolphins and Dall's porpoises (*Phocoenoides dalli*) and the use of harpoon guns to take short-finned pilot whales (*Globicephala macrorhynchus*) and other medium-sized cetaceans. A large commercial hunt for short-beaked common dolphins (*Delphinus delphis*), common bottlenose dolphins

(*Tursiops truncatus*), and harbor porpoises (*Phocoena phocoena*) was conducted annually in the Black Sea from the nineteenth century through the mid-1960s. The Soviet Union banned dolphin hunting in 1966; hunting with rifles and purse seines continued in the Turkish sector of the Black Sea until at least 1983.

Aboriginal hunters in Russia, the United States (Alaska), Canada, and Greenland kill several tens of bowhead whales, 100–200 gray whales (*Eschrichtius robustus*), and thousands of white whales (*Delphinapterus leucas*), narwhals (*Monodon monoceros*), and harbor porpoises (Greenland only) each year (Fig. 1). This hunting is primarily for food and the products are consumed locally or sold within proscribed markets (see Section V). In recent years, aboriginal whalers in Washington State (USA), British Columbia (Canada), and Tonga (a South Pacific island nation) have expressed interest in reestablishing their own hunts for large cetaceans. In the spring of 1999, the Makah tribe in Washington took their first gray whale in more than 50 years.

II. Pinnipeds

Sealing began in the Stone Age when people attacked hauled-out animals with clubs (Bonner, 1982). Later methods included the use of harpoons thrown from skin boats and gaff-like instruments for killing pups on ice or beaches. Traps and nets were used as well. The introduction of firearms transformed the hunting of pinnipeds and caused an alarming increase in the proportion of animals killed but not retrieved, especially in those hunts where the animals were shot in deep water before first being harpooned. This problem of “sinking loss” also applies to many cetacean hunts.

In addition to their meat and fat, the pelts of some seals, especially the fur seals and phocids, have had value in the garment industry. Markets for oil and sealskins fueled commercial hunting on a massive scale from the late eighteenth century through the early twentieth century (Busch, 1985). The ivory tusks and tough, flexible hides of walrus (*Odobenus rosmarus*) made these animals exceptionally valuable to both subsistence and commercial hunters. At least 10,000 walrus are still killed every year by the native people of northeastern Russia, Alaska, northeastern Canada, and Greenland. The killing is accomplished mainly by shooting. The meat, BLUBBER, and skin are eaten by people or fed to dogs, while the tusks are either used for carving or sold as curios. Native hunters in the circumpolar north also kill more than a hundred thousand seals each year, mainly ringed seals (*Pusa hispida*) but also bearded (*Erignathus barbatus*), ribbon (*Histiophoca fasciata*), harp (*Pagophilus groenlandicus*), hooded (*Cystophora cristata*), and spotted seals (*Phoca largha*). Seal meat and fat remain important in the diet of many northern communities, and the skins are still used locally in some areas to make clothing, dog traces, and hunting lines. There is also a commercial export market for high-quality sealskins and a strong demand in Oriental communities for pinniped penises and bacula. The sale of these items, along with walrus and narwhal ivory, white whale and narwhal skin (maktak), and polar bear (*Ursus maritimus*) hides and gall bladders, is a significant source of revenue in some local hunting communities.

The scale of commercial sealing, like that of commercial whaling, has declined considerably since the 1960s. It continues, however, in parts of the North and South Atlantic. Norwegian and Russian ships continue to visit the harp and hooded seal grounds in the Greenland Sea (“West Ice”) and Barents Sea (“East Ice”). After a period of drastically reduced killing in the 1980s, the Canadian commercial hunt for harp seals has been reinvigorated, at least in part as a result of governmental subsidies (Lavigne, 1999). The total annual commercial catch of harp seals in the North Atlantic is still in the hundreds

Figure 1 People living in villages along the rivers of West Africa hunt, trap, and net manatees (*Trichechus senegalensis*) for food and to prevent the animals from raiding their rice crops. In the absence of any kind of management or monitoring, it is impossible to make a meaningful assessment of the status of West African manatee populations. However, with such active, unrestricted persecution, the species has undoubtedly declined, and perhaps even been extirpated, in many parts of its formerly extensive range. Gbandakor, Malen River, Sierra Leone, April 1982. Photograph by Harry Spaling.

of thousands. Although some molting pups are clubbed to death on the sea ice, most of the killing nowadays is by shooting. Tens of thousands of South African fur seals (*Arctocephalus pusillus pusillus*) are killed annually in Namibia (until 1989 also in South Africa) and large numbers of South American fur seals (*A. australis*) were taken Uruguay until 1991 when the commercial hunt there ended. These hunts are (or were) centuries old, having been driven initially by commercial markets for skins and oil and, more recently, by the Oriental demand for seal penises and bacula. Also, especially in Africa, the hunt has been justified as a response to concerns about competition between seals and fisheries.

III. Sirenians

Sirenians have been hunted mainly for their delectable meat and blubber and their strong hides. The Steller's sea cow (*Hydrodamalis gigas*) was hunted to extinction within about 25 years of its discovery by European sea otter and fur seal hunters. Much like tortoises on tropical islands, the sea cows were easy to catch and provided local sustenance to ship crews, enabling the men to carry on their pursuit of fur, oil, and other valuable resources. Local people in West Africa and Central and South America used manatee hides to make shields, whips, glue, and plasters for dressing wounds. Large-scale commercial killing of Amazonian manatees (*Trichechus inunguis*) to supply mixira (fried manatee meat preserved in its own fat) took place in Brazil from the 1780s to the late 1950s, and manatee hides were in great demand for making heavy-duty leather products and glue between 1935 and 1954 (Domming, 1982). The total number of manatees (three species, combined) killed by villagers each year in West Africa and South America is probably in the thousands (Fig. 2). Dugongs (*Dugong dugon*), like manatees, have long been a prized food source for seafaring people throughout their (formerly) extensive Indo-Pacific range. Hunting continues in much of that range, including areas of Southeast Asia and Indonesia where few dugongs survive (Marsh *et al.*, 2002).

Sirenians have been captured using many different methods, apart from simply stalking and lancing or harpooning them from boats, or setting nets to enmesh them. People in West Africa and South America developed ingenious fence traps and drop traps to catch manatees. These can be baited to attract the animals or just placed strategically to take advantage of their natural movements through constricted channels. Dugong hunters in some areas used underwater explosives to kill their prey. In Torres Strait between Australia and New Guinea, portable platforms were set up on sea-grass beds, and the hunters waited there overnight for opportunities to spear unsuspecting dugongs as they grazed.

IV. Sea Otters and Polar Bears

Sea otters were cursed by the luxuriance of their pelts, which are among the most desirable of all mammalian furs. They were hunted remorselessly to supply the Oriental market from the 1780s onward—until very few were left and protection came in 1911. As otters were depleted in a region, hunting efforts there would be redirected at fur seals. Although anchored nets were sometimes used to catch sea otters (Kenyon, 1969), most of the hunting was conducted by men in boats, using lances initially and rifles later on. In California, otters were sometimes shot by men standing on shore, and in Washington, shooting towers were erected at the surf line and Indians were employed to swim out and retrieve the carcasses (Busch, 1985). Aboriginal people in Alaska are still allowed to hunt sea otters as long as the furs are used locally to make clothing or authentic handicraft items.

Polar bears have always been prime targets of Eskimo hunters, and non-Eskimo sport hunters have taken large numbers of bears as trophies. At least several hundred polar bears are still killed each year, most of them by Eskimos for meat and the cash value of their hides and gall bladders. Some polar bears are also killed in self-defense each year by Arctic residents or visitors to the North. In Canada, hunting permits allocated to native communities are often sold to sport hunters, on condition that local guides accompany the hunters and that only the heads and hides be exported. These expeditions generally involve dogsled travel, thus reinvigorating a traditional mode of winter transportation. Today, most polar bears are killed by shooting with high-powered rifles, but in the past they were also hunted with baited set-gun traps in Svalbard.

Figure 2 Adult white whales (belugas, *Delphinapterus leucas*) killed by Eskimos in Kasegaluk Lagoon near Point Lay on the Chukchi Sea coast of Alaska in July 1993. Canoes powered by outboard motors are used to drive the whales toward shore before killing them with rifles (top). The flukes, flippers, and skin with adhering blubber (locally called maktak) are saved as a delicacy (bottom). Courtesy of Greg O'Corry-Crowe.

V. Market (Commercial) vs Subsistence (Household-Use) Hunting

A distinction is often made between hunting for profit and hunting as a means of survival. This distinction is more than academic. The nature and degree of regulation have often depended on how a given hunter's enterprise was classified. The dichotomy between "commercial" and "subsistence" exploitation has had particular meaning in the context of the worldwide regulation of whaling. The IWC recognizes "aboriginal subsistence" whaling as a special category and has traditionally exempted certain groups of whalers from regulation (Reeves, 2002). Similarly, many national and multilateral restrictions on sealing have applied only or primarily to industrial operations and not to "aboriginal" hunters hunting for "subsistence" (e.g., the US Marine Mammal Protection Act and the North Pacific Fur Seal Convention).

Initially, the reasoning behind such special treatment was that these hunters used less destructive or wasteful gear and methods, and served only local, relatively small markets. However, those criteria are now called into question as aboriginal hunters have adopted modern weaponry and mechanized transport, and increasingly sell their produce for cash. Some products, notably sealskins, polar bear skins and

gall bladders, and the ivory obtained from walruses and narwhals, enter a global marketplace.

Anthropologists argue that the term “subsistence” should be broadly defined and not exclude cash-based exchanges when these occur within a context that emphasizes local production and consumption. They point to the fact that modern Eskimos, e.g., are simply adapting to a changing world by hunting marine mammals with rifles, outboard motors, and snowmobiles. Only by selling skins, tusks, and, in the case of polar bear hunting, their own services as guides are these traditional hunters able to obtain the cash needed to live comfortably while continuing to engage in a domestic mode of production, providing highly esteemed and nutritious food for their home communities. Indeed, the IWC still considers Greenland whaling for baleen whales to be “aboriginal subsistence” whaling even though most of the whales are killed with deck-mounted harpoon guns firing explosive grenades and the meat and other products enter a country-wide, cash-based exchange network (Caulfield, 1997). At the same time, the IWC has resisted Japan’s efforts to have “small-type coastal” whaling, which also serves a domestic but cash-based market, reclassified as something other than commercial whaling.

The difficulty of distinguishing commercial from subsistence hunting is not unique to situations involving marine mammals. Similar issues have arisen in relation to the trade in “bush meat” in Africa, Asia, and the Neotropics. Unregulated hunting is incompatible with the concept of sustainability. Considering the enormous increases in killing power afforded by firearms and mechanized transport, together with rapid human population growth and the attendant rise in resource consumption, the time is long past when racial or cultural entitlement could be allowed to preclude a vigorously enforced management regime based on conservation principles.

VI. Future Hunting

For two reasons, the hunting of marine mammals in the foreseeable future is unlikely to approach the scale at which it was pursued throughout the nineteenth and much of the twentieth centuries. First, the populations of many species remain far below the earlier levels. Even if some recovery is achieved, the environmental carrying capacity has almost certainly declined in many instances. Considering the low productivity of these relatively large, long-lived animals, it is unrealistic to expect their numbers to return to “pristine” levels in a world so thoroughly transformed by human endeavor. Second, attitudes toward marine mammals have changed considerably in some parts of the world, and any initiative to expand the scope or scale of hunting is subject to public scrutiny as never before. Many people, particularly in North America, Europe, Australia, and New Zealand, are morally opposed to the killing of cetaceans, if not all marine mammals (Lavigne *et al.*, 1999). Although this does not mean that hunting will stop altogether, it does make it ever more likely that hunters will need to demonstrate that their enterprises are both sustainable (within the productive capacity of the affected animal populations) and humane.

Hybridism

MARTINE BÉRUBÉ

I. Introduction

Hybridization denotes the successful mating between two individuals, each from different and reproductively isolated gene pools (i.e., species). Hybridization is observed frequently among higher plants but only rarely among vertebrates. Within mammals, hybrids have been recorded in a number of marine as well as terrestrial species (Gray, 1972). The evolutionary consequences of such hybrids vary among incidences depending on the frequency, the degree of genetic differences between the parental species, mating system, and the ecological circumstances (Grant and Grant, 1997).

The examination of hybrids has always attracted much attention, as such incidences and their frequency might provide clues on reproductive behavior, dispersal capabilities, and phylogenetic relationship of species. As might be expected, hybrids are more common within genera where the different species have similar life histories and habitat requirements. When the frequency of hybridization is low, the fitness of the hybrids is generally low as well and hybrids usually are non-viable or sterile, thus not representing a threat to the genetic constitution of the parental species (Mary, 1963). However, as the

frequency of hybridization increases, so may the number of viable and reproductive hybrids, which in turn may cause the breakdown of previous reproductive barriers between the two species. One evolutionary consequence of such a scenario is termed introgression; the gradual diffusion of the genes from one species into the gene pool of another. A recent well-documented example of introgression is the high incidence of coyote genes in what morphologically appear to be gray wolves (*Canis lupus*) observed in North America (Lehman *et al.*, 1991). The ultimate evolutionary consequence of introgression is the extinction of the species whose genome is being replaced by that of the other species.

With regard to marine mammals, a total of some 74 cases of putative hybridization events have been described; 53 within Cetacea and 21 within Pinnipedia. Putative hybrids have been observed in captivity and in the wild. Most hybrids among marine mammals reported so far have only been described morphologically. However, recently molecular techniques have been applied to identify hybrids and their parental species.

II. Evidence of Mating Between Marine Mammal Species

Interspecific sexual interactions between a number of sympatric cetacean species have been described. Attempts at *interspecific mating* have been observed between pinniped species where no hybrids have yet been reported. Such mating appears to be aggressive and usually the *hetero-specific* (of a different species) male is much larger than the female. Often the female does not survive such a mating.

This kind of aggressive *interspecific mating* was first observed between a male gray seal (*Halichoerus grypus*) and a female harbor seal (*Phoca vitulina*) (Wilson, 1975). Later reports of such aggressive behaviors include mating between a male New Zealand sea lion (*Phocarctos hookeri*) and a dead female New Zealand fur seal (*Arctocephalus forsteri*), a South American sea lion (*Otaria flavescens*) and a South American fur seal (*A. australis*), a female California sea lion (*Zalophus californianus*) and a male Steller sea lion (*Eumetopias jubatus*), and between Southern elephant seals (*Mirounga leonina*) and Australian fur seals (*A. pusillus*). The aggressive mating undertaken by sea lions with *hetero-specific* females has been interpreted as “excess of violent sexual selection” (Miller *et al.*, 1996). This aggressive behavior seems to be widespread in the family Otariidae, and the number of hybrids is possibly much higher than reported to date.

III. Reported Hybridizations in Captivity

Among captive cetaceans, 28 hybrids have been identified, all within the suborder Odontoceti. All hybridizations occurred among seven species of the Delphinoidea superfamily, and the common bottlenose dolphin (*Tursiops truncatus*) was one of the parental species in all cases (Table I). The majority of these hybrids have not survived. However, a viable first-generation hybrid between a bottlenose dolphin and a false killer whale (*Pseudorca crassidens*) has given birth twice after mating with a common bottlenose dolphin (Duffield, 1998). When this was reported in 1998, one of the two calves from the second generation was still alive. A similar event occurred for a hybridization between a common bottlenose dolphin and a long-beaked common dolphin (*Delphinus capensis*), where two first-generation hybrids gave birth to a live-born backcross calf sired by a bottlenose dolphin. In this case, however, the calves died shortly after birth. Within the Pinnipedia hybridization in captivity

has only been observed within the families Phocidae (true seals) and Otariidae (eared seals) (Table I).

IV. Reported Hybridizations in the Wild

Probably the most impressive cases of hybridization among marine mammals are those identified within the Mysticeti (baleen whales). A total of 11 hybrids between baleen whale species have been reported so far, all were identified in the wild during commercial whaling operations. In all cases, the parents were a blue whale (*Balaenoptera musculus*) and a fin whale (*B. physalus*). The first report was in 1887 by A. H. Cocks, whom recorded six hybrids, or “Bastards,” along the Lapland coast. However, this number is likely to be an under-estimate, since, as the author mentioned, hybrids sometimes were entered in the records as a fin whale instead of “Bastard.” Later, Doroshenko (1970) reported a hybrid between a blue and a fin whale, taken in 1965 off Kodiak Island (in the Gulf of Alaska); it was identified by its exceptional and intermediate morphological traits.

More recently, three anomalous baleen whales, one female and two males, were caught during Icelandic whaling operations between 1983 and 1989 and described morphologically as fin \times blue whale hybrids. The parental species of these specimens were later confirmed by molecular analyses based upon the maternally inherited mitochondrial genome and biparentally transmitted nuclear genes (Arnason *et al.*, 1991; Spilliaert *et al.*, 1991). Interestingly, the female Icelandic fin \times blue whale hybrid was in her second pregnancy. Molecular analyses of the fetus revealed the fetus was the result of a mating between the hybrid mother and a male blue whale. Finally, a fin \times blue whale hybrid caught off Northwest Spain in 1984 was identified first from its morphology and subsequently by molecular analyses, which identified the maternal and paternal species as blue and fin whale, respectively (Bérubé and Aguilar, 1998).

Within the Odontoceti, the first three hybrids described were from a stranding on the West Coast of Ireland in Blacksod Bay reported by Fraser in 1940. The morphological analysis concluded that the three stranded specimens were hybrids from mating between common bottlenose and Risso’s dolphins (*Grampus griseus*). Three hybrid individuals in the same stranding, each a cross of the same parental species, is highly unusual given the overall low rate of hybridization among cetaceans *per se*. For the same reason Fraser himself first thought the hybrids to be a novel species rather than hybrids. Since the stranding in Blacksod Bay, three more cases of hybridization in the wild has been reported within the family Delphinidae identified from intermediate morphological traits. First, a specimen caught by fishermen off the Peruvian coast was determined to be a hybrid between a common (*D. capensis* or *D. delphis*) and a Dusky dolphin (*Lagenorhynchus obscurus*) (Reyes, 1996). Recently, two more interspecific hybrids have been reported, the first one between a spinner dolphin (*Stenella longirostris*) and a pantropical spotted dolphin (*S. attenuata*), the second one between a spinner dolphin (*S. longirostris*) and a Clymene dolphin (*S. clymene*) (Silva *et al.*, 2005).

In 1990, an anomalous whale skull was collected in Disko Bay off West Greenland. The morphological characteristics of this skull were intermediate between those of adult narwhals (*Monodon monoceros*) and belugas (*Delphinapterus leucas*). The authors hypothesized that the specimen was likely a hybrid from a mating between a narwhal and a beluga (Heide-Jørgensen and Reeves, 1993).

Hybridization has also been reported within Phocoenidae between a Dall’s (*Phocoenoides dalli*) and a harbor porpoise (*P. phocoena*). The hybrid (identified by its morphology and by molecular

analyses) was a female fetus recovered from a dead Dall's porpoise (Baird *et al.*, 1998; Willis *et al.*, 2004).

In Pinnipedia, most hybrids in the wild have been observed within the families Phocidae and Otariidae. The most common hybridization is between the Subantarctic (*A. tropicalis*) and the Antarctic (*A. gazella*) fur seals (Table II). Based upon the abundance of the two species and the frequency of hybrids, the rate of hybridization between the Subantarctic and the Antarctic fur seal has been estimated at 1% of the population, and the rate of backcrosses to the parental species at 2.4% (Kerley, 1983). A study on Macquarie Island found that although both sexes of each species are present on the island, 91% of the mothers of the Subantarctic and the Antarctic fur

seal hybrids are Antarctic fur seals. The New Zealand fur seal (*A. forsteri*) is also present on the Island, but females are rarely observed. For that reason, it was presumed unlikely that the New Zealand fur seal was involved in hybridization to the degree observed between the Subantarctic and the Antarctic fur seal. However, a recent molecular analysis detected high level of hybridizations (17–30% of the pups were hybrids), not only between *A. tropicalis* and *A. gazella* as expected but also between *A. tropicalis* and *A. forsteri* as well as *A. gazelle* and *A. forsteri* (Lancaster *et al.*, 2006).

V. Evolutionary Implications of Hybridization

The evolutionary significance of hybridization is unknown, but it provides an opportunity for gene flow between otherwise isolated gene pools (e.g., exchange of adaptive traits). Marine mammals are genetically relatively similar. In comparison, the level of genetic divergence between the fin and the blue whale is similar to that observed between human (*Homo sapiens*), chimpanzee (*Pan troglodytes*, *P. paniscus*), and gorilla (*Gorilla gorilla*) (Arnason and Gullberg, 1993). Most cetacean species have the same number of chromosomes ($2n = 44$, with a few exceptions where $2n = 42$) and similar *karyotypes*, even though mysticetes and odontocetes probably diverged some 40 million years ago. Pinnipeds display a higher degree of variation in chromosome number, with the number of diploid chromosomes varying from 32 to 36 (Arnason, 1990). The relatively similar genetic background and often sympatric existence (in feeding or breeding range) among closely related marine mammals would seem to favor hybridization. However, as mentioned earlier, hybridization is rare, and where several hybrids have been observed (such as between the fin and the blue whale), the genetic integrity of the parental species is intact.

Haldane argued in 1922 that hybrids of the heterogametic sex (males in mammals with a single X- and Y-chromosome) was most likely to be sterile or unviable. Since then evolutionary geneticists have attempted to test “Haldane’s rule.” Among cetaceans, and specifically the family Mysticeti, the only two male blue × fin whale hybrids examined to date were both sexually immature despite their relatively advanced age. Although this observation is consistent with Haldane’s rule, which has been supported by a number of studies of hybridization in terrestrial mammals, the small sample size of mysticete hybrids makes it impossible to assess with statistical rigor if the Haldane’s rule applies to marine mammals as well.

The cases of anomalous marine mammals reported so far have shown that hybridization does occur in captivity as well as in natural settings. Among cetaceans, hybridization has been shown to occur between a variety of species (Tables I and II). However, the overall rate appears to be quite limited, and no introgression has yet been identified. The apparent scarcity of hybrids may not be a true reflection of the actual rate, i.e., it is possible that hybrids simply are overlooked or not reported (during commercial or subsistence whaling) in order to avoid sanctions for killing protected species (e.g., blue whales). Furthermore, the identification of hybrids so far has relied primarily upon morphological characters, which usually requires that the specimen be killed. However, the recent introduction of non-lethal

methods to obtain the necessary tissue for molecular methods as skin biopsies from free-ranging cetaceans makes it a simple task to identify hybrids today.

Within Pinnipedia, multiple cases of hybrids have been carried to term and survived and even reproduced, as observed among the fur seals. It seems that despite the viability of the fur seal hybrids, the rate remains low and some mechanism ensuring species recognition is acting as a barrier to hybridization, keeping the involved species genetically distinct. In the case of captive animals, it is difficult to assess if the seemingly low viability of the offspring is related to their hybrid origin or the general low rate of survival in captive-born cetaceans.

I

Identification Methods

RANDALL S. WELLS

Individual identification is an important tool for studies of animal behavior, ecology, and population biology. Much can be learned from recognition of individuals within a population or social unit, or from tracking individuals through time. Repeated observations of a recognizable individual can help to define its ranging patterns or site fidelity, or to quantify habitat use. Behavioral studies benefit greatly from the ability to recognize individuals. Individual identification is essential to understanding group compositions, and this understanding is enhanced when the individual's sex, age, genetic relationships, and reproductive condition are known. Similarly, interpretation of social interactions requires the ability to distinguish between the players. Behavioral descriptions often involve measurements of rates of occurrence of behaviors. These rates are measured most accurately when a selected individual is followed through time, or when the individual's behaviors are recorded at pre-determined intervals, a process referred to as focal animal behavioral observations (Altmann, 1974).

Descriptions of life history patterns and empirical measures of population dynamics can be facilitated by individual identification (Hammond *et al.*, 1990). By following individuals through time it is sometimes possible to determine age at sexual maturity, calving intervals, calf survivorship, and life span, providing measures of reproductive success. Combined, such individual measures can provide population level vital rates, including birth rates, mortality rates, and recruitment (Wells and Scott, 1990). Mark–recapture techniques use individual identification to arrive at abundance estimates. Individual identification provides one of the best tools for documenting exchanges of individuals between populations, allowing estimation of rates of immigration and emigration.

Selection of specific identification techniques depends on the research questions being addressed and the species under study. Frequent monitoring of individuals may require the ability to readily identify animals from a distance at each encounter, whereas other studies may only need to recognize an animal when it is handled subsequently, alive or at the end of its life. Some species exhibit individually specific natural markings that facilitate identification in the field. Other species lack such distinctive markings and require the attachment of artificial marks, or tags, if individual identifications are desired. Some species are visible on land at times, whereas others are entirely aquatic. Morphological, behavioral, and ecological features must be considered in order to determine what kind of tag or attachment is most appropriate, in terms of safety to the animal and effectiveness for the research. It

is now also possible to collect small samples of tissues that allow the identification of individuals genetically. Individual identification techniques have been summarized for cetaceans, pinnipeds, and sirenians (Hammond *et al.*, 1990; Scott *et al.*, 1990; Würsig and Jefferson, 1990; Erickson *et al.*, 1993; Wells *et al.*, 1999).

I. Cetaceans

A. Natural Markings

Cetaceans exhibit a variety of individually distinctive natural features. In most cases, features appearing above the surface of the water during the respiratory cycle are most useful. In particular, heads, backs, dorsal fins, and flukes are used most frequently for individual identification, with variations occurring in color patterns, skin patches, body scarring, and nicks and notches along fin edges (Hammond *et al.*, 1990). Some individuals of most cetacean species acquire distinctive scars from previous wounds or injuries, which are often used for identifications. Perhaps the most unique features used to identify individual cetaceans are the callosities of the right whales, *Eubalaena* spp. (Payne *et al.*, 1983). These individually distinctive raised patches of roughened skin are present on the rostrum anterior to the blowholes in a pattern referred to as the bonnet, on the chin, lower lips, above the eyes, and near the blowholes. Whale lice (*Cyamus* spp.), cyamid crustaceans that frequently live on the callosities, often give them a white, orange, yellow, or pink appearance. Callosities have allowed for the reliable recognition of individuals over periods of decades.

Color variations, where they exist among cetacean species, have been used with much success for individual identification, especially among the mysticetes (Hammond *et al.*, 1990). Reminiscent of “Moby Dick,” a few anomalously white individuals have been noted for several species of large and small cetaceans, offering unusual opportunities for individual identification. Blue whales (*Balaenoptera musculus*) and gray whales (*Eschrichtius robustus*) exhibit individually distinctive mottling on their backs (Fig. 1). The dorsal fin and dorsal ridge, respectively, are used as reference points for locating mottling patterns on these species. Bowhead whales (*Balaena mysticetus*) often have a distinctive pattern of white pigmentation on the chin and/or caudal peduncle. These patterns are readily seen from

Figure 1 Distinctive color patterns of a blue whale (*Balaenoptera musculus*). Photo by R. S. Wells.

aircraft, the most commonly used observation platform for this arctic species. Fin whales (*Balaenoptera physalus*) exhibit strongly asymmetrical body pigmentation, with the lower and upper lips and first third of the baleen on the right side of the head appearing white or pale gray, whereas the left side lips and baleen are dark. A light-colored “blaze” sweeps back on the right side, and a V-shaped light-colored “chevron” occurs on both sides behind the blowhole. Minke whales (*B. acutorostrata* and *B. bonaerensis*) exhibit a pattern of pale lateral pigmentation on the body, often divided into three distinct swaths, with the relative brightness of the three swaths apparently varying consistently between Northern and Southern Hemispheres. The distinctive dark and white patterns of the flippers and ventral surface of the flukes are familiar identification features for humpback whales (*Megaptera novaeangliae*) (Katona *et al.*, 1979).

Some of the smaller cetaceans also exhibit useful color variations, from the perspective of the researcher. Most notable are the light colored saddle patches behind the dorsal fin of the killer whale (*Orcinus orca*), which differ in size and shape. Similar features are used for short-finned pilot whales (*Globicephala macrorhynchus*), though the saddle marks are less distinct. Dorsal fin and/or back pigmentation variation has proven useful in studies of Dall’s porpoises (*Phocoenoides dalli*), Pacific white-sided dolphins (*Lagenorhynchus obliquidens*), Risso’s dolphins (*Grampus griseus*), and Hector’s dolphins (*Cephalorhynchus hectori*); and facial color patterns were used to identify the now-extinct baiji (*Lipotes vexillifer*). Extensive speckling develops with age in spotted dolphins (*Stenella attenuata* and *S. frontalis*). Such speckling has provided much opportunity for individual identification from both above and below the surface of the water in behavioral studies of Atlantic spotted dolphins (*S. frontalis*).

A variation of the color pattern is scarring that results in pigment variations. For example, Risso’s dolphins acquire distinctive long-term white scars on their otherwise brown or gray bodies, and belugas (*Delphinapterus leucas*) acquire dark scars on their otherwise white bodies. Bottlenose dolphin (*Tursiops* spp.) scars on the dorsal fin often are white, in contrast to their general gray coloration. Cookie cutter shark (*Isistius* spp.) bite wounds leave permanent small diameter oval-shaped scars which are often depressed and pigmented differently from the rest of many pelagic cetaceans’ bodies.

Dorsal fins typically are prominent features that are visible to researchers during most cetacean surfacings. In many cetacean species dorsal fins develop distinctive shapes or acquire nicks and notches, often through intraspecific or interspecific interactions, that allow for individual identification. Among the larger whales, fin, Sei (*Balaenoptera borealis*), Bryde’s (*B. edeni*), minke, humpback, and sperm whale (*Physeter macrocephalus*) dorsal fins serve as useful identification features. Building on the pioneering work of Bigg (1982) with killer whales and Würsig and Würsig (1977) with bottlenose dolphins, studies based on dorsal fin identifications of various delphinids and other small cetaceans have blossomed in the last three decades (Hammond *et al.*, 1990; Scott *et al.*, 1990; Würsig and Jefferson, 1990; Wells *et al.*, 1999). Species that have received the most attention include killer whales, bottlenose dolphins, pilot whales, humpbacked dolphins (*Sousa* spp.), Pacific and Atlantic (*Lagenorhynchus acutus*) white-sided dolphins, dusky dolphins (*L. obscurus*), Risso’s dolphins, spinner dolphins (*Stenella longirostris*), Atlantic spotted dolphins, Heaviside’s dolphins (*Cephalorhynchus heavisidii*), Hector’s dolphins, harbor porpoises (*Phocoena phocoena*), Amazon River dolphins (*Inia geoffrensis*), tucuxi (*Sotalia* spp.), long-finned pilot whales (*Globicephala melas*), Irrawaddy dolphins (*Orcaella brevirostris*), and baiji (Fig. 2). The frequency of occurrence of distinctive fin features varies from species to species

Figure 2 Killer whale (*Orcinus orca*) dorsal fins and saddle patches provide reliable identification cues. Photo by R. S. Wells.

Figure 3 Distinctive dark and light patterns on the ventral surface of a humpback whale’s (*Megaptera novaeangliae*) fluke. Photo by R. S. Wells.

and in some cases from population to population. Along the central west coast of Florida, approximately 60–80% of bottlenose dolphins are considered to be distinctive based on dorsal fin features. Unlike color patterns that vary from one side of the animal to the other, dorsal fin features are often equally visible from both sides and are distinctive under a broad range of lighting conditions, facilitating data collection in the field.

Some cetacean species regularly lift their flukes from the water prior to a dive, providing predictable opportunities for researchers to note the occurrence of nicks, notches, and other features on the trailing edge of the flukes. Humpback whales offer both distinctive color patterns as well as trailing edge features for identification (Fig. 3). Humpback whale flukes were among the first natural markings on cetaceans to be recognized for their individual specificity, and the technique has achieved extensive application worldwide in studies of population size and structure (Smith *et al.*, 1999). Sperm whales also demonstrate much individual-specific variability in fluke edge features.

Many of the cetacean features used by researchers for individual identification are visible above the surface of the water only briefly

during respiratory cycles, or are too subtle to be of use for accurate identification in real time. Most cetacean individual identification research involves the collection of permanent records of the distinctive features for subsequent detailed analysis, through a process generally referred to as photo-identification. As the name indicates, the process frequently involves 35-mm photography of cetaceans. Digital imaging through still cameras and video has greatly expanded the capabilities and possibilities for individual identification, and facilitating image processing, storage, and sharing.

At its most basic level, photo-identification involves trying to obtain high quality, high resolution, full frame images of identifying features (Würsig and Jefferson, 1990). Though photo-identification can sometimes be accomplished from shore, typically scientists in research vessels, whale-watching boats, or aircraft attempt to place themselves in position to be able to obtain an image of the features that is parallel to the photographic plane (lens oriented perpendicular to the feature of interest). Telephoto lenses aid the researcher in enlarging the features to fill the photographic frame. Motor drives or video allow multiple images to be taken in quick succession to optimize capturing fins, backs, or flukes at their greatest perpendicularity and height above the surface of the water, for example. Time and date data printed on the image provide additional assurance that images and data records can be matched correctly during subsequent analyses.

High-resolution digital cameras have now largely replaced film cameras for photo-identification work (Markowitz *et al.*, 2003). In the past, film selection varied with species, lighting conditions, and researcher preference. The film had to have sufficiently fine grain to be able to resolve distinctive features, while allowing a shutter speed setting sufficiently fast to “freeze” the animal but slow enough to optimize depth of field for focus. Some researchers have used black and white film, especially if expense or ease of manual processing were concerns. Color film has often been used when documentation of wounds or the freshness of fin features is desired, for example. High-resolution digital cameras, typically with high-speed autofocus, provide high-quality color images in real-time, eliminating delays resulting from the need to wait for film to be developed.

Techniques for image storage, retrieval, and analysis vary greatly across research situations, but the development of digital photography has greatly increased efficiency and decreased costs for image manipulation and storage. Historically, images in the form of slides, prints, or negatives were labeled and stored chronologically in archival plastic sheets in binders, then examined under magnification through a handheld lupe or dissecting microscope. Digital images, obtained either directly from high-resolution digital cameras or from scans of photographs, offer tremendously increased capacity for manipulation, including cropping and enlarging identifying features, electronic storage, or transmission over the Internet.

Digital images also facilitate computer-assisted automated analysis. Previously, photographic matches were made through the laborious process of individual comparison by eye of the image of interest to all possible matches in a catalog of distinctive individuals. Computer software has been developed that can search thousands of images of such animals as sperm whales, humpback whales, bottlenose dolphins, or other odontocetes in a very short time to produce a limited set of potential matches. The researcher can then make the final match using the exceptional resolving capabilities of the human eye. Additional rigor is often incorporated into the process using multiple judges for difficult final identifications. Computer-assisted matching is becoming increasingly important as catalogs are now incorporating many thousands of individuals, and as contributions to centralized catalogs are being made by numerous researchers

in widely dispersed locations (Hillman *et al.*, 2003; Bas *et al.*, 2005; Adams *et al.*, 2006).

Other kinds of “natural markings” that are being used increasingly are genetic markers from skin biopsy samples. Molecular analyses of small samples allow determination of sex and individual identification from genotypes provided by microsatellite loci. This technique was developed for large-scale use during an ocean-basin-wide study of humpback whales, in which photographs were used to identify 2998 individual whales, and microsatellite loci were used to identify 2015 whales (Smith *et al.*, 1999). Based on the results of these initial studies, molecular techniques hold a great deal of promise for studies of a variety of cetaceans.

B. Temporary Markings

Natural temporary markings include skin lesions on parts of the body visible to researchers (Wilson *et al.*, 1999), and soft-bodied barnacles that attach to dorsal fins, for example. Such markings can be useful for distinguishing between otherwise unmarked animals within a group, but their changeable nature make them less reliable for accurate identifications over long periods. Skin lesions may take weeks to months to fully heal and disappear, but their characteristics change during the healing process. Soft-bodied barnacles favor dorsal fin tips for attachment, leading to low variability in positioning, thus minimizing their value for identification.

Anthropogenic temporary markings have been found to be of limited utility with cetaceans (as reviewed by Scott *et al.*, 1990). Remotely applied paint and tattoos have been tested with small cetaceans, and in all cases the animals were either not re-identified or the markings disappeared within 24 h, due to skin sloughing. In some cases, zinc oxide-based, brightly colored sun protection ointments have been applied to dolphins’ dorsal fins prior to release. These have allowed for the short-term identification of animals otherwise lacking in distinctive marks, and transfer of colors between animals can indicate social interactions.

C. Scarring and Branding

Dorsal fin notching has been attempted in a few cases with killer whales, bottlenose dolphins, pantropical spotted dolphins, and spinner dolphins (Scott *et al.*, 1990). Notching provides the same kinds of features used in photographic identification of natural marks. Such notching requires capturing the animals, which also provides opportunities to learn the sex and age of the marked dolphin, as well as other biological information. One report indicated minor but persistent bleeding as a result of notching, but this has not been reported by others.

Freeze branding, using metal numerals 5–8 cm high applied to the animals’ body or dorsal fin for 10–20 sec, has been used safely and successfully with a variety of small cetaceans, including bottlenose dolphins, spinner dolphins, short-beaked common dolphins (*Delphinus delphis*), Pacific white-sided dolphins, short-finned pilot whales, false killer whales (*Pseudorca crassidens*), Amazon River dolphins, and rough-toothed dolphins (*Steno bredanensis*) (Irvine *et al.*, 1982; Scott *et al.*, 1990). Freeze-brand application typically results in little or no reaction by dolphins, but minor skin lesions may occur if brands are applied for too long. Readable white marks usually appear within a few days (Fig. 4). Freeze brands fade over time, but the marks can often still be identified for many years in good quality photographs even if they are not readily visible in the field. Fading appears to be age related, with brands disappearing more rapidly

Figure 4 Dorsal fin and back of a 41-year-old male bottlenose dolphin (*Tursiops truncatus*), showing a 12-year-old freeze brand (“48”) in the center of the dorsal fin, and on the back centered below the caudal insertion of the fin. The healed notch near the base of the fin is from a rototag applied 16 years before. Photo by Sarasota Dolphin Research Program.

and more completely on younger animals, but remaining readable on adults for as long as 11 years or more (Irvine *et al.*, 1982; Scott *et al.*, 1990).

D. Attachment Tags

The use of attachment tags for identification purposes (rather than telemetry, covered elsewhere in this volume) including Discovery tags, spaghetti tags, button tags, and rototags, has been reviewed by Scott *et al.* (1990). Discovery tags are numbered metal cylinders shot into the blubber from whaling ships or research vessels. The tags have been used primarily with baleen and sperm whales, and are recovered when the whales are captured and rendered, providing information on two points within the animals' range. Tagging was initiated in 1932 and continued until the whaling moratorium in 1985. More than 20,000 Discovery tags have been used, but return rates have been low, typically below 15%. Smaller versions of these tags have been used with small whales without notable success, and use with cetaceans less than 4.6-m long has been discouraged because of risk of serious injury.

Streamer or spaghetti tags, originally developed for fish tagging, are colored vinyl-covered strands of wire cable of variable length with steel or metal dart tips that are applied with either a crossbow or a jab stick, with the intent of anchoring the tip between blubber and muscle. Thousands of these tags have been applied to dolphins, porpoises, and belugas, especially in association with the tuna seine net fishery in the eastern tropical Pacific Ocean. Because of poor retention and high risk of injury to the animal, use of spaghetti tags with small cetaceans has been discouraged for many years (Irvine *et al.*, 1982).

Dorsal fins or ridges are commonly used for tag attachment because of their structure, prominence, and regularity of appearance above the surface of the water. Button tags, typically numbered and colored fiberglass or plastic disks or rectangular plates designed after the Peterson disk fish tags have been applied to several species of small cetaceans, including bottlenose dolphins, pantropical spotted dolphins (*Stenella attenuata*), spinner dolphins, common dolphins

(*Delphinus* spp.), Pacific white-sided dolphins, belugas, and harbor porpoises (Evans *et al.*, 1972; Scott *et al.*, 1990). Usually button tags are attached through the dorsal fin by means of one or more plastic (especially delrin) or stainless steel bolts or pins that connect the tag halves on each side of the fin. Although some button tags have lasted for several years on pelagic dolphins, inshore animals often lose the tags within weeks or months, often by breaking them through rubbing on the shallow sea floor. Use of button tags has been largely discontinued due to poor tag retention and the potential for injury to the animals (Irvine *et al.*, 1982).

Small plastic cattle ear tags, or rototags, clipped through the trailing edges of dorsal fins have proved successful for identifying small cetaceans in the field, including bottlenose dolphins, pantropical spotted dolphins, spinner dolphins, common dolphins, rough-toothed dolphins, Pacific white-sided dolphins, short-finned pilot whales, and harbor porpoises (Fig. 4; Norris and Pryor, 1970; Scott *et al.*, 1990). Typically, a small hole is made in the thin tissue of the trailing edge using a sterile technique, and the tag is clipped through the fin with special pliers. Though the written markings are too small to be read at a distance, number of tags, color, and position on the fin provide a useful degree of variation. Rototags have remained in position for a period of years, although often they are lost within months. Rototag halves may separate, leaving a healed hole in the fin, or they migrate through the trailing edge of the fin, leaving a small, healed notch; both pose minimal risks to the animals but offer continuing identification features. Barnacle and algae fouling, and pressure necrosis are infrequent problems. As a modification of this technique, small VHF radio transmitters have been attached to rototags for short-term tracking (up to 30 days), with a modification involving the use of a corrosible nut system to release the tag at that time.

Other attachment techniques, such as the use of tethers or plastic-coated wires or polypropylene or soft rubber tubing have proved to be ineffective and injurious to the animals when attached to the caudal peduncle. Tag loss rates have been high, and abrasions were frequently noted.

II. Pinnipeds

A. Natural Markings

Natural body markings have been used in only a few studies of pinnipeds such as gray seals (*Halichoerus grypus*), northern elephant seals (*Mirounga angustirostris*), Steller sea lions (*Eumetopias jubatus*), Hawaiian monk seals (*Monachus schauinslandi*), harbor seals (*Phoca vitulina*), and California sea lions (*Zalophus californianus*). Yochem *et al.* (1990) examined pelage patterns of harbor and largha (*P. largha*) seals to distinguish between populations and individuals. Using black and white photographs they scored the presence or absence of spots, clarity of spots, relative density of spots, complexity of spots, presence of rings, and spacing of rings in selected body areas (especially sides of the head, neck, and chest). Hiby and Lovell (1990) described a computer aided matching system for screening a library of digitized natural mark photographs of gray seals. Their system created a three-dimensional model to locate features on the seal's body, especially using the side of the neck. Harting *et al.* (2004) devised a computer-assisted system for photo-identification of Hawaiian monk seals. For most pinniped species, studies using natural markings are hampered by a lack of distinctive markings, and the large numbers of individuals or pack ice distributions of many species (Erickson *et al.*, 1993). Most pinniped researchers have resorted to the use of artificial markings and tags for individual identification.

B. Temporary Markings

Techniques for temporary markings of pinnipeds include paints, dyes, bleaches, and pelage clippings (Erickson *et al.*, 1993). These techniques offer the advantages of often being able to be applied without having to restrain the animals and permitting remote identification without disturbance. However, these marks are typically lost upon molting, precluding the continuity of identification beyond a single season. A variety of paints (marine, highway, rubber-based, quick-drying cellulose, aerosol sprays, and house paint) have been used to mark seals and sea lions. Paints have been applied from brushes or rollers on poles, and from plastic bags thrown at the animals. Quick-drying paint has proved relatively effective, with a useful lifespan of about 1 month on average. Northern fur seals (*Callorhinus ursinus*) have been successfully marked for 2–12 months with a fluorescent plastic resin, naphtha-based paint. This technique apparently results in matting of guard hairs, which then break off leaving an outline of the mark. High-gloss marine enamel applied from aerosol cans to mark Hooker's sea lions (*Phocarctas hookeri*) has resulted in markings lasting 3 months, even after the animals have been at sea. Carbon dioxide powered paint guns firing small capsules have proved less effective for marking elephant seals due to reliability problems and the small size of the marks.

Dyes have been used with several species of pinnipeds, especially light-colored species (Erickson *et al.*, 1993). Successful dyeing usually occurs when permanent dyes are used and when the animals are dry and remain out of the water for a period of time following application. Colored dyes and black Nyanzol D have lasted 3–4 months on gray seals, harbor seals, and California sea lions. The addition of alcohol to the Nyanzol D leaves a more distinct marker because it dissolves fur oils, and it also prevents dye solution from freezing. Yellow picric acid in a saturated alcohol solution has been used with gray seals, with results that last through pup molting, appearing on the adults as well. This solution can be applied from a back-pack tree sprayer to wet or dry seals. Fluorescent dye mixed with small quantities of epoxy resin has also been used with success. In some cases, such as southern elephant seals (*Mirounga leonina*) dyes have been less successful.

Bleach offers a very effective and sometimes longer-lasting alternative to paints and dyes (Erickson *et al.*, 1993). Many of the bleach solutions can be applied to sleeping animals via a squeeze bottle, thus minimizing risk, effort, and disturbance. Commercially available products such as Lady Clairol Ultra Blue dye in combination with various chemicals has been used most often, resulting in a white or cream-colored mark that is most visible on dark pelages. Combinations resulting in thicker consistency allow for distinct lines. Bleach marks on elephant seals last until molt, sometimes for 6 months, and have lasted for two seasons on fur seals. Combinations of bleaches and dyes have also been used in some cases such as northern elephant seals (Fig. 5).

Hair clipping is somewhat more difficult than the previous techniques, but effective when the underfur is a different color from the guard hairs (Erickson *et al.*, 1993). This technique involves clipping or singeing the pelage to create a distinctive mark. It has been used with success with northern fur seals, Steller sea lions, and Antarctic fur seals (*Arctocephalus gazella*).

C. Scarring and Branding

Punch marks and amputations have been used extensively with fur seals, with poor success and concerns about injury to the animals (Erickson *et al.*, 1993). Initial efforts to mark northern fur seals and Antarctic fur seals by punching holes in flippers in unique combinations of numbers and positions found this technique to be unreliable

Figure 5 Bleach markings on a northern elephant seal (*Mirounga angustirostris*). “Bilbo” is marked in black dye for identification through the summer molt, and in bleach for the winter breeding season. Photo by C. J. Deutsch.

due to healing and occlusion. Hair on the flippers of phocids seals precludes utility with these species. Flipper notching was also found to be unreliable due to tissue regrowth. Although ear notching was used successfully for cohort marking in northern fur seals, it is no longer used because of concerns regarding interference with diving abilities.

Both hot branding and freeze branding have been used with great effect with pinnipeds (Erickson *et al.*, 1993). Hot brands have been used since 1912 with thousands of northern fur seals, Cape fur seals (*Arctocephalus pusillus*), southern elephant seals, Weddell seals (*Leptonychotes weddellii*), gray seals, and leopard seals (*Hydrurga leptonyx*). Some marks have remained readable for up to 20 years. The technique seems best suited to colonial seals due to the bulky nature of the branding tools and heat source. Typically, brands are heated to red hot, and applied with firm, even pressure for 2–7 sec, depending on whether the hair has been clipped. Brands are applied to the upper saddle, middle back, or upper shoulder to optimize sightability.

Freeze branding differs from hot branding in that it involves the selective killing of pigment-producing cells through contact with a super-cooled metal numeral or symbol (typically 5-cm high) (Erickson *et al.*, 1993). Brands are cooled with liquid nitrogen or a dry ice and alcohol mixture and applied for about 20 sec to an area where hair has been removed. Correct freeze brand application results in a non-pigmented pelage mark, ranging from dark (elephant seals, California sea lions) to pink (California sea lions, walrus, *Odobenus rosmarus*). Freeze branding has had mixed success. Many freeze brands on pinnipeds have been found to re-pigment within 1–2 years, perhaps as a result of excessive branding. Readable brands have been obtained for elephant seals (up to a year, discernable for 3 years) California sea lions (readable for 1.5 years, discernable for up to 4 years), walrus (readable for many years), and Australian sea lions (*Neophoca cinerea*) (legible on flippers for 7 years, on flanks for 4 years).

D. Attachment Tags

Plastic or metal attachment tags are used more widely than any other kind of individual identification system with pinnipeds (Erickson *et al.*, 1993). Monel or stainless steel tags such as those

Figure 6 Flipper tag on a northern elephant seal (*Mirounga angustirostris*). Photograph by B. J. LeBoeuf.

used to mark livestock are the most common metal tags. These metal strap tags are self-piercing and are attached by means of special pliers to the trailing edge of the fore flippers of otariids, and to the interdigital web of the hind flippers of phocids. Typically, the tags are stamped with an organization address and serial number. Thousands of metal tags have been attached to phocids. Retention rates on phocid seals are low, with post-attachment tears and cuts sometimes becoming infected. Hundreds of thousands of metal tags have been attached to otariids, with similar poor results.

The use of plastic tags is now much more common than metal tags for identifying pinnipeds (Fig. 6). Two kinds of plastic tags are used commonly, rototags and Allflex tags. Both consist of self-piercing male and female elements that are applied with special pliers, as with the metal tags. Plastic tags are available in a variety of colors, leading to more than 300 unique color combination possibilities. The visibility of both metal and plastic attachment tags can be enhanced using streamer markers such as nylon cloth strips reinforced with vinyl, which may last for a year or more.

Tagging success with both metal and plastic tags is less than desired. Loss rates of the two kinds of plastic tags are variable, but tend to be lower than for metal tags, about 10% annually. However, the long-term durability of metal tags is better than plastic. Wounds from metal tags are more common than from plastic.

III. Sirenians

A. Natural Markings

The process of developing new techniques and applying existing technology to studies of sirenians was reviewed by G. Rathbun in Wells *et al.* (1999). Natural marks, including deformities and scars have been used to identify individual Florida manatees (*Trichechus manatus latirostris*) since the 1950s. Among the marks that have proven most useful for individual identification are the scars from collisions with boats, especially propeller scars. Most manatees in Florida waters bear scars from boat collisions, often from more than one event. Boat scars occur over all parts of the manatee's body, but especially the dorsal surface and paddle, where notches may be cut by propellers (Fig. 7). Individual identification progressed from sketches of marks to surface and underwater 35 mm photography. Photography

Figure 7 Identifying scars from boat collisions on a Florida manatee (*Trichechus manatus*). Photograph by J. K. Koelsch.

allowed for tracking of changes in identifying characteristics through time, and for distinguishing between manatees with similar markings. Technological advances have resulted in photographic images of scar patterns being saved, cataloged, and searched with the assistance of computers.

B. Temporary Markings

No widely accepted techniques currently exist for temporarily marking sirenians. Paint, flipper bands, and harnesses have been tested, but have been found to be ineffective (Irvine and Scott, 1984). "Paintstiks," oil-based crayon-like markers, have remained visible for 3–7 days during field tests, though rubbing eventually smears or removes them. Aerosol paint was short-lived, and application startled the animals and polluted the water.

C. Scarring and Branding

Although not intentional, the most widely used features for identifying individual manatees are propeller scars. In recent years, scientists have begun cutting small notches in the paddles of manatees. The positions of the notches around the paddle are coded to provide information on cohorts. Freeze branding is also used with manatees that have been captured or rehabilitated on occasion, with some success (Irvine and Scott, 1984). Though most brands fade with time, some have remained readable at distances of 15 m for as long as 4 years. Success may vary with whether the manatees are shedding, as well as season, water temperature, and salinity.

D. Attachment Tags

Lacking dorsal fins, sirenians provide few opportunities for tag attachment. As described for cetaceans, spaghetti tags have been tested with manatees (Irvine and Scott, 1984). These 20-cm-long plastic streamer tags attached to a metal dart have been applied with either a lance or a crossbow, attempting to anchor the tag about 2 cm below the skin. Spaghetti tags demonstrated poor retention, and caused abscesses on some manatees.

The most effective technique for tag attachment involves a breakaway “belt” looped around the animal’s peduncle. This belt is designed to minimize chafing, break away if it should become snagged on an obstacle in the environment, and carry a floating very high frequency (VHF) or satellite-linked radio transmitter at the end of a tether. Each transmitter float is color coded to allow for individual identification visually. The tethers can be replaced by swimmers as necessary.

Passive integrated transponders, or PIT tags, have been implanted in nearly every Florida manatee that has been handled in recent years (Wright *et al.*, 1998). These glass-encapsulated microchips are about the size of a rice grain. They are implanted subcutaneously at a depth of about 3.5 cm, dorsal and caudal to the ear, and medial to the scapula. A small incision is made, and the tag is inserted via a 12 ga. needle. Each is programmed with a unique identification code that is activated by a handheld scanner when it passes nearby. PIT tags are relatively easy to implant, last a long time, are reusable, rarely infect the animals, have an unlimited number of potential codes, and allow for easy data recording and transfer, but suffer from the fact that they must be scanned from no more than 15 cm away and the receivers are not waterproof.

Indo-Pacific Beaked Whale

Indopacetus pacificus

ROBERT PITMAN

I. Characteristics and Taxonomy

The Indo-Pacific beaked whale, also known as Longman's beaked whale or tropical bottlenose whale, is an uncommon tropical ziphiid that was until very recently one of the least known extant cetaceans. Originally described as *Mesoplodon pacificus* from a beach-worn skull collected in Queensland, Australia in 1882 (Longman, 1926), the validity of the species was initially challenged by researchers who variously suggested that it was a subspecies of True's beaked whale (*Mesoplodon mirus*) or an adult female southern bottlenose whale (*Hyperoodon planifrons*). These allegations were refuted and the validity of the species confirmed by the discovery of a second skull from the coast of Somalia in 1955 (Azzaroli, 1968). After further study, Moore (1968) found it sufficiently distinct to warrant establishing a new genus *Indopacetus*. These two skulls were the only evidence that this species existed until very recently when a series of at-sea sightings of an unidentified beaked whale from the tropical Indian and Pacific oceans were compiled and more closely analyzed. Some of these sightings had previously been tentatively identified as of southern bottlenose whales (*Hyperoodon planifrons*), but color pattern differences ruled out that species and the suggestion was made that it could be the long lost *I. pacificus* (Pitman *et al.*, 1999). This identification was subsequently confirmed by genetically matching stranded animals (that had previously been identified as *H. planifrons*) with the holotype of *I. pacificus* in the Queensland Museum (Dalebout *et al.*, 2003). This has led to the identification of dozens of at-sea sightings, and *I. pacificus* has now become one of the more frequently identified beaked whales.

The Indo-Pacific beaked whale is identified in the field as a relatively large ziphiid with a prominent melon sharply set off from a fairly long beak, a prominent dorsal fin, and a subtle but distinctive color pattern (Fig. 1). The calf is dark gray with a conspicuously pale head. The light color of the melon extends only as far back as the blowhole (this is important because in the otherwise similar-looking *Hyperoodon* spp., the paleness on the melon extends 10cm or so posterior to the blowhole). Much of the face, lower jaw and throat are also pale. Immediately posterior to the blowhole the dark gray dorsal coloration extends ventrally to form a dark patch around the eye; it also extends ventrally and backward to the insertion of the flipper, forming a broad band. There is a small white "ear spot" embedded in the dark area behind the eye. Immediately posterior to the dark flipper band, and setting it off, is a large white patch formed by the white from the ventral area extending high up on the sides of the animal. This white thoracic coloration apparently darkens with age because it has only been seen on calves.

Adults are similar to calves except that the beak is longer and the color pattern changes somewhat (Fig. 2). Adult females appear brown in good light and grayer with lower light levels. Adult males are similarly colored but often appear lighter than females due, at least in part, to an accumulation of scars from tooth rake marks by other males. Although females have very few of the linear scars found on adult males, both sexes often have numerous white, oval scars that appear to be mainly healed bites from cookie cutter sharks (*Isistius* sp.; Fig. 2). As in calves, the melon of adults is often a pale tan color; this paleness is not evident on all individuals, suggesting

Figure 1 *Indopacetus pacificus* near the Maldives Islands in the central Indian Ocean showing the pale prominent melon, distinct beak, and conspicuous blow. Photograph by R. C. Anderson.

Figure 2 An apparently emaciated 6-m female *Indopacetus pacificus* that stranded in Kagaoshima, Japan in 2002; the white spots are bite scars from cookie cutter sharks (*Isistius* sp.). Photograph by Kagoshima City Aquarium, courtesy of T. Yamada.

that it may become obscured with age. This species is large enough that it produces a clearly visible, low, bushy blow, which is usually angled slightly forward. As in all ziphiids with apical dentition, the gape in both sexes is straight throughout most of its length but turned up slightly at the posterior end. A dip behind the melon (seen in profile) is confluent with the blowhole. The dorsal fin is set approximately two-thirds of the way back on the upper body and it is relatively large, perhaps larger than in any other species of beaked whale. Similar to other ziphiids, the pectoral flippers are small and can fit into depressions that make them flush with the body. *I. pacificus* is the only beaked whale known to exhibit polydactyly.

Adult length measurements are available from only three animals: (1) a pregnant female that stranded in the Maldives in January 2000 was 6m long (curvilinear measurement) and (2) a physically mature female that stranded in Kagoshima, Japan in July 2002 was 6.5-m long, which may be a maximum for this species, and (3) a 5–65-m female (and her 4.20-m calf) stranded in Taiwan in 2005. A neonate that stranded in South Africa was 2.9m long.

The skull of the adult (pregnant) female that stranded in the Maldives measured 123cm. This species has a single pair of teeth set

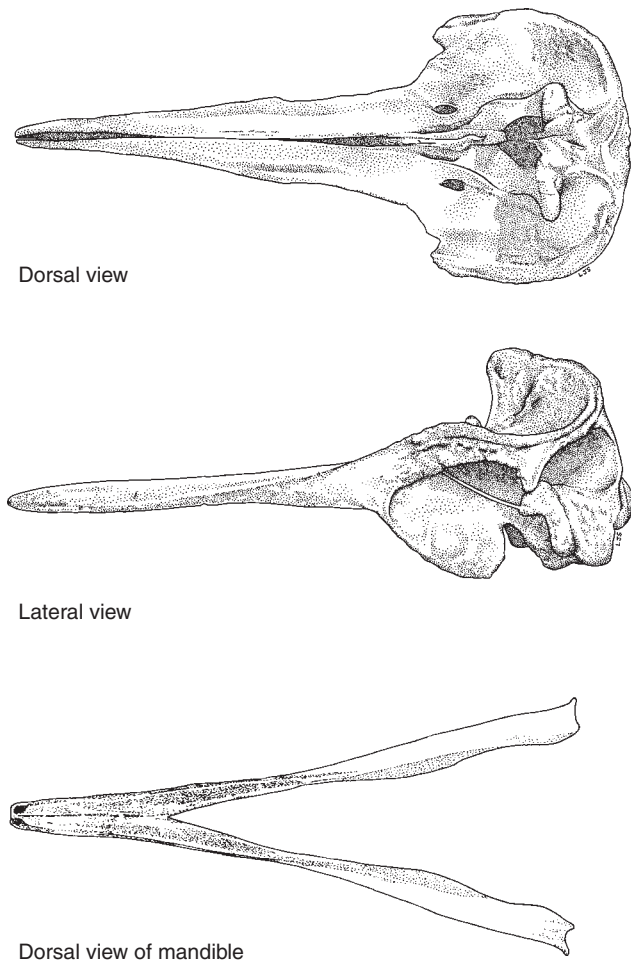

Figure 3 Skull of *Indopacetus pacificus*. Courtesy of the Food and Agriculture Organization of the United Nations; from Jefferson et al. (1993), *Marine Mammals of the World*, FAO, Rome.

near the tip of the lower jaw, which presumably erupt only in adult males (as they do in most species of ziphiids), but no adult male is known to have been examined. A 5.73-m immature male that stranded in the Philippines in 2004 had teeth that were just starting to erupt. The teeth are conical in shape and oval in cross section, set in relatively shallow alveoli (sockets), and likely project slightly forward in adult males. In addition to these tooth characteristics, the skull of *I. pacificus* (Fig. 3) is distinguishable from those of *Mesoplodon* and the other living genera of beaked whales by the following features (1) frontal bones occupy an area of the vertex equal to or greater than that of the nasal bones; (2) premaxillary crest with extremely short posterior processes; (3) a deep horizontal groove in the maxillary bone just above the orbit; and (4) about mid-length in the beak, there is a swelling of the lateral margins so that the beak does not grow narrower throughout its entire length (Moore, 1968).

Historically, the validity of the genus *Indopacetus* as distinct from *Mesoplodon* has not been universally accepted. A recent molecular genetics analysis found support for species level differences in *I. pacificus*, but the available samples were too degraded to resolve validity of the genus (Dalebout et al., 2003). The same study, however, was able to verify the morphological characters that Moore (1968) used to diagnose the genus and also identified two other possible diagnostic characters: rib count and number of fused cervical

vertebrae. The more recent study concluded that the genus should be retained pending further evidence to the contrary.

II. Distribution and Abundance

The Indo-Pacific beaked whale appears to be uncommon or rare throughout much of its range. Before 2003, there were no confirmed live sightings in the wild, and for over 75 years its distribution was inferred from only two skulls collected in east Australia and Somalia, respectively. Since then however, there have been at least 8 new stranding records (including two previously misidentified as *Hyperoodon planifrons*), and at least 65 at-sea sightings. Based on this, *I. pacificus* is now known to inhabit tropical waters throughout the Indo-Pacific, from the west coast of Mexico to the east coast of Africa and the Gulf of Aden (Fig. 4). It is rare in the eastern Pacific but appears to be more common in the western Pacific and is also at least fairly common in the western tropical Indian Ocean, suggesting an affinity for western ocean basins. The only population estimates to date were based on systematic surveys in Hawaiian (EEZ) waters (1007 animals) and the eastern tropical Pacific (291 animals; Barlow et al., 2006).

III. Ecology

Practically nothing is known about the ecology of *I. pacificus*. Beaked whales are in general mainly squid-eaters and *I. pacificus* appears to be no exception. Stomach contents are known from only two specimens. A stranded animal from Davao, Philippines had only squid beaks in its stomach. Another stranded specimen, from Kagoshima, Japan, contained squid beaks, plastic bits, and nematodes in its stomach; there were no fish remains. Of a total of 69 squid beaks identified, 83% were *Taonius pavo*; other species present included *Moroteuthis loennbergi*, *Onychoteuthis borealijaponica*, *Chiroteuthis imperator*, and *Histioteuthis corona inermis*.

Most sightings have been in deep water (>2000m), where the sea surface temperatures were $\geq 26^{\circ}\text{C}$. Although a fair number of sightings have been recorded along continental slope areas (200–2000m), this may reflect a bias for surveys to be more nearshore. It has usually been observed in monospecific groups, but among the 65 sightings recorded to date it has also been associated with short-finned pilot whales (*Globicephala macrorhynchus*; five times), pilot whales and common bottlenose dolphins (*Tursiops truncatus*; two times), and only bottlenose dolphins (one time). Photographs of both stranded and live specimens often show numerous white oval scars, which are probably the healed wounds of cookiecutter shark bites (*Isistius* spp.): the Kagoshima stranding had hundreds of scars giving it a spotted appearance (Fig. 2).

IV. Behavior and Physiology

Group size tends to be larger than in other beaked whale species except perhaps *Berardius* spp. Evidence to date also suggests there may be regional differences in group size. In the Pacific, mean group size was 18.5 individuals (range 1–100). In the western vs the eastern Pacific, it was 29.2 and 8.6, respectively (Pitman et al., 1999). In the western Indian Ocean, group size averaged 7.2 individuals (range 1–40; Anderson et al., 2006). *I. pacificus* tends to travel in close groups, often with adult males, adult females, and calves present. When traveling fast at the surface, animals bring their head and beak high out of the water, or sometimes porpoise low like large dolphins. Diving and surfacing is largely synchronous within the group. Dive times recorded to date have ranged from 11 to 33 min; one animal was suspected of diving for at least 45 min, and it is probable that maximum dive times may be considerably longer.

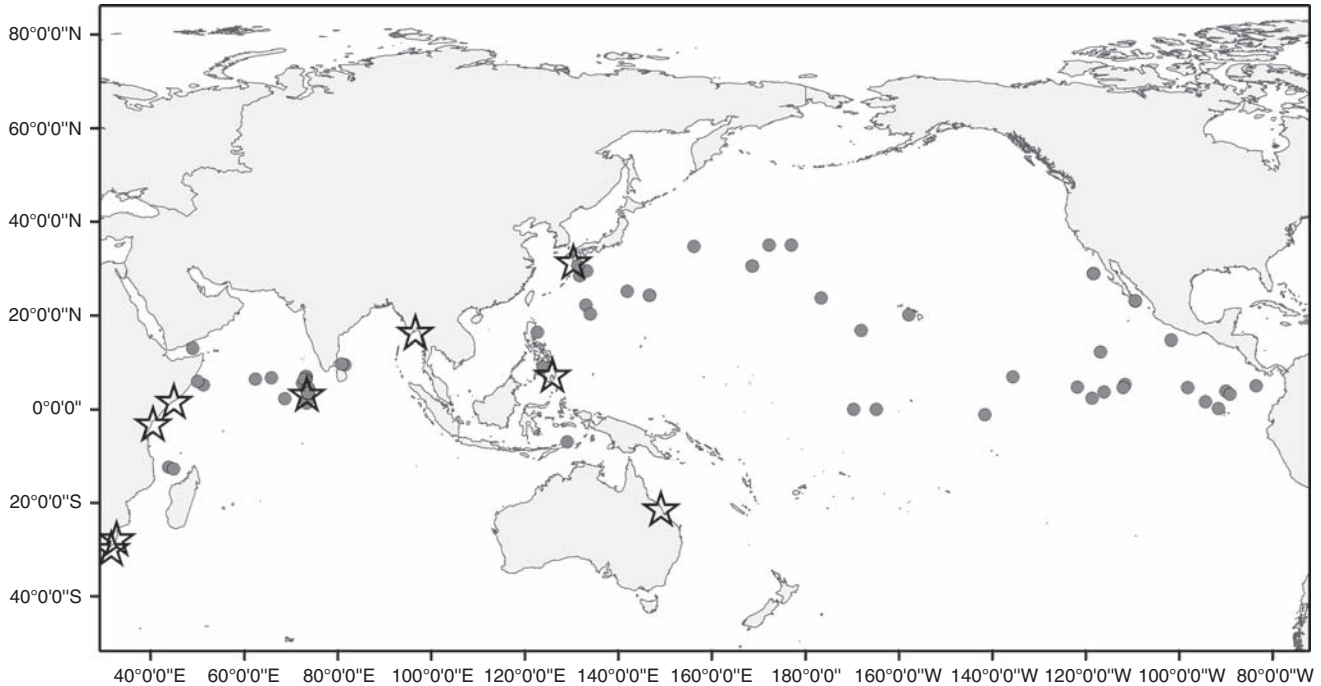

Figure 4 Records of *Indopacetus pacificus* from the tropical Indian and Pacific oceans: circles, sightings; stars, strandings. Data from Pitman et al., 1999; Dalebout et al., 2003; Anderson et al., 2006; Watson et al. (2008); NOAA Fisheries/SWFSC unpublished data; additional stranding information from J. Acebes (philippines), T. Yamada (Japan) and T. Tun (Myanmar).

V. Life History

Little is known of the life history of this whale: a 6-m female was pregnant; another 5.65-m female with a 4.2-m calf was lactating and had 2 corpora albicantia in the left ovary (Watson et al., 2008).

VI. Interactions with Humans

Juvenile bottlenose whales that were probably of this species have been caught by gillnet fishermen from Sri Lanka, and the thousands of pelagic gillnet vessels that currently operate across the tropical Indian Ocean are an unknown but potentially significant threat to all whale populations there (Anderson et al., 2006). Unidentified whales that were possibly of this species have also been taken on longline gear in Hawaiian waters, indicating a potential susceptibility to this type of fishing also. Beaked whales in general are known to be particularly vulnerable to loud anthropogenic sounds in the ocean, including active sonar and seismic surveys. An apparently healthy mother and calf *I. pacificus* stranded in Taiwan in 2005 along with numerous other cetaceans perhaps as a result of naval exercises that had just off the coast there. A sub-adult male that stranded in the Philippines reportedly had pieces of plastic bags in its stomach.

Indo-Pacific Bottlenose Dolphin

Tursiops aduncus

JOHN Y. WANG AND SHIH CHU YANG

I. Characteristics and Taxonomy

This dolphin was initially named *Delphinus aduncus*. *Tursiops* is the combination of the Greek words "Tursio" for dolphin and "ops" for appearance; *aduncus* is from the Latin word

meaning hooked (possibly referring to the lower jaw being slightly upturned distally).

A. Taxonomy

The taxonomic status of *Tursiops aduncus* was uncertain until about 2000 when it gained wide acceptance after studies demonstrated two sympatric forms of *Tursiops* were reproductively isolated, the evidence being the maintenance of congruent and consistent molecular and morphological differences (Wang *et al.*, 1999, 2000a, b). Subsequent studies have also supported the distinct species status of *T. aduncus*. Still, considerable taxonomic uncertainties exist within the genus *Tursiops*, even amongst dolphins that appear to be *T. aduncus*. For example, the dolphins of Shark Bay (Western Australia) are one of the best-known populations of bottlenose dolphins, but their species identity still stymies researchers (note: in this review, the Shark Bay dolphins are considered *T. aduncus*). Although polytypy of *T. aduncus* has been suggested (Natoli *et al.*, 2004), this view is not widely accepted at present. Furthermore, mtDNA analyses have been interpreted as evidence that *T. aduncus* is most closely related to *Stenella frontalis* (LeDuc *et al.*, 1999), which is inconsistent with osteological characters. The osteology of *T. aduncus* (discussed later) is very different from that of *Stenella* spp. and closely resembles *T. truncatus*, to the point that distinguishing between the two species is difficult and was one of the reasons for the long-standing uncertainty about the taxonomic status of *T. aduncus*. Well-designed studies using multiple independent characters are needed to resolve some of these issues.

Other factors contributing to the continuing taxonomic confusion include the wide distribution of *Tursiops* across highly variable environments, thus resulting in great variation exhibited by many locally adapted populations of two (and possibly more) species; the sympatry of the two species in many regions; the lack of *Tursiops* specimens from many regions; and the differences in research methods and designs.

Due to the long-standing taxonomic uncertainties within *Tursiops*, many studies often made no distinction between *T. aduncus* and *T. truncatus* specimens in their analyses. To prevent further confusion with the species' biology, this review only includes information from studies in which *T. aduncus* has been identified and was treated separately (especially in areas where it is sympatric with *T. truncatus*) or in which bottlenose dolphins appear likely to have been *T. aduncus* even though the taxonomy remains to be confirmed. Only when the taxonomy of *Tursiops* becomes clearer worldwide, will our knowledge of *T. aduncus* improve.

B. External Features

This species appears to be highly plastic and inhabits a variety of coastal habitats through a wide distribution. Nevertheless, *T. aduncus* is generally smaller than *T. truncatus*, reaching a maximum total length of about 2.7 m and about 200 kg (in eastern Asian waters) in weight; the dolphins in some populations do not grow longer than about 2.5 m. In some areas males appear to be slightly larger, sexual dimorphism in the species does not appear to be obvious or consistent. Compared with *T. truncatus*, the appendages (dorsal fin, flipper, and flukes) of *T. aduncus* are generally larger and broader relative to body size, but overall the body appears more slender: the snout is longer and thinner, the melon is less bulbous, and the head has a more pointed profile (Fig. 1). The eye region also appears to bulge out laterally when viewed from above. The length of the rostrum as a proportion of the total body length or relative to the distance from the tip of the rostrum to the middle of the eye is greater than for

Figure 1 Indo-Pacific dolphins in the Red Sea. Photograph copyrighted by Beno Steinacher.

T. truncatus (Wang *et al.*, 2000a). In Chinese waters, the rostrum length of *T. aduncus* (excluding young calves) is longer than in *T. truncatus* regardless of body length (Wang *et al.*, 2000a). The overall appearance of dolphins from the northern Philippines, Solomon Islands, Taiwan, and Japan is similar, whereas dolphins from Indonesian, Western Australian, and South African waters look “stubbier” and possess shorter beaks and smaller bodies.

As with *T. truncatus*, the pigmentation of *T. aduncus* is fairly simple, with a dark to medium gray dorsal surface (often appearing as a cape) progressing to light gray on the flanks. The belly is whitish, often with a pinkish hue. A light spinal blaze may be present on some animals. In most regions, *T. aduncus* possess dark spotting on the light ventral half of the body, but some individuals may possess a few spots dorsally as well. The intensity and specific body locations of the ventral spotting appear to be regionally and individually variable, but the general development of spotting is similar. Spotting begins around the onset of sexual maturity and increases in intensity with age (the spots also darken with age). Spotting can be very intense on the oldest animals. The mouth line and tip of the beak also become whiter with age. Calves are generally slightly lighter in overall color and are unspotted. Spotting patterns may be used in individual recognition, to roughly indicate the stage of maturity and also in defining population differences. Dolphins of some populations begin to become spotted as short as 1.6 m long and become intensely spotted at less than 2.2 m, whereas those in other populations may not start to develop spots until at least 2.2 m long. Dolphins of some populations are apparently more or less unspotted (e.g., Jervis Bay and Port Stephens, New South Wales, and southeast Australia).

C. Osteology

There are only a few, subtle distinguishing features between the skulls of *T. aduncus* and *T. truncatus* (Ross, 1977, 1984; Wang *et al.*, 2000b). The skull of *T. aduncus* is relatively smaller and possesses a narrower rostrum with a prominent premaxillary convexity (when viewed laterally) or “pinch” (when viewed dorsally) that is situated at about one-third of the rostral length anterior of the base of the rostrum (this feature of the rostrum is the attachment point for connective tissues associated with the melon and defines the apex of the melon). The position of the premaxillary convexity is also reflected externally by a longer beak compared with that of *T. truncatus*. The width of the external nares (relative to the parietal width) is also greater in *T. aduncus* than in *T. truncatus*. Teeth of *T. aduncus* are

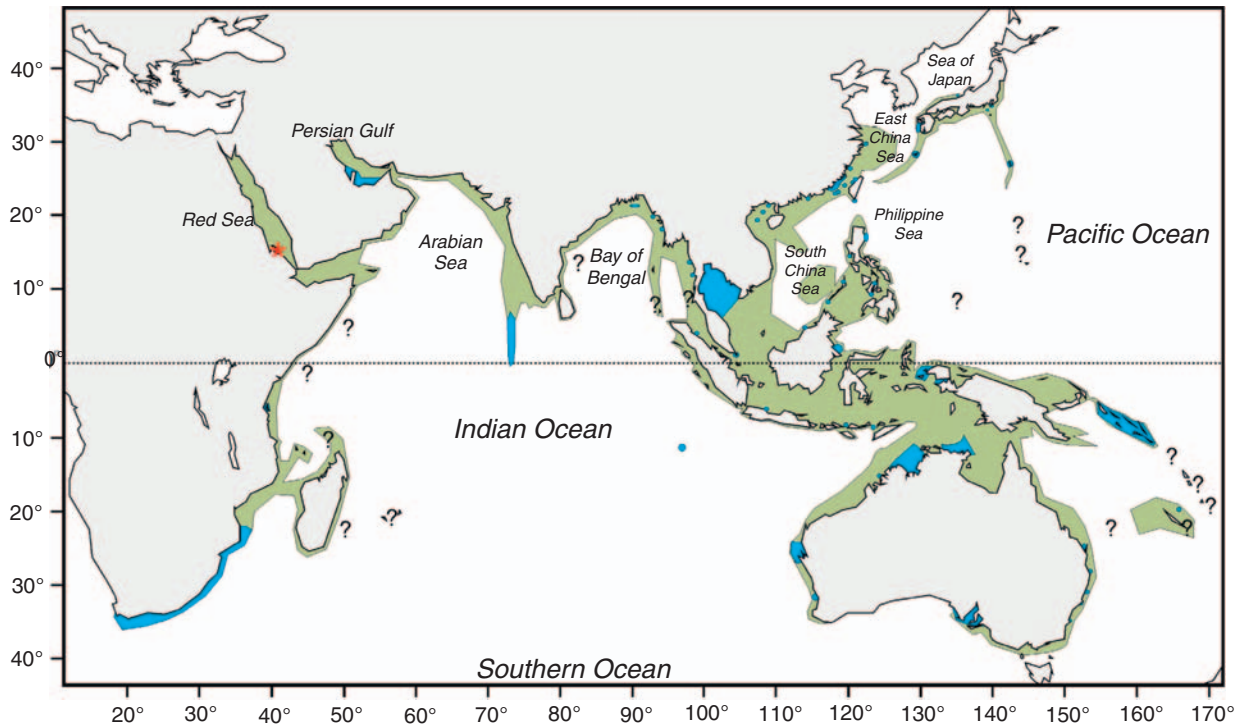

Figure 2 Distribution of the Indo-Pacific bottlenose dolphin. Confirmed records are shown in blue and hypothesized distribution in olive. Question marks indicate uncertain records, and red star represents the type locality.

generally smaller in diameter and more numerous than in *T. truncatus* (in Chinese and South African waters, *T. aduncus* has 23–29 teeth in each row with a total of 97–111 teeth, whereas *T. truncatus* possesses 19–27 teeth per row with a total of 80–106).

The number of vertebrae is fewer than in *T. truncatus*, and although the distributions differ only slightly they do not appear to overlap. The total vertebral count for *T. aduncus* is 59–62, whereas it is 64–67 for *T. truncatus*. There may also be slight differences in the morphology of the cervical vertebrae.

D. DNA

The mtDNA control regions of *T. aduncus* and *T. truncatus* differ by several fixed nucleotide bases and are highly divergent (at least 4.4%) from each other (Wang *et al.*, 1999). Intraspecific analysis suggested an isolation-by-distance model for the *T. aduncus* of Shark Bay, with females tending to be more philopatric than males (Krützen *et al.*, 2004).

II. Distribution and Abundance

Because the taxonomic status of *T. aduncus* was only recently accepted and distinguishing this species from *T. truncatus* can be difficult, information about the distribution of *T. aduncus* is patchy, but it clearly indicates that the species is widespread. Confirmed presence of the species in some regions is a reflection of research effort, whereas gaps reflect either absence or lack of cetological studies. It is likely distributed throughout the coastal waters of the Indian and western Pacific oceans from the Solomon Islands and New Caledonia in the east to the southern tip of South Africa in the west and from central Japan to southeastern Australia. However, the level of continuity in the distribution is unknown (Fig. 2). There are

several small apparently isolated, resident populations around a few oceanic islands of Japan and elsewhere, and it is likely that dolphins will be found around more offshore islands throughout the range.

There is no global abundance estimate for the species, and local abundance estimates are relatively few (e.g., Yang *et al.*, 1997; Yang *et al.*, 2000; Shirakihara *et al.*, 2002; Chilvers and Corkeron, 2003; Shirakihara *et al.*, 2003; Kogi *et al.*, 2004; Stensland *et al.*, 2006). It can be the most commonly recorded cetacean in some coastal areas (e.g., southeast coast of South Africa—Ross, 1977, 1984, Arabian Gulf—Preen, 2004) partly because of its near-shore distribution. Because population structure and boundaries are poorly understood in most cases, local estimates must be interpreted cautiously. In Japanese waters, there are an estimated 218 dolphins and at least 160 individuals identified for the Amakusa-Shimoshima and Mikura Island populations, respectively. In Australian waters, there are local estimates for the populations of Shark Bay (>600 dolphins in an area of about 300 km²), Point Lookout (700–1000 dolphins within 150 km²), and Moreton Bay (334 dolphins). In east Africa, a resident population in the waters of Zanzibar (Tanzania) was estimated to contain between 136 and 179 dolphins within a study area of 26 km². There are no abundance estimates for the waters of Taiwan or the Philippines. However, from photo-identification studies, there were at least 24 dolphins within a 110 km² area of southern Taiwan and 44 dolphins in the inshore waters (~200 km²) of the Northern Sierra Madres Natural Park (northeast Philippines). Small populations also appear to exist in the outer part of Malampaya Sound and in and around Tañon Strait in the Philippines. In a small part of the western Taiwan Strait between Xiamen and Dongshan (China), the density was estimated to be less than 5 dolphins per 100 km².

There is little information on population structure. Based on the available information, the species appears to be composed of

many relatively small localized populations that are fairly isolated from each other. Dolphins of different regions appear to exhibit strong year-round residency and natal philopatry in both sexes with males being more dispersive than females. There appear to be clear regional differences in the size of the dolphins. The dolphins in the western North Pacific appear to be larger than those of other regions. Spotting intensity also seems to be regionally variable as well (discussed earlier). The great individual and regional variations in size and spotting patterns may be useful for understanding population structure and require more study. Based on cranial and spotting differences, dolphins of Natal and the eastern Cape of South Africa were considered to be of different populations that were year-round residents of those areas (Ross, 1977, 1984). In Japanese waters, dolphin whistles appear to differ amongst populations (Morisaka *et al.*, 2005).

There are indications that this species (like other localized coastal cetaceans) has experienced dramatic declines in the Arabian Gulf and in Vietnamese and Chinese waters. Even in Shark Bay, which is still relatively pristine, a decline in the dolphin population due to activities of tour operators targeting the dolphins has been reported (Bejder *et al.*, 2006). The latter observation further emphasizes the particular vulnerability of this near-shore species to human threats.

III. Ecology

The species appears to prefer continental shelf waters near shore and in areas with rocky and coral reefs, sandy bottom, or sea grass beds. The dolphins can be found in waters more than 200 m deep but are much more common in water less than 100 m deep. In some areas, estuaries may concentrate dolphins, but they do not seem to frequent muddy estuarine waters. The inshore waters of at least a few small oceanic islands are also home to small populations of dolphins. Although generally considered a coastal species, movement across deep oceanic waters has been reported. However, it is unknown if this behavior is common. The main distribution of the species is in tropical to warm temperate waters of the Indian and western Pacific oceans, but some have been found in cooler waters in Japan, northern China, southern Australia, and South Africa. Sea surface temperatures where *T. aduncus* are found are between 20°C and 30°C, but water temperature can vary greatly by region. The lowest water temperature reported for *T. aduncus* was 12°C in the waters of Amakusa-Shimosima, Japan.

Tursiops aduncus has broadly overlapping distributions with many species but mainly *T. truncatus* *Sousa chinensis*, *Neophocaena phocaenoides*, *Stenella longirostris*, *S. attenuata*, and *Orcaella* spp. Areas in which sympatry with *T. truncatus* occurs include the waters of central and southern China, western Taiwan, the southern half of Japan, Philippines, Australia, South Africa, and likely other regions. In these areas, *T. aduncus* seems to occupy more coastal waters than *T. truncatus*. In areas where they are sympatric with *S. chinensis*, the distribution of *T. aduncus* is comparatively more offshore.

There are reports of mixed schools with *T. truncatus*, *Pseudorca crassidens*, *Delphinus capensis*, *Sousa chinensis*, *Delphinus* sp., and *Stenella longirostris*. The interspecific associations may differ regionally (e.g., no schooling with *Sousa chinensis* has been observed in western Taiwan where both species exist).

There is great geographical variability in the species' diet. Throughout most of the distribution of *T. aduncus*, the primary prey species are benthic and reef-dwelling fish and cephalopods of continental shelf waters (Ross, 1977, 1984) but some pelagic and epipelagic species are also consumed. Its prey is usually less than about 300 mm

long and belongs to several families such as Belontiidae, Mugilidae, Sciaenidae, Engraulidae, Sepioteuthidae, Sepiidae, Sepiolidae, Loliginidae, and Octopodidae. For dolphins inhabiting waters of oceanic islands, a considerable part of their diet appears to be epipelagic fish and cephalopods (Kakuda *et al.*, 2002), but benthic crustaceans can contribute substantially. On the odd occasion, small benthic sharks have also been recorded as prey. At least in some areas, there appears to be little overlap in prey species between sympatric populations of *T. aduncus* and *T. truncatus*. From studies of captive specimens, the daily food required by adults appears to be about 4–5% of their body mass but can increase with lower water temperatures (Ross, 1984).

Little is known about predators in most regions. Sharks are a main cause of mortality for some populations, with the main predators being tiger shark (*Galeocerdo cuvieri*), white shark (*Carcharodon carcharias*), bull shark (*Carcharhinus leucas*), and dusky shark (*Carcharhinus obscurus*). For some populations, shark-bite frequency is very high (e.g., >74% of the non-calf dolphins of Shark Bay bear scars from shark attacks—Heithaus, 2001). Shark-bite scars are much less frequent in Moreton Bay (eastern Australia) and South African waters, at about 37% and 10–20%, respectively (however, it is uncertain if these data include both *T. aduncus* and *T. truncatus*). There are no records of killer whale predation. In addition to predation, dolphins have died as a result of accidental injuries caused by needlefish and the spines of sting rays.

Compared with other species, relatively few parasites and other pathogens have been recorded (Kakuda *et al.*, 2002). However, this is almost certainly due to a lack of research effort. Ectoparasites reported include the cirripede *Xenobalanus globicipitis* and cyamids. There are also some indications that small sharks may behave as ectoparasites by taking small bites out of dolphins living around oceanic islands (e.g., Mikura Island); the dolphins possess scars that have been attributed to “cookie cutter” sharks (*Isistius* sp.). Endoparasites include nematodes in the pterygoid sinuses (possibly *Crassicauda* sp.) and stomachs (likely *Anisakis* sp.), tapeworms in the intestines, *Halocercus lagenorhynchi* in the lungs and respiratory tract, and cestodes of the genus *Phyllobothrium* in the blubber (mainly around the urogenital region) and possibly *Monorygma* internally. Serological tests have shown that dolphins of the western Pacific Ocean are likely exposed to the protozoan *Toxoplasma gondii* (Omata *et al.*, 2005) and dolphin morbillivirus (Van Bresseem *et al.*, 2001).

IV. Behavior and Physiology

Acoustically, *T. aduncus* appears to be similar to *T. truncatus*. However, regional differences in whistle characteristics amongst Japanese populations appear to exist (Morisaka *et al.*, 2005).

Group size tends to be small in most places the species has been studied (note: group size is highly dependent upon how researchers define “group”). In South Africa, up to 2000 individuals were observed on one occasion, but this large aggregation was composed of many smaller groups. The most common group size appears to be between 20 and 50 individuals. In Plettenberg Bay, the mean group size was reported as 140 individuals, but again this was composed of several smaller groups (Ross, 1984). In Japanese waters, more than 100 are commonly seen together (Shirakihara *et al.*, 2002), whereas in Taiwan no group greater than about 35 individuals has been recorded in recent times. Even though past drive-hunting may have caught hundreds in single operations in the Penghu Islands, the last drive in 1993 captured only about 20 individuals; this may be an indication of local depletion after decades of unregulated hunting.

A fission–fusion society best describes the social organization of the species; there are many parallels with that of *T. truncatus* as well as some primates (Connor *et al.*, 2000b). There is great individual variation in social strategies that is dependent upon social context. Males form cooperative alliances (usually as two or three individuals) to challenge other similar alliances for access to females and to help herd them. Females form coalitions, possibly to reduce shark predation, help rear calves, and thwart male coercion. In some regions, associations appear to have correlations with kinship. The mother–calf bond is strong. In the first week after birth, neonates have a strong following response, and their mothers are strongly possessive of their calves (this may be a period of imprinting). Group size tends to be larger when young calves are present, and allomaternal care can be given by other females. Such behavior may reduce shark attacks on small calves as well as their mothers. Mothers have been observed to stay with and protect their deceased calves for extended periods. Social dominance has not been studied directly in wild populations but likely exists (based on captive and some field observations).

In places where the species has been studied extensively, the dolphins appear to exhibit strong year-round residency in fairly limited coastal areas (e.g., around Mikura Island and Shark Bay). Some seasonal movements may occur, but this is uncertain. Based on a few individuals that were marked and followed, minimum home ranges covered more than 200 km distance. At least in some regions, they are philopatric to their natal sites and as with most mammals, males tend to range more widely than females. The normal swimming speed is between 1.5 and 4 km/h, but high-speed bursts can reach at least 16–19 km/h. Maximum dive depth is unknown, but based on their distribution, preferred prey species and typically short submergence times (<5–10 min), dives are mostly, if not always, shallower than 200 m.

A wide variety of foraging techniques is employed depending on prey species. Some techniques are unique and are likely to have been transmitted through learning or may even have been a genetic component. Foraging methods used by dolphins of the Shark Bay population include the use of tail slaps to flush out prey (“kerplunking”), carrying sponges, possibly to protect the tip of the beak from rubbing against the ocean floor, and chasing prey onto beaches and beaching to catch them (Connor *et al.*, 2000a; Krützen *et al.*, 2005; Sargeant *et al.*, 2005).

V. Life History

Demographic information is limited (Ross, 1984; Connor *et al.*, 2000b; Kogi *et al.*, 2004; Mann and Watson-Capps, 2005). For the Mikura Island population several parameters were estimated: mean annual birth rate = 0.071, mean fecundity rate = 0.239, and mean recruitment rate = 0.068. The sex ratio at birth is about equal, but there are more males at sub-adulthood and then more females at adulthood. This was interpreted to mean that females may have higher survivorship to adulthood than males, but it was uncertain why the sex ratio would be skewed toward males prior to adulthood. Mortality of first-year calves varied from 0.133 (Mikura Island) to 0.29 (Shark Bay). In both the Mikura Island and the Shark Bay populations, 44% of the calves died before weaning and reaching independence (~3-years old). Mortality was especially high for calves of primiparous females.

In a population of at least 160 dolphins, the emigration of five individuals from the Mikura Island population to adjacent waters was documented, but immigration from other regions into this population was not observed. The emigration events seem to have been permanent.

In most regions, the peak calving season is very broad with most births occurring in the months with highest water temperatures after a gestation period of about 12 months. The inter-birth interval is most commonly between 3 and 6 years but can be as low as 2–3 years for captive animals (for the Mikura Island population, the mean is 3.4 years; for the Shark Bay population, 4.1 years). Females that lose calves early can become pregnant soon afterwards and give birth in the following year, and females can be simultaneously pregnant and lactating. Nursing usually lasts 3–5 years (sometimes longer if calves are not as healthy) but can be as short as 18–20 months in captivity, where foraging for solid food requires little learning or practice. Length at birth is about 1 m and the birth weight varies from 9 to 15 kg.

Typically, age of first reproduction for females is about 12–15 years, whereas males reach sexual maturity at between 10 and 15 years (some may reach sexual maturity earlier). The length at sexual maturation varies greatly over the large geographical distribution. Although the smallest mature female reported was less than 1.9 m long, dolphins of Shark Bay more typically reach maturity at about 2.0–2.1 m, whereas South African dolphins are slightly larger with maturity beginning at about 2.1–2.4 m. The largest minimum size at sexual maturation is likely to be found in the waters of eastern Asia (the northern part of the species’ distribution).

Ovulation is spontaneous and sporadic. The left ovary is larger (with more corpora) than the right and appears to begin activity earlier. Males have relatively small mature testes compared with other delphinids, but the testes are still very large relative to those of other mammals (combined testes mass about 2 kg).

The maximum age estimated for this species is about 40 years, but some preliminary aging of the teeth of some known old individuals show that they may be 50 or more years of age. Old dolphins can be difficult to age when the pulp cavity of the tooth occludes, which usually coincides with physical maturity (i.e., epiphyseal fusion of all vertebrae). Studies have shown that each dental growth layer group (GLG) is consistent with 1 year.

There is little information on growth curves. Similar to most marine mammals, rapid growth occurs in the earliest years of life. Given the large regional differences in body size, growth curves are sure to vary considerably. For South African animals (Ross, 1984), the length to mass function is $M = 8.0 \times 10^{-9} X^{3.057}$ (where M = mass in kilograms, and X = length in millimeters).

VI. Interactions with Humans

In many regions, the species is taken directly (usually by some form of spear) for human consumption or bait for shark fishing operations (e.g., Philippines, Taiwan, east Africa). It is also a preferred species of the captive display industry throughout Asia, and with the recent explosion of dolphinarium facilities, particularly in China, over the last decade, there are concerns that local populations may become depleted, if not already so. The infamous drive hunt of the Penghu Islands, which ceased in the early 1990s, and the recent captures of about 100 and several tens of dolphins from the waters of the Solomon Islands in 2003 and 2007, respectively, supplied dolphins for several aquariums and tourist resorts including facilities in Europe, Mexico, and Dubai. These were both from unassessed populations and are likely to be unsustainable. Captures in Southeast Asian waters and other regions with minimal monitoring of the numbers being taken are of great concern.

Mortality due to interactions with fisheries is likely to be the most serious, immediate anthropogenic threat to the species. Bycatch in

gillnet (trammel and other bottom set gillnets, driftnets, etc.) fisheries throughout their range is of great concern in many inshore areas but is poorly understood. A large number (possibly >2000 per year) of this species was taken incidentally in northern Australian waters by a Taiwanese drift gillnet fishery (Harwood and Hembree, 1987) that later moved its operation into the neighboring waters of Indonesia after strict regulations were established. The fishery continued largely unmonitored and almost certainly captured dolphins from some of the same populations that straddle political boundaries. In Chinese coastal waters alone, there are more than 3.5 million gillnets in use (not including those of Taiwan) (Zhou and Wang, 1994), and although the level of cetacean mortality is poorly known, the impact of such a large fleet on this coastal species is of concern.

In the South China Sea and parts of eastern Australia, *T. aduncus* has been observed feeding behind bottom trawl nets or on trawl net discards. This behavior increases the risk of incidental capture and in some cases may also expose the animals to higher rates of shark attacks as the dolphins are focused on the trawls, which also attract sharks.

Increasingly, the habitat of coastal cetaceans is being occupied by expansive aquaculture operations (shellfish, finfish, etc.), and dolphins are being displaced physically from parts of their range by the structures (stakes, pens, concrete walls, fences, etc.) associated with this industry (Mann and Watson-Capps, 2005). The impact on local populations being excluded from parts of their habitat (in Australia, western Taiwan, and eastern China) is direct, immediate, and may be very serious.

Heavy industrialization and coastal development in many parts of Asia (e.g., Taiwan and China) with little to no consideration for coastal cetacean species has resulted in severe physical habitat degradation for this and other coastal species. Coastal destruction is still continuing, more or less unabated, with more large-scale development projects being proposed and approved. Along with industrialization in coastal areas comes the associated pollution and degradation of coastal waters. Due to the rapid and massive industrialization of both sides of the Taiwan Strait, pollution is suspected to be especially serious in this region.

Even human activities that are generally considered to have low-level impacts on cetaceans can affect this particularly vulnerable near-shore species. The species is the target of many dolphin-watch tours, and in at least one case a relatively low level of tourism pressure appears to have caused a decline in the dolphin abundance (in Shark Bay—Bejder *et al.*, 2006). Commercial dolphin-swim (e.g., Mikura Island and Zanzibar) and dolphin-feeding tours (Shark Bay) are also likely to have an impact on natural dolphin behavior (Stensland and Berggren, 2007). The feeding of wild dolphins by tourists appears to increase calf mortality and decrease the reproductive success of females in Shark Bay (Mann *et al.*, 2000). Also, noise from dolphin-watch tours, pleasure boating, and commercial vessels can alter the swimming and acoustic behavior of dolphins (Lemon *et al.*, 2006). Vessel collisions have not been identified as an issue yet. In some coastal waters (South Africa and Australia), nets are set around swimming areas to protect the bathers from sharks. Both *T. aduncus* and *Sousa chinensis* are victims of incidental entanglement in these anti-shark nets.

Due to the lack of information needed for assessing the status of the species globally, *T. aduncus* is classified by the IUCN Red List as “Data Deficient.” However, this should not be seen as a more favorable status than any of the threatened categories (as is often perceived erroneously and results in less attention being afforded to species classified as such). Once adequate information allows

for an assessment, this species may well meet one of the categories of threat. There are serious concerns about the depletion of local populations because the species appears to be resident (likely with limited exchange with adjacent populations) and exists in relatively small numbers in many areas.

Indo-West Pacific Marine Mammals

PETER RUDOLPH AND CHRIS SMEENK

The Indo-West Pacific is defined here as the tropical and subtropical (warm temperate) waters of the Indian and far western Pacific Oceans, from the Cape of Good Hope in South Africa to the Red Sea and Persian Gulf, and from Australia and Southeast Asia to about 30°N.

The Indo-West Pacific probably offers the greatest diversity of marine mammal species in the world. Within it live representatives of 11 of the 13 families of the Cetacea, with more than 40 of the 85-odd species recognized by most authors, as well as one member of the order Sirenia. We have not included species of the order Carnivora (sea lions, walruses, and seals), nearly all of which normally live in higher latitudes. Only the ranges of the Cape and Tasmanian fur seals (*Arctocephalus pusillus pusillus* and *A. p. doriferus*), the south Australian fur seal (*A. forsteri*), and the Australian sea lion (*Neophoca cinerea*) (family Otariidae) include the southernmost part of the area considered, in South Africa and in southern Australia, respectively.

I. Endemic Taxa

Many species occurring in the Indo-West Pacific have a cosmopolitan or pantropical distribution, and several Northern and Southern Hemisphere species extend their range to within the confines of the area. However, a relatively large number of species or currently recognized subspecies are endemic to the Indo-West Pacific; the taxonomic position and distribution of some forms are still insufficiently known. Most of these occur mainly in shelf and/or fresh-water ecosystems, although *Tursiops aduncus* is also found in pelagic waters. Two forms of dolphin seem to be largely confined to shelf areas: *Delphinus capensis tropicalis*, and *Stenella longirostris roseiventris*, as well as the small baleen whale *Balaenoptera edeni* (specific status still unclear); five or six species have a decidedly coastal, estuarine, or even partly riverine distribution: *Sousa chinensis/plumbea* (Fig. 1), *Orcaella brevirostris*, *O. heinsohni*, *Neophocaena phocaenoides*, and the sirenian *Dugong dugon*; and two or three are true river dolphins: *Platanista gangetica gangetica*, *P. g. minor*, and *Lipotes vexillifer* (now probably extinct). The distribution and habitat preference of the recently distinguished *B. omurai* are still insufficiently known. In addition, at least two oceanic species: *Mesoplodon ginkgodens* and *Indopacetus pacificus*, appear to be endemic to deep waters of the tropical and subtropical Indo-Pacific at large (including the central and the eastern Pacific), and the same may hold true for the Indo-Pacific form of *Kogia sima*.

II. Zoogeography

The shelf areas of the Indo-West Pacific show a high primary productivity, the result of monsoon-related currents and strong upwelling. Although the shallow waters of Southeast Asia and Australia would seem to constitute a barrier between the Indian and Pacific Oceans, the deep passages through the eastern Indo-Malayan Archipelago offer suitable dispersion routes for oceanic species, most of which, including sperm whales (*Physeter macrocephalus*), have indeed been recorded from the deeper straits and seas between the islands. Not considering the river dolphins, none of the marine

Figure 1 The Indo-West Pacific is home to a wide variety of marine mammals, including many endemic taxa e.g. the Indo-Pacific humpback dolphin. Photograph by Thomas Jefferson.

mammals in the area is restricted to either the Indian Ocean or the Pacific side of the archipelago, except the western form of the coastal humpback dolphin (*Sousa chinensis/plumbea*).

The center of speciation and distribution in the Indo-West Pacific, containing the greatest diversity of marine mammals, is in the seas of Southeast Asia and northern Australasia, covering the Sunda and Sahul Shelves and neighboring waters. All marine (sub)species endemic to the Indo-West Pacific occur in this area, although they differ in the extent of their range. *S. longirostris roseiventris* (as far as known) and the two species of the genus *Orcaella* appear to be restricted to the Sunda and Sahul Shelves. The deep waters between these shelves form a barrier for some coastal species, which has led to genetic isolation or even speciation within the populations of *Orcaella* and *Sousa* on either shelf. Apart from such shelf forms, the Indo-West Pacific endemics also occur further west and north in the Indian and Pacific Ocean, respectively. In the east, the deep waters of the Pacific form a barrier to further dispersion, although the dugong has penetrated beyond the continental shelves, occurring as far east as Micronesia and, as a vagrant, to Fiji; the eastern confines of *T. aduncus* and of *B. omurai* are not known. In the north, *N. phocaenoides* has extended its range as far as Korea and Japan, and the two baleen whales *B. edeni* and *B. omurai* too have been found off Japan. In the southwest, *S. chinensis/plumbea* and *T. aduncus* occur as far as South Africa. Here, the cold waters off the Cape apparently have prevented their dispersion into the Atlantic Ocean, although the West African *Sousa teuszii* is probably a relatively recent descendant from its Indo-Pacific congener. In the northwest, *S. chinensis/plumbea* occurs in the Suez Canal; this species, as well as the dugong, has even strayed into the Mediterranean Sea.

III. Annotated Species Accounts

A. Rorquals, Family Balaenopteridae

Most species of baleen whales undertake extensive seasonal migrations between cold, productive summer feeding grounds in temperate or high latitudes, and winter mating and calving areas in tropical or warm-temperate waters, suggesting that there is only little mixing of Southern and Northern Hemisphere populations. Baleen whales of the Indo-West Pacific, particularly the Indian Ocean, are poorly known.

The modern whaling industry, following the invention of the explosive grenade harpoon, was initially based mainly on rorquals, although sperm and right whales were also taken. In the Indian Ocean, whaling stations existed in South Africa, Mozambique, and Western Australia. Although most pelagic whaling occurred below 40°S, it was practice for whalers to take baleen whales as well as sperm whales in tropical waters on their passage to and from the Antarctic. Newly revealed data on illegal Russian whaling operations between 1947 and 1972 have shown that baleen and sperm whales were taken in the central and northern Indian Ocean, near Madagascar and Australia, as well as in Indonesian waters. These included blue whales (*Balaenoptera musculus*), caught mainly after 1965 when the species had already received protection from the IWC; humpback whales (*Megaptera novae-angliae*) off Oman, Pakistan, and India; as well as southern right whales (*Eubalaena australis*) around the Crozet and Kerguelen Islands and in the central Indian Ocean.

In the period 1963–1967, Russian whalers caught 848 Bryde's whales (probably *Balaenoptera brydei*) in the Gulf of Aden, near the Maldives, and near the Seychelles. During the seasons 1976/77–1978/79, Japanese whalers caught 232 small baleen whales, at the time identified as Bryde's whales (possibly consisting of both *B. brydei* and *B. edeni*) in the western Indian Ocean, the eastern Indian Ocean south of Java and the Lesser Sunda Islands, and in the West Pacific near the Solomon Islands. A small series of specimens caught in the Solomon Sea and near the Cocos Keeling Islands in the eastern Indian Ocean have recently been distinguished as a separate species: *B. omurai*. Relatively small-scale, directed catches of baleen whales are today only known from the Philippines and from Lamakera on Solor Island, Indonesia. In the Philippines, small baleen whales (also collectively called Bryde's whales but including *B. omurai*) were or are still hunted off Pamilacan, Bohol, and Camiguin Islands. The whaling off Pamilacan, now legally prohibited, was seasonal and opportunistic. It started in January and ended in June, with most whales taken in April and May. The animals were caught using a hook of stainless steel, which was driven into the whale by one of the hunters jumping onto the whale's back and using his weight to drive the hook in.

1. *Humpback Whale* Growing evidence shows that discrete populations of humpback whales, *Megaptera novaeangliae*, live year-round in the Arabian Sea, including the Gulf of Oman and Gulf of Aden, the Red Sea, and in the Bay of Bengal, with at least some of these animals feeding and breeding there. A young animal caught in October 2007 in a fishing net at the south coast of Bali, Indonesia, is the first confirmed record for the Indo-Malayan Archipelago. Biological examination of 238 humpback whales caught illegally by Russian whalers in November 1966 off Oman, in the Gulf of Kutch off Pakistan, and west of Bombay, India, showed that they differ significantly from Antarctic humpbacks in size, coloration, body scars, and pathology (Mikhalev, 1997). The song structure of humpback whales recorded off Oman is also different from that in the North Pacific and North Atlantic. Southern Hemisphere humpback whales, which feed in Antarctic waters, winter near Mozambique, around Madagascar, off northwest and northeast Australia, and elsewhere in the tropical Pacific. In Southeast Asian waters, humpback whales have been reported from Vietnam, the Philippines, the South China Sea, and the waters around Taiwan; probably, these are animals that spend the summer in the Northwest Pacific. In the nineteenth and twentieth centuries, humpback whales were hunted off Mozambique, Madagascar, and northwestern Australia.

2. *Minke Whales* Two species of minke whales extend their ranges into the Indo-West Pacific: the common minke whale (*B. acutorostrata*), and the Antarctic minke whale (*B. bonaerensis*). The North Pacific population of the common minke whale has been

distinguished as the subspecies *B. a. scammoni*. In summer, it occurs as far south as the East China Sea and the central Pacific at about 30°N; its winter range extends into warm-temperate and tropical waters. Reports of minke whales from the Red Sea, Persian Gulf, and Vietnam are probably all based on confusion with *B. brydei* or *B. edeni* (Andersen and Kinze, 2005). A small, distinctly colored and as yet unnamed southern form, the “dwarf minke whale” (as yet unnamed subspecies), occurs in tropical and warm-temperate waters of the Southern Hemisphere. In the Indo-West Pacific, it is known from South Africa and Australia (Arnold *et al.*, 2005) and has recently been recorded of northwestern New Guinea.

The Antarctic minke whale also ranges into tropical waters; it has been found as far north as about 7°S. Important breeding grounds in the eastern Indian Ocean may lie between 10° and 20°S. The species occurs in part sympatrically with the dwarf minke whale, with the latter seeming to have a more coastal distribution.

3. Bryde's Whale and Sittang Whale These small baleen whales, which until recently were considered conspecific (with the name *B. edeni* taking priority), have a primarily tropical and warm-temperate distribution. The taxonomic status of these whales is still unsettled. The larger form, the “true” Bryde's whale, nominally *B. brydei*, has a cosmopolitan distribution in tropical waters. In the Indo-West Pacific it has been identified from the Indian Ocean, including the Red Sea and Persian Gulf, as well as from the (sub)tropical West Pacific; the limits of its range and the movements of the various populations are still unknown (Kanda *et al.*, 2007).

There are several distinctly smaller, more coastal populations. Of these, the “Sittang whale” has been identified from coastal and shelf areas in the eastern Indian Ocean and (sub)tropical West Pacific: the Andaman Sea, Indo-Malayan Archipelago, Australia, the South China Sea, and southwestern Japan. Molecular evidence, as well as osteological comparisons, have shown that these animals genetically and morphologically do not belong with the larger Bryde's whale and almost certainly form a distinct species. The name *B. edeni* would apply to this species if the holotype, which is from the mouth of the Sittang River in Burma (Myanmar), indeed proves to be of this form.

Despite these differences, several authors still use the name *B. edeni* for both the larger and the smaller forms, pending a molecular-genetic study of the holotype (see chapter Bryde's Whales).

4. Omura's Whale During Japanese scientific whaling operations, two series of small baleen whales were caught near the Solomon Islands (Solomon Sea) in the West Pacific in October 1976 (6 animals) and near the Cocos Keeling Islands in the eastern Indian Ocean in November 1978 (2 animals). They have proved morphologically and genetically distinct from the small *B. edeni* as identified earlier. In 2003, they were described as a new species, *B. omurai*, the holotype being a fresh animal stranded in September 1998 on Tsunoshima Island, in the southern Sea of Japan (Wada *et al.*, 2003; Sasaki *et al.*, 2006). The species has also been identified from a sample taken in the Philippines. All these localities are very far apart and the distribution and ecological requirements of this species are still largely unknown.

5. Sei Whale The sei whale, *Balaenoptera borealis*, appears to be uncommon in tropical waters. None of the published recent records from the northern Indian Ocean is convincing. Sei whales have been confused with Bryde's or fin whales by observers who were not familiar with these species. The sei whale has also been reported from the South China Sea, but this too needs confirmation. Sei whales from the Southern Hemisphere, often distinguished as *B. b. schlegelii*, generally winter as far north as South Africa and Western Australia

(to about 25°S). There is one specimen from the north coast of Java: the holotype of *B. b. schlegelii* (Rudolph *et al.*, 1997). Japanese scouting and research vessels reported seeing sei whales south of Sumatra (5°–10°S) during November in the period 1974/75–1984/85.

6. Fin Whale The fin whale, *Balaenoptera physalus*, also appears to be uncommon in tropical waters. A North Pacific population is thought to winter from the Sea of Japan south to the Philippine Sea, with concentrations in the East China and Yellow Seas. There are a few records from Philippine and Indonesian waters and several reports from the northern Indian Ocean, Persian Gulf, and off the Seychelles. Southern Hemisphere fin whales, which have been distinguished as the subspecies *B. p. quoyi*, winter in the Indian Ocean off South Africa, Madagascar, and Western Australia. Fin whale sightings reported by Japanese vessels in the period 1974/75–1984/85 were concentrated in two longitudinal areas: one west of 50°E, the other at 70–100°E. The northern limits of the species' range in March were found to be at 40–45°S.

7. Blue Whale The blue whale, *Balaenoptera musculus*, is distributed throughout the Indo-West Pacific, in areas with high primary productivity. The species occurs year-round in the Indian Ocean, but some populations undertake seasonal migrations. The taxonomic status and distribution of the various populations of blue whales are still unsettled (Branch *et al.*, 2007). The animals of the northern Indian Ocean, from the Arabian Sea to Southeast Asia, are distinct from Southern Hemisphere blue whales in call pattern and reproductive season. They are often regarded as a separate subspecies *B. m. indica*, although the distinguishing characters of this form are poorly defined. The blue whales of the southern Indian Ocean, off South Africa, Madagascar, the Chagos Archipelago, as well as those from southern Indonesia and off Western Australia and South Australia, are smaller and also have a distinctive call pattern. They have been referred to the subspecies *B. m. intermedia* or, more recently, to the “pygmy blue whale,” *B. m. brevicauda*. Finally, Antarctic blue whales probably extend their winter range into the southern confines of the pygmy blue whale. The distribution of blue whales in the northwestern Pacific is poorly known; the species has been recorded from southern China and the Philippines.

Two other species of baleen whale occur in the Indian Ocean. The southern right whale, *Eubalaena australis* (family Balaenidae), extends its range northward to southern Mozambique, Madagascar, and Western Australia. In the nineteenth and early twentieth centuries, right whales were hunted in the Indian Ocean between 30° and 40°S, around Crozet, Kerguelen, and Amsterdam Islands, and on their calving grounds off South Africa and southeastern Australia. The pygmy right whale, *Caperea marginata* (family Neobalaenidae), has been recorded north to 33°S off southwestern Australia. The critically endangered western population of the gray whale, *Eschrichtius robustus* (family Eschrichtiidae), known as the Korea-Okhotsk stock, winters off southern China, with records from the Yellow, East China, and South China Seas, as far south as Hainan. It has been suggested that breeding and calving grounds exist off Guanglong Province in southern China, but this should be investigated.

B. Sperm Whales, Family Physeteridae

Sperm whales, *Physeter macrocephalus*, occur in all oceans of the world. Concentrations such as found in the traditional whaling grounds appear to be associated with oceanic fronts, steep bottom topography, and high productivity. (Sub)adult males reach temperate or even polar waters and return to lower latitudes to breed, whereas females and immatures are restricted to tropical and warm-temperate

seas. The sperm whale is found in deep waters of the Indian Ocean, including the Gulf of Aden, Gulf of Oman and probably the southern Red Sea, and in the West Pacific; its main distribution is well known from records of nineteenth century whalers. The species is sometimes found in shallow waters. The deep passages and seas between the islands of the Indo-Malayan Archipelago have been supposed to form a migration route of sperm whales between the Indian and the Pacific Ocean.

In the western Indian Ocean, exploitation of sperm whales began at about 1800 on the whaling grounds near the Cape of Good Hope, and in later years extended northward to Mozambique, Madagascar, the Comoros, Seychelles, the East African coast, Arabia, and the waters west of Sri Lanka. In the eastern Indian Ocean and western Pacific, sperm whales were taken south of Sumatra and Java, in the Timor Sea, and off Western Australia, in the Moluccan and Sulu Seas, the waters north of New Guinea, and off Japan. Whaling declined for economic reasons toward the close of the nineteenth century. Today, sperm whales are only hunted in subsistence whaling in Indonesia. The whalers of Lamalera on Lembata Island specialize in catching sperm whales and other toothed whales (Rudolph *et al.*, 1997). The animals are caught by using hand harpoons from open rowing boats called “peledang.” During the whaling season, mainly from May to October, the boats search an area of up to a few kilometers south of the coast. When a whale is approached, the harpooner leaps from a small platform on the bow and adds his weight to drive the harpoon into the whale’s back, similar to the technique used by whalers of the neighboring Solor Island and in the Philippines, who hunt baleen whales.

C. Pygmy and Dwarf Sperm Whale, Family Kogiidae

Our knowledge of the distribution of the pygmy sperm whale, *Kogia breviceps*, and dwarf sperm whale, *K. sima*, is sketchy and mainly based on animals stranded or caught in fishing gear. A study of *K. sima* has revealed that animals from the Indo-Pacific are genetically distinct from Atlantic ones, perhaps warranting recognition of two species. The waters off the Cape may form the boundary between these two clades, but the taxonomic and ecological situation is still unresolved (Chivers *et al.*, 2005).

Pygmy and dwarf sperm whales occur in tropical and warm-temperate seas, with the pygmy sperm whale extending its range into slightly colder waters. They are often difficult to observe at sea and probably are much more common than sighting records would suggest. Although their diets overlap, prey composition indicates that the pygmy sperm whale has a more oceanic distribution, whereas the dwarf sperm whale prefers shelves and shelf edges.

In the Indo-West Pacific, both species have been recorded from South Africa north to Oman, east to Australia and the Indo-Malayan Archipelago, and north to southern Japan. Dwarf sperm whales appear to be common in the Maldives, particularly over the atoll slopes (Anderson, 2005).

Both species are killed accidentally in Sri Lanka; the dwarf sperm whale is caught in directed fisheries and incidentally in gill net and seine fisheries in the Philippines. In Indonesia, the dwarf sperm whale is taken by subsistence whalers of Lamalera on Lembata Island.

D. Beaked Whales, Family Ziphiidae

Eleven species of beaked whales have been recorded from the Indo-West Pacific. Only four of these are regularly distributed in tropical seas. The other seven normally live in temperate and cold waters of the Southern Hemisphere, and occasionally migrate or

stray into lower latitudes (MacLeod *et al.*, 2006). All are oceanic species, most of them are mainly known from stranded animals.

1. *Cuvier’s Beaked Whale* Cuvier’s beaked whale, *Ziphius cavirostris*, is the most wide spread of the beaked whales, occurring worldwide in tropical and warm-temperate waters. It has been reported from South Africa, the Comoros and Seychelles, the Arabian Sea, the Maldives, Sri Lanka, Australia, the Indo-Malayan Archipelago, the Philippines, Taiwan, and southern Japan.

2. *Ginkgo-Toothed Beaked Whale* The ginkgo-toothed beaked whale, *Mesoplodon ginkgodens*, is distributed in tropical and warm-temperate waters of the Indian and the Pacific Oceans. In the Indo-West Pacific, there are possible sightings from the Arabian Sea; stranded specimens have been found in the Maldives, Sri Lanka, Malacca, southeast Australia, Guam, northern China, and Japan.

3. *Blainville’s or Dense-Beaked Beaked Whale* Blainville’s beaked whale, *Mesoplodon densirostris*, occurs in tropical and warm-temperate waters of all oceans. It has been reported from South Africa, Mauritius, the Seychelles, Maldives, Sri Lanka, Australia, the Philippines, China, Taiwan, and Japan.

4. *Longman’s or Indo-Pacific Beaked Whale* In recent years, this large beaked whale, *Indopacetus pacificus*, has become clearly defined and its external, morphological, and genetic characters are now well known. Previous sighting records of unidentified “tropical bottlenose whales” and several stranded specimens have now been attributed to this species, and many new records have become known (Dalebout *et al.*, 2003). The Indo-Pacific beaked whale is widely distributed in deep waters of the tropical and warm-temperate Indian and Pacific Oceans, and appears to have a preference for areas over or near deep bottom slopes (Anderson *et al.*, 2006). In the Indo-West Pacific, sightings and (skeletal material from) strandings have been reported from South Africa, the Comoros, Kenya, Somalia, the Gulf of Aden, the Maldives, Sri Lanka, northeastern Australia, the Indo-Malayan Archipelago, the Philippines, and north to southern Japan.

Two species—the strap-toothed whale *Mesoplodon layardii* and the scamperdown whale *M. grayi*—occur perhaps seasonally within the southern confines of the area considered. The remaining five probably are irregular visitors: Arnoux’s beaked whale (*Berardius arnuxii*), Andrew’s beaked whale (*M. bowdoini*), Hector’s beaked whale (*M. hectori*), True’s beaked whale (*M. mirus*), and the southern bottlenose whale (*Hyperoodon planifrons*). A skull of the last species (the holotype) was found in the Dampier Archipelago, Western Australia, at about 20°S.

E. River Dolphins, Families Platanistidae and Lipotidae

Two or three species of river dolphins are represented in the Indo-West Pacific region: the Indian river dolphin or susu, genus *Platanista* (family Platanistidae), and the Yangtze dolphin or baiji *Lipotes vexillifer* (family Lipotidae; See Yan *et al.*, 2005). Two (sub)species of the Indian river dolphin are distinguished: the Ganges dolphin or susu, *P. gangetica gangetica* of the Ganges/Brahmaputra River system of India, Bangladesh, Nepal, and possibly Bhutan, and the Indus dolphin or bhulan, *P. g. minor*, formerly common throughout the Indus River and its tributaries, but now only found in a restricted area in Pakistan. Some authors regard these as distinct species. Both forms are endangered, particularly the Indus dolphin with an estimated population of 1200 in 2001, suffering from habitat degradation (pollution, construction of dams) and mortality in fishing gear.

The Yangtze dolphin in China was restricted to the lower Yangtze and Qiantang River systems in China. In the 1990s, its population had decreased to an estimated minimum of 13 animals. A survey in 2006 failed to find the species, which is now considered to be likely extinct (Turvey *et al.*, 2007), although one unconfirmed sighting was reported in 2007. Apart from habitat degradation, bycatch in fishing gear and electric fishing operations are regarded as the proximate causes of extinction.

F. Dolphins, Family Delphinidae

1. *Rough-Toothed Dolphin* The rough-toothed dolphin, *Steno bredanensis*, inhabits tropical and warm-temperate waters, mainly along the edge of shelf areas. In the Indo-West Pacific, it ranges from South Africa to the Gulf of Aden and Arabian Sea, perhaps the southern Red Sea, and east to the Indo-Malayan Archipelago, Australia, the Solomon Islands, Philippines, and north to southern Japan.

2. *Humpback Dolphins* The taxonomy and geographic history of the genus *Sousa* remains unresolved. In the Indo-West Pacific, several authors have distinguished two species: *S. chinensis* and *S. plumbea*. Recent studies of skull morphology support the division into these two forms, although they may not (yet) be specifically distinct (Jefferson and Van Waerebeek, 2004). Humpback dolphins inhabit tropical and warm-temperate waters. The *plumbea* form occurs from South Africa and Madagascar to the Red Sea including the Suez Canal (it has even strayed into the Mediterranean Sea) and Persian Gulf, west to the Bay of Bengal, perhaps extending as far east as Thailand and northwestern Malaysia. The *chinensis* form (Fig. 1.2B) may occur sympatrically with the *plumbea* form in the Bay of Bengal (Sutaria and Jefferson, 2004) and is further known from the strait of Malacca, off northern Java and Borneo, the Gulf of Thailand, and north along the coast of China as far as the Yangtze, with a possibly isolated population off the west coast of Taiwan. It also occurs off northern Australia, ranging to about 24°S along the west, and 34°S along the east coast (Fig. 2). A recent study has shown that this population may represent a distinct species (Frère *et al.*, 2008).

Humpback dolphins have a coastal distribution and often occur in mangroves, river deltas, and estuaries. They ascend far up the main rivers of Asia as, e.g., the Ganges and the Yangtze. They are reported to be on the decline in the areas where they have been studied in detail. Off South Africa they appear to be killed in anti-shark nets at an unsustainable rate, and a decline is also suspected in Hong Kong waters and off Thailand. Incidental catches in fisheries are known throughout their range. Humpback dolphins have been caught for oceanaria along the coast of Thailand.

3. *Bottlenose Dolphins* The taxonomic situation of bottlenose dolphins, *Tursiops aduncus* and *T. truncatus*, is complicated. The existence of at least two species is now generally accepted. The smaller and longer-beaked form, often with spotted abdomen, is the Indo-Pacific bottlenose dolphin *T. aduncus* (Fig. 3). It is restricted to the tropical and warm-temperate Indo-West Pacific, where it is the more common *Tursiops*. Analysis of mtDNA cytochrome *b* sequences has suggested that this species may be closer related to the genus *Stenella* (LeDuc *et al.*, 1999). It ranges throughout the area, from South Africa to the Red Sea and Persian Gulf, east to Australia, the Solomon Islands and New Caledonia, the Indo-Malayan Archipelago, the Philippines, and north to southern Japan, perhaps including the Ogasawara (Bonin) Islands. It has a predominantly coastal distribution. Genetic analyses of animals from South African and Chinese waters, respectively, have shown that

Figure 2 The finless porpoise (A) and the Indo-Pacific humpback dolphin (B) are endemic to the Indo-West Pacific. Photographs by Thomas Jefferson.

Figure 3 The Indo-Pacific bottlenose dolphin is also endemic to the Indo-West Pacific; photographed at Shaab Abu Salama, Hurghada, Egypt, Red Sea. Photograph copyrighted by Bernd Kledt, Eco Diving Society.

these populations may be specifically distinct, but the situation here and in the intermediate areas is unresolved (Natoli *et al.*, 2004) (Fig. 3).

The larger, cosmopolitan common bottlenose dolphin, *T. truncatus*, also occurs in many parts of the Indo-West Pacific. Genetic analyses have identified it from near Mauritius, the Maldives, China, and Taiwan. It has also been found in South Africa, the Seychelles, the Red Sea, off Oman, the Maldives, eastern and southern Australia,

and southern Japan. It occurs in both coastal and oceanic waters, but in general has a more oceanic distribution than *T. aduncus*.

Incidental and directed catches of *Tursiops* sp(p). occur in several kinds of fisheries in the Indo-West Pacific. Direct catches have been reported from Sri Lanka, Thailand, the Philippines, and Taiwan.

4. Pantropical Spotted Dolphin The pantropical spotted dolphin, *Stenella attenuata*, occurs throughout the tropical and warm-temperate Indo-West Pacific, from South Africa to the Red Sea and Persian Gulf, east to Australia and beyond, the Indo-Malayan Archipelago, the Philippines, and north to southern Japan. Mixed groups of spotted and spinner dolphins have been reported from Indonesia, the western Indian Ocean and Red Sea, often associated with concentrations of seabirds and tuna. (See Rudolph *et al.* 1997; Balance and Pitman, 1998).

Spotted dolphins are caught in harpoon fisheries in the Laccadives, Sri Lanka, Indonesia, and the Philippines. A drive fishery at Malaita in the Solomon Islands may take several hundred dolphins a year, spotted dolphins, as well as other species. Spotted dolphins are incidentally caught in gillnet fisheries in Pakistan, Sri Lanka, northern Australia, and the Philippines.

5. Spinner Dolphin The spinner dolphin, *Stenella longirostris*, ranges throughout the tropical and warm-temperate Indo-West Pacific, from South Africa to the Red Sea and Gulf of Oman, east to Australia and beyond, the Indo-Malayan Archipelago, the Philippines, and north to southern Japan. It probably is the most numerous cetacean species in tropical waters of the area. In several places, there are morphological and genetic differences between inshore and offshore populations, the taxonomic implications of which are not clear. Apart from this, two forms of spinner dolphin have been identified in the Indo-West Pacific, based on external, morphological, and behavioral differences, as well as habitat preferences (Perrin *et al.*, 1999). The nominate, pelagic form inhabits the Indian Ocean and West, Central, and South Pacific. The other form, the "dwarf spinner dolphin," has been distinguished as the subspecies *S. l. roseiventris*. It is smaller, with fewer vertebrae and teeth than the pelagic nominate type. It has been identified from shallow inner waters of Southeast Asia: the Gulf of Thailand, off Borneo, the Moluccan Sea, and northern Australia. It appears to feed mainly on benthic and coral reef fishes and invertebrates, whereas the pelagic animals feed primarily on mesopelagic fish and squid.

Off Oman, two types of spinner dolphin have also been recorded, one of them consisting of very small, dark-colored animals (Van Waerebeek *et al.*, 1998); similar dolphins may occur in the Maldives (Anderson, 2005). The taxonomic and ecological position of these animals is still unresolved.

Spinner dolphins are hunted with harpoons in Sri Lanka, Indonesia, and the Philippines. Incidental catches in fishing gear have been reported from Pakistan, India, Sri Lanka, northern Australia, and the Philippines.

6. Striped Dolphin The striped dolphin, *Stenella coeruleoalba*, is primarily a warm-water species, but its range extends into higher latitudes than that of the spotted and spinner dolphins. The species primarily occurs in pelagic waters and mainly approaches the shore where there is deep water close to the coast. It has been reported from South Africa to the Gulf of Aden near the entrance of the Red Sea, east to Australia, and from the Philippines to Japan. Records from the Indo-Malayan Archipelago are scarce. In Southeast Asian waters, the species appears uncommon. It is suspected that animals from Southeast Asia migrate seasonally into Japanese waters, where they are subject to heavy exploitation by drive fishery, which may

seriously have affected their numbers. Striped dolphins are incidentally caught in gillnets, e.g., in Sri Lanka.

7. Common Dolphins Common dolphins, *Delphinus capensis* and *D. delphis*, are distributed in tropical and warm-temperate, mainly coastal, waters of the Indo-West Pacific. The taxonomic situation is complicated. The existence of at least two species is now widely accepted: the long-beaked *D. capensis*, and the short-beaked *D. delphis*, both with a worldwide, but rather disjunct, distribution. However, the affinities of the various populations, particularly within the long-beaked forms, are still unresolved (Natoli *et al.*, 2006).

In the Indian Ocean, only the occurrence of long-beaked animals has been confirmed. *D. capensis* has been identified from coastal waters of South Africa; the situation in East African waters and Madagascar is unknown. In coastal waters of the northern Indian Ocean and West Pacific, a very long-beaked form occurs, with a longer rostrum and a greater number of teeth than in other populations of *D. capensis*. This is now often included in *D. capensis* as a separate subspecies: *D. c. tropicalis* (Jefferson and Van Waerebeek, 2002). It has so far been documented for the Red Sea, Gulf of Aden and the waters off Somalia, the Arabian Peninsula, Gulf of Oman and Persian Gulf, Pakistan, India and Sri Lanka, the southwestern and southeastern Bay of Bengal, Strait of Malacca, off Borneo, Cambodia, the Gulf of Tongking and the South and East China Sea, north to about Shanghai. Long-beaked animals from the East China Sea and southern Japan have been arranged with *D. capensis*, but the taxonomic relation between this population and the animals living off South Africa is still unclear.

The short-beaked common dolphin *D. delphis* mainly lives in (warm-)temperate seas. In the West Pacific it occurs off southern and eastern Australia, even as far as New Caledonia. In the northwestern Pacific, it perhaps extends into the range of *D. capensis*.

8. Fraser's Dolphin Fraser's dolphin, *Lagenodelphis hosei*, was described in 1956 from a skeleton that had been found before 1895 on a beach in Sarawak, Borneo. The species has a worldwide distribution and occurs primarily in deep tropical, and warm-temperate waters. In the Indian Ocean, it has been reported from South Africa, Madagascar, the Seychelles, Maldives, southern India and Sri Lanka, Australia south to about 38°S, the Indo-Malayan Archipelago, Thailand, Vietnam, the Philippines, China, Taiwan, and southern Japan. In Indonesian and Philippine waters, Fraser's dolphin has been observed in mixed groups with other dolphin species.

Directed catches have been reported from Indonesia, the Philippines, and Taiwan and bycatches from the Philippines.

9. North Pacific White-Sided Dolphin and Dusky Dolphin Two species of the genus *Lagenorhynchus* as recognized by most authors, mainly occurring in temperate waters, extend marginally into the Indo-West Pacific. The North Pacific white-sided dolphin *L. obliquidens* has been found as far south as Taiwan. The Southern Hemisphere dusky dolphin *L. obscurus* in some years enters the coastal waters of southern Australia.

10. Risso's Dolphin Risso's dolphin, *Grampus griseus*, is distributed throughout tropical and temperate seas, particularly seaward of steep shelf edges. In the Indian Ocean it is found from South Africa to the Red Sea and Persian Gulf, east to the Bay of Bengal, Australia, the deeper waters of the Indo-Malayan Archipelago, and throughout the West Pacific.

Risso's dolphins are known to be directly caught in the Indonesian subsistence whaling off Lembata Island and in Palawan in the Philippines, Taiwan, and Japan. Between 1983 and 1986, 241 animals

were reported landed in Sri Lanka gillnet fisheries, but the actual numbers killed here may have been about 1300 per year.

11. Melon-Headed Whale The melon-headed whale, *Peponocephala electra*, is mainly found in deep tropical and warm-temperate waters. In the Indo-West Pacific it has been recorded from the Seychelles to the Arabian Sea and Bay of Bengal, Australia, the Indo-Malayan Archipelago, the Philippines, Gulf of Thailand, Taiwan, and southern Japan. There are a few records from South Africa at about 34°S and from southern Australia at about 32°S. Mass strandings are known from the Seychelles, Indonesia, Australia, and Japan.

There is a direct catch of melon-headed whales in the subsistence whaling off Lembata Island in Indonesia, and at Pamilacan Island in the Philippines.

12. Pygmy Killer Whale The pygmy killer whale, *Feresa attenuata*, is mainly found in deep tropical and warm-temperate waters. In the Indo-West Pacific, it has been recorded from South Africa to the Gulf of Aden and Gulf of Oman, east to Australia, the Indo-Malayan Archipelago, the Philippines, Taiwan, and southern Japan.

Incidental and directed catches of melon-headed whales have been reported from Sri Lanka with an estimated 300–900 animals taken per year. Although not yet confirmed by a specimen, the species may also be taken in the subsistence whaling off Lembata Island in Indonesia.

13. False Killer Whale The false killer whale, *Pseudorca crassidens*, is mainly found in deep tropical and warm-temperate waters. It occurs throughout the Indian Ocean, from South Africa to the Red Sea and Persian Gulf, east to Australia and the Solomon Islands, the Indo-Malayan Archipelago, Thailand, Cambodia, Vietnam, the Philippines, and north to the Yellow Sea and southern Japan. In Australia, mass strandings occur relatively often: since 1970, about once every 2.5 years, on average involving about 100 individuals. Mass strandings have also been reported from (southwestern) South Africa, Tanzania, and Sri Lanka.

In ancient times, false killer whales were hunted for their ivory in the Arabian Sea. Incidental catches have been reported from South Africa, India, Sri Lanka, and northern Australia. The species is sometimes taken in the subsistence whaling off Lembata Island, Indonesia.

14. Killer Whale Killer whales, *Orcinus orca*, have generally been considered to form a single, cosmopolitan species, although recently species status has been suggested for different forms/ecotypes that appear reproductively isolated, in the southern oceans and in the North Pacific, based on color pattern, morphological characters, genetic differences, habits, and ecology. The occurrence of different types of killer whales in the Indo-West Pacific is still unknown. Killer whales have been reported throughout the Indian Ocean including the Red Sea, and in the West Pacific there are records for all months and latitudes, although densities in tropical and subtropical waters would seem low.

Usually, killer whales were secondary targets of whalers, but some have been taken by whalers operating from Durban in South Africa, and possibly by Russian pelagic whaling operations in the 1970s, although the localities and size of these catches were not reported to the IWC. Small numbers are caught in the subsistence whaling off Lembata Island, Indonesia. Catches in net-fisheries, though rare, have been reported from Sri Lanka.

15. Pilot Whales The two species of pilot whales, *Globicephala macrorhynchus* and *G. melas*, have a largely parapatric distribution. The short-finned pilot whale, *G. macrorhynchus*, mainly occurs in tropical and warm-temperate waters. In the Indo-West Pacific, it

occurs from South Africa to the Red Sea and Gulf of Oman, east to Australia and the Solomon Islands, the Indo-Malayan Archipelago, the Philippines, and north to Taiwan and Japan. Mass strandings often occur and have been reported from India, the Indo-Malayan Archipelago, and Australia.

The long-finned pilot whale, *G. melas*, has a circumpolar distribution in temperate waters. Southern Hemisphere animals are distinguished as *G. m. edwardii*. In the Indo-West Pacific, its northern limits extend into the range of the short-finned pilot whale off the Cape Province in South Africa and off southern Australia; occasionally, the species strays further north.

Short-finned pilot whales are caught in coastal fisheries off Pakistan and Sri Lanka and are taken in subsistence whaling off Lembata Island in Indonesia, and in the Philippines.

16. Snubfin Dolphins Two species of *Orcaella* are currently recognized, *O. brevirostris* and *O. heinsohni*. The Irrawaddy dolphin, *O. brevirostris*, occurs in the Bay of Bengal, Strait of Malacca, the Indo-Malayan Archipelago, and Gulf of Thailand. It generally lives in muddy, coastal waters and has distinct coastal, estuarine, and riverine populations. Along the Southeast Asian mainland, the species is known from northeastern India, Bangladesh, Burma (Myanmar), Malaysia, and Singapore; Thailand, Cambodia, Laos, and Vietnam. Irrawaddy dolphins have entered the systems of the Ganges/Brahmaputra, Ayeyarwadi (Irrawaddy), Mekong, and several other rivers, with populations originally living as far as about 1300km upstream in the Ayeyarwadi, and nearly 1000km up the Mekong/Sekong. In the Indo-Malayan Archipelago, it has been recorded from eastern Sumatra, Belitung, Java, and many places in and around Borneo, including the Barito, Mahakam and Kajan Rivers, and their major tributaries and lakes, and from Malampaya Sound at Palawan in the Philippines. Its occurrence off western Sulawesi needs confirmation. In many coastal areas, numbers have decreased and the distribution appears disjunct. Riverine populations in particular have reached dangerously low levels and are now only found in restricted parts of their original range or may have disappeared altogether. In 1978, the population in the central Mahakam River and lake system was estimated to number 100–150 animals, whereas an estimate made in 1999–2000 over the whole course of the river arrived at 48–55 individuals, with the highest density in the central part, between 180 and 350km upstream (Kreb, 2004).

The form that is found on the Sahul Shelf is now distinguished as a separate species: the Australian snubfin dolphin, *O. heinsohni*. It was described in 2005, the holotype being an animal caught in 1972 in a shark-net in Horseshoe Bay, Magnetic Island, Queensland. It occurs off northern Australia, on the east coast as far south as Brisbane River (27°S), as well as in southern New Guinea (Beasley *et al.*, 2005). Its presence off northern New Guinea needs confirmation. The species appears restricted to marine environments, up to about 20km offshore.

The main threats for snubfin dolphins, particularly the riverine populations, are habitat degradation and pollution, mortality in fishing gear, and disturbance by boat traffic.

G. Porpoises, Family Phocoenidae

Finless Porpoise The finless porpoise, *Neophocaena phocaenoides* (Fig. 2A), is distributed over a narrow band of shallow water along the coasts of southern and eastern Asia. The species occurs in inshore waters, mangrove zones, and delta areas, including the lower reaches of the major river systems such as the Indus, Ganges/

Brahmaputra, and Mekong. Three subspecies are reasonably well differentiated: *N. p. phocaenoides* occurs from the Persian Gulf to the South China Sea and southern part of the East China Sea, and the western Indo-Malayan Archipelago, east to Java; *N. p. sunameri* is found along the coast of northeastern China, Korea, and southern and eastern Japan. The only population that exclusively inhabits fresh water: *N. p. asiaorientalis*, occurs in China in the lower and middle course of the Yangtze River and adjacent lakes, originally ranging over an area of almost 1670 km. Some populations have become seriously depleted, mainly due to mortality in fishing gear and habitat degradation.

H. Dugongs, Family Dugongidae

Dugongs, *Dugong dugon*, live in tropical and subtropical coastal waters of the Indo-West Pacific. Some authors have recognized two subspecies: *D. d. hemprichii* in the Red Sea, and *D. d. dugon* elsewhere in the Indo-West Pacific, discontinuously distributed from Mozambique to the Gulf of Aden, and from the Persian Gulf east to northern Australia. Its range includes many islands in the western and northern Indian Ocean, the Indo-Malayan Archipelago, the Philippines, north to southern China, Taiwan (where probably extinct), and the Ryukyu Islands, east to Guam, Palau, Yap, Pohnpei, the Bismarck Archipelago, Solomon Islands, Vanuatu, New Caledonia, and, as a vagrant, to Fiji. In many areas, the dugong has been reduced to widely separated relict populations, mainly by over-hunting. The waters off Papua New Guinea and northern Australia are now the most important stronghold for the species. Dugongs live in areas where there are large quantities (“meadows”) of seagrass (family Zosteridae).

Although the dugong is now protected over most of its range, direct hunting for food and other products, as well as indirect catches in fishing gear, are still substantial in many areas: East Africa, India, Sri Lanka, the Indo-Malayan Archipelago, the Philippines, and Australia, but few data on numbers taken are available. Habitat degradation too, constitutes a threat (Marsh *et al.*, 2002).

For extensive reviews of research on marine mammals in Southeast Asia, see the volumes edited by Perrin *et al.* (1996, 2005), Smith and Perrin (1998), and Jefferson and Smith (2002); also see the species accounts.

Intelligence and Cognition

BERND WÜRSIG

Dolphins and sea lions are wonderful crowd pleasers in oceanaria: they leap, toss balls, swim through hoops or other obstacles, and vocalize on demand. In nature, they race toward boats, surf in the bow wave, and perform amazing acrobatics for—it seems—the pure joy of it. They are highly social, communicate, enjoy contact with humans, and appear to spend much of their time playing. It is therefore easy to understand why one of the most common questions asked by nonmarine mammal researchers is: “They are very intelligent, are they not?” This question is an excellent one, for it forces us to attempt to analyze what we mean by intelligence and how marine mammals might fit our definition of the concept.

Intelligence and cognition go hand in hand. The former refers to the mental capabilities of a human or nonhuman animal and usually is described by assessing problem-solving skills. The latter refers to the information processing within the animal and may be inferred by an analysis of how it appears to plan an action or alter it based on past experience. A “more intelligent” animal responds to an environmental stimulus faster or more accurately than the “less intelligent” one; the “more cognitive” action or animal may indicate more insight and more awareness of the problem than the “less cognitive” one. Unfortunately, past determinations of the concepts tended to be biased by our own human problem-solving skills and sensory systems and, to large degree, still are. However, we now know that indicators of intelligence can even be very different for different human societies or cultural backgrounds, i.e., within species. Can we say that the nature-living Australian aborigine who scores very low on an “intelligence” test designed with problem-solving questions of our modern industrial/electronic society is less intelligent than the student who

takes the test in the industrialized world? If we answer “yes,” we should be forced to “take the test” on the Aborigine’s terms, perhaps by coming up with solutions of survival in the alternately extremely hot and cold, rugged, and food-poor outback. Similarly, it is not reasonable to study intelligence in dolphins and sea lions by asking them to solve problems relative to our linguistic communication or hand manipulation skills (in cognitive psychology, this is called the comparative approach). It is also unreasonable to compare “intelligences” of river dolphins with those of oceanic species by asking them to solve the same problems of space or objects.

An alternative to the comparative approach of describing intelligence and cognition is often called the “absolute method.” It involves an attempt to find out how an animal thinks about things. Thinking is defined as mental manipulation of the internal representation of the external world, the stimulus. The cognitive animal is influenced to change its internal manipulations in part by past experience, and the more adept animal does this better than the “less intelligent” one. While it is difficult to judge mental processes, approximate tests and observations to do so have been devised and will be described later on.

One important window into intelligence and cognition for social species (and all marine mammals show a reasonable to very high level of sociality) is certainly communication. The individuals and species that communicate among each other in sophisticated and at times novel and interactive ways are likely the “more intelligent” (by, in this case, the prime criterion of communication) than those whose communication may be structured more rigidly or less complicated. The great US ethologist Donald Griffin has argued persuasively that communication is a major “window into the mind,” not only of humans, dolphins, and other mammals, but of ants and honeybees as well (Griffin, 1981). He went on to postulate that it may be more parsimonious to explain the dance language of bees by considering them to be aware of their actions than it is to consider them reacting to complicated chains or sets of stimuli in unthinking (“noncognitive”) fashion. This intriguing idea is not yet widely accepted by behavioral researchers and cognitive ethologists. However, most researchers now accept the possibility of “intelligences” and cognition in nonhuman animals, potentially very different in operating modes from our own, and not testable by traditional comparative approaches.

I. Brain Size and Characteristics

A brain is needed to think and to have the chance of being aware (as a modern book, we need to mention the “brain” of artificially intelligent computers as well). Within a particular taxonomic group, larger and more complex brains tend to show a crude relationship to greater flexibility of behavior, adaptiveness to novel situations, and communication skills, i.e., intelligence. The relationship is imperfect, however, and is notoriously difficult to measure. For example, the entire brain has usually been used for descriptions of size and relative complexity, but there are motor, body function, and sensory parts of the brain that have very little to do with storing, processing, and integrating aspects of memory and thought (the latter occur only in the cerebrum).

Large mammals tend to have larger brains than small ones so brain size to body size ratios have been devised. One of these is the encephalization quotient (EQ), championed by Jerison (1973) and accepted by many researchers, albeit with often slightly different forms of calculation. The EQ is the ratio of brain mass observed to the brain mass predicted from an allometric equation of brain mass/body mass ratio of mammals as a whole. Therefore, an EQ of 1 means that the animal has an “average” brain size. It has been found for terrestrial mammals that EQs tend to be higher for those

TABLE I
Brain and Body Weights of Some Marine Mammals as Compared to Humans^a

Species	Brain weight (g)	Body weight (ton)	(Brain weight/body weight) × 100
Pinnipeds			
Otariids			
Northern fur seal (<i>Callorhinus ursinus</i>)	355	250 (male)	0.142
California sea lion (<i>Zalophus californianus</i>)	363	101	0.359
Southern sea lion (<i>Otaria flavescens</i>)	550	260	0.211
Phocids			
Bearded seal (<i>Erignathus barbatus</i>)	460	281	0.163
Gray seal (<i>Halichoerus grypus</i>)	320	163	0.196
Weddell seal (<i>Leptonychotes weddellii</i>)	550	400	0.138
Leopard seal (<i>Hydrurga leptonyx</i>)	542	222	0.244
Walrus (<i>Odobenus rosmarus</i>)	1,020	600	0.170
Odontocetes			
Common bottlenose dolphin (<i>Tursiops truncatus</i>)	1,600	154	1.038
Short-beaked common dolphin (<i>Delphinus delphis</i>)	840	100	0.840
Pilot whale (<i>Globicephala</i> sp.)	2,670	3,178	0.074
Killer whale (<i>Orcinus orca</i>)	5,620	5,448	0.103
Sperm whale (<i>Physeter macrocephalus</i>)	7,820	33,596	0.023
Mysticetes			
Fin whale (<i>Balaenoptera physalus</i>)	6,930	81,720	0.008
Sirenian			
Florida manatee (<i>Trichechus manatus latirostris</i>)	360	756	0.047
Human	1,500	64	2.344

^aModified from Berta and Sumich (1999).

species that have few offspring, delayed physical and sexual maturity, long parental care, and generally high behavioral complexity (as estimated by degree of sociality and amount of behavioral flexibility). Examples are primates and social carnivores such as cats and canids. Within the primates, EQs tend to be higher for those in the categories just mentioned than for others, demonstrating that meaningful life history–brain size comparisons can be made at least in that group. Some aspects of general intelligence appear to be correlated with those higher EQs, from tree lemurs at the low end of the scale to the great apes at the pinnacle. Nevertheless, the very concept of EQ represents a general statement for potential comparison within or between taxa but does not represent a fundamental phenomenon *per se*.

Polar bears (*Ursus maritimus*), sea otters (*Enhydra lutris*), and pinnipeds have EQs around 1, as predicted by the overall regression line of brain weight to body weight among mammals. Their brains tend to weigh between 0.1% and 0.3% of their bodies. In other words, there is nothing unusual in brain size of these mammals relative to their terrestrial carnivore cousins. Because brains are energetically expensive, it has been postulated that those of pinnipeds that dive to great depths and hold their breaths for long periods of time might be smaller. At first glance, this appears to be the case for such divers as Weddell (*Leptonychotes weddellii*) and elephant seals (*Mirounga* spp.), but analyses by Worthy and Hickie (1986) for pinnipeds and Marino *et al.* (2006) for cetaceans showed that brain size and dive capability have no clear relationship.

Dolphins and whales have large brains but not all have large brain to body weights or EQs. The sperm whale (*Physeter macrocephalus*) has the largest brain on earth, weighing about 8 kg. This brain is in a body that weighs about 37,000 kg, however. The brain is only 0.02% of the weight of the body, or one-fifth of the size ratio of the smallest-brained pinnipeds. However, at large sizes, a straight-line allometric comparison is probably not fair by any measure, and perhaps the body of the sperm whale simply does not need relatively much brain mass for muscle movement, skin sensation, visceral action, and so on. The common bottlenose dolphin (*Tursiops truncatus*), however, has a brain weighing 1.6 kg in a body that weighs about 160 kg, making it—at 1% of body weight—one of the largest relative brains on earth. This competes only with several other dolphins, great apes, and humans (whose brains are about 1.5 kg in a 65-kg body, or about 2.3%) (Table I).

Baleen whales, like sperm whales, have large absolute brains (about 7 kg in an 80,000-kg fin whale, *Balaenoptera physalus*), but none have brain to body weight ratios as large as even the relatively small ones of the sperm whale. Sirenians have neither absolute nor relatively large brains, with the Caribbean manatee (*Trichechus manatus*) having a 300-g brain in a 750-kg body (0.04% of body weight). It has been postulated that the sirenian, an herbivore, increased body size to house a large gut for processing low-energy food, and a concomitant increase in brain size was not needed to support this size. Similarly, the huge size of baleen whales allows them to have huge mouths and to fast for extended periods. Again, this is a very

Figure 1 Comparison of pinniped, *Otaria flavescens* (A); cetacean, *Tursiops truncatus* (B); and sirenian, *Dugong dugon* (C) brain, dorsal views. Illustrated by P. Adam. From Berta and Sumich (1999).

different allometric growth than that of a cow, for example, that is “simply” scaled up in size from a sheep (*Ovis* spp.).

Brain weight/body weight relationships are of general interest and have some relationship to relative information-processing capabilities. However, a larger absolute or relatively sized brain than that of another animal does not necessarily serve a “smarter” animal. The concept of intelligence is not a linear one; because there are so many “intelligences” depending on measure or the describer’s concept of what is important, intelligence is not definable in absolute terms. All of the marine mammals have well-developed cerebrums. The brains of toothed whales have especially high amounts of neocortical folding and therefore high surface areas (Fig. 1). This quality is believed to be related to thought processes and behavioral flexibility. Polar bears, sea otters, and pinnipeds show a general “terrestrial carnivore” level of folding, whereas baleen whales and sirenians have very smooth cerebrums, with minimal surface areas. Nevertheless, the internal structure of whale and sirenian cerebrums is as well developed as those of other social mammals, and there is no reason to believe that these animals are “dumber” than others based on brain size and gross morphology. Perhaps their ways of finding and securing food, without the need of sophisticated hunting strategies as by toothed whales and carnivores, coupled with some aspects of their communication and society interactions, simply do not require the elaborate neocortical folding seen in many other mammals. Although much more work on brain size and sensory capabilities needs to be done, it is known that toothed whales and dolphins, who echolocate and use sounds intensively for communication, have well-developed auditory processing lobes. Pinnipeds and especially polar bears, however, have well-developed areas for processing smell.

Although brain size and complexity issues used to dominate our thinking about relative intelligence, it is becoming apparent that these can give only vague indicators of complexity of thought. It is likely that brains are structured more along lines of how an animal interacts with others and with its ecology. Higher brain function is a complex mixture of sensory inputs; processing, storing, and reactions to stimuli; innovation; and retrieval and use of previously stored events. Our inability to find clear links of these with measures of brain size and aspects of gross complexity may simply be because of the relatively primitive state of cognitive science, or it could be that clear “all-encompassing” rules of relationships simply do not exist. Promising avenues for future brain studies are noninvasive electrophysiological and chemobiological studies from remote sensing of brain tissue while it is undergoing particular tasks. The findings to come

from such work will make our present discussions of brain function seem very primitive indeed.

II. Learning

We know that dolphins and sea lions do marvelously complex things in captivity, but we also know that most of these behaviors have been reinforced from existing simpler ones and shaped into that dramatic leap to catch a fish. It is positive reinforcement behavior, or operant conditioning, that is at work; the animal gets a food or other reward for having done a good job. Typically, a sea lion or dolphin reward is one to three small fish per performed action. This is not unlike “training” a cat to run into the kitchen when it hears the sound of a can opener or the guppies in a home aquarium all aggregating near the top when a drawer with dried shrimp is opened. Operant conditioning can be performed on just about all animals on earth, and only speed of learning and some aspects of the amount of behavioral shaping can be indicators of a measure of “smartness” or relative intelligence. The animals learn, but there is not necessarily insight to their learning.

A. Language Studies

It has long been known that dolphins have squeaks and whistles that appear to be used for communication. In captivity, bottlenose dolphins (*Tursiops* spp.) at times appear to imitate or mimic human and other sounds. These observations led an early dolphin communication researcher, John Lilly (Lilly, 1961), to attempt to communicate with dolphins by teaching them human speech. The results were a total failure, with not one clearly definable mimicked human sound; although dolphins are quite good at matching the staccato rhythm, in the form of bursts of sounds emitted in air (or underwater), of human speech. Dolphins do not have the vocal apparatus to produce human speech and may not have the neural wiring for it either. Nevertheless, Lilly’s association with dolphins did not stop him from postulating that dolphins have great “extraterrestrial” intelligence. He used their large brains and their purported friendliness as arguments, but could not muster communicative interactions with humans as a part of the argument. Unfortunately, his popular writings have swayed countless laypersons; and a substantial “cult” of believers in extremely high dolphin intelligence and sophisticated human–dolphin communication, even at the nonverbal extrasensory level, has evolved. No other scientists have made similar claims, but the unscientific nature of Lilly’s assertions deterred many others from studying dolphin and whale communication, and early on addressing intelligence and cognition in an obviously

behaviorally flexible taxonomic order of mammals. By the way, some seals and beluga whales (*Delphinapterus leucas*) do have the ability to mimic human sounds, and one now-deceased harbor seal, *Phoca vitulina*, (“Hoover”) at the New England Aquarium used to delight visitors with his rendition of simple sentences mimicked from a human pool cleaner, replete with the pool cleaner’s Maine harbor-side accent. This ability does not indicate greater intelligence than in other seals and toothed whales that do not mimic. Instead, the ability (generally found in male pinnipeds) may relate to the way the animals use natural sounds in order to work out dominance relations for mating access to females and for other social interactions.

Two researchers who were not scared off by the unfounded claims of John Lilly and who nevertheless began language communication research, were Lou Herman of the University of Hawaii and Ron Schusterman of the University of California at Santa Cruz. Their studies began in the 1970s and are still ongoing, with a cadre of graduate students and postdoctoral researchers (Herman, 2002; Schusterman *et al.*, 2003).

Lou Herman’s work consists of pioneering language studies conducted on dolphins. As in some of the successful studies with chimpanzees (*Pan troglodytes*), who like dolphins also cannot utter sophisticated human sounds, Herman uses a modified form of sign language, with volunteers’ arms at poolside “talking to” common bottlenose dolphins. This is thus a gestural, not vocal, language. While Herman and his team have delved into many fascinating aspects of dolphin abilities, the basic study goes somewhat like this. Teach a dolphin a simple sentence, such as “fetch ball hoop,” to indicate taking the ball from the hoop and bringing it to poolside. Once this command, reinforced by operant conditioning, is perfected, then the dolphin is presented with new, untrained challenges. Perhaps it is asked to “fetch hoop ball,” or either hoop or ball or both objects are replaced with novel items never before put into this context. It is clear that dolphins quickly grasp the basic concept of “object 1,” “object 2,” and “command” and act correctly a large percentage of the time. These sentence structures have been made more complicated, with similarly positive results. The dolphins are reasonably good at syntactic structure, and they also seem to be able to conceptualize general categories of items. In other words, the ball used in training can be substituted successfully by another ball, and a gestural symbol (“word”) can be made to refer to an item very specifically or to be more general, just as in human word use (Herman, 1986, 2006).

Ron Schusterman has repeated many of Herman’s studies and invented other experiments of his own, but with California sea lions (*Zalophus californianus*). His results are essentially the same: sea lions are also adept at learning and extrapolating from human-like syntactic structure (Schusterman and Krieger, 1986). Interestingly, the conclusions drawn by these two fine researchers are quite different, indicating the state of knowledge and vibrant nature of the field of animal language and cognition. Herman interprets his findings as the animals using language. “Fetch hoop ball” represents a verb, a direct object, and an indirect object. Schusterman, however, states that there is no reason to believe that the animal perceives this interaction as anything more than an action command and that the linguistic concept “verb” need not enter into the equation. It is true that human children, for example, do not learn language in the structured operant conditioning style as performed here. Instead, we learned (mainly) from people talking around us and from acquiring words and syntactic rules as we went along. It was not until language was already well formed that we were required in school to understand syntactic structure by diagramming or labeling the parts of sentences.

Language acquisition learning in dolphins and sea lions has taught researchers much about imitation, learning, and mental processing abilities. It is undeniable that dolphins learn the basic concepts very rapidly (sea lions a bit less rapidly) and faster than most mammals except for chimpanzees and humans. This by itself indicates a high level of that nebulous and poorly defined “intelligence.” However, whether these studies can be called language, or whether that is even an important question, is open to debate. We humans have taken human syntax and foisted it on nonhuman species. Nevertheless, the animals have done remarkably well with what they were given. Perhaps they can do even better as they communicate among each other with signs and symbols and emotive content for which they have evolved.

B. Inventive Dolphins

Pinnipeds, sea otters, polar bears, and sirenians show elements of learning and play in captivity, but do not show the same kind of quick thinking or innovation as do some dolphins. However, most work has been done with dolphins, so there is some element of bias. Nevertheless, bottlenose dolphins and rough-toothed dolphins (*Steno bredanensis*), both with very large brains, are known as “the best” of performers in oceanaria. It is not clear whether these animals adjust better to captivity than others or whether they are innately more behaviorally flexible than others.

One interesting story of behavioral flexibility comes from a study carried out on two rough-toothed dolphins at Sea Life Park, Hawaii, in the mid-1960s. Karen Pryor, then head trainer at Sea Life Park, introduced a new demonstration into her on-stage performance with one of her dolphins named Malia. The intent was for Pryor to demonstrate to the audience how a previously unconditioned behavior could be reinforced by operant conditioning. In order to do so, she could not use a previously trained repertoire, but each day had to choose a simple behavior (such as a particularly high surfacing or loud blow) that the animal did and then reinforce it. After several days of this, Malia “spontaneously” recognized that “only those actions will be reinforced which had not been reinforced previously” (Pryor *et al.*, 1969). In order to receive rewards rapidly (or for the pure fun of it), Malia “began emitting an unprecedented range of behaviors, including aerial flips, gliding with the tail out of the water, and ‘skidding’ on the tank floor” (Pryor *et al.*, 1969). None of these behaviors had been shaped, none had even been seen before in the basic repertoire of dolphin behaviors at Sea Life Park! Pryor and her colleagues then repeated the work with an untrained female rough-toothed dolphin named Hou in order to assess experimentally whether creativity could be induced by operant conditioning in another dolphin and how long it would take. The experiment succeeded splendidly, and in a few trials, Hou was also presenting a new “act” after each one that received an operant reward.

Pryor *et al.* (1969) discussed their results very cautiously and reminded the reader that such training for novelty can probably be successful in horses and perhaps even pigeons as well. Many students of animal behavior and intelligence agree and are content to explain the development of novel behavior as simply a trained response. However, others have taken the experimental results further and suggested that much more insight than normal is required for the animal to “learn to learn” (the great philosopher Gregory Bateson called this “deuterolearning”) and that the relatively quick manner in which dolphins “caught on” confirms their high intelligence. By the way, similar nonverbal training of reinforcement for novel behaviors has also been conducted for humans; the humans took about as long

to realize what was being trained as did the dolphins (Maltzman, 1960). For Hou and for the humans, there was a period of strong frustration (even anger, in the humans) where they had not “caught on.” They would be reinforced for a behavior, do it, and then not be rewarded for it ever again. It took some time for the “realization” to come that they then needed to exhibit a new behavior to get a reward. Once realized, the humans expressed great relief at having figured out “the problem,” whereas the dolphins raced around the tank excitedly and displayed more and more novel and body-twisting behaviors—to the obvious delight of the researchers.

An interesting observation about dolphins is that they—at least bottlenose dolphins—readily recognize images of humans and of themselves in mirrors (Marino, 2002) and on television screens. Herman *et al.* (1990) were able to elicit correct answers from the televised image of a human giving sign-based directions, even to the point where only white-gloved hands were shown going through the signaling motions. This demonstrates that the animals were able to use representations of the gestural instructions. Several investigators have shown dolphins mirrors and real-time video images of themselves; the dolphins react to the images with curiosity and playfulness, moving their rostrums rapidly and following their own eye movements. Furthermore, the reactions to video images of other dolphins appear to indicate that the viewing animals recognize different individuals on the screen, including themselves. This indicates a “sense of self” and has been described as an important insight into cognition. Interestingly, most chimpanzees and other apes do not have this innate capability to see images on a flat screen as representations of themselves, others, or humans. They can be taught to process the images meaningfully, but only after prolonged exposure.

III. Behavioral Complexity in Nature

A. Carnivores and Sirenians

Most marine mammals are highly social, and we would expect that they have sophisticated ways of communicating with each other by showing innovative and variable behaviors in the face of social strategies and interactions. However, the less social species are also behaviorally complex. Examples are polar bears and sea otters. Polar bears have a large repertoire of “sneaking up” on their generally ice-bound prey. They move against the wind, come from the side of the sun glare, and use ice obstructions and stealth in order to surprise their prey. It has been reported that in captivity, they figure out rapidly how to unlatch (and unhinge) doors in order to escape or to move from pen to open enclosure. Sea otters are tool users, prying mussels and abalone from the substrate with rocks or stones they keep cached in an armpit while not in use. At the surface, they retrieve the tool in order to break open their shellfish food; at times using the rock as a hammer and at times laying it on their stomach and using it as an anvil. Individual sea otters have preferred methods of tool use, implying learning and innovation. Polar bears and sea otters are obviously “bright,” but few behavioral studies or systematic investigations of learning have been conducted.

Pinnipeds are also behaviorally adept, and—as we have seen—sea lions can learn tricks and some aspects of language in captive training settings. They are all social mammals, especially while hauled out on land in order for males (of most species) to work out dominance relations with each other and for females to mate, give birth, and take care of their altricial (not well developed) young. Vocalizations, body postures, and smell are important aspects of communication. In the sea, most pinnipeds are less social (with the walrus, *Odobenus rosmarus*, being a strong exception), but they likely use

more individualized but sophisticated strategies for finding and securing enough prey to survive. We expect that the animals need to periodically adapt to different types of prey, learn which could be physically harmful or poisonous, and learn how to detect and avoid large sharks, killer whales (*Orcinus orca*), and leopard seals (*Hydrurga leptonyx*). Many pinnipeds do not take their young out to sea with them, and therefore all learning to hunt and to survive needs to be without substantial help from more experienced adults. The author suspects, but has no proof for, that the brains of pinnipeds are adapted for relatively quick self-learning to survive and are less adapted or structured for social communication except as that needs to develop for procreation. Polar bears, sea otters, and sirenians would be an exception, although while generally less social than other marine mammals, mothers take prolonged care of their young while the young develop feeding and other skills. We assume, but again have no direct proof for this assertion, that the young learn more easily and completely in the presence of their mother.

B. Baleen Whales

Baleen whales are social creatures, especially during mating times. Vocal communication is extremely important to them, with drum-like sounds of gray whales (*Eschrichtius robustus*), long low-frequency moans of blue whales (*Balaenoptera musculus*), short low-frequency grunts of fin whales, and the rich repertoire of groans, moans, and scream-like sounds of the right (*Eubalaena* spp.) and bowhead (*Balaena mysticetus*) whales. Whereas all whales appear to produce sounds, the most elaborate (and best-studied) sounds are the songs of male humpback whales (*Megaptera novaeangliae*), which likely serve as a male–male (intrasexual) dominance signal, male–female (intersexual) mating advertisement, or both. The songs are copied from listening to each other, are long and complicated, and must require reasonably formidable powers of learning and memory. Baleen whales on the mating grounds also sort out dominance relationships in either aggressive (humpback) or more gentle but highly maneuvering surface-active groups of gray whales (*Eschrichtius robustus*), right whales, and bowhead whales. In the latter gray, right, and bowhead whale groups, it is likely that multiple males allow each other to inseminate a particular female and practice a form of sperm competition instead of physical competition to increase the chances of fathering a young. It is also likely, although behavioral researchers have gathered only incomplete glimpses of the possibility, that female whales make it more difficult for some males than others to mate with them, thereby performing mate choice of preferred partners. If true, it must be important for females to gauge the relative “goodness” of males from the complicated matrix of social sounds and close-up interactions that present themselves. In right and bowhead whales, an adult female has only one young every 2 to 5 years. The calf gestates in her body for 1 year and then is nursed for another. This low-reproductive rate means that she must take very good care of the young to attempt to assure its survival, and researchers would not be surprised at all to find that she also wants to choose the father of her young with care.

Baleen whales tend to be less social on the feeding grounds, although recent behavioral research indicates that at least some long-term bonds of affiliation persist between breeding and feeding grounds. This does not appear to be the norm, however. Generally, blue, humpback, gray, right, and bowhead whales (these five are the best-studied baleen whale species) aggregate at particular areas because of food concentrations. An aggregation due to an outside stimulus is not necessarily a social unit, although it can result in one. Some social interactions do occur, and it is even likely that

the whales are paying close attention to each other in order to detect perhaps new or better feeding opportunities somewhere else. As well, blue whales often lunge into their food in tandem, apparently so as to provide a wall next to each other toward which fast-moving krill will not escape. Bowhead and right whales will swim in staggered formations of “echelons,” side by side, apparently for the same purpose (Würsig, 1988).

The winner in the baleen whale feeding complexity department must surely be the amazing humpback whale. Humpback whales lunge into their fish food, alone and in coordinated groups up to an observed 22 animals. They are not merely aggregated in such a case, but all lunge (from below and toward the surface) at essentially the same time, coming to the surface within about 6sec of each other. Apparently, although this is not yet proved, there is a vocal signal at the beginning of these highly coordinated lunges. One whale signals and others follow. Hitting the prey, a huge fish or bait ball, at one time presumably allows for each mouth to be better filled in the resultant prey's confusion than if one or a few mouths attacked. Humpback whales also flick their tails at prey and then circle to engulf it; they flick their long flippers forward as their mouths open, presumably to flash the white undersides of these flippers at the prey and to herd it more efficiently into the mouth. Finally, they release a stream of bubbles from their blowholes while circling around the prey and upward. The rising bubble screen forms an effective net around the prey, and the humpback (alone or with several others) then lunges toward the surface in the center of the “net,” filling its capacious mouth with concentrated prey. It is unclear how flexible the several feeding behaviors are, but it is certain that several need social coordination. It is also likely that young humpbacks need to learn and perfect the techniques, and we assume that social learning is the major vehicle to do this.

C. Toothed Whales

Toothed whales are highly social creatures, except for older adult male sperm whales who tend to be loners, some lone killer whales, and an extremely (“aberrant”) low level of singles in many species of dolphins. Some of the deep-ocean beaked whales may be loners as well, but we have no good data on this point. Whereas most species are social, there are very different forms. Hector's dolphins (*Cephalorhynchus hectori*), harbor porpoises (*Phocoena phocoena*), and river dolphins tend to occur in small groups of up to a dozen animals, rarely more. We surmise that in at least some of these dolphins, individuals know each other well. Pantropical spotted (*Stenella attenuata*) and striped (*S. coeruleoalba*) dolphins of the open ocean, however, travel in “herds” of thousands of animals. Although there appear to be subgroups with at least some interindividual fidelity, it is very unlikely that all members of the herd know each other; some may never even meet each other. However, the herd acts as a coordinated unit, traveling at the same speed (which must be near the speed of the slowest animals), turning in essential unison, often diving in synchronized fashion. If a disturbance occurs along a flank or somewhere below, e.g., a shark zooms out of depth, there is rapid information transfer from animal to animal so that the group cascades away from the perceived danger in coordinated fashion. The information transfer is so rapid that we assume that animals are aware not only of their nearest neighbors, but are “looking beyond others,” by sight when possible and probably also by echolocation. This is sort of a chorus line effect, where dancers coordinate their movements better by not merely paying attention to their nearest neighbors, but by anticipating the wave of raised legs, for example, as it (the wave) approaches. As well, it is likely that each dolphin

pays attention to the vocalizations and movements of others nearby and thus integrates response information in what the great cetacean researcher Ken Norris called a sensory integration system for dolphins (Norris *et al.*, 1994). Jerison (1986) used the idea of shared echolocation among dolphins to postulate that the animals share sensory inputs in a way that might synergistically enhance an expanded sense of “self.” A human analogy would be if several people of a group could know their world and their place in it better by sharing neural data of aggregate visual systems. Jerison postulated that this potential sharing of echolocation data might itself account, at least in part, for large dolphin brains, but we have no direct information on this provocative point.

Coordination of group movements and activities need not be a matter of high intelligence and cognition, of course; and sensory awareness and a collective sensory integration system are well developed in schooling fishes, flocking birds, and so on. Instead, we might do better to look at the complexities of social interactions to gain “a window into the dolphins' minds” (after Griffin, 1981). Unfortunately, we do not yet know very much about the details of communication in delphinid cetaceans, but we do know enough to call it “complex.” This complexity, at least for bottlenose dolphins, seems to be on a level of complexity of anthropoid primates such as some monkeys, the great apes, and humans (Marino, 2002).

Dolphins in a group are constantly aware of each other. A flipper touch here, a glance there, a slow echolocation-type click, a whistle. They interact by all sensory modalities available to them. We guess (and it is only a guess) that they are constantly gauging each other, deciding dominance/subservience relationships, seeking the comforting presence of relatives or those that they have found to be helpful in previous encounters, and avoiding those that might be aggressive. We know that there are at least occasions of political intrigue. Indian Ocean bottlenose dolphin (*Tursiops aduncus*) males of Shark Bay, southwestern Australia, have a strong tendency to form alliances to kidnap females. They apparently do so to gain access to reproductive females—access that might otherwise not be available because these males may not be of sufficiently high dominance status or would not be chosen by the females. Interestingly, super alliances of two or more alliances form in order to steal females from another male alliance (Connor *et al.*, 2000). Richard Connor speculates that great cognitive abilities and concomitant large brain evolution in humans, elephants, and some odontocetes may have evolved due to mutual dependence based on threats from predators as well as from members of the same species, i.e. social competition (Connor, 2007).

Toothed whales appear often to be structured along matriarchal (female-based) lines. Sperm whales, killer whales, pilot whales (*Globicephala* spp.), and bottlenose dolphins (of at least several populations) have close ties between mother and female young even after weaning, and in sperm and pilot whales, these ties appear to last for life. This means that potential cultural transmission of knowledge, from generation to generation, is expected to flow especially efficiently along female lines. Mom teaches young, young teaches its children, and so on. In a society of relatively resident killer whales of the US and Canadian Pacific Northwest, female and male offspring stay within the pod for life. This society is thus socially “closed.” However, females mate with males outside, and the males mate with females of neighboring pods. Each pod is therefore reproductively matriarchal. These societies of relatively stable long-lived individuals are likely to develop behavioral cultures of their own. We have some evidence: killer whale pods have individually distinctive sound repertoires, or dialects. Individuals of pods can recognize each other easily as of that pod. It is likely, but not proved, that individuals also

recognize each other as individuals by sound. In the more open but still matriarchal societies of at least one population of common bottlenose dolphins, studied by Randy Wells and colleagues (Wells 2003), of Sarasota, Florida, male offspring develop signature whistles (individually distinct sounds) more like those of their mothers than do female offspring. The moms and female offspring stay together as daughters mature. The sons, however, leave the natal group, roam elsewhere, and only now and then interact with their natal groups as adults. It is hypothesized that the similar signature sounds of moms and sons may provide an efficient means of recognition and thereby inbreeding avoidance (Sayigh *et al.*, 1995). Signature whistles are also copied by dolphins who are answering the original whistler. This rapid imitation may serve as a societal binding mechanism. It has been postulated that basic greetings and verbal recognition were prerequisite to the development of human language. Dolphins have the signature recognition portion of this capability (Janik, 2000).

Sound has been studied recently relative to kin and others of a society, and much more sound-based learning is likely to come to light as studies progress. This is to be contrasted with the relatively stereotyped sounds of the great apes, for example, that do not change much with age or social association (but then, in all fairness, apes are generally less vocally communicative and more visually based than cetaceans). However, it is also likely that not only vocal evidence for learning and social transmission will come to light. We have some hints, and only hints, here as well. Killer whales of Patagonia, Argentina, beach themselves in order to take South American sea lion (*Otaria flavescens*) and elephant seal pups. The beaching maneuver requires great skill, as the predator needs to gauge exactly where the prey is on the beach, after having seen the prey only from a distance and through murky nearshore waters, beyond the surf zone through which it needs to make its rush to the beach. As well, it needs to beach with such velocity and angle as to be certain that the spilling waves will allow it to reach deep water again. Killer whale adults have been described as making sham rushes at a beach and then waiting along the sides while young killer whales attempt the maneuver, usually clumsily and ineffectively, again and again. Now and then, the adult makes an intervening rush and then retreats to the side again. This behavior was pointed out as probable teaching by Argentine killer whale researchers Juan Carlos and Diana Lopez (1985) and has been studied in greater detail and verified since. It is unclear how well youngsters would learn beaching “on their own,” but it is likely that it is transmitted culturally, as killer whale beaching behavior is found in only several populations worldwide. In Galveston Bay, Texas, certain female bottlenose dolphins and their young follow shrimp boats much more so than others, even maneuvering into the shrimp nets to take live fish and then wriggling out again while the shrimper is under way. This activity, video taped underwater, requires skill and dexterity to avoid being entangled in the fishing gear. The dolphins who exhibit this behavior do so “with ease,” whereas others do not fish at all in this manner. Again, we wonder whether cultural learning and societal transmission of knowledge is important here. While culture has been explored in birds and nonhuman primates, less has been written on this subject for marine mammals (but see Whitehead, 1998; Rendell and Whitehead, 2001; Laland and Janik, 2006).

Even on an hour-to-hour basis, dolphins of a group are likely to be coordinating their activities superbly well. Although there are many potential examples (and each behavioral observer has his or her favorite ones), the author prefers one that he and his wife have studied for some time. Dusky dolphins (*Lagenorhynchus obscurus*) of the shallow waters of Patagonia, Argentina, coordinate activities to corral fish schools. It appears, and much more work is needed to

properly describe the individual behaviors, that dolphins (circling while vocalizing, tail swiping, and blowing bubbles) surround the prey ball and thereby cause it to tighten. They also herd the prey ball to the surface and then use the surface as a wall through which the prey cannot escape. Interestingly, dolphins do not appear to feed until the prey has been tightened and is at the surface. There may be a form of “temporary restraint,” with all animals working toward the common good of getting the prey secured. This coordinated activity stands in stark contrast to taking individual advantage of the prey by grabbing a mouthful here or there and causing the prey to scatter and escape. As an example, sea lions that enter the area work on their own and are highly disruptive to the herding efforts of the dolphins. While we still need to look at the details of this behavior, to see whether kin, for example, help each other more often, we assume that much communication, learning, and individual trust need to go into such coordination. It is likely, but unknown at present, that animals know each other well enough as to have preferred “working” partners and have mechanisms for detecting and effectively ostracizing those cheaters who do not help or are disruptive at critical phases of prey gathering (Würsig *et al.*, 1989).

Such activities require individual recognition, concepts of strategies for dealing with different behaviors of fish schools, coordination, memory of past events, and potential teaching or at least learning from others; in short, considerable behavioral sophistication and flexibility. In New Zealand, far from Argentina and in a different deep-water environment, most dusky dolphins feed not on schooling fishes but on mesopelagic (“midwater, deep ocean”) fishes at night. It has been found that a small subsegment of the dolphin population—the same individuals on a regular basis—travels to bays where dolphins take seasonal advantage of fish stocks to herd prey into tight balls as described earlier for Argentina. Because it is apparently the same animals doing so year after year, we believe that there might be cultural transmission of information here as well; only some have learned (or care) to take advantage of this particular foraging style.

A final example of at-times sophisticated-seeming behavior is certainly play. Almost all young mammals play, and this has been interpreted as gaining skills necessary to survive. It certainly seems like much fun as well. In dolphins and a handful of other mammals, adults habitually engage in behavior that is difficult to rationalize as anything but play. Dusky dolphins pull on the legs of floating birds, and individuals of several species perfect the balancing of pieces of kelp or other objects on their rostrums, flippers, dorsal fin, and tail. Play is not the purview of only dolphins, however. Adult baleen whales, sea lions, sea otters, and polar bears play with objects, at times for up to an hour or more. Play seems less common in phocid seals, but the imitative sounds of “Hoover” the harbor seal may have represented a form of vocal play. Play seems more rare (or absent?) in wild adult sirenians, but then long-term studies underwater have not been conducted.

IV. Conclusions

Marine mammals are not of one taxonomic group and live in many varied ways; we therefore are not surprised to find that they have different brain sizes and ways of adapting to their ecologies, social structures, and behaviors. Because all use marvelously adaptive behaviors to help them survive, they are all “smart.” However, such a general definition is not very satisfying. The polar bear, sea otter (and marine otter, *Lontra felina*, of Chile), pinnipeds, sirenians, and baleen whales all have behavioral characteristics and ways of living that might refer to “intelligences” not all that different from terrestrial mammals. Several of the dolphins (not all) stand out as being

exceptionally large brained and behaviorally sophisticated; they are quick learners in captivity and have social structures and behaviors that appear to be highly complex and variable. While much of the large brains of these odontocetes may well be taken up by the neural processing required for ECHOLOCATION and other senses, as has often been speculated, it is highly likely that a large part of it also deals with relationships, learning, and long-term memory of events (Schusterman *et al.*, 1986).

Much more needs to be learned about dolphin whistle and click communication. However, it does not seem likely that their combinations of whistles and clicks can be termed “language” in the sense of putting sets of (for example) whistles together as referential communication for different objects or constructs (ideas). Instead, vocalizations seem to carry emotive content, signature information, and may well serve as an important tool for binding social relationships (Janik, 2000). Nevertheless, there are certain to be surprises to be gained from studies on delphinid communication as more information is gleaned. One important avenue for exploration is the extent to which communication and behavior have been transmitted from generation to generation, resulting in distinct cultures in such animals as sperm whales, killer whales, and several species of dolphins (Whitehead, 1998).

While we think of dolphin and other marine mammal “intelligences” and cognitive processes and realize what marvelous animals they are, it is also fair to contemplate their limits. Dolphins are beautifully tuned to the environments in which they have evolved for millions of years, but they do not necessarily have the capability to make behavioral extrapolations that seem to us very simple. A prime example is the fear (or mental incapability) of most wild dolphins to leap over obstructions. This has been a major problem for the tuna purse seining industry—dolphins caught in a net could easily all leap to freedom as the net is pursed. They do not do so because it is not in their repertoire to do so and are caught (and at times entangled and killed) as a result. Only dolphins trained to leap over nets will do so or some animals that seem to have “accidentally” (perhaps the most innovative ones?) discovered the capability in nature. This article ends on this theme of focused mental capabilities because it illustrates two related points: (1) dolphins are not those “super intelligent” beings as claimed by some aspects of the news media and many books and films and (2) dolphins are indeed “intelligent” for those things that they need to solve and interact with in their natural world, but their natural world is very different from ours.

The International Whaling Commission

G.P. DONOVAN

The International Whaling Commission (IWC) is the intergovernmental body established in 1946 to conserve whale stocks and regulate whaling. Membership is open to any sovereign state. There were 78 member nations (Table I) in December 2007.

I. Historical Background

Whaling cannot be put forward as an example of the successful sustainable management of a renewable resource. From the start of

the “commercial” exploitation of whales, the story was usually one of eventual overexploitation. Modern commercial whaling began with the invention of the explosive harpoon combined with the development of steam-powered catcher boats in the 1860s (Tønnessen and Johnsen, 1982). This allowed whalers to take the faster-swimming rorquals (e.g., the blue, *Balaenoptera musculus*, and fin, *B. physalus* whales). The promise of large numbers of whales caused whalers to investigate the Antarctic, and the first whaling station was established on South Georgia in 1904 and took 195 whales. By 1913, there were 6 true land stations and 21 floating factories that had to be moored in suitable harbors; the total catch was 10,760 whales. The invention of the stern slipway in 1925 allowed vessels to operate in offshore waters and by 1930/31, 41 factory ships took over 37,000 whales. This overproduction led to a catastrophic decline in the price of whale oil.

It was the fear of low prices rather than the fear of overexploiting whale stocks that was the driving force behind early moves to limit catching. Despite attempts under the auspices of the League of Nations to establish some international control, the production agreements negotiated amongst themselves by the whaling companies produced the first effective limitation of catches in the early 1930s.

World War II caused a world shortage in the supply of fats and several nations had their eyes on profits from pelagic whaling. It was in this light, and the experience gained in developing international agreements just before the war, that discussions were held in London in 1945 and in Washington in 1946 on the international regulation of whaling.

II. Establishment of the IWC

The International Convention for the Regulation of Whaling was signed at the 1946 Conference. It was a major step forward in the international regulation of natural resources as it was one of the first to place “conservation” at the forefront (Gambell, 1977; Allen, 1980). The Convention was established to *provide for the proper conservation of whale stocks and thus make possible the orderly development of the whaling industry*. This was a laudable aim, but finding the difficult balance between conservation (*achieve the optimum level of whale stocks*) and the interests of the whaling industry (*without causing widespread economic and nutritional distress*) has dominated the history of the IWC.

An important feature of the Convention was that it established a mechanism whereby regulatory measures included in the *Schedule* to the Convention (catch limits, seasons, size limits, inspections, etc.) could be amended when necessary by a three-quarters majority of members voting (excluding abstentions).

The Convention also formally assigned importance to the need for scientific advice, requiring that amendments to the regulations “shall be based on scientific findings.” To this end, the Commission established a Scientific Committee comprising scientists nominated by member governments (and latterly invited experts when appropriate).

Despite this, there are aspects of the Convention that have attracted criticism. For example, any government can “object” to any decision with which it does not agree within a certain time frame. This (along with the right of nations to unilaterally issue permits to catch whales for scientific purposes) has led to accusations that the IWC is “toothless.” However, it should be recognized that without these provisions, the Convention would probably have never been signed.

From a management perspective, a more serious flaw was that the IWC could neither restrict operations by numbers or nationality nor allocate quotas per operation. Although it may be questioned whether the IWC could have agreed to national quotas or numbers

of vessels, certainly if such limitations had been reached this would have reduced the management problems associated with increasing numbers of vessels chasing limited quotas.

The Convention formally established the IWC. The IWC comprises one Commissioner from each government who has “one vote and may be accompanied by one or more experts and advisers.”

III. The IWC Before 1972

Perhaps the most serious problem of early management was the use of the *Blue Whale Unit (BWU)*. In terms of oil yield, one blue whale was considered equal to 2 fin, 2.5 humpback (*Megaptera novaeangliae*), or 6 sei (*Balaenoptera borealis*) whales. In 1945, a catch limit of 16,000 BWU was set (suggested by three scientists as being a “reassuring” value in between their estimate of 15–20,000; in fact scientific information on stock status was poor). The flaw in the BWU system is apparent—it allows catching of depleted species below levels at which catching that species alone would be economically unviable. This is apparent from the catch data up to the 1970s, which reveal that as blue whale catches declined, so fin whale catches (the next largest species) increased until they too were overexploited and sei whale catching began.

The lack of national quotas resulted in an “Olympic” system, where it became a race to catch as many whales as possible before the total quota was reached—leading to waste during processing and the use of increasing numbers of catcher boats (129 in 1946/47 and 263 in 1951/52). This neither made economic sense nor encouraged conservation.

Despite the early optimism, as early as 1952 many recognized that the catch quota was too high. The difficulty was in getting all the whaling nations to agree to a reduction—if one nation objected, then all objected. This was the start of a difficult period for the IWC. A combination of short-term economics, greed, and a lack of incontrovertible scientific evidence led to a critical situation for whale stocks; the benefit of the doubt was always given to the industry. Even a single voice on the Scientific Committee (often the Dutch scientist, Slijper) negated its attempts to persuade governments of the desperate need for quota reductions. At one stage, both the Netherlands and Norway withdrew from the Commission and its survival seemed in doubt. The Commission even appointed a group of three, later four scientists—experts in the relatively new science of population dynamics to produce independent advice (Allen, 1980). After considerable argument and controversy, by 1971/72, the catch limit had been reduced to 2300BWU and certain species, including blue and humpback whales had been protected from commercial whaling.

IV. A Period of Change: 1972 to the “Moratorium”

In 1972, the UN Conference on the Human Environment called for an increase in whale research, a 10-year “moratorium” on commercial whaling and a strengthening of the IWC. Although proposals for a 10-year moratorium were subsequently tabled at the IWC, they failed to reach the required three-quarters majority, largely because the IWC Scientific Committee believed that management on a stock-by-stock basis (Antarctic catches were first set by species in 1972) was the most sensible approach—if required each stock could be independently protected.

The UN resolution was, however, taken seriously by the IWC. By 1976, a permanent Secretariat had been established in Cambridge, an International Decade of Cetacean Research had been declared,

and a management procedure (the *New Management Procedure* or *NMP*) had been adopted. The NMP was aimed at bringing all stocks of whales to an optimum level at which the largest number of whales can be taken consistently (the *maximum sustainable yield* or *MSY*) without depleting the stock. It also gave complete protection to stocks at 54% of their estimated pre-exploitation size, i.e., well before they became endangered.

The NMP was regarded as a major step forward in the management of whaling. It appeared to take the issue of catch limits largely out of the hands of the politicians and into those of the Scientific Committee. In addition, from 1973, the long-awaited international observer scheme was in operation, aimed at ensuring that new catch limits were enforced.

A major feature over this period was the increase in IWC membership. In 1963, there were 18 member nations, of which only 4 were non-whaling countries; in 1978, there were 17 of which 8 were non-whaling and by 1982, membership was 39. Of the 13 whaling nations, 3 had only aboriginal/subsistence operations (Denmark, the United States, and St. Vincent and The Grenadines).

The 1979 meeting was a turning point in the Commission's history. Doubts had been expressed by some over (1) the theoretical and practical application of the NMP and (2) the morality of whaling, irrespective of the status of the stocks. At that meeting, a proposal to end pelagic whaling for all species except minke whales was adopted and a Sanctuary was declared for the Indian Ocean outside the Antarctic. Whereas the onus in the past had been for positive evidence of a decline in stocks before a reduction in catch limits was agreed, positive evidence was now required if a catch limit was to be set. By 1982, a *Schedule* amendment was adopted that implemented a pause in commercial whaling (or to use popular terminology, a "moratorium") from 1986. Originally, four whaling nations, Japan, Norway, Peru, and the USSR, lodged objections to this decision; Peru and Japan subsequently withdrew theirs. In the year 2000, only Norway carried out commercial whaling.

One obvious question to ask as the IWC's moratorium came into effect was whether the Commission been a success. At one level the answer must be no—indeed it could be argued that it had been a disaster. For example, in the Antarctic, the most important area to the IWC initially, (a) blue and fin whales had been reduced to at best 5% and 20% of their original numbers, and possibly much less, respectively—hardly a good example of "conservation of whale resources," and (b) the 1983/84 catch was 6655 minke whales (mainly Antarctic minke whales, *Balaenoptera bonaerensis*), a species not considered worth catching in 1947/48 when the catch in BWU was 25 times greater—hardly "the orderly development of the whaling industry."

So, had the IWC achieved anything? First of all, while it is easy with current levels of knowledge to criticize the IWC's performance, it has to be said that modern whaling had not resulted in the extinction of any species—IWC actions, while insufficient, were better than nothing. Since the 1970s, the trend has been very much toward conservative catch limits based on scientific advice, to a degree probably unparalleled in any fisheries commission. It has been argued by some that this trend reached unreasonable limits with the introduction of the "moratorium." It is indicative of the inherent problems within the Commission that the same decision is hailed by some as its greatest success and others as its most abject failure.

V. The Commission Today

Since 1976, the IWC has had a full-time Secretariat (of 15–20 people) with headquarters in Cambridge, United Kingdom. Each year,

the Annual Meeting of the Commission is held, either by invitation in any member country, or in the United Kingdom. The Scientific Committee (comprising up to 200 scientists) meets in the 2 weeks immediately before the main Commission meeting, and it may hold special meetings during the year. The information and advice it provides form the basis upon which the Commission develops the regulations for the control of whaling.

A. Management Issues

The primary function of the IWC is the conservation of whale stocks and the management of whaling. In addition to commercial whaling, the IWC has recognized the discrete nature of aboriginal subsistence whaling and allowed aboriginal catches from stocks that have been reduced to levels at which commercial whaling would be prohibited.

1. Commercial Whaling After the moratorium decision, the Scientific Committee recognized the need to develop management procedures that did not repeat past mistakes and the limitations of both the data it had and the data it was likely to obtain. In order to test the possible management strategies, it took the innovative and far-reaching approach of using computer simulations of whale populations over a long (100-year) period.

The most important part of any development process is the determination of *management objectives*. These were set by the Commission and can be summarized as (1) catch limits should be as stable as possible, (2) catches should not be allowed on stocks below 54% of the estimated carrying capacity (as in the NMP), and (3) the highest possible continuing yield should be obtained from the stock. The highest priority was given to objective (2).

After 8 years of intense work, the Committee developed a procedure for determining safe catch limits that required knowledge of only two essential parameters: (1) estimates of current abundance taken at regular intervals and (2) knowledge of past and present catches. Intensive testing of the procedure to numerous assumptions and problems had been undertaken and some of these are summarized in Table II.

The way in which catch limits are calculated from the required information is specified by the *Catch Limit Algorithm (CLA)*. This is a "feedback" procedure—as more information accumulates from sighting surveys (and catches, if taken), then the estimates of necessary parameters are refined. In this way, the procedure constantly monitors itself. Catch limits are set for a period of 5 years. The *CLA*

TABLE II
Some Examples of the Trials the Management Procedure Had to Be Able to Cope With

- Several different population models and associated assumptions
- Different starting population levels, ranging 5–99% of the "initial" population size
- Different MSY levels, ranging 40–80%
- Different MSY rates, ranging 1–7% (including changes over time)
- Various levels of uncertainty and biases in population size
- Changes in carrying capacity (including reduction by half)
- Errors in historic catch records (including underestimation by half)
- Catastrophes (irregular episodic events when the population is halved)
- Various frequencies of surveys

was initially tested on the assumption that it is applied to known biological stocks. To date, testing for specific species and areas has only been carried out for common minke whales (*Balaenoptera acutorostrata*) in the North Atlantic and North Pacific, Antarctic minke whales, and Bryde's whales (*B. edeni*) in the western North Pacific. Unless such testing has occurred and the results indicate otherwise, catch limits under the Revised Management Procedure (RMP) will be zero. It is clear that for very many populations, such as blue whales in the Southern Hemisphere, it will be a very long time before catches would be allowed under the RMP.

The *CLA* plus the rules about, *inter alia*, stock boundaries, allocation of catches to small areas, what to do if many more of one or other sex are caught, form the *Revised Management Procedure* or *RMP*. The RMP sets a standard for the management of all marine and other living resources. It is very conservative and this is a reflection of the relative priorities assigned to the objectives, the level of uncertainty in the information on abundance, productivity and stock identity of whale stocks, and the fact that many years are required before the *CLA* refines its estimates of the required parameters.

Although these scientific aspects were adopted by the IWC in 1994, its actual implementation is a political decision. The IWC will not set catch limits for commercial whaling until it has agreed and adopted a complete Revised Management Scheme (RMS). Any RMS will also include a number of nonscientific issues, including inspection and enforcement, and perhaps humaneness of killing techniques. The importance of an international inspection scheme was highlighted by the recent discovery of widespread falsification of catch data by Soviet whaling operations prior to 1972. There is at present a stalemate in discussions over an RMS. The only commercial whaling being undertaken in 2007/08 is that for common minke whales off Norway, who objected to the moratorium decision.

2. Aboriginal Subsistence Whaling Aboriginal subsistence whaling is permitted from Denmark (Greenland: bowhead—*Balaena mysticetus*—, fin and common minke whales), the Russian Federation (Siberia: gray—*Eschrichtius robustus*—and bowhead whales), St. Vincent and The Grenadines (Bequia: humpback whales), and the United States (Alaska: bowhead and gray whales). It is the responsibility of the Committee to provide scientific advice on safe catch limits for such stocks. With the completion of the RMP, the Scientific Committee began the process of developing a new procedure for the management of aboriginal subsistence whaling (AWMP) that takes into account the different objectives for the management of such whaling as compared to commercial whaling. Following the simulation approach used in the RMP development process, the Committee has developed Strike Limit Algorithms for bowhead and gray whales. It is focussing work now on the Greenlandic fisheries. The Commission will be establishing an Aboriginal Whaling Scheme that comprises the scientific and logistical (e.g., inspection/observation) aspects of the management of all aboriginal fisheries. The scientific component will comprise some general aspects common to all fisheries and an overall AWMP within which there will be common components and case-specific components.

3. Scientific Permit Whaling A major area of discussion since the moratorium has been the issuance of permits by national authorities for the killing of whales for scientific purposes. The right to issue them is enshrined in Article VIII of the Convention (that furthermore requires that the animals be utilized once the scientific data have been collected) and prior to 1982, over 100 permits had been issued by a number of governments, including Canada, United States, USSR,

South Africa, and Japan. Since the “moratorium,” Japan, Norway, and Iceland, have issued scientific permits as part of their research programs. The discussion has centered on accusations that such permits have been issued merely as a way around the moratorium decision contrasted with claims that the catches are essential to obtain information necessary for rational management and other important research needs. All proposed permits have to be submitted for review by the Scientific Committee, but the ultimate responsibility for their issuance lies with the member nation. The Committee has been divided on the value of the programs reviewed to date. Only Japan has issued scientific permits for the year 2007/08 [850 ± 10% Antarctic minke whales and 50 fin whales in the Antarctic; 150 minke, 50 Brydes, 50 sei, and 10 sperm whales (*Physeter macrocephalus*) in the western North Pacific]. As in previous years, a majority of the Commission members urged Japan to refrain from issuing the permits.

4. Small Cetaceans It can be argued that no species of large whale is endangered by whaling today and will not be by any resumption of whaling under the RMS or AWMP. Threats to those species, such as the North Atlantic right whale (*Eubalaena glacialis*) and the western gray whale, that remain severely reduced, do not include direct hunting. The most seriously threatened cetaceans (by direct hunting and incidental captures in fisheries) are a number of species and populations of the smaller cetaceans. At present, there is no single international body responsible for their conservation and management. There is considerable disagreement within the IWC as to whether the present Convention is sufficient to allow the IWC to assume such a role. Fortunately, there is general agreement that the IWC Scientific Committee can consider the status of small cetaceans and provide advice to governments even though the IWC cannot set management regulations—it is to be hoped that governments individually and collectively respond. It remains a matter of some urgency that an international agreement or series of regional agreements be reached to ensure the conservation of small cetaceans.

5. Whalewatching The IWC is involved (in a monitoring and advisory capacity) with aspects of the management of whalewatching as one type of sustainable use of cetacean resources. It has adopted a series of objectives and principles for managing whalewatching proposed by the Scientific Committee.

B. Other Scientific issues

The Commission funds and acts as a catalyst for a good deal of cetacean research (in the year 1999/2000 some \$400,000 was allocated to scientific research in addition to the IWC-related work undertaken by individual member governments. One major program is a series of Antarctic cruises to estimate abundance that has been carried out since 1978. These are now called SOWER circum-polar cruises (Southern Ocean Whale and Ecosystem Research) and include a component dedicated to blue whales.

With increasing awareness that detrimental environmental changes may threaten whale stocks, the IWC has recently accorded priority to research on the effects of such changes on cetaceans. Whilst the RMP adequately addresses such concerns, the Scientific Committee has agreed that the species most vulnerable to such threats would be those reduced to levels at which the RMP, even if applied, would result in zero catches. It has developed considerable effort into examining the effects of chemical pollutants on cetaceans, the effects of noise, including seismic surveys, and habitat degradation, including the effects of climate change and ozone depletion. It is also increasing collaboration and cooperation with governmental,

regional and other international organizations working on related issues.

The work in these areas carried out by the IWC Scientific Committee is recognized worldwide. The Commission has increasingly published scientific reports and papers; this culminated in the launch of the *Journal of Cetacean Research and Management* in 1999.

C. Politico-ethical Issues

Of prime consideration from both a scientific and an ethical viewpoint is the possibility of extinction of any population due to whaling. No population of whales is currently under threat of extinction from whaling, and it is clear that any acceptable management procedure will ensure that this cannot happen. However, this presumes an acceptance that whales are a natural resource to be harvested. While this is certainly the stated position of many members of the IWC, it is not universally accepted. A wide range of opinions have been expressed, ranging from the belief that whales are such a “special” group of animals that they should not be killed under any circumstances, through the view that they should not be commercially killed as whale products are not essential, to the view that whales are a natural resource to be used like any other.

In this regard, the question of humane killing has once more arisen within the IWC, with some nations stating that even if a safe management procedure is adopted, catch limits should not be set unless a “satisfactorily humane” killing method is available. This subject has been addressed several times during the history of the IWC and the Commission has been active in promoting work on more humane killing techniques for both commercial and aboriginal subsistence whaling. However, obtaining agreement on what comprises a “satisfactorily humane” technique will not be simple. In particular, in the case of aboriginal subsistence whaling, arguments of tradition and culture can clash with the adoption of modern technology.

VI. Conclusion

Many of the earlier discussed “politico-ethical” issues are linked to questions of culture and freedom; they are complex and almost inevitably will not be resolved unanimously. There is clearly a divergence of opinion within the IWC on such matters to an extent unparalleled in any similar organization. It is, for example, difficult to think of any fisheries organization where some of the members believe it is immoral to catch fish under any circumstances. This is not the place to enter into a philosophical debate over the rights of nations or groups of nations to impose their moral values on others, but merely to point out the necessity of such a debate and the need for a degree of compromise if the IWC is not going to fragment, with potentially serious consequences for the world’s whales and other cetaceans (Donovan, 1992).

Inuit and Marine Mammals

ANNE M. JENSEN, GLENN W. SHEEHAN, AND
STEPHEN A. MACLEAN

Inuit is a northern Alaskan term meaning “people” that has come to include the native “Eskimo” peoples of Chukotka, northern Alaska, Canada, and Greenland (Fig. 1). Inuit represent one extreme of the hunter–gatherer paradigm, relying almost exclusively on hunting to thrive in one of Earth’s harshest environments, the Arctic. Most Inuit hunting has focused on marine mammals, with the bowhead whale (*Balaena mysticetus*) making up a central part of the harvest, particularly in the Western and Eastern Arctic coastal areas. Whaling was important to Inuit from Alaska to Greenland and underwrote the formation and survival of permanent sedentary villages on Alaska’s arctic coast. When whaling was not feasible, Inuit depended upon caribou (*Rangifer tarandus*) and other marine mammals.

Inuit have hunted marine mammals and caribou for thousands of years. The Birnirk culture (AD 400–900) was the first to successfully incorporate whale hunting into their subsistence regime. Whaling was completely integrated into the succeeding Thule culture starting around AD 900. Around AD 1200, Thule folk and their whaling culture spread out of Alaska and into Canada and Greenland.

The ancestral Inuit tool kit employed raw materials from hunted species plus worked stone and driftwood. Their technology depended heavily on compound (multipart) tools often incorporating several types of raw material. A harpoon might employ a driftwood shaft, a foreshaft made from caribou antler, a socket piece from walrus (*Odobenus rosmarus*) bone, a finger rest made from walrus ivory, lashings made from caribou sinew, a head made from whale bone, a blade made from slate, a line made from walrus hide, and a sealskin float.

The harpoon head toggled, or turned, 90° once it was thrust into the animal, preventing withdrawal. As the head toggled, the shaft fell away, leaving a hide cord running from the head back to the hunter or to a float. The float was a sealskin with all but one of its orifices sewn shut. The remaining orifice was used to inflate the float through an ivory inflation nozzle, which was then plugged with a piece of driftwood. The float marked the prey’s location and slowed it down, tiring it as it attempted to swim or dive. The first commercial whalers to enter the northern sea near Greenland in the fourteenth century found Inuit hunting bowhead whales from umiat (skin-covered driftwood framed boats), using compound harpoons with toggling heads. By the early seventeenth century, Greenlandic Inuit were severely impacted by commercial whaling, which decimated the whale stocks, perhaps even eliminating the Svalbard stock upon which the east Greenlanders seem to have depended. In Canada, much commercial

Figure 1 Coastal Arctic inhabited by the Inuit. Redrawn from Freeman et al. (1998).

whaling for the European trade came to be shore based and carried out by local Inuit crews, entailing major alterations to Inuit lifestyles compounded by the destruction of the whale stocks.

Westerners first reached northern Alaska in 1826. However, Inuit lifestyles there were relatively unaltered by contact with the West until the second half of the century, when depredation of the bowhead whale stocks by commercial whaling and the spread of European diseases had disastrous consequences.

Inuit clothing was superior to Western cold weather gear and was often sought by Yankee whalers in Alaskan waters. Entire Inuit families were hired to travel aboard commercial whaling ships in the Arctic; women skin sewers made and mended clothing for the crew while the men hunted with the Yankees. By the late nineteenth century, Yankee whalers also adopted toggling harpoons, perhaps based on the Inuit model (Brower, 1942; Bockstoce, 1986).

The Inuit diet relied upon meat and blubber from whales, seals, and polar bears (*Ursus maritimus*). Caribou meat was eaten with seal oil or whale oil. Inland Inuit relied upon traded seal oil for a critical part of their dietary intake (Sheehan, 1997). Skins for boats came from seals and walrus. These, along with caribou and birds, also provided skins for clothing. Whale and seal oil provided fuel for lamps, the only source of heat other than body heat in houses. Alaskan coastal kitchens were separate from the houses and typically had two cooking areas, one fueled by oil, and the other by driftwood.

In Alaska, driftwood semi-subterranean houses incorporated long entrance tunnels made of whale bones, whereas in areas of Canada and Greenland, where driftwood was scarce, even the houses were constructed with whale bones, or with stone and bone. The only prehistoric qargi, or whalers' ceremonial house, that has been excavated in north Alaska was made almost entirely of whale bones.

Pokes (seal skins) filled with seal oil were used to preserve meat. Prehistorically in Alaska, i.e., prior to 1826 and even past the middle of the nineteenth century, seal oil and whale oil pokes were major trade items from coastal areas (Maguire, 1988). Return trade from

inland Inuit was primarily caribou skins for clothing and blankets, sinew for sewing, and antler for tools. The economy left nothing to waste, with dog (*Canis lupis familiaris*) teams consuming old clothing as well as any of the harvest not used directly by the Inuit.

Whaling provided a dependable food surplus to the prehistoric coastal Alaskan communities, allowing them to organize their lives around the whale hunt (Sheehan, 1997). This whaling culture was successful for a 1000 years. Whaling remains the organizing focus of Inuit life today in northern Alaska and is still an important part of Inuit ideology in other parts of the Arctic. Marine mammal hunting continues to underpin Inuit subsistence activities and social interactions.

I. Precontact Whaling

It is commonly believed that indigenous whaling developed in the Bering Sea and Bering Strait region about 2000 years ago with the Okvik and Old Bering Sea cultures. A florescence in the diversity and complexity of tools used for hunting and processing marine mammals took place from approximately 100 BC to AD 600, although such tools and weapons have continued to be a focus for technological innovation. This suggests an increased dependence on large whales and other marine mammals (Stoker and Krupnik, 1993). There appear to be two significant differences between the early groups that hunted whales but did not rely upon them and later groups that were dependent for their survival on the whale hunt. One of these differences was technological, the other social. The introduction of drag float technology may have transformed whale hunting from a "status" activity resulting in lucky "windfalls," into a "normal" activity resulting in a regular and substantial payoff. Transformation of the umialik (whaling captain) from a temporary hunt leader into a permanent political leader responsible for distributing the whaling surplus throughout the community allowed the population to thrive and grow. The combination of technological and social change culminated in the period of the Punuk and the Thule cultures starting at AD 800–900.

It is generally agreed that widespread large whale hunting started when the Thule culture spread across North America to Greenland, but whaling itself may have developed independently in several areas at different times. The earliest of these may be the Maritime Archaic tradition of Labrador and Newfoundland, dating from approximately 3000 BC. The Maritime Archaic is believed to be one of the earliest cultures to use the toggling harpoon head. Møbjerg (1999) reported that the Saqqaq culture of Greenland's west coast, part of a broader Arctic small tool tradition, which stretches across the North American Arctic, may have been hunting baleen whales as early as 1600–1400 BC. One of the most interesting cases is the so-called Old Whaling culture of Cape Krusenstern, near Kotzebue Sound in Alaska, which appeared suddenly around 1800 BC, but disappeared shortly thereafter. These people used large lance and harpoon points, possibly to hunt for baleen whales. The abundance of whale bones in the area suggested to the original excavators that whaling was practiced, but there is no evidence that the technology was passed to later cultures (Giddings, 1967), and subsequent reanalysis of the materials has called the evidence for whaling into question (Darwent, 2006).

The Thule whaling culture developed in northwestern Alaska around ad 850–900 and a few hundred years later spread very quickly across arctic Alaska and Canada to northern Labrador and Greenland. It then spread into more northerly areas in the central Arctic. The rapid expansion of the Thule whaling culture was perhaps influenced by a period of climatic warming. The warmer weather may have resulted in seasonally open water across the entire coast from northwest Alaska to eastern Canada and Greenland, making Pacific and Atlantic populations of whales contiguous and more numerous. These conditions would encourage the expansion of a shore-based whaling culture.

The climate of the far north did not remain warm and stable for long. Colder weather and a resulting increase in expanse and duration of ice cover reduced the distribution and perhaps the numbers of whales in the Arctic. A concomitant reduction in the geographic range that could sustain a whaling-focused economy made reliance on whales risky in areas that were more marginal. Thule people who could no longer succeed in whaling focused more heavily on smaller marine mammals and other game. Some parts of the central Canadian Arctic were depopulated.

The climatic variations resulted in dramatic changes to the Thule whaling culture throughout its range. The remnant Thule cultures gave rise to the contemporary Inuit cultures of present-day Canada, Greenland, and Alaska. In Alaska, whalers were able to continue their primary reliance on whale hunting by clustering in large permanent villages at points of land, where every spring they could rely on currents and geography to place them within walking distance of nearshore leads in the ice. Whales followed the leads as they went north for the summer. The leads became the foci of the whale harvest, supplemented by fall whaling in open water, as the whales passed the points on their way south.

II. Mysticetes

A. Bowhead Whale, *agviq*

The bowhead whale is the largest animal hunted by any prehistoric or historic hunter-gatherer society. Adults reach at least 20 m and weigh 50,000 kg or more. The slow moving, blubber-rich whale is a particularly suitable target, as it often travels close to shore in predictable migration patterns.

The advent of commercial whaling and the consequential contact with Europeans forever changed the patterns of indigenous bowhead

whaling. Commercial whalers reduced bowhead populations to levels too low to support a subsistence hunt in most of the whales' range. The Chukotkan natives continued bowhead whaling until the late 1960s when Soviet authorities replaced the shore-based hunt with a catcher-based hunt, primarily for gray whales (*Eschrichtius robustus*). In 1997, the Alaska Eskimo Whaling Commission (AEWC) began sharing their quota of bowhead whales with Chukotka natives, assigning them five of the total annual strikes allowed under the rules of the International Whaling Commission (IWC). With assistance and training by Alaskan whalers, the Chukotkan natives have begun to hunt bowhead whales again. The Canadian Inuit ceased traditional bowhead hunting around World War I due to low whale numbers and active discouragement by the Canadian government. In 1991, the Canadian Inuit at Aklavik, in the Mackenzie River delta, landed a bowhead for the first time since the early twentieth century. An unsuccessful hunt was carried out in 1994 and a successful hunt in 1996, but they haven't chosen to hunt since then. Greenlandic Inuit hunted bowheads for many centuries before commercial whaling depleted the Atlantic stocks nearly to extinction. Greenlandic Inuit were employed by Danish commercial whalers from the late eighteenth century until 1851, when depleted bowhead numbers brought a halt to commercial hunts.

Currently, the bowhead whale is hunted under the quota system in northern Alaska, in the villages of Savoonga, Gambell, Little Diomedea, Wales, Kivalina, Point Hope, Wainwright, Barrow, Nuiqsut, and Kaktovik, along the Bering, Chukchi, and Beaufort Seas.

After commercial whaling ceased in the early twentieth century, Alaskan Inuit returned to a strictly subsistence bowhead hunt. Bockstoce (1986) estimated that an average of 15–20 whales was landed each year from 1914 to 1980. After 1970 there was a significant increase in the number of bowheads landed in Alaska. This was a result of a combination of factors. There was an increase in cultural awareness by Native Americans in general and Alaska Natives in particular, brought about by the passage of the Alaska Native Lands Claim Settlement Act in 1971. The discovery of oil in Prudhoe Bay in 1968 and the construction of the Trans-Alaska pipeline provided significant cash input into the economy of northern Alaska, which prompted a large increase in the number of whaling captains. The position of whaling captain in northern Alaskan Inuit whaling communities has always been one of great respect and authority. Traditionally, only those hunters who demonstrated great hunting success and respect for customs rose to the position of whaling captain. The expense of obtaining whaling gear limited the number of crews and ensured that only experienced whalers rose to the position of captain. The influx of money and employment in the 1970s resulted in a doubling of the whaling crews in northern Alaska from 44 in 1970 to 100 in 1977. The number of whales landed also increased from an average of 15/year to about 30/year from 1970 to 1977. There was also a large increase in the number of whales struck but lost and presumably killed.

The increase in the number of struck but lost whales, combined with a NOAA estimate that only 600–2000 bowheads remained in the Arctic, prompted the IWC to call for a total ban on bowhead whaling. The Inuit reacted strongly to this ban, arguing that the bowhead population was much larger than the IWC scientists were estimating. They formed the AEWK, composed of whaling captains from each whaling village. In 1978 the AEWK, through the US delegation to the IWC, negotiated a quota of 12 bowheads landed or 18 struck for the 9 Alaskan whaling villages. Since then the IWC has established quotas for Alaskan whalers, and the AEWK has distributed strikes to the 10 Alaskan whaling villages (Little Diomedea joined AEWK in 1992). Research paid for and conducted through the AEWK and the North Slope Borough (NSB, the regional government in northern

Alaska) Department of Wildlife Management proved the Eskimo whaling captains were correct when they asserted that there were many more whales than estimated by NOAA and presented to the IWC; however, the high mortality rates (>111 strikes in 1977) were probably not sustainable. Careful censuses (George *et al.*, 2004) of the Bering–Chukchi–Beaufort Seas bowhead population estimated that the bowhead population in the western Arctic numbered 10,470 in 2001, (SE = 1351; 95% CI 8100–13,500). The rate of increase (ROI) from 1978 to 2001 is 3.4% per year (95% CI 1.7–5%).

In consequence, the number of strikes allotted to Alaskan whalers was increased to the estimated “need” level based on Inuit population size and patterns of customary and traditional usage of whale products. In 2007, a block quota was set for the years 2008–2012. The quota of 280 whales for that period includes five whales allocated to Chukotka by the AEWC.

Some Alaskan Inuit hunt bowhead during both the spring and fall migration. In spring, bowheads migrate from wintering grounds in the Bering Sea north through the Bering Strait to feeding areas in the eastern Beaufort Sea. Whereas specific dates vary somewhat by year, typically, the whales move along open leads in the ice created when drifting pack ice shears away from the grounded, shore-fast ice. These leads occur in predictable places along the Alaskan coast. Bowheads begin the migration north from the Bering Sea in late March through early April and pass the whaling villages of Gambell and Savoonga soon thereafter. The whales pass by Point Barrow from mid-April to early June and arrive in the eastern Beaufort Sea in May. Bowheads begin the fall migration across the central Beaufort Sea in early September and pass Alaska’s north coast from mid-September to early October. Some whales may continue across the northern Chukchi Sea arriving in Chukotka in November, and others may move southward, likely crossing the central Chukchi Sea.

Equipment used in the modern whale hunt is a combination of precontact technology and tools adopted from Yankee whalers. The boat used for the hunt is a skin-covered frame called an umiaq. The frame was traditionally made of driftwood lashed with baleen with some whale bone fittings, but now is made from prepared lumber. The cover is made from the skins of bearded seals (*Erignathus barbatus*) or walrus hunted the previous summer. The skins are left to ferment which softens the skin and allows the hair to be stripped off easily. The skins are sewn together using a special waterproof stitch and stretched over the frame using rawhide thongs or, more recently, jute or nylon line. The average umiaq in Barrow requires six bearded seal skins for the cover, is 6.5–8.5 m long, 1.5–1.8 m across the beam, and weighs approximately 160 kg when dry (Stoker and Krupnik, 1993). The skins are usually replaced every 1 or 2 years, depending on their condition. In some places, aluminum or wooden boats powered with outboard motors have replaced the umiat (plural of umiaq). However, in areas where heavy ice is often encountered, umiat are still used because they are easier to move across and through heavy ice. During fall whaling in Barrow, Nuiqsut, and Kaktovik and during spring whaling in areas where leads are wide and whales travel farther from the lead edge, aluminum or fiberglass boats powered with outboard motors are used.

Weapons used for hunting are essentially the same equipment used by commercial whalers at the end of the nineteenth century. The darting gun and shoulder guns were introduced by Yankee whalers soon after the Civil War and were adopted by Inupiat hunters in the last decades of the nineteenth century (Brower, 1942; Bockstoce, 1986). The harpoon consists of a wooden shaft 1.5–2 m long tipped with a detachable steel harpoon with a brass toggling head attached to a float with 55 m of strong nylon line. The harpoon is tipped with

a plunger trigger-driven gun that fires an 8-gauge, brass bomb simultaneously with the harpoon strike. A second darting gun that resembles the harpoon but without the toggling head harpoon is used to deliver a second bomb. Heavy brass shoulder guns are also used to fire bombs from distances greater than can be attempted with the darting gun. The brass-encased bombs are charged with penthrite, which replaced black powder in 1998. Penthrite bombs deliver a sudden concussion and kill by shock rather than laceration and tissue damage. This reduces the number of whales that are struck but lost. Other equipment includes flensing tools hand-made of steel blades (often from hand saws) attached to long wooden handles, heavy-duty block and tackle to haul the whale onto the sea ice, an aluminum or fiberglass boat used to chase and retrieve a whale after a strike is made from the umiaq, and snowmobiles used to tow equipment to and from camp and to carry meat and maktak back to the village.

Preparations for whaling begin well before the whales arrive. Male members of the crew clean weapons and the ice cellar for storing meat and build sleds and other equipment needed for the camp on the ice. The wives of the captain and crew members sew a new skin cover for the umiaq frame. When the skins are dry, the umiaq is lashed to a sled for the wait until a lead opens.

Sometime before the arrival of the first bowheads the captain will decide where to place his camp. One or several “roads” are built across the ice to the selected sites. The roads are built to smooth the route across the maze of pressure ridges on the ocean ice. Smoothing the route eases the task of hauling sled loads of meat and maktak in the event of a successful hunt and provides a quick escape route if ice conditions become unsafe. Stakes with colors or symbols are often placed along the roads. Camps are located on the ice edge, often in “bays” in anticipation of whales swimming under projecting points and surfacing in those bays, or on points that provide good views of approaching whales.

Inuit believed, and many continue to believe, that whales give themselves willingly to hunters worthy of their sacrifice. Traditionally, many taboos governed activities in whaling camps, and these taboos were strictly followed to ensure a successful hunt. Tents, sleeping gear, and cooking were prohibited in camps. Most taboos have been relaxed or dispensed with, but traditions still govern activity in camps. One tent is set up in camp to allow crew members to sleep in short shifts and for cooking meals. The tent is placed away from the lead and to the right of the boat to prevent approaching whales from seeing the camp. The umiaq is kept ready at the water’s edge with a smooth ramp cut into the edge so that it can be launched silently. The harpoon and darting gun are positioned in the bow of the umiaq with the line from the harpoon neatly coiled on the bow. The weapons, lines, and floats are always kept on the right side of the boat, and the strike is always made over the right side of the boat to prevent ENTANGLEMENT in the line. At least one crew member remains on watch at all times, scanning the lead for any sign of an approaching whale.

When a whale comes within range and is determined suitable, the umiaq is launched silently with the harpooner ready in the bow. Two to five paddlers are situated along each side of the umiaq, with a steersman in the stern to steer the umiaq toward the whale. The umiaq is paddled silently, with all crew members stroking in unison. The steersman directs the umiaq to where he or the captain hopes the whale will surface next. The harpooner strikes the whale from as close as possible, often from point-blank range. The preferred target is the postcranial depression just forward of the back. A hit here will often kill the whale instantly. If this target is not available, the spine, heart, or kidney regions are targeted. As soon as the whale is struck, the float is thrown overboard on the starboard (right) side. If possible,

a senior crew member other than the harpooner will fire the shoulder gun to plant another bomb into the whale. Other crews, alerted by VHF radio, quickly converge on the site of the strike in aluminum boats powered by outboard motors and may fire another bomb into the whale in an attempt to kill it quickly. Aluminum boats are much faster than umiat and help ensure that a struck whale will not be lost.

Immediately after the whale is killed the captain of the crew that first struck the whale says a prayer (to the Christian God). The prayer is often broadcast over VHF radio and is the first signal of a successful hunt to villagers waiting on shore. The whale's pectoral flippers are then lashed together and the flukes may be removed to reduce drag. A long line is attached to the caudal section forward of the flukes and all available boats attach to the line, with the successful crew at its head, to tow the whale tail-first to the butchering site on the ice. Word of the successful hunt is sent to the village by snowmobile, and the whaling flag of the successful crew is raised over the captain's home. Many members of the community then travel to the butchering site to help with hauling the whale onto the ice and butchering it.

At the butchering site a large block and tackle is attached to the ice and used to haul the whale onto the ice. Every available crew member and community member hauls on the free end of the line running through the block and tackle, pulling on commands from the whaling captains. If the whale is too large to haul onto the ice, some butchering may commence in the water. The tongue or SKULL may be removed to ease the task of hauling the carcass onto the ice. Butchering begins as quickly as possible after the whale is hauled onto the ice because the thick blubber layer retards heat loss and the meat in an unbutchered whale quickly spoils. The whale is butchered according to strict customs governing the distribution of shares (Fig. 2). Parts of the whale are reserved for the captain of the crew that struck the whale. Most of that portion will be shared with the community at feasts and festivals

that occur throughout the year. Additional shares are divided among the successful crew and the crews that assisted in killing, towing the whale to the butchering site, hauling the whale onto the ice, and butchering. Individuals not representing a crew are also offered shares of meat and maktak. A group of 20–25 people can butcher an average size bowhead in 6 or 7 h. No shares are distributed until the butchering is complete. Traditionally, following butchering some skulls were rolled into the ocean to allow the spirits of the whales to enter other bodies and again be hunted. The spirit of the whale would remember that the captain treated it well and so sacrifice itself to that captain again. Other skulls were brought ashore and placed at the beginning of the tunnels that led to the entrances of villagers' semi-subterranean homes. These symbolically placed skulls suggested that as you entered the home you also entered the world of the whale. The prehistoric qargi or whalers' ceremonial house was built entirely of whale parts to represent a complete whale (Sheehan, 1990). Today, some skulls are not returned to the ocean but are taken ashore where they are cleaned and displayed in the village. The remainder of the skeleton is left on the ice for gulls, foxes, and polar bears.

Bowhead maktak, served boiled fresh or raw and frozen, is the most prized food in the Arctic. Shares of meat and maktak are widely distributed among family and neighbors, often to family members living in cities who would not receive traditional foods otherwise. Meat is eaten raw and frozen, boiled, or fermented in blood. Many internal organs are also eaten. The kidney, intestines, and heart are boiled. The huge tongue of the bowhead is considered a delicacy when boiled. Baleen was traditionally used to make toboggans, for lashing of umiaq frames, for bird snares, and to make fish nets and seal nets that could easily be freed of the ice that forms on nets immediately as they are removed from the water. A simple snap of the net broke off the ice from this resilient material. Now baleen is crafted into artwork and sold.

Figure 2 Division of bowhead whale (*Balaena mysticetus*) shares in Barrow, Alaska. From Harry Brower, Jr.

On the day following butchering, the captain of the successful crew opens his home to the community in celebration. All comers are offered food and drink. In early June the umiat of the successful whaling crews are hauled off the ice in ceremonies (apugauti). Once again, the captain supplies food and drink to all who attend. Nalukataq, the formal whaling festival, takes place in June. Each successful crew will have their own nalukataq, or several crews will hold one together. At nalukataq, the members of successful crews distribute the majority of the meat and maktak reserved for the community. The captain and crew also distribute other foods collected during the year, such as caribou meat and soup, duck soup, goose soup, and many other traditional foods. Fruit and candy are also distributed, and coffee, tea, and soft drinks are served throughout the day.

After the food is distributed, the blanket toss begins. Skins from the successful umiak are removed from the boat and resewn to form a blanket with rope handles along the edge. Community members climb onto the blanket, one at a time, and are thrown into the air by people pulling on the handles in unison. The objective is to jump as high and as many times as possible without falling. Members of successful crews will often climb onto the blanket with bags of candy to fling to the crowd while jumping. After the blanket toss a traditional dance is usually held in the community center. Each successful crew and their families will dance by themselves, but most dances are open to anyone. Nalukataq is one of the most joyful times in the village, and the traditional dance that is the culmination of nalukataq can last late into the night.

B. Gray Whale, *agvigluaq*

Only the Chukotkan Inuit of the Russian Far East regularly hunt gray whales. Historically, Chukotkan Inuit hunted both bowhead and gray whales from shore-based stations. The traditional shore-based hunt was banned by the Soviets and replaced by a catcher boat-based hunt in 1954 (Freeman *et al.*, 1998). As a result, the cultural traditions were lost and few people now remember traditional hunting methods. The Soviet catcher boat Zvyozdnyi last hunted in 1992 (Freeman *et al.*, 1998). After the catcher boat stopped whaling, the villagers began to hunt marine mammals again to supplement dwindling food supplies.

The return to traditional, shore-based whaling was a difficult and costly endeavor. The lack of equipment and knowledge had serious consequences in several villages. Hunters from the village of Nunlingran died in several hunting accidents, and one whaling boat from Sireniki was sunk, killing all aboard. Fortunately, material assistance and training by the AEWG and the NSB helped ease the transition. However, the hunters from seven Chukotkan villages landed 51 gray whales in 1994 (Freeman *et al.*, 1998). In Lorino, several experienced marine mammal hunters were able to teach younger hunters the proper use of harpoons, spears, and rifles. Hunters from Lorino landed 38 gray whales in 1994. Several other villages solicited aid from Lorino, and with training from experienced hunters began to successfully hunt gray whales. The hunt is now sanctioned and controlled by the IWC, with a quota of 120 gray whales landed in Chukotkan villages from 1998 to 2002. Gray whale hunting has again become an important part of Chukotkan Inuit cultural and dietary lives.

Gray whale hunting is carried out in the summer when gray whales move into the Bering Sea from their wintering grounds. Whaling is conducted from shore stations using skin boats (baidara) or wooden whaling boats. The harpoon-spear is a special whaling implement traditionally used by the Inuit of Chukotka (Freeman *et al.*, 1998), consisting of a wooden shaft with a detachable metal

spear that is attached to a line with a small float. Each boat carries 7–10 of the metal spears and one wooden shaft. The spear is thrown by hand and the metal spear detaches from the wooden shaft. The wooden shaft is retrieved from the water, fitted with another harpoon-spear, and the whale is approached again. The harpooner aims for the back of the whale, trying to hit the main blood vessels or vital organs. Once harpoons have been set, the whales are shot with rifles and darting guns. This form of hunting is often dangerous. Gray whales are known to fight aggressively. Two boats are used to ensure the hunters' safety. The hunters also try to take small- or medium-sized whales.

Gray whales are taken for their meat and blubber. The meat and maktak are eaten frozen, thawed and raw, or boiled. Oil is rendered from the blubber and used as food by itself or added to edible roots, willow leaves, and other vegetables.

In northern Alaska during the early historic period, commercial trade for baleen from bowhead whales created wealth that allowed people to increase the number of dogs in their teams. As a consequence, some gray whales were hunted primarily to feed sled dogs, although some hunters also found the meat to be very tasty. Gray whales are no longer hunted in Alaska.

C. Humpback Whale (*Megaptera novaeangliae*) and Fin Whales (*Balaenoptera physalus*)

Greenlandic Inuit hunted humpback whales from skin boats in much the same way they hunted bowhead whales. Humpback whales are slow-swimming whales, and the techniques used for bowhead whales were successful for humpbacks as well. Although Greenlandic bowhead hunting ceased in the mid-nineteenth century, humpback whaling continued until the 1980s.

In the 1920s, changing sea ice conditions caused food shortages among the Greenlandic Inuit who could no longer catch seals or humpback whales using traditional means. The Danish government operated a steel catcher boat, the Sonja, with a Danish crew from 1924 to 1949. The Sonja was able to catch larger and faster-swimming whales. In 1927 the Sonja caught 22 fin whales, 9 humpbacks, 7 blue whales (*Balaenoptera musculus*), and 2 sperm whales (*Physeter macrocephalus*). The meat was provided to Inuit of western Greenland and the blubber was shipped to Denmark, where it was rendered to oil and sold. In 1950, the Sonja was replaced with the larger Sonja Kaligtoq. From 1954 onward, the whales were taken to a single flensing station where meat and maktak were frozen for distribution and sale throughout Greenland. In addition to the government catcher boats, in 1948 some local fishermen began installing harpoon cannons on their boats and hunting whales. Fin and humpback whales were taken to the community where meat and maktak were sold. In the late 1980s the IWC eliminated the humpback whale quota, so fin and minke (*Balaenoptera acutorostrata*) whales are currently the only baleen whales that are hunted in Greenland.

D. Minke Whale

Minke whales have been hunted in Greenland since 1948. The minke whale hunt is now controlled by quotas set by the IWC and administered by the Greenland Home Rule Authority. The variable quotas consider the socioeconomic, cultural, and nutritional needs of the people and the regional abundance of whales. In the 1990s the quota varied from 110 to 175 per year. Minkes are hunted in summer and fall when ice conditions permit.

Hunts from fishing boats and small skiffs are opportunistic. Hunts take place from fishing boats whenever whales are sighted or

from skiffs when enough small boat hunters are available. Whalers on fishing boats use deck-mounted harpoon cannons, whereas those aboard skiffs use hand-thrown harpoons and rifles. In each case the whales are towed back to the community for flensing and distribution. Shares are distributed to the vessel owner and crew members, and a large share is reserved for the boat. Little personal share of meat or maktak is sold, but the boat share is sold to contribute to the cost of operating a commercial fishing boat. In the small skiff hunt, shares are divided equally among the participants of the hunt and those helping with the flensing.

III. Odontocetes

A. Beluga Whale (*Delphinapterus leucas*), qilalugaq

Beluga whales are hunted across their range in Chukotka, Alaska, Canada, and Greenland. Ancestors to the modern Inuit were involved in beluga hunting as early as 5500 years ago in Alaska (Freeman *et al.*, 1998). The techniques used by the ancestral Inuit are the same as those used in Alaska, Canada, and Greenland before contact with commercial whalers. Entire communities were involved in a collective whale hunt or drive. A shaman typically guided the hunt, which was led by a distinguished hunter from one of the communities involved. Freeman *et al.* (1998) quoted an elder from Escholtz Bay, Alaska, describing a traditional drive from around 1870: "They made a line and moved together. They hollered, splashed their paddles, waved their harpoons to scare them into real shallow water. . . . When a hunter got a beluga, he ties it to his qayaq (kayak) and brought it to shore; if he get two, he'd tie one on each side. . . . If wind came up while men were out hunting, women would take umiaqs (skin boats) off the racks and go to help those hunters who were towing two belugas. People always helped together when they landed and pulled those beluga on the shore." Friesen and Arnold (1995) determined that beluga whales were a focal resource for precontact Inuit of the Mackenzie delta, constituting up to 66% of their meat. Two or more hunters would cooperate in a beluga hunt. The whales were approached by hunters in kayaks who threw harpoons attached to sealskin floats. After the whale tired, it was lanced in the heart with a blade attached to one end of the kayak paddle. In some locations, hunters in kayaks working cooperatively would drive belugas into shallow water where they were killed. In northern Greenland, and possibly elsewhere, belugas were hunted at large cracks in the ice where the whales congregated to breathe.

In the eighteenth, nineteenth, and early twentieth centuries, Canadian Inuit were hired by commercial whaling enterprises to hunt belugas. Skins and blubber from the belugas were shipped to European markets. The Inuit hunters kept the meat and some of the maktak and received trade goods, which often included wooden boats.

Methods changed with the introduction of rifles, fiberglass and aluminum boats, and outboard motors. Today, hunters in Alaska use one of four methods to hunt belugas: harpooning or shooting from the ice edge in spring, shooting from motorized boats in open water, netting, or driving the whales into shallow water. Ice-edge hunting occurs during the northward migration, sometimes concurrently with bowhead whaling. Belugas can also be shot directly from shore if the migrating whales are close enough, as has happened in Barrow in some recent years. Open-water hunting is common in summer and fall when the ocean is free of ice. Netting occurs at headlands where predictable movement patterns make netting practical. Shallow water drives are most common in shallow bays and estuaries, such as Point Lay and Wainwright, Alaska.

Sealskin kayaks were last used to hunt belugas in the 1960s in communities in northern Quebec and the Belcher Islands. Now

hunters use skiffs or freighter canoes powered with outboard motors. Harpoons with detachable heads attached to floats are still used, although now floats are made from manmade materials rather than seal skins. Rifles (0.222–30.06 caliber) are used to kill the whales after harpoons have been attached.

Belugas are the most commonly and widely taken whale species in Canada (Freeman *et al.*, 1998). Beluga maktak is highly prized by Canadian Inuit. After a successful hunt the meat and maktak are distributed to family members and neighbors according to traditional customs. In some communities a successful hunt is announced over community radio and all community members are invited to collect a share. Because beluga maktak is so highly prized, very little of it is sold for redistribution through retail outlets in the Canadian Arctic. Beluga maktak is usually eaten raw and fresh, although some now deep-fry it. The meat is usually air dried before being eaten. In some communities, sausages are made by placing meat in sections of intestine that are lightly boiled before being dried or smoked. Beluga oil was used for lamp oil, softening skins, and cleaning and lubricating guns and other equipment.

Beluga hunting in Greenland has followed a history similar to hunting of other larger whale species. For many centuries, local hunters supplied meat and maktak to meet community needs. In colonial times, beluga blubber and oil became an important trade commodity. As a result, the Greenland Trade Department established commercial beluga drives and hired local hunters to carry out the hunt. Commercial drives continued until the 1950s when the European market for whale oil disappeared. Commercial whale drives reappeared in the 1960s when improved coastal communication and refrigeration made it possible to transport beluga meat and maktak from northern hunting communities to southern Greenland. Today, belugas are hunted with rifles (30.06 caliber to 7.62mm) from small boats. Typically, kayaks and motorized skiffs are used to hunt belugas, often singly or in pairs, but sometimes a larger number of small boats cooperate to hunt belugas swimming together. Meat and maktak are distributed throughout the community, including sale at the local market, and in retail stores throughout Greenland.

Beluga hunting in Russia only occurs in a few villages in Chukotka, and the numbers taken are small. Belugas in Russia are associated with the distribution of fish, especially arctic cod (*Arctogadus glacialis*) and arctic char (*Salvelinus alpinus*). Hunting occurs opportunistically when belugas are encountered during other activities. Hunting occurs either from shore or from the ice edge. Hunters hide behind hummocks of ice and shoot the whales with rifles (7.62 or 9mm). Meat is dried, frozen, boiled, or fried. Maktak is eaten raw, fresh, boiled, or fried. The skin is used for boot soles, belts, and lines. The oil is used with fish and salad plants. Historically, beluga oil was traded for reindeer (i.e., caribou) meat and skins, although when Soviet state-run fur farms were operating the oil was sold to the farms (Freeman *et al.*, 1998).

B. Narwhal (*Monodon monoceros*), qilalugaq tuugaalik

Narwhals have been hunted in Greenland and eastern Canada for centuries, and may have brought the Greenlandic Inuit in close contact with the Norse in Greenland beginning in the tenth century. Narwhal ivory was bartered among Inuit long before European contact. Narwhal tusks were highly valued by European traders in the Middle Ages, who sold the tusks in Europe mislabeled as unicorn horn, sometimes for their weight in gold. The royal throne of Denmark, from the fifteenth century, is made almost entirely of narwhal ivory. Narwhal tusks were the basis of trade between Greenlandic Inuit and Europeans from the 10th through the 19th

centuries, and were important to Canadian Inuit after the collapse of commercial bowhead whaling in the late nineteenth century. Inuit in Greenland and Canada used the tusks to create durable and functional tools, especially harpoon foreshafts.

Narwhals were hunted from kayaks either along the flow edge, in ice cracks, or in open water. Near ice, the narwhals were harpooned and hauled ashore. In open water, hunters worked together to drive the narwhals into shallow water where they were killed. Another method was to station hunters with rifles on cliffs who would shoot the whales as they swam by. Several hunters in kayaks would wait offshore and harpoon the whales once they were shot. Now, hunting in Canada takes place with small skiffs, rifles, and harpoons attached to floats. Narwhal hunting in northern Greenland is still accomplished with kayaks. Five-meter skiffs or 10–12 m cutters are used in southern Greenland, although occasionally narwhals are shot from shore or netted.

Maktak from narwhals is prized and is eaten fresh raw or aged. Narwhal oil was considered of higher quality than seal oil and was used in lamps for heat and light. The tusk remains the most highly prized product from narwhal. Today tusks are used for artwork or sold. Narwhal ivory sold for an average of \$100/foot (30 cm) in 1997 (Freeman *et al.*, 1998). Narwhal meat was used to feed hunters' dog teams.

IV. Other Small Cetaceans

Small numbers of other cetaceans are taken in eastern Canada and Greenland. The principal species taken in Canada are common bottlenose dolphin (*Tursiops truncatus*) and harbor porpoise (*Phocoena phocoena*). In Greenland, killer whales (*Orcinus orca*), long-finned pilot whales (*Globicephala melas*), northern bottlenose whales (*Hyperoodon ampullatus*), harbor porpoise, white-beaked dolphins (*Lagenorhynchus albirostris*), and Atlantic white-sided dolphins (*Lagenorhynchus acutus*) are taken.

V. Pinnipeds

A. Ringed Seal (*Pusa hispida*), natchiq; Bearded Seal, ugruk; and Harp Seal (*Pagophilus groenlandicus*)

Seals are probably the most widely distributed, abundant, and reliable food resource available to coastal Inuit populations. Ringed seals are available nearshore for much of the year. Bearded seals are also important, although less abundant and less widely available than ringed seals. They are important not only for their meat but also as a source of raw materials, particularly their hides (Jensen, 1987). Harp seals are seasonally very abundant in certain areas of Greenland and eastern Canada, and were taken when present. Ribbon seals (*Histiophoca fasciata*), Larga seals (*Phoca largha*), and harbor seals (*P. vitulina*) are only occasionally encountered. All of these pinnipeds are hunted in similar ways and have been combined for the following discussion.

Natchiq (ringed seal) are ice adapted. They are hunted at breathing holes, in subnivean lairs, on drift ice, and in open water. Other seals are not as ice adapted as the natchiq. They can also be hunted on drift ice and in open water. Harbor seals and Larga seals tend to stay away from ice if it is present in significant amounts. Ugruk are common on ice pans and commonly hunted on pans or in open water. Harbor seals tend to be more common than natchiq in more southerly areas (southern Greenland, Labrador), although they have been regarded as shy and also potentially aggressive. Harp seals were generally taken from kayaks in open water or when hauled out on

offshore drift ice, although they could be harpooned from shore or from the ice edge under certain circumstances.

Traditionally, natchiq were hunted at breathing holes on the ice, at pupping dens, while basking in the sun, by netting at the breathing hole, from the ice edge, or from boats in open water. Breathing-hole hunting was most common, as the ocean is ice covered for much of the year. Ringed seals carve out and maintain breathing holes in the ice throughout the winter. In flat ice the breathing holes may be visible from the surface, but often they are covered with snow, and practically invisible. Ringed seals maintain numerous breathing holes, so there was never any guarantee that a seal would visit the hole where the hunter was waiting.

Breathing-hole hunting was a difficult and cold endeavor, and is no longer practiced to any great extent anywhere in the Arctic. Boas (1964) presented an excellent description of pre-rifle seal hunting methods and equipment. A hunter would first locate a breathing hole with the use of one of his sled dogs. Once the hole was found, the hunter set up his equipment around the hole. The hunter sat on an ice block with his feet resting on a piece of fur or stood on the fur with his harpoon in his hand or at his side and waited for the seal to arrive at the breathing hole. There was never any way to determine how long the hunter would have to wait. If the village needed food, it was not uncommon for hunters to wait 24 h or longer for a seal to arrive. Now, more efficient and less strenuous methods are preferred.

When a seal arrives at a breathing hole, the first breath is a short, shallow sniff for any sign of danger. If the seal does not detect danger, the next breath will be deeper. On this second breath, the hunter thrust his harpoon straight down the hole, striking the seal on the head or neck. The toggling head detached, preventing the seal from escaping. The seal was killed and the breathing hole enlarged to pull the seal through. Once rifles became available, seals were shot when they came to the hole, then immediately harpooned to prevent the seal from drifting away or sinking.

After the breeding season, seals enlarge their breathing holes located on large areas of flat ice so they can climb out and bask in the sunshine. Traditionally, Inuit had several methods for hunting seals at this time, described in detail in Nelson (1969) and Boas (1964). A hunter might simply wait near one of the holes for a seal to surface. The water within the hole pulsates when a seal arrives at its hole. When the seal broke the surface of the water, it was speared or shot. Occasionally, hunters placed lines with several hooks along the wall of a breathing hole to catch seals backing into the water after surfacing.

Another traditional seal hunting technique required great stealth and skill. The hunter emulated the behavior of a seal, sliding along the ice on his side, often with a piece of sealskin beneath him to reduce friction and keep his clothing dry. Often hunters would scrape the ice with seal claws attached to a piece of wood to mimic the scratching sound made by resting seals. A skilled hunter could approach very close to a seal basking in the sun. In this way hunters were often able to kill 10–15 seals in 1 day. In a variant of this method, the hunter pushed a small sled with a white shield that hid him from the seals.

Seals could also be netted at their breathing holes. Netting was done at night to prevent the seal from seeing and avoiding the net. This also reduced the hunters' vision and exposed the hunter to many dangers. Four holes were cut around a breathing hole and the net lowered into the water to approximately 10 ft. Seals generally approach breathing holes along the surface, so they did not encounter the net. When the seals dove from the hole, they dove straight down and became entangled in the net. Seal netting was discontinued in the 1960s.

In spring, pregnant ringed seals hollow a natal den in the snow covering one of their breathing holes. Hunters again use one of their dogs to find the dens. The hunter cut a small hole in the wall of the den through which he could watch for the return of the mother seal. When the seal returned, the hunter jumped through the snow between the seal and its hole, trapping it. Prior to the introduction of rifles the seals were killed with a spear or club; later they were shot through the wall of the den.

Traditionally, ice-edge hunting was accomplished with a small harpoon that was thrown at seals swimming near the edge. A line was attached to the harpoon to retrieve struck seals. Hunters were limited by how far they could accurately throw the harpoons, usually 10–20 ft (Foote, 1992). The introduction of the rifle changed the nature of seal hunting. Hunting seals from the ice edge using rifles is easier and more efficient than breathing-hole hunting, and the range of the hunters has been increased greatly by the rifles. The increased range brought about two new inventions specifically for use in ice-edge rifle hunting: the retrieving hook (manaq or manaqtuun) and a small skin boat (umaiggaluuraq). The manaq consists of a rope up to 200-ft long, attached to a piece of wood with four hooks extruding from the sides. A float is attached to keep the hooks afloat for winter hunting (when seals float after being shot), and a sinker is attached for summer hunting to retrieve seals that sink to the bottom. Once a seal is shot, the hunter grabs his manaq to retrieve the seal from the water. The line is coiled and held in the left hand, while the right hand holds the line 3–5 ft from the hooks. The hook is thrown beyond the seal, the line is slowly drawn in until the hooks are near the seal, a sharp tug sinks the hooks into the hide, and the seal is carefully pulled to the ice edge.

The umaiggaluuraq (literally “small umiaq”) is 7–10 ft long and 36–40 in. wide (Nelson, 1969). Two bearded sealskins are used to cover a wooden frame. Once a hunter shoots a seal, he pulls the boat to the ice edge, often with the help of another hunter to prevent damage to the skins by dragging the boat. The boat is rowed to the seal with two short oars lashed to the gunwales. When the hunter reaches the seal, he tows it back to the ice edge with a small hook and line.

Open-water hunting and hunting of seals basking on drift ice became most popular after the introduction of rifles. Before rifles were introduced, hunters occasionally harpooned seals from kayaks, but only in calm water. After rifles and outboard motors became readily available, several men would hunt together from a single umiaq. The hunters were often members of the same whaling crew using the captain’s boat. Seals were shot with rifles ranging from 22 to 30.06 caliber and harpooned. Now, aluminum boats have replaced skin boats, but the same methods are used. Open-water hunting from aluminum boats is currently the most popular way to hunt both the ringed and the bearded seal in northern Alaska. Harpoons are still used in the Yukon-Kuskokwim Delta because people feel that shot seals sink too quickly. In Greenland, certain areas still forbid motorized boats in the hunt, although they may be used to travel to the hunting area.

B. Walrus, aiviq

Walrus are often associated with pack ice and are hunted when the pack ice is close to shore. They do haul out on shore in certain locations, and this may become more common as sea ice diminishes due to climate change. Nelson (1969) reported that hunters in Wainwright, Alaska, only traveled offshore as far as land was still visible on the horizon. However, Spencer (1959) reported that hunters in Barrow often traveled 50–100 miles into the ocean to find walrus. The distances traveled are probably dependent on the proximity of the pack ice to

shore and undoubtedly changed with the introduction of outboard motors.

Hunting walrus was, and remains, a collective hunt. The size of the walrus and the logistics of butchering and transporting the meat back to the village make it necessary for several hunters to work cooperatively. Traditionally, walrus were hunted using large harpoons similar to the harpoons used in bowhead whaling. Long lines, often made of walrus skin, were attached to the harpoons and fastened to a large piece of ice or were held by the hunter who used a smaller spear to drive the end of the line into the ice. Walrus were harpooned while they were lying on the ice. When the harpooned walrus dove, the line prevented it from escaping. When the walrus tired, it was killed with a lance through the heart. Occasionally, walrus were hunted from umiaqs when they were encountered away from the pack ice. In those circumstances, floats were attached to the line or the line was fastened to the umiaq. The walrus was killed with a lance once it tired. Nelson (1969) summarized an elder recounting one traditional method of hunting walrus in which two hunters harpooned two walrus facing opposite directions. The lines from the two harpoons were quickly tied together, and the walrus pulled against each other until they tired enough to be killed with lances through the neck. Now, large rifles are used instead of harpoons, but the methods used to approach the walrus are the same. When a walrus herd is sighted, the ice surrounding the herd is evaluated. There must be enough ice-free water to allow approach and to allow sufficient time for the killed walrus to be butchered before ice closes in.

Walrus are approached slowly with the outboard running. Generally, walrus are approached to within 10 ft before they are shot. All hunters shoot at the same time and continue the volley until enough have been taken or the herd escapes into the water. Walrus must be shot in the brain or the anterior portion of the spinal cord to insure a kill. Walrus will not float once killed, so any dead or seriously wounded walrus that fall into the water are considered struck and lost. Fay *et al.* (1994) reported that up to 42% of walrus struck in Alaskan hunts from 1952 to 1972 were lost. Wounded walrus are often dangerous, and Nelson (1969) recounted several instances in which wounded walrus damaged boats. In fact, walrus can be so aggressive that they have disrupted mail delivery by kayak and even forced the abandonment of a settlement in Greenland.

Walrus flippers “ripened” in seal oil are considered a delicacy in much of the Arctic. Select portions of meat are eaten, but the bulk of the walrus was used to feed the hunters’ dog teams. The skin, bones, and especially the tusks were the most valuable parts of the walrus. Walrus skins often replaced bearded seal skins on umiaqs in places where bearded seals were not abundant. Walrus skins were also used to create strong lines that were attached to harpoons used in seal, walrus, and whale hunting. The bones of walrus were used to make tools and mandibles were used as chocks in house construction. The ivory tusks were often used to make harpoon points and foreshafts. Now, ivory is used in artwork and much is sold to generate a cash income.

C. Polar Bear, nanuq

Polar bears are found throughout the Arctic and are hunted through much of their range. Polar bears remain on the pack ice for most of the year, and most hunting takes place during the winter on the pack ice. Polar bears are also taken opportunistically when they are encountered on land or in open water.

Polar bear hunting is considered one of the most dangerous hunting activities and successful hunters often enjoy high status

in village communities. Traditionally, single hunters using spears, lances, or knives hunted polar bears. Boas (1964) and Nelson (1969) both described polar bear hunts before the introduction of rifles. In the Canadian and Greenlandic Arctic, it was common to release dogs to chase the bears and tire them. Once the bears stopped, they were approached on foot and killed with lances or spears. Dogs were not used commonly in Alaska, but were released if the bears were on young, unsafe ice. Spears and lances were quickly given up once rifles became available.

Hunting for polar bears is now nearly always done on the sea ice, and hunters often travel far offshore to find bears. Walking used to be the preferred method of transportation because it offered the advantages of a silent approach and the ability to hide quickly among the ice hummocks and ridges. Now, snowmobiles are preferred. With snowmobiles, hunters can pull sleds to transport the meat and hide back to the village, eliminating the need to drag the hide and then return with dogs to transport the meat.

Hunters usually find tracks rather than finding the animal itself. From the tracks hunters can tell the size of the animal, its direction and speed, and how long ago the bear passed. Tracks are followed until the bear is sighted. The hunter can then either move quickly to overtake the bear or move ahead to wait in ambush. In either case, it is important to get as close to the bear as possible to ensure a lethal shot. Wounded polar bears are dangerous and sometimes attack the hunter. If the bear is in a position that the hunter cannot reach, the hunter will sometimes try to lure the bear closer by mimicking a sleeping seal. Once the bear stalks close enough, the hunter picks up his rifle and shoots. Sometimes hunters leave seal blood or blubber on the ice and return to the area later to see if any bears have been lured by the smell. When bears venture close to villages or whaling camps they are almost always shot.

Polar bears are hunted for both their meat and their hides, which are divided among the village according to local tradition. In Greenland, the person who sights the bear becomes its "owner" regardless of whether they participate in the hunt. Any other people who shoot the bear or touch it before it is killed also receive shares of the bear. In Alaska and Canada, shares were traditionally distributed widely within the village. A young hunter's first bear was shared among all the people in the hunting party or was distributed to the elders in the village if he was hunting alone. Now, the shares are distributed less formally, but meat is usually shared with family members and others outside the family. The successful hunter usually keeps the hide.

Polar bear meat is prized by many people in the Arctic. Meat is always well cooked to prevent trichinosis, and the liver is never eaten due to high concentrations of vitamin A. In Alaska the sale of polar bear hides is prohibited by the Marine Mammal Protection Act of 1972. Hides are used for clothing such as boots, mittens, or trim for parkas and also for sleeping mats when camping on the ice. In Greenland, polar bear skins were used for warm hunting pants, but now all skins are sold to Greenland's trading department. Since 1994, polar bear hunters in Greenland have been able to sell bear meat to restaurants and hotels.

VI. Conclusion

Inuit and their ancestors have hunted marine mammals for thousands of years. The technology and techniques of hunting marine mammals evolved in a culture intimately associated with the sea and the creatures that inhabit it. In modern times, the technology and techniques of hunting marine mammals have changed, but the cultural

importance remains, backed up by tradition, beliefs and a web of interlocking obligations. Marine mammal hunting provides access to status within the community and a sense of self-worth for a generation of Inuit struggling to cope with the burdens of cultural assimilation. The product of the hunt provides a sustainable healthy diet. There is every reason to believe that as circumstances continue to change, these subsistence and cultural practices will continue to thrive.

Irrawaddy Dolphin

Orcaella brevirostris

BRIAN D. SMITH

I. Characteristics and Taxonomy

A. Names and Taxonomic History

Vernacular names used for Irrawaddy dolphins include *ikan pesut* or *pesut Mahakam* in Kalimantan, Indonesia; *lumba lumba* in Malaysia; *pa kha* in Laos; *pla loma* (generic word for dolphin); *hooa baht* (monk's bowl, which refers to the resemblance of the dolphin's head) in Thailand; and *Labai* in Myanmar.

Orcaella has been placed in the monotypic family Orcellidae (Nishiwaki, 1963), the family Delphinapteridae along with the beluga, *Delphinapterus leucas* (Kasuya, 1973), and in the family Monodontidae that includes both the beluga and narwhal, *Monodon monoceros* (Barnes *et al.*, 1985). Concordant evidence from cladistic analysis of morphology (Arnold and Heinsohn, 1996) and genetics (Arnason and Gullberg, 1996; LeDuc, 1999) place the genus decisively in the family Delphinidae.

The species *Orcaella brevirostris* was recently split into two species based on concordant character differences in external features, osteology, and genetics (Beasley *et al.*, 2002, 2005) between the dolphins occurring in five freshwater systems and nearshore waters of Southeast Asia extending west across the Bay of Bengal and south along the east coast of India to Vishakhapatnam (now considered *O. brevirostris*) and those occurring in coastal waters of northern Australia and southern Papua New Guinea (the newly described Australian snub-fin dolphin *O. heinsohni*). Genetic evidence also supported the existence of two clades within *O. brevirostris*, one occurring in the Mekong River and the other from marine and freshwater sites in Indonesia, Philippines, and Thailand. With systematic examination of a larger sample of specimens there may prove to be additional phylogenetic/taxonomic structure within the species (LeDuc *et al.*, 1999; Beasley *et al.*, 2005).

This account addresses *O. brevirostris*, and caution should be exercised when referring to previous reviews of the “species” (Marsh *et al.*, 1989; Stacey and Arnold, 1999; Arnold, 2002) because much of the information in these pertains to *O. heinsohni*.

The nineteenth century naturalist Dr. John Anderson described Irrawaddy dolphins in the Ayeyarwady (formerly Irrawaddy from where the dolphin takes its common name) River as morphologically distinct from *O. brevirostris* and classified them as a separate species, *Orcella [sic.] fluminalis* based on an exhaustive lists of differences in anatomical features (Anderson, 1879). However, subsequent authors (Pilleri and Gihl, 1974) rejected Anderson's arguments because the features he described are variable among individuals and his comparisons were limited to two adult males from the Ayeyarwady and two females, one immature and one pregnant, from the Bay of Bengal.

B. External Characteristics

The Irrawaddy dolphin has a rounded head that overhangs the mouth, which is oriented at a posterior–dorsal angle toward the eye, and a crescent-shaped blowhole positioned to the left of midline (Fig. 1). A posterior neck crease is visible in some individuals, although this feature is apparently less distinct in the Irrawaddy dolphin compared to the Australian snub-fin dolphin. A shallow dorsal

Figure 1 Irrawaddy dolphin from Malampaya Sound in the Philippines. Notice the bulbous head, posterior neck crease, and rounded fin. Photograph by M. Matillano.

groove runs from the neck crease to the dorsal fin, a feature absent in the Australian snub-fin dolphin. In some larger individuals, a conspicuous dorsal hump underlies the dorsal groove; this feature may be sexually dimorphic. The dorsal fin is small, triangular, slightly falcate with a blunt tip, and located about 60% of the body length posterior to the tip of the upper jaw. The flippers have a convex leading edge and are relatively large for delphinids, about one-sixth of the total body length long and about half this length for the width. Span of the flukes is more than one-fourth the total body length, with a concave leading edge and median notch. The species is uniformly dark gray on the dorsal and lateral fields, with variable shading among individuals, and much lighter on the ventral field, which extends from the lower chin to the anus, giving the animals a two-toned appearance. This is in contrast to the tripartite coloration of the Australian snub-fin dolphin (Beasley *et al.*, 2005).

Body lengths of sexually mature Irrawaddy dolphins have been measured at 2.1–2.2 m for females and as large as 2.8 m for males. External morphometrics that differentiate the Irrawaddy dolphin from the Australian snub-fin dolphin include lesser total size and dorsal fin height and longer measurements for the tip of upper jaw to eye, tip of upper jaw to gape, tip of upper jaw to flipper, anterior margin of flipper, and maximum flipper width (Beasley *et al.*, 2005).

C. Skeletal Characteristics

Irrawaddy dolphins have 62–63 vertebrae (Lloze, 1973; Anderson, 1879), which is slightly less than the number reported for Australian snub-fin dolphins. Only the first two cervical vertebrae are fused and these have greatly reduced transverse processes, giving the head substantial mobility. The acromion process of the scapula is generally larger than the coracoid process, which appears to be the opposite in the Australian snub-finned dolphin (Beasley *et al.*, 2005).

The skull is globe-shaped with an expansive facial region and relatively short rostrum and mandibular symphysis. There are about 68 peg-like teeth, each about 1-cm long: 19 in the upper jaw and 15 in the lower jaw, although all of these may not be erupted. A unique characteristic of the skull is that the tympanoperiotic bones are attached to a triangular ventral pad located on the mastoid portion of the zygomatic arch, rather than within the cavity formed by the squamosal, exoccipital and basioccipital bones, such as the arrangement in other members of the Delphinidae (Stacey and Arnold, 1999).

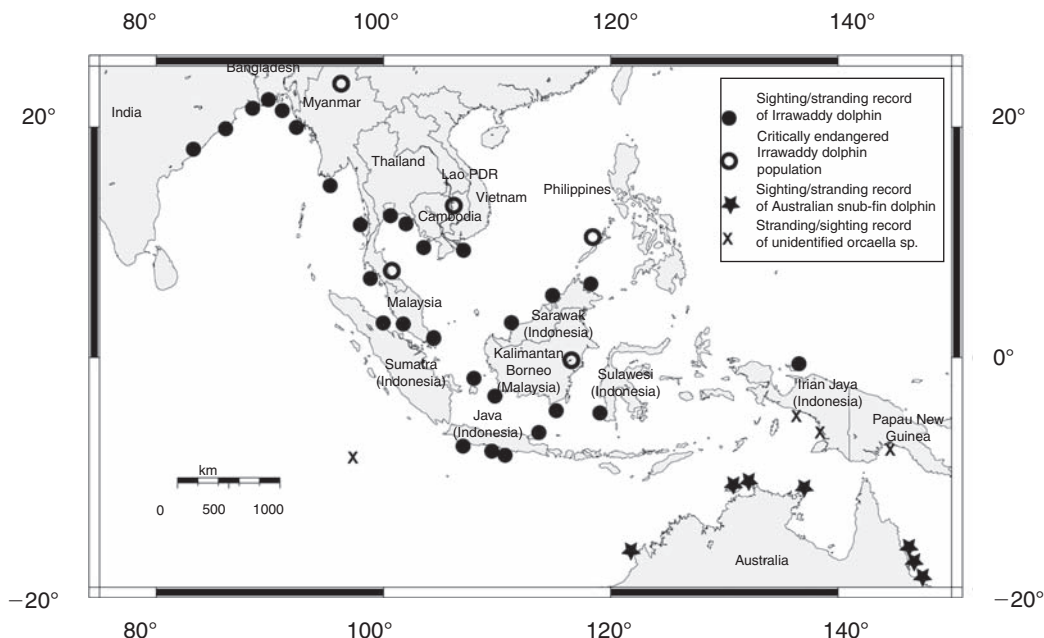

Figure 2 Distribution map for Irrawaddy and Australian snub-fin dolphins.

Cranial morphometrics differentiating the Irrawaddy dolphin from Australian snub-fin dolphin, in order of decreasing importance, include shorter length of antorbital process, shorter height of temporal fossa, shorter length of rostrum, smaller number of nasal bones/ossicles, less separation between the posterior margin of mesethmoid plate and anteriormost nasal bones/ossicles, shorter length of temporal fossa, smaller condylobasal length, greater minimum distance between pterygoid hamuli, greater depth of pterygoid region, and greater average width of nasal bones/ossicles (Beasley *et al.*, 2002).

II. Distribution and Abundance

Freshwater populations occur in three river systems: the Ayeyarwady (formerly Irrawaddy) of Myanmar (formerly Burma), Mahakam of Indonesia, and Mekong of Cambodia, Lao PDR and Vietnam. They also inhabit two partially isolated freshwater/brackish lakes or lagoons: Chilika of India and Songkhla of Thailand. All five freshwater populations are believed to be demographically isolated from members of the species occurring in marine waters (Fig. 2).

In the Ayeyarwady River (Fig. 3), the linear extent of Irrawaddy dolphin occurrence has declined by nearly 60% (or 488 km) since the nineteenth century and the animals are presently confined during the dry season to a 370-km river segment located about 1000 km from the sea upstream of Mandalay (Smith and Mya, 2007). Irrawaddy dolphins in the Mahakam River are generally confined to a 195-km river segment of the mainstem starting from about 180 km above the river mouth and inclusive of the lower reaches of the Kedang Rantau, Kedang Kepala, Belayan, Kedang Pahu, and Ratah tributaries and the southern portion of Semayang Lake (Kreb *et al.*, 2007). The range of Irrawaddy dolphins in the Mekong River is a 190-km river segment located about 500 km upstream of the river mouth in Kratie, Cambodia, to Khone Falls slightly upstream of the Lao PDR–Cambodia border (Beasley *et al.*, 2007). Dolphins previously

Figure 3 Irrawaddy dolphin surfacing after cooperating with a cast-net fisherman in the Ayeyarwady River, Myanmar.

inhabited Tonle Sap (Great Lake) in Cambodia but have apparently been extirpated there. In Chilika Lake, 66% of Irrawaddy dolphins sighted in 2003–2006 were concentrated in 16 km² of the outer channel. (Pattnaik *et al.*, 2007). In Songkhla Lake, 23 of 24 sightings between 2002 and 2004 were within 241 km² while 12 were within 27 km² of the mid-upper portion of Thale Luang, which constitutes the largest part of the lake (Kittiwattanawong *et al.*, 2007).

There are published records of strandings between Vishakhapatnam and Calcutta, India (Owen, 1869; James *et al.*, 1989; Pattnaik *et al.*, 2007) but little is known about the distribution of Irrawaddy dolphins in northeastern India. In Bangladesh, the species occurs in waterways of the Sundarbans Forest (Smith *et al.*, 2006) and in coastal waters offshore of the Sundarbans and Meghna River mouth (Smith *et al.*, in press-a). In Myanmar, Irrawaddy dolphins have been reported from a semi-enclosed bay offshore of the Kyaukpyu and Tinnasarim River mouths in the Mergui Archipelago (Smith *et al.* in press-b), in the Ayeyarwady Delta (Smith and Mya, 2007), and in the lower reaches and estuaries of the Myebone, Kalidan, and Kyaukpyu Rivers along the Rakhine (Arakan) coast (Smith *et al.*, 1997). The species occurs in nearshore waters of Thailand, in the Gulf of Thailand at the mouths of the Chao Phraya, Mae Nam Chin, Chanthaburi and Pattani Rivers, and was reported by fishermen to occur in Phang Nga Bay and in certain areas of the Andaman Sea (Chantrapornsyl *et al.*, 1996). Irrawaddy dolphins occur in marine waters of Cambodia along the coast of the Koh Kong Province, Kompong Som Bay, and Raem National Park (Perrin *et al.*, 2005). The species has been recorded in the Belawan Deli River of northeastern Sumatra, and Belitung Island and Cilacap of southern Java, in Surabaya of northeastern Java, in Ujung Pandang or Makassar of Sulawesi, and around Biak Island and various river mouths of the southwestern coast of Irian Jaya (Mörzer Bruyns, 1966). In northern and eastern Borneo of Malaysia and Brunei, Irrawaddy dolphins have been recorded in coastal waters near Muara Island, in Sandakan and Kuching Bays, and in the mouths of the Brunei, Sarawak, Rajang, Kinabatangan, Baram, and Batang Rivers (Mörzer Bruyns, 1966; Beasley and Jefferson, 1997; Dolar *et al.*, 1997). The only records from southern Borneo in Indonesia, outside of the Mahakam River (discussed earlier), are second-hand reports from the Kumay and Kendawangan River mouths (Rudolph *et al.*, 1997). A small isolated population also occurs in Malampaya Sound, Philippines (Dolar *et al.* 2002).

Rigorous abundance estimates are available for only a few portions of the species' range: 77 (CV 27%) in Malampaya Sound, Philippines (Smith *et al.*, 2004a); at least 127 (CV = 7%) in the Mekong River (Beasley *et al.*, 2007); 70 (CV = 10%) in the Mahakam River, Indonesia (Kreb *et al.*, 2007); 58–72 in the Ayeyarwady River, Myanmar (Smith *et al.*, 2007); 62–98 in Chilika Lake, India (Pattnaik *et al.*, 2007); 5383 (CV = 40%) in freshwater affected coastal waters of Bangladesh (Smith *et al.*, in press-a); and 451 (CV = 10%) in waterways of the Sundarbans mangrove forest of Bangladesh (Smith *et al.*, 2006).

III. Ecology

Irrawaddy dolphins are adapted to relatively rare and patchily distributed ecological conditions—deep pools of large rivers and nearshore marine environments (including appended lakes or lagoons) with freshwater inputs. Sighting data from waterways of the Sundarbans mangrove forest in Bangladesh show clear seasonal movements in response to changes in freshwater input, with the species moving seasonally along a south–west/north–east axis following the salinity gradient (Smith *et al.*, 2006). High salinity does not appear, however, to have direct adverse effects on the species, because in

Malampaya Sound there was no difference between the mean salinity values recorded for the outer and inner portions when freshwater inputs were particularly low, while the dolphins remained confined to the latter area. This implies that the affinity of the dolphins for low-salinity waters is likely due to ecological preferences (probably related to prey) rather than physiological intolerance to high-salinity conditions (Smith *et al.*, 2004a).

IV. Behavior and Physiology

Surfacing behavior is relatively inconspicuous, with only the uppermost dorsal surface of the animal generally becoming visible during a slow rolling dive. Leaps are infrequent but occasionally occur when the dolphins are disturbed, socializing or swimming against a strong current. Spyhopping, body rubbing, and tail slaps are also sometimes observed. The animals occasionally engage in water spitting where a narrow, well-directed stream is expelled from the mouth to a distance of 1–2 m. This behavior is believed to be associated with feeding and is sometimes used in the context of social interactions (Smith *et al.*, 1997). Irrawaddy dolphins are not known to bowride.

Reported mean group sizes vary but are normally between 2 and 6 individuals, with up to 15 when two or more groups come together. In the Mahakam River, the average daily home range of 27 groups followed for more than 6 h was 10 linear km, and the ranges for 53 photoidentified dolphins over a 3.5-year period averaged 61 linear km (Kreb *et al.*, 2007).

Vocalizations from two captive Irrawaddy dolphins were fairly basic, with a dominant frequency of about 60 kHz emitted in short pulses of 25–30 μ sec. These pulse trains, believed to be used for echolocation, were fairly regular and no audible whistles or pure tones were detected (Kammings *et al.*, 1983).

In the Ayeyarwady River (Fig. 3), the dolphins engage in a cooperative fishery with cast-net fishermen. During this fishing practice, fishermen search for dolphins and summon them by tapping the sides of their boat with a conical wooden pin called a *labai kway*. One or two lead dolphins then swim in smaller and smaller semi-circles, herding the fish toward the shore. With a wave of their half-submerged flukes, the dolphins deliver a concentrated mass of fish to the fishermen. During cooperative fishing the animals often dive steeply with flukes aloft just after the net is thrown and create turbulence under the surface around the outside of the net. The dolphins appear to benefit from the fishing activity by preying on fish whose movements are confused by the sinking net and those that are momentarily trapped around the edges of the lead line or stuck on the mud bottom just after the net is pulled up (Smith *et al.*, 2007).

V. Life History

Based on observations in captivity, gestation is believed to last about 14 months and weaning occurs at about 2 years. Births are believed to peak in the pre-monsoon season (April–June) but may take place year-round. A 210-cm female dolphin from the Bay of Bengal near Calcutta was recorded by Anderson (1879) with an 86-cm fetus in June, and a 105-cm newborn was recorded in the Mekong in May (Stacey and Leatherwood, 1997).

VI. Interactions with Humans

A. Threats

Irrawaddy dolphins have been documented accidentally caught in fishing nets in almost all areas where they have been studied. In the

Mekong River, 13 of 15 deaths caused by humans between 2001 and 2005 were due to gillnet entanglement (Beasley *et al.*, 2007), and in the Mahakam River 32 of 48 deaths caused by humans between 1995 and 2005 were due to gillnet entanglement (Kreb *et al.*, 2007). Mortality from drifting gillnets has also been documented in nets targeting elasmobranchs in coastal waters of Bangladesh (Smith *et al.*, in press-a) and in bottom-set nylon gillnets used for catching crabs in Malampaya Sound, Philippines (Smith *et al.*, 2004a).

Fishing with electricity is considered the direst threat to Irrawaddy dolphins in the Ayeyarwady River. This destructive technique has been cited as being responsible for the largest number of recent known deaths of the baiji *Lipotes vexillifer* (Zhang *et al.*, 2003), a freshwater dolphin that now may be extinct (Dalton, 2006).

Many dams have been proposed that may adversely affect Irrawaddy dolphins in the Mekong River Basin. Of greatest concern are the large run-of-the-river dams proposed for the Mekong mainstem near Stung Treng and Sambor (Perrin *et al.*, 1996). In waterways of the Sundarbans mangrove forest, the dependence of the Irrawaddy dolphins on relatively deep waters and channel confluences suggests that the animals may be particularly susceptible to habitat loss from increased sedimentation caused by declining freshwater supplies due to upstream withdrawals (Smith *et al.*, in press-c).

Increased sedimentation resulting from deforestation of surrounding watersheds has resulted in decline of water depths in Songkhla, Chilika, and Semayang Lakes. A source of habitat loss and population fragmentation in several areas has also been the proliferation of fixed fishing gears. In the middle and southern portions of Songkhla Lake about 40,000 fixed fishing nets create more than 8000 km of linear barrier in multiple rows. These fishing structures restrict dolphin movements such that their habitat is substantially reduced and the potential for demographic interaction with individuals in the Gulf of Thailand is eliminated (Smith *et al.*, 2004b). Fixed fishing gears also occupy most parts of Semayang Lake and limit dolphin movements to a narrow, dredged channel that is subject to intensive vessel traffic (Kreb *et al.*, 2007).

Removal from the wild for live display is an additional threat. The charismatic appearance of Irrawaddy dolphins and behavioral characteristics they exhibit in the wild (e.g., spitting water, spyhopping, fluke-slapping, etc.) make them especially attractive for live displays. Irrawaddy dolphins are also the subject of nature tourism programs in the Mekong River and Chilika Lake. Although this form of tourism has in some cases been promoted as a substitute for captive displays, in the latter two situations there is concern that collisions with dolphin watching vessels and harassment caused by this activity may threaten the viability of these populations (Smith *et al.*, 2007).

B. Conservation

The Irrawaddy dolphin is classified in the IUCN Red List as Vulnerable (VU), and five geographically isolated populations (in Malampaya Sound, Philippines, Chilika Lake, India, Ayeyarwady River, Myanmar, Mahakam River, Indonesia, and Mekong River, Lao PDR, Cambodia, and Vietnam) are listed as “Critically Endangered” (IUCN, 2008). Irrawaddy dolphins are included in CITES Appendix I in response to concern about the potential for international trade in live specimens to adversely affect wild populations.

Directed taking of cetaceans is prohibited in Bangladesh, India, Laos, Malaysia, Myanmar, and Thailand. The legal status of Irrawaddy dolphins in Indonesia, and Timor Leste is unclear. In Cambodia, a new fisheries law and royal decree will provide protection

to all cetaceans. In Vietnam, all cetaceans are protected by a decree of the national assembly. Some cetaceans are given legal protection in the Philippines, but as of 2002 Irrawaddy dolphins were not included in the list of species (Perrin *et al.*, 2005).

Although a few areas where the species occurs have been designated as protected, little has been done to conserve dolphin habitat. Malampaya Sound in the Philippines was proclaimed a Protected Seascape in 2000, but this is the lowest possible national prioritization given to a protected area (Smith *et al.*, 2004-a). Portions of Irrawaddy dolphin habitat in the Sundarbans Delta of Bangladesh and India are included within Protected Forests and UNESCO World Heritage Sites but no specific provisions have been implemented for conserving dolphins or their habitat. The Cambodian Department of Fisheries has drafted a Royal Decree for protection of Irrawaddy dolphins in the Mekong River, which includes the designation of eight protected areas (5721 ha) in a 190-km segment of the river above Kratie (Beasley *et al.*, 2007). In December 2005, the Department of Fisheries, Myanmar, announced the establishment of a protected area for Irrawaddy dolphins in a 74-km segment of the Ayeyarwady River between Mingun and Kyaukmyaung. Protective measures in the area include requiring fishermen to immediately release dolphins if found alive and entangled in their nets and prohibiting the catching or killing of dolphins and trade in whole or parts of them and the use of electricity fishing and gill nets that obstruct the water-course, are more than 300-ft long, or spaced less than 600 ft apart (Smith and Mya, 2007).

J

Japanese Whaling

TOSHIO KASUYA

Whaling is a fishing activity that targets whales, but the term does not often fit because of the ambiguity of *whale*, sometimes construed to exclude small cetaceans. This is also true in Japanese whaling. This chapter adopts the broadest meaning for the term Japanese whaling to include activities of hunting any cetaceans in Japanese territory, by Japanese companies, or by any companies known to be sponsored by them.

I. Subsistence Whaling

Numerous bones of gregarious dolphins in a site of the Jomon Era (10,000 BP–3200 BC) on the Noto coasts, Sea of Japan, suggest the presence of a drive fishery. Other sites of similar antiquity on the Pacific coasts of central and northern Japan and on the coasts of northern Kyushu facing the Sea of Japan/East China Sea revealed remains of small cetaceans and detachable harpoon heads. The Okhotsk Sea culture of Hokkaido in the fifth to fourteenth centuries left skeletons, harpoons, and drawings depicting whale harpooning. Ainu people on Uchiura Bay, Pacific coast of southern Hokkaido, opportunistically hunted whales in the late nineteenth century using aconite-poisoned detachable harpoon heads and floats. Skeletal remains from these sites represent at least 13 species of cetaceans: North Pacific right whale (*Eubalaena japonica*), common minke whale (*Balaenoptera acutorostrata*), sei whale (*B. borealis*), humpback whale (*Megaptera novaeangliae*), sperm whale (*Physeter macrocephalus*), false killer whale (*Pseudorca crassidens*), long-finned pilot whale (*Globicephala melas*), Pacific white-sided dolphin (*Lagenorhynchus obliquidens*), common dolphin (*Delphinus* sp.), common bottlenose dolphin (*Tursiops truncatus*), Dall's porpoise (*Phocoenoides dalli*), harbor porpoise (*Phocoena phocoena*), and unidentified beaked whales (Ziphiidae) (Kasuya, 1975). Differentiation of whales hunted from those stranded, however, is often difficult.

II. Traditional Commercial Whaling

Harpooning whales that are found in a harbor could have taken place widely. Records of such takes in a harbor at Ine, Sea of Japan, included 167 humpback, 148 fin (*Balaenoptera physalus*), and 40 right whales in the period 1656–1913 (Omura, 1984). A village next to Ine took small cetaceans in the same way. A similar fishery was also recorded in the fourteenth century at villages on Tsushima Island, off northern Kyushu. A cooking recipe in 1489 recommended whale meat for noble guests.

Records of “harpoon whaling” started in the 1570s at Morosaki at the entrance of Mikawa Bay, a bay attached to Ise Bay that opens to the Pacific. The whalers first used light harpoons with a detachable head and line. Harpoons with fixed heads and lancing followed. The winter operation continued to the early 1800s and took gray (*Eschrichtius robustus*) and humpback whales for oil and meat. This practice soon spread eastward to Katsuyama at the entrance of Tokyo Bay for Baird's beaked whales (*Berardius bairdii*) and survived until the late nineteenth century (Fig. 1). It also spread westward to the nearby Ise and Kii areas (before 1606), Shikoku (1624), northern Kyushu (1630s), and Nagato (around 1672) (Hashiura, 1969).

Harpoon whaling on the Ise and Kii coasts mostly ceased before 1770. A whaling group at Taiji, Kii was an exception. They modified old harpoon whaling learned from Morosaki in 1606 into new “net whaling” in 1677 (Fig. 2). During the whaling season (winter and spring), harpoon boats waited offshore for a signal from the spotters on cliffs. Receiving signals by flag and smoke indicating species, number, and position of whales, they drove the whales toward the shore where net boats waited to place nets in front of the whales to entangle them. Then the procedures of harpoon whaling followed, i.e., harpooners threw harpoons (fixed head) and lances followed. When a whale became weak, a harpooner swam to the whale to tie ropes through holes made near the blowholes and the back of the body to prevent the carcass from sinking. Boats on each side of the whale towed it, using these ropes and additional ropes that surrounded the body, to the beach for flensing. This method spread to Shikoku (1681) and northern Kyushu (1684). The preference was to harpoon calves first and then their mothers to secure both with ease.

American and European sailing whalers operated off Japan after around 1820. A decline in Japanese coastal whaling became evident in the late nineteenth century, and some whaling groups started modern Norwegian-type whaling, whereas others attempted to improve their traditional method. A few net whalers moved to new grounds in Hokkaido and southern Sakhalin and took gray whales (Hattori, 1887–1888).

Meat and most of the blubber were sold for human consumption fresh or salted. Oil was extracted from chopped bones and some BLUBBER and was used for lighting, for human consumption, and as a pesticide in rice paddies nationwide in Japan.

The traditional whaling was very labor intensive and inefficient. A Tsuru group in Shikoku in the late 1890s used 15 harpoon boats, 2 whale towers, and 14 net boats. The total full-time workers were 356, including 10 whale spotters, 12 flensers, 2 carpenters, 1 cooper, and 2 blacksmiths (Yanada, 1902). Another group in Nagato recorded 587 workers in the early 1800s. Each group took low tens of whales yearly (Table I). Annual expenditures of 12,423–15,864 yen made a profit of 987–25,640 yen (mean 9778) for a group at Kawajiri, Nagato, during 1884–1893 (Tada, 1978).

III. Modern Coastal Whaling

A Russian, A. Dydymov, started modern Norwegian-type whaling in the western North Pacific in 1889 using a land station east of Vladivostok, Russia. In 1891, the Pacific Whaling Company was established at Vladivostok and operated from the Korean to Sakhalin coasts (Tonnessen and Johnsen, 1982). Large amounts of whale meat sold by Russians at Nagasaki stimulated the Japanese to begin similar operations. After several attempts that caught the first whales in 1898 and survived only for a short period, Nihon Enyo Gyogyo (Japan Far Seas Fishery) founded in 1899 at Senzaki, Nagato established modern whaling in Japan using Norwegian gunners. The company expanded the business and renamed themselves Toyo Gyogyo (Oriental Fishery)

TABLE I
Number of Whales Taken by Japanese Net Whaling at Kawajiri (Tada, 1978) and Tsuru (Yamada, 1902)^a

Seasons	Humpback	Right	Gray	Blue	Fin	Bryde's	Total
<i>Kawajiri, Nagato</i>							
1698–1737	391(9.8)	105(2.6)	60(1.5)		22(0.6)		518(13.0)
1738–1840 ^b	304(5.4)	113(2.0)	72(1.3)		3(0.1)		492(8.8)
1845–1889	198(5.0)	39(1.0)	37(0.9)		131(3.3)		405(10.1)
1894–1901	28(3.5)	7(0.9)	9(1.1)		55(6.9)		99(12.4)
<i>Tsuru, Shikoku</i>							
1849–1865	209(12.3)	19(1.1)	101(5.9)	5(0.3)	0(0)	35(2.1)	369(21.7)
1874–1890	108(6.4)	21(1.2)	82(4.8)	24(1.4)	9(0.5)	41(2.4)	285(16.8)
1891–1896	26(4.3)	2(0.3)	18(3.0)	18(3.0)	5(0.8)	31(0.5)	100(16.7)

^aAverage annual catches are in parentheses.

^bRecords for 47 years in this period are missing.

in 1904, absorbing other whaling companies. In 1908, a total of 12 modern whaling companies operated using 28 catcher boats. Toyo Gyogyo and five others merged in 1909 to form the new Toyo Hogeï (Oriental Whaling), which owned 20 land stations (3 in Korea) and 21 whale catcher boats. Six others remained independent. Data on whales taken by them are not available by species, but comparison with later records throws some light on the species and cetacean fauna during earlier whaling (Table II) (Akashi, 1910).

In November 1909, the Japanese government placed hunting of sperm and baleen whales other than minke whales under its control and limited catcher boats to 30 (Omura *et al.*, 1942). This was further decreased to 25 (1934–1963) and to 5 (1984) in several steps (Kondo, 2001). On June 8, 1938, Japan enacted the protection of certain whales, i.e., cows accompanied by calves and whales below minimum size limits. However, it allowed the taking of right and gray whales, and the size limits, particularly for blue whales (*B. musculus*), were smaller than those existing in international agreements. In November 1945, Japan adopted for all the whaling activities international regulations of the time by the order of the General Headquarters of Allied Forces (GHQ) and joined the International Convention for the Regulation of Whaling of 1946 in April 1951 (before the Peace Treaty).

Postwar coastal whaling started in September 1945 and continued until March 1988 by five major companies using a maximum of 20 land stations (Fig. 1) on the four major islands of Japan. Use of a land station on Hahajima Island, Bonin Islands, started in 1981 to take the then increased Bryde's whale (*B. edeni*) quota and continued to 1987. This whaling was called large-type whaling to distinguish it from small-type whaling established in December 1947 (Ohsumi, 1975). The fishing season and land stations used changed over time. The last season of the fishery (1987/1988) used a land station in the Bonin Islands for 317 Bryde's whales, and four stations at Yamada and Ayukawa (both in Sanriku), Wadaura (Boso), and Taiji (Kii) took 188 sperm whales.

Japan started a national sperm whale quota in 1959. The quota for the North Pacific whaling countries (Canada, Japan, USA, and the USSR) replaced this starting in 1971. The four countries set quotas for fin, sei, and Bryde's whales in 1969; these were replaced by quotas of the International Whaling Commission (IWC) in 1972. The IWC prohibitions by species and dates of enforcement were blue (1965), humpback (1966), and fin and sei whales (1976).

Maximum annual catches by species since 1911 and their dates are 300 blue (1911); 1043 fin, 160 humpback, and 155 gray whales (1914); 14 right whales (1932); 1035 sei whales (1959); 504 Bryde's

whales (1962); and 3747 sperm whales (1968). The whaling companies manipulated coastal statistics, particularly for sperm whales and Bryde's whales (Kasuya, 1999).

IV. Pelagic Whaling in the Antarctic

A. Before World War II

In 1934, Nihon Hogeï ("Japan Whaling", renamed from "Toyo Hogeï" in 1934), which merged with Nihon Suisan in 1937, purchased the Norwegian factory ship *Antarctic* (9600 tons) and five catcher boats for £55,000, which was three times the profit from one Japanese Antarctic fleet in 1937/1938. On the way to Japan the *Antarctic* and three catcher boats operated from December 1934 and took 213 whales. This was the first Japanese Antarctic operation. This company built a second fleet in 1936/1937 and a third one in 1937/1938 (Itabashi, 1987).

Hayashikane Shoten, the antecedent of Taiyo Gyogyo (Ocean Fisheries), sent the *Nisshinmaru* fleet to the Antarctic in the 1936/1937 season and had a second fleet in 1937/1938. Kyokuyo Hogeï (Polar Sea Whaling) sent the *Kyokuyomaru* fleet in the 1938/1939 season. Thus, the total Japanese Antarctic operation increased to six factory ships in 5 years.

The Japanese government enacted regulations of pelagic whaling on June 8, 1938, including a fishing season from November 1 to March 15; protection of gray whales and right whales (*Eubalaena* spp) (except for the North Pacific north of 20°N) and cows accompanied by calves; minimum size limits; processing within 36h; and full utilization of the catch. This differed from international agreements of the time in a season about 6 weeks longer and the blue whale size limit about 1.4m shorter, allowing taking of blue whales that migrated earlier in the season.

The main product of these operations was whale oil for export. The government strictly limited the importation of Antarctic whale meat until the 1939/1940 season to protect coastal whaling. Some of the whale oil of the last two seasons (1939/1940 and 1940/1941) was landed in northern Korea and was exported to Germany via Siberia (Tokuyama, 1992).

B. Postwar Operations

In order to feed the starving Japanese population, GHQ issued a permit for Antarctic whaling in August 1946. Taiyo Gyogyo converted an oil tanker into *Nisshinmaru No. 1* and Nihon Suisan another vessel to *Hashidatamaru*. These fleets caught 932 BWU, or 6% of the world catch of the 1946/1947 season, and produced 12,260 tons

^bBryde's whales.

^cMostly Bryde's whales.

^dMostly sei whales.

of whale oil and 22,167 tons of other edible products. The meat production resulted in total products of 36.9 tons/BWU, almost double the maximum prewar production of 19.0 ton/BWU. Whale meat became an important product of Japanese whaling. Kyokuyo Hogeï sent the *Baikarumaru* fleet for sperm whales only in 1951/1952, before it returned to the Antarctic in 1956/1957.

Although world Antarctic fleets recorded an increase from 9 (1946/1947) to 21 (1960/1961–1961/1962) and a subsequent decline, the decline of Japanese fleets was slightly slower, i.e., from a peak of 7 fleets in 1960/1961–1964/1965 to 1 in 1977/1978–1986/1987. In 1956, Japan purchased a foreign fleet to expand its operation. The objective of the purchases changed in 1962, when Japan got a quota allocation of 33%, and a further increase was permitted with the fleet purchase (Tonnessen and Johnsen, 1982). Out of 9 fleets purchased by Japan in the postwar period, 4 were for their quotas.

The total Japanese fleet and number of workers involved varied by quota and species hunted. The *Nisshinmaru No. 1* fleet in the 1950/1951 season, when it processed 631 blue and 1014 fin whales, had 348 persons on the factory ship, 604 on three freezing and salting vessels, and 197 on nine catcher boats. The total was 1149 (Tokuyama, 1992).

Takes of significant numbers of sei whales started in 1949/1950 and reached a maximum of 11,310 in 1965/1966, and that of minke whales (*B. acutorostrata* subsp. and *B. bonaerensis*) started in 1971/1972 and reached 3950 in 1976/1977.

Three Antarctic whaling companies split off their whaling sections to merge them into a new company, Nihon Kyodo Hogeï (Japan Union Whaling) in 1976. The new company sent two fleets to the Antarctic in 1976/1977 and one in 1977/1978 to 1986/1987. The last two seasons were operated under objection to the IWC moratorium on commercial whaling.

Southern humpback whales were completely protected as of 1963/1964, "true" blue whales as of 1963/1964, all southern blue whales as of 1964/1965, fin whales as of 1976/1977, sei whales as of 1978/1979, and sperm whales as of 1981/1982.

V. Pelagic Whaling in the North Pacific

A. Before World War II

The *Tonanmaru* fleet was sent out in the 1940 and 1941 seasons by Hokuyo Hogeï (Northern Sea Whaling), established jointly by three whaling companies, and caught 74 blue, 659 fin, 114 humpback, 9 sei, 333 sperm, 58 gray, and 4 North Pacific right whales in the two seasons off southern Kamchatka and in the Bering and Chukchi Seas (Maeda and Teraoka, 1952).

B. Postwar, off the Bonin Islands

Whaling had been operated in 1923–1944 using land stations on the Bonin Islands (Ogasawara Islands) for humpback, Bryde's,

Figure 1 Location of major land stations used by Japanese whaling. Closed circles represent harpoon or net whaling, open circles represent large-type whaling during pre- and postwar periods, and arrows indicate five land station currently in use by small-type whaling.

and sperm whales, but the 1945 permit of the GHQ to whale off the Bonin Islands prohibited the use of land stations. Therefore, Taiyo Gyogyo converted a navy vessel to a factory ship and whaled in March–April 1946. The number of fleets and companies involved subsequently varied by season; the last fleet was sent out in 1951. In 1952, pelagic whaling started in the northern North Pacific, and operations off the Bonin Islands ceased. In the six seasons they took 923 Bryde's, 606 sperm, and 29 other whales. Only 20 humpback whales were taken because of the offshore nature of the operations (Maeda and Teraoka, 1952).

C. Northern North Pacific

The Peace Treaty came into effect in April 1952, and Japan sent out the *Baikarumaru* fleet to the North Pacific. The fleets increased to two in 1954 and three in 1962, and then in 1976–1979 only the Kyodo Hogeï fleet remained. The operation was a joint venture of most of

the Japanese whaling companies; Kyokuyo Hogeï, Nihon Suisan, and Taiyo Gyogyo were the major ones. Factory ships and quotas changed frequently (Tato, 1985). The IWC ban on pelagic whaling for species other than minke whales came into effect in the 1979/1980 Antarctic and 1980 northern summer season. The first national quota of 350 BWU was for a 1-year test operation by one of the two fleets in 1954. This was followed by a blue whale quota of 70 (1955–1961) or 60 (1962–1965) and quotas of about 800 BWU (1957–1964) and 1000 BWU (1965–1968) for species other than blue whales. Sperm whale quotas were from 1500 to 1800 (1957–1961), 2460 to 2700 (1962–1965), and 3000 (1965–1968).

The North Pacific whaling countries set quotas by species in 1969, which were followed by quotas of the IWC, as of 1971 for baleen whales and 1972 for all large whales. The IWC has protected blue and humpback whales since 1966 and fin and sei whales since 1976.

Figure 2 A scene of net whaling (from Oyamada, 1832). A harpooner is climbing on a humpback whale to attach a line to the animal. Boats are ready to kill the animals with lances.

The *Miwamaru*, a whale catcher–factory ship, operated in the 1973–1975 seasons and reported takes of 279 common minke and 6 Baird’s beaked whales. The operation was not inspected, and caution should be taken in accepting the statistics.

VI. Whaling under Foreign Jurisdiction

Since 1957, Japanese whaling has expanded into foreign territories (Tato, 1985), presumably for new whale stocks, efficient vessel allocation, unregulated operation, or for new business opportunities.

A. Taiwan, 1957–1959

Taiwan was outside the ICRW. Kyokuyo Hogeï whaled for two seasons jointly with a local company using a land station in southern Taiwan but took only 29 humpbacks and a sperm whale. The Taiwanese partner operated for a few additional years.

B. Okinawa, 1958–1965

Under supervision of the US military, the Ryukyu government governed the Ryukyu Islands from the end of World War II to 1972, when the islands were returned to Japan. Hand-harpoon fishermen at Okinawa took humpback whales using harpoon guns beginning around 1950. In 1958, the Ryukyu government introduced IWC regulations. Only a group of Nago fishermen and two other local companies got the new licenses. Two Japanese whaling companies, Taiyo Gyogyo and Nitto Hogeï, offered crew and catcher boats to each of the latter. The land stations were at Nago, Sashiki, and Itoman. In addition to catches of 52 humpback whales by the Nago group (1950–1957), the three groups took 788 humpback, 31 sperm, and 1 Bryde’s whale in 1958–1965.

C. Brazil, 1959–1984

Two groups whaled off Brazil, each inviting a Brazilian partner. The Taiyo group whaled in 1960–1963 from a land station at Cabo Frio, and the Nichirei group in 1959–1984 from Costina. Catches were mostly sei whales in 1959–1964 (3214 whales in the six seasons) and then shifted to minke whales (*B. spp.*) with a maximum recorded catch of 1036 in 1975. Sperm, fin, and blue whales were also taken (decreasing order). Some of the supposed sei whales were Bryde’s whales.

D. Canada, 1962–1972

Japanese whalers operated jointly with Canadian partners off Newfoundland and Vancouver Island. The Taiyo group operated in 1962–1967 using a land station at Coal Harbor, Vancouver Island, and caught mostly sei (2153), sperm (1108), and fin (837) whales, but some blue and humpback whales were also taken. Off Newfoundland, the Kyokuyo group operated in 1966–1972 using a land station at Dildo, and the Taiyo group in 1967–1972 using a Williams Port station. Their catch was mostly fin whales (1168) and a few humpback, sei, and sperm whales. The Canadian government closed commercial whaling in 1973.

E. South Georgia, 1963/1964–1965/1966

Two Japanese expeditions operated using South Georgian land stations leased from the United Kingdom. Their total catches were 1273 fin, 919 sei, and 218 sperm whales. Under international pressure, the United Kingdom agreed at the 1966 IWC conference to voluntarily retain the South Georgian catches at or below the level of the 1964/1965 seasons. This terminated Japanese expeditions.

F. Chile, 1964–1968

Chile, Peru, and Ecuador jointly regulated whaling in their territorial waters until 1979, when Chile and Peru joined the ICRW. Nitto Whaling and its local partner whaled using one or two land stations and took 516 blue, 582 fin, 1061 sei, and 1221 sperm whales. The catch of blue whales occurred only in 1965 and 1966. Some of the supposed sei whales were probably Bryde's whales.

G. Peru, 1967–1985

A local company sponsored by Nihon Kinkai Hogeï (Japan Coastal Whaling) whaled using a station at Paita. The operation ended in March 1985. The fishing season lasted almost 12 months of the year, with occasional interruptions of 1 or 2 months in winter. The total catch was 291 (1968–1977), 3408 Bryde's (1973–1983), 232 sei (1973–1978), 2304 Bryde's or sei (1968–1972), and 14,331 sperm whales (1968–1981) (Valdivia *et al.*, 1984).

H. Philippines, 1983–1984

A local company whaled for two seasons using the *Faith No. 1*, the renamed *Miwamaru* catcher–factory ship of Japan. One of the Japanese sponsors had taken part in an earlier *Miwamaru* operation in Japan. A take of 9 Bryde's whales in 1983 and 47 in 1984 was reported with production of 277 tons of meat in 1984. The operation ended due to Japanese rejection of meat import and new regulation for her nationals concerning participation in foreign whaling. The local company operated in 1985 and took 40 Bryde's whales.

VII. Small-Type Whaling

This is defined as a whaling activity that takes minke whales and toothed whales other than sperm whales using a vessel and a whaling cannon below a certain size limit. This fishery started around the start of the twentieth century, e.g., the Baird's beaked whale fishery off the Boso coast introduced Greener harpoon guns in 1892 and Taiji fishermen 20-mm five-barrel harpoon guns for pilot whales in 1904. The fishery was placed under control of the Minister of Agriculture and Forestry in December 1947 (Ohsumi, 1975). Before this the operation was unregulated except for the Boso coast where the Baird's beaked whale fishery required a license from Chiba Prefecture (since 1920).

About 20 vessels operated the fishery off northern Kyushu, Kii, Boso, and Sanriku before World War II. The number increased to 53 in 1942 and 80 in 1950 and then it declined rapidly to 9 in 1970, 4 in 1988, and 5 since 1992. Conversion from several small vessels to one larger vessel contributed to the earlier decline. During the war the vessel size was 5–20 tons. The size limit was 30 tons in 1947, 40 tons in 1963, and is now 50 tons. The maximum caliber of harpoon gun changed from 40 mm (1947) to 50 mm (1952–present). Other regulations included the prohibition of killing calves and cows accompanied by calves and a fishing season of 6 months. The vessels usually leave port in the morning and return in the evening.

This fishery had no quota until 1977 and took common minke, Bard's beaked, pilot, and killer whales (*Orcinus orca*). Dolphins and porpoises were also taken (Fig. 3). The IWC set a quota for minke whales for the seasons 1978–1987. The government of Japan set a national quota for Baird's beaked whales at 40 (1983–1987), 60 (1988), 54 (1989–1998), 62 (1999–2004), and 66 (2005–2007).

The Japanese government maintains that target species of this fishery other than the minke whale are outside the IWC competence, thus the decision of IWC to cease commercial whaling does not prohibit

Figure 3 A hand harpoon fishing vessel operating for Dall's porpoise off Pacific coast of Hokkaido in a summer 1990s (photo by Tomio Miyashita).

take of these species. Currently five catcher boats operate using five land stations: Abashiri on the Okhotsk Sea coast of Hokkaido, Hakodate on the southern Hokkaido for Sea of Japan operation, Ayukawa on the Sanriku coast, Wadaura on the Boso coast, and Taiji on the Kii coast. Their quota as of 2007 was 66 Bard's beaked whales, 36 short-finned pilot whales (*Globicephala macrorhynchus*, 36 for each of the two populations), and 20 Risso's dolphins (*Grampus griseus*).

VIII. Dolphin and Porpoise Fisheries

In Japan, dolphins and porpoises are taken by drives, hand harpoon, and small-type whaling. The catch quota for this fishery remained almost unchanged since 1993, but in the 2007/2008 season it had some modification and Pacific white-sided dolphins became a fishing target. Catches are used for human consumption.

At least 52 villages have operated dolphin drive fisheries since the fourteenth century on the Sea of Japan and Pacific coasts, but the number declined throughout the nineteenth and twentieth centuries. When it was placed under the license system of the prefecture governments in 1982, only five groups acquired licenses (Kasuya and Kishiro, 1993). Currently, two groups, at Futo on the Izu coasts and Taiji on the Kii coasts, operate drive fisheries, with quotas of about 3000 dolphins of seven species (170 Pacific white-sided dolphins, 513 striped dolphins, 913 common bottlenose dolphins, 809 pantropical spotted dolphins, 295 Risso's dolphins, 277 southern-stock short-finned pilot whales, and 70 false killer whales). The fishermen drive schools of gregarious dolphins into harbor using several fast boats. Other equipment used is a cone-shaped steel disk welded to one end of a 2-m-long steel pipe. The cone is placed underwater and the other end of the pipe in the air is hammered to scare dolphins acoustically.

Harpoon fisheries started in prehistoric time (see earlier discussion), but large-scale commercial hunts began around 1920 off the Sanriku region for Dall's porpoises accompanied by introduction of motor-driven vessels. Dolphins and porpoises are harpooned when they come to bow ride. An electric shocker is usually connected to the hand harpoon with a detachable head. This fishery came under the control of prefecture governor or regional fishery coordination committees in 1989. In 2007/2008 season, 338 vessels out of Hokkaido, Sanriku, Boso, and Kii operate with a quota of about 18,000 dolphins and porpoises (8707 *dalli*-type Dall's porpoise, 8168 *truei*-type Dall's porpoises, 190 Pacific white-sided dolphins, 172

striped dolphins, 95 common bottlenose dolphins, 70 spotted dolphins (*Stenella attenuata*), and 246 Risso's dolphins).

Okinawa hunters use crossbows to shoot harpoons constructed of steel pipe; their efficiency is superior to hand harpoons for pilot whale hunts. The fishing season is variable among locations. In the 2007/2008 season, 6 crossbow fishermen operated with a quota of 121 dolphins (9 common bottlenose dolphins, 92 southern-stock short-finned pilot whales, and 20 false killer whales).

IX. Trap Net Fishery

On the coasts of Noto and northern Kyushu, whales were hunted until the end of the nineteenth century by placing small trap nets at whale passages. This fishery has been extinct for some time. However, there are about 20,000 trap nets (also called "set net") of various types now operating in Japan for fish; these occasionally take great whales (Tobayama *et al.*, 1992). In 1990, the Japanese Fisheries Agency prohibited commercial utilization of baleen whales found in the trap net. However, the Ministry of Agriculture and Fisheries Agency changed the rule in July 2001 to make it possible to sell such carcasses. This regulation change resulted in a sudden increase of reported catches to such high level that they cannot be ignored for management purposes. In recent years, the fishery has reported annual take of over 100 minke whales and occasional captures of gray and humpback whales (Kasuya, 2007).

XI. Scientific Whaling

During 1956–1979, Japan issued several permits to take whales for research purposes based on Article 8 of the ICRW. The scientific collection accompanied the operation of ordinary commercial whaling. It killed a relatively small number of whales or lasted for only a few seasons. This scientific whaling differed from that of the later period.

The ban on commercial whaling by the IWC came in effect in the 1985/1986 Antarctic season and the 1986 coastal season. Japan withdrew its objection to this IWC decision on July 1, 1986, taking effect from May 1, 1987 (pelagic), October 1, 1987 (coastal minke and Bryde's whales), and April 1, 1988 (coastal sperm whales). In November 1987, Nihon Kyodo Hogeishi dissolved. Half of the staff formed Nihon Kyodo Senpaku (Japan Union Shipping) to operate vessels acquired from Nihon Kyodo Hogeishi, and the others merged with Geirui Kenkyusho (Whales Research Institute) to establish Nihon Geirui Kenkyusho (Institute of Cetacean Research, ICR).

ICR started to take 300 Antarctic minke whales (*Balaenoptera bonaerensis*) for scientific purposes in the 1987/1988 Antarctic season using a factory ship and catcher boats chartered from Nihon Kyodo Senpaku. This operation moved into the second phase in the 2005/2006 season. In 1994, ICR expanded the project to the North Pacific to take 100 minke whales, which continued in 2000. The numbers of species and individuals to be taken by the projects increased with time. The current projects, both of which are stated to continue for an unlimited period, intend to take annually 850 plus-or-minus 85 Antarctic minke whales, 50 fin whales and 50 humpback whales in the Antarctic and 220 common minke whales, 50 Bryde's whales, 100 sei whales, and 10 sperm whales in the western North Pacific of which 120 North Pacific minke whales are taken by small-type whaling (Kasuya, 2007). Proceeds of products from these operations, about 5 billion yen/year (US\$ = 100–110), and subsistence and contract of about 1 billion yen from the Japanese government financed activities of ICR in the 2003/2004 fiscal year, when it proposed to take 660 plus-or-minus 40 whales.

K

Killer Whale *Orcinus orca*

JOHN K. B. FORD

I. Characteristics and Taxonomy

With its striking black and white markings and cosmopolitan range, the killer whale, or orca, is one of the most easily recognized and widely distributed of all cetaceans and is unlikely to be confused with any other species (Fig. 1). It is a large dolphin, attaining maximum body lengths of 9.0 m in males and 7.7 m in females. Maximum measured weights are 6600 kg for a 7.65-m male and 4700 kg for a 6.58-m female (Yamada *et al.*, 2007). In addition to sexual dimorphism in size, mature males develop disproportionately larger appendages than females (Fig. 2). This includes the pectoral flippers, tail flukes (the tips of which curl downward in males), and dorsal fin, which is erect in shape and may attain a height of 1.8 m in males. At birth, neonate killer whales are approximately 2–2.5 m long and weigh approximately 200 kg.

The most distinguishing feature of the killer whale is its striking coloration. Killer whales are generally black dorsally and white ventrally. Above and behind the eye on each lateral side of the whale's head is a conspicuous, elliptically shaped white patch, referred to as the post-ocular patch (or colloquially, the “eye-patch”). On the posterior lateral sides of the whale, the ventral white region continues dorso-posteriorly to form flank patches that extend almost half-way to the dorsal ridge. At the posterior base of the dorsal fin is a gray-pigmented area of variable shape termed the “saddle patch.” In neonates, the normally white-pigmented areas on the body have an orange hue, and the saddle patch is indistinct or absent for the first year of life. Considerable variation exists among killer whale populations and individuals in the size and the shape of white and gray patches. In some populations, particularly in the Southern Hemisphere, killer whales have a faint gray pigmentation over much of their body, and a black dorsal “cape” anterior to the dorsal fin.

The skull of the killer whale can be distinguished from those of other odontocetes by its shape, size, dental formula, and large teeth. Typically, 10–12 (up to 14) teeth are found per row, with teeth usually up to 10 cm in length. Upper and lower teeth interlock when the jaws are closed, which may result in considerable wear along their anterior and posterior facets. In some populations, extreme wear of the tooth crowns has been observed, even in young individuals, which may relate to diet.

Taxonomically, the killer whale is the largest species of the family Delphinidae. Only a single species, *Orcinus orca*, is currently

Figure 1 Part of a matriline of resident killer whales off Vancouver Island, British Columbia, showing representative dorsal fin nick and saddle-patch scars that are used in photographic identification of individuals. Photo by G. Ellis.

recognized, though the existence of morphologically, ecologically, and genetically distinct populations indicate that taxonomic revision may be warranted. In the northeastern Pacific, at least two distinct ecotypes—fish-feeding *residents* and mammal-hunting *transients*—co-occur in sympatry but maintain social and reproductive isolation. It has been suggested that residents and transients may constitute subspecies or incipient species. In the Antarctic, three distinct ecotypes—types A, B, and C—have been described from differences in coloration, morphology, and apparent dietary specialization (Fig. 3) (Pitman and Ensor, 2003). Type B and/or C may correspond to one or both of two putative species, *O. nanus* and *O. glacialis*, which were independently proposed in the early 1980s by Soviet researchers for populations of purportedly small individuals in the Antarctic (Mikhalev *et al.*, 1981; Berzin and Vladimirov, 1983). These new proposed species have not received general acceptance due to inadequate

Figure 3 Ecotypes of killer whales, known as types A (top), B (middle), and C (bottom), described in waters around Antarctica. Illustration by U. Gorter.

documentation and the lack of holotype specimens. Recently, aerial photogrammetry studies have determined that type-C killer whales are on average up to 50% smaller than type-A whales, which supports the possibility of species-level variation (Pitman *et al.*, 2007). At present, it remains unclear whether killer whale ecotypes represent a single species, multiple species, or subspecies.

II. Distribution and Abundance

The killer whale is second only to humans (and possibly our associated pest *Rattus norvegicus*) as the most widely distributed mammal in the world. It has a cosmopolitan distribution, being found in all oceans and most seas, but is most common in coastal, temperate waters, particularly in areas of high marine productivity (Forney and Wade, 2006). Greatest densities occur in waters along the northwestern coast of North America and the Aleutian Islands, along the coast of northern Norway, and in the higher latitudes of the Southern Ocean. In the Antarctic, killer whales are commonly found up to the pack ice edge in many areas and may extend well into ice-covered waters. In the Arctic, killer whales are rarely seen in the vicinity of pack ice but do visit the region during the open-water season in late summer. Information on the species' distribution in most tropical and offshore waters is limited, but numerous scattered records and sightings during cetacean surveys attest to its widespread, if rare, occurrence.

Because of its wide distribution and scarcity in most regions, the killer whale is a difficult species to census. Photo-identification studies in nearshore waters of the northeastern Pacific Ocean from

the Aleutian Islands to California have yielded a total population count of approximately 1600 whales (Ford *et al.*, 2000; Forney and Wade, 2006). Similar studies have identified 450 whales off northern Norway (Similä, 1997), 115 around New Zealand (Visser, 2000), and approximately 900 in waters off the Russian Far East. Line-transect vessel surveys have yielded estimates of 8500 killer whales over an area of 19 million square kilometer in the eastern tropical Pacific, and at least 25,000 in the Southern Ocean. Population counts and estimates from surveys provide a minimum global abundance estimate of 50,000 killer whales, although the total abundance is almost certainly greater than this because estimates are not available for large oceanic areas (Forney and Wade, 2006).

III. Ecology

The killer whale is the oceans' apex marine predator, capable of preying on a great diversity of vertebrates and invertebrates. It has no natural predators other than humans. Over 140 species have been recorded as killer whale prey. It is the only cetacean that routinely preys upon marine mammals, with attacks or kills documented for 50 different species. Mammalian taxa that are prey of killer whales include other cetaceans—both mysticetes and odontocetes—pinnipeds, sirenians, mustelids and, on rare occasions, ungulates. A variety of fish species are also important food of killer whales, notably salmon (*Oncorhynchus* spp.), herring (*Clupea* spp.), cod (*Gadus* spp.), tuna (*Thunnus* spp.), and various sharks and other elasmobranchs (Ford *et al.*, 1998; Dahlheim and Heyning, 1999; Visser, 1999; Saulitis *et al.*, 2000). Other animals recorded as killer whale prey include squid, octopus, sea turtles, and sea birds.

Although the killer whale is a generalist predator on the global scale, local populations can exhibit remarkable foraging specializations. Best known are two sympatric ecotypes found in coastal waters of the northeastern Pacific, fish-feeding residents and mammal-hunting transients. Residents show strong seasonal movements associated with the coastal migrations of salmon. Observational studies and analyses of stomach contents from beach-cast carcasses have shown that salmon is the principal prey of residents and that they forage selectively for the largest or the fattiest available species [chinook (*Oncorhynchus tshawytscha*) in British Columbia and Washington, and coho (*O. kisutch*) in Prince William Sound, Alaska; [Ford *et al.*, 1998; Saulitis *et al.*, 2000; Ford and Ellis, 2006 (Fig. 4)]. Smaller salmonids such as pink salmon (*O. gorbuscha*) and sockeye salmon (*O. nerka*) are seldom eaten despite their far greater seasonal abundance. Squid and a variety of non-salmonid fish species are also eaten by residents (2006), but there is no evidence that marine mammals are consumed. Foraging groups of residents typically ignore marine mammals in their vicinity, and seldom elicit avoidance responses from those species (Jefferson *et al.*, 1991; Deecke *et al.*, 2002).

Transients show relatively little seasonal change in distribution, most likely because their preferred prey species are present year-round in coastal waters. Harbor seals (*Phoca vitulina*), harbor porpoises (*Phocoena phocoena*), and Dall's porpoises (*Phocoenoides dalli*) are the primary prey of transients, although Steller sea lions (*Eumetopias jubatus*), California sea lions (*Zalophus californianus*), northern elephant seals (*Mirounga angustirostris*), and Pacific white-sided dolphins (*Lagenorhynchus obliquidens*) are also important (Ford *et al.*, 1998). Common minke whales (*Balaenoptera acutorostrata*) are occasionally attacked by transient killer whales in British Columbia and Alaska (Fig. 5), and gray whale (*Eschrichtius robustus*) calves are targeted by transients along the coast of California during their first migration north with their mothers (Ternullo and

Black, 2002). Attacks on larger baleen whales by transient killer whales are rare. Transients have not been observed to eat any species of fish, and no fish remains have been found in the stomachs of stranded transients.

Such extreme dietary specialization in sympatric populations is without precedent in mammals. These specializations likely evolved slowly and incrementally by means of increasingly refined and successful foraging strategies that were learned by individuals and passed across generations. Effective foraging for the disparate types of prey of residents and transients may require such divergent skills and tactics that lifestyles dependent on one or the other prey type have become mutually exclusive. Foraging specializations may have played a role in the historical separation of ancestral resident and transient groups, leading to the social and the eventual reproductive isolation of the two populations. Residents and transients are highly distinct in both mitochondrial and nuclear DNA composition (Hoelzel *et al.*, 1998, 2007; Barrett-Lennard, 2000).

More recently, a third sympatric form has been documented in coastal waters off British Columbia south to California (Ford *et al.*, 2000). Provisionally termed “offshores,” these whales are seldom encountered in protected inshore waters and have not been observed

mixing with either the resident or the transient population. They form a genetically distinct group, although they are more closely related to residents than to transients (Barrett-Lennard, 2000). The dietary habits of this population are poorly known, but they have been observed to prey on fishes, including Pacific halibut (*Hippoglossus stenolepis*) and carcharinid sharks (Dahlheim *et al.*, 2008).

Killer whales in other regions may also be highly specialized in feeding habits. Of the three ecotypes described in Antarctic waters, type A is an open-water mammal hunter that may specialize on Antarctic minke whales (*Balaenoptera bonaerensis*), type B feeds on pinnipeds in loose pack ice, and type C is apparently a fish-feeder that inhabits dense pack ice (Pitman and Ensor, 2003). Off the northern coast of Norway, a population of killer whales moves seasonally in relation to the migration pattern of its principal prey, herring (Similä, 1997). It is likely that populations with dietary specializations exist wherever sufficiently abundant and reliable prey resources are available to sustain them year-round. In other regions, more generalist foraging strategies may be expected. For example, in the subantarctic Crozet Islands, killer whales feed seasonally on southern elephant seal (*Mirounga leonina*) pups, but also forage for fish.

As the top predator in the oceans, killer whales have the potential to play important roles in marine ecosystem dynamics. Recently, it has been proposed that prey switching by killer whales drove precipitous declines of marine mammal populations in the North Pacific after commercial whaling depleted their alleged preferred prey, the great whales (Springer *et al.*, 2003). This hypothesis has been rebutted on a variety of grounds, primarily that no compelling evidence has been presented that the large baleen whales targeted by whaling ever represented an important component of the diets of mammal-hunting killer whales (Mizroch and Rice, 2006; Trites *et al.*, in press).

IV. Behavior and Physiology

A. Group Structure

Killer whales are social animals that are usually observed traveling in groups containing a few to 20 or more individuals. Reports of larger groups likely involve temporary aggregations of smaller, more stable social units. Long-term photo-identification studies have provided information on the social organization of the species in several regions of the world. The most detailed of these are studies in coastal British Columbia, Washington, and Alaska, particularly for the *resident* ecotype (Bigg *et al.*, 1990; Matkin *et al.*, 1999; Ford *et al.*, 2000).

Resident societies can be arranged into a number of groupings based on maternal genealogy, social association, and acoustical relationship. The basic social unit of *residents* is the *matriline*, which is a highly stable group of individuals linked by maternal descent. A typical matriline is comprised of a female, her sons and daughters, and the offspring of her daughters. Because females may live up to 80–90 years of age, and females have their first viable calf at about 15 years of age, a matriline may contain as many as four generations of matrilineally related individuals. Some matrilines contain only one generation, which can result if a matriarch dies and leaves only sons or daughters that have no young of their own. The bonds among members of a matriline are extremely strong, and individuals are seldom seen apart from the group for more than a few hours. No permanent dispersal of individuals has been observed from a resident matriline.

The next level of social organization in resident killer whales is the *pod*, which is a group of related matrilines that likely shared a common maternal ancestor in the recent past. Matrilines within pods are thus more closely related to one another than to matrilines in other pods. Pods are less stable than matrilines, and member matrilines frequently

travel apart for periods of weeks or months. However, these matrilineal groups still tend to travel more often with others from their pod than with matrilineal groups from other pods (Ford *et al.*, 2000). The majority of pods are comprised of 1–3 matrilineal groups. Resident pods in British Columbia, Washington, and Alaska contain a mean of 18 whales (range 2–49).

A further level of social structure is the *clan*, which is defined by the acoustic behavior of pods. All pods within a clan have similar vocal dialects (see *Socializing*) which likely reflect their common matrilineal heritage from an ancestral pod through a process of growth and fragmentation along matrilineal groups. Those pods with many shared features in their dialects are probably more closely related, and have split more recently, than those with more divergent features. Clans are sympatric, and pods from different clans frequently travel together. Clan membership is occasionally—but not usually—reflected in patterns of association. It is not clear how clans are related to each other, as they have no acoustical features in common, nor is the origin of clans known.

The top level of structure in resident killer whale society is the *community*, which is made up of pods that regularly associate with one another. The community is thus defined solely by association patterns rather than maternal genealogy or acoustic similarity. Pods from one community have rarely or never been seen to travel with those from another, although their ranges may partly overlap. Three communities of *residents* have been described in coastal waters of British Columbia, Washington, and Alaska: *southern* (3 pods, 1 clan), *northern* (16 pods, 3 clans), and *southern Alaskan* (11 pods, 2 clans) (Matkin *et al.*, 1999; Ford *et al.*, 2000).

Social organization in mammal-eating transient killer whales is not as well known as in residents. Similar to residents, the basic social unit is the matriline, but unlike residents, offspring often disperse from matrilineal groups for extended periods or permanently, either as juveniles or as adults. As a result, transient matrilineal groups tend to be smaller than those of residents, and lone individuals, particularly males, are often observed. Small group sizes of transients appear to reflect the marine mammal foraging specialization of this population (Baird and Dill, 1996; Ford and Ellis, 1999). Association patterns of transient matrilineal groups are dynamic, and they do not form consistent groupings of matrilineal groups equivalent to resident pods. All transient groups in a community have been observed to interact within this network of associations. Three communities of transients have been described in coastal waters of the northeastern Pacific, the *West Coast Transients* extends from central California north to roughly 56°N latitude in Alaska, the *Gulf of Alaska transients* range from southeastern Alaska to at least Kodiak Island in the west, and the *ATI transients*, which is a very small population of 11 whales that inhabits Prince William Sound and the Kenai Fjords area in the northern Gulf of Alaska (Ford and Ellis, 1999).

Social organization based on matrilineal descent may be typical of killer whales globally. In other regions where long-term photo-identification studies have been undertaken, close and prolonged associations of mothers and offspring are commonly seen (e.g., Norway, Crozet Islands, Argentina). Temporal persistence of these bonds may be a primary variable determining group sizes and structure.

The activity states of killer whale groups are of four basic types: foraging, traveling, resting, and socializing (Ford, 1989; Saulitis *et al.*, 2000). Minor differences in definitions and classification criteria of activities by different researchers make detailed comparisons difficult, but general patterns are evident. Foraging and traveling are the predominant activity states noted in all populations, although the proportions of the activity budget dedicated to these activities vary. Mammal-eating transients in coastal waters of the northeastern Pacific spend the great majority of their time (~90–95%) foraging

and traveling, whereas fish-eating residents spend only about 60–70% of their time doing so, at least during summer when salmon is abundant. Residents spend considerably more time resting and socializing than do transients. Fish-eating killer whales in northern Norway have activity budgets very similar to those of northeastern Pacific residents (Similä, 1997).

B. Foraging

Behavior patterns observed during foraging by killer whales vary considerably among populations and prey types. Groups of salmon-hunting residents often disperse over large surface areas while foraging, with members moving at roughly the same speed (mean = 6.0 km/h) and direction. Foraging episodes are typically 2–3 h in duration, but may last longer. Individual salmon are pursued, captured, and eaten by single animals or shared within small subgroups, usually a mother and a juvenile offspring. Norwegian killer whales feed on herring in a coordinated manner referred to as “carousel feeding” (Similä, 1997). Using percussive actions such as tail lobbing, releasing blasts of bubbles, and flashing the white ventral side of their bodies, the whales herd herring into a tight ball close to the surface. The whales then stun fish by striking the edges of the ball with their tail flukes and eat the debilitated prey. Killer whales in New Zealand have been observed to forage benthically for three species of rays (Visser, 1999). In the Strait of Gibraltar, killer whales catch bluefin tuna (*Thunnus thynnus*) following prolonged directional pursuits that appear to drive these fish to exhaustion (Guinet *et al.*, in press).

Mammal-hunting transient killer whales in the northeastern Pacific typically forage in smaller groups than fish-eating killer whales. Transient groups hunt harbor seals in groups averaging 3–4 individuals (Baird and Dill, 1996; Ford *et al.*, 1998; Saulitis *et al.*, 2000), usually close to shore and near seal haul-out sites. Although foraging, transients remain acoustically quiet, apparently to avoid detection by potential prey and possibly to locate prey by passive listening (Barrett-Lennard *et al.*, 1996). Harbor seals are killed and shared among group members relatively quickly compared to Steller sea lions or California sea lions, which may take over 2 h to kill and consume. Sea lions are usually rammed or butted with the whales’ heads, and slapped repeatedly with tail flukes, until the animal is debilitated sufficiently to be taken underwater and drowned. When hunting porpoises or dolphins, transients forage in slightly larger groups (averaging five members) that spread out in open water in a rough line abreast. Once an individual porpoise has been singled out, the whales chase it until it tires, then ram it or jump upon it to complete the kill (Ford *et al.*, 1998). Larger schools of Pacific white-sided dolphins are often driven by transients into confined bays where individual dolphins are trapped against the shore and killed.

A variety of specialized tactics have been described for killer whales hunting marine mammals in other regions. In Patagonia, Argentina, killer whales hunt southern sea lion and elephant seal pups in the shallows along sloping pebble beaches and often intentionally strand themselves temporarily in the process (Fig. 6). These whales hunt cooperatively and share their prey after capture. Killer whales in the Crozet Islands hunt elephant seal pups in a manner similar to those in Patagonia, and adults appear to teach this technique to their offspring (Guinet and Bouvier, 1995). In the Antarctic, type-B killer whales have been observed to locate seals hauled out on ice floes by spyhopping, then dislodge them by grouping together and rushing at the ice floe, creating a large wave in the process which tilts and washes over the floe (Fig. 7; Jisser *et al.*, 2008). Attacks on baleen whales or sperm whales often

involve groups of 10–20 killer whales working together in a coordinated manner to subdue the prey. Although some group members attempt to grasp the tail flukes or pectoral flippers to immobilize the larger whale, others attack the head and blowhole area, evidently to prevent the whale from breathing. Once a large whale has been killed, killer whales often consume only the tongue, lips, and blubber (Jefferson *et al.*, 1991). Because most baleen whales sink upon death, killer whales may only be able to feed extensively on carcasses of whales killed in shallow waters (Guinet *et al.*, 2000).

C. Traveling

Traveling killer whales move in a single direction at a consistent, fast pace, with no evidence of foraging or feeding. Groups often travel in a line abreast, with synchronized dives and surfacings. Resident killer whales have been documented to travel at speeds of over 20 km/h (mean = 10.4 km/h; Ford, 1989).

D. Resting

When resting, resident killer whales usually swim tightly together side by side, forming a *resting line*. Group diving and surfacing become closely synchronized and regular, with longer dives of 2–5 min duration separated by 3 or 4 short, shallow dives. Rate of forward progression is slow compared to foraging and traveling, and resting groups may stop altogether and rest motionless at the surface for several minutes (Ford, 1989; Similä, 1997).

E. Socializing

Socializing activity includes a wide range of physical displays and social interactions. Aerial behaviors are frequent, and may include spyhops, breaches, flipper slaps, tail lobes, and head stands. Juveniles often chase each other, roll and thrash at the surface, and engage in various other forms of play behavior, including playing with objects such as kelp or sea jellies. Sexual interactions involving penile erections are commonly observed, predominantly in all-male play groups. Some individuals may rest quietly at the surface whereas other pod members actively socialize. Rubbing on beaches or kelp is a common behavior observed during socializing in some populations. Killer whales belonging to the northern resident community in British Columbia visit certain beaches repeatedly to rub their bodies on smooth pebbles in shallow water (Fig. 8; Ford, 1989).

F. Sound Production

Similar to most delphinids, killer whales are highly vocal. They produce a wide variety of clicks, whistles, and pulsed calls for echolocation and social signaling. Studies of resident killer whales in British Columbia have documented vocal variations associated with activity state and group identity (Ford, 1989, 1991). Vocal exchanges among foraging resident whales are dominated by highly stereotyped, repetitive discrete calls from a repertoire averaging 12 call types (range 7–17 call types) per pod. Resting activity is usually associated with greatly reduced vocal activity, and occasional use of certain calls heard predominantly, but not exclusively, in such contexts. Socializing whales use mainly whistles and non-repetitive, variable pulsed calls, and aberrant versions of discrete calls. Excitement or motivational levels of vocalizing individuals is reflected in minor variations in pitch and in duration of discrete calls.

Call repertoires of resident killer whale pods have features that are distinct, forming systems of group-specific dialects. The entire call repertoire appears to be shared by all pod members. Some portions of a pod's call repertoire may be shared with certain other pods, whereas other portions may be unique. Levels of similarity in these group-specific dialects appear to reflect the degree of relatedness of different pods better than do patterns of travel association. Divergent variations in dialects among related matrilineal groups likely accompany the gradual fission that leads to pod formation. Young whales presumably learn their pod's dialect via mimicry of their mother and siblings, and dialects are retained in the matriline due to the lack of individual

dispersal. Thus, dialects likely provide an acoustic means of maintaining group identity and cohesion, and may serve as indicators of relatedness that help in the avoidance of inbreeding between closely related whales (Ford, 1991; Barrett-Lennard, 2000). Dialects have also been documented within a community of pods of killer whales in northern Norway and likely exist elsewhere.

Mammal-eating transient killer whales in the northeastern Pacific have greatly reduced vocalization rates compared to residents. Transients are generally silent when foraging, and even echolocation has been found to be used 27 times less often from foraging transients than foraging residents (using an index adjusted for group size; Barrett-Lennard *et al.*, 1996). Transients are more likely than residents to use individual (or “cryptic”) clicks rather than click trains, presumably to avoid alerting potential prey to their approach. Transients often become highly vocal, however, following a successful kill; West Coast transients off the coasts of southeastern Alaska to California produce a number of calls that are shared among all groups in the community. Certain other calls seem exclusive to transient groups in different portions of this range. Group-specific dialects as seen in resident pods are not evident, presumably due to the reduced stability of social structure in transients (Ford and Ellis, 1999).

V. Life History

Most detailed information on reproduction, mortality, and other life history parameters of killer whales have been derived from long-term photo-identification studies of *resident* killer whales in British Columbia and Washington (Olesiuk *et al.*, 1990, 2005). The reliability and completeness of this information is due to the extremely stable social structure of residents, in which emigration from the natal group does not take place and individual mortalities can be reliably documented (see *Interactions with Humans* for more details). It is not known whether these life history parameters are typical of other populations or regions.

Studies of captive whales indicate that sexually mature females have periods of polyestrous cycling interspersed with noncycling intervals of 3–16 months. The gestation period is 15–18 months (Duffield *et al.*, 1995). In resident killer whales, calving appears to be diffusely seasonal with a peak in the autumn. Neonate mortality may be high, with an estimated 43% dying within the first 6 months (Olesiuk *et al.*, 1990). Calves are nursed for at least a year, but may start taking solid food from the mother while still nursing. Typical age at weaning is not known, but is likely between 1 and 2 years of age.
