Figure 5 Family album wall hanging, New England, circa 1850. This unusual, elaborate construction features 12 tintype photographic portraits mounted in a triangular framework of walrus ivory and bone. The polychrome engraving on the walrus tusks is particularly interesting, as the woman-and-child portrait pair on the right is no doubt copied from a magazine fashion plate (in typical whalers’ fashion), whereas the woman with-telescope on the left appears to be an original image. Height 50cm. Kendall Collection, New Bedford Whaling Museum.

historic Japan expedition in the 1850s, engraved two walrus tusks with portraits of the Powhattan and Susquehanna, exotic Oriental watercraft, and glimpses of Japan, Hong Kong, and Brunei. Even a Confederate infantryman tried his hand: Hampton Wilson, Irish immigrant, North Carolina sharecropper, Confederate draftee, and Union prisoner of war, while recuperating in a military hospital in Kentucky successfully “flowered” a pair of walrus tusks with military and naval vignettes, using materials and methods presumably supplied by a Yankee whaling veteran among his fellow patients.

Most scrimshaw pictures were inspired by or adapted from illustrations in contemporaneous books and periodicals; copying and even direct tracing were standard scrimshaw conventions. Because of their specific functional objectives, scrimshaw implements and architectonic forms were also mostly derivative. However, some of the best pieces—and many of the worst—were truly original creations, drawn from the maker’s experience or imagination. A few have authentic stature as significant art, whereas others are little more than mere valentines. In the aggregate, anonymity and quality aside, as an indigenous occupational genre scrimshaw comprises some of the most characteristic and revealing documents of any occupational group, capable of providing profound insights into the life, work, and intentionality of the mariners who made them.

V. Museum Collections

The famous Kendall Collection (the former Kendall Whaling Museum), which includes what is by far the world’s largest and most

comprehensive array of scrimshaw, has since 2001 been incorporated into the New Bedford Whaling Museum (Old Dartmouth Historical Society) in New Bedford, Massachusetts. With the two enormous collections now combined, the New Bedford Whaling Museum is the home of the national Scrimshaw Collectors' Guild, houses the world's only Scrimshaw Forensics Laboratory® (to authenticate scrimshaw from institutional and private owners), hosts the annual Scrimshaw Collectors' Weekend, and has taken over the Kendall inventory of scrimshaw publications.

The Nantucket Whaling Museum (Nantucket Historical Association) on Nantucket—the birthplace of sperm whaling and the hometown of scrimshaw pioneers Edward Burdett and Frederick Myrick—holds an eminent collection that was newly installed in a rejuvenated gallery opened in 2006.

Mystic Seaport Museum, Mystic, Connecticut, has a large and comprehensive collection that includes important loan deposits from other private and institutional collection, notable for an informative catalogue and various scrimshaw-related publications.

The Peabody Essex Museum of Salem, Massachusetts, founded in 1799 as the East India Marine Society, was the first institution to include scrimshaw among its nautical relics (circa 1830) and today holds an outstanding collection of American scrimshaw.

The superb collection of the Dietrich American Foundation in Philadelphia is primarily intended for loan exhibitions to qualified institutions.

The Hull Maritime Museum (formerly the Town Docks Museum) in Kingston on Hull, East Yorkshire, a municipal museum in one of England's most historic Arctic whaling ports, holds the most significant scrimshaw collection outside the USA and Australia.

In addition, there are modest but worthwhile collections at the Christensen Whaling Museum (Sandefjord, Norway), the Penobscot Marine Museum (Searsport, Maine), the Providence (Rhode Island) Public Library, the Scott Polar Research Institute (University of Cambridge, England), South Street Seaport Museum (New York City), Whaler's Village (Lahaina, Maui, Hawaii), the Whaling Museum at Cold Spring Harbor (New York), and several state, maritime and municipal museums and libraries in Australia (Sydney, Melbourne, Hobart, and Launceston, Tasmania).

Sea Lions: Overview

DARYL J. BONESS

Sea lions, like the fur seals, are members of the family Otariidae. There are presently seven sea lion species in five genera, with one genus exclusive to the Northern Hemisphere (Steller sea lion, *Eumetopias jubatus*), one that occurs in both hemispheres [in the north, the California (*Zalophus californianus*) and Japanese (*Z. japonicus*) sea lions, and in the south, the Galapagos sea lion (*Z. wolfebaeki*)] and three that are solely in the Southern Hemisphere (southern sea lion, *Otaria flavescens*; Australian sea lion, *Neophoca cinerea*; New Zealand sea lion, *Phocarcos hookeri*).

I. Origins, Classification, and Size

Sea lions originated in the Northeast Pacific region, sharing a common ancestor with fur seals. Although the fossil record for sea lions is poor, it appears they crossed into the Southern Hemisphere about three million years ago (Berta and Sumich, 1999). For many years, sea lions were thought to be a separate subfamily, the Otariinae, within the family Otariidae. However, genetic analyses now conclusively show a basal split between the Phocidae and the Otarioidea (Otariidae and Odobenidae families) and that the northern fur seal (*Callorhinus ursinus*) is sister to all other sea lions and fur seals (Arnason *et al.*, 2006; Wynen *et al.*, 2001). The fossil record suggests this group splitting off about 6 million years ago. Beyond this level of detail, genetics and fossil record can only show us that there are four sea lion groups (known as clades) and five fur seal ones that evolved rapidly in time. The relationship among these groups, however, is yet to be determined.

The only substantial diagnostic morphological distinction between sea lions and fur seals is the presence of an underhair in fur seals but not in sea lions. Sea lions do tend to be larger than fur seals, with both groups exhibiting substantial differences in body mass, and smaller differences in body length, between males and females, a phenomenon known as sexual dimorphism. Male sea lions are between two and four times heavier than females and up to one and a half times the length. The body mass of males in the different sea lion species ranges from about 250 to 1000 kg and in females from about 75 to 325 kg. In contrast, the heaviest fur seal male is about 300 kg and the heaviest female is about 75 kg. Lengths of male and female sea lions range from 205 to 330 and 180 to 270 cm, respectively.

II. Morphology and Physiology

Sea lions, like fur seals and walruses (*Odobenus rosmarus*), differ anatomically from the true seals (phocids) in several ways. Probably most notable is their ability to walk or run rather than crawl on land (Pabst *et al.*, 1999). Underlying this capability is the ability to rotate the pelvis to a position that allows bringing the hind flippers under the body. As a result, sea lions tend to have more efficient terrestrial locomotion than phocids. Another obvious anatomical feature of sea lions is the extended and flattened fore flippers. This is a feature they have in common with their fur seal cousins, whereby the walrus and phocids have relatively short fore flippers. These differences reflect the different swimming modes of the two groups of seals. The sea lions and fur seals use fore flippers to provide thrusting power while the walrus and phocids use their rear flippers. While one might expect the different swimming styles to yield different swimming speeds, this is not the case. There is marked similarity in the cruising swimming speeds of all seals studied, which is about 2 m/s.

The ability to dive and stay underwater is an important characteristic for all marine mammals, including sea lions. Although large lung volume is important for diving animals, the lung volume for sea lions is equally proportional to their body size as to other marine mammals and even terrestrial mammals. Thus the relatively greater diving capability of sea lions and other marine mammals over terrestrial mammals is controlled by factors more than lung volume. Mechanisms for increased oxygen stores play an important role (Williams and Worthy, 2002). Consistent with being shallow divers, sea lions have lower oxygen stores (40 ml O₂/kg) than true seals (60 ml O₂/kg), which are generally deep divers, but still much higher stores than humans (20 ml O₂/kg), for example. In addition, the relative distribution of oxygen stores is different for sea lions. Sea lions have about 47% of their oxygen in blood, 35% in muscle, and 19% in their lungs. Phocids, however, have 64% of their oxygen in blood, 31% in muscle, and only 5% in their lungs. This larger percentage of oxygen in the lungs of sea lions correlates with the smaller degree to which the lungs collapse from water pressure. In humans, 51% of the oxygen is stored in the lungs.

III. Life History and Reproduction

Sea lions follow a life style typical to that of all the otariids, with some characteristics common to all seals (Boness *et al.*, 2002). They are long-lived (probably 15–20 years), have delayed sexual maturation, and have physical and social sexual bimaturation, with males maturing more slowly than females. In all species of sea lions, most females give birth for the first time between 4–6 years of age. This may vary to some extent with ecological conditions and population status. Males typically become capable of impregnating a female around the age of 5–8 years of age, but socially cannot achieve a status that gives them access to females for copulation until they are several years older (probably 10–12 years old). For six of the seven sea lion species, there is an annual breeding cycle, but one species, the Australian sea lion, has a unique cycle of just less than 18 months (Gales *et al.*, 1994). The net result of this cycle is that there is a gradual shift in the time of year and season when the breeding period occurs. For example, over a 19-year period, between 1973 and 1991, the median date of pupping occurred in every month of the year. No other species of seal exhibits such a pattern. Why this pattern exists is unclear, but it does link to a lactation length of about 17 months in this species. This may be related to having to forage in marginal ecological conditions that place energetic constraints on females and their pups (Costa and Gales, 2003).

Sea lions generally choose sandy beaches as sites for breeding. This is in contrast to their fur seal cousins, which more often choose beaches with boulders or rocky shelves. The reasons for these

differences are not clear, but may be related to methods of behavioral thermoregulation.

The reproductive behavior of female sea lions follows the typical maternal foraging strategy seen in all other otariids (Boness and Bowen, 1996). Almost without exception females give birth to a single pup each breeding season. During what has been termed a perinatal period lasting from about 7–10 days immediately after parturition, the female fasts, remaining with her pup continuously and nursing it frequently. This period of uninterrupted maternal energy transfer allows the pup to rapidly store energy and begin growth. Also during the perinatal period, both female and pup call to each other and sniff one another frequently. This behavior appears to be the basis for establishing a strong bond, which includes mutual vocal and olfactory recognition. This recognition becomes a critical component later in lactation that allows mothers and pups to reunite when the mother comes back from a foraging trip. Without this recognition system in place, females would likely spend critical amounts of milk energy wasted on pups other than their own, potentially compromising the successful weaning of their pup. Because females have been fasting during the perinatal period they will have depleted stores of body fat and need to begin periodic foraging trips to sea. During the foraging trips they will be left behind because they are not adequately developed to make the trips with their mothers. In some species, just before beginning the periodic foraging trips females will come into estrus. However, in other species estrus will occur after foraging trips have begun.

The duration of foraging trips is variable both within and between species (ranging from about 0.5 to 5 days), although they tend to be shorter among the sea lions than among the fur seals (1–12 days). Between foraging trips, females return to their pups on land, nursing them every few hours over a period of 0.5–1.5 days. This cycle is continued throughout lactation, which for most females in each species lasts about a year, except for the Australian sea lion mentioned earlier, which has a 17-month lactation. A small proportion of females in several sea lion species will nurse a pup for longer than a year, and even after they have given birth to a new pup. The number of females that do this may be dependent on the availability of food resources. For at least some sea lion species, the increasing duration of foraging trips over the season appears to be due more to prey movement than the increasing energy demands of growing pups, though both play a role (Boness and Bowen, 1996).

A physiological component of the maternal strategy of sea lions is relatively high-fat milk, which provides the energy needed by the pups as they try to grow and develop during the “feast and famine” situation produced by maternal foraging. We do not have measures of milk fat for all sea lion species, but for those that have been studied the fat content of maternal milk ranges from about 15 to 45%. Most likely the varying levels of fat in milks relate to the typical length of foraging trips. The best example of this is seen in *Zalophus* spp. The California species, which has maternal foraging trips of upward of 3–4 days, produces milk with 43% fat, whereas the Galapagos species, in which females forage for less than a day at a time before returning to pups, has milk containing only 21% fat. Interestingly, the daily growth rates of sea lion pups, after taking the body size of adults into account, are very similar, suggesting that the maternal strategies are finely tuned to ecological conditions.

The reproductive behavior of male sea lions has been investigated unevenly among the various species. We know almost nothing about the New Zealand, and Japanese sea lions but a considerable amount about the California, Galapagos, Steller and southern sea lions. Because females gather on land to give birth and care for their young and estrus is temporally linked to parturition, the conditions

are ideal for strong sexual selection through male–male competition. In brief, the tendency for female sea lions to be highly clustered, indeed lying in contact with one another, provides the potential for males to compete for and maintain control over multiple females. The ability to control and mate with multiple females in a given reproductive period is known as polygyny.

As is typical of virtually all otariids, male sea lions return to traditional breeding grounds and vie for positions in areas where females have previously given birth or spent time cooling off during the hottest part of the day. In some species or populations, males may actually defend sites or territories, whereas in others they may be more flexible, defending females directly. Factors that are most important in determining which behavior is typical at a colony are the extent to which females move before they become receptive and the level of competition that exists among males. Female movement is most often associated with the need to cool off because of high ambient temperature. One species for which all studies have shown males to defend territories only is the Steller sea lion. This is likely a result of the high latitude at which this species breeds, eliminating the need for females to engage in thermoregulatory movements.

In contrast, the southern and California sea lions have been shown to behave variably depending on the breeding habitat. At sites where there tend to be large numbers of tidal pools, around which females cluster, males defend territories. However, where there are long narrow sand or pebble beaches, females shift up and down the beach with changes in the state of the tide and air temperatures. Under these conditions, males do not defend territories but shift as females do and defend the females directly.

The level of reproductive success, or number of females mated by the most successful males, may be similar regardless of which pattern of behavior is typical. What seems to constrain the maximum success is the degree to which females are clustered in space and time (Boness, 1991). If receptive females are too dispersed in time, an individual male may not have enough energy stores to remain competitive throughout the entire season. As food sources are usually not close to the breeding grounds, males must fast during the breeding season; rarely are individual males seen leaving their positions on land. This is true even during the hottest part of the day in many breeding colonies, although in some places nearer the equator some sea lion males may either occupy positions in the water or make movements to the water. Minimum estimates of the maximum mating success for the most successful male among the sea lion species are highly variable. The estimate for the most successful Australian sea lion male, a species in which females tend to be quite dispersed, is 7 females mated compared to between 30 and 50 females for California and New Zealand sea lions, species in which females are much more clustered. Recent genetic paternity studies of male success in several species of seals indicate that success levels based on behavioral observations are probably overestimates, however. Some females are fertilized by males other than those with which they are seen mating.

The intense competition among males is what produces the extreme sexual dimorphism we see in sea lions and many other seals (Boness, 1991). At this point it is unclear as to whether the large size of male sea lions is most important in direct competition, i.e., fights and threats with one another, or in the ability to remain ashore for longer periods of time because larger males can store more body fat. In some energetic studies of phocid seals, evidence suggests that it is the amount of energy stores that is more important.

IV. Feeding Habits

Our understanding of sea lion foraging ecology is much poorer than that of fur seals. What we know comes from both analysis of

diving behavior and diet studies based mainly on analysis of food remains in scats (i.e., feces). Most sea lions are relatively shallow divers, diving to much less than 100m. New Zealand sea lions, however, dive to as deep as 130m and spend over 50% of their time at sea submerged. All seven species of sea lions eat both fish and cephalopods (e.g., squid and octopus). For most species fish appears to be the predominant food item, but in contrast the Australian sea lion appears to feed more on cephalopods. Special dietary items are found occasionally in the stomachs of some species. These include penguins in the southern, Australian and Galapagos sea lions, all of which live in proximity to penguin populations, and fur seal pups in the two larger sea lions—Steller and southern sea lions. Diets are not necessarily constant. They may change seasonally and during periods of environmental events, such as El Niño and La Niña, which are unusually high warming or cooling of sea surface temperatures, respectively.

V. Population Status

The status of sea lion populations is variable. The Japanese sea lion has not been sighted since the 1970s and is now considered extinct. According to the International Union for Conservation of Nature (IUCN), three species—the California, Australian and southern sea lions—are currently considered as being at low risk of extinction. The California sea lion population is likely between 250,000 and 300,000, and the Australian sea lion population, while small, appears to be stable. The southern sea lion is a species that may require reassessment since its last one in 1996 because recent surveys of this species at the Falkland Islands and in Argentina suggested population reductions of 93% since its highest levels in the late 1930s. Some of this decline may be due to a severe El Niño in 1997–1998.

The Galapagos and New Zealand sea lions are considered vulnerable to extinction. In the case of the Galapagos sea lion, the major threat continues to be a level of uncontrollable exploitation, whereas in the case of the New Zealand sea lion, although there is currently an increasing trend in the population level, its restricted habitat use and small overall population could lead to rapid depletion under a number of circumstances.

The sea lion species for which there is greatest concern at present and is listed as endangered and at high risk of extinction by the IUCN is the Steller sea lion. Although it is not the smallest population by far (estimated at about 96,000), it declined by about 80% between the 1970s and 1990s. There are two stocks that are managed separately in the United States—the western and eastern stocks. Under the U.S. Endangered Species Act the western stock is considered endangered and the eastern stock threatened. The western stock reached its low point in 2000 and now appears to be stable or may even slightly increasing. The eastern stock is increasing overall, but still decreasing slightly at some colonies. Despite substantial research over the past decade, we still are not able to determine conclusively the cause(s) of the decline. One recent hypothesis is that with the historical decline of many large whale species by human hunting killer whales have been driven to shift their primary prey from large whales to other marine mammals, e.g., sea otters (*Enhydra lutris*), harbor seals (*Phoca vitulina*), and sea lions (Williams *et al.*, 2004). Circumstantial evidence based on energetics data, for example, supports the plausibility of this hypothesis, but much more evidence is needed to be confident in the validity of this hypothesis.

as the “seje” or saithe (*Pollachius virens*). There are a variety of other common names, but English forms have disappeared from usage in favor of the sei whale.

The sei whale is a typical, sleek rorqual (Fig. 1). It is the third largest whale, reaching a maximum length of almost 20 m. More typically it is 15 m, weighing 20 metric tons (Horwood, 1987). Identification at sea can be difficult. By size alone, adult blue and fin whales are obviously larger and minke whales smaller. The dorsal fin is a useful cue, being relatively taller than that of blue and fin whales. It is also strongly concave on its dorsal edge, similar to that of a minke whale. For a long time it was not distinguished from its close relative, the warm-water Bryde’s whales (*B. edeni/brydei*). The Bryde’s whales have three distinct ridges, running the length of the head, whereas the sei whale has only one. Nevertheless, it is easy to confuse the sei whale with these other species at sea.

The color helps in identification. It is dark gray dorsally and on the ventral surfaces of the flukes and flippers. There is no whitening of the lower lip as found in fin whales. However, in a few individuals some white baleen plates occur. Often the body can be heavily scarred with healed lamprey bites. Sei whales dive more by sinking than an arched dive, but again other rorquals can also dive in this quiet manner.

A more detailed external inspection, seldom possible at sea, allows a more definite identification. In sei and minke whales the ventral grooves end well before the umbilicus. In other *Balaenoptera* spp., including Bryde’s whales, they end at, or posterior to, the umbilicus. The number of ventral grooves varies considerably from whale to whale. In sei whales they vary between 40 and 65 with a mean number of about 50. This is less than in blue (*B. musculus*), fin (*B. physalus*), and minke (*B. acutorostrata* and *B. bonaerensis*) whales, but about the same as in Bryde’s whales.

The baleen of sei whales is a dark gray, but often with a yellowing-brown hue, and often with some anterior white plates. The plates number about 350 on each side of the jaw, and the largest is less than 80 cm long. The width of the plate is relatively narrow compared to blue, fin, and Bryde’s whales. In the sei whale the length-to-breadth ratio is typically over 2.2, whereas in the Bryde’s whale it is always less than 2.2. The bristles of the baleen are particularly fine in sei whales. At their base they are about 0.1 mm in diameter compared with 0.3 mm for the other rorquals.

The sei whales are separated from the other rorquals by the external physical characteristics described above but also by internal characters such as vertebral number, skull and hyoid morphometry, and a bicuspid first rib. Genetically, the rorquals are all very similar having a diploid number of 44 chromosomes. Mitochondrial DNA shows the sei whale is more closely related to the Bryde’s whales, and the newly described *B. omurai*, than to the blue, fin and minke whales (Wada et al., 1991, 2003). Genetic differences exist between northern and southern hemisphere forms, and the southern sei whales grow to a larger size.

Sei Whale

Balaenoptera borealis

JOSEPH HORWOOD

I. Characteristics and Taxonomy

The diversity of thought about our great whales is characterized by quotes from the biologist R. C. Haldane on the sei whale. He described the species as the “most graceful of all the whales, as its proportions are so perfect, and wanting the clumsy strength of the two larger *Balaenoptera*, sperms and *Megaptera*.” He added, “It is also far the best to eat, the flesh tasting of something between pork and veal and quite tender.” The name “sei” whale comes from the Norwegian “*sejhalv*,” as it would arrive off Norway at the same time

II. Distribution and Abundance

The sei whale can be found in all ocean basins. It is an oceanic form and is uncommon in shelf seas. Sei whales undertake extensive, seasonal, latitudinal migrations, spending the summer months feeding in the subpolar higher latitudes and returning to the lower latitudes to calve in winter. Fig. 2 shows the global distribution in summer and winter. In the Southern Hemisphere, they rarely penetrate as far south as blue, fin, and minke whales, with summer concentrations mainly between the sub-tropical and Antarctic convergences.

Figure 1 *The sei whale (C. Brett Jarrett).*

Figure 2 *Global distribution of sei whales. Filled areas are the summer feeding distributions, and hatched areas represent breeding areas. The distribution is undetermined in the Indian Ocean.*

Genetic studies have to date not clearly defined different populations of sei whales within the Northern or Southern Hemispheres (Kanda *et al.*, 2006). However, biologists have separated populations, for management purposes, on the basis of different migrations and biological characteristics. In the Southern Hemisphere, six populations are assumed, as for the other rorquals. In the North Pacific, two or three populations have been proposed. In the North Atlantic, as many as eight populations have been suggested, but only three are considered for management purposes.

The size of populations is poorly determined, but whaling significantly depleted populations in all areas. In the Southern Hemisphere the original population was about 100,000, and in 1980 was thought to be 24,000. In the North Pacific, a population of over 60,000 was reduced to about 15,000. By now there may be 70,000 in both areas. The status of the North Atlantic sei whale is more uncertain, but recent sighting surveys indicate about 10,000 sei whales in the central and northeastern North Atlantic. At least in the western North Pacific it does not appear as if the depletion of the population has resulted in any genetic “bottleneck” effects.

III. Ecology

As with the other rorquals, it is the feeding ecology that determines the great latitudinal migrations between summer, polar feeding areas and winter breeding areas. It is also differences in prey that determine some of the unique features of the sei whale.

The sei whale is grouped with the gray (*Eschrichtius robustus*), and possibly minke, whales as “skimmers and swallows,” in contrast to the right whale (*Eubalaena* spp.) “skimmers” and other rorqual

Figure 3 *A feeding sei whale (courtesy of J. Sigurjónsson).*

“swallowers.” The fine baleen structure of the sei whales allows them to skim the surface waters for patches of their preferred copepod prey (Fig. 3). The other rorquals would probably find copepod food densities too low. Sei whales also feed on euphausiids, shoals of fish (hence their name) and squid if they are encountered (Kawamura, 1980).

Feeding is predominantly at dawn, lessening in frequency during the day. The behavior appears less bimodal than in other rorquals and is associated with the vertical migrations of the prey species. In the summer about half of the population is feeding on any one day,

and stomach contents are about 150 kg. In winter, there is still a high incidence of feeding but consumption is low.

It has been speculated that the wide feeding niche allowed the southern sei whales to expand into the areas occupied by the depleted fin and blue whales; however, it is not possible to substantiate this hypothesis.

IV. Behavior and Physiology

The key behavior is linked to the annual cycle of migration between the tropical and sub-tropical breeding grounds and the sub-polar feeding grounds. The timing of migration differs by sexual status and age. As with the other rorquals, the pregnant females leave for the feeding grounds first, and adults precede immature whales. Migration to the feeding grounds tends to be later than in blue and fin whales (Anon., 1997).

School sizes are poorly determined and vary with the location and migration. In the warmer waters they are most reported in mixed schools of 2–5 in number. In the temperate waters, during migration, they are often solitary. On the feeding grounds they can be solitary or form large aggregations of 20–100.

V. Life History

Maturity is at about 10 years in both sexes (Masaki, 1976). In most seas, the age of maturity declined by 2–3 years after the populations were depleted by whaling. The peak of conceptions is in June in the Southern Hemisphere and December in the Northern Hemisphere. The young are carried for almost a year and are born at a size of 4.5 m. Most calves are weaned in 7 months, after they have migrated to colder waters with their mothers.

Sei whales reach larger maximum sizes in the Southern than in the Northern Hemisphere. In the south, males mature at about 13–14 m and females at 14 m.

As for most mammals, sei whales can be expected to have increased rates of mortality when very young or old, but actual rates are poorly known. From observations of age compositions, the rate of natural mortality is typically about 5–10% per year. They die naturally from predators, such as killer whales, and weakening from disease and parasites. The population biology of the sei whale is described in detail by Horwood (1987).

VI. Interactions with Humans

A fast, offshore rorqual, the sei whale was not exploited until the era of modern whaling at the end of the 1800s. Off north Norway, 4000 sei whales were killed between 1885 and 1900. Since then, sei whales were caught in the North Atlantic from land stations in Canada, Faeroes, Iceland, Ireland, Iberia, Norway, and Scotland. In the North Pacific, they were caught from California, Canada, Japan, Kamchatka, and Kuril and by pelagic fleets. In the Southern Hemisphere, they were caught from Brazil, Chile, Peru, South Africa, and South Georgia.

The largest catches were made by the Antarctic pelagic fleets, after the numbers of blue and fin whales had been reduced. Between 1960 and 1970 over 110,000 sei whales were killed.

Whaling is regulated by the IWC. Whaling for sei whales ceased in the North Pacific in 1975 and in the Southern Hemisphere in 1979. Whaling was prohibited in the North Atlantic from 1986. Nevertheless, limited catches continued through subsistence whaling from Greenland and under the IWC scientific special permit. Special permit catches were taken off Iceland, and more recently in the offshore North Pacific.

Sensory Biology: Overview

J.G.M. THEWISSEN

This chapter provides a brief overview of the sense organs of cetaceans, sirenians, and pinnipeds. vision, hearing, and balance are discussed separately in this book and their treatment here is extremely cursory. Instead, this chapter focuses on those sense organs that are not treated elsewhere, namely the chemical senses, haptosense (the sense of touch, also called mechanosense), and electrosense.

I. Chemical Senses

Chemical cues in water are registered by sense organs (taste buds) that are located on the tongue and in the throat. These stimuli are mediated by Cranial Nerves VII, IX, and X in mammals and this sense is commonly referred to as taste (gustation). The sense of smell (olfaction) is sensitive to airborne chemicals which dissolve in the mucous inside the nasal cavity. These stimuli stimulate Cranial Nerve I. A third chemical sense (absent in humans) is processed by the vomeronasal organ (Organ of Jacobson). The vomeronasal organ is located in the floor of the nasal cavity, but its ducts open just behind the incisors in the oral cavity, and the organ registers stimuli on the palate. The vomeronasal organ is sensitive to large molecules that are caught on the mucous membrane of the palate, and those stimuli are carried to the brain by Cranial Nerve I. Also located in the mouth, but technically not part of gustation are the sensory organs on the tongue that register texture, structure, and temperature of food; these are mediated by Cranial Nerve V, and the process is called chemesthesis.

Pihlström (2008) presented a review of the chemical senses in aquatic mammals. Cetacean tongues are simpler in structure than those of land mammals, with few or no taste buds (Somntag, 1922).

In spite of this, experimental evidence has shown that, in some cetaceans, thresholds for detecting certain chemicals in water are similar to those of humans (Nachtigall and Hall, 1984). Modern cetaceans lack the vomeronasal organ, and in odontocetes the olfactory bulbs (the parts of the brain that receive olfactory stimuli from the nose) are missing. In mysticetes the olfactory bulbs are present and it is anatomically possible that they have a sense of smell. The presence of a sense of smell in mysticetes could be useful to detect their prey, planktonic invertebrates, which give off a peculiar smell. Experiments show that krill-eating seabirds have olfactory capabilities greater than those of most birds and are attracted by such smells (Verheyden and Jouventin, 1994).

Sirenian tongues have more taste buds than cetacean tongues, but the presence of a vomeronasal organ is disputed. The olfactory bulbs are small but present, suggesting that sirenians have a sense of smell. Pinniped tongue anatomy indicates that they have a sense of taste, but gustation is probably less well developed than in land carnivores. Pinnipeds have a good sense of smell (Kowalewsky *et al.*, 2005) and retain a vomeronasal organ.

II. Vision

Cetaceans and pinnipeds have well-developed vision, and both groups display adaptations for vision in air and underwater. This is unlike sirenians, which have small eyes used exclusively underwater, and have poor vision (Kröger and Katzir, 2008). Cetaceans living in turbid water, such as river dolphins have reduced vision (Lipotidae) or are nearly blind (Platanistidae). Frequency specializations occur in pinnipeds. In deep-water diving species, such as the elephant seal (*Mirounga spp.*), optimum frequencies of retinal pigments are shifted to the blue-green (high frequency) end of the spectrum, since higher frequency light dominates in deeper waters (Reuter and Peichl, 2008).

III. Hearing

Hearing in marine mammals was reviewed by Wartzok and Ketten (1999) and Nummela (2008). In odontocete cetaceans, HEARING is the most important sensory modality and is an integral part of ECHOLLOCATION. Odontocete sound transmission mechanisms differ greatly from those of land mammals, and are also different from those in mysticetes. Mysticete hearing is poorly understood. Pinnipeds hear well above and underwater, and some pinnipeds (odobenids and phocids) have highly specialized middle ears. Hearing in sirenians is poor.

IV. Balance

The sense of BALANCE is different from other sense organs in that the stimulus (linear and angular accelerations and decelerations of the head) is basically the same in water and air. However, the organs of balance in cetaceans, and to some extent sirenians and pinnipeds, are very different from those of their land relatives (Spoor and Thewissen, 2008). This may be related to specific means of locomotion or mobility of the neck in these species.

V. Haptosense

Whereas the other sense organs are concentrated on the head of an animal, haptosense (mechanosense, sense of touch) is diffuse, spread out over much of the body's surface. Unlike the other sensory receptors in the skin (temperature, pain), haptosense in water differs

significantly from that in air because of the density of water, which allows animals living in water to detect disturbances in their medium (water currents) at some distance. Haptosense in aquatic mammals was reviewed by Dehnhardt and Mauck (2008).

Very little is known about haptosense in cetaceans, although it is likely that in those species that have bristles on their faces (such as the Amazon River dolphin, *Inia geoffrensis*, and the bowhead whale, *Balaena mysticetus*) deflection of these hairs serves to inform these animals about close-distance disturbances of the water.

In pinnipeds, haptosense is highly developed. Whereas in terrestrial mammals vibrissae (whiskers) are circular in cross section and have a straight shaft, whiskers of pinnipeds are oval in cross section, and, in phocid seals, the shaft of each whisker thickens and thins in an undulating pattern. These hairs are anchored in a vibrissal follicle sinus complex, where bending of the hair shaft causes bowing of its root, and can be registered by an array of sensitive nerve endings. The resulting system can register even weak disturbances in the medium around them. Behavioral experiments have shown that walrus (*O. rosmarus*), California sea lions (*Zalophus californianus*), and harbor seals (*Phoca vitulina*) are capable of identifying objects by touching them with their vibrissae (Dehnhardt and Mauck, 2008). Harbor seals that have been blind-folded can detect the vortices of swimming fishes, and may be able to use this sensory modality to search for and capture prey. This is consistent with anecdotes about blind pinnipeds that appear healthy and well fed. In sirenians, numerous vibrissae are used for haptoreception, and can even bring food items to the mouth.

VI. Electrosense

Just like other delphinids, the Tucuxi (*Sotalia fluviatilis*) has a row of hair follicles on either side of the snout below the eye. In delphinid embryos, these follicles have hairs, but no hairs occur in adults. The follicles of *Sotalia* are larger than those of other delphinids and are sensitive to weak electric currents (Wilkins and Hofmann, 2008) such as those that would be emitted by the muscles of prey fish buried in the sediment. It is unknown from behavioral work in nature whether they are actually able to use this sensory modality, but it is very likely that they do.

Sexual Dimorphism

KATHERINE RALLS AND SARAH MESNICK

Dimorphism means two forms. "Sexual dimorphism" means that the two sexes of a species differ in external appearance or other features. Males and females may differ in size, color, shape, the development of appendages (such as horns, teeth, feathers, or fins), and also in scent or sound production. Species in which male and females are identical in appearance or other features are said to be "monomorphic." This article describes the types of dimorphic traits found in marine mammals and explains some of the reasons why these traits might have evolved and what can be inferred about the lives of males and females in a particular species from the pattern of sexual dimorphism. The quality of the information available on sexual dimorphism varies widely across marine mammal species. We know quite a lot about a few species, which are used repeatedly as examples, and virtually nothing about others. Despite the technical difficulties of studying marine mammals, our understanding of the evolution of sexual dimorphism is increasing steadily as observations of rarely encountered species accumulate and new techniques are developed.

I. Evolution of Sexual Dimorphism

Sexual dimorphism has fascinated biologists since before the time of Darwin. Darwin considered that most sexual dimorphism was due to sexual selection, in which evolutionary forces acted separately on the sexes (Darwin, 1871). For example, females might choose to

mate with highly ornamented males (e.g., the peacock's tail) or males might develop characters useful for fighting with other males to win in contests for access to females (e.g., large body size and antlers in deer). Today, these two processes are often referred to as female choice and contest competition, respectively. More recently, scientists have learned that males compete not only by physical fighting and display but also, in species where females mate with more than one male, by sperm competition within the female reproductive tract. Recent reviews have both questioned the very notion of sexual selection (Roughgarden *et al.*, 2006), and reaffirmed it, albeit with acknowledgment of much greater complexity than described by Darwin (Clutton-Brock, 2007).

Although Darwin's ideas about sexual selection have stood the test of time, some cases of sexual dimorphism seem to be best explained by natural selection. For example, males and females in some species of birds [e.g., Galapagos finches (genus *Geospiza*) and the extinct New Zealand huia (*Neomorpha acutirostris*)] have radically different bill morphologies that are best explained by sex differences in foraging habits (Andersson, 1994). In some species, females appear to be larger than males primarily because big mothers are better mothers (more eggs, better at defending their brood; Ralls, 1976). The emerging view is that the degree of sexual dimorphism in a species is the result of the difference between the sum of all the selective pressures (natural selection and sexual selection) affecting the male and the sum of those affecting the female.

II. Types of Sexual Dimorphism

The adult males and females of a species may differ in size, color, shape, the development of appendages (such as horns, teeth, feathers, or fins), scent, or vocalizations (Figs 1–6). In marine mammals, one of the most striking sexually dimorphic characters is size. In some species, males are dramatically larger than females. For example, in southern elephant seals (*Mirounga leonina*), adult males (maximally at 3700 kg) weigh 4–10 times as much as the adult

Figure 1 Size. Adult male South American sea lions (*Otaria flavescens*) are two–three times heavier than females; males grow to 2.8 m and weights of 340 kg; females to 2.2 m and 144 kg. There is extreme sexual dimorphism in body shape and pelage as well as size; males have massive necks, a broad head with a characteristically upturned muzzle, and a thick mane of long guard hairs. Photo by William Conway.

Figure 2 Dorsal fins. A pod of killer whales (*Orcinus orca*), Alaska. In adult males, the dorsal fin is erect and may grow to 1.8 m in height whereas the dorsal fins of females are less than 0.7 m and distinctly falcate. Sexual dimorphism also occurs in body size, flipper size, and genital pigmentation pattern. Photo by Flip Nicklin (Minden Pictures).

Figure 3 Teeth and Tusks. Dueling male narwhals (*Monodon monoceros*), Canada. The unicorn-like tusk of the narwhal is actually a greatly enlarged left upper tooth. The tusk generally erupts only in males and may exceed 3 m in length and 10 kg in weight. Sexual dimorphism also occurs in body size, pigmentation pattern, and the shape of the flukes and pectoral fins. Photo by Flip Nicklin (Minden Pictures).

females (which weigh 350–800 kg). Males in some species also possess greatly enlarged TEETH that are lacking in females and are used in fights between males. The best known example is the unicorn-like tusk of the NARWHAL (*Monodon monoceros*). The tusk, which is actually a greatly enlarged left upper tooth, usually erupts only in males and can grow to an extraordinary size, exceeding 3 m in length and 10 kg in weight. In some odontocete species (e.g., bottlenose whales, genus *Hyperoodon*), males have greatly enlarged and densely ossified heads, which they use to ram other males during fights. In otariids, males have thick necks and massive chests that tend to be covered by a dense mane of hair. The noses of males are sometimes bizarrely modified. For example, the most distinctive feature of the male hooded seal (*Cystophora cristata*) is an inflatable

Figure 4 Teeth and Tusks. Blainville's beaked whales (*Mesoplodon densirostris*) have a single pair of teeth (which may be better described as tusks) in the lower jaw which appears to primarily function in male–male aggression. Stalked barnacles (*Conchoderma auritum*) often grow in clusters on the erupted teeth, enlarging their effective size and increasing the abrasiveness of the tusks. Adult males also have a distinctive ridge along the dorsum, posterior to the blowhole, which appears to be the area targeted during intra-specific fighting, resulting in heavy scarring from tooth-rakes of other adult males (Diane Claridge, personal observation.). The densely ossified rostral bone may function to reinforce the skull when males fight. Photo by Diane Claridge @ Bahamas Marine mammal Research Organization.

Figure 5 Noses. Threat vocalizations resonate in the greatly enlarged proboscis of adult male northern elephant seals (*Mirounga angustirostris*), Año Nuevo, California. There is extreme dimorphism in body size and shape; males grow maximally to 4 m and 2300 kg and females to 3 m and 360–710 kg. The skin on the neck of adult males is thick, rugose, and scarred by fights and the canine teeth are sexually dimorphic in size and shape. Males are darker brown than females. Photo by Sarah L. Mesnick.

hood and bright red nasal sac that may function in agonistic and courtship displays. The appendages of males (flippers, flukes, caudal peduncles, and dorsal fins) are sometimes greatly enlarged. The best-known example of dorsal fin enlargement is seen in male killer whales (*Orcinus orca*; Fig. 2).

Figure 6 Post-anal hump. The post-anal hump of adult male eastern spinner dolphins (*Stenella longirostris orientalis*) is tremendously exaggerated. The dorsal fin of adult males is also forward-canted and the tips of the flukes curl up. Photo by Protected Resources Division, Southwest Fisheries Science Center, NOAA Fisheries Service.

Although sexual dimorphism traditionally referred to differences in morphological traits, the sexes can also produce different vocalizations or odors or be differently colored or patterned. Among marine mammals, differences in color are usually limited to fairly minor differences in pattern or density of pigmentation. For example, in ribbon seals (*Histiophoca fasciata*), the banding pattern is similar in both sexes but paler and less distinct in females. There are numerous examples of sexually dimorphic vocalizations in marine mammals, such as the roars and bellows of male sea lions and fur seals (Otariidae), the songs of male humpback whales (*Megaptera novaeangliae*), and the loud clicks of male sperm whales (*P. macrocephalus*). In terrestrial mammals, males and females often produce different scents via urine, feces, or specialized scent glands. This has not been observed much in marine mammals but may well occur. It is known, for example, that male ringed seals (*Pusa hispida*) produce a strong odor in the breeding season. Male sea otters (*Enhydra lutris*) frequently investigate the anogenital areas of other otters, and male common bottlenose dolphins (*Tursiops truncatus*) investigate the genital region of possibly estrous females with their rostrums.

III. Taxonomic Distribution

A. Baleen Whales

Sexual size dimorphism is “reversed” among the 13 species of baleen whales with females attaining asymptotic lengths that are generally 5% longer than males. Baleen whales typically undertake long-distance migrations between their northern or southern feeding areas and their tropical breeding areas and may not feed while migrating or on the breeding grounds. Females have the added stress of pregnancy and lactation during the non-feeding periods; a larger size may enable them to store more energy resources in the form of BLUBBER to meet their greater reproductive demands.

Sexually dimorphic vocalizations are well known in humpback whales. Male humpbacks sing lengthy, elaborate songs, the function

of which has been the subject of much speculation. Songs might function to attract females, signal status to other males, space males on the breeding grounds, synchronize estrus in females, or some combination of these. The humpback song is particularly intriguing because songs change over time, yet all members of a population sing similar songs at any one time. Male fin whales (*Balaenoptera physalus*) have a patterned call, which has been termed a breeding display, but observations of COURTSHIP or competitive interactions are sparse. Sexually dimorphic vocalizations may also exist in blue whales (*B. musculus*). There is dimorphism in the shape of the upper jaw of fin whales and, to a lesser extent, Bryde’s whales (*B. edeni*), but the function of this dimorphism is unknown.

Observations of clear AGGRESSION between males are known only in humpback and southern right whales (*Eubalaena australis*). Thus, it is not surprising that there are few accounts of sexually dimorphic structures that might be used in contest competition. Male right whales, however, have larger and more numerous callosities (the raised thickened patches of skin on the head) than females, which may function as weapons in contests between males. Male right whales are also scarred more heavily than females.

B. Toothed Whales

The relative size of the sexes varies widely among the more than 70 species of toothed whales. Males are larger than females in many species, with the most pronounced dimorphism in sperm whales, killer whales, bottlenose whales, narwhals, belugas (*Delphinapterus leucas*), and pilot whales (genus *Globicephala*). In sperm whales, for example, females reach about 11 m in length and 15 tons, whereas physically mature males are approximately 16 m long and weigh 45 tons. Females are slightly larger than males in Baird’s beaked whales (*Berardius bairdii*), the franciscana (*Pontoporia blainvillei*), the Indian river dolphin (*Platanista gangetica*), harbor porpoise (*Phocoena phocoena*), and dolphins in the genus *Cephalorhynchus*. Some species are monomorphic in size, including the Clymene dolphin (*Stenella clymene*), Atlantic spotted dolphins (*S. frontalis*), dwarf and pygmy sperm whales (genus *Kogia*), tucuxi (*Sotalia fluviatilis*), and some dolphins in the genus *Lagenorhynchus*.

Differences between the sexes may occur in the size and shape of the head, teeth, thoracic girth, flukes, flippers, dorsal fin, caudal peduncle, postanal hump, and length of the beak. In general, males tend to have larger appendages than females, the exception being the few species in which females have longer rostra than males [both species of south Asian river dolphin, the franciscana, and the rough-toothed dolphin (*Steno bredanensis*)]. Dimorphism in the size and shape of the head may be a result of enlargement of the nose (in sperm whales) or the forehead [in bottlenose whales (genus *Hyperoodon*), pilot whales, and to a lesser extent in bottlenose dolphins] of adult males. The massive nasal complex of adult male sperm whales may be one-quarter to one-third the length of the animal and is probably used in the generation of sound (Cranford 1999). In bottlenose whales, the forehead is extremely steep and the surface becomes flattened in mature males. Dimorphism in the density of ossification of the bones in the head occurs in bottlenose whales (the cranium) and beaked whales of the genus *Mesoplodon* (the rostrum, which has one of the highest reported densities of any mammalian tissue). Differences between the sexes in the ossification of the head in these species are not surprising given observations of head butting between adult male bottlenose whales and heavy scarring on adult males of several beaked whale species of the genus *Mesoplodon*. The sexually dimorphic pattern of scarring in *Mesoplodon* species is consistent with the idea that

adult males use their rostrum, and the exposed teeth on the lower jaw, in fights with other males.

Dimorphism in the size, shape, and/or number of teeth is known in the narwhal, sperm whale, Cuvier's beaked whale (*Ziphius cavirostris*), bottlenose whale, and in beaked whales of the genus *Mesoplodon*. In most of these species (exceptions being sperm whales and narwhals) the teeth erupt only in males and only at sexual maturity.

Differences between the sexes are known in flipper length (killer whales and melonheaded whales, *Peponocephala electra*), serration (Heaviside's dolphins, *C. heavisidii*), and shape of the trailing edge (belugas). In some species, including sperm whales and Dall's porpoises (*Phocoenoides dalli*), males have deeper caudal peduncles than females, which may function to give more power to the flukes. Postanal humps (thought to be composed of muscle and connective tissue) are exhibited in mature males of several species, although they have been properly described and correlated with age and sex in only a few. The postanal hump of the male eastern spinner dolphin (*S. longirostris orientalis*) is exaggerated tremendously (Fig. 6). Although the function of the postanal hump remains unknown, it has been suggested to be an anchor for external genitalia and may serve to enhance sexual performance. It may also serve as a visual signal that makes adult males easily recognizable. Dorsal fins may be larger and more erect in males than females, more hooked, or more forward canted (Figs. 2 and 6). The most exaggerated examples of dorsal fin enlargement are seen in male killer whales and pilot whales. The significance of these differences in dorsal fin size and shape is unknown but they may serve a thermoregulatory function and/or as a visual signal. Differences between the sexes also occur in the flukes, which may be longer and broader in males, or differently shaped. In Dall's porpoises and sperm whales, for example, the trailing edge of the flukes of males are convex, and in male eastern spinner dolphins, the tips of the flukes curl up. As is true for mammals in general, the distance between anal and genital openings of odontocetes tends to be greater in males than in females.

Sexual differences in pigmentation patterns are most common in the genital area but are also known to occur on the face, head, and body. Sexual dimorphism in genital pigment patterns is known in several species [killer whales, dolphins in the genus *Cephalorhynchus* and *Lissodelphis*, shortbeaked common dolphins (*Delphinus delphis*), Burmeister's porpoises (*P. spinipinnis*), and Dall's porpoises]. Pigmentation differences may be related to sexual recognition, advertisement (for either males or females), or may help suckling young locate the teats. In most species of beaked whales, the body gets lighter in color with age. The lightening is especially noticeable in adult males and is primarily due to an accumulation of body scars, but may also be due to changes in pigmentation and, in several species, both. In Risso's dolphins (*Grampus griseus*), ontogenetic lightening and an accumulation of body scars make older animals appear almost pure white, and the pattern may be more prevalent in males. Adult male spotted dolphins (*S. attenuata*) bear conspicuous white rostrum tips, visible at a great distance. In Fraser's dolphins (*Lagenorhynchus hosei*), the intensity and thickness of the eye-to-anus stripe becomes more exaggerated (darker and thicker) in adult males. Another type of pigment dimorphism is the occurrence of visible (white or nonpigmented) linear scarring, suggested to result from a lack of pigmentation of damaged tissue from the tooth rake wounds of conspecifics. In some odontocete species, both sexes exhibit heavy scarring [e.g., Baird's beaked whale (genus *Berardius*) and Risso's dolphins]. However, in others (*Mesoplodon* spp., narwhal, and the sperm whale), males are scarred more heavily than females. In these species, scarring is likely the result of wounds inflicted during male fights.

At present, acoustically dimorphic calls are known only in sperm whales. However, because odontocetes produce a wide range of sounds, dimorphic acoustic signals are likely to occur in several other species as well. Because larger animals make larger sounds, it is also reasonable to expect that other sexually dimorphic species, such as pilot whales, will produce acoustically dimorphic calls.

C. Pinnipeds

The 36 species of pinnipeds show the greatest range in sexual size dimorphism of any higher vertebrate group (Fig. 7). Adult males are up to 10 times as heavy as adult females in some species, whereas females are slightly larger than males in others. For virtually all pinnipeds studied to date, data support, or are highly suggestive of, a polygynous mating system. However, the potential for polygyny varies greatly among species and there is a strong correlation between the degree of polygyny and the degree of dimorphism. The mating system in turn, depends to a large extent on whether breeding takes place on land or at sea. In terrestrially mating pinnipeds [this includes sea lions and fur seals and three species of phocid, the northern and southern elephant seal (genus *Mirounga*) and the gray seal (*Halichoerus grypus*)], extreme polygyny is possible because females gather in dense groups on islands to give birth and mate. Under these conditions, a successful male can defend many females. In these species, males exhibit not only large size but also other characteristics useful in fights over females, such as large canines, massive necks and chests, and dense pelage. Large size may also help males of these species achieve greater reproductive success by enabling them to remain longer on the breeding rookery because larger males have bigger energy reserves in the form of blubber.

In the remaining pinnipeds, the WALRUS (*O. rosmarus*) and nearly all of the phocids, mating takes place in the water. Females of many species give birth on ice (and therefore are not as spatially clumped as terrestrially breeding species in part because they have larger expanses of suitable habitat available) and the mating season is short. Thus, males have less opportunity to defend and mate with multiple females. These characteristics inhibit the development of the extreme polygyny and sexual dimorphism found in terrestrially mating otariids and phocids. In general, males of aquatically mating species are only slightly larger than females or females may be slightly larger than males [bearded (*Erignathus barbatus*), Weddell (*Leptonychotes weddellii*), Ross (*Ommatophoca rossii*), crabeater (*Lobodon carcinophaga*), and leopard (*Hydrurga leptonyx*) seals]. The hooded seal is a notable exception, with males considerably larger than females. In ice-breeding species, large female size may help a mother provide large quantities of fat-rich milk for her pup, and because mating takes place in the water in these species, agility, rather than size or strength, may be important in male contests for females.

In addition to the sexual size dimorphism mentioned earlier, the sexes may also differ in pelage length and color, shape of the head and chest, canine development, and the pattern of scarring on the neck and chest. Adult male otariids tend to be bulkier than females and are distinguished readily by their thicker and more powerful necks and their massive chests. The head, neck, and chest of males tend to be covered by longer, rougher hairs, which gives the impression of a mane [e.g., the South American sea lion (*Otaria flavescens*); Fig. 1]. In older males, the guard hairs are lighter in color and tinged with white, silver, or tan. Adult male California sea lions (*Zalophus californianus*) also develop a pronounced forehead, or sagittal crest, and adult male southern sea lions have a distinctive upturned muzzle. The skin on the necks of adult male elephant seals and gray seals

Figure 7 Sexual size dimorphism in pinnipeds. A composite phylogenetic tree of the Pinnipedia on which sexual dimorphism, mating location, and degree of polygyny have been overlaid. Sexual size dimorphism varies greatly across pinniped species, and there is a strong correlation between the degree of dimorphism and the mating system. In otariids and three species of phocid (both elephant seals and the gray seal), mating takes place on land and extreme polygyny is possible because a successful male can defend many females. Males are much larger than females (2–10 times larger) and also exhibit other characteristics useful in fights over females, such as large canines. In the remaining pinnipeds, the walrus, and nearly all the phocids, mating takes place in the water or on ice. There is less opportunity for males to mate with multiple females and agility, rather than size or strength, may be important in male contests for females. Males are equal, slightly, or moderately (up to 1.5 times) larger than females or females may be slightly (up to 1.1 times) larger than males in these species. ¹Females are slightly larger than males in the Hawaiian monk seal (*Monachus schauinslandi*); males are slightly larger than females in the Mediterranean monk seal (*Monachus monachus*). ²Among phocines, the gray seal (*Halichoerus grypus*) represents a notable case because it can exhibit both terrestrial and aquatic mating and males are maximally three times larger than females. Pieter A. Folkens/Higher Porpoise DG.

is thickened and wrinkled and marked by scars from fights. In general, adult male otariids, as well as adult males in some species of phocids, tend to be more darkly pigmented than females.

Many pinnipeds have sexually dimorphic vocalizations that may function to establish and maintain dominance relationships or to attract females. In some species, the sounds are amplified or resonated in the proboscis (as in hooded and elephant seals; Fig. 5) or an internal air sac (as in ribbon seals, bearded seals, and walruses). Hooded seals produce numerous sounds as they inflate and deflate their hood and bright red nasal sac in response to disturbances and as part of the courtship display. Male elephant seals also have greatly enlarged noses, and snouts of male gray seals are broader and more elongated than those of females. Males of these species establish dominance hierarchies through stereotyped visual and airborne acoustic threats and, less often, physical aggression. Male harbor, bearded, ribbon, Weddell, ringed, and harp (*Pagophilus groenlandicus*) seals are known for their acoustic courtship displays. Male harbor seals engage in complex hierarchical acoustical mating displays in which several subordinate males passively muzzle singing dominant males underwater. Much of the roaring and bellowing of adult male otariids is thought to intimidate rivals but acoustic displays may also be used to advertise to females. The walrus has the most elaborate

courtship display of all pinnipeds involving intricate acoustic and visual components. Vocalizing adult male walruses apparently compete for females in lek-like groups in the water near ice floes on which females gather to pup and rest. Their surface vocal repertoire includes barks, whistles, and growls, and underwater vocalizations sound bell like. It is also thought that the massive tusks may play a role as a visual symbol of rank and as a display to females. Male walruses are larger than females in both body and tusk size. In marine mammals, the only well-documented sexually dimorphic scent of which we are aware occurs in the ringed seal. Male ringed seals give off a strong scent during the breeding season.

D. Sirenians, Sea Otters, and Polar Bears

Manatees (genus *Trichechus*) are generally monomorphic in size and appearance. Dugongs (*Dugong dugon*) exhibit no obvious sexual dimorphism apart from the short tusks (upper incisors), which usually erupt in adult males, although females may grow to a slightly larger size than males. Male dugongs compete for access to females by patrolling exclusive areas and engaging in threats, fights, and song. Adult male sea otters are larger than adult females. Second only to pinnipeds, polar bears (*Ursus maritimus*) exhibit the greatest

sexual size dimorphism among mammals. Male polar bears may be over twice as heavy as females.

IV. What Can We Infer from Sexual Dimorphism?

The variation in sexual dimorphism among marine mammal taxa is striking. The sexes are visually indistinguishable in some species, whereas in others the differences between the sexes are so extreme that males and females live essentially separate lives except when they meet to mate. This rich variation in sexual dimorphism has prompted scientists to offer a variety of explanations. The various mechanisms of sexual selection—female choice, contest competition, and sperm competition—probably account for a large proportion of sexual dimorphism in marine mammals. However, some dimorphic traits may reflect ecological differences between the sexes (e.g., differences in beak length between the sexes in south Asian river dolphins). Others may be important for females and their young (e.g., larger females make better mothers or urogenital pigment patterns may highlight the mammary glands and help young to find them).

The functional significance of most sexually dimorphic traits in marine mammals remains untested, which is not surprising given the difficulty of observing, let alone experimenting on, most species. In general, the behavior of pinnipeds (which often breed where they can be observed) is better known than the behavior of cetaceans that breed at sea. However, extended observations of behavior have also been possible in a few cetacean species (e.g., bottlenose dolphins, humpbacks, and right whales) that breed close to shore. Nevertheless, we can often infer the functional significance of sexual dimorphism in species whose behavior is poorly known by analogy to well-studied species. The type and degree of sexual dimorphism and its association with other characteristics such as relative testis size and pattern of bodily scarring provide clues to the intensity of sexual selection (the skew in male mating success) in a species and the probable underlying mechanisms of sexual selection.

Based on studies of terrestrial mammals, a positive correlation is generally assumed between the amount of sexual dimorphism in a species and the deviation of the breeding system from monogamy. Thus, in polygynous species, male competition for access to females is severe and males are expected to exhibit traits, such as large size and big canines, favored in fights with other males over access to females. The correlation between sexual size dimorphism and the degree of polygyny has been shown across pinniped taxa (Alexander *et al.*, 1979). For example, among otariids, the northern fur seal (*Callorhinus ursinus*) and Steller sea lion (*Eumetopias jubatus*) show the greatest relative dimorphism in body weight and defend the greatest number of females in their territories as compared to less dimorphic species. Within a species, a large body size has also been shown to be correlated with greater mating success (via dominance rank, endurance, and tenure on rookeries; e.g., elephant seals, gray seals). It is important to note, however, that species that lack sexual size dimorphism do not necessarily lack male–male competition for mates. In these species, sexual selection may be intense, but due to different forms of competition among males for access to mates, and the consequences may not be reflected in size but in other characters, such as song, visual display, or agility.

Sexual dimorphism in size and weaponry (big teeth, enlarged heads, and strong flukes) suggests that contest competition for access to mates plays an important role in the mating strategies of males in many marine mammal species. Contest competition may take the form of ritualized displays (visual or acoustic), by which potential rivals

assess relative size or strength, or physical aggression. Among odontocetes, dimorphism in weaponry is correlated to patterns of body scarring and observations of head butting among males. In certain species, such as sperm whales, beaked whales, and narwhals, teeth erupt or are enlarged only in adult males, a pattern that suggests their function has shifted from feeding to use in social interactions. Adult males of many of these same species are heavily scarred, another trait that suggests males use their teeth in physical battles with other males.

Among terrestrial mammals, the relationship between relative testis size and mating system is so strong that the former can be used as a good indicator of the mating system (Gomiendo *et al.*, 1998). In general, where copulatory frequency is high, the testes are large, and where it is low, the testes are small. In right whales, observations of multiple males mating with single females, together with huge (1 ton) testes, strongly suggest that sperm competition is a principal mating strategy in this species, and probably also in bowhead (*Balaena mysticetus*) and gray (*Eschrichtius robustus*) whales (Brownell and Balls, 1986). Odontocete species such as sperm whales and beaked whales that exhibit dimorphic traits associated with intense physical combat (e.g., large size, enlarged teeth) tend to have small testes. The testes of sperm and beaked whales represent less than 0.5% of the body weight, weigh only a few kilograms, and can be held in one hand. At the other extreme, species having the largest testes, suggesting the likelihood of significant sperm competition, do not exhibit the extreme dimorphic traits associated with physical combat. These species tend to be sexually monomorphic or have dimorphic traits that may be associated with agility or visual display. For example, harbor porpoises, finless porpoises (*Neophocaena phocaenoides*), and dusky dolphins (*L. obscurus*) have testes that represent greater than 5% of their body weight. Humans, for comparison, at about the same body mass as these dephinid species, have testes of only 0.08% of body mass (Kenagy and Trombulak, 1986).

In three-dimensional habitats, agility, rather than size or strength, may sometimes determine the outcome of male contests. Agility may be useful in scramble competition for access to mates and it may function as a visual display for female choice. This may be the case in some species, such as the aquatically mating phocids, in which males compete underwater and are smaller than females. Among odontocetes, larger body size typically means that the male's propulsion structures are also proportionally larger than those of the female. The importance of speed and maneuverability is suggested by sexual dimorphism in the flippers, flukes, caudal peduncle, and dorsal fin. Tolley *et al.* (1995) suggested that the larger body size, caudal peduncle, flukes, and dorsal fin of male bottlenose dolphins, and the pattern of dorsal fin scarring, are consistent with males competing for access to dispersed females. Features such as flukes and dorsal fins are used for propulsion, maneuvering, and thermoregulation and in offensive or defensive encounters with other males. More power to the flukes could increase the strength of blows and greater speed could aid in the herding of females.

Traditionally, behavioral ecologists have tended to emphasize the importance of male–male competition in the evolution of exaggerated male traits. More recently, based primarily on bird data, they have found that female choice often plays a critical role. Recordings of male song and the existence of exaggerated morphological traits that make adult males easily recognizable suggest the importance of female choice in marine mammals. The same features that appear to provide advantages in contests between males, such as large size, big canines, or deep roars, may also be used by females to select mates and/or may function to control or intimidate females (Wells *et al.*, 1999). Whether females actually use these traits to assess males

or what these traits might signal (e.g., status, fitness, or readiness) is unknown. The enlarged postanal hump of males in some dolphins and porpoises may serve an important biomechanical function for males by facilitating copulation. It may also be important as a visual signal that makes adult males easily recognizable within schools, by both females and other males. Similarly, enlarged dorsal fins, which may have a thermoregulatory function, may also serve as a visual signal. The calls of male pinnipeds may function as male displays to females, in species recognition, and in contests between males. Evidence supporting the idea of lekking in walrus and dugongs suggests an increasing role for female choice in the evolution of vocal mating displays.

Caution is warranted when making inferences about the evolution of sexually dimorphic traits (Roughgarden *et al.*, 2006; Clutton-Brock, 2007). First, our knowledge of sexual dimorphism across marine mammal taxa is incomplete. There are rarely encountered species for which we have very little information about sexual dimorphism. Although our understanding of morphological differences between the sexes is growing, our knowledge of acoustic and pheromonal differences is in its infancy. As we fill in these gaps in our knowledge, our ability to understand the underlying evolutionary patterns and processes will increase. Second, a sexually dimorphic trait may have evolved for different reasons in different species. For example, among odontocetes, males are much larger than females in sperm whales, “resident” killer whales, and long-finned pilot whales (*G. melas*), but it is unlikely that a single explanation fits all three cases. In sperm whales, adult males are solitary and roam great distances searching for females. Males possess large teeth, have massive heads, are scarred, and have been observed ramming each other head-on. It is likely that large size serves male sperm whales well in contest competition over access to females. In contrast, adult male “resident” killer whales and long-finned pilot whales live in stable social groups with their maternal relatives, are not scarred, and we know of no accounts of aggressive interactions between males. In contrast to sperm whales, “resident” male killer whales and long-finned pilot whales may increase their reproductive success, not only by mating with females in other pods, but by assisting kin in their natal pods. At this point, we can only speculate about the advantages that large size confers on males of these species, but assistance in a communal foraging strategy (“resident” killer whales) and protection of the pod (long-finned pilot whales) are possibilities. Females may prefer large males as mates in all these species, but large size may confer different advantages to individuals in each of the three cases.

Despite the technical difficulties of studying marine mammals, our understanding of the evolution of sexual dimorphism is increasing steadily. New techniques, such as scoring molecular genetic markers from tissue samples, are providing insight into social structure and variance in male reproductive success. Video, acoustic recordings, and “critter cams” (small television cameras that can be mounted on individual animals) are providing exciting new data on the behavior and interactions of animals underwater. Clearly, research opportunities abound, and the prospects for increased future understanding of the abundant sexually dimorphic traits in marine mammals are bright.

Shepherd's Beaked Whale

Tasmacetus shepherdi

JAMES G. MEAD

I. Characteristics and Taxonomy

Shepherd's beaked whale (*Tasmacetus shepherdi*) (Oliver, 1937) is the only beaked whale to have a full set of functional teeth (Mead, 1989) (Fig. 1). It has between 17 and 21 upper teeth on each side and between 18 and 28 lower teeth. The first tooth in

Figure 1 *Tasmacetus shepherdi* USNM 484878 660cm female, 1 February 1973, Peninsula Valdez, Argentina. A. dorsal view of skull; B. ventral view of skull; C. right lateral view of skull; D. right lateral view of mandible.

Figure 2 External view of an adult female *Tasmacetus shepherdi* (reconstruction by Pieter Folkens).

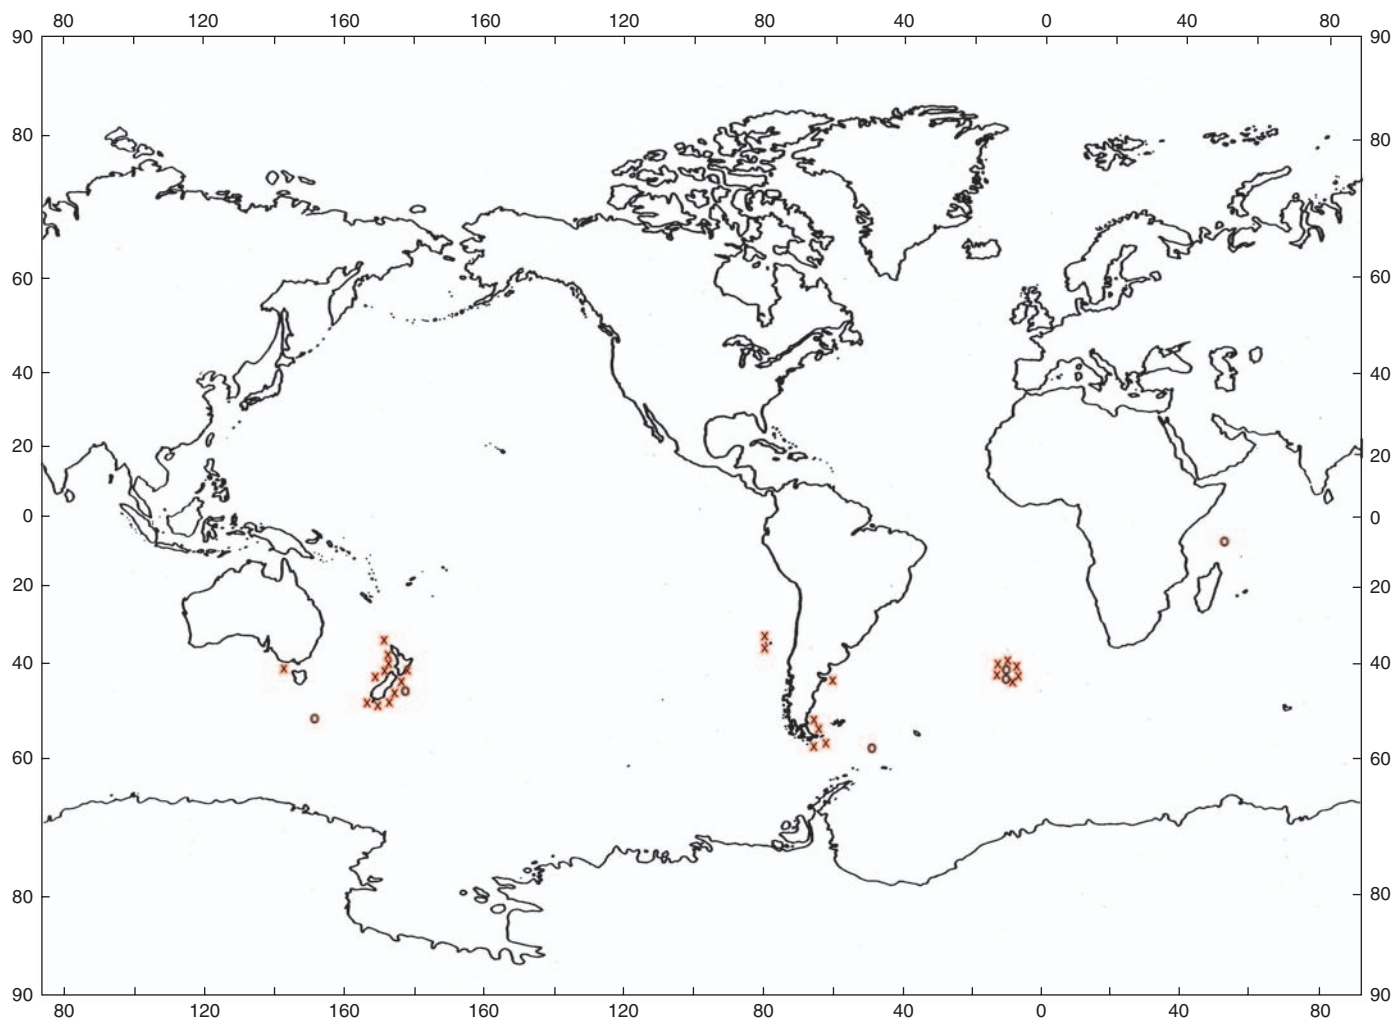

Figure 3 Geographic records of *Tasmacetus shepherdi*. Crosses represent strandings, open circles represent published sightings.

the mandible is enlarged, and it is thought that size difference makes it homologous to the single mandibular tooth of other beaked whales. It was initially thought to be a primitive member of the beaked whale family (Ziphiidae) on the basis of retention of teeth. There has not been a good study of the evolutionary relationships of the beaked whales, but *Tasmacetus* seems in ways other than the teeth to be just as specialized as the remainder of the family. The pigmentation pattern (Fig. 2) is dark gray dorsally, with a white field ventrally extending dorsally on both the anterior and posterior sides of the flipper (Pitman *et al.*, 2006). The dark dorsal field extends onto the flipper.

Another extension of the white ventral field lies dorsal to the anus. The dorsal surface of the head is pale and the rostrum is darker.

II. Distribution and Abundance

The geographic records of *Tasmacetus* are illustrated in Fig. 3. It is known from strandings in New Zealand (13), Australia (1), Argentina (5), Juan Fernandez Islands (2), and Tristan da Cunha (6). There are six published sightings attributed to this species, one from New Zealand, one from the Seychelles Islands, one from the South

Sandwich Islands, two from Tristan da Cunha and one from south of Tasmania. It is limited to temperate waters and may not ordinarily come as far north as the tip of Africa.

III. Ecology

This species presumably feeds primarily on squid and fish. One adult female that stranded in Argentina had traces of bottom fish, squid, and one small crab (Mead and Payne, 1975). A calf had plastic debris in its stomach, but it is not known whether it had begun to take normal solid food. Another stranded adult from Tristan da Cunha had only remains of cephalopods in its stomach. All of the beaked whales that are moderately well known feed offshore in deep water.

IV. Behavior and Physiology

Recent studies have defined the appearance of this species at sea. Groups of up to 10 animals have been sighted, but behavioral observations are rare.

V. Life History

Adults are between 6 and 7 m in length. The only known calf was 340 cm long. One adult male had 23 growth layer groups in its teeth and was presumably 23 years old.

VI. Interactions with Humans

Shepherd's beaked whale has not been known to be involved in any fisheries and certainly has not been kept in captivity. It was first known to science by a publication on a stranded adult female which Shepherd found and collected in 1933.

Signature Whistles

LAELA S. SAYIGH AND VINCENT M. JANIK

Signature whistles were first described for several species of captive delphinids by Melba and David Caldwell in the 1960s (Caldwell and Caldwell, 1965) and reviewed in Caldwell *et al.* (1990). They found that individual dolphins, while isolated for medical attention, produced primarily one stereotyped individually distinctive whistle contour (pattern of frequency changes over time). Other researchers had speculated that dolphins would share a specific whistle for each context, such as being in isolation or in distress, or to indicate presence of food. However, it was difficult to

support or refute these claims since dolphins do not make any visible movement associated with vocalization, and thus it was not possible to identify which dolphin produced a sound at any given time. By recording isolated dolphins in captivity, the Caldwells were able to get around this problem. The signature whistle is defined as the most common whistle type that an individual uses when in isolation (Fig. 1). Signature whistles have now been documented in more than 300 individual bottlenose dolphins, *Tursiops truncatus*, in a variety of locations, both captive and wild, and there is evidence for them in four other delphinid species (common dolphins, *Delphinus delphis*, Caldwell and Caldwell, 1968; Pacific white-sided dolphins, *Lagenorhynchus obliquidens*, Caldwell and Caldwell, 1971; spotted dolphins, *Stenella plagiodon*, Caldwell *et al.*, 1973; and Pacific humpback dolphins, *Sousa chinensis*, van Parijs and Corkeron, 2001).

Although a study of captive dolphins by McCowan and Reiss (2001) suggested that signature whistles do not exist, more recent studies confirmed that signature whistles are an important component of the bottlenose dolphin vocal repertoire (Janik *et al.*, 2006; Sayigh *et al.*, 2007). In addition, McCowan and Reiss have recently acknowledged that there is evidence for a referential identity-labeling system based on signature whistles, which appears to lay the previous controversy to rest (Marino *et al.*, 2007).

Since the Caldwells' pioneering work, most work on signature whistles has focused on the bottlenose dolphin, and it has focused on four major questions, each of which are addressed below. First, how often do dolphins use signature whistles? Second, how do signature whistles function in the natural communication system of dolphins? Third, what is the role of signature whistle copying in the natural communication system of dolphins? Fourth, how do signature whistles develop in young animals?

The Caldwells had found that isolated animals in captivity tended to produce signature whistles almost exclusively; however, later studies showed that signature whistles are only one component of the whistle repertoire of bottlenose dolphins. For example, Cook *et al.* (2004) used data from brief capture-release studies to identify signature whistles in wild bottlenose dolphins and then followed these animals in other contexts to investigate signature whistle usage in the wild. They found that 52% of whistles produced by undisturbed wild dolphins in Sarasota Bay, FL, were signature or probable signature whistles. Thus, signature whistles are an important component of the whistle repertoire, but dolphins also produce a variety of other whistle types.

Signature whistles function both in individual recognition and in maintaining group cohesion. In playback experiments conducted during brief capture-release events in Sarasota Bay, FL, dolphins responded more strongly to whistles of related than non-related (but familiar) individuals (Sayigh *et al.*, 1999). These experiments were replicated using artificial stimuli resembling the contour shape of whistles of individual dolphins with all voice cues removed, demonstrating that animals actually recognized whistle contours (Janik *et al.*, 2006). The role of signature whistles in maintaining group cohesion was shown by Janik and Slater (1998), who found that captive dolphins were more likely to produce signature whistles when one group member voluntarily isolated itself from the rest of the group. This function of whistles was also supported by Smolker *et al.* (1993), who found that dolphins in Shark Bay, Western Australia, whistled during reunions. Dolphins can also encode information other than identity in their signature whistles (e.g., their own motivational state) by varying whistle parameters while keeping the overall gestalt of the whistle contour constant (Janik *et al.*, 1994).

The first study to address copying, or imitation, of signature whistles was conducted by Tyack (1986). He used a telemetry device called

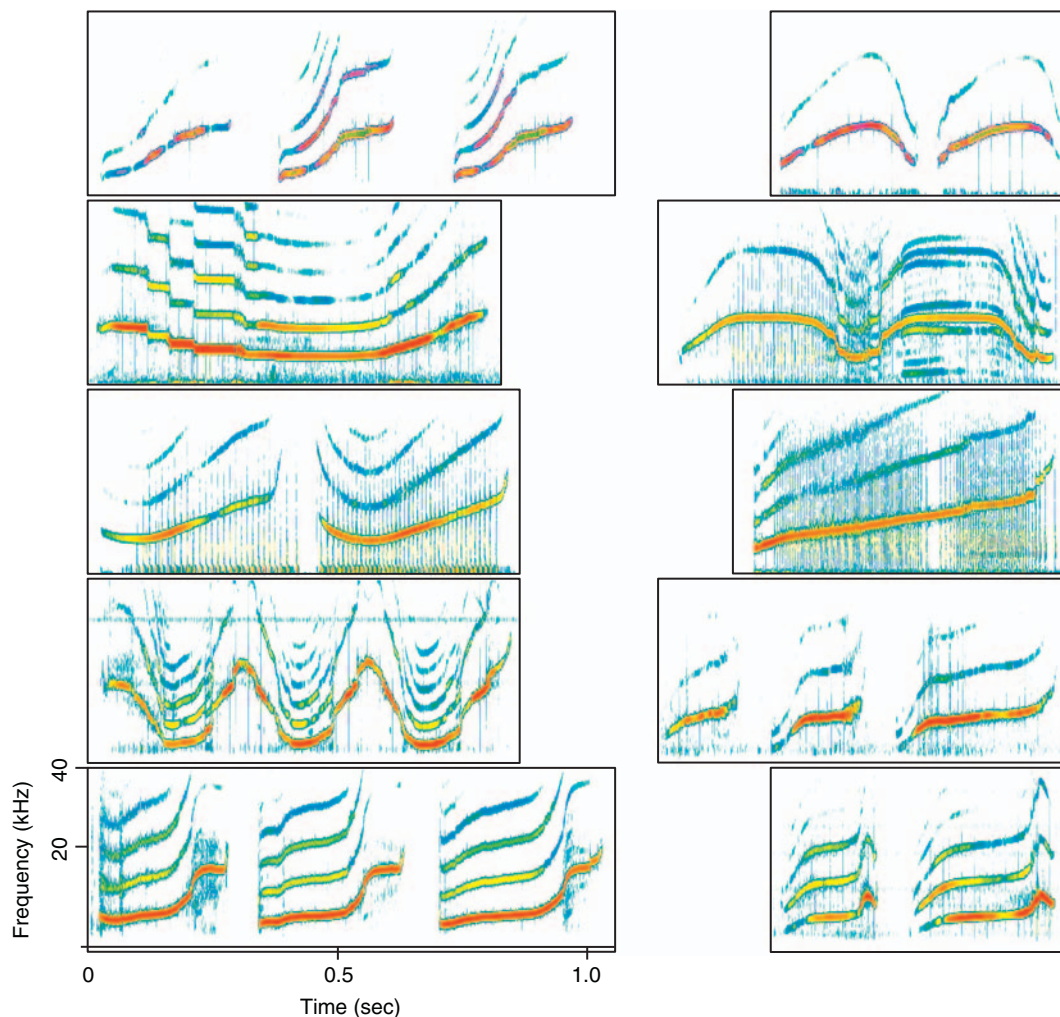

Figure 1 Examples of signature whistles of ten different individual bottlenose dolphins (*Tursiops truncatus*) recorded during temporary capture in Sarasota, Florida. Spectrograms were made with AVISOFT SASLab Pro, at a sample rate of 80,000 Hz and a 256 point FFT.

a “vocalight,” which dolphins wore on their heads and which lit up when a sound was produced, and found that socially interactive dolphins not only produce signature whistles, but that they also produce imitations of one another’s signature whistles. Janik (2000) found that free-ranging dolphins in Scotland also engage in such matching whistle exchanges. In addition, in both Shark Bay, Western Australia, and Sarasota, FL, close male associates can converge on a similar signature whistle type that they then use even outside of direct whistle interactions (Smolker and Pepper, 1999; Watwood *et al.*, 1999). Signature whistles of females, on the other hand, usually remain stable for more than a decade (Sayigh *et al.*, 1990, 1995). New technologies that enable localization of vocalizing animals are necessary to study how both signature and non-signature whistles (including whistle copies) are used in the natural communication system of dolphins.

In addition to discovering signature whistles, Caldwell and Caldwell (1979) were the first researchers to investigate vocal development in bottlenose dolphins. They found that young dolphins produce tremulous, quavery whistles, and then gradually converge on a stereotyped whistle contour during their first year of life. Sayigh *et al.* (1990, 1995) found that female dolphin calves in Sarasota, FL, tended

to produce whistles that were highly distinct from those of their mothers, whereas males were more likely than females to produce whistles similar to those of their mothers. This raised the possibility that dolphins may be learning their signature whistles from conspecifics. Much evidence supports the idea that dolphins learn whistles, which sets them apart from many other non-human mammals, in which vocal production is less flexible (Janik and Slater, 1997). Fripp *et al.* (2005) found that free-ranging dolphins in Sarasota appeared to learn their signature whistles from other community members, and Miksis *et al.* (2002) found that captive dolphins can incorporate human-made model sounds into their signature whistles. However, little is known about what factors govern the “choice” of whistle contours by calves. Again, studies that utilize acoustic localization with concurrent behavioral observations promise to shed light on this interesting question.

Signature whistles are an important class of vocalizations produced by bottlenose dolphins. They are learned vocalizations that function both in individual recognition and in maintaining group cohesion. Much work remains to be done in order to learn how these whistles develop and how they are used in the natural communication system of dolphins.

Sirenian Evolution

DARYL P. DOMNING

Sirenians are the order of placental mammals comprising modern sea cows (manatees and dugongs) and their extinct relatives. They are the only herbivorous marine mammals now living, and the only herbivorous mammals ever to have become totally aquatic. Sirenians have a known fossil record extending over some 50 million years (early Eocene–Recent). They attained a modest diversity in the Oligocene and Miocene, but since then have declined as a result of climatic cooling, other oceanographic changes, and human depredations. Only two genera and four species survive today: the three species of manatees (*Trichechus*) live along the Atlantic coasts and rivers of the Americas and West Africa; one, the Amazonian manatee, is found only in fresh water. The dugong (*Dugong*) lives in the Indian and southwest Pacific oceans. For comprehensive references to technical as well as popular publications on fossil and living sirenians, see Domning (1996).

I. Sirenian Origins

The closest living relatives of sirenians are the Proboscidea (elephants). The Sirenia, the Proboscidea, the extinct Desmostylia, and probably the extinct Embrithopoda together make up a larger group called Tethytheria, whose members (as the name indicates) appear to have evolved in the Old World along the shores of the ancient Tethys Sea. Together with the Hyracoidea (hyraxes), tethytheres seem to form a more inclusive group long referred to as Paenungulata. The Paenungulata and (especially) Tethytheria are among the least controversial groupings of mammalian orders, and are strongly supported by most morphological and molecular studies. Whereas morphological evidence associates these groups with the ungulates, however, molecular studies have placed them in the Afrotheria, together with insectivores, elephant shrews, and aardvarks. This discrepancy is unresolved (Gheerbrant et al., 2005). In either case, their ancestry is remote from that of cetaceans or pinnipeds; sirenians re-evolved an aquatic lifestyle independently of (though simultaneously with) cetaceans, ultimately displaying strong convergence with them in body form.

II. Early History, Anatomy, and Mode of Life

Sirenians first appear in the fossil record in the late early Eocene, and the order was already diverse by the middle Eocene (Fig. 1). As inhabitants of rivers, estuaries, and nearshore marine waters, they

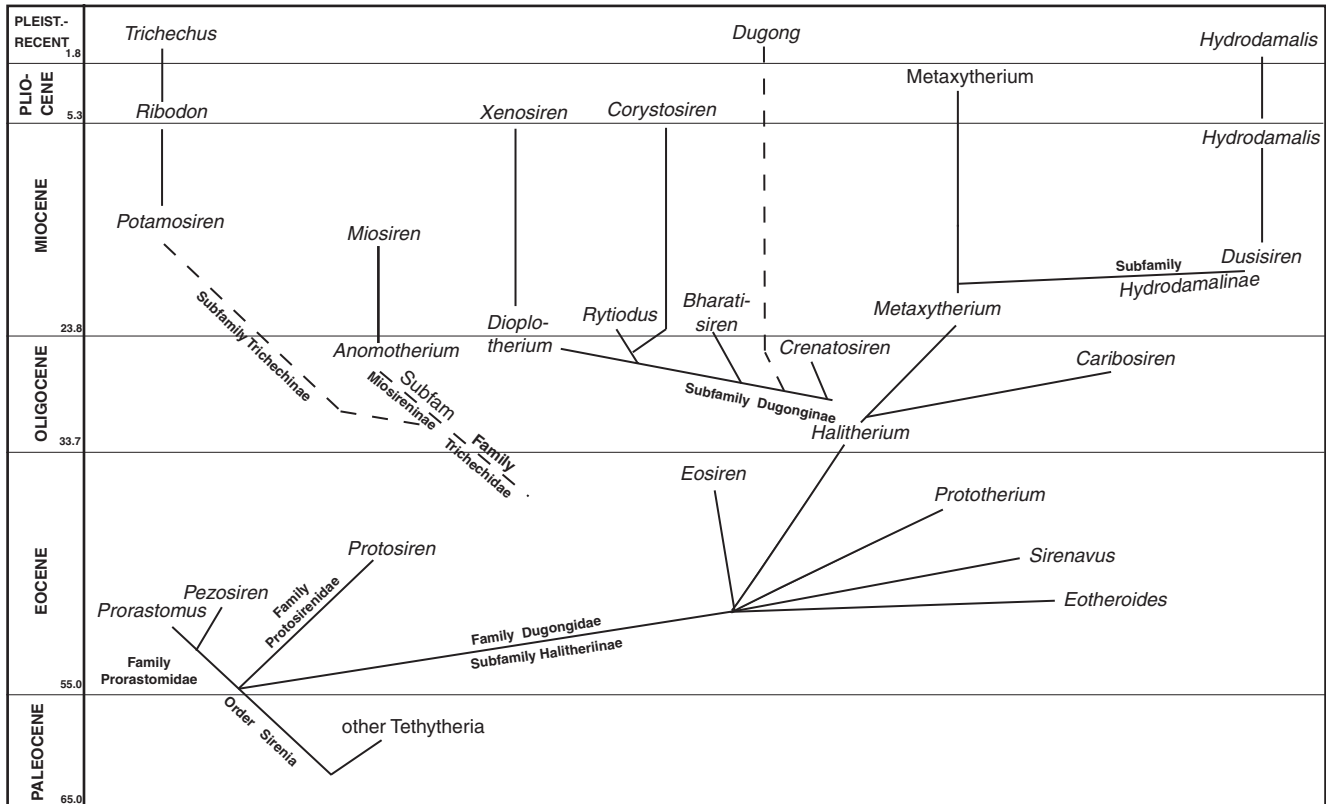

Figure 1 Simplified phylogeny of Sirenia, including better-known genera. The time scale (at left) is in millions of years. Undocumented “ghost lineages” that span multiple epochal boundaries are shown as dashed lines.

were able to spread quickly along the coasts of the world’s shallow tropical seas; in fact, the most primitive sirenians known to date (*Prorastomus*, *Pezosiren*; Fig. 2) were found not in the Old World but in Jamaica (Savage *et al.*, 1994; Domning, 2001a).

The earliest seacows (families Prorastomidae and Protosirenidae, both confined to the Eocene) were pig-sized, four-legged amphibious creatures (Fig. 2). By the end of the Eocene, with the appearance of the Dugongidae, sirenians had taken on their modern, completely aquatic, streamlined body form, featuring flipper-like front legs, no hind legs, and a powerful tail with a horizontal caudal fin, whose up-and-down movements propel them through the water, as in whales and dolphins (Fig. 3). The last-appearing of the four sirenian families (Trichechidae) arose from either protosirenids or primitive dugongids, probably during the Eocene. The sirenian fossil record now documents all the major stages of hindlimb and pelvic reduction from completely “terrestrial” morphology to the extremely reduced condition of the pelvis seen in modern manatees, thereby providing one of the

most dramatic examples of evolutionary change to be seen among fossil vertebrates.

From the outset, sirenians were herbivores, and probably depended on seagrasses and other aquatic angiosperms (flowering plants) for food. To this day, almost all members of the order have remained tropical, marine, and eaters of angiosperms. No longer capable of locomotion on land, sirenians are born in the water and spend their entire lives there. Because they are shallow divers with large lungs, they have heavy skeletons, like a diver’s weight belt, to help them stay submerged: their bones are both swollen (pachyostotic) and dense (osteosclerotic), especially the ribs, which are often found as fossils (Domning and de Buffrénil, 1991).

The sirenian skull is characterized by an enlarged and more or less downturned premaxillary rostrum, retracted nasal opening, absence of paranasal air sinuses, laterally salient zygomatic arches, and thick, dense parietals fused into a unit with the supraoccipital. Nasals and lacrimals tend to become reduced or lost, and in most

Figure 3 Skeleton of *Metaxytherium floridanum*, a Miocene halitherine dugongid. Total length about 3.2 m. After Domning (1988); reproduced with the permission of the Journal of Vertebrate Paleontology.

forms the pterygoid processes are large and stout. The periotic is snugly enclosed by a socket in the squamosal and is fused with a ring-shaped tympanic. The mandibular symphysis is long, deep, laterally compressed, and typically fused and downturned; in all but prorastomids the mandibular foramen is enlarged to expose the dental capsule. Incisors, where present, are arranged in parallel, longitudinally aligned rows. In all but the most primitive taxa, the infraorbital and mental foramina are enlarged to accommodate the nerve and blood supply to the large, prehensile, vibrissae-studded lips, which are moved by muscular hydrostats (cf. Marshall *et al.*, 1998).

Eocene sirenians, like Mesozoic mammals but in contrast to other Cenozoic ones, have five instead of four premolars, giving them a 3.1.5.3 dental formula. Whether this condition is truly a primitive retention in the Sirenia is still being debated. The fourth lower deciduous premolar is trilobed, like that of many other ungulates; this raises the further unresolved question of whether the three following teeth (dp5, m1, and m2) are actually the homologs of the so-called m1–3 in other mammals.

Although the cheek teeth are relied on for identifying species in many other mammalian groups, they do not vary much in morphology among the Sirenia, but are almost always low-crowned (brachyodont) with two rows of large, rounded cusps (bunobilophodont). (The most taxonomically informative parts of the sirenian skeleton are the skull and mandible, especially the frontal and other bones of the skull roof; Fig. 4.) Except for a pair of tusk-like first upper incisors seen in most species, front teeth (incisors and canines) are lacking in all but the earliest fossil sirenians, and cheek teeth in adults are commonly reduced in number to four or five on each side of each jaw: one or two deciduous premolars, which are never replaced, plus three molars. As described below, however, all three of the Recent genera have departed in different ways from this “typical” pattern.

III. Dugongidae

Dugongids comprise the vast majority of the species and specimens that make up the known fossil record of sirenians. The basal members of this very successful family are placed in the long-lived (Eocene–Pliocene) and cosmopolitan subfamily Halitheriinae (Fig. 1). This paraphyletic group included the well-known fossil genera *Halitherium* and *Metaxytherium*, which were relatively unspecialized seagrass eaters.

Metaxytherium (Fig. 3) gave rise in the Miocene to the Hydrodamalinae, an endemic North Pacific lineage that ended with Steller’s sea cow (*Hydrodamalis*)—the largest sirenian that ever lived (up to 9 m or more in length) and the only one to adapt successfully to temperate and cold waters and a diet of marine algae. It was completely toothless, and its truncated, clawlike flippers, used for gathering plants

and fending off from rocks, contained no finger bones (phalanges). It was hunted to extinction for its meat, fat, and hide circa AD 1768.

Another offshoot of the Halitheriinae, the subfamily Dugonginae, appeared in the Oligocene (Fig. 4). Most dugongines were apparently specialists at digging out and eating the tough, buried rhizomes of seagrasses; for this purpose many of them had large, self-sharpening blade-like tusks (Domning, 2001b). The modern *Dugong* is the sole survivor of this group, but it has reduced its dentition (the cheek teeth have only thin enamel crowns, which quickly wear off, leaving simple pegs of dentine) and has (perhaps for that reason) shifted its

diet to more delicate seagrasses and ceased to use its tusks for digging (Domning and Beatty, 2007).

IV. Trichechidae

Trichechidae have a much less complete fossil record than dugongids. Their definition has been broadened by Domning (1994) to include the Miosireninae, a peculiar and little-known pair of genera which inhabited northwestern Europe in the late Oligocene and Miocene (Fig. 1). Miosirenines had massively reinforced palates and dentitions that may have been used to crush shellfish. Such a diet in sirenians living around the North Sea seems less aberrant when we consider that modern dugongs and manatees near the climatic extremes of their ranges are known to consume invertebrates in addition to plants.

Manatees in the strict, traditional sense are now placed in the subfamily Trichechinae. They first appear in the Miocene, represented by *Potamosiren* from freshwater deposits in Colombia. Indeed, much of trichechine history was probably spent in South America, whence they spread to North America and Africa only in the Pliocene or Pleistocene (Domning, 2005).

During the late Miocene, manatees living in the Amazon basin evidently adapted to a diet of abrasive freshwater grasses by means of an innovation still used by their modern descendants: they continue to add on extra teeth to the molar series as long as they live, and as worn teeth fall out at the front, the whole tooth row slowly shifts forward to make room for new ones erupting at the rear. This type of horizontal tooth replacement has often been likened, incorrectly, to that of elephants, but the latter are limited to only three molars. Only one other mammal, an Australian rock wallaby (*Peradorcas concinna*), has truly evolved the kind of tooth replacement seen in manatees (Domning and Hayek, 1984).

Sirenian Life History

DANIEL K. ODELL

Sirenians are unique among the marine mammals in that they are herbivores. The mammalian order Sirenia has fossil representatives on the order of 50 million years old (Eocene epoch), making them as old as the cetaceans. While there are similarities between the two groups in terms of adaptation to the aquatic environment (e.g., streamlining, loss of hind limbs, use of the tail for propulsion), the sirenians stayed on the path to herbivory while the cetaceans switched from the herbivorous habits of their terrestrial ancestors to become carnivores. Modern sirenians include three species of manatees (family Trichechidae: Amazonian manatee, *Trichechus inunguis*; West African manatee, *T. senegalensis*; West Indian manatee, *T. manatus*; the latter is divided into two subspecies: Antillean manatee, *T. m. manatus*, and Florida manatee, *T. m. latirostris*). The Sirenia also includes the family Dugongidae: dugong, *Dugong dugon*, and Steller's sea cow, *Hydrodamalis gigas*). The manatees, as their common names suggest, are distributed in the coastal tropical and subtropical regions of the Atlantic Ocean. The dugong is found in the South Pacific and Indian Ocean regions. The manatees and the dugong are considered endangered or threatened under various national laws and international conservation schemes. The Steller's sea cow is the exception, not only is it extinct (eliminated by over-hunting about 25 years after its discovery in 1765) but it inhabited the islands in the western reaches of the Aleutian archipelago in the North Pacific Ocean. Definitely not a tropical clime!

I. Methodology

Ricklefs (1973) stated that “The life history of an organism can be described in terms of fecundity, growth and development, age at [sexual] maturity, parental care, and longevity.” These parameters are closely linked and are acted on by natural selection. While these parameters are easy to state, they are not always easy to measure. It is easy to study a colony of mice in the laboratory but not so with an animal like the Florida manatee that may reach a length of over 4m

and a weight in excess of 1500 kg. How, then, does one get this information for Sirenians? Approaches to this question involve both field and “laboratory” (i.e., animals in captivity in marine zoological parks and zoos) studies. In the field, one can learn to identify individual animals using shape, size, and various markings and color patterns or one can mark) using various methods) individual animals. For large, long-lived, aquatic mammals like the sirenians, this becomes an extremely expensive and time-consuming operation. However, in many cases, it is the only way to obtain the desired information. Alternatively, one can collect data from animals that die from both natural and unnatural (i.e., human-related) causes. Animals killed for human consumption or those killed as a result of other human activities provide a sample, albeit potentially biased (nonrandom), of males and females of all age classes. Marine mammal stranding networks collect life history data on animals found dead (i.e., stranded, beach cast, beached). In Florida, the Florida Fish and Wildlife Conservation Commission operates a network dedicated to the collection and examination of all manatees found dead in the state. From these carcasses one can gather information on, among others, reproductive status (immature, mature, pregnant, number of pregnancies) and age. Estimating the age of an animal is critically important in the estimation of life history parameters. Toothed cetaceans and pinnipeds, for example, have permanent teeth with roots that grow continually (but slowly) from birth to death. One can section these teeth and, under the microscope, count growth layer groups (GLGs). If one then knows the frequency with which these GLGs are deposited (e.g., one per year, 2 per year), GLG counts can be directly converted to and estimated age in years. The frequency of GLG deposition can be estimated using known age animals and using chemical markers deposited in the teeth of live animals. There is variability in the reliability of this process from species to species and the only way to know the true age of an animal is to follow it from birth to death. Growth layers are also often deposited in growing bone. The dugong has tusks that erupt through the gums in the male but not in the female. These tusks grow throughout the life of the animal and GLGs accumulate on an annual (assumed) basis. Manatees, however, do not have permanent teeth. While some growth layers are present in the tooth roots in young animals, these are lost through resorption, as manatees have a continual, horizontal (back to front) tooth replacement throughout life. However, because other growing bones accumulate GLGs, scientists discovered that GLGs in manatee ear bones can be used to estimate age. Studies with chemical markers demonstrated that manatee GLGs accumulate on an annual basis.

Studies with dead animals are very useful and relatively inexpensive, but long-term studies on live animals are necessary to fill in the life history blanks. For example, by following a female from year to year, it is possible to document when she has a calf and how much time elapses between successive calves. While radio and satellite tracking allows scientists to follow individual manatees over long periods of time, it is virtually impossible to watch them from minute to minute. However, studies on manatees in captivity (aka “the laboratory”) can fill some of these life history gaps, particularly in the areas of reproductive biology and growth and development. In captivity manatees *can* be observed continually if necessary. Blood and urine samples can be collected to document estrous cycling and gestation in females and testicular activity cycling in males. Parental care of the offspring can be documented in great detail.

II. Longevity

Detailed age estimation studies have only been done for the Florida manatee and for the dugong. Using tetracycline marking,

we know that Florida manatees deposit one GLG per year. Based on growth layer groups in the ear bone complex, some Florida manatees may live to be 60 years of age. However, due to bone resorption, 60 years may be a minimum estimate. A manatee born in the Miami Aquarium in 1948 is alive and well today (July 2007) at an aquarium in Bradenton, Florida. This animal provides a good measure of validation for the 60-year estimate. The average longevity for Florida manatees has not been well estimated but is probably on the order of 30 years less. This estimate may be biased downward by manatee deaths resulting from human activities (e.g., watercraft collisions). Average longevity may vary between sexes and among year classes. Longevity data do not exist for Antillean, Amazonian, or West African manatees.

Based on GLGs in their tusks, the oldest dugong examined to date was a female with 73 GLGs, which translates to 73 years if we assume one GLG per year. Tusks in male dugongs erupt through the gums and are worn down, eliminating the early GLGs in older animals. Minimum maximum longevity estimates for male dugongs are about 35 years.

III. Age at Sexual Maturity

Female Florida manatees reach sexual maturity between 2.5 and 6 years of age. Male Florida manatees reach sexual maturity between 2 and 11 years of age based on the presence of active spermatogenesis in the testes. It is important to note that even if a male manatee is sexually mature at an early age, it may not be physically large enough to compete for mating rights in an estrous (mating herd). However, under circumstances wherein there are not other competing males, small manatees may be able to mate successfully and produce offspring. There are no data on age at sexual maturity for Antillean, Amazonian, or West African manatees.

Even though the estimated maximum life expectancy for the dugong is similar to that of the Florida manatee, dugongs appear to mature at greater ages, and the age at sexual maturity may vary among populations. Female dugongs in Australia and Papua New Guinea mature at 9.5–17.5 years. Male dugongs in the same areas mature at 9–16 years of age. These differences could reflect distinct genetic differences between populations or the effects of density-dependent factors.

IV. Parental Care

In both manatees and dugongs the male plays no apparent role in the care of the young. After mating, males and females go their separate ways. Florida manatee calves will stay with their mothers for 1 year on average. Most calves (about 70%) stay with their mothers through one winter season and the remainder through two winter seasons. Nutritional weaning is a gradual process but there are few data on the length of lactation in the Florida manatee or in the dugong. Lactation may last 1.5 years in dugongs and is probably similar in the manatee. Some wild and captive manatees appear to lactate for several years under certain circumstances. Most Florida manatee and dugong calves start feeding on vegetation at a few weeks of age and may be nutritionally independent before they reach the age of 1 year. However, at least in the case of the Florida manatee, calves probably learn the locations of feeding areas and warm water refugia by following their mothers through at least one winter season. The latter is extremely important for weaned juvenile survival during cold winters.

V. Growth and Development

Florida manatee calves average about 120 cm in length at birth, but viable calves may have a birth length ranging from about 80 to 160 cm. This, along with variable individual growth rates, results in a highly variable length at age distribution. For example, 2-year-old manatees at Blue Spring (Florida) may range from 210 to 260 cm total length. From a sample of carcasses of Florida manatees in the age class >1 and <2 years, total lengths ranged from about 120 to over 260 cm. Florida manatees grow rapidly during the first few years, and body length becomes asymptotic at about 300 cm and an age of 8–10 years. The birth weight for Florida manatees ranges from 30 to 50 kg and the average adult body weight is about 500 kg. The Antillean and West African manatees are probably similar to the Florida manatee in these respects. The Amazonian manatee is smaller and has a birth length of 85–100 cm and a birth weight of 10–15 kg. Large adults may reach lengths of 280 cm and weights of 480 kg. The dugong has a birth length of 100–130 cm and a birth weight of 25–35 kg. Adult dugongs average 270 cm in length and 250–300 kg body weight.

VI. Fecundity

As with other aspects of sirenian life history, data on fecundity are limited and based primarily on studies of the Florida manatee and the dugong. A key factor in assessing fecundity is the gestation period, which, despite numerous conceptions and births of Florida manatees, is not known for any sirenian species. However, scientists generally agree that gestation for the Florida manatee and the dugong is in the range of 12–14 months and that the other species of sirenians are probably similar. The known inter-birth interval for wild Florida manatees averages 2.5–2.6 years. The estimated inter-birth interval for Florida manatees ranges from 2.5 to 3.0 years when gestation period estimates of 12, 13, and 14 months are applied. This suggests that the true gestation period may be close to 12 months. Estimated inter-birth intervals for the dugong range from 2.7 to 5.8 years depending on the length of the gestation period assumed (12, 13, or 14 months) and the population of dugongs used. We do know that Florida manatees resume estrous cycling within 1–2 months after the loss of a calf and become pregnant shortly thereafter. Whereas manatees and dugongs (both males and females) display seasonal reproductive activity, there is scant evidence to suggest that they have reproductive senescence as many mammals, including humans, do.

Other factors important in the calculation of fecundity are the number of offspring per birth and the sex ratio of offspring at birth. Wild Florida manatees have been documented producing twin offspring (but no more) in about 1.4–1.8% of births. Estimates of twinning based on Florida manatee carcass studies are as high as 4%. Limited and/or anecdotal data suggest that twinning occurs in the Antillean manatee and in the dugong. The sex ratio of the offspring at birth appears to be 1:1 for both the Florida manatee and the dugong. It is probably reasonable to assume that both Amazonian and West African manatees have similar patterns of twinning and offspring sex ratio.

Applying all of our knowledge of and assumptions about Florida manatee life history, the average fecundity (number of female births per female per year) for age classes 4–29 years was estimated at 0.189, 0.238, and 0.127 using different sets of data obtained from the examination of carcasses. Similarly, estimates of annual pregnancy rate (APR) and gross annual recruitment rate (GARR) ranged from 0.190 to 0.394 and 0.044 to 0.90, respectively, depending on the set of carcass data and gestation period used. Similar calculations for the dugong based on a smaller data set yielded apparent (annual) pregnancy rates of 0.093–0.353 over a series of years. Both the State of Florida

(Haubold *et al.*, 2006; Florida Fish and Wildlife Conservation Commission, 2006) and the US Fish and Wildlife Service (2007) have used life history parameters to assess the status of the Florida manatee. These reports include references to several population modeling projects that were in progress and that were not (at the time the reports were released) available for general public consumption in the peer-reviewed or gray literature.

VII. Summary

Even though the Florida manatee and the dugong have been studied intensively since the 1980s, detailed data on many aspects of their life history are only beginning to be elucidated and there is considerably less information on the other species of sirenians. Given the threatened or endangered status of this unique group of marine mammals, every effort should be made to learn about their biology so that we may ensure their survival.

DKO has been involved with marine mammal studies since 1965 and has worked on pinnipeds, Sirenians and the smaller cetaceans. He has held positions at the University of Miami's Rosenstiel School of Marine and Atmospheric Science, and in Corporate Zoological Operations for the Busch Entertainment Corporation (SeaWorld and Bush Gardens parks). He has served as president of the Society for Marine Mammalogy and president of the Florida Academy of Sciences. He has worked on sirenians, particularly the Florida manatee, since 1974 and was a co-founder of the Florida manatee carcass salvage program.

Skeleton, Postcranial

SENTIEL ROMMEL AND JOHN E. REYNOLDS, III

The postcranial skeleton includes all the bones and cartilages caudal to the head skeleton; it is subdivided into axial components (the vertebral column, ribs, and sternbrae, which

are “on” the midline) and appendicular components (the forelimbs, hindlimbs, and pectoral and pelvic girdles, which are “off” the midline). The skeleton supports and protects soft tissues, controls modes of locomotion, and predominantly determines overall body size and shape. The marrow of some bones may generate the precursors to certain blood cells. Skeletal elements may store lipids (particularly in the Cetacea) and calcium (particularly in the Sirenia) and thus influence buoyancy (Kipps *et al.*, 2002). Because bones are continuously remodeled in response to biochemical and biomechanical demands over the life span of the marine mammal, they offer information that can help interpret life history events after death.

We discuss the skeletons of seven different species of marine mammals: the Florida manatee (*Trichechus manatus latirostris*), the harbor seal (*Phoca vitulina*), the California sea lion (*Zalophus californianus*), the North Atlantic right whale (*Eubalaena glacialis*), the bottlenose dolphin (*Tursiops truncatus*), the polar bear (*Ursus maritimus*), and the sea otter (*Enhydra lutris*). We use the domestic dog skeleton (*Canis familiaris*) to provide a familiar reference. These marine mammal species were chosen, in part, because much is known about them and they provide a wide range of biomechanical morphologies. The skull morphology of these seven species is described in the chapter entitled SKULL ANATOMY of this encyclopedia. The manatee, dolphin, and right whale represent the many species that have lost their hindlimbs and are permanently aquatic; the other species may spend at least some of their life on land.

Visualize the articulated (assembled) skeleton by first considering individuals in an absolute sense (left and lower parts of Fig. 1) and then in a relative sense (upper right of Fig. 1). Consider what decisions morphologists make when comparing features among individuals that differ substantially in size. Contrast the two methods of scaling by using the human swimmer as a reference. Because relational comparisons (such as proportions and percentages) are intuitive, we use the relative scheme for most of this chapter.

We will refer to the manatee when describing individual morphological structures but refer to the seven selected marine mammal species when discussing marine mammals in general (for details on the same structures in the dolphin, see Rommel 1990; for the true seals, see Pierard, 1971; Pierard and Bisaillon, 1978; for the dog, see Evans, 1993; for mammals in general, see Flower, 1885).

I. Axial Skeleton

A. Vertebral Structures

A few terms are necessary to better grasp the functional morphology of the vertebral column. Each *vertebra* (plural *vertebrae*) has several parts (Fig. 2A). The body or *centrum* (plural *centra*) of each vertebra forms the primary mechanical support of the vertebral (spinal) column (Fig. 2B). Several projecting parts or *processes* may extend from the centrum and provide connective tissue attachment sites, protection for soft tissues, or both. The largest and most common lateral processes are transverse processes, which tend to be long and robust in the lumbar vertebrae. In the cervical region, there may be two transverse processes extending from each side of a single vertebra.

Dorsal to the centrum is the *neural arch*, an arch of bone that protects the spinal cord. Interestingly, in some marine mammal species, the neural arch is considerably enlarged to accommodate relatively large masses of vascular tissue and/or fat that surround the spinal cord. Because of these enlargements, the neural canal may not reflect the dimensions of the spinal cord as it does in most terrestrial species (Giffen 1992). In addition, each neural arch may extend

dorsally as a *neural spine* (spinous process). Neural spines function as levers to increase the mechanical advantage of the epaxial (epiaxial) muscles to dorsoflex the body (Pabst, 1993).

Relative motion between adjacent vertebrae is controlled, in part, by the size and shape of the *intervertebral disks* (Fig. 2C). Intervertebral disks are flexible yet resist compression; they consist of a fibrous outer ring, the *annulus fibrosus* and a gelatinous inner mass, the *nucleus pulposus*. The jelly-like nucleus forms a dynamic joint that can adjust its shape within the elastic fibers of the annulus. Intervertebral disks are resilient structures that support complex forces of bending. The same design of surrounding a deformable core with elastic fibers is used in baseballs and golf balls.

Flexibility of the vertebral column depends, in part, on the thickness of the disks. Disk thickness varies within and among species, and intervertebral disks represent a substantial proportion (10–30%) of the length of the vertebral column. Relaxed (neutral) curvature of the vertebral column is determined by the shapes of the individual vertebrae, *not* by the shapes of the intervertebral spaces. Intervertebral disks provide flexibility, whereas curvature is provided by (nonparallel) vertebral body faces (Fig. 3).

Adjacent vertebrae may have other surfaces of articulation (facets); *zygapophyses* (singular, *zygapophysis*) may be located on the neural arch, neural spine, and/or the transverse processes. *Zygapophyses* are bilaterally paired articular facets, found on the cranial and caudal aspects of each vertebra (Fig. 2D). The cranial pair are termed *prezygapophyses*, and the caudal pair *postzygapophyses*. The region of articulation between *prezygapophyses* and *postzygapophyses* is typically a synovial joint if the facets overlap.

The *zygapophyses* in the neck and cranial thorax tend to be oriented horizontally to allow axial rotation (twisting) and lateral (side-to-side) motions. The *zygapophyses* in the caudal thorax and tail tend to be oriented vertically to facilitate dorsoventral (up-and-down) motions. In some regions of the vertebral column adjacent vertebrae may have reduced or absent *zygapophyses*. Test these *zygapophyseal* constraints on yourself by bending and twisting your body—note how your thorax (rib-bearing region) flexes (most of the axial rotation and some lateral flexion occurs here) when compared with your lumbar (low back) region (where most of the allowable dorsoventral flexion occurs).

B. Vertebral column

Traditionally, the typical mammalian vertebral column is separated into five regions, each of which is defined by what is or is not attached to the vertebrae. These regions are cervical, thoracic (“dorsal” in the older literature), lumbar, sacral, and caudal (Fig. 3). The *vertebral formula* is an alpha-numerical abbreviation for the numbers of vertebrae in each region. For example C6:T17:L1:S0:Ca25 describes the 6 cervical, 17 thoracic, 1 lumbar, 0 sacral, and 25 caudal vertebrae in the Florida manatee. Individual vertebrae in each region are also referred to by their position using one or two (regiospecific) letters and a number. For example, the third cervical vertebra is designated as C3. The total number of vertebrae, excluding the caudal vertebrae, is surprisingly close to 30 in most mammals (Flower and Lydekker 1891). Using the vertebral formula, contrast the vertebral column of the selected species (Fig. 3).

C. Cervical Region

Cervical vertebrae (Figs. 3, 4A) are cranial to the rib-bearing vertebrae of the thorax. Most mammals have seven cervical vertebrae; but all the sirenians and the two-toed sloth (*Choloepus*) have six and

Figure 1 Selected marine mammal skeletons (the Florida manatee, the harbor seal, the California sea lion, the North Atlantic right whale, the bottlenose dolphin, the polar bear, and the sea otter) compared with the skeleton of the domestic dog. The drawings on the left and bottom are scaled so that 1 m on any one species equals 1 m on all the others in this group. The range of adult total body lengths (snout-tip to tail-tip; note that human height is measured differently) is given in meters beneath each drawing. This group is sized to fit the right whale onto the page. Skeletons in the group on the upper right are scaled so that the distance between the shoulder and the hip joints are equal in all seven species. Thus, the body cavities of this group are approximately the same length. A reference line representing 1 m is given below each of these drawings; note that it is different for each skeleton in this scaling scheme. Both groups are sized so that the dolphins on the right and left are equal in length. Copyright S. A. Rommel.

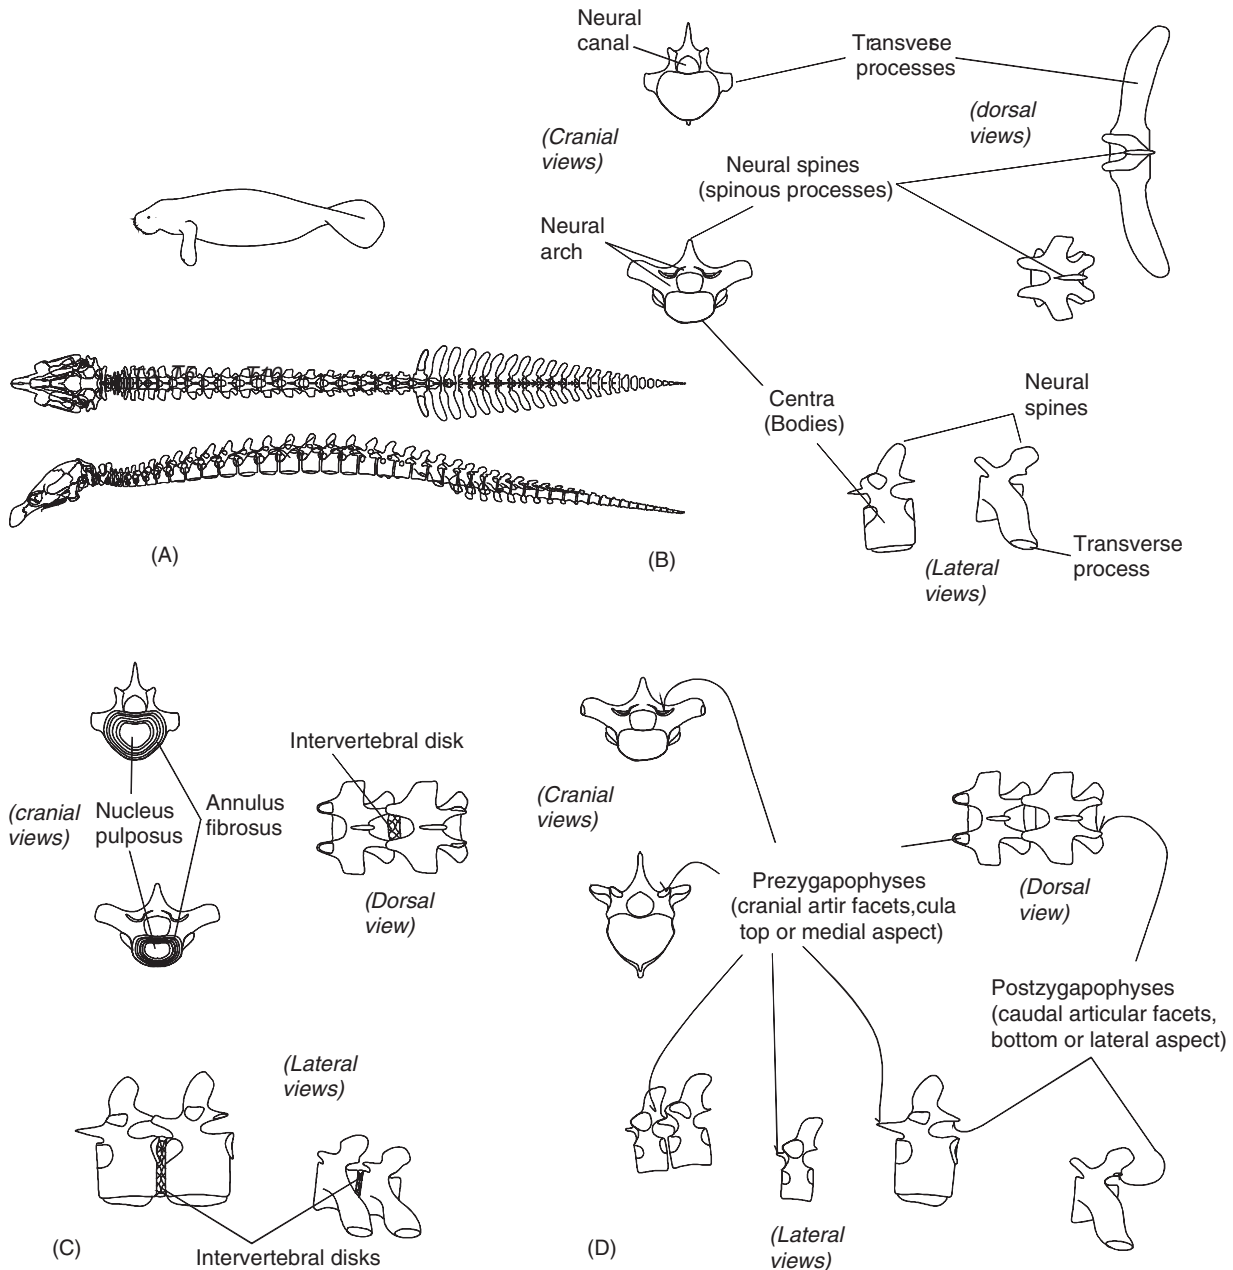

Figure 2 (A) Dorsal and lateral views of the manatee and its vertebrae. (B) Parts of a vertebra. The centrum (body) of each vertebra is the primary mechanical support of the vertebral column. Vertebral centra help prevent the body of the animal from collapsing when large body muscles contract. Dorsal to the centrum is an arch of bone, the neural arch; within the arch is the neural canal. The neural arch protects the spinal cord and it may extend dorsally as a neural spine (spinous process). (C) The flexible region between adjacent centra functions as a tough joint, the intervertebral disk. These intervertebral fibrocartilage joints have two parts: the inner nucleus pulposus and the outer annulus fibrosus. (D) Zygapophyses are articular facets that constrain motions between adjacent vertebrae. The cranial pair on each vertebra are prezygapophyses and the caudal pair are postzygapophyses. The region of articulation between prezygapophyses and postzygapophyses of adjacent vertebrae is typically a synovial joint if the facets overlap. In some regions of the vertebral column the facets do not overlap and they may be connected by collagen fibers. Copyright S. A. Rommel.

the three-toed sloth (*Bradypus*) has nine. Serial fusion (ankylosis) of two or more cervical vertebrae is common in cetaceans, but all cetaceans have seven cervical vertebrae. Contrary to what has been reported in some published works, the cervical vertebrae in some

cetaceans (e.g., the narwhal, beluga, and river dolphins) are unfused and provide considerable neck mobility.

The first two cervical vertebrae are named the *atlas* (C1) and the *axis* (C2). Unlike all other vertebrae, the atlas and axis of most

Figure 3 The axial skeletons plus pelvis of the seven selected marine mammal species. There are typically five separate vertebral regions: cervical, thoracic, lumbar, sacral, and caudal. In this illustration, each skull and vertebral column is scaled to similar shoulder-~hip distances. Sacral vertebrae are, by definition, associated with an attached pelvis; therefore, the permanently aquatic species with (unattached) pelvic vestiges, have no sacral vertebrae. The permanently aquatic species (manatee, dolphin, and right whale) have pelvic vestiges. The vertebral formula, an alpha-numerical abbreviation for the numbers of vertebrae in each region is located below each common name; the numbers given are for the specimens illustrated; some of these numbers vary between individuals of each species. Vertebral ribs extend from the vertebral column to join the sternal ribs, which extend from the sternum. The sternum develops from a series of sternabrae. In some species (e.g., humans, right whales, and manatees), the sternabrae fuse into a single bony unit. Copyright S. A. Rommel.

mammals are not separated by an intervertebral disk but rather by a synovial joint, similar to the skull-atlas joint (Fig. 4A); the shapes of these first two vertebral joints dictate the range of motion between the skull and the vertebral column. Typical skull motions on the atlas are up-and-down and side-to-side (Fig. 4A). The axis has an elongated centrum, the *dens* (odontoid process), which restricts motions between the atlas and axis to rotations. Test these constraints on yourself by bending and twisting your head and neck. Head nodding, as in expressing “yes,” is constrained by the skull-atlas joint; head rotations expressing “no,” are constrained by the atlas-axis joint.

Typically, the permanently aquatic marine mammals have relatively short necks; in contrast, the pinnipeds have relatively long necks. Comparison of the skeletons of the seal and sea lion reveals that they have similar neck lengths, although external appearance is very different. Seals often hold their heads close to the thorax, which causes the neck to form a deep “S” curve, providing them with a “slingshot potential” for grasping prey (or inattentive handlers).

Cervical vertebrae may have distinct *transverse foramina* that protect blood vessels when the neck is flexed. Transverse foramina are particularly distinct in the cervical vertebrae of the carnivorous marine mammals. A pair of notches (or foramina) in the neural arch of the atlas may be present (Fig. 4A); these openings are for the first spinal nerve pair that exits the neural canal between the back of the skull and the neural arch of C1. Rarely, one finds *cervical ribs*, which are moveable extensions of the ventral transverse processes; cervical ribs do not extend to the sternum.

D. Thoracic Region

The thoracic region (thorax) is defined by the presence of more or less movable (i.e., not fused to the respective vertebrae) ribs (Figs 3, 4B). The thoracic and lumbar vertebrae support the trunk. By definition, the first thoracic vertebra has a pair of ribs that, unlike cervical ribs, extend to the sternum. Most thoracic vertebrae have ribs that possess two segments. The proximal, dorsal segment is attached to the vertebral column and is termed a *vertebral rib* (Fig. 3). A distal, ventral segment is attached to the sternum and is termed a *sternal rib* (Rommel and Parsons, 1986). A joint between the vertebral rib and sternal rib may help accommodate flexibility of the thorax. The distinction between vertebral and sternal ribs is more common in birds and some reptiles, but it is less common in mammals because most mammals have cartilaginous sternal ribs termed costal cartilages. We make this distinction because, unlike most other mammals, some odontocete cetaceans have bony rather than cartilaginous sternal ribs (Rommel 1990; Cotten *et al.*, in press).

As suggested above, the mechanics of motion of the thoracic vertebrae are different from those of either the cervical vertebrae or the post-thoracic vertebrae. Typically, the thorax is relatively more flexible axially and laterally than dorsoventrally. Thoracic vertebrae have dual functions of longitudinal body support and (with their ribs) support of the respiratory muscles. This dual function is reflected in the arrangement, size, and shape of the zygapophyses. The last thoracic vertebrae have ribs associated with them, but these last ribs may not be attached to their respective vertebrae, with little or no indication on their respective vertebrae to indicate their presence. The attachment sites of ribs on the vertebrae are called *rib facets* (costal facets; ribs = costae) if the region of attachment has a distinct articulation (Fig. 4B). Rib facets may be located on the vertebral centrum, on the transverse processes, or on both. Some rib attachments are made via long connective-tissue fibers; these ribs do not actually contact the respective vertebra, and there is no obvious structure on the (cleaned) vertebrae to suggest rib attachment. For this reason, dogmatic adherence to narrow definitions of numbers of thoracic or lumbar vertebrae, or both should be avoided. The cetaceans and pinnipeds have very mobile rib cages. Surprisingly, diving mammals have considerable dorso-cranial to ventro-caudal “tilt” to their ribs. In these species, the double-headed ribs (see below) have joints that are aligned to allow for substantial cranial to caudal swing of the attached vertebral ribs. This extreme mobility of the rib cage can help accommodate the lung volume changes that accompany changes in pressure with depth. It may also have evolved to accommodate rib cage dynamics that occur during lung ventilation (Cotten *et al.*, submitted) caused when abdominal muscle contractions prevent caudal displacement of the diaphragm during inspiration; in this case ribs, could be moved forward to increase lung volume.

Some thoracic vertebrae have ventral vertebral projections called *hypapophyses*—not to be confused with chevron bones (chevrons typically span the intervertebral joints and are not parts of the vertebrae themselves; Figs. 3, 4C). In the manatee, the central tendon of the diaphragm is firmly attached along the midline to hypapophyses. Hypapophyses also occur in some cetaceans (i.e., *Kogia*, the pygmy and dwarf sperm whales) in the caudal thorax and cranial lumbar regions; these hypapophyses are associated with the diaphragm.

Thoracic neural spines are often longer than those in other regions of the body (Figs. 3, 4) to provide mechanical advantage for neck muscles. Interestingly, terrestrial species with large heads tend to have long neural spines; however, the buoyancy of water may negate the need for such long neural spines in the marine mammals—contrast the animals that come onto land with the fully aquatic ones in this regard.

Figure 4 (A) The cervical vertebrae. At the top of this illustration, these vertebrae are filled in on the dorsal and lateral views of the manatee skeleton. The first and second cervical vertebrae are named the atlas and the axis, respectively. Cervical vertebrae may have transverse foramina, which perforate the bases of the transverse processes. Typical skull motions on the atlas are up-and-down and side-to-side. The axis has an elongated centrum, the *dens*, which extends into the large neural canal of the atlas. The shape of the *dens* restricts motions between the first two vertebrae to rotations parallel to the long axis of the body. (B) Thoraco-lumbar vertebrae. Thoracic vertebrae support the ribs, which anchor the diaphragm muscles. Some ribs are double headed and articulate with their respective vertebrae via capitula and tubercula. Each capitulum articulates with one or more costal facets on the vertebral centrum at or near the intervertebral disk. Each tuberculum articulates with a facet on the transverse process of its respective vertebra. Lumbar vertebrae are trunk vertebrae without ribs—instead they have pronounced transverse processes. In manatees there may be a rib on one side and a transverse process on the other side of the same lumbar vertebra. (C) Caudal vertebrae are found in the tail. At the top of this illustration, these vertebrae are filled in on the dorsal and lateral views of the manatee skeleton. In the permanently aquatic marine mammals that have no direct attachment between the pelvic vestiges and the vertebral column, the transition between lumbar and caudal vertebrae is defined by the presence of chevron bones. The chevron bones are ventral intervertebral ossifications. By definition, each chevron is associated with the vertebra cranial to it. Copyright S. A. Rommel.

Ribs and transverse processes are homologous structures, but the presence of a movable joint ultimately distinguishes a rib from a transverse process in an adult. An “unfinished” joint may be indicative of developmental age; in manatees, there may be a movable “riblet” (pleurapophysis, *pleura* = side or rib) on one side and an attached “transverse process” on the other side of the same (typically the first lumbar) vertebra. Pleurapophyses are more common in some of the lower vertebrates (Romer and Parsons, 1986; Kardong, 1998).

A rib may attach to its respective vertebra (Fig. 4B) at one or more locations. Typically the first few ribs are “double-headed” and have two distinct articulations with their juxtaposed vertebrae. The cranial-most articular part of a double-headed rib is the *capitulum* (plural, *capitula*) or head, and it articulates (via a synovial joint) with the body (or bodies) of one or two vertebrae. The *tuberculum* (plural, *tubercula*) is the second attachment site of a double-headed rib; it articulates (either with a synovial joint or by connective tissue fibers) to a transverse process of the respective vertebra. Since the *capitula* of some double-headed ribs touch two vertebrae, the vertebra with the transverse process attachment is used to identify the respective vertebra.

The caudal-most ribs have single attachments and are referred to as “single-headed”. In most mammals, the single-headed ribs have lost their tubercula and are attached to their respective vertebrae by the *capitulum* at the centrum. In contrast, the single-headed ribs of cetaceans lose their *capitula* and are attached to their respective vertebrae by their tubercula at the transverse processes (Rommel, 1990), as occurs in some reptiles. The transverse processes of cetacean thoracic vertebrae may be longer than those of other mammals. Thus, the single-headed ribs of cetaceans attach to the vertebrae farther from the midline than do the single-headed ribs of other mammals. The last ribs often “float” free at one or both ends, that is, they are attached to neither their associated vertebra nor the sternum.

E. Sternum

Embryonically, the sternum is formed from serial elements, called sternebrae (the sternal equivalent of vertebrae, Fig. 3). The first and last sternebrae are called the *manubrium* and *xiphisternum*, respectively. In some odontocetes, all mysticetes, and all sirenians, the sternebrae fuse into a single unit. Sternal ribs extend from the sternum to join the vertebral ribs. Seals have an elongated *prester-nal cartilage* extending cranially from the manubrium; some taxa, particularly the sea lion, have an enlarged post-sternal cartilaginous extension, the *xiphoid cartilage*.

F. Lumbar Region

The lumbar vertebrae are trunk vertebrae that typically do not bear movable ribs (Fig. 3). Recall that ribs and transverse processes develop from homologous embryonic structures. Occasionally, a distinct *pleurapophysis* may be found in this region. As noted above, pleurapophyses are commonly found in manatees; these “lumbar ribs” are clearly distinct from thoracic ribs (Fig. 4B). Typically, the lumbar vertebrae are more flexible dorsoventrally than they are laterally and they may have no axial flexibility. Some of the mobility of the lumbar vertebrae may be constrained by the ribs in front of them.

As already noted, the number of lumbar vertebrae is usually closely linked to the number of thoracic vertebrae; an increase in number in one section typically means a reduction in the other. For example, there are 19 thoraco-lumbar vertebrae in all species of

Artiodactyla, whereas there are 20 or 21 in the Carnivora; compare these numbers with those of the selected marine mammals (Fig. 3).

G. Sacral Region

There are at least two commonly accepted definitions for sacral vertebrae: (a) serial fusion of post-lumbar vertebrae, only some of which may attach to the ileum of the pelvis and (b) only those vertebrae that attach to the ileum, whether or not they are serially fused. Both definitions have merit. In species where there is contact between the vertebral column and the pelvis, it is relatively easy to define sacral vertebrae. However, it is not easy in the cetaceans and manatees because there is no direct attachment between the pelvic vestige and the vertebral column and there are no serially fused vertebrae in this region (dugongs have a ligamentous attachment between the vertebral column and the pelvic vestiges). Thus, most of the permanently aquatic species have, by either definition, no sacral vertebrae. In other mammals, the number of sacral vertebrae is commonly 2–5. Within a species, the number of serially ankylosed vertebrae may vary, particularly with age.

H. Caudal Region

Caudal (*cauda* = tail) vertebrae are found in the tail (Figs. 3, 4C). The number of caudal vertebrae varies widely. Long tails usually require numerous caudal vertebrae. Florida manatees have between 22 and 27 caudal vertebrae, and bottlenose dolphins 25–28—for cetaceans, the minimum is 13 in *Caperea marginata* (pygmy right whale); the maximum is 49 in *Phocaenoides dalli* (Dall’s porpoise). Note that the caudal vertebrae of cetaceans extend to the tip of the tail (fluke notch), whereas manatee vertebrae stop 3–9 % of the total body length from the fluke tip (Fig. 1). Caudal vertebrae range from being robust, important locomotory structures in the permanently aquatic species, to being relatively small vertebrae in the pinnipeds and polar bear.

I. Chevron Bones

The *chevron bones* or chevrons (Fig. 4C) are ventral intervertebral ossifications found only in the caudal region. They are relatively large in the permanently aquatic species but can be found as small ossifications in many other species, including the dog. Chevrons function to increase the mechanical advantage of the hypaxial muscles to flex the tail ventrally. By definition, each chevron is associated with the vertebra cranial to it (note that there is some controversy over which is the “first” caudal Rommel 1990). Pairs of chevron bones form arches, creating a ventral channel called the hemal canal. Within the hemal canal, the blood vessels (caudal arteries and veins) that supply the tail are protected. In sirenians and some cetaceans the chevron bone pairs fuse at the ventral midline.

II. Appendicular Skeleton

A. Pectoral Limb Complex

The forelimb (Fig. 5) is referred to as a flipper in the permanently aquatic species (in true seals and sea lions the hindlimb is also referred to as a flipper). The forelimb includes the scapula, humerus, radius and ulna, the multiple bones of the manus, and the clavicle.

The scapula is attached to the axial skeleton only by muscles; there is no functional clavicle in the marine mammals (Klima *et al.*, 1980; Strickler, 1978). The scapula consists of an essentially flat (slightly concave medially) blade with an elongate scapular *spine* extending laterally from it. The distal tip of the spine is the *acromion*.

Figure 5 The forelimb (pectoral appendage) includes the humerus, radius and ulna, and manus. The forelimb attaches to the pectoral girdle which is made of bilaterally paired scapulae. The scapula is a flat (slightly concave medially) blade with an elongated scapular spine extending laterally from it. The distal tip of the spine is the acromion process. The humerus has a ball-and-socket articulation with the glenoid fossa of the scapula. The humerus articulates with the radius and ulna at the elbow. The radius and ulna articulate with the proximal aspect of the manus at the wrist. The manus includes the carpals, metacarpals, and phalanges. There are five “columns” of phalanges, each “column” is called a digit. The digits are numbered, using Roman numerals, starting from the cranial aspect (associated with the radius, in humans—the thumb). Copyright S. A. Rommel.

The scapular spine is roughly in the center of the scapular blade in most mammals. However, in cetaceans and manatees, the scapular spine is close to the cranial margin of the scapular blade, and its acromion process extends beyond the leading edge of the blade.

The proximal humerus has a ball-and-socket articulation in the *glenoid fossa* of the scapula; this is a relatively flexible joint. The humerus

articulates distally with the radius and ulna; this is also a flexible joint in most mammals, but it is mechanically constrained in cetaceans. The olecranon is a proximal extension of the ulna that increases the mechanical advantage of the triceps muscles, which extend the forelimb. In species like the polar bear and the sea lion, the olecranon is robust; however, in cetaceans it is relatively small. The radius and ulna

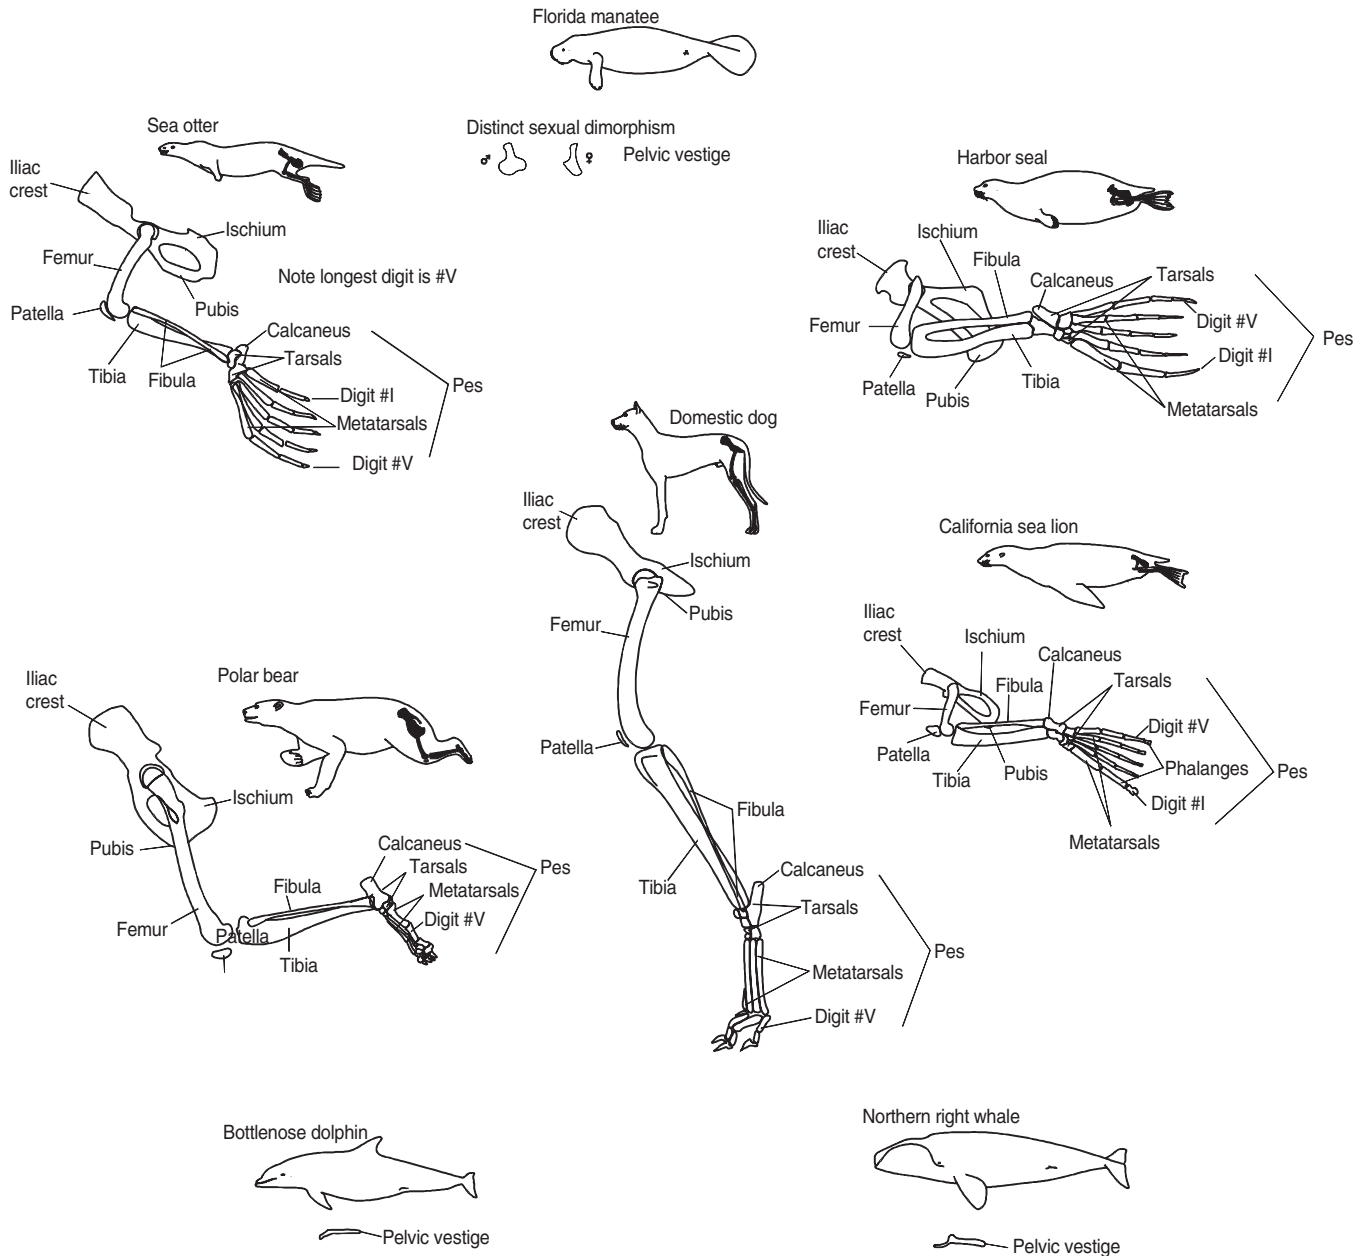

Figure 6 The pelvic appendage (hind limb) and pelvic girdle. The typical mammalian pelvis is made of bilaterally paired coxae attached to one or more sacral vertebrae. Each coxa is made of three elements: the ilium, ischium, and pubis. The crest of the ilium is a prominent landmark; it flares forward and outward beyond the region of attachment between the sacrum and the ilium. The two halves of the pelvis join at the ventral midline pubic symphysis. In the permanently aquatic marine mammals there is only a vestige of a pelvis. The hindlimb, if present, is attached to the pelvic girdle via a ball (femoral head) and socket (acetabulum) joint at the hip. The proximal limb bone is the femur. Distally, the femur articulates with the tibia and the fibula at the knee joint. The tibia and fibula distally articulate with the pes at the ankle. Note that the pes is oriented in different “planes” in some of the selected species. The pes consists of the tarsals proximally, the metatarsals medially, and the phalanges distally. Copyright S. A. Rommel.

of manatees fuse at both ends as the animal ages. This fusion prevents axial twists that pronate and supinate the manus. The cetacean radius and ulna are also mechanically constrained by the surrounding connective tissues but are not typically fused. The forelimbs of the sea otter are very mobile allowing for the manipulation of food.

The distal radius and ulna articulate with the proximal aspect of the manus. The manus includes the carpals, metacarpals, and phalanges.

There are five “columns” of phalanges, each of which is called a digit. The digits are numbered, using Roman numerals, starting from the cranial aspect (the thumb; associated with the radius). Note that the longest digit may be different in the different species (Fig. 6).

In many of the marine mammals, the “long” bones of the pectoral limb (humerus, radius, and ulna) are relatively short, and the phalanges are elongated. Cetaceans are unique among mammals in

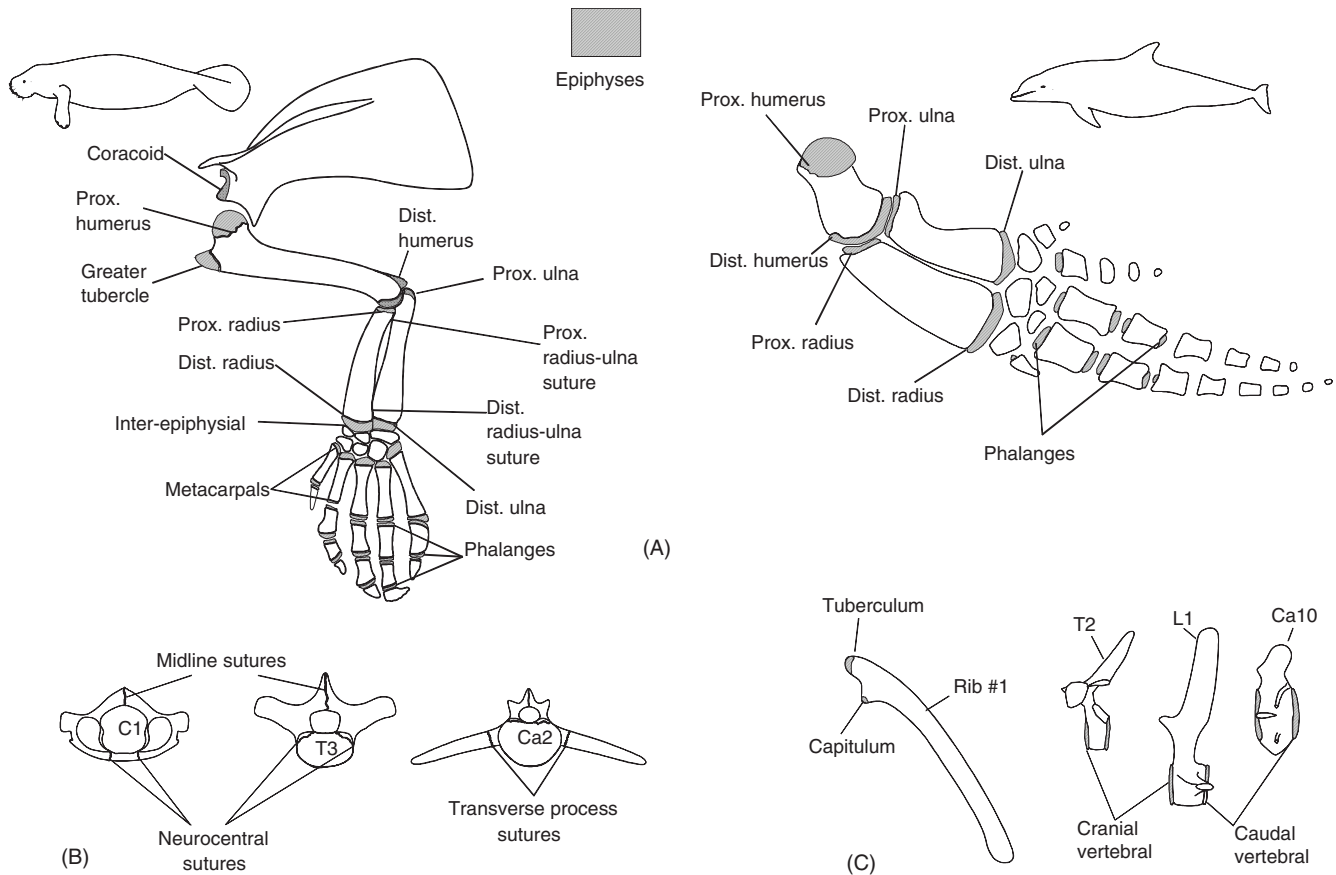

Figure 7 (A) Postcranial features that change with age. Some post-cranial elements grow in length by separate ossification centers, the epiphyses, at the margins of the bony element. The humeral head and distal humerus develop as epiphyses (filled parts in illustration). Patterns of fusion of these epiphyses provide information about aging. The epiphyses illustrated here have been used for relative aging of manatees and dolphins. (B) Non-epiphyseal sutures also indicate age in the postcranial skeleton. The transverse processes and the neural arches have sutures that disappear early in adolescence. In addition, the two halves of the neural arch ankylose at the dorsal midline to the base of the neural spine. (C) Epiphyses may occur on the ends of ribs and the tips of transverse processes and neural spines. Most mammals have distinct vertebral epiphyses at each end of their growing vertebrae. Vertebral epiphyses fuse to their respective vertebral centra at physical maturity of the vertebra. Copyright S. A. Rommel.

that they have more phalanges than do any of the other mammals (Fig. 6); this condition is known as hyperphalangy (Howell 1930, Cooper *et al.*, 2007). The number varies between individuals of each species—the pilot whale has the most (14), the bottlenose dolphin has a maximum of 9, and the right whale has a maximum of 7.

Notice the “plane” in which each manus is oriented (Fig. 6). The sea otter’s manus, much like that of humans, is very dexterous. The polar bear manus, much like that of the dog and other terrestrial quadrupeds, is more dexterous. The permanently aquatic species hold the manus roughly parallel to the midsagittal plane of the body or parallel to the nearest body surface.

B. Pelvic Limb Complex

The typical mammalian pelvis is made of bilaterally paired bones: ilium, ischium, and pubis (Fig. 7). Each half of the pelvis attaches (via the ilium) to one or more sacral vertebrae; the attachment may vary from simple apposition in juveniles to fusion in adults. The crest of the ilium, which is a prominent landmark, flares forward and outward beyond the region of attachment between the sacrum and the

ilium. The two halves of the pelvis join at the pubic symphysis on the ventral midline. In the permanently aquatic marine mammals, there is only a vestige of a pelvis to which portions of the rectus muscles of the abdomen may attach; the male reproductive organs may be supported by these vestiges as well (Pabst *et al.*, 1998). Occasionally, in some of the large whales, a non-functional hindlimb rudiment articulates with the pelvic vestige.

The hindlimb, if present, is attached to the pelvis via a ball and socket joint at the hip. The proximal limb bone is the femur, whose head articulates with the socket of the pelvis, the acetabulum. Distally the femur articulates with the tibia and the fibula at the knee. The tibia and fibula articulate distally with the pes or foot at the ankle (Fig. 7). The pes is composed of the proximal tarsals, the medial metatarsals, and the distal phalanges. Note that the digits of the sea lion terminate a significant distance from the tips of the flipper. Of the chosen group of marine mammals, the limbs of the polar bear are closest in gross appearance to those of the terrestrial mammals. In contrast, many of the other marine mammals have relatively short “long” bones (femur, tibia, and fibula) and relatively long

phalanges. The femurs of some phocids (e.g., the harbor seal) are so short that the knee cannot contact the ground.

Note that the pes is oriented in different “planes” in some of the selected species (Fig. 7). The pes of the polar bear is oriented in a fashion similar to that of the dog. The sea otter, seal, and sea lion all orient the pes parallel to the sagittal plane when swimming. The sea lion can rotate its pelvis and hind flippers to “walk” on land, and the sea otter can manipulate its hind flippers to hold food. Compare the positions of the first and last digits in the sea otter with those of the seal and sea lion, and note how the sea otter’s fibula crosses the tibia to achieve this orientation.

C. Sexual Dimorphisms

In many mammals the adult males are larger than the adult females, and among marine mammals, this dimorphism is extremely pronounced in certain pinnipeds and the sperm whales. In contrast, in baleen whales and some other species the adult females are larger than the adult males. In the permanently aquatic marine mammals, there may be sexual dimorphisms in the pelvic vestiges (Fagone *et al.*, 2000). The penises of mammals are supported by tough fibrous structures, the crura, which attach to the pubic bones of the pelvis. The muscles that engorge the penis with blood are also attached to the pelvis, and presumably the mechanical forces associated with these muscles influence pelvic vestige size and shape, particularly in manatees. Males in some groups of mammals, particularly the carnivores, have a bone within the penis (the baculum or os penis) that helps support the penis.

III. Sutures and Epiphyses

Many bony features change in size and shape as the individual develops and matures; these features can be used as milestones in life history studies, and in some cases, they can be fairly accurate estimators of age. Some postcranial elements grow from separate ossification centers at the margins of the bones (Fig. 7A). *Epiphyses* (*epi-*, upon, and *physis-*, grow or generate) are regions at the ends of bones (most often at or near a joint) associated with longitudinal growth in mammals. Epiphyses allow the portion of the bone near a joint to grow at a different rate than the rest of the bone and allow new bone to be laid down away from the articulating surface. Growth occurs at a cartilaginous plate between the epiphysis and the *diaphysis* (*dia-*, between; body or shaft). At the completion of growth, the epiphysis fuses with the rest of the bone, and the cartilage plate disappears. Eventually the suture between the two parts also disappears. Because most marine mammals are large, their epiphyses are more evident than those of the smaller terrestrial mammals.

The best-studied epiphyses are those of the long bones. There are, however, other epiphyses that are less well known. For example, the proximal finger bones may have epiphyses (Fig. 7B). The pattern of epiphysal fusion in the flipper can be used to determine relative age of an individual, when compared to the fusion pattern in other animals of known age. Occasionally epiphyses are found on the proximal ends of ribs, on the scapula located at or near the coracoid (Fig. 7A), or on the tips of neural spines and transverse processes.

Among the epiphyses most important to mammalian osteologists are those located at each end of the vertebral centrum (Fig. 7C). Most mammals have distinct bony plates at each end of their growing vertebrae. These plates are vertebral epiphyses. Manatees (and humans) are among the few species of mammals that have indistinct or no vertebral epiphyses. In manatees, the vertebral epiphyses are

delicate irregular films of bony tissue found within the cartilaginous surfaces at the cranial and caudal ends of the centrum. After these epiphysal sutures are completely fused, the skeleton cannot grow in length and the individual is considered skeletally mature. Skeletal maturity may or may not coincide with other forms of maturity, such as reproductive maturity.

Non-epiphysal sutures can also be used to estimate age of parts of the postcranial skeleton (Fig. 7C)—for example, the two halves of the neural arch ankylose at the dorsal midline to form the base of the neural spine. These sutures may persist well into adulthood in cetaceans.

There is much more to learn about the postcranial skeleton. Consult Pabst *et al.* (1999) for additional functional morphology on marine mammals, Young (1975) for information on mammals in general, and Alexander (1994) for vertebrates. For principles on size and scaling try Calder (1966) and Schmidt-Nielsen (1984).

Skull Anatomy

SENTIEL A. ROMMEL, D. ANN PABST, AND
WILLIAM A. MCLELLAN

To appreciate skull anatomy, take a moment and look at your own face in a mirror. The structures above the neck are designed for the acquisition and initial processing of nutrients and respiratory gases, the acquisition of sensory information about light, sound, touch, odor, and taste, and the broadcast of information about your own thoughts and emotions. Sensory and motor information is processed and sent from here to coordinate body functions. Complex signals can be sent to others of our species via vocalizations and/or the contractions of facial muscles. The head is our window for contact, perception, and communication with our world, and the skull provides the framework, the armature, for the head. Thus, the skull is interesting in itself. It is also fundamentally important in our picture of evolutionary biology. This article describes the skull morphology of the evolutionarily diverse group of marine mammals (Reynolds *et al.*, 1999).

We discuss the skulls of seven different species of marine mammals: the manatee (*Trichechus manatus*), the harbor seal (*Phoca vitulina*), the California sea lion (*Zalophus californianus*), the north Atlantic right whale (*Eubalaena glacialis*), the bottlenose dolphin (*Tursiops truncatus*), the polar bear (*Ursus maritimus*), and the sea otter (*Enhydra lutris*). These marine mammal species were chosen, in part, because much is known about them and they illustrate a wide range of morphological adaptations. We use the domestic dog (*Canis familiaris*) to provide a familiar reference.

I. Defining the Term “Skull”

The term “skull” is inexact. It has been used to describe the entire skeleton of the head. It has also been used to refer to only

the cranium, which is the housing for the brain and sensory organs and the upper jaw. We use the word skull to refer to the entire head skeleton, including the cranium and the derivatives of the first three visceral arches, i.e., the lower jaw (or mandible) and the hyoid apparatus. The mandible and hyoid apparatus of marine mammals have received less attention in the literature, but they are particularly important in adaptations for feeding and in some cases hearing (see below).

The skull acts as a mechanical foundation for the fat, muscle, skin, vascular, and sensory structures that form the head. Thus, the skull alone does not dictate the contours of the head (Fig. 1). For example, odontocete cetaceans have a melon, a fatty facial pad, the shape of which is only partly defined by the underlying bones (Harper *et al.*, 2008; Mead, 1975; Rommel *et al.*, 2006). The relationships between the bones and the soft tissues of the head vary among species, perhaps with major differences in head and skull profiles found in the sperm whales. Contrarily, the dorsal surface of the right whale’s head follows closely that of the underlying skull, though the right whale also has huge lower lips that follow the contour of the upper jaw but are not predicted by the outline of the lower jaw. The size and shape of the head may also influence the mechanics of locomotion, balance, and hearing. The completely aquatic species (cetaceans and sirenians) have shorter necks and less need for “anti-gravitational” muscles that support the head than do terrestrial mammals (imagine a right whale moving its head and neck around in the air the way a sea lion does).

II. Feeding and Swallowing

The specific characteristics of a skull (including dentition) often reflect the animal’s methods of feeding (Figs 2, 3). For example, the “typical” heterodont dentition (Kardong, 1998) of terrestrial carnivores, such as the dog, is also found to various degrees in the seal, sea lion, sea otter, and polar bear. Heterodonty is tooth shape differences in different parts of the mouth—incisors and canines rostrally and cheek teeth (premolars and molars) caudally. Although each of these tooth types may vary in shape, their definitions are specific and are related to tooth attachment to the bones of the upper jaw (Hildebrand, 1995). Incisors are found only in the premaxillary (incisive) bone; canines are found in the maxilla, in or very near the suture with the premaxilla. Incisors, canines, and premolars are deciduous teeth; molars are not. Developmentally, there are two sets—milk (or “baby”) teeth and adult teeth. Premolars erupt from the maxillary bones, they are deciduous cheek teeth that are found rostral to the molars; molars are nondeciduous cheek teeth that erupt from the maxillae. Each tooth shape may perform a distinct function, sort of a “Swiss Army mouth” (Greg Early, personal communication). Incisors, if chisel-like, are for slicing and chipping, and if pointed, for piercing. Long, pointed canines are good for capturing and piercing. Relatively blunt cheek teeth are good for crushing and grinding.

Teeth are also found in the lower jaw (mandible). The mandible is made up of bilaterally paired dentary bones (Fig. 3). The rostral ends of the two dentaries are joined by a mandibular symphysis. The mandibular symphysis ankyloses with age in many mammals making the jaw a single compound bone; this occurs at an early age in manatees whereas it may only fuse in very old dolphins. In contrast, the unfused dentaries of the mysticetes may undergo complex axial rotations, particularly while lunge-feeding in rorquals (Lambertsen, 1983).

In most mammals, each dentary has a horizontal body that presents the teeth. In most mammals the dentary has a vertically

Figure 1 Skulls and first two cervical vertebrae (except in the cetaceans illustrated here, in which all, partly fused, vertebrae are fused) of a selection of marine mammals for comparison with those of the dog. Each species is scaled so that the distances between the shoulder and the pelvis are similar; body cavities are therefore roughly similar in length, allowing one to compare head sizes with visceral volumes among species. Note how the outline of the head differs from the midline contour of the skull. Copyright S. A. Rommel.

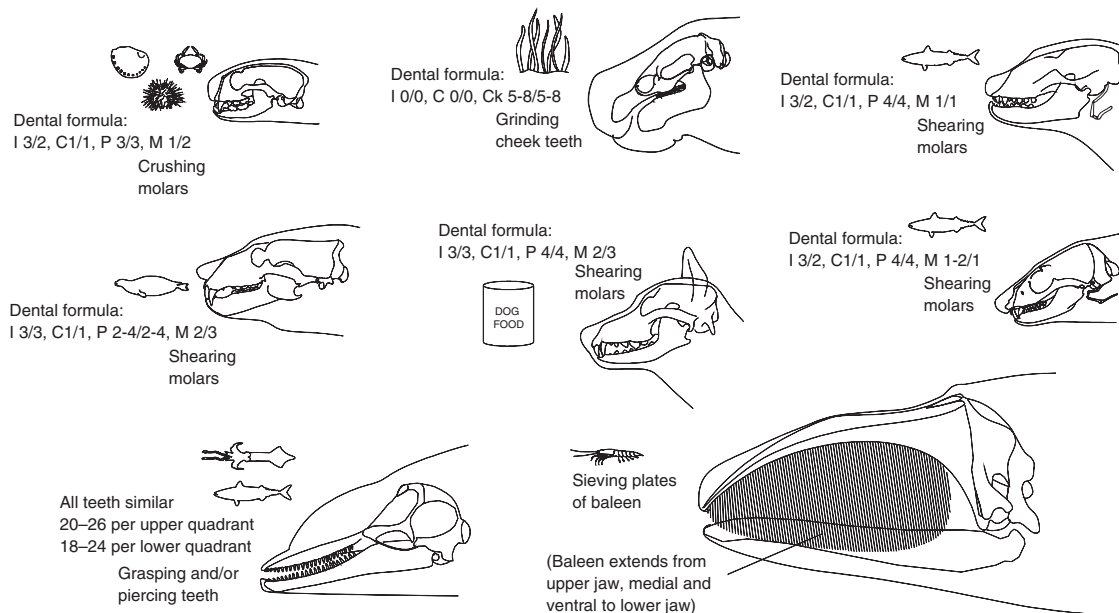

Figure 2 Feeding apparatus and typical food. Dominant tooth type is also given. Note that in manatees there are no incisors or canines and that all the cheek teeth (C) are continuously replaced. Also note that the embryonic teeth of the right whale have been replaced with horny plates of baleen in the upper jaw only. Copyright S. A. Rommel.

directed ramus that projects into the temporal fossa; in dolphins, the ramus is reduced or absent. Typically, the labial surface (lateral aspect) of the dentary has small openings at its rostral end (mental foramina) for the blood vessels and nerves of the chin; manatee mental foramina are relatively large.

Dentition complexity in mammals may be more indicative of food type than is the case for many other vertebrates. The hardness of teeth (which increases their likelihood of preservation in the fossil record) and specificity of dentition contribute significantly to our current understanding of the ecology and evolution of different taxa.

Figure 3 Left lateral views of the dog (A), manatee (B), and dolphin (C) skull with attached hyoids and medial views of the isolated right mandible. Bony elements of the hyoids are colored in gray except where they lie deep to the mandible. The manatee hyoid apparatus is presented in two positions to illustrate its motion during swallowing. Muscles between the tongue and basihyal move the hyoid apparatus up and forward (position 1). Muscles between the basihyal and the sternum move the hyoid apparatus down and back (position 2 is exaggerated to illustrate the process). The joint between left and right dentaries (mandibular symphysis) is cross-hatched. The mandibular foramen is enlarged in the manatee and greatly enlarged to form a mandibular hiatus in the dolphin. The mandibular hiatus of the dolphin dentary is a large opening on the medial aspect of the lower jaw. Within this hollow region there is an intramandibular fat body that extends to encompass the ear—this fat functions as an acoustic channel for the reception of sound. TMJ = temporomandibular joint. Teeth and hyoid apparatus of the dog after Evans (1993). Copyright S. A. Rommel

Typically, deciduous teeth are replaced vertically; the developing permanent teeth are deep to the milk teeth. These teeth are replaced only once. In contrast, manatee (but not dugong!) teeth are continuously replaced. Manatee tooth replacement is horizontal, beginning at the back of the tooth row (Fig. 3). This unusual method of horizontal tooth replacement is found in only a few other mammals such as elephants and kangaroos. In addition, unusual for manatees is the lifelong generation of new tooth buds, which develop in the dental capsule at the caudal end of each tooth row. Each manatee tooth moves forward and the roots grow in length as the crown erupts. The crown of the tooth begins to wear as it occludes with the opposite teeth; simultaneously, the root begins to resorb (Domning and Hayek, 1984); the processes underlying this phenomenon are

not yet fully understood. Thus, as each manatee tooth moves forward in the jaw, it becomes smaller at the top and bottom; when it reaches the rostral end of the tooth row the small flattened vestige falls out. Manatees typically do not have incisors, although small rudiments of premaxillary incisors occasionally are observed in fetuses. Baleen whales lose their embryonic teeth and develop baleen (Fig. 2). Postweaning, baleen whales acquire food by sieving plankton, small fish, and (in the case of gray whales), benthic invertebrates, using plates of horny (keratinized) baleen suspended from their upper jaws (Pivorunas, 1979).

In some species, all of the teeth have the same shape—this is the homodont condition. The homodont dentitions of odontocetes and manatees differ in shape and function (they are single-rooted,

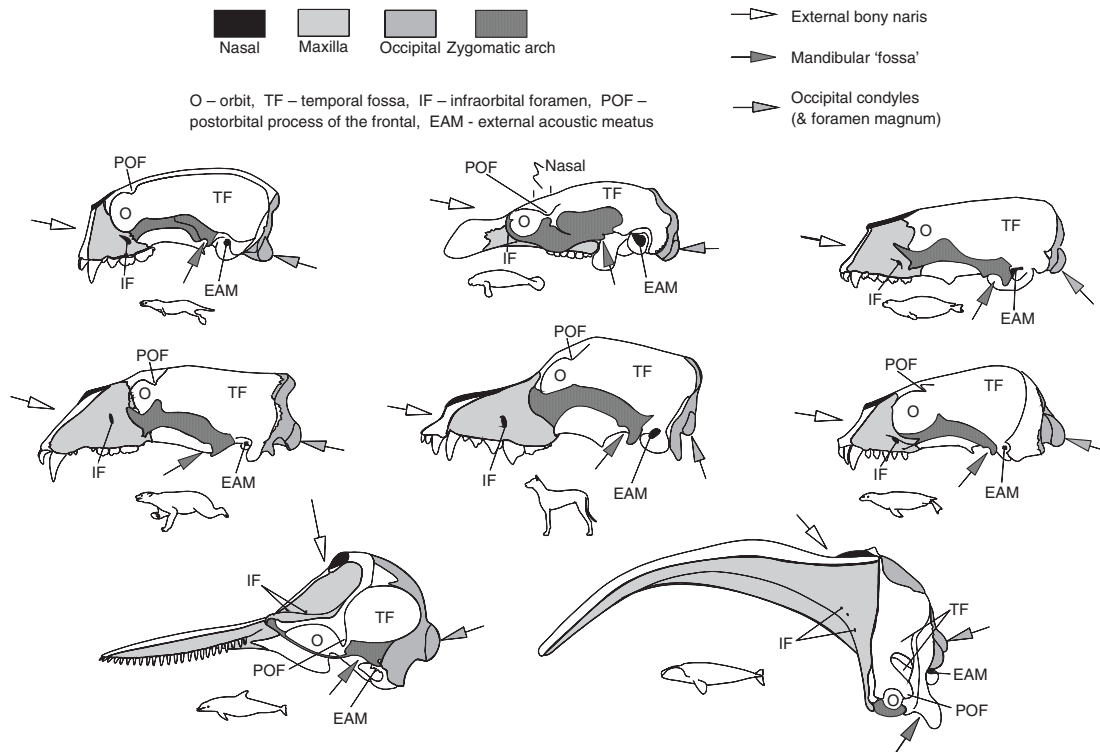

Figure 4 Selected bony features of the cranium. The rostrum, composed of the premaxilla, maxilla, and occasionally the nasal, forms the “face” or muzzle of each species. The zygomatic arch, which supports the masseter muscles, may be composed of a single bone (the jugal) or parts of as many as three bones in some species. Arrows indicate directions of air flow at the external bony nares, vertebral column articulation at the occipital condyles, and lower jaw articulation at the mandibular fossa; note that the mandibular fossa of the manatee includes a convex tubercle. Postorbital processes of the frontal may be present; it is absent in the seal, small in the sea otter, and relatively large in the dolphin and right whale. The region spanned by the tympanic membrane is visible in manatees but hidden within the middle ear of the other species. Copyright S. A. Rommel.

conical, grasping teeth for dolphins and multi-rooted, multi-cusped, grinding teeth for manatees).

The dental formula is an alphanumeric abbreviation for the adult numbers of incisor, canine, premolar, and molar teeth—the number of each tooth type in the upper and lower half of the jaw (Fig. 2). For example, I 3/2, C1/1, P 3/3, M 1/2 describes the dentition of the sea otter. Thus, the adult sea otter has 3 incisors on each side of the upper jaw and 2 incisors on each side of the lower jaw, etc. The lower jaw generally mirrors some of the features of the upper jaw, particularly the dentition (Figs. 2, 3).

Feeding habits may also be reflected in the shapes of the rostrum, the zygomatic arch, and the temporal fossa (Fig. 4). Relatively large temporal muscles and their fossae are typical of carnivorous mammals that tear or shear flesh without finely dividing it in the mouth, and/or have teeth for killing and temporarily holding prey (Hildebrand, 1995). Carnivorous mammals have upper and lower tooth rows that have little or no horizontal motion but rather occlude with a chopping motion, using a simple hinge joint. Their temporomandibular joint or TMJ is roughly in line with the tooth row. In contrast, the TMJ in herbivores is typically above the tooth line (Figs 2, 3). Relatively large masseter muscles, and robust zygomatic arches that support them, are more typical of herbivorous mammals that use a crushing and rolling action to chew. This feeding style requires a TMJ that can slide horizontally and a large masseter to apply force

along the cheek tooth row. Thus, the shape of the TMJ also reflects feeding habits. In carnivores a dorsally-convex mandibular condyle of the dentary bone fits into a distinct, ventrally-concave fossa of the squamosal bone (Figs 3, 4). In herbivores, the TMJ shape is more complex than that of the carnivores. In some ungulates such as the horse and pig, there is a distinct squamosal articular tubercle (tuberculum articulare) that articulates with the mandibular condyle (Nickel *et al.*, 1986; Popesko, 1979).

TMJs of sea otters, seals, sea lions, and polar bears are mechanically constrained, allowing up and down movement but little or no transverse motion of the lower jaw. Of the skulls illustrated, the mandibular fossa of the otter is the most restrictive with a deep concavity that grips the mandibular condyle (in some cleaned skulls the mandible cannot be removed without damaging the margins of the mandibular fossae). The mandibular fossae of the seal, sea lion, and polar bear are shallower, and more similar to that of the dog. The TMJs of odontocete cetaceans appear to be mechanically less constrained because of their relatively large radii of curvature. Live dolphins, however, exhibit simple up-and-down (opening-and-closing) jaw movements similar to those observed in the dog. As mentioned above, odontocetes have simple fish-and-squid-grasping teeth. The TMJs of rorquals are relatively unconstrained; they can move up and down, forward and back, and rotate along the long axis of the dentary. These relatively unconstrained joints are tough and pliable fibrous

structures that can absorb the mechanical shock associated with lunge feeding. Rorqual lower jaws must support the large, pleated gular sac into which flows a large volume of water and prey during lunge feeding. Gular sac contraction forces water out through the relatively short baleen plates trapping the prey (Lambertsen, 1983; Pivorunas, 1979). Right whale TMJs restrict jaw movements to up and down and rotation of the mandible along its long axis (Werth, 2004). The jaws of these skimmers support massive lower lips that guide an almost continuous stream of water past long baleen plates (Pivorunas, 1979; Werth, 2004). Gray whales, which are bottom feeders, have relatively robust lower jaws. The mandibular condyles of manatees are slightly flattened sub-cylinders that articulate with a distinct articular tubercle, which is located rostral to the shallow mandibular fossa (Fig. 3). Manatees must have a relatively mobile TMJ to accommodate grinding their food. The motions of the manatee TMJ include influence of the robust pterygoid process as a pivot, creating a slightly arched transverse travel of the occluding tooth rows. These motions, which include lateral and a small amount of rostral motion, provide the action required for grinding vegetation as well as stimulating the rostral migration of the teeth (Domning, 1978).

The shapes of the dentaries of the three marine mammals that are illustrated in Fig. 3 are dramatically different—that of the dog is roughly similar to those of the sea otter, seal, sea lion, and polar bear (Fig. 1). Note the angular process in these latter species; it is located ventrocaudal to the TMJ—that of the polar bear is much more pronounced than those of the other marine mammals. The dolphin dentary is elongate with a reduced ramus and a very small angular process. The manatee dentary has a forward-directed, robust coronoid process and a relatively flat mandibular condyle; there is no discernable angular process.

Feeding includes swallowing. Chewing involves positioning of the food between the teeth by the tongue; swallowing requires the coordinated action of these muscles and bones as food leaves the oral cavity and moves through the pharynx. How do the bones of the head accommodate swallowing? The hyoid apparatus is an important structure in both feeding and swallowing (Fig. 3); it is a complex of hinged bony and cartilaginous elements that are suspended from the ventral aspect of the cranium and lie between the dentaries. The hyoid bones (labeled with the suffix *-hyal* to minimize confusion with hyoid muscles, Reidenberg and Laitman, 1994), provide the mechanical support of many of the muscles that act upon the tongue and the larynx. Muscles between the tongue and basihyal move the hyoid apparatus up and forward. Muscles between the basihyal and the sternum move the hyoid apparatus down and back (Fig. 3). The tongue may also help exclude water from food that is swallowed under water.

In most mammals, the hyoid apparatus is attached to the ventral skull at one of the bony elements of the compound temporal bone, at or near the external auditory meatus (Figs 3, 4): in carnivores via the mastoid process of the petriotic bone; in man, ruminants, and horses via the styloid process of the tympanic bone; and in the pig via the nuchal process of the squamosal bone (Nickel *et al.*, 1986). The seal, sea lion, and sea otter all have hyoid apparatuses that are similar in configuration and attachment to that of the dog. The dolphin and manatee have relatively robust hyoid apparatuses when compared to the other marine mammals. In suction feeders, such as the squid-eating beaked whales, pilot whales, and kogiids, the hyoid apparatus and its associated muscles are massive (Reidenberg and Laitman, 1994). In contrast to most other mammals, the manatee and the dolphin hyoid apparatus is attached to the ventral skull at the paracondylar (paroccipital) processes of the exoccipital bones (see below) in a position caudolateral to the tympanoperiotic complex. There are

distinct concavities for hyoid attachment in the paracondylar processes (Fraser and Purves, 1960). This attachment helps acoustically isolate the hyoid apparatus from the bones of the tympanoperiotic complex, which are themselves not fused to the rest of the cranium (see below). Interestingly, in the live dolphin there is an air sinus (posterior sinus) at the rostral aspect of the concavity, between the hyoid attachment and the tympanoperiotic (Fraser and Purves, 1960), which would add to the mechanical isolation. In some odontocetes (i.e., *Kogia*, *Ziphius*) there are large, well-developed mastoid process of the tympanoperiotic. These mastoid processes are similar in position to the paracondylar process of the dolphin. There are no deep concavities on these mastoid processes but there are similar but shallow regions, medial to the jugular notches, on the caudolateral margins of the relatively thick crests of the basioccipital bones.

III. Bony Features and Bones

One approach to studying the skull is to focus on a few specialized bony features (Fig. 4). Bony features are morphological characters or landmarks that make up one or more bones. Size, shape, and positions of bony features reflect evolutionary, developmental, and mechanical pressures in a grossly visible manner. For example, the zygomatic arch, which supports the masseter muscle that helps close the jaws, may be composed of one, two, or three bones depending on the species. The rostrum or muzzle may be elongate and may or may not include the nasal bones. Thus, to characterize individual skulls without having to identify individual bones, biologists use the morphology of bony features such as the postorbital processes; zygomatic arch shape and composition; rostrum length; orbit size, shape, and position; and jaw articulation.

In general, large, forward-facing orbits are characteristic of predators that rely on vision as their primary sensory modality, whereas laterally facing orbits are more typical of non-predatory species (Hildebrand, 1995). Also note that the orbits of most species in Fig. 4 are open caudally (having small postorbital processes), in contrast to those of the fully aquatic mammals. In the species in which the orbit is open, there is a postorbital ligament caudal to the eye that extends between the ventrally projecting postorbital process of the frontal bone and a dorsally projecting postorbital process of the jugal and/or the squamosal bones (a bony feature on the dorsal aspect of the zygomatic arch); these postorbital processes are prominent in the polar bear.

In all species, the external bony nares are bordered by the nasal bones. The positions, relative to the rostrum and braincase, of the external bony nares may reflect respiratory adaptations to diving, feeding, and locomotion. The occipital condyles position the head on the neck and influence the flexibility of this joint (Figs. 1, 2). Some marine mammal species have short necks, placing the base of the skull very near the shoulder joint and the thoracic cavity. Species with long necks may have a wide range of neutral head positions and may also have a greater range of movement than the fully aquatic species (King, 1983). In most mammals the joint between occipital condyles and the first cervical vertebra (atlas) is restricted to two degrees of mechanical freedom; an additional degree of freedom is acquired with the rotation between the atlas and axis vertebrae. In cetaceans with fused cervical vertebrae three degrees of freedom are potentially available in the joint between the condyles and the atlas.

IV. Ground Plan of the Skull Bones

What other factors shape the skull? In all vertebrates, the skull bones develop from ossification centers in a basic pattern that partially or completely encloses the brain and encapsulates the sensory

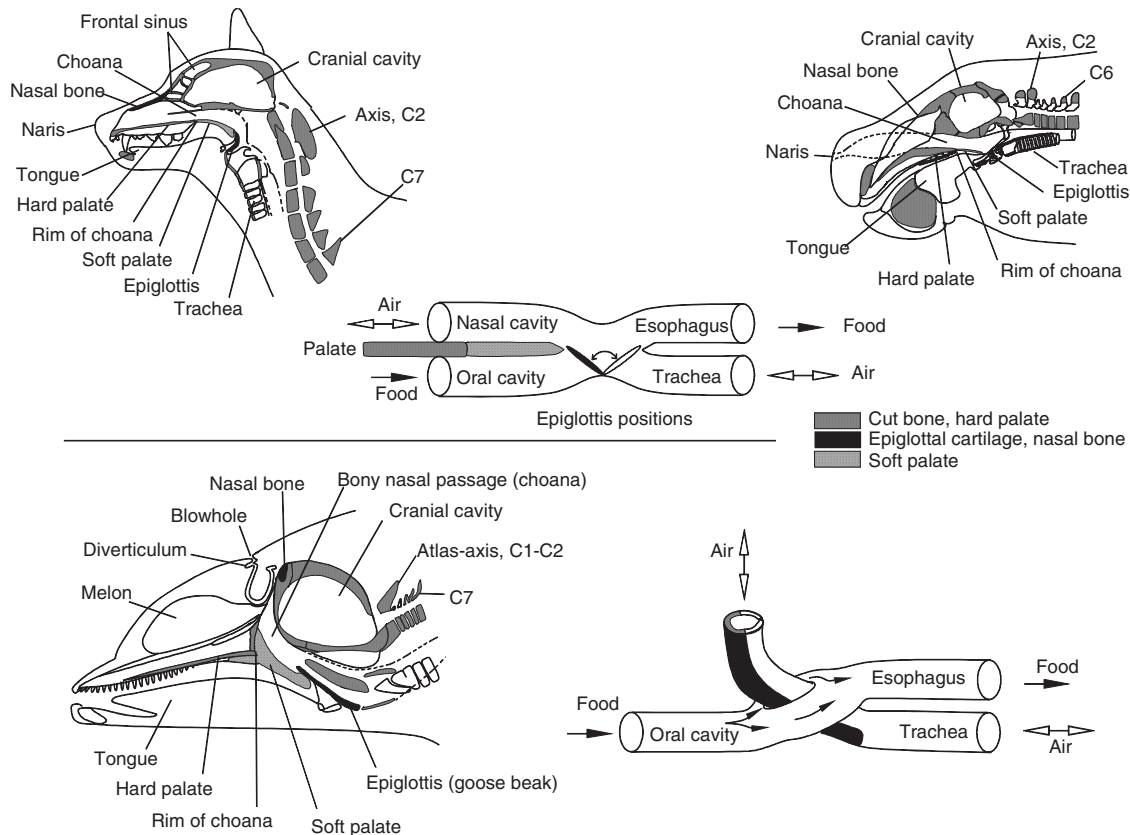

Figure 5 Comparisons of the morphological adaptations of the mammalian head that allow respiration while food is in the mouth. Separation of oral and nasal cavities accommodates prolonged chewing and allows teeth to be modified accordingly. The dog and manatee are schematically represented in the upper panel. In the dolphin (lower panel) further modification is shown to accommodate the migration of the respiratory opening to the top of the head. Copyright S. A. Rommel.

Figure 6 Schematic illustration of ventral views of the developing vertebrate skull. Modified after Kent and Miller (1997). The basic plan of encapsulation of the senses and brain is illustrated in the left two drawings. The right drawing illustrates the ossification centers that will eventually become the replacement bones of the cranium.

organs of olfaction, vision, hearing, and balance (Fig. 6). Tissues that are preformed in cartilage and that eventually develop into bone are referred to as endochondral or replacement bones (these form the chondrocranium); those tissues deposited directly as bone within specialized connective tissue membranes are referred to as dermal or membrane bones (these form the dermatocranium). The distinction between endochondral and dermal bones is valuable in establishing homologies with skull bones of the lower vertebrates; however, once

bony tissues are formed, the two kinds of bone are indistinguishable microscopically (Nickel *et al.*, 1986).

How does one determine which bones of the skull are homologous between species? A systematic but simplified approach that allows one to compare homologous elements is to utilize a generalized schematic skull (Fig. 7). This schematic is a particularly useful way to avoid the "mental indigestion" of having to memorize all the individual bones in several species (Romer and Parsons, 1977).

Figure 7 Left lateral schematic of the mammalian skull illustrating relative bone positions. Most skull bones are bilaterally paired. This schematic approach has been used for more than 100 years and provides a framework in which to compare a wide variety of mammalian skulls. Modified after Flower (1885), Kent and Miller (1997), and Evans (1993). Recall that the nose, eyes, and ears are encapsulated early in development; these three sensory areas are represented by circular regions in the schematic. Endochondral bones are indicated with an asterisk. Copyright S. A. Rommel.

In some species, individual bones fuse (ankylose) to form compound bones¹; these include the occipital, temporal, and sphenoid “bones.” Of particular interest is the temporal “bone,” which is made up of many separate bony elements and/or ossification centers (Kent and Miller, 1997). These separate bones include the squamosal, the periotic, the tympanic, the middle ear ossicles, and in some species a distinct mastoid. In many mammals, once skeletal maturity is reached, the bulk of each temporal is a single unit with no visible sutures between the bony elements. Thus, it is common with terrestrial mammals to refer to the temporal as a single bone, but this is inappropriate for several of the marine mammals, particularly some of the cetaceans and the sirenians because the earbone complex (periotic and tympanic) do not ankylose to the rest of the skull.

The exploded diagram of the cranium of the Florida manatee illustrates how some bones fit together simply whereas in other places they overlap (Fig. 8). The compound occipital bone, which forms a ring around the foramen magnum, is composed of the basioccipital, exoccipitals, and supraoccipital (Jollie, 1973; Kellogg, 1928; Romer and Parsons, 1977).

Figure 9 is a left lateral view of the individual cranial bones for our representative marine mammals. Contrast this illustration with Fig. 4 to reinforce the distinction between bones and bony features; see Fig. 1 to compare skull size to total body size.

¹We have used three different terms incorporating the word “bone”. Bones are discrete ossifications that can be traced phylogenetically. Compound bones are structures that appear to be single units in adults of some species because the joints between the component bones have been resorbed or are not apparent. Bony features are gross features, such as the zygomatic arch, that are made up of discrete and distinct bones or parts of bones (e.g., the zygomatic process of the squamosal bone).

V. Cranial Joints

Skull bones can meet in several ways and attach to each other by more than one type of material (e.g., cartilage and other connective tissue). Joints between adjacent cranial bones are referred to as sutures or synchondroses. Sutures are fibrous joints between dermal bones; synchondroses are cartilaginous joints between endochondral bones. Sutures and synchondroses are regions of growth between individual bones; in adults they may also function to relieve stresses that are produced in the skull (Gordon, 1988). At parturition, some joints provide the flexibility for a relatively large brain within the cranium to pass through a relatively narrow birth canal. In the illustration of the exploded manatee cranium (Fig. 8), the hatched regions represent (Fig. 9) joints or regions of overlap. In Fig. 10, some of the joints of the dog skull are compared with those of the manatee and dolphin skull. The type of joint generally reflects the mechanical forces acting on the adjacent bones. Different types of joint may be found between the same bones in different species; types may also be different in different parts of the same joint, probably to reflect differences in forces. Interlocking joints can absorb mechanical energy. Movable joints eliminate shearing forces. Butt joints can support little shear but are strong in compression. Squamosal or scarf joints allow more surface contact between adjacent bones and are stronger than simple butt joints. Some bone configurations affect the complexity of joints, and this complexity, in turn, affects the action and strength of the joints. Relative aging of skulls may be determined by evaluating the sequence of ankyloses of sutures and synchondroses, unfortunately few systematic studies have been completed (Moore, 1981).

VI. Foramina

The development of the skull bones proceeds at a pace different from that of the soft tissues of the head. Bone is constantly being

Figure 8 Left lateral view of an exploded cranium of the Florida manatee. This figure illustrates the overlapping and/or abutting margins of bones that make up the sutures and synchondroses of the cranium. Copyright S. A. Rommel.

Figure 9 Left lateral illustrations of individual cranial bones of selected marine mammals and the dog. Abbreviations are the same as in Figs. 7 and 8. Use Figure 8 to help visualize how the basic plan of mammalian skull morphology is modified in each species. Endochondral bones are indicated with an asterisk. Copyright S. A. Rommel.

remodeled; this takes place at the level of the individual during its lifetime in response to trauma, nutrition, and localized conditions. Remodeling also takes place at the population level over longer time spans and thus can indicate evolutionary processes. This plasticity is

reflected in the way individual skull bones form around vessels and nerves. The resulting openings, or foramina (singular, foramen), are often phylogenetically conserved and so can be used to establish homologies of the same bones across different species. An individual

Figure 10 Joint types in the cranium of the dog (A), manatee (B), and dolphin (C). Sutures are fibrous joints between dermal bones; synchrondroses are cartilaginous joints between endochondral bones. Joints allow growth of adjacent bones, provide limited flexibility and absorb mechanical forces. Suture types are defined by their shape. PLA, plane or butt joint (harmonious suture, sutura plana)—an approximately straight suture with nearly squared-off margins. SQA, squamous or scarf joint (sutura squamosa)—a suture with tapered overlapping margins. FOL, foliate joint (sutura foliata)—a regular suture with small alternating vertical bony plates, in which adjoining bones interleave. SER, serrate joint (sutura serrata)—an irregular suture, in which adjoining bones interlock. A synchrondrosis (synchrondroses cranii), SYN, has persistent cartilage between bones. Below, simplified, sagittally sectioned crania illustrate those joints that can be observed on the midline. Definitions are from a variety of sources; parenthetical names are from Schaller (1992). Copyright S. A. Rommel.

nerve or blood vessel may be completely surrounded by a bone or bones of the skull, resulting in a specific foramen. Because this process occurs early in the development of the individual and appears to be similar in all vertebrates, we use cranial nerve foramina to help us identify the skull bones (Figs 11, 12).

In some species, or even in individuals of the same species of different ages, instead of a single foramen for each individual nerve, one or more nerves may exit the braincase through a single opening. Some openings are very large and irregular and are referred to as hiatuses (Fig. 12). The cranial hiatus of the dolphin (Fraser and Purves, 1960) and manatee may include the following nerve openings: optic foramen, orbital fissure (anterior lacerate foramen), and oval foramen—plus the openings for vessels between the last two. The cranial hiatus is not present in the other marine mammals because their skulls have earbone complexes that are firmly attached to the other bones of the skull (see the compound temporal bone above). The tympanic and periotic bones are often referred to as the earbone complex or the tympano-periotic complex. The earbone complexes of the manatee and dolphin have loose connections with the rest of the skull bones, presumably to produce an acoustic isolation from the rest of the skull; in cleaned skulls the earbone complexes may fall out of the skull in these taxa. In life, the odontocete tympanoperiotic is surrounded by peribullar sinuses that add to this acoustic isolation (Fraser and Purves, 1960; Houser *et al.*, 2004). The

cranial hiatus includes the petrooccipital fissure, which is an irregular opening between the tympanic and periotic bones (housing the ear) and the alisphenoid, basisphenoid, basioccipital, and exoccipital bones of skull base (Nickel *et al.*, 1986; Schaller, 1992). In the terrestrial mammals, the margins of the petrooccipital fissure may join to form one or several foramina (foramen ovale, jugular foramen, carotid foramen, hypoglossal foramen, caudal lacerate foramen).

The mandible also has a number of foramina. At its caudal end, the medial aspect (lingual surface) of the dentary has a mandibular foramen, which is the opening of the mandibular canal for the alveolar vessels and nerves. In manatees, the mandibular foramen is relatively large because of the large amount of soft tissues and perial bristles of the chin supplied and innervated via the mandibular canal. In dolphins, the mandibular foramen is even larger; it is referred to as a hiatus (Fraser and Purves, 1960). The odontocete dentary is almost hollow and is filled with a well-vascularized mandibular fat body, which performs the acoustic function of receiving and guiding sound energy to the earbones (Norris and Harvey, 1974; Koopman *et al.*, 2006).

In some cetaceans (e.g., *Kogia*, *Ziphius*) the internal auditory meatus is a long narrow canal (Fig. 13) (Rommel *et al.*, 2006). Interestingly, as mentioned above, these cetaceans have distinct mastoid bones. Fraser and Purves (1960) describe secondary growth of the basioccipital, parietal, and squamosal bones around the margins

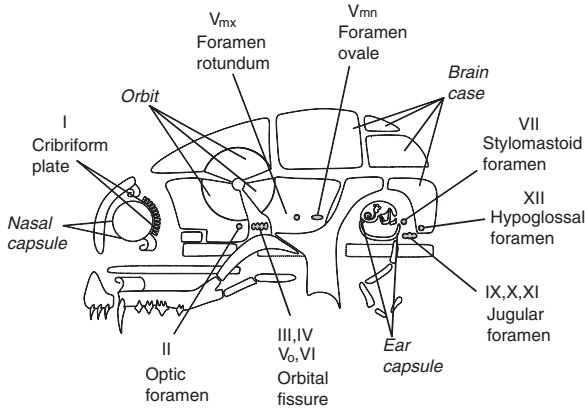

Figure 11 Left lateral schematic of openings, or foramina of the skull. Foramina can be used to establish homologies of the same bones in different species; each foramen associated with one or more of the 12 cranial nerves (labeled I through XII) has a name that is used (fairly) consistently by vertebrate morphologists. Thus the cribriform plate, found at the rostral margin of the braincase, is associated with the olfactory nerves (this will be parenthetically referred to as I-olfactory n.) in all of the species that have a sense of smell (even odontocetes, which do not have olfactory nerves as adults, have these perforations (Rommel, 1990). The second cranial nerve passes through the optic foramen and usually perforates the orbitosphenoid bone (II-optic n.). The orbital fissure is usually at the orbitosphenoid bone-alisphenoid bone suture (also anterior lacerate foramen; III-oculomotor n., IV-trochlear n., V_o-ophthalmic branch of trigeminal n., VI-abducens n.). The foramen rotundum (Vmx-maxillary branch of the trigeminal n.) and the foramen ovale (Vmn-mandibular branch of the trigeminal n.) perforate the alisphenoid bone. The stylomastoid foramen is located at the tympanic bone-basioccipital bone suture (VII-facial n.). (Nerve VIII-vestibulocochlear n. is not shown; it perforates the petiotic bone through its internal auditory meatus.) The jugular foramen (also caudal lacerate foramen) is at the exoccipital bone-basioccipital bone suture (IX-glossopharyngeal n., X-vagus n., XI-accessory n.). The hypoglossal foramen usually perforates the exoccipital (XII-hypoglossal n.). An additional cranial nerve (O-terminal n.) was discovered after the numbering system was developed. This nerve is found rostral to the olfactory nerve; it has been described only (of the species illustrated) in the odontocetes and is not illustrated here. Copyright S. A. Rommel.

of the cranial hiatus, which narrows and elongates the channels for the facial and acoustic nerves.

VII. Skull Cavities

The cranial cavity (Figs 5 and 13) houses the brain, its meninges, and its vasculature (Nickel *et al.*, 1986, Romer and Parsons, 1977). The roof (calvarium) and lateral walls of the braincase are typically made up of the frontal and parietal bones with the caudal wall formed by the supraoccipital and exoccipitals (Figs 7, 8, and 9). Rostrally, there is the ethmoid bone with its perforated cribriform plate, medial extensions of the inner lamina of the frontal bone, and portions of the sphenoids (see below). In odontocetes lateral wings of the vomer also contributes to the rostral wall of the cranial cavity.

The floor of the cranial cavity is formed by the basioccipital, the basisphenoid (including the depression for the pituitary) with its lateral wings (the alisphenoids), and the presphenoid with its lateral wings

(the orbitosphenoids) (Figs 7, and 12). The alisphenoid and orbitosphenoid wings extend dorsolaterally between the more dorsal skull bones in a wide variety of shapes and sizes—these two winged bones (collectively called the sphenoid bone) have most of the foramina for the cranial nerves and may be the most variable and difficult to recognize in different taxa (Figs 7, 9, and 11).

The nasal cavity is separated from the oral cavity by the secondary palate. The secondary palate is formed by the hard and soft palates (Fig. 5). The secondary palate makes a very important contribution to the evolutionary forces that shaped mammal skulls as it allows prolonged chewing while breathing, providing additional time for food processing in the mouth. The nasal cavity extends from the external bony nares to the perpendicular plate of the ethmoid bone. The nasal cavity is typically a roughly tubular structure that occupies the entire length of the rostrum of the skull in most mammals, but not in cetaceans. In some terrestrial species, it may be paralleled on either side by enclosed maxillary sinuses. The bony supports for the nasal cavity are formed by the premaxillae, maxillae, frontals, vomer, palatines, and in some species the lacrimals and jugals (Nickel *et al.*, 1986; Romer and Parsons, 1977). There is often a dorsoventral medial nasal septum in the nasal cavity; it is formed by cartilage rostrally and by a bony extension of the ethmoid caudally. The vomer (an unpaired, relatively thin, ventral midline bone) may also contribute to the ventrolateral aspects of the nasal septum.

The nasal septum divides the nasal cavity into separate left and right air channels called choanae (Fig. 5). Caudally, the choanae may lose their septum near the junction of the soft and hard palates (rim of the choanae; Figs 5 and 12). In many species, a thin layer of the vomer extends caudally along the ventral midline to cover the ventral aspects of the presphenoid and basisphenoid as the animal ages. In some mammals, particularly dolphins, this portion of the thin vomer is often fenestrated, exposing the synchondrosis between the basisphenoid and presphenoid bones (Fig. 12).

Conchae (turbines, turbinals) are thin lamellae of bone (covered with mucous membrane in life) that project into the nasal cavity. Conchae increase the surface area in the nasal cavity for heat exchange, water balance, and olfaction (Moore, 1981). The more rostral conchae develop as outgrowths of the maxillae and nasals, the more caudal conchae develop from the ethmoid bones (Nickel *et al.*, 1986). In stark contrast to most other mammals, the nasal cavities of cetacea are not part of the rostrum. Instead, cetacean nasal cavities are almost vertical channels just rostral to the braincase (see telescoping below) and are devoid of conchae; the bones dividing and bordering the nasal cavity are displaced by the vomer and the pterygoid (Mead and Fordyce, 2008; Rommel, 1990). This helps allow for the rapid respiratory cycle of cetaceans (Pabst *et al.*, 1999). The conchae of sea otters, sea lions, and seals are very convoluted, almost filling the nasal cavity with lace-like networks of bone. These structures significantly increase in surface area and have been shown to be important for water and heat conservation in seals and sea otters (Folkow *et al.*, 1988; Huntley *et al.*, 1984).

Skull bones of most mammals are mechanical marvels. Only relatively recently in engineering history has man built composite structures (monocoques) that approach the efficiency of design found in the mammalian skull (Gordon, 1988). In many species, some of the skull bones are made up of a layer of spongy bone (diploe) and/or air-filled sinuses (Fig. 5) sandwiched between two thin “panels” of rigid cortical bone commonly referred to as the internal and external laminae (singular lamina) (Nickel *et al.*, 1986; Schaller, 1992). This excavation of sinuses within bones is called pneumatization (Nickel *et al.*, 1986). The resulting multilayered structure is strong, yet has

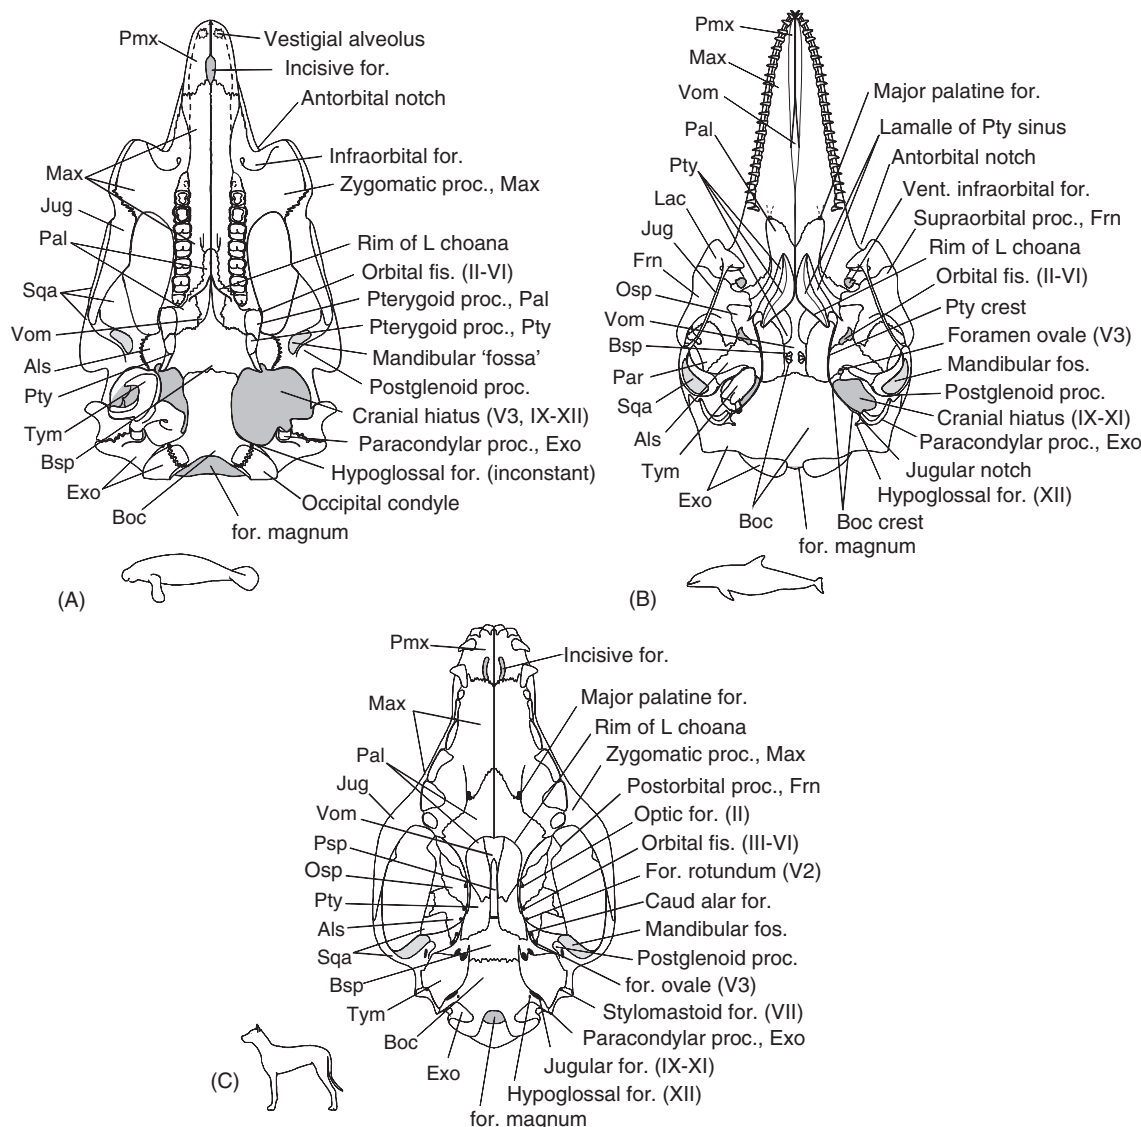

Figure 12 Comparison of the basicranial morphology of the manatee, dolphin, and dog. The base of the skull has important morphological features that help with keying out different species. Note the large opening (cranial hiatus), which is illustrated for the manatee and dolphin; it is not present in the other marine mammals because their skulls have earbone complexes that are firmly attached to the other bones of the skull. The earbone complexes of the manatee and dolphin have loose connections with the rest of the skull bones as part of their acoustic isolation from the rest of the skull. The following abbreviations are used: for, foramen; fis, fissure; fos, fossa; proc, process; L, left; R, right. Roman numerals denote cranial nerves. Fenestrations may occur in the vomer ventral to the joint between the basisphenoid and basioccipital bones; these fenestrations make the margins of these bones and this suture visible through the vomer. Copyright S. A. Rommel.

less weight than other bony structures. In the skull bones of most placental mammals, pneumatized paranasal sinuses develop embryonically as invaginations from the adjacent air spaces. These sinuses vary considerably even within species; they become larger and more numerous as the individual ages (Moore, 1981). In many species, paranasal sinuses help form three-dimensional bracing systems by minimizing the mass of bone that provides the framework needed for mechanical support of different parts of the head². Some paranasal

²Similar bracing systems are found in the wings and fuselages of aircraft and the hulls of large ships (Gordon 1988).

sinuses increase the available surface area for olfactory epithelium to detect odors (Nickel *et al.*, 1986). Sinuses that are well vascularized may help provide evaporative cooling (Schaller, 1992). In terrestrial mammals, paranasal sinuses may also act as resonators that modify sounds generated by the individual (Moore, 1981). Paranasal sinuses occur in the frontal (Fig. 5) and maxillary bones of the dog and in the frontal, ethmoid, and presphenoid bones of man; in other terrestrial mammals they also occur in the exoccipital, jugal, lacrimal, nasal, palatine, parietal, basisphenoid, and vomer (Moore, 1981; Nickel *et al.*, 1986; Schaller, 1992).

In contrast to most other mammal skulls, manatee skull bones are thick and made of almost solid medullary bone (Fawcett, 1942).

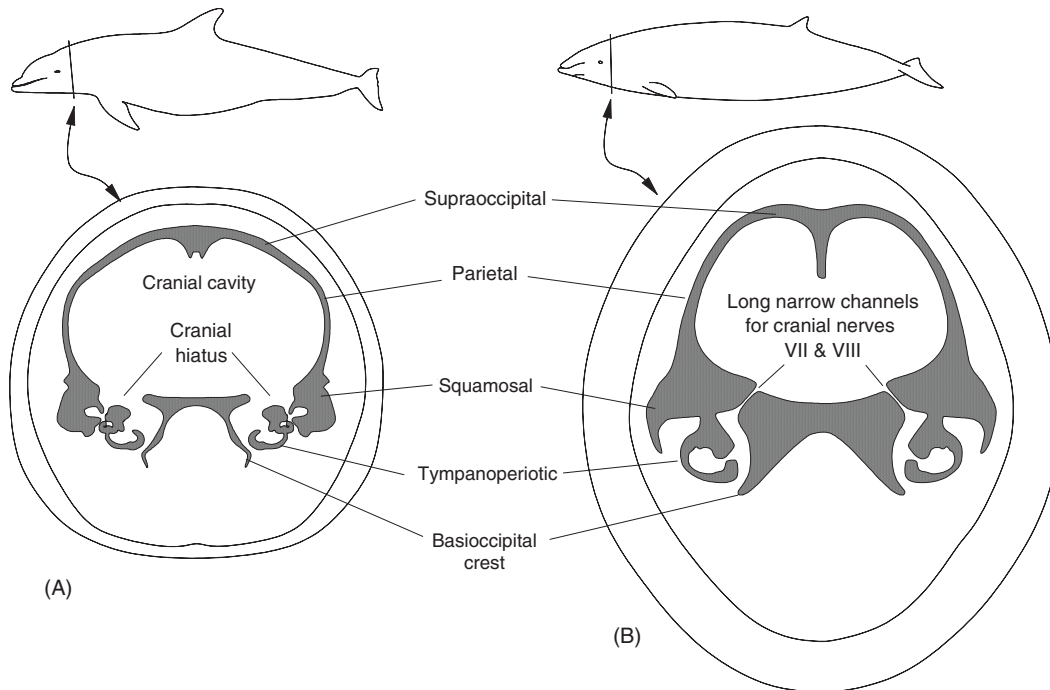

Figure 13 Cross sections of the skulls of Tursiops (A) and Ziphius (B). The cross sections (at the level of the ear) are scaled to have similar areas of braincase. In Tursiops, the pathway out of the braincase for cranial nerves VII and VIII is a short open cranial hiatus bordered by relatively thin bones, whereas in Ziphius it is a narrow, relatively long channel. The ziphiid basioccipital bones are relatively massive with thick ventrolateral crests; in contrast, delphinid basioccipital bones are relatively long and tall, but thin and laterally cupped. Note that in contrast to the Ziphius calf cross section, the adult head would have a greater amount of bone and the brain size would be relatively smaller. Modified from Rommel et al. (2006).

Figure 14 Dorsal (A), lateral (B), and schematic (C) views illustrating telescoping in odontocetes (left, e.g., Tursiops) and mysticetes (right, e.g., Eubalaena). Telescoping refers to the elongation of the rostral elements [both fore and after in the case of the premaxillary and maxillary bones (Pmx and Max), the vomer, and mesorostral cartilage], the dorso-rostral movement of the caudal elements [particularly the supraoccipital bone (Soc)], and the overlapping of the margins of several bones. This overlap or sliding over each other of these elements resembles old-fashioned telescopes.

In some large terrestrial mammals, such as the elephant the skull is vastly enlarged with pneumatized bones in part to accommodate the large muscles of the head (Nickel *et al.*, 1986). In contrast, the skulls of the larger cetaceans (i.e., *Ziphius* and *Eubalaena*) are enlarged to accommodate the larger muscle masses and larger food processing requirements but are not pneumatized.

In diving mammals, air-filled cavities within rigid enclosures of bone could be damaged during dives when subjected to large rapid pressure changes associated with variations in depth. If air-filled paranasal sinuses are present in divers, they have to be open-ended so that air or other fluids (e.g., blood, lymph, cerebrospinal fluid) in adjacent vascularized structures can move into and out of them to compensate for changes in air volume in response to changes in ambient pressure (Molvaer, 2003); alternatively they must have flexible walls that are capable of collapse. Of the carnivores, terrestrial bears (Moore, 1981) have the most extensive sinuses; to our knowledge, those of polar bears have not been described. Cetaceans particularly odontocetes, have several air-filled regions, those on the ventral aspect of the skull are associated with pneumatized bones. These air-filled sinuses have large openings that are connected to the respiratory system via the Eustacean tube (Fraser and Purves, 1960; Houser *et al.*, 2004). Interestingly, in contrast to the pneumatized bones found in terrestrial mammals, it is the cetacean pterygoid bones that are the most pneumatized. Typically pterygoid bones are small in mammals but in cetaceans they are significantly enlarged (slightly more than 40% of the ventral length of the skull in *Ziphius*; Rommel *et al.*, 2006). In many cetaceans, the pterygoid sinuses have thin medial and lateral bony walls called lamellae. Some species with relatively large pterygoid sinuses (e.g., ziphiids and physeterids) have lost the lateral lamellae and the medial bony wall of the sinus is relatively thick (Fig. 13). In place of bony lateral lamellae, the large pterygoid sinuses of these divers are walled with a tendinous sheath to which the muscles of the palate attach (Fraser and Purves, 1960). In manatees, a large ventromedial pterygoid process of the palatine bone and a large ventrolateral pterygoid process of the alisphenoid both join the relatively small pterygoid bone to produce a robust structure that supports the large pterygoid muscles (Figs 8, 10, and 12).

The walls of the pterygoid sinuses are well vascularized, perhaps to help with adjusting volume as ambient pressures change. The air-filled spaces of live dolphins have been shown to be dynamic structures that function as reflectors to help isolate the earbones from the sound producing apparatus of the head and to help isolate the two ears so that they can have better directional abilities (Houser *et al.*, 2004).

VIII. Telescoping

Telescoping is a process often discussed when describing the skulls of cetaceans (Figs 14, 15). The term, coined by Miller (1923), refers to the elongation of the rostral elements and the dorsorostral movement

of caudal elements (Kellogg, 1928; Miller, 1923; Rommel, 1990). The relative placement of the skull bones in cetaceans results in considerable overlap of some adjacent bones. If the skull is sectioned, one can observe as many as four different bones overlapping each other—this overlap resembles old-fashioned collapsible telescopes. In cetaceans, the external bony nares have been displaced to the dorsal apex of the skull, so the nasal bones are located just caudal to the external bony nares (as in other mammals) but dorsal to the brain case instead of at the apex of the rostrum. The premaxillary and maxillary bones have been extended at their rostral tips; their caudal aspects are pulled up and back over the frontal bones and maintain their relative positions with the nasal bones. The narial passages are essentially vertical in cetaceans, which eliminates the nasal bones as roofing bones of the nasal passages. The nasal bones are, instead, relatively small vestiges that lie in depressions of the frontal bones. Thus, the roof of the cetacean mouth is not the floor of the nasal passages as it is in most other mammals. Caudally, telescoping differs in odontocete and mysticete cetaceans (Fig. 14). The changes in the mysticetes are dominated by a ventrocaudal extension of the maxillary bones, whereas in the odontocetes, the premaxillary and maxillary bones are shifted more dorso-caudally (Kellogg, 1928). Interestingly, whereas the odontocete facial muscles have moved dorsocaudally over the eye, the temporal muscles of the mysticetes have moved dorsorostrally over the eye. Thus, the temporal fossae of the mysticetes are very different from those of the odontocetes.

The remodeling associated with telescoping is reflected in the number and positions of the cranial nerve foramina in the maxilla (Fig. 15). Consider the nerves that are associated with the muscles of the face—the (sensory) trigeminal nerve (V) and the (motor) facial nerve (VII). The right and left facial nerves control such muscle activity as facial expression in the dog, feeding in the manatee, and focusing of sonar pulses in the dolphin. The trigeminal nerves signal the brain to coordinate the muscular activities in the same region. The relatively large sizes of these two nerves in the dolphin and manatee reflect the importance of these neuromuscular actions. The nerve diameters are reflected by the size of the infraorbital foramina through which the trigeminal nerve pierces the maxilla (Fig. 15). In odontocetes, the bones and muscles of the face are reshaped and accommodate the melon and its need for complex mechanical manipulation and the sensory and motor nerves are moved up and over the orbit. The homologous (and thus same-named) opening, which is *infra*-orbital in most species, is now actually dorsal to the orbit (that is, *supra*-orbital) in cetaceans!

In conclusion, we can state that a glance at a skull tells us a great deal about an organism—how it senses its environment, how it feeds, how big its brain is, etc. It is also very important in understanding phylogenetic history and species description. Rather than becoming bogged down in trying to memorize names of bones or bony features, study a skull with an open mind (pun intended) about adaptations and function.

Figure 14 (continued) One result of telescoping is the displacement of the external bony nares (and the associated nasal bones) toward the dorsal apex of the skull—up and over the rostral margin of the brain! Telescoping is quite different in odontocete and mysticete cetaceans; in most odontocetes the rostrum is dorsally concave, whereas in mysticetes the rostrum is ventrally concave. The temporal fossae of the mysticetes have moved up and forward over the eye; the temporal fossae in odontocetes are in a more typical mammalian position. Relatively more bone mass is moved up and over the orbit in the odontocetes, whereas relatively more bone mass is moved down and under the orbit in mysticetes. In the lower schematic, arrows indicate the directions of relative movement as each skull is remodeled to accommodate the brain and the respiratory, feeding, and acoustic apparatus of the two types of cetaceans. Note that in C the brains are scaled to fit in the lateral views of the crania in B above them; the odontocete brain makes up a larger percentage of the cranial volume than does the brain of the mysticete. Copyright S. A. Rommel.

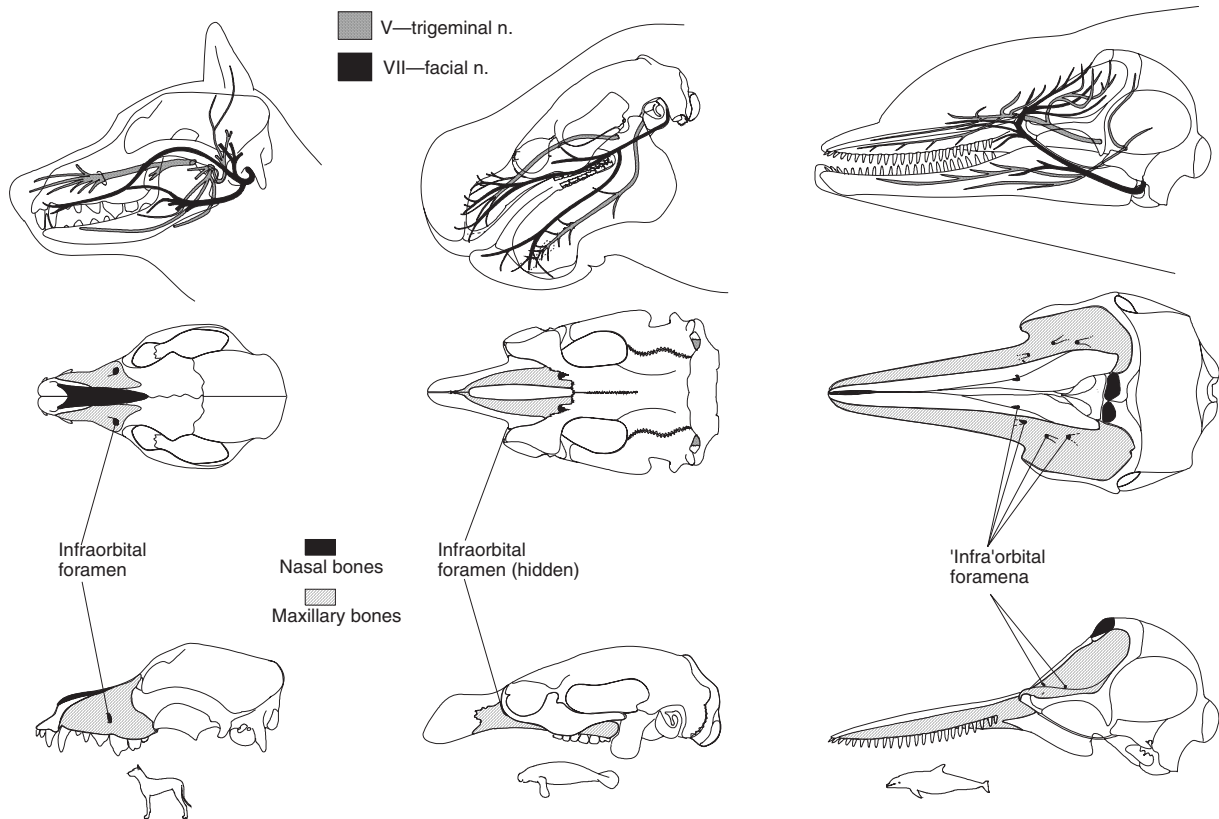

Figure 15 The nerves associated with the facial muscles also reflect telescoping. These are the trigeminal and the facial nerves. Here the dog is compared with the manatee and the dolphin. The relatively large sizes of the trigeminal nerves are reflected in the relatively large foramina through the maxillae (infraorbital foramina); the larger the nerve, the more information it can carry. The process of telescoping has remodeled the bones of the rostrum and included in this process are the reshaping of the muscles of the face and the nerves that innervate them. Also note that some odontocete cetaceans have notable bilateral asymmetry in the dorsal elements of the skull. Copyright S. A. Rommel.

- population genetics, of the species in question. Sociobiological investigation also increasingly attempts to characterize the genetic breeding system, as well as the population dynamics and structure, which importantly influence the effectiveness of evolutionary processes in molding species characteristics.
- The sociobiological approach assumes that selection at the individual level is the force producing adaptation. A proper understanding of social phenomena, therefore, needs an understanding of the benefits and costs that the individual derives from its interaction with the social environment. Explicitly, group selection is relegated to a secondary position as in most circumstances selection operates more strongly at the individual than at the group level because fertility, dispersal, and mortality events are more frequent and act much more forcefully on individuals than on groups. Explaining social phenomena such as group formation, parental care, and mating systems from the action of selection at the level of the individual forms the core of sociobiological inquiry.
- As the majority of sociobiological research in the field of marine mammals has been done on whales and pinnipeds, these two groups form the focus of the following sections. Relevant information on sea otters (*Enhydra lutris*) and manatees (*Trichechus* spp.) is mentioned briefly in Section V.

II. Group Formation

The most obvious phenomenon of social life is group formation. Suitable feeding or breeding habitat may initially lead to an aggregation of individuals, thus setting the stage for selective processes molding the evolution of elaborate social interactions. In contrast to the term “aggregation,” “group” implies that individuals come together to derive benefits from interactions that follow from this proximity. Such a grouping may serve social, foraging, predator avoidance, or defense against predators. Groups may also be established for mating and to share parental care. These kinds of advantages constitute the selective processes that promote group formation in a wide variety of animals. Sociobiology tries to explain groupings from the advantages and disadvantages incurred by individuals (Krause and Ruxton, 2002).

A. Whales

The open ocean habitat offers few options for hiding from predators. Consequently, predation by large sharks and killer whales (*Orcinus orca*), particularly on newborns, is one important factor selecting for group formation in whales and dolphins. Direct observational evidence for this hypothesis is scarce, but signs of scarring provide evidence of frequent encounters with predators. For example, about one-third of all humpback whale (*Megaptera novaeangliae*) calves carry tooth marks on their flukes when arriving in the foraging areas, presumably from encounters with killer whales or sharks during migration to the feeding grounds (Mann *et al.*, 1999). The most spectacular groupings are found in open ocean species such as spotted dolphins (*Stenella* spp.) which benefit most from the advantages of grouping as protection against predators, but such species may also benefit from group foraging.

Several effects play a role in the protection offered to an individual by a group. The “dilution effect” acts by reducing the probability of an individual to be attacked by a predator who has noticed the group, if the predator takes only one individual out of the group. This effect thus dilutes the chances of an attack on a given individual dramatically (to 1/group size). The “confusion effect,” many individuals rushing back and forth through the visual field of an attacking

Sociobiology

FRITZ TRILLMICH

I. The Nature of Sociobiological Inquiry

Sociobiology is the study of social behavior and social evolution based on the theory of adaptation through selection. As such it is primarily concerned with the adaptiveness of social behavior and the selective processes producing and maintaining adaptiveness. Understanding the selective processes involved includes studying the ecology, physiology, and behavior, as well as the demography and

predator, makes it more complicated for the predator to concentrate on one prey to catch. Finally, animals in the middle of a group can in effect use other individuals around them as shields against predatory attack, as there will always be other individuals geometrically closer to a predator that attacks from the edge of a group. This is the so-called “geometry of the selfish herd,” which allows an individual to use other group members as protection. These effects may also partly protect individuals in groups against parasites, such as the cookie cutter shark (*Isistius brasiliensis*), which takes little bites out of the side of its victim. The advantages of grouping using dilution, confusion, or cover against predation do not depend on individual recognition or social bonds among individuals, but also function perfectly well in a totally anonymous group.

Eventually, the advantage of gaining protection in the group will be counteracted by increasing food competition among individuals in a large group and will thereby determine the upper size of groups. Because food competition depends on abundance, distribution, and behavior of food organisms, which are little known for whale prey, the importance of food competition is largely unknown. However, signs of territorial behavior between killer whale groups provide at least some evidence for the role of food competition in limiting group size.

For more powerful animals such as killer and sperm whales (*Physeter macrocephalus*), grouping offers the additional option to defend smaller, more vulnerable individuals against predators by taking them into the middle of the group. This kind of group action has a completely different quality than the examples given earlier because it involves bonds among the individuals in the group, which are presumably well cemented by individual recognition. Individuals in these groups actively take some risk to defend others, mostly calves, against predators. This has traditionally been explained by the fact that the individuals involved in such cooperative behaviors are kin to each other (Hamilton, 1964). However, it may also be based on mutualistic cooperation or group augmentation (Kokko *et al.*, 2001). The evolution of mutualism would be eased in kin groups through kin selection, but group augmentation involves a different mechanism. Here individuals attach to a group because survival and reproduction are enhanced or only possible in the protection of a group.

However, grouping can also be of advantage for a predator. Foraging groups have perhaps been best analyzed for killer whales. For the mammal-hunting the so-called *transient* killer whales in British Columbia, groups of three individuals proved most efficient in terms of energy intake per unit time when hunting harbor seals (*Phoca vitulina*) (Baird and Dill, 1996). Optimal efficiency of this group size results because a group of three cooperatively hunting whales seems to be better at detecting and catching prey than single animals or duos. At the same time, competition in such a small group is less than in a larger group, once it comes to sharing a harbor seal carcass. For more evasive prey such as Dall porpoise (*Phocoenoides dalli*), larger groups may be more successful because more animals are better at intercepting fleeing prey. Dusky dolphins (*Lagenorhynchus obscurus*) herd schools of fish cooperatively toward the surface and presumably thereby increase food intake. Such activities have also been observed in other dolphins that herded fish schools into bays or against fishing nets and thereby may increase food intake for all individuals in the group.

Social systems in whales differ widely between mysticetes and odontocetes. Mysticetes often live solitarily and, except for the mother–calf association during the rearing period, show little evidence of long-term social bonds. This is most likely caused by the nature of their food resources and the fact that due to their body size they have largely escaped predation. They may, however, aggregate during

feeding in particularly productive areas and during the mating season (see Section IV).

In contrast, almost all odontocetes are quite social. The social groupings of sperm whales, killer whales, pilot whales (*Globicephala* spp.), and bottlenose dolphins (*Tursiops* spp.) are best documented. In whales, groupings represent matrilineal lines in which male offspring may (in killer and pilot whales) or may not (sperm whales) remain for life. In sperm whales, the grouping of kin serves protection of offspring. During foraging, these animals routinely dive to 400 m depth and stay at depth for 40–60 min. During this period, young would be unprotected, waiting at the surface. This is avoided by adults in a group staggering their diving in such a way that one or more adults almost always attend the calves at the surface. Clearly, such behavior provides indirect fitness gains if the individuals in a group are relatives (such as mother, daughter, granddaughter). Kin selection effects may also explain the lack of dispersal of young in killer whales (in this case of both sexes). In resident, fish-eating groups, male offspring in a matrilineal group may offer protection to relatives as well as help in the defense of foraging areas. Females that stay with their mother may likewise gain fitness from cooperation with close relatives. The size of the group will be limited by food competition, and indeed large groups split up, when they have grown too much, into smaller units along matrilineal kinship lines. Limitation of group size by the potential for food competition is particularly evident, as the so-called *transient*, mammal-eating groups are much smaller (no more than three–five animals) than those of fish-eating *residents*, presumably because otherwise the disadvantage of food competition would offset the advantage of close cooperation with kin. Pilot whales show a similar social structure where male and female offspring stay with mothers (Amos *et al.*, 1993). Advantages and disadvantages of this social structure are less understood for the pilot whale than for the other species mentioned previously.

Bottlenose dolphins and some other inshore odontocetes live in quite open fission–fusion societies in which females associate frequently with many different partners. These associations may be useful in foraging or vigilance and maybe defense against predators, but the last hypothesis seems less likely because females with calves tend to be less gregarious. Whether this is due to food competition is unclear. Females may also sometimes group to avoid harassment by males (see Section IV). Male associations vary between study sites and seem to serve mating purposes (Mann *et al.*, 1999).

B. Pinnipeds

As a group, pinnipeds are characterized by an amphibious lifestyle. They forage at sea but females need to return to a firm substrate, land or ice, for parturition. A strong selective force during this period of birth and subsequent pup rearing is predation on mother and pup. In land-breeding pinnipeds, mostly otariids but also elephant seals (*Mirounga* spp.), monk seals (*Monachus* spp.), and the largest populations of gray seals (*Halichoerus grypus*), predator avoidance has led to the choice of predator-free oceanic islands for breeding. In comparison to the wide expanse of ocean used for foraging, these islands are limited in area, automatically leading to high densities of females on land. Otariid females come into estrus shortly after parturition, which sets the stage for sexual selection on males trying to station themselves in these female aggregations to breed (see Section IV).

Primarily, the concentration of females on land has all the characteristics of an aggregation, but females of most land-breeding species stay closer together than necessitated by available habitat. Indeed,

sea lion colonies were found to show internal social network structure (Wolf *et al.*, 2007). One reason for such active groupings may be to avoid harassment by ardent males trying to mate with females (Bartholomew, 1970; Trillmich and Trillmich, 1984). In addition, subadult males of some species of otariids abduct and herd pups, molesting them to the extent that they may die. In this dangerous situation, grouped pups profit from the dilution effect, which might select for tighter grouping of females (Campagna *et al.*, 1992).

Thermoregulation may also further grouping: Sea lions and the South African (*Arctocephalus pusillus pusillus*) and Australian (*A. p. doriferus*) fur seals tend to rest in body contact after leaving the water, which may serve to keep the body shell warm at minimal metabolic cost to the individual. This is not necessary for a fur seal with its highly insulating, air-trapping fur, and the function of clumping in the South African and Australian fur seal is therefore doubtful.

In contrast, ice-breeding seals tend to be more widely dispersed, be it on pack ice or fast ice. In these species, different factors select for some gregariousness. Most important for many species is predation: in the Arctic by polar bears (*Ursus maritimus*) and in the Antarctic by leopard seals (*Hydrurga leptonyx*) and killer whales. Some kind of a grouping advantage is perhaps operating that might equally benefit animals resting between foraging excursions and animals breeding on the ice. Indeed, harp seals (*Pagophilus groenlandicus*) are well known for breeding—even if dispersed—in well-defined local concentrations. It is not certain whether these concentrations are true social groupings or could also be induced by the characteristics of the ice in combination with the food resources below it, i.e., are aggregations due to resource distribution. It may actually be a combination of both. Weddell seals (*Leptonychotes weddellii*) group around tide cracks in fast ice, which offer holes for entry into the water where the seals forage under the ice. Because suitable holes are limited, this leads to a concentration of animals around entry holes and importantly influences the mating system.

Principally, pinnipeds are solitary foragers. There is little evidence for social foraging except occasional observations of sea lions herding fish into bays and communally preying on the trapped schools of fish. Aggregations of foraging sea lions and fur seals occur quite frequently near large fish schools where pinnipeds, birds, and whales may gather in so-called feeding frenzies. True cooperativity in these aggregations has not been demonstrated. This does not exclude that loose groups of pinnipeds may be more likely to locate food and through signs of foraging activity attract other animals to the site, an advantage frequently exploited by group-foraging birds.

III. Parental Investment Strategies

There is no convincing evidence of paternal investment in the rearing of young in any whale or pinniped. Lack of paternal care is typical for the majority of mammals and reflects that females alone provide for offspring during pregnancy and lactation, which frees males of parental duties (Clutton-Brock, 1991). Only in a few whale societies, e.g., killer whale matrilineal groups, males—most likely never the fathers of young in the group—act as helpers in defense and perhaps feeding of young.

Maternal strategies in whales and pinnipeds are characterized by massive energetic investment in young through the production of large precocial young and extremely lipid-rich milk. However, parental investment is measured not by energy expenditure, but rather by a reduction in future fitness, a cost incurred by the mother through a loss in subsequent fertility or an increase in mortality due to a expenditure that benefits the offspring by increasing its fitness

(Trivers, 1972). Evidence of parental investment, so defined, is rare in whales and pinnipeds.

The patterning of parental effort differs widely between mysticete whales and odontocetes. Mysticete females gather the material and energy for pregnancy (lasting about 1 year) and lactation during a feeding season of about half a year when food is plentiful and starve for the other half-year. Extraordinary fast fetal growth rates in blue whales (*Balaenoptera musculus*, 27 mm/day) permit even the largest mysticete whale—with the exception of the bowhead (*Balaena mysticetus*), sei (*Balaenoptera borealis*), and gray (*Eschrichtius robustus*) whale—to produce a calf within 1 year. By migrating to warmer oceans in the non-feeding period, mysticete whale females seem to minimize the metabolic overhead for themselves and newborn and sucking calves. Females suckle their young for a short period of 6–8 months on very lipid-rich milk, which is produced from maternal body stores, and wean abruptly. After lactation, mothers need to replenish body reserves, which usually takes a year. Females, therefore, generally breed every other or every third year. Females of the tropical Bryde's whale (*Balaenoptera edeni*) have similar gestation and lactation lengths but show much less of a seasonal breeding pattern. Despite the impressive energy flux involved in pregnancy and lactation in mysticetes, there is no strong evidence that this reproductive effort incurs fitness costs. In other words it does not constitute parental investment, for example, by reducing the probability of a successful pregnancy in the year following lactation.

Large odontocetes have pregnancy periods lasting longer than 1 year and take 8–36 months to wean their young, but reports on 13-year-old sperm whales with milk in their stomachs also exist. All larger odontocetes need more than a year to wean. Females consequently need much longer than 2 years to complete one reproductive cycle. The long period of nursing, even in dolphins, allows young to profit from the milk supply while gradually developing independent hunting skills.

It is presently speculated that the difference in rearing strategy between the two groups depends largely on the difference in hunting strategy. Mysticetes prey on small schooling prey, which are supposedly easy to catch for recently weaned young, particularly since weaning seems to coincide with the annual peak abundance of prey. In contrast, odontocetes hunt large prey individually, which forces them to use more complex foraging tactics. They may need to learn more about prey distribution and behavior before young can feed themselves successfully. This may even involve teaching by mothers as is likely for the technique of beaching used by southern killer whales hunting pinnipeds as observed on Southern sea lion (*Otaria flavescens*) breeding beaches of Argentina.

Another peculiar feature of some odontocetes is the occurrence of menopause. This phenomenon was documented for short-finned pilot whales (*Globicephala macrorhynchus*), and killer whales. One idea about the functional significance of menopause, which finds some support in studies on humans (Mace, 2000), is that menopausal females may help their last born and previous daughters in the group through prolonged maternal and allomaternal care, respectively, and by representing a living memory of how to deal with scarce resources and rare ecological disturbances. In matrilineal societies, menopause could be selected through indirect effects on the fitness of kin if the benefit to kin was larger than the benefit an old female could gain through further reproduction.

Sperm whales, long-finned pilot whales (*Globicephala melas*), false killer whales (*Pseudorca crassidens*), and bottlenose dolphins show evidence of reduced fertility with age, perhaps caused by extended periods of lactation. This change in maternal lactation strategy is expected from life history theory because old females have

a lower reproductive value and may therefore invest more in current offspring than young females. Alternatively, prolonged lactation in older mothers might be a sign of senescence or it may be caused by a reduction in condition through previous parental care episodes and could then be considered a cost of reproduction.

Despite marked sexual size dimorphism in many species, there is little evidence for sex-biased investment in sons versus daughters. In short-finned pilot whales sons may be suckled for longer than daughters. Males had milk in their stomachs up to an age of 15 years, but females only up to an age of 7 years. This fits with the observation that males grow faster than females and are consistently larger at weaning than female juveniles. Similar observations have been reported for sperm whales. If such a difference in effort expended on the two sexes were consistent in the population, one would predict from models of sex allocation (Frank, 1990) that the sex ratio at birth or at weaning should be biased toward females. There is as yet no evidence for such a sex ratio bias.

A. Pinnipeds

Pinniped females produce one pup per year, instances of twinning are exceptional. Otariids have a postpartum estrus, whereas phocids copulate around the time of or after weaning of young. Implantation is delayed for 3–4 months and is then followed by an 8–9-month pregnancy. The young are reared on lipid-rich milk and are usually weaned at an age less than 1 year, thus allowing an annual cycle of reproduction. Pinnipeds follow one of two alternative pup-rearing strategies. Females may nurse pups for a short time, a few weeks, from body reserves and then wean abruptly. This is termed the *fasting strategy* and is typical for larger phocids. Smaller phocids and otariids nurse young post-partum from body reserves for a short period, in otariids lasting about 1 week. Thereafter they alternate regularly between foraging close to the colony and nursing ashore; they follow a *foraging cycle strategy* of pup rearing. Phocids wean pups after a shorter duration of lactation, 4–65 days, at a about 25–35% of maternal mass, whereas otariids wean after 120 days to 3 years, at 35–55% of maternal mass (Costa, 1993; Trillmich and Weissing, 2006).

The rearing strategy appears to depend on both female body mass and on phylogenetic grouping (Boyd, 1998; Schulz and Bowen, 2005). The larger a female, the richer a food resource she needs to support pup rearing by foraging during lactation. This is because the energetic costs of traveling to and from the food resource and maintaining the metabolism of mother and pup during the foraging sojourn become too high for large pinnipeds to make foraging during lactation a feasible strategy. Therefore, large species separate foraging completely from lactation, store massive energy reserves during a long foraging period in rich feeding areas often far away from breeding sites, and then fuel lactation out of body reserves. Because phocid females are on average larger (median maternal mass for all species 140 kg) than otariid females (median 55 kg), this might explain why phocids usually follow a fasting strategy and otariids a foraging cycle strategy (Boyd, 1998; Schulz and Bowen, 2005; Trillmich and Weissing, 2006). The largest otariid, the Steller sea lion (*Eumetopias jubatus*) with a female mass around 250 kg, needs to take its unweaned young close to the foraging areas to maintain lactation by alternate foraging and suckling. Similarly, walrus (*Odobenus rosmarus*) females take their young to foraging areas where they are suckled while the mother can forage nearby. Ecological constraints thus play a role in shaping maternal strategy, but phylogenetic constraints also importantly influence presently found lactation strategies.

Evidence is mixed that the energetic effort expended on pup rearing induces fitness costs of reproduction (Boness and Bowen,

1996; Trillmich, 1996). In the northern elephant seal (*Mirounga angustirostris*) primiparous—giving birth for the first time—young females are less likely to bear a pup in the year following birth than older females, thus suffering reduced fertility as a consequence of early onset of reproduction. Also, survival seems to be reduced when females first reproduce at 3 rather than 4 years of age, implying a mortality cost. However, these results were obtained at one but not another site on the Californian islands and the interpretation is not entirely clear. In otariids, Galápagos fur seal (*Arctocephalus galapagoensis*) females incur fitness costs of reproduction in terms of reduced fertility because they frequently lose a newborn pup when still accompanied by their previous young, be it a yearling or a 2-year-old, by the time the next pup is born. This arises because young Galápagos fur seals grow extremely slowly and therefore take unusually long, up to 3 years, to become independent of their mothers. They may suckle for a second or third year if environmental conditions are poor, and thus preclude rearing of another pup by their mother (Trillmich and Wolf, 2007). Clear evidence for a fertility cost of reproduction was also found for Antarctic fur seals (*Arctocephalus gazella*). Parturient females of all ages were significantly less likely to reproduce in the subsequent year than nonparturient females. In addition, females that reproduce in a given year are less likely to survive to the following year than nonreproducing females—a clear mortality cost of reproduction (Boyd *et al.*, 1995). In this species and the northern fur seal (*Callorhinus ursinus*), females older than about 13 years appear to show reproductive senescence. These old females are less fertile and produce smaller newborns than prime-age females. Particularly for otariids, there is thus evidence that the high energetic effort expended by females on pup rearing indeed constitutes maternal investment because it produces fitness costs to the mother.

It has been claimed repeatedly that female pinnipeds of highly polygynous species invest differentially in male and female offspring. Following sociobiological arguments, this would be expected if an increased investment in males, the larger sex showing greater variance in reproductive success would lead to a greater expected reproductive success of such males. In many polygynous pinnipeds, males are born heavier and grow faster than females. This was taken as evidence for greater maternal investment in sons. However, this is no proof of greater investment in male offspring because male pups of some otariids store less fat and produce more lean body mass than female pups. Fat has a higher energy density than lean body mass, and consequently smaller female pups may have taken as much energy from their mothers as the larger, leaner male pups. Also, the most important growth spurt determining later male adult size and probably reproductive success occurs generally after weaning, thus making it less likely that male offspring derive direct benefits for their future reproductive success from increased maternal investment (Trillmich, 1996). Nevertheless, recent data demonstrate a greater cost of male offspring at least for one otariid species (Trillmich and Wolf, 2007).

IV. Mating Systems

Mammalian females are producers that are limited by the time and resources needed for pregnancy and lactation, as well as by the recovery of condition after a reproductive cycle. This constitutes strong selection to optimize acquisition and efficiency of resource use before and during reproduction. Because the maximal reproductive rate of female mammals is necessarily much lower than that of males, which in the extreme need only the time of one copulation to produce offspring, females become a limiting resource for the reproduction of males. This leads to sexual selection on males for an

increased ability to get access to and breed with as many females as possible leading to often extreme sexual size dimorphism. In mammals such as whales and pinnipeds, where males do not contribute to the care of offspring, males are expected to conform to the description of “ardent” males, eagerly searching for females and even harassing them for copulation. Females distribute themselves in relation to the distribution of resources, food, and adequate habitat for reproduction, and males map onto this distribution of females. This difference in the selection on reproductive strategies of males and females leads to the phenomenon that quite often the sexes behave and morphologically look as if they belonged to different, competing species.

Sociobiological reasoning therefore leads to the expectation that observed mating systems represent the compromise arising from the conflict of the sexes. Competition among males for access to females can take the form of aggressive competition, but can also occur via sperm competition when several males copulate with one female, as demonstrated for northern elephant seals. Such sperm competition, if occurring regularly, is expected to lead to the evolution of large testis mass, as larger testes produce more sperm and thus increase a male's chances to fertilize the ova of females in competition with sperm of other males. Such an increase in relative testis mass was documented in other mammalian orders where species in which multiple copulation is frequent have larger testes than species where only one male copulates with a given female, whether the social system is monogamous or polygynous.

A. Whales

Whale mating systems are still largely unknown partly due to the problem that copulations are hard to observe. Except for a few particularly observable species, this leaves only indirect methods of investigation, such as genetic analyses, to determine the mating pattern in the more elusive species (Connor *et al.*, 1998).

Among mysticete whales, much is known about the humpback whale, so well known for its spectacular songs. During the mating season, males station themselves well spaced out and advertise their position. This is very similar to the lek structures observed in many birds. The song may attract females and keep competing males away, but there is presently no firm evidence for this inference. Alternatively, males follow females, and several males may be doing this simultaneously, leading to competition for proximity to the female. Apparently these males compete over mating access to a female. Because humpback whales have small testes for their size, it is unlikely that females will copulate with several males, thus inducing sperm competition. In contrast, sperm competition is likely to occur regularly in right whales (*Eubalaena* spp.), which—weighing about 50 tons—have testes weighing 1 ton, in strong contrast to blue whales, which weigh about 100 tons but have a testis mass of only about 70 kg. Copulation is observed frequently in right whales but has never been described convincingly in humpbacks, despite much more study of the latter.

Mating patterns in odontocetes are somewhat better known from a few species (Connor *et al.*, 1998). Male strategies vary from singly roving males in the sperm whale to males that cooperate to herd and perhaps force females into copulation in the bottlenose dolphins. Sperm whales show a mating pattern similar to that of elephants in which single fully adult, highly aggressive males rove among female groups in search of receptive females. They stay only briefly with each one of the female groups and then go on. Presumably, the long intervals between estrus in females make it unprofitable for these males to stay with any one group of females waiting for one of the females to enter estrus. Only fully adult males appear able to compete in this system, and

subadult males as well as non-roving males stay at higher latitudes, often in small schools, feeding and maximizing energy intake in this way to grow to a competitive size. It is unclear why these males might stay in small groups as bachelors because they are certainly not endangered by predation and it is unknown which foraging advantages they might derive from grouping.

The killer and pilot whale mating system is the most surprising, least understood of the whale mating systems and has no parallel in terrestrial mammals. Genetic evidence shows that males who remain philopatrically in their maternal group never father offspring in their own group, but apparently in other groups. Some evidence suggests that several related males of one group may mate with several females in another group, presumably during repeated encounters of these pods. This was concluded from the genetic observation that offspring in a group seem to be paternally related.

B. Pinnipeds

The pattern of mating interactions among individuals depends greatly on the dispersion of females during the breeding season, which in turn reflects the availability of a suitable habitat for pupping and foraging. In pinnipeds, pack ice, fast ice, and land-breeding species differ widely in this respect (Boness, 1991; Le Boeuf, 1991).

Phocids breeding on ice floes seem to have a mating system best described as serial monogamy in which a male stays with a female that has recently pupped until she comes in estrus. He then leaves after copulation to search for another female. The reproductive success for males in such a mating system depends more on their aptness to locate females ready to mate than on fighting abilities. In such species, sexual dimorphism tends to be small, slightly reversed (males smaller than females), or nonexistent.

Some fast-ice breeding species also show reversed sexual dimorphism, which is best analyzed in the mating system of the Weddell seal. Females gather around cracks in the fast ice where they dive for food from holes in the ice. During the reproductive season, they pup near these holes and males claim territories under the ice and defend the holes against other males. Under these conditions, maneuverability is considered more important than sheer size in male–male competition. This may be the reason for the observed reversed sexual size dimorphism. Alternatively, females may be selected for larger size, enabling the production of larger young or the storage of more massive fat reserves for lactation, and males may have remained smaller for lack of such selection. Copulation is underwater and consequently little is known about the reproductive success of males in this mating system.

Phocid seals, such as the harbor seal, which breed in the water close to land areas where females loosely aggregate, seem to engage in fights for the best stations where females have to pass by, and such males are often wounded. Fighting males seem to have the highest reproductive success and, in some places, the mating system of this species may be similar in structure to a lek.

When female otariids or land-breeding phocids come together on predator-free islands, the resulting high female density permits males to station themselves among females and attempt to monopolize access to females. This competitive situation sets up sexual selection for an ever increasing male size, leading to impressive sexual size dimorphism in a few phocid and many otariid species (Lindenfors *et al.*, 2002), such as the northern fur seal in which males weigh six times as much as females. In addition, a larger size also enables males of these species to remain fasting on territory for long periods, thus increasing their chances to mate with females.

Otariid mating systems have been described as resource defense, female defense, or leks. The presence of resources important to females with pups, such as shade or access to tide pools, on male territories was demonstrated experimentally for a few species. However, resource distribution is not sufficient to predict the exact location of female aggregations nor does it explain female gregariousness, i.e., an active tendency of females to approach each other. Because high female density correlates with increased pup mortality in breeding colonies, there is a marked cost to female gregariousness, which must be compensated by comparable benefits. Bartholomew (1970) suggested that female choice of genetically superior males was responsible for female gregariousness, but little evidence supporting this view has come forward. New studies suggest a strong selection of female gregariousness through avoidance of interaction with large males, whether territorial or not. In many otariid species and in elephant seals, interactions with a much larger male can be dangerous or even deadly to a female. Females can minimize the probability of interaction with territorial males by aggregating into a “selfish herd.” Through this effect and by avoidance of dangerous and sometimes directly fatal harassment of females and pups by marginal males, females are selected to group much more closely than can be explained by resource distribution. Thus, the stationing of large adult males on clustered territories among parturient and estrous females creates a resource “peace from marginal male harassment” (Trillmich and Trillmich, 1984). Except for this socially created resource, the system could also be described as one in which males are lekking on areas where females are forced to stay for a while because they spend the period between parturition and postpartum estrus near-stationary on land. Males may benefit from clustered territories by the reduced chances of losing females when disturbed by marginal subadult or adult males. Within this system, the male defense of access to females varies intra- and interspecifically with habitat and female density, from female defense to territorial site defense with larger or smaller territories reminiscent, respectively, of a resource defense or a lekking system.

Dominating males in these land-based breeding systems gain most copulations and can reach quite extreme reproductive success, sometimes up to 100 copulations in one breeding season. However, genetic studies have shown that observed number of copulations does not always correlate well with actual paternity, suggesting that peripheral, apparently “excluded” males may also gain some reproductive success by keeping close to female groups. There is no evidence of female choice beyond the mechanism that females in dense groups attract the strongest males in the best condition because only these are competitive enough to station themselves in the middle of female groups. Female elephant seals protest when they are attacked and forced into copulation by subadult or peripheral males, thereby attracting the attention of the dominant male who will often chase off the smaller male and copulate with the female. In this way females indirectly choose dominant males as copulation partners.

Gray seal mating systems on land strongly resemble the otariid system. Whether female choice plays a more important role in gray seal colonies remains to be seen. Genetic analysis of subsequent offspring of individual females suggests that females copulate year after year with the same male, even though they may stay in the territories of different males. This would suggest that they actively choose a particular male or, in case of multiple copulations, have mechanisms to choose among sperm of several males. In more dispersed breeding species, such as harbor seals, males have no chance to defend access to females as these are too mobile and not available continually in the same areas, depending on tide level and sea conditions. In situations in which females breed on sandbanks, harbor seal males

were observed to station themselves in areas where females are likely to pass by and make themselves obvious through vocal display. Whether this and similar observations on walrus males that station themselves near females and produce bell-like sounds can be considered a lek display needs further investigation.

V. Sirenians and Sea Otters

Much less is known about the social life of sirenians and sea otters and, therefore, these two groups are treated only briefly here.

The only clearly recognizable social structure in sirenians is the mother–offspring bond, which may last for up to 3 or 4 years. Other than that, it appears that the dispersion of most sirenians relates directly to the distribution pattern of food, aquatic macrophytes, fresh water for drinking (in the Florida manatee, *Trichechus manatus*) and, particularly in winter, warm water areas. Animals may migrate for large distances between such resources. However, it seems possible that underlying the apparent asocial pattern may be a subtle pattern of individualized relationships. This might be hypothesized from “greeting” displays exchanged between individuals that meet only occasionally at widely distant sites.

Cows in estrus seem to induce male scramble competition. In Florida, manatee herds of up to 20 males may follow an estrous female and compete by pushing to get into a favorable position for mating. In dugong (*Dugong dugon*) males, competition may take a more aggressive form in which males may wound each other with their tusks. For West Australian dugongs, mating competition may lead to a form of lekking (Anderson, 2002). However, the evidence is largely circumstantial.

Sea otter spatial dispersion is related to the need to live close to the coast where they forage relatively shallowly for macroinvertebrates. Females claim year-round foraging territories along the coastline that often overlap. They sometimes aggregate in small groups—so-called “rafts.” Young males, and fully adult males outside the reproductive season, also frequently form rafts close to areas of rich feeding resources. Such rafting is presumably related to the reduction of predation risk.

During the reproductive period, fully adult males establish territories that may overlap with more than one female territory. This provides males with a chance for a mild form of polygyny, but hard evidence for paternity of such males is at present missing.

VI. Concluding Remarks

Much of the sociobiological interpretation of observations on marine mammals is still in an early stage. This situation reflects our lack of detailed knowledge about the marine environment and in particular the macro- and microdistribution of resources and predators of marine mammals. More observation, more comparative studies, and especially more experimental work are urgently needed to understand the sociobiology of these magnificent animals. Obviously, experimental work will be particularly challenging and can only be successful if built on the thorough knowledge of marine mammal natural history. However, a well-founded functional understanding of the social behavior of marine mammals cannot be achieved without experimental tests of our many assumptions. Ingenious instrumentation and molecular genetic tools, developed during the last decade, should prove most helpful in making this summary of marine mammal sociobiology soon outdated.

Song

JIM DARLING

I. Characteristics

A. First Descriptions

Although likely heard by sailors for millennia, the first recordings of humpback (*Megaptera novaeangliae*) songs were made via US Navy hydrophones in the 1950s off Hawaii and Bermuda. Scientists first recognized these sounds in the 1960s as coming from humpback whales. The first technical description was published in *Science* in 1971 by Roger Payne and Scott McVay with the revealing subheading, “Humpbacks emit sounds in long, predictable patterns ranging over frequencies audible to humans.” Their analysis led to a structural context in which to view the sounds introducing the terms units, phrases, themes, and song. With the observation that humpback whales “produce a series of varied sounds then repeat the same series with considerably precision” these authors called the performance “singing” and the repeated series of sounds the “song.”

The biological definition of song is a series of sounds that are repeated over and over. Many animals, therefore, have songs, ranging from the simple “ribet” of frogs, to the huge variety of bird songs, to the loud repetitive signals of the whales. Although whale song was introduced and has been virtually synonymous with the humpback whale, recent studies indicate that other species of baleen whales, including bowheads (*Balaena mysticetus*), blues (*Balaenoptera musculus*), fins (*Balaenoptera physalus*), and minke (*Balaenoptera acutorostrata*), also repeat patterned sequences of sounds that fit the song definition. Studies of the songs of other mysticetes are young—although this is changing quickly. To date, no known songs are quite as complex and dynamic as those of the humpback whale.

B. Song Structure

The humpback whale song is composed of a sequence of highly varied sounds ranging from high-pitched squeaks to midrange trumpeting and screeches to lower frequency ratchets and roars, and combinations of all these. This sequence is typically about 10–15 min in duration, although it may range from 5 to 30 min. It is then repeated without a break (Payne and McVay, 1971; Winn and Winn, 1978).

The song has a predictable structure or framework. Discrete sounds are termed *units*. Several different sounds or units in a sequence compose a *phrase*. A phrase is repeated some variable number of times (for example, 10 times), and this series of the same phrase is called a *theme*, say, “theme 1.” After several minutes of singing theme 1 the singer changes to a different set of phrases (composed of different units or sounds) and repeats it a number of times. This might be called “theme 2.” This pattern repeats until the whale cycles back to its theme 1. A typical song may contain six themes. A singer may sing in order themes 1–2–3–4–5–6 and then start at 1 again. The number of themes in a song varies from population to population and

from year to year. A song session may continue without a break for hours (Payne and McVay, 1971).

Several characteristics of this song display are notable. First is the precision by which a singer repeats its complex song in any song session. An undisturbed singer may repeat the same themes, phrases, and units faithfully for hours as if on a continuous tape. The second characteristic is that all the singers in a humpback assembly, and there may be hundreds, follow the same structural rules and broadcast essentially the same song (Payne *et al.*, 1983; Noad *et al.*, 2000). At the same time, however, there is some variation in song presentation and some songs are exceptional to the point that they have been termed “aberrant” by investigators (Frumhoff, 1983). The significance of this variability is not yet understood.

C. Song Progression

One of the more unique characteristics of the humpback song is that it gradually changes over time. Different sounds, and arrangements of sounds, form to create new phrases and themes. These are incorporated into the song gradually, while older patterns are lost. After a period of several years the song may bear little resemblance to the original version (Payne and Payne, 1985; Noad *et al.*, 2000). This is a rare, although not unique, characteristic of biological songs. Several bird species are known to vary their song over time.

The song apparently changes as it is being sung, i.e., the progressive changes occur during the singing or breeding season, not during the off-season. For example, as winter progresses, one unit in a particular phrase may be heard less and less while another becomes more common, or two units in one phrase that had been separate may become joined as one sound. These small changes may eventually lead to new phrases and themes (Payne *et al.*, 1983). During the non-singing or summer season, the song appears to remain relatively stable, to begin to progress again once singing begins the following season. The biological forces or mechanism behind the progression of the song is not known.

The change in the song display occurs in a collective or common way throughout a population of humpback whales, i.e., at any one time all the singers in a population produce fundamentally the same version of the gradually changing song. This is a generalization in that there is certainly some range in when individuals incorporate new elements into their song. However, the majority of singers produce many if not all the same clearly recognizable units, phrases, and themes in the same general order in any one season (Payne *et al.*, 1983; Cerchio *et al.*, 2001). Changes in the song are apparently incorporated throughout the population. The mechanism by which this occurs is not known. All indications are the changes are learned, with some whales making changes and others copying them. This was emphasized by a discovery that, over a 2-year period, the humpback whales off eastern Australia essentially adopted the western Australian humpback song, presumably introduced to that region by the mixing of whales (Noad *et al.*, 2000)

The similarity and collective change of the song may occur not only within one population of humpbacks, but between populations separated by thousands of kilometers. For example, humpback populations that winter in Japan, Hawaii, and Mexico sing similar versions of the song at any one time (Payne and Guinee, 1983; Cerchio *et al.*, 2001). In contrast, the Atlantic humpback song would be substantially different—but at least two populations of humpback whales within the South Atlantic, off Gabon and Brazil, sing similar songs at any one time (Darling and Sousa-Lima, 2005). The means by which this occurs is not known. Some degree of mixing occurs among all populations in the North Pacific in that individual whales may visit

the different winter assembly areas over several years or even in one year. Perhaps this mixing is reflected in the similarity of songs. It is important to emphasize that whereas the generalities described here are striking, much further research is required to conclude on the relationship of songs, singers, and populations.

II. Singing Behavior

A. Seasonality

Singing is a seasonal behavior pattern. It occurs primarily during the winter half of the year, throughout the peak of the humpback breeding season. Although a few songs have been recorded during midsummer, they are rare. Songs become increasingly common on the feeding grounds as fall progresses into winter; they are heard regularly during migrations and predominate on the warm water winter breeding grounds. It is not clear when the singing activity declines in the spring, but song has been recorded on early summer feeding grounds.

B. A Male Communication

The evidence to date indicates that only male humpbacks sing. The sex of a sample of singers has been determined both by photographs of the genital region and by genetic analysis of skin samples, and so far all were males. Also, singing is a behavior pattern common to individual whales that may escort a cow with calf or compete in mating groups—both distinct male behavior patterns (Darling and Berube, 2001). Because there are no confirmed observations of female humpback whales singing, the song may be a male secondary sexual characteristic or display that functions during the breeding season.

A singer on the breeding ground is typically a lone adult male. Also, it is not unusual for an “escort,” the adult male accompanying a cow with calf, to be singing. Occasionally a singer has a companion adult or juvenile in the close vicinity (Darling *et al.*, 2006). Often the singer is stationary, remaining in one geographic location for many hours while singing. In these situations the singer generally adopts a motionless, head-down, tail-up posture approximately 50–100 feet beneath the surface. It maintains this posture until it surfaces to breathe and then immediately after diving resumes it. At other times a singer travels steadily as it is singing and may move tens if not hundreds of kilometers across the breeding ground during a song session.

One study in Hawaii indicated that the amount of singing increases significantly at night versus day-time; the reason is unknown (Au *et al.*, 2000). In a study of humpback whale swim speeds during migration off eastern Australia, singers were found to swim significantly slower than the average; the reason for this is also unknown (Noad and Cato, 2007).

C. Interactions with Singers

Humpback songs are loud and can be heard underwater for at least several kilometers and, in some circumstances in deep ocean basins, possibly hundreds of kilometers. A collection of dozens of singing humpbacks produce a substantial noise, clearly designating the location—on almost an oceanic scale—of an assembly of humpback whales during the breeding season. It is likely that individual humpbacks interact with the collective singing herd over extensive oceanic distances.

On a smaller scale, several studies have focused on the interaction of individual singers with other whales. Generally, singers sing until one of two things happen: First, they are joined by other single adults, the singing stops, and the two interact in some way, ranging from a single pass to rolling, tail lobs, or breaches by one or both animals.

The large majority of these interactions are non-agonistic and brief, with the pair splitting after a few minutes. One or the other may start singing again shortly after the interaction. All evidence to date is that the lone adults that join male singers are also males. Second the singer stops singing without any close approach by another whale and then rushes to approach or join a passing group of whales—often a surface active or competitive group; at times a cow with calf. In these cases, the singer joins a group that includes a potentially breeding female (Darling *et al.*, 2006).

One study carried out by the author, that included extended follows of individual singers, found that the common interaction of a singer joined by another lone male was often just one of a series of similar interactions across the breeding ground. For example, one singer in this study, over a 4-hour period, interacted with 3–4 other males, for 5–6 min each over a distance of 13 km. The singer was joined, stopped singing, then itself joined and split from two separate singers, then began singing again—and was joined again. These observations made it clear that song serves to connect males across a breeding ground, and “singing” and “joining singers” are readily interchangeable male roles. The function of this behavior is not yet known. In several cases in this study, the interacting males (at times joined by a third male) joined either a lone female or a female accompanied by one or more males, as a non-agonistic, and possibly cooperative, unit (Darling *et al.*, 2006). However, such observations around a female are extremely limited, and the behavior pattern is far from understood at this time.

III. Function

The function of the song has been the subject of much speculation. Much of this has revolved around proposals of the song as a male display that functions to attract females, signal status to other males, or a combination of these. However, other suggestions include that the songs serve as a means to synchronize estrus, a spacing mechanism between males, a migratory beacon, and as sonar by males to find females. A relatively young hypothesis proposes that the song may function as an index of association between males, perhaps as a basis for organizing males during breeding season. Recent research has widened the basis for the speculation but is far from resolving it.

Conservatively, the song is a communication from male humpbacks during the breeding season. It serves to provide the location of the singer, and by association the entire herd, and signals that breeding activity is underway. The song also likely broadcasts information about the individual singer, but what information and who the recipients are remain speculative. The collective, gradual change of the song seems to confound many simple explanations as to its function.

Several early investigations proposed that the song by males serves to attract females, and went further to suggest that changes in the song are driven by female choice (Tyack, 1981). This notion has persisted and predominates in the popular literature; however, there are no data to support it. There is little question that singers join and accompany females, but no evidence that females are attracted by, and voluntarily join, individual singers.

In a related idea, several researchers have proposed that the humpback song functions as part of an aquatic lekking behavior (Clapham, 1996). A lek, as generally defined for land animals, is a seasonal assembly where males display their attributes to attract females for the purpose of mating. This seems to describe the overall breeding assembly of humpbacks, including the male song display; however, if, when, or how females choose a mate is unclear.

Another proposal suggests that the song is a display of males aimed primarily at other males—perhaps signaling social status or position.

In this view the song may enable the male–male interactions that are integral to the establishment and maintenance of the dominance—ordered, polygynous mating system that has been hypothesized for humpback whale (Darling and Berube, 2001). This proposal accounts for the common interactions between male singers and male joiners, and the lack of evidence that females approach, choose, or join singers; however, it does not account for the song characteristics of collective change and similarity.

Regardless of whether the song display is directed at females, males, or both, these potential explanations suggest that song displays should vary with some attribute of the singer. That is, the song should reflect dominance class, fighting ability, or some other measure of the “fitness” of the male. At this stage, research has not revealed any evidence that this is the case. Indeed, the marked similarity of the song between individuals, and maintenance of that similarity, better characterizes the display than individual differences.

An alternative hypothesis, based on the maintenance of song similarity between individuals, and the observations that it mediates non-agonistic male interactions, is that the song may facilitate temporary male associations, cooperative units or coalitions in breeding scenarios. It is clear that non-agonistic and cooperative relations do occur between males on the breeding ground (Clapham *et al.*, 1992), but the extent of this behavior is unknown and its relationship to song is speculative (Darling *et al.*, 2006).

At this time, the function (s) of the song is not clearly understood. With some confidence, we can say that singing is a male behavior, which occurs in the winter season, hence very probably functions in breeding. And, at the least, it is clear that the song functions in mediating brief, non-agonistic male–male interactions. The connection between this behavior and actual mating, or other potential functions of the song remain to be revealed.

Sound Production

ADAM S. FRANKEL

Most terrestrial mammals rely heavily on vision and smell. These senses are limited in water by the absorption of light and the slow physical movement of water. As a result, marine mammals have evolved to use sound and hearing as their primary means of communication and sensing their world.

This article briefly reviews the basics of sound and the physical ways sounds are produced by marine mammals. The main focus is on characteristics of sounds made internally by marine mammals. Non-vocal sounds, such as tail slaps, are not treated in detail here. Certain species that stand out as particularly unusual or particularly well studied get special attention. Other species are treated in taxonomic groups, when their acoustic characteristics are similar or less well known. In addition, the odontocetes are organized according to their three main sound types: clicks, pulsed sounds and whistles.

I. Fundamentals of Sound

Imagine throwing a rock into a calm lake. You can easily picture the ripples, or water waves, that move out in an expanding circle. In these ripples, the water’s surface moves up and down, in a smooth progression from crest to trough. Sound waves are similar to these water waves. A sound wave is created by a structure that vibrates, such as a radio loudspeaker or our larynx. The crests of a sound wave are areas of high pressure, and the troughs are areas of low pressure. Like the water wave, there is a smooth progression between these areas of high and low pressure. A sound wave is a propagating (moving forward) alternation of these areas of high and low pressure.

Several terms are used to describe the characteristics of sound. The amount of time it takes for a complete cycle between the highest pressure of a sound wave to the lowest, and back to the highest,

is referred to as the *period* of the sound wave and is measured in seconds. The reciprocal of the period is called the *frequency* of the wave and measured in s^{-1} , or more commonly Hertz (Hz). Frequency is a physical characteristic of sound. Our perception of frequency is known as pitch. Humans hear from about 20–20,000 Hz (or 20 kHz). Sounds below 20 Hz are termed infrasound, whereas those above 20 kHz are termed ultrasound.

Marine mammalogists often want to know the loudness of a sound, whether produced by a whale, dolphin, ship, or oil rig. The loudness, or *amplitude*, of a sound is described in decibels (dB). Decibels are defined as a ratio of measured sound pressure level to a reference sound pressure level. The reference sound pressure level in water is one microPascal (μPa). Therefore, in-water decibels are expressed as XX dB re $1\mu\text{Pa}$. Because sound amplitude decreases with distance, the standard method is to measure the sound level 1 m from the sound source. This measurement is known as the *source level*, and is expressed as XX dB re $1\mu\text{Pa}$ at 1 m. For example, fin whale (*Balaenoptera physalus*) source levels have been measured at 171 dB re $1\mu\text{Pa}$ at 1 m (Charif *et al.*, 2002).

It is also important to remember that in-air and in-water decibels are not the same, due to different reference levels and the physical characteristics of air and water. Generally, adding 61.5 dB to an in-air measurement will convert it to an in-water measurement. Additional information and a technical discussion of sound level measurements can be found in other texts (Hartmann, 2004; Richardson *et al.*, 1995; Urlick, 1983).

A sound is said to be frequency modulated (FM) when its frequency changes over time. Dolphin whistles are usually frequency modulated. Amplitude-modulated (AM) signals are those that change loudness, usually rapidly, over time. Many mysticete calls are amplitude modulated and can sound like growls.

A visual record of pressure versus time is known as a *waveform*. Animal sounds are more often represented as a *spectrogram* with frequency on the y-axis and time on the x-axis. Fig. 1 shows both the waveform and spectrogram of two blue whale (*Balaenoptera musculus*) calls. The first is an AM signal, and the second an FM signal. The AM signal shows individual amplitude pulses in the waveform, while the FM signal displays a smooth envelope (or waveform outline). Note also that the AM signal shows the sidebands typical of an AM signal, while the FM signal has a downward sweep from about 20 to 15 Hz. Notice the “extra lines” above the main “line” of the FM signal. This is the lowest frequency or fundamental frequency contour. The additional “lines” above the fundamental frequency are harmonics, which are integer multiples (e.g., 2x, 3x, 4x) of the fundamental frequency. They result from the physical characteristics of the sound-producing structure. Harmonics can occur only with FM calls and are strictly integer multiples of the fundamental frequency. The sidebands of AM signals may resemble harmonics, but are actually the product of the rate of amplitude modulation.

Recently, marine mammal vocalizations have been found to contain spectral features called nonlinear phenomena. These are illustrated in Fig. 2 and include frequency jumps, subharmonics, biphonation, and deterministic chaos. Frequency jumps occur when the frequency of a signal changes almost instantaneously. Subharmonics are additional spectral bands that occur below the fundamental frequency. Animals are also capable of biphonation, or the production of two different harmonically unrelated sounds at the same time. There exists a phenomenon known as deterministic chaos that results from vocal folds oscillating asynchronously. While these signals appear random, they actually are deterministic and repeatable (Fitch *et al.*, 2002).

Figure 1 Illustration of part of a blue whale (*Balaenoptera musculus*) song. The waveform is shown above and the spectrogram below. One can clearly see the series of loud pulses in the waveform of the first sound, which is amplitude modulated (AM). These produced the sidebands seen in the spectrogram below. The second sound has a smooth envelope of its waveform. The spectrogram of the sound shows change with time, so this is a frequency modulated (FM) signal. The lines of energy above the bottom frequency contour are known as harmonics.

Figure 2 Examples of linear and nonlinear signals are shown: (A) typical linear signal (B) frequency jump, (C) subharmonics, (D) biphonation, and (E) deterministic chaos.

II. Sound Production Mechanisms

A. Terrestrial Mammals

When most terrestrial animals vocalize, the lungs push air through the larynx. The vocal folds (more commonly referred to as vocal cords) in the larynx open and close as the air rushes past them, breaking the exhalation up into a series of air puffs or pulses. The resulting undifferentiated sound then passes through the vocal tract of the throat, tongue, mouth, and lips. These structures can move to change the shape of the vocal tract, literally shaping the buzzing sound from the larynx into a vocalization. This mechanism is known as the source-filter model, where the vocal folds are the source of the sound and the vocal tract modifies (or filters) the signal. The source-filter model traditionally has been applied to terrestrial animals, but recently has been employed to investigate sound production in pin-nipeds (Sanvito *et al.*, 2007).

B. Mysticetes

Mysticetes also have a larynx with vocal folds that are believed to be the source of their sound production (Reidenberg and Laitman, 2007). The vocal folds in mysticetes are combined into a single U-shaped fold that is parallel to the airflow (Fig. 3), in contrast to the perpendicular folds in terrestrial mammals. In addition, in mysticetes, a laryngeal sac is found underneath the larynx. The function of the sac is not known. It may serve as an additional acoustic radiating structure, or may help adjust air pressure in the laryngeal structure, or recycle air within the body of the whale. Observations of singing humpbacks (*Megaptera novaeangliae*) show that they do not exhale while singing, indicating a dependence on recycled air.

C. Odontocetes

Odontocetes can produce clicks, pulsed sounds and whistles. Clicks are often used for echolocation, as described elsewhere in the encyclopedia. Pulsed sounds and whistles are more likely to be used for communication. The production mechanism for these sounds has been the source of considerable debate.

Like mysticetes, delphinid odontocetes have a vocal fold structure in their larynx. These folds may be used in the production of some sounds (Reidenberg and Laitman, 2007). However, it is known that clicks and most (and perhaps all) whistles are produced in the nasal region of the head (Cranford, 2000). All odontocetes, except sperm whales, have a pair of structures known as the “monkey lips”/dorsal bursae (MLDB) complex located in the upper portion of their heads,

Figure 3 Details of the mysticete larynx are shown. The vocal folds (in yellow) are parallel to the direction of airflow. The large laryngeal sac below the larynx, unique to the mysticetes, may function to recirculate air, act as resonator, or modulate air pressure in the larynx. Redrawn from Reidenberg and Laitman, 2007 with permission.

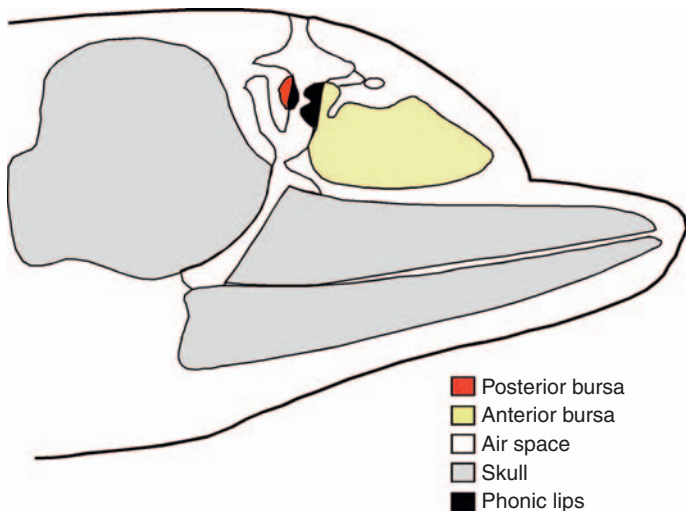

Figure 4 A diagram of the MLDB complex and sound production structures in the head of a dolphin. Redrawn from Cranford, 1999 with permission.

just below the blowhole (Fig. 4). The MLDB complex consists of two lipid-filled sacs or bursae connected to the phonic lips or monkey lips that protrude into the nasal passage. The MLDB creates sound when air pushes past the phonic lips, which then open and slap shut, creating vibration in the dorsal bursae. The air used to create the sound can either be returned to the lower nasal passage or released into the water. Whistling dolphins sometimes, but not always, release air as bubble streams from their blowhole (Fripp, 2005).

Figure 5 The anatomy of the sperm whale (*Physeter macrocephalus*) head is shown. B, brain; BL, blowhole; Di, distal air sac; Fr, frontal air sac; Ju, junk; Ln, left naris; Ma, mandible; Mo, monkey muzzle/museau de singe; Ro, rostrum; Rn, right naris; So, spermaceti organ. Clicks are produced on the left at the monkey lips, propagating in all directions. Sound that travels toward the skull is reflected off the frontal air sac and then moves forward out of the head. Some of the sound can be reflected again by the distal sac and frontal air sac again, resulting in a second round trip in the head before being emitted from the forehead. Redrawn from Madsen et al. (2002) with permission.

The vibration generated by the MLDB is transmitted through the lipid-rich melon, which couples and focuses the sound into the water. In dolphins, the melon sits on top of the skull behind the rostrum (Fig. 4). It also functions as an acoustic lens to focus clicks into a beam. This is similar in function to the focusing of light into a beam by the lens and reflector of a flashlight. The beam pattern (or amount of focusing) is frequency dependent, with a more tightly focused beam at higher frequencies (Au, 1993). Unlike other odontocetes, belugas are able to alter the physical shape of their melon, perhaps to adapt to sound transmission differences due to their movements between the open ocean and less saline estuarine waters (Norris, 1968).

All odontocetes except the sperm whale (*Physeter macrocephalus*) have two MLDB complexes. It appears that they can operate these two structures independently, creating two different sounds simultaneously. Furthermore, in many delphinid species, one of these structures can be larger than the other, thus creating different spectral peaks (Cranford, 2000).

The click production mechanism in sperm whales is related to the dolphins but is somewhat more complex. The huge head of the sperm whale almost certainly evolved as a sound production structure. It appears that the spermaceti organ is the analog of the melon in dolphins, and is used to transmit and focus sound.

Clicks produced by sperm whales make multiple trips through the head (Fig. 5) before being emitted into the water, resulting in a series of pulses that form individual clicks. First, the clicks are produced near the front of the huge head in an organ called the *museau de singe* or monkey's muzzle. A portion of that click goes forward directly into the water while the remainder moves backward, reflecting off the skull into the water as a second sound pulse. Finally, part of this reflected sound can make one more round trip, producing a third pulse of sound by reflecting backward off the distal sac and forward again off the skull (Norris and Harvey, 1972; Møhl, 2001).

This pattern of pulses in the sperm whale click has been known for many years, but the relatively low intensity of the early recordings lead some to doubt that clicks were useful for echolocation. However, it has recently been shown that sperm whales can produce directional high intensity clicks that are sufficiently intense for use in echolocation and foraging (Møhl *et al.*, 2000; Miller *et al.*, 2004).

D. Sirenians and Carnivores [Polar Bear (*Ursus Maritimus*) and Pinnipeds]

Although sound production in sirenians is poorly studied, it is known that manatees (*Trichechus* spp.) and dugongs (*Dugong dugon*) possess a rich repertoire of sounds. Both sirenians and polar bears may produce sound with their larynxes, similar to terrestrial mammals.

Sound production mechanisms in pinnipeds are not well known. When in air, most pinnipeds exhale while vocalizing and probably use their typical mammalian larynx to produce sounds (Tyack and Miller, 2002). However, other sound production mechanisms are found in pinnipeds. For example, male hooded seals (*Cystophora cristata*) have a specialized nasal hood and septum that can be partially extruded out a nostril and then inflated. By alternately deflating and inflating this apparatus, they produce a variety of sounds. Walruses (*Odobenus rosmarus*) also have the ability to create a variety of airborne sounds such as whistles, made by blowing air through the lips, and gong-like sounds, made with their pharyngeal sacs.

Underwater, pinnipeds rarely exhale while vocalizing, indicating that air is shunted between the lungs and mouth/nasal structures. Rather than vocal folds in the larynx, they may use vibrating membranes in the trachea to produce sound underwater. Underwater observations of pulsations in the chest or throat seem to confirm a tracheal mechanism for underwater sound production in many phocids (Tyack and Miller, 2002), as is likely for the long trills of the bearded seal (*Erignathus barbatus*).

III. Characteristics of Vocalizations by Groups and Selected Species

A. Pinniped Sounds

Acoustic signal structure varies widely within the 33 species of pinnipeds (Schusterman and Van Parijs, 2003). All pinnipeds are amphibious to some degree, and how they proportion their activities on land and at sea significantly affects their social system, and therefore their acoustic behavior.

Most of the signals of aquatic mating species occur in the water, whereas terrestrial breeding pinnipeds produce a wide variety of vocalizations while hauled out. These signals are often loud, directional, broadband and highly repetitive (Schusterman and Van Parijs, 2003).

Aquatic mating species have evolved a wide variety of signals that are used during the mating season. A review of two phocid species [bearded and Weddell (*Leptonychotes weddellii*) seals], for which there are year-round recordings, found a strong peak in the rate of vocal production associated with breeding (Stirling and Thomas, 2003). Bearded seals became silent after breeding, while Weddell seals continued to vocalize at a low rate, suggesting that they may have been defending breathing holes. This temporal pattern of vocalization indicates, but does not confirm, that these signals are used to attract mates (Van Parijs, 2003).

One notable aspect of life history in many pinniped species is the need for the mother to leave her offspring to forage during lactation. The use of acoustic signals to help reunite mother and pup has been

demonstrated in both otariids and phocids. Otariid mothers regularly leave their pups to forage during lactation. This behavior has led, in part, to otariid pups and mothers evolving individually distinct and stereotyped vocal signals that facilitate reunion when the mother returns. These calls tend to be low frequency and about a second in duration. Within a species, there can be significant differences in the fundamental frequency, amplitude modulation and frequency modulation that make the calls distinguishable.

Phocid mothers do not regularly leave their pups during lactation, and their calls are not as individually distinctive. Species with very short lactation periods have no individual recognition mechanisms. Hawaiian monk seals (*Monachus schauinslandi*) are an extreme case. Mothers nurse indiscriminately and do not have individual recognition ability. In general, the amount of individual information in pinniped calls and recognition ability is greater in polygynous societies, those that have a longer lactation period and more crowded breeding colonies (Charrier and Harcourt, 2006).

1. **Phocids Ringed seals** (*Pusa hispida*), like many seals, were long thought to be silent while underwater. However, they are now known to produce at least six types of underwater calls. These include clicks, burst pulses, knocks, chirps, yelps and a variety of low-frequency calls similar to those produced in air (Kunnsaranta *et al.*, 1996). Clicks are very short, lasting between 6 and 8 msec with energy between 2 and 6 kHz. Burst-pulse sounds are low frequency and narrowband, typically composed of a short sequence of pulses (~5 msec). Knocks are low-frequency sounds, from 150 Hz to 2 kHz that occur in a sequence of increasing frequency pulses. Each knock lasts 40–80 msec, and the entire sequence lasts between 500 and 900 msec. Chirps are FM tonal calls, descending from 1,000 to 500 Hz and lasting between 100 and 300 msec. Yelps show slight frequency modulation around a fundamental frequency of ~1 kHz, and last 100–200 msec (Kunnsaranta *et al.*, 1996). The proportion of calls recorded in the Arctic varied seasonally, consistent with a reproductive function (Stirling, 1973).

Bearded seals are an aquatic mating species with an extensive repertoire composed of four basic call types: trill, moan, sweep and ascent (Risch *et al.*, 2007). Considerable variation exists within each of these call types. Trills are one of the most distinctive signals produced by marine mammals. They are usually long downsweeps, but some variations include a near-constant frequency contour or alternating increases and decreases of frequency. Typically they start between 3 and 6 kHz, lasting from 30 sec to more than a minute and are characterized by repeated frequency jumps during the signal. In some populations, the long trill is followed by a rapid upsweep to 3 kHz that lasts 1–2 sec (Fig. 6).

Moans are characterized by a short duration, low frequency composition, and lack of frequency modulation. Sweeps resemble a short trill, typically with a rapid decrease in frequency in the second half of the signal. Sweeps are not produced by all populations. Ascents are relatively simple frequency upsweeps lasting from 6 to 25 sec; they are found in those populations that lack sweeps.

The vocalizations of bearded seals show significant variation between individual males of the same populations, as well as significant differences between different populations (Risch *et al.*, 2007). They are thought to function as advertisement displays during the mating season.

Hooded seal sounds can be grouped into three major classes. Two of these are produced by normal vocal mechanisms. The third is produced with the hood and septum, a set of specialized anatomical structures. The most common calls are produced both in air and in water. They are pulsed and rarely frequency modulated, with energy

Figure 6 The long downward trill and rapid upsweep of a bearded seal from Alaska are shown in this spectrogram.

ranging from 500 Hz to 6 kHz. These are used in a variety of circumstances, including male displays, female responses, and interactions between females and pups. The second type, growls or roars, appear to be used as low-level threats by both males and females fighting with other males. The third type of signals, produced by the inflation and deflation of the hood and septum, are short-duration, broadband with rapid onsets, and little or no frequency modulation. It is possible that only males make these sounds, described as “bloops”, “wooshes”, “metallic pings”, “clicks”, and “knocks” (Ballard and Kovacs, 1995).

Harp seals (*Phoca groenlandicus*) aggregate at the ice edge in March in the Northwest Atlantic. At least 19 different call types have been described for this species, ranging from a nearly pure sine wave to pulsed sounds, high-frequency chirps, “broadband warbles,” trills, squeaks, and grunts (Terhune, 1994). The maximum source level of these calls is between 135 and 140 dB re 1 μ Pa at 1 m. Harp seals also produce clicks that are about 25 dB louder than their other calls. Call types have been shown to be stable over a period of tens of years (Serrano and Terhune, 2002). The calls may help individuals locate the herd, and once in the aggregation, may be used to find a mate. Comparisons of different breeding aggregations found many shared calls, but some that were unique to particular breeding areas, suggesting that the populations may be reproductively isolated.

Ribbon seals (*Histiophoca fasciata*) are a close relative of harp seals. However, there is only one report on their vocalizations, which describes them as “puff sounds” and frequency downsweeps (Watkins and Ray, 1977). Downsweeps were broken into three categories. Long downsweeps descend from as high as 7100 to 2000 Hz and last up to 4.7 sec. Medium sweeps range from 5300 down to

100 Hz, and last up to 1.8 sec. Finally, short sweeps last less than a second and descend from 2000 to 300 Hz. Puff vocalizations are broadband, below 5 kHz, and last also less than a second.

Harbor seals (*Phoca vitulina*) have a mating system with a low degree of polygyny. Females have not been found to vocalize underwater while males produce five types of underwater acoustic displays: roar, bubbly growl, grunt, groan, and creak (Hanggi and Schusterman, 1994). Roars are one of the primary vocalizations of male harbor seals, lasting between 2 and 11 sec, with energy between 20 and 1550 Hz. There is good evidence that the frequency of roars varies between individual males. Roars have been shown to function in territorial behavior (Hayes *et al.*, 2004). Bubbly growls are another long vocalization, lasting between 1 and 8 sec and sounding as if the seal were blowing bubbles underwater. Grunts are short tonal calls from 100 to 4000 Hz lasting less than a second. Groans are a longer version of grunts, lasting between 1 and 5.5 sec. Creaks are tonal calls lasting up to 6 sec with rich harmonic content.

Spotted seals (*Phoca largha*) in captivity produced six types of underwater vocalizations: “growls”, “drums”, “snorts”, “chirps”, “barks” and “cranky door U” (Beier and Wartzok, 1979). These vocalizations include pulsed and tonal signals. The sounds ranged from 500 Hz to 3.5 kHz and durations from 19–400 msec. Males produce signals at a rate approximately 2.5x times that of females, again suggesting that males are producing signals as part of mating behavior.

Gray seals (*Haliochoerus gryppus*) recorded in Canada produce calls that have been classified into seven types (Asselin *et al.*, 1993). The most common is a short duration call (~0.2–1.0 sec) that begins with a near-constant low frequency component that then sweeps upward sharply in frequency to about 3 kHz. The second most

common call ranges from 0.1 to 2.9 sec in duration, and is composed of a gradual low-frequency downsweep followed by a second component that began at a slightly higher frequency, first sweeping up and then down. Other call types produced much less frequently include growls, knocks, clicks, roars and a pulsed signal called a “trot” (Page *et al.*, 2002).

Elephant seals (*Mirounga* spp.), especially males, are known to use acoustic signals in agonistic encounters. They mate on land where males compete for dominance and access to females. Males use threat displays and fights to establish dominance. Male elephant seals make three main types of calls during AGGRESSION: “snores”, “snorts”, and “clap threats”. Snores are used as a low-intensity threat. Dominant males snort more aggressively when approached by a challenging male. Snorts range between 200 and 600 Hz. The clap threat ranges up to 2.5 kHz (Sandegren, 1976; Shipley *et al.*, 1981; Shipley *et al.*, 1986). It is thought that in-air threat calls produced by males are also transmitted through the ground, and can elicit responses from other elephant seals (Shipley *et al.*, 1992). Females produce a low-frequency “belch roar” in aggressive situations and a 500 Hz–1 kHz bark to attract the pup (Bartholomew and Collias, 1962).

Recently the acoustic characteristics of these signals have been compared to the physical attributes of the signaler. While there is only a weak relationship between body size and signal loudness, the signal structure accurately represents the age, size, and resource-holding potential of the signaler (Sanvito *et al.*, 2007). Therefore, in many cases individuals can assess the relative dominance of each other and resolve the interaction without fighting.

Elephant seals are known to make underwater sounds, but these remain poorly described (Poulter, 1968).

Monk seals (*Monachus* spp.) are not a very vocal species. They do produce in-air vocalizations composed of soft “liquid bubble sounds”, guttural expirations, roars and a “belch-cough”. Most of the energy of these calls is below 1 kHz (Miller and Job, 1992).

Weddell seals are a very vocal species. Males produce long complex displays that are known as song. Signals appear to vary between different geographic areas. One of the best descriptions of song is based on the Davis Straight population, where seals produced ten different calls consisting of roars, whistles and trills.

Roars can last over 5 sec and vary in frequency from a few hundred to several thousand Hz. Whistles can be both upswept and downswept, ranging to 10 kHz or higher. Trills, produced only by males, may be the most distinctive Weddell seal vocalization (Oetelaar *et al.*, 2003). Trills are long downswept FM calls, beginning above 10 kHz and sweeping down to 1–2 kHz, producing a curved spectrogram. Songs appear to have individually distinct variations in their basic sound units and seem to function in both territorial defense and mate attraction (Terhune and Dell’Apa, 2006).

Leopard seal (*Hydrurga leptonyx*) vocalizations show considerable structural variability. Their calls include low-frequency tonal calls, narrowband and wideband high-frequency pulses, and FM calls ranging from 50 Hz to 8 kHz. Males in Prydz Bay, Antarctica, produce a lengthy ordered pattern of five different calls that appears to function as a reproductive display. The structure of these signals varies between individuals (Rogers and Cato, 2002). There is also considerable geographic variation in the signals produced by males of different populations (Thomas and Golladay, 1995). Females in estrus are also known to produce a collection of signals, collectively known as broadcast calls that may serve to indicate their reproductive condition (Rogers *et al.*, 1996). Hauled-out leopard seals that were approached by a researcher made explosive, broadband vocalizations

termed “blasts” and “roars” that may have been used as threats or territorial calls.

Crabeater seal (*Lobodon carcinophaga*) vocalizations are poorly known. Only one vocalization has been reported. The groan-like signal had a mean duration of 2.12 sec with most energy below 1.5 kHz (Stirling and Siniff, 1979).

Ross seal (*Ommatophoca rossii*) in-air vocalizations include 1–1.5 sec long FM upsweeps and downsweeps between 100 and 1,000 Hz. They also produce sequences of 5–12 short frequency down-swept pulses, each lasting 50–100 msec. Sounds produced in water are similar to in-air sounds, except that the frequency range is wider and the longer FM calls possess sidebands not present in air (Watkins and Ray, 1985).

2. **Otariids** The eared seals appear to lack the complex social signals of many phocids. This is probably because phocids tend to mate in the water, and sounds are often, although not always, related to social/sexual interaction. Otariids, however, tend to mate on land, and they are in large part relatively quiet in the sea.

California sea lions (*Zalophus californianus*) make bark-like sounds, groans, and grunts in air. The sound of a group of hauled-out California sea lions is loud and far reaching. Barks tend to have most energy below 2 kHz. These sounds and other interactions help produce the structural organization of sea lion society on a beach or headland. Sea lions also bark underwater, in similar fashion as in air (Schusterman and Balliet, 1969).

Galapagos fur seals (*Arctocephalus galapagoensis*) have been recorded making few vocalizations while at sea. These include a long growl, lasting 8 sec and composed of a series of discrete low-frequency sounds with energy less than 1 kHz. They also produce knocks, which are single short broadband pulses lasting less than 100 msec with energy above 2 kHz (Merlen, 2000).

South American sea lion (*Otaria flavescens*) sound production differs between males and females. During the breeding season, males produce four types of vocalizations: growls, barks, high-pitched calls (HPC), and exhalations, while females produce grunts. Mothers, pups, and yearlings all produce “primary” calls that are used for female-offspring interactions (Fernández-Juricic *et al.*, 1999). Growls are AM calls used during male-female interactions, lasting about one second, with energy between 200 and 2,000 Hz. Barks are a series of short, 0.2 sec, low-frequency pulses produced by males during low-level agonistic interactions. HPCs are short, ~0.4 sec, FM calls with fundamental frequencies between 300 and 500 Hz. Produced during agonistic encounters between males, they are highly directional, suggesting that they can be directed toward specific individuals. Females can produce low intensity, low frequency, 490 Hz, and brief, ~0.4 sec, calls referred to as grunts usually made during female-female agonistic encounters.

South American fur seals (*Arctocephalus australis*) make at least 11 types of calls, which appear to fall into 4 functional classes: investigative, threat, submissive, and affiliative (Phillips and Stirling, 2001). Barks are short broadband pulses that occur in a sequence up to several minutes in duration. Barks are used for non-agonistic investigation of other individuals. “Threat calls” are composed of several sounds produced by forceful inhalation or exhalation. Call amplitude can be changed, with louder calls indicating a higher threat level. Threat calls are all amplitude modulated with energy between 400 and 700 Hz. “Submissive calls” are FM tonal calls between 600 and 1600 Hz lasting about a second. Finally, the affiliative calls include pup-attraction calls that last up to 2 sec. These are composed of a pulsed component followed by a tonal component between 700 and 1000 Hz, ending with

Figure 7 The hierarchical structure of humpback whale (*Megaptera novaeangliae*) song. Redrawn from Payne et al. (1983) with permission.

a downsweep. Female-attraction calls are similar in structure, though they may have more frequency modulation. Both attraction calls have a large degree of inter-individual variability.

Australian fur seals (*Arctocephalus pusillus*) produce in-air barks during male–male interactions. Each bark is a short call, ~0.25–sec, with multiple harmonics extending to about 5kHz and is typically produced in a series. There is enough individual variation to indicate that males may recognize each other with their barks (Tripovich *et al.*, 2005).

3. **Odobenid Walrus** adults use roars, grunts, and guttural sounds as threats while hauled out (Miller, 1985). Roars are long, loud mostly low-frequency calls that last a second or more. Grunts vary greatly in amplitude, last between 100 and 400msec and range from 50 to 250Hz. The most common acoustic threat is the guttural sound, a series of low frequency, wideband pulses ranging from 13Hz to 4kHz. Walruses also bark, usually in a series of short, FM calls ranging from 90 to 260msec in length and between 300 and 500Hz. Adult barks indicate submission; louder barking may indicate greater submission. Calves bark in a wide variety of situations. For example, calves separated from their mothers bark loudly and then may continue to bark softly once the two are rejoined. As the calf matures, its bark changes, gradually becoming a longer single call, with both frequency and amplitude modulation. While females do not call to attract the calf, they do produce a short, soft contact call when mother and calf are in close proximity. The call is usually frequency modulated, either as a downsweep or as an alternation of up-and-down sweeps.

Male walruses sing on the mating grounds. Songs are loud, repetitive, and stereotyped sequences of pulsed sounds with bell-like sounds interspersed between them (Sjare *et al.*, 2003). These animals make two types of pulsed sounds: the intense “knock” and the less intense, quickly repeating “tap”. Knocks range between 0.2 and 8kHz and are produced at a rate of 1–3/sec. Taps are produced at a higher rate, 10/sec, and range in frequency from 0.2 to 4kHz (Stirling *et al.*, 1983). As a courting display, males also make a gong-like sound, both in air and underwater, inflating their throat pouches, sometimes striking their throat with their flippers to augment the sound (Tyack and Miller, 2002). Male walruses also make aggressive nonvocal clacking sounds with their teeth.

B. Mysticete Sounds

Mysticetes produce a wide variety of sounds, from the blue whale’s 7Hz infrasonic pulses to the humpback whale’s songs whose harmonics can range to at least 24kHz. Individual signals can last less than a second or as long as 30sec or more. The range of signal types

varies from simple growls to loud complex modulated high frequency calls. Four mysticete species are now known to sing: humpback, bowhead (*Balaena mysticetus*), blue and fin whales. Song is typically defined as a repetition of patterned signals. Humpback whale song was first described scientifically in the early 1970s. Bowhead song was recognized in the 1980s. Blue whale song was described in the 1990s and fin whales were recognized as singers in the early 2000s.

Humpback whale songs were first described by Roger Payne and Scott McVay in 1971. Only males sing, primarily on the mating grounds in winter, and it is surmised that song is a mating display; intersexual, for males to attract females; intrasexual, as a male dominance display; or both (Frankel *et al.*, 1995). Humpback whale songs have a hierarchical structure, from the shortest utterance to long bouts of singing that can last for days. Individual calls (somewhat analogous to musical notes) are referred to as song units. These units are repeated and combined to form phrases that are then repeated to form longer themes. A song is typically composed of 4–12 themes. Songs can last from 5 to 30 min in length before beginning again. Individual humpbacks are known to sing for as short as a few minutes and as long as 48h or more. Song units are highly variable, including upsweeps, downsweeps, AM units and complex FM sweeps (Fig. 7). Song units range widely in frequency as well, from fundamental frequencies of about 20Hz to harmonics reaching 24kHz or higher. Individual units can last from fractions of a second to several seconds.

Individual whales slowly change the structure of their songs over time (Payne *et al.*, 1983). To illustrate this, consider a theme with two upsweeps and a growl. One type of change would be the addition of a third and then a fourth upsweep. Usually, these changes occur gradually, over a period of about one month. However, the pace of change in song structure is variable as well. In some years the song changes slowly and in other years it evolves rapidly.

Another unique feature is that all humpback whales of a population typically sing essentially the same song, with only minor variations (Payne and Guinee, 1983). It is not known how this uniformity is maintained while the song itself keeps changing. However, it is likely that whales within a discrete area pay attention to each other’s song, and some whales copy others. Thus humpback whale song represents an example of cultural evolution.

Once they have evolved, it seems that individual themes are not reused. All themes are created *de novo* (Payne and Payne, 1985). The longest that an individual theme has been known to persist was 5 years (Eriksen *et al.*, 2005).

While most song is produced on the wintering or breeding grounds, it is also heard during migration and on the summer feeding grounds, albeit at a reduced rate (Clark and Clapham, 2004; Gabriele and Frankel, 2002).

Humpback whales on the breeding grounds also produce a rich repertoire of non-song vocalizations, generally termed social sounds. Social sounds can be thought of as a subset of the song units, uttered in a non-patterned fashion. These sounds appear to be used by males as acoustic threat displays in conjunction with visual displays and direct physical contact (Silber, 1986). Humpback calves are also known to produce short, low-frequency calls, although the function of these calls remains unknown (Zoidis *et al.*, 2008).

Finally, humpbacks produce vocalizations during feeding. One call is made during a foraging strategy known as social lunge feeding. This entails a group of 6–12 or more humpbacks all vertically lunging through the surface of the water in a coordinated fashion. The accompanying call is a sequence of “cry” vocalizations. The cry typically begins with a short upsweep, followed by a long near-constant frequency tone, finishing with a short downsweep. There is little variation in the frequency of the call within a sequence, but there is strong variation between different sequences, suggesting the presence of individual variation (Cerchio and Dalheim, 2001). In experiments, these calls were played to herring, which responded by fleeing, suggesting that the most likely function of the call is prey manipulation (Sharpe, 2001).

More recently, humpbacks foraging in the Northwest Atlantic were found to produce click trains and buzzes while feeding at night. Although these signals are reminiscent of odontocete echolocation signals, the function of these “megapclicks” has not yet been established (Stimpert *et al.*, 2007).

Bowhead whales were discovered to sing during the acoustic population census of bowhead whales during the spring migration from the Bering Sea to the Chukchi Sea. Songs are usually heard more often at the beginning of the migration and less so at the end. This suggests that most of the singing occurs in the Bering Sea in winter. More recently, songs have also been recorded from the Davis Strait population in Greenland between February and May (Outi *et al.*, 2007).

Song notes are usually longer than non-song moan and grunt-like calls. Bowheads sing between one and three themes, most often two. Unlike humpback whales, bowhead songs regularly show substantial change in structure in successive years. Within a year, all whales within a population sing the same basic version of song, but there is considerable inter- and intra-individual variation. Most of the sound energy of bowhead calls and songs falls below 1000 Hz. The songs are frequently composed of both AM and FM components. Bowhead whales produce fewer units and in a narrower frequency range than humpbacks, yet their signals have great variation in tone, resulting in a wide variety of different sounding song notes.

In addition to songs, bowheads produce a host of calls. There are two main groups: the simple, low-frequency FM calls and complex calls. These FM calls can be categorized by their FM contours, i.e., upsweeps, downsweeps, constant, and inflected contours. FM calls are almost always less than 400 Hz in frequency. The complex calls have been described as pulsive, pulsed tonal, and high. High calls have frequencies above 400 Hz and sound like a whine. The pulsed tonal is a combination of both frequency and amplitude modulation. Pulsive calls are a mixture of pulses, with both frequency and amplitude modulations. Pulsed tonal calls are often below 400 Hz, but pulsed calls can exceed 1000 Hz.

Migrating bowheads will sometimes produce calls for periods ranging from a few minutes to several hours. These are often made

in the context of whales counter-calling with each other. Thus it has been suggested that these calls are used to maintain group cohesion. They may also be used to help orient themselves in ice fields. A group of whales was observed approaching a large block of ice. The first whales to encounter the ice only swam around it when they were very close. The following whales deflected much earlier, suggesting that they were listening to the echoes of the early whales and using the acoustic information to avoid the ice (George *et al.*, 1989).

Fin and blue whales are the two largest species of extant cetaceans. They both produce the loud and well-known low frequency 20 Hz sounds that are capable of traveling over great distances. In fact, their sounds have been heard at distances covering at least several hundred kilometers. It has been hypothesized that, at least prior to the rise of motorized shipping, whales could hear each other over ocean basin extents (Payne and Webb, 1971). This is possible due to the deep sound channel that propagates low-frequency sound extremely well.

While similar in frequency, blue and fin whale calls differ in length. Most fin whale sounds last about 1 sec, whereas many blue whale signals can be up to 30 sec.

The frequency range of fin whale calls varies in different ocean basins. Most calls from the Atlantic are 1 sec downsweeps from 23 to 18 Hz while those in the Gulf of Mexico sweep down from 42 to 20 Hz (Thompson *et al.*, 1992). These 20 Hz pulses often occur as a long, regularly patterned series of calls. The interval between pulses typically ranges from 6 to 37 sec. In addition to the 20 Hz pulses, fin whales also make tonal pulses at higher frequencies.

In temperate waters, fin whales produce regular sequences of short downswept pulses from about 30 to 15 Hz, predominately during winter. This temporal pattern suggests that these signals may serve a reproductive function (Watkins *et al.*, 1987). Furthermore, only males produce these long patterned sequences, now described as song (Croll *et al.*, 2002). While pulses occur year round, they are less patterned during the non-winter months. It may be that fin whale song is used for reproduction while the less patterned calls may serve another function (Moore *et al.*, 1998).

Male blue whales also produce songs throughout the year (McDonald *et al.*, 2001; Oleson *et al.*, 2007) and it is surmised that they may also serve as a reproductive display. There are at least nine, and probably more, song populations. Songs within a population appear to have a stable structure while song structures differ between populations (McDonald *et al.*, 2006). Some of these song populations have only simple tonal calls, while others exhibit more complex songs that include pulsed as well as tonal units.

As an example, the song of the North Eastern Pacific blue whale population contains both tonal and pulsed components: the pulsed A call, tonal B call, an A–B combination, and downsweeps known as D calls (Thompson *et al.* 1996; McDonald *et al.* 2001). The amplitude-modulated A call typically lasts 17 sec and has a fundamental frequency of 16 Hz. The frequency-modulated B call lasts about 19 sec, sweeping down from ~18 to ~15 Hz and often has strong harmonics. The D call is a short downsweep lasting a few seconds that starts at about 90 Hz descending to about 30 Hz.

Song has been recorded solely from traveling animals. Individual (i.e., non-song) A or B calls were produced from animals in a variety of behavioral states (Oleson *et al.*, 2007), suggesting different functions for non-song calls. Blue whales in the Eastern Tropical Pacific have a higher rate of B call production when their vertically migrating prey is near the surface, suggesting a possible foraging function for the B calls (Stafford *et al.*, 2005). Similarly, the D calls are

produced by both sexes, frequently during foraging (Oleson *et al.*, 2007).

Minke whales (*Balaenoptera acutorostrata*) are known to produce a variety of different calls with a wide frequency range. These include clicks, tonals and FM signals. Minke signals also have significant geographic variation in their call structure. Because minke whales are often difficult to observe in the wild, it has taken many years to associate them with their sounds. Some have only been described in recent years, others almost certainly remain undiscovered.

One notable sound type is the pulse train. These are a repetitive series of pulses, which can either be a narrow-bandwidth (e.g., 80–140 Hz) “growl”, or a wider bandwidth “thump” ranging from 100 to 800 Hz (Winn and Perkins, 1976). Thump trains can last over a minute.

Australian dwarf minke whales make a vocalization so unusual that it has been termed the “Star Wars” call (Gedamke *et al.*, 2001). This call consists of a series of three 100 msec pulses ranging between 50 Hz and 9.4 kHz. These pulses are produced simultaneously with harmonically unrelated low frequency, AM pulses between 50 and 750 Hz. Following the pulses, the whale produces a pulsed tone at 1.8 kHz along with a tonal call at 80 Hz. The tonal call shifts up to 140 Hz as the final component of this complex set of vocalizations. The communicative function is unknown.

North Pacific minke whales were recently discovered to be the source of the “boing” sound (Rankin and Barlow, 2005). Boings have been known and recorded since the 1950s (Wenz, 1964). Those recorded in the Eastern Pacific are longer and have a lower pulse repetition rate than those recorded in the Central Pacific (Rankin and Barlow, 2005).

Sei whales (*Balaenoptera borealis*) rarely have been recorded. In the Northwest Atlantic they are known to produce two phrases that are each 0.5–0.8 sec long. The phrases are composed of 10–20 FM sweeps between 1.5 and 3.5 kHz, each 30–40 msec in duration (Knowlton *et al.*, 1991; Thompson *et al.*, 1979) with an interval of 0.4 and 1 sec between the two phrases. Recordings off Cape Cod found low frequency downsweeps from 90 to 40 Hz lasting a few seconds in duration (Esch *et al.*, 2007). Sei whales in Antarctica produced low-frequency tonal calls, FM sweeps, and broadband signals. The tonal and FM sweeps ranged from approximately 100 to 1000 Hz, lasting from 0.2 to 1.8 sec and often including a frequency jump. The source levels for these calls ranged from 147 to 156 dB re 1 μ Pa at 1 m (McDonald *et al.*, 2005).

Bryde’s whales (*Balaenoptera edeni*) recorded from the Gulf of California contained short low-frequency moans between 70 and 245 Hz and lasting between 0.2 and 1.5 sec. Source levels range between 152 and 174 dB re 1 μ Pa at 1 m (Cummings *et al.*, 1986). A captive juvenile Bryde’s whale produced a pulsed moan, ranging between 100 and 900 Hz and between 0.5 and 51 sec in duration. These moans were similar, though longer, than those recorded in the wild. Finally, wild calves have been recorded making a series of discrete pulses between 700 and 900 Hz (Edds *et al.*, 1993). Bryde’s whales in the Eastern Tropical Pacific produce at least six different call types. Most of these are lower in frequency than previous recordings, between 20 and 60 Hz, with one type being a frequency downsweep from 207 to 75 Hz. Durations ranged from 1.1 to 4.9 sec (Oleson *et al.*, 2003). Bryde’s whales off New Zealand also produced low-frequency calls, predominately a broadband pulse followed by a 25–22 Hz downsweep and a 5 sec long 22 Hz tonal call (McDonald, 2006).

Right whales (*Eubalaena* spp.) from the southern hemisphere produce an “up” call, an upsweep from 50 to 200 Hz that lasts for about a second. This call appears to be used to bring individuals

together, because calling stops once the whales rejoin. “Down” calls are downsweeps from 200 to 100 Hz that are also about a second in length. They may serve to maintain acoustic contact, if not physical proximity. “Constant” calls have a nearly constant frequency between 50 and 500 Hz and are 0.5–6 sec in duration. These calls are typically produced by whales that are simply swimming or engaged in a low level of activity (Clark, 1983).

Three call types are associated with surface-active or sexually active right whales: “High” calls are higher in frequency, up to 1 kHz, often with rapid frequency modulations, notably a downsweep at the end. These typically last 0.5–2.5 sec. “Hybrid” calls are similar to the high call, but then end with an AM pulse. “Pulsive signals” are mostly broadband AM signals (Clark, 1983).

Sounds made by North Atlantic right whales (*Eubalaena glacialis*) are similar to their southern counterparts, with one known exception. North Atlantic right whales also make a short broadband vocalization called the “gunshot”. Produced only by males, gunshots may be used to attract females. Alternatively, they may be used as an agonistic signal directed toward other males, or may serve both functions (Parks *et al.*, 2005). North Pacific right whales are only known to make calls similar to the southern right whale’s up, down, and constant calls.

Right whales feeding with their upper jaw raised above the water’s surface can produce a nonvocal sound called “baleen rattle”. As water flows through the lower portion of the baleen plates, they apparently rattle together, producing a series of short broadband pulses between 1 and 9 kHz, with most of the energy between 2 and 4 kHz. This sound is audible both in air and underwater, and may be simply a by-product of feeding (Watkins and Schevill, 1976).

Pygmy right whales (*Caperea marginata*) have only recently been recorded. A juvenile found in a harbor produced only one sound type. It was a short tonal downsweep that began between 90 and 135 Hz and swept down to 60 Hz. Pulses lasted between 140 and 225 msec in duration and were separated by intervals of 430–510 msec. Source levels were estimated between 153 and 167 dB re 1 μ Pa at 1 m. These calls were very simple and their function remains unknown (Dawbin and Cato, 1992).

Gray whales (*Eschrichtius robustus*) most frequently produce sounds referred to as “knocks” and pulses. These range in frequency from 20 Hz to 3 kHz. Gray whales are fairly vocal while feeding, relatively quiet while migrating, and the most vocal during mating activities. The source levels of gray whale vocalizations range between 167 and 188 dB re 1 μ Pa at 1 m (Petrochenko *et al.*, 1991).

Six major signal types have been recorded from gray whales on the mating grounds: a series of 2–30 metallic-sounding pulses; a single pulse lower in frequency and longer in duration than the first; a relatively low frequency and long duration “moan”; short “grunts”; a loud “bubble blast” produced by releasing a large amount of air underwater; and finally, a sixth sound type produced by the exhalation of a series of bubbles (Dahlheim *et al.*, 1984). Recordings made on summer feeding grounds contained three signals similar to those heard on the wintering grounds (Moore and Ljungblad, 1984).

C. Odontocete Sounds

The toothed whales, or odontocetes, are vocal animals *par excellence*. They probably all produce clicks for echolocation, and many produce complicated sets of pulsed sounds and whistles, the latter two for communication. Not all odontocetes make all of these sound types, and there are signals that cross categorical bounds and others, that defy categorization. Nevertheless, these three broad categories can be useful and descriptive. Rather than attempt to consider the

signals of each odontocete species individually, this section will focus on the three sound types, with specific examples provided for each.

1. Click Sounds Most of the odontocetes are known to produce clicks. In many (if not all) species, these clicks are used for echolocation. An echolocating animal produces a click that travels to and reflects off a target, such as a prey item. The amount of time elapsed between click production and echo reception (i.e., the two-way travel time) provides a measure of the distance to the target. Many species are also able to determine direction to the target. The clicks are usually produced at an interval greater than the two-way travel time. Presumably this is to allow the echo to be processed before the next click is produced. However, some species, such as the beluga (*Delphinapterus leucas*), can produce clicks with intervals shorter than the two-way travel time (Turl and Penner, 1989). When a dolphin approaches an object, it decreases the outgoing level of its clicks to maintain the returning echoes at a near constant sound level (Au and Benoit-Bird, 2003) and increases the rate of click production as the two-way travel time decreases.

Click structure varies between phylogenetic groups. Clicks produced by sperm whales, beaked whales, dolphins, and porpoises can be differentiated by duration, waveform type, and frequency emphasis (Tyack *et al.*, 2006). Sperm whale clicks typically range from 400 Hz to at least 15 kHz (Goold and Jones, 1995). The clicks of Blainville's (*Mesoplodon densirostris*) and Cuvier's (*Ziphius cavirostris*) beaked whales have most of their energy in the 20–50 kHz region (Johnson

et al., 2004). Delphinid clicks generally range from 60–120 kHz. Porpoise clicks are narrowband and usually well above 120 kHz.

Sperm whales are the largest toothed mammals on earth and have a disproportionately huge head. It is likely that the evolution of their huge head has, in large part, been driven by the loud and complicated structure of their relatively low-frequency clicks that are used for communication and echolocation.

Sperm whales produce a variety of clicks in a variety of contexts. Clicks can occur singly at different intervals, in a short pattern of distinct clicks called “codas,” or in a long sequence of tightly spaced clicks known as “creaks.” The frequency content of clicks differs between sexes. It is known that large males have lower frequency content in their clicks than females and young males (Goold and Jones, 1995).

“Usual” clicks are produced in a regular sequence at intervals of 1.17–1.95 sec with a duration between 2 and 24 msec (Goold and Jones, 1995). The click interval varies greatly between individuals (Goold and Jones, 1995), but appears to be stable within the click trains of an individual whale (Fig. 8).

The stereotyped, repetitive patterns of clicks or codas are produced primarily, if not only, by female sperm whales (Marcoux *et al.*, 2006). While it had been suggested that codas serve the function of individual identification, it is now known that coda repertoires are shared between individuals within a group (Rendell and Whitehead, 2004). This suggests that codas are used in social communication, and perhaps group identity (Weilgart and Whitehead, 1997). In

Figure 8 The spectrogram and waveform of “usual” sperm whale (*Physeter macrocephalus*) clicks.

addition, individual social groups of sperm whales appear to belong to clans that share similar coda repertoires. These repertoires may be created and evolve through cultural transmission (Rendell and Whitehead, 2003). This is supported by the finding that the degree of similarity of coda structure is inversely related to the distance between the groups. (Rendell and Whitehead, 2005).

“Creaks” are a rapid sequence of clicks sounding more like a continuous buzzing sound than individual clicks. They occur when a sperm whale is approaching a potential prey item much like a dolphin’s terminal buzz (Miller *et al.*, 2004; Watwood *et al.*, 2006).

Sperm whale ‘trumpet sounds’ are usually produced at the start of a dive in some but not all populations. These sounds are a series of repeated calls, each about 0.2 sec long that occur in sequences lasting between 0.6 and 3.5 sec. Each of these calls is composed of an AM tonal waveform with a complex harmonic structure. The spectrum contains a low frequency component at 500 Hz and a mid-frequency component at 3 kHz (Teloni *et al.*, 2005).

Mature sperm whale males produce another type of click, called a “slow click” for its low repetition rate. These clicks are of longer duration, with a mean of 72 msec compared to 24 msec for usual clicks. Slow clicks have consistent energy concentrations at 1.8 and 2.8 kHz, whereas the energy distribution in the spectra of usual clicks is much more variable. It has been suggested that slow clicks may serve as a long-range social communication signal (Madsen *et al.*, 2002).

Dolphins, with the exception of those in the genus *Cephalorhynchus*, produce short clicks lasting only a few cycles. The short duration necessarily produces a broadband signal with most of the energy typically found between 40 and 300 kHz across most species (Au, 1993). The spectrum of white-beaked dolphin (*Lagenorhynchus albirostris*) clicks can span this entire range (Rasmussen and Miller, 2002) while other species may have much narrower bandwidths. The clicks of many species contain two frequency peaks (Au and Würsig, 2004). This may be the result of size differences in the two MLDB sound-generating structures in the dolphin’s head (Cranford, 2000). Click source levels can range between 150 and 230 dB re 1 μ Pa at 1 m (peak to peak).

Dolphins are able to alter the spectral characteristics and source level of their clicks. For example, when a captive beluga was moved from San Diego Bay to Kaneohe, Hawaii, it increased the frequency of its clicks from 40–60 to 100–120 kHz (Au *et al.*, 1985). Furthermore it has been shown that dolphins alter the source level of their clicks while echolocating. They click loudly when far away from the target and more softly as they approach the target. This is apparently done to decrease variation in the level of the returning echo (Au and Benoit-Bird, 2003). Finally, there appears to be a relationship between the source level and the dominant frequency of the click, with louder clicks generally having higher frequency peaks (Au and Würsig, 2004).

Porpoises, the genus *Cephalorhynchus*, the pygmy sperm whale (*Kogia breviceps*) and franciscana (*Pontoporia blainvillei*) produce a very different type of click than the short broadband clicks described above. Called a narrowband high frequency (NBHF) click, they have relatively low power, a narrow bandwidth and a high center frequency (Morisaka and Connor, 2007). NBHF clicks are longer (tens of cycles) than typical delphinid clicks, and have a smooth amplitude envelope (Au, 1993). It may be that the evolution of these higher frequency NBHF clicks was an anti-predation response to killer whales (*Orcinus orca*), who may be unable to hear them (Morisaka and Connor, 2007).

Beaked whales have recently been tagged with acoustic recorders. Data from these recordings have provided both a description of beaked whale clicks and evidence that they are used for echolocation (Johnson *et al.*, 2004). The measured source level of the clicks

is as high as 214 dB re 1 μ Pa at 1 m (peak to peak). The clicks of Blainville’s and Cuvier’s beaked whales typically show an upward frequency modulation and have very little energy below 20 kHz (Johnson *et al.*, 2004). A similar lack of low-frequency energy has been reported for the clicks of other beaked whale species (Dawson *et al.*, 1998).

2. Pulsed Sounds Pulsed sounds are a series of sound pulses with short intervals. The pulses can occur so quickly, one after the other, that they may be perceived as continuous sound (Watkins, 1967). Short, discrete bursts of broadband sound pulses are referred to as burst-pulses. Typically, most of the energy is in the lower frequencies. However, the burst-pulses of some species can lack the low frequency components and extend up to 60 kHz or higher (Lammers *et al.*, 2003).

Burst-pulses appear to be used for communication between members of the group. Hawaiian spinner dolphins (*Stenella longirostris*) were closer together when they produced burst-pulses than when they used whistles, suggesting a differential function between these two signals (Lammers *et al.*, 2006). Stereotyped patterns of burst-pulse sounds have been described in right whale dolphins (*Lissodelphis borealis*), suggesting that these sounds may have a communicative function similar to stereotyped whistles in other dolphins (Rankin *et al.*, 2007).

In addition to their well-known click sounds, sperm whales produce rapidly pulsed sounds (up to ~1600 pulses/sec) that are described as “squeals” (Weir *et al.*, 2007). These squeals are lower in frequency than their clicks, with most energy below 2 kHz and lasting about 1 sec.

Killer whales produce a large number of pulsed signals. The high repetition rate of up to 4000 pulses/sec lends a tonal character to their sounds. Most of the energy in these well-studied signals occurs between 1 and 6 kHz (Ford, 1989). Resident killer whales in the Northeast Pacific share stereotyped pulsed calls or dialects within their stable social pods. Each pod has evolved its own dialect but may share calls with other pods. Pods with similar dialects that share calls are grouped together in acoustic clans (Ford, 1991). Resident pods from different acoustic clans are known to associate, but not to share call types.

Dialects may have evolved through behavioral drift as ancestral groups divided into newer subgroups. The different dialects serve important social functions for group cohesion and inter-group recognition (Ford, 1991). Resident killer whales in Norway may have a similar dialect system (Strager, 1995).

Transient killer whales of the Pacific Northwest (of the United States, and of southern Canada), that feed on marine mammals instead of fish, have dramatically different vocal behavior. They remain silent most of the time, emitting calls for specific functions such as locating other transient killer whales (Saulitis *et al.*, 2005). They also echolocate much less often than resident killer whales (Barrett-Lennard *et al.*, 1996). It is likely that this reduction in acoustic behavior evolved in response to the hearing abilities of their marine mammal prey.

3. Whistles Whistles are narrowband FM signals with a wide variety of contours (*i.e.* frequency-modulation pattern) ranging from short and simple chirps to long complex signals. The frequency range of the fundamental frequency of whistles is typically between 1 and 30 kHz. Whistles can be as short as tens of milliseconds, most often between 500 and 1000 msec, and as long as 3 sec or more. Most dolphin species produce whistles, although some, like those in the genus *Cephalorhynchus*, do not (Morisaka and Connor, 2007). All of the whistles of delphinid species share many characteristics and it

can be difficult to discriminate between them (Oswald *et al.*, 2007). However, additional recordings and analyses are helping to improve the identification process.

There are no universally accepted classifications for whistles, although measures of beginning, ending, minimum and maximum frequency, and kind of frequency modulation are usually described. Whistles in some species can be readily grouped into categories while others form a continuum of structure. In bottlenose dolphins (*Tursiops* spp.), researchers tend to come up with tens of distinct whistle sounds, with many intergrading variations among them (Deecke and Janik, 2006).

4. Signature Whistles Bottlenose dolphins, and probably quite a few other species as well, produce individualized whistle contours called signature whistles. These have been shown to function in maintaining group cohesion (Janik and Slater, 1998) and to convey individual identity information that may be analogous to a “name.” This individual identity is encoded in the frequency contour of the whistle and not in the individual characteristics of the vocalization (i.e., the “voice”) (Janik *et al.*, 2006). Bottlenose dolphins are the only nonhuman animals yet shown to have this capability. Dolphins are also able to mimic the signature whistles of other individuals in their group, an ability that appears to help maintain social bonds.

The formation of signature whistles is a learned behavior. Dolphin calves learn their signature whistles within their first few months and retain them their entire lives. Interestingly, signature whistles in Florida bottlenose dolphins appear to be more alike in mothers and their male offspring than in mothers and their daughters (Sayigh *et al.*, 1995). The Sarasota, Florida, population of dolphins is generally matriarchal, with daughters being closely affiliated for many years or for life. However, sons leave the natal group as subadults. It has been hypothesized that sons and mothers thereby recognize each other easily after prolonged times apart, perhaps even for years. This recognition may help avoid inbreeding and facilitate other kin-related social behaviors, such as lowered aggression. Further research has shown that the Sarasota calves are more likely to model their signature whistles on those of other Sarasota dolphins, but ones with whom they rarely associate (Fripp *et al.*, 2005).

Debate continues over which dolphin species have signature whistles. It has been suggested that Pacific humpback dolphins (*Sousa* spp.) (Van Parijs and Corkeron, 2001) and Atlantic spotted dolphins (*Stenella frontalis*) (Herzing, 1996) produce them and it is likely that additional species possess them as well.

The complexity of whistle production may well relate to the complexity of behavior or “excitement” level. For example, resting long-finned pilot whales (*Globicephala melas*) make very simple non-wavering whistles. Whistle complexity increases during feeding and bouts of socializing, and variability of whistles and other sounds increases greatly when two pilot whale groups approach each other (Weilgart and Whitehead, 1990). There is a general relationship between the activity level of Hawaiian spinner dolphin groups and their vocalization rate. A resting group produces few sounds, whereas a feeding or socially active group produces many sounds. Higher vocalization rates may result from increased vocalization by all members or from only a subset of individuals within the group. Vocalization behavior may also be related to differences in age, social status, alertness, and gender (Norris *et al.*, 1994).

D. Sounds of Sirenians and Other Groups

Manatees are rather quiet but do produce sounds between 0.15 and 1 sec in duration. Signal structure can be complex, and frequencies

range between 600 Hz and 12 kHz, with most energy found between 2.5 and 5 kHz. The fundamental frequency is at times less intense than the first harmonic. The source level has been estimated at 112 dB re 1 μ Pa at 1 m (Phillips *et al.*, 2004). Calls consist mainly of “chirp-squeaks,” “squeals,” and “screams.” Their calls contain persistent inter-individual differences, particularly in fundamental frequency, which is inversely correlated with body size (O’Shea and Poche, 2006). Mothers and calves counter-call while rejoining each other, suggesting that they recognize individual call characteristics (O’Shea and Poche, 2006).

Dugongs appear to vocalize more often than the manatees, producing three major sound types: chirp-squeaks, barks, and trills (Anderson and Barclay, 1995). They also make intermediate sounds that include components of the three main types. Chirp-squeaks are short FM signals extending upward to 18 kHz. They are about 60 sec in duration, typically trend slightly downward in frequency, and have two to five harmonics. Barks are loud broadband signals that range between 500 Hz and 2.2 kHz, lasting between 0.03 and 0.12 sec. Trills are a series of individual notes, lasting between 100 and 2200 msec. Notes typically begin at about 3.1 kHz and rise to 3.9 kHz. Instead of a linear sweep, the frequency contour has an oscillating character. While the functions of these sounds are uncertain, it is likely that they are used for social communication.

Sea otters (*Enhydra lutris*) produce at least 11 different airborne sounds: screams, baby cries, whistles, whines, hisses, snarls, coos, grunts, squeals, squeaks, and whimpers (McShane *et al.*, 1995). These vocalizations are short, lasting less than a second, and extremely variable in frequency and structure. Airborne vocalizations serve to maintain the mother-pup bond. For example, a pup at the surface often vocalizes continuously until the mother resurfaces following a dive. However, if the mother surfaces and does not find the pup, she vocalizes and awaits the pup’s response (Sandegren *et al.*, 1973). Pups also vocalize to elicit nursing or grooming. No underwater vocalizations have been recorded.

Polar bears may not be quite as vocal as many other carnivores. Males chuff and snort with powerful rapid exhalations, especially in competitive interactions with other males. Females produce low mew-like calls that may be used for mother/pup recognition. Other calls include roars, growls, and bellows (Brown, 1993).

IV. Conclusions

Marine mammals have a very rich behavioral tapestry of sounds. The basic description here merely hints at this richness in an environment where sight and smell are not transmitted as efficiently as sound. Sound is used for communication and for wresting information from the environment. While only toothed whales are thought to have sophisticated echolocation, it is likely that many sounds give information on depth of water, obstruction ahead, or even silent conspecifics, simply by the alteration of sound reflections in different environments.

Our acceptance that sound is critically important to marine mammals also gives us cause for concern. Since the advent of motorized shipping and more recently industrial seismic, military sonar and other human sources of sound, ambient noise levels in major parts of the oceans are increasing. We do not yet know the details of how this noise may affect the communication and behavior of marine mammals.

South American Aquatic Mammals

ENRIQUE A. CRESPO

I. South American Marine and Fresh Water Ecosystems

The marine and fresh-water ecosystems of South America are very rich in aquatic mammals. Seventy-one species have been reported to occur within these ecosystems (Table I); most breed locally, and only five species that appear occasionally belong to Antarctic or subantarctic ecosystems (Jefferson *et al.*, 1993). A number of species are found in South America that occur in other parts of the world or the Southern Hemisphere, such as rorquals, ziphiids, and some delphinids. However, 20 species can be considered endemic to the coastal waters or the river systems of South America.

The distribution of marine mammals at sea is related to the distribution pattern of ocean currents that is defined by the characteristics of the major water masses, mainly temperature and salinity. The marine mammal assemblages of South America can be explained in part by the water masses that move around the continent (Fig. 1). However, depth and ocean productivity may also play an important role in the presence, absence, or high concentration of individuals of a given species. Four different water masses each have their own wildlife marine mammal assemblage. These are Humboldt Current, Equatorial Front of the Eastern Tropical Pacific, Malvinas (=Falkland) Current, and Brazil and South Equatorial Atlantic Currents. In addition, a fifth wildlife component is found in continental waters; it is heterogeneous due to the isolation between some of the river basins. Finally, a sixth assemblage that could be defined as "erratic circumpolar" can also be found. However, it is composed of isolated individuals from Antarctic or sub-antarctic populations that breed or live southward of the Polar Front but move erratically in northern water masses.

II. Marine Mammals of Cold Water Marine Ecosystems

In the extreme south of the continent, the Antarctic Circumpolar Current moves from West to East and splits into two branches: the Malvinas Current in the Atlantic and the Humboldt Current in the Pacific. The cold marine ecosystem in the Pacific almost reaches

the equator with waters between 8 and 15°C, but in the Atlantic, the cold-temperate system reaches only to 40°S. Off Perú an upwelling system gives rise to high levels of primary and secondary productivity.

Several cold-water marine mammals are found in both the Humboldt and the Malvinas Currents (Cárdenas *et al.*, 1986). Among those species the most common in coastal waters are two otariids (the South American sea lion *Otaria flavescens* and the South American fur seal *Arctocephalus australis*) and two small cetaceans (the dusky dolphin *Lagenorhynchus obscurus* and Burmeister's porpoise *Phocoena spinipinnis*). Other small cetaceans like the dolphins of the genus *Lagenorhynchus* (*L. australis* and *L. cruciger*, the latter more pelagic and less known) and the southern right whale dolphin (*Lissodelphis peronii*) can be included. Two related species, the Chilean dolphin (*Cephalorhynchus eutropia*) in the Pacific and the Commerson's dolphin (*C. commersonii*) in the Atlantic are endemic to the southern parts of the ecosystems.

One of the most conspicuous species in the southwestern Atlantic is the southern right whale (*Eubalaena australis*). With a geographic distribution between 20 and 55°S, one of the highest breeding concentrations is at Península Valdés (42°S) (Cappozzo *et al.*, 1991). After long-term depletion of its population size; it is now recovering at rates over 7%, like other stocks in South Africa, Australia, and New Zealand. The whales can be observed in several places in the Atlantic: Uruguay, southern Brazil, and Buenos Aires Province in Argentina. At Santa Catarina, Brazil, a new breeding area was established and connected to Península Valdés. On the Pacific side, there are signs of recovery and a possible northward extension of the distribution range. The stocks of Península Valdés and South Africa use the waters around South Georgia as a feeding ground.

The spectacled porpoise (*Phocoena dioptrica*) is known from the eastern coast of South America and several subantarctic islands, and the South American marine otter (*Lontra felina*) is known from Perú to Staten Island in the southern South Atlantic. Two fur seals (*Arctocephalus galapagoensis* and *A. philippi*) are endemic to the Galápagos and the Juan Fernández Archipelagos, respectively. The latter is also found in a few other places in Perú and Chile. The Galápagos are also home to an endemic sea lion, *Zalophus wollebaecki*.

The long-finned pilot whale (*Globicephala melas*), Risso's dolphin (*Grampus griseus*) and killer whale (*Orcinus orca*) can be included in the cosmopolitan species with locally abundant populations. Eight species of Balaenopteridae and eight ziphiids are common to cold waters of both sides of South America. However, the pygmy beaked whale *Mesoplodon peruvianus* has been recorded only from Peruvian waters of South America (also recorded from México and California) and a recently described species, Bahamonde's beaked whale *M. bahamondi*, from the Juan Fernández Archipelago, Chile.

The dynamics of oceanographic and biological processes that sustain the high productivity of the Peruvian ecosystem can be disturbed by what has been called the El Niño southern oscillation (ENSO event), whose main characteristic is the inflow of tropical waters into the upwelling region around December (Reyes, 1992). The nature of ENSO is irregular and unpredictable, and the impact on the intermediate levels of the food chain (e.g., abundance of anchovies) affects seabirds and marine mammals. Demonstrated effects of ENSO events on fur seals, sea lions, dusky dolphins, and seabirds, have included those on survival, recruitment, and the general condition of the individuals as a consequence of reduced food availability. An ENSO event is part of a more general pattern of oceanographic change affecting not only the Peruvian ecosystem but also the entire Southern Ocean.

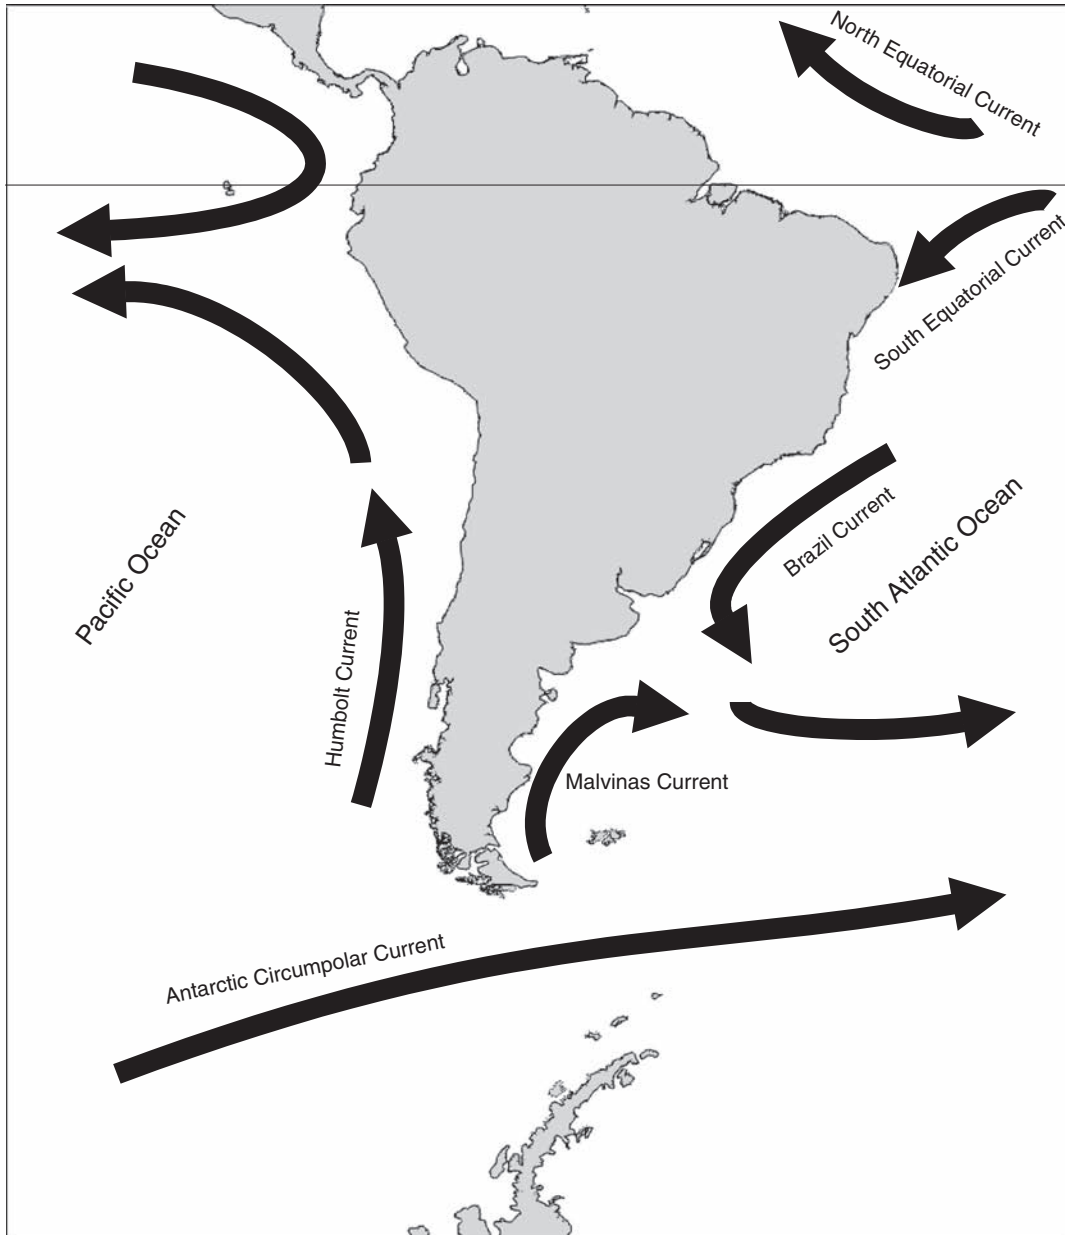

Figure 1 Water currents around the South American continent.

III. Marine Mammals in the Tropical Water Ecosystems

On the Atlantic side, the South Equatorial Current moves from east to west and turns southward, becoming the tropical Brazil Current with exclusive influence up to 28°S. The northern Equatorial Current moves northward and turns clockwise in the Caribbean zone. Between 33 and 40°S, the South Atlantic marine ecosystem shows mixed characteristics of the opposing flows of the Malvinas and Brazil Currents. In addition, this region of the Atlantic receives the input of large continental runoffs like La Plata River and Los Patos Lagoon. On the Pacific side of South America, the Humboldt Current turns to the West after forming the Tropical Front around 5°S.

Both the Atlantic and Pacific tropical systems show species assemblages typical of warmer waters globally (Piñedo *et al.*, 1992; Reyes, 1992; Vidal, 1992). They include dolphins of the genus *Stenella*, (*S. attenuata*, *S. longirostris* and *S. coeruleoalba*), common dolphins (*Delphinus delphis* and *D. capensis*), melon-headed whale (*Peponocephala electra*), rough-toothed dolphin (*Steno bredanensis*), Fraser's dolphin (*Lagenodelphis hosei*), Bryde's whale (*Balaenoptera borealis*), both species of Kogidae, short-finned pilot whale (*G. macrorhynchus*), pygmy killer whale (*Feresa attenuata*), and false killer whale (*Pseudorca crassidens*), among others. The Clymene dolphin (*Stenella clymene*), Atlantic spotted dolphin (*S. frontalis*), marine tucuxi (*Sotalia guianensis*), and Atlantic manatee (*Trichechus manatus*) are found only in the Atlantic. Some species, such as the

common dolphins, false killer whale, and bottle-nosed dolphin (*Tursiops truncatus*), range from the tropics far south in the Atlantic, in the area of mixed waters of the Brazil and Malvinas Currents. Gervais' beaked whale (*Mesoplodon europaeus*) is known from the east coasts of North America and Caribbean islands, and the eastern Atlantic Ocean.

IV. Aquatic Mammals in the River Basins

South America is very rich in river basins, and all the aquatic mammals in continental waters are endemic (Olson *et al.*, 1998). The most important hydrographic systems are the Amazon, the Orinoco, and the Paraná-Uruguay rivers. However, other small river systems are located in cold and high-latitude parts of the continent. Most of those systems are isolated from each other. The Amazon and Orinoco basins hold important populations of aquatic mammals. The most conspicuous include the boto (*Inia geoffrensis*), a freshwater population of the tucuxi (*Sotalia fluviatilis fluviatilis*) and the Amazon manatee (*Trichechus inunguis*). Two otters are also found in those basins and also in the Paraná-Uruguay River systems: the giant otter (*Pteronura brasiliensis*) and the long-tailed otter (*Lontra longicauda*) (IUCN, 1991). The cold river systems in southern Argentina and Chile sustain populations of the southern river otter (*Lontra provocax*) which is also found on Staten Island at the extreme southern end of the continent.

V. Occasional Visitors from the Antarctic

Five species of pinnipeds that breed on subantarctic islands or the Antarctic ice (the Antarctic fur seal *Arctocephalus gazella*, subantarctic fur seal *A. tropicalis*, leopard seal *Hydrurga leptonyx*, crabeater seal *Lobodon carcinophagus*, and Weddell seal *Leptonychotes weddellii*) move erratically to more northerly waters of both sides of South America. Probably as a consequence of population increases over the last few decades, it has become more frequent to sight individuals moving as far north as the Equator. The southern elephant seal (*Mirounga leonina*) can be included in this list; while most breeding groups are circumpolar, there is an important and increasing breeding stock at Península Valdés, Patagonia, around 42°S in the Atlantic Ocean.

VI. Problems Faced by Aquatic Mammals in South America

The problems faced by marine mammals in South America are much like those faced in other parts of the world. They include incidental catch in fisheries, direct exploitation, competition for fishing resources, and habitat loss and degradation (Reeves *et al.*, 2003; Hucke-Gaete *et al.*, 2004). Most of the species in South America are insufficiently known. For most of them, there is no information about abundance and population trends. Exceptions include the pinnipeds, the southern right whale, and several species of small cetaceans such as the dusky and Commerson's dolphins in Patagonia and river dolphins in the Amazon. However, abundance has been estimated for only small parts of their ranges.

While large whales are fully protected, giving them the opportunity to recover, a long list of species of small cetaceans are taken

incidentally in coastal and high-seas fisheries both in the tropics and in cold-water ecosystems. The most critical situation is probably that of the franciscana, *Pontoporia blainvillei* (Crespo, this book, CROSS REFERENCE). However, there are other species or local stocks, which interact heavily with different types of fisheries in direct and incidental takes. Examples include the marine tucuxi in some parts of Brazil, local populations of dusky dolphins in Perú and Patagonia, both species of common dolphins and Burmeister's porpoises in Perú, Commerson's dolphins in Patagonia, and Chilean dolphins in southern Chile. The problem of incidental catch of aquatic mammals in fishing gear has not been addressed as part of fishery management in the countries of the region.

Direct takes mostly for food, oil, or bait also include the use of genital organs for aboriginal beliefs in the case of small cetaceans, and illegal small-scale commerce between South American and Asian countries in a black market in the case of otariids. Economic reasons were involved in turning an incidental into a direct catch in Perú during the 1980s. These conditions can be amplified with poverty and hyperinflation. Direct takes are also a matter of concern with other aquatic groups, such as the hunting of river otters for furs in the river systems.

Regarding competition for fishing resources, there is a general perception by fishermen around the world that some marine mammals, mostly pinnipeds, are currently depleting the target species of fisheries. The perception is sustained by the relative increase of marine mammal populations in the past several decades, and the decrease of fishing stocks in the same period. In South America, this is thought to be the case with the South American sea lion. Even though there has been no formal proposal for culling in the countries of the region, with the exception of Perú where the problem has been discussed by the GOVERNMENT, the private sector, and NGOs, sea lions are shot illegally by fishermen in many places throughout their range. There is also a general belief that reducing the populations of competitors will increase the stocks of the target species of the fishery, a supposition that to date has not been supported by data; culling carried out around the world has not increased levels of target species or catches.

Loss of habitat is the most important problem that faces freshwater and coastal species. Indiscriminate clearing of rainforest for the use of land in agriculture and cattle (*Bos taurus*) growing is currently going on, and many species are declining sharply. During the past years, this process was accelerated by large international demand of soya (*Glycine max*), to which the countries of the region responded with increases of the agricultural frontier at the expense of rainforests. Dams and other barriers in large rivers have been or are being planned for hydroelectric power, irrigation, or flood control. These projects have significant impact on regional development and positive benefits for society. Nevertheless, negative consequences in the river ecosystem for river dolphins, manatees (*Trichechus* spp.), river otters, and other wildlife include the isolation of populations of aquatic mammals and their prey, and unnatural water flows and interruption of migratory paths. In addition to dam construction, other threats include pollution, mining, use of dynamite for fishing, and incidental and direct catches in fisheries. In coastal areas, the most important problems include intensive fishing and pollution by hydrocarbons, agrochemical and heavy metal products, and intensive boat traffic. Recently, construction of buildings for tourism has rapidly increased in large portions of coastline, with detrimental consequences on the coastal ecosystem. The importance of each of these varies with the area considered.

VII. The Need for International Agreements in Conservation Policies

With the exception of endemic species, most South American aquatic mammals have a wide distribution and occur or breed passing through political boundaries, e.g., those of Brazil, Perú, Uruguay, Argentina, and Chile. Legal protection or status is not the same in each country and sometimes there is little or no enforcement. For example, the South American sea lion is shot by fishermen in southern Brazil and Uruguay, is one of the tourist targets in Argentine Patagonia, is allowed to be killed if necessary in Chile, and is a potential culling target in Perú. The dusky dolphin is incidentally and directly taken in Perú and northern Chile, and incidentally taken in Patagonia. South American fur seals and Commerson's and Peale's (*Lagrorhynchus australis*) dolphins were used for crab bait for many years in the southern tip of South America. Franciscana cross the boundaries of Brazil, Uruguay, and Argentina, and while they are protected by law in the three countries, there is no enforcement and incidental mortality is a major cause of concern.

At the national level, incidental mortality or bycatch should be considered in fishery management models and decision making. At the international level, agreements should be promoted among the countries of the region in order to give general or particular status of protection for a given species. For example, in 1991, Colombia, Chile, Ecuador, Panamá, and Perú approved the Action Plan for the Conservation of Marine Mammals in the Southeast Pacific, in order to help the governments of the region to agree on appropriate policies for marine mammal conservation and management. This agreement has little or no effective enforcement, and the Atlantic region even still lacks such an agreement.

South American Sea Lion *Otaria flavescens*

HUMBERTO LUIS CAPPOZZO AND WILLIAM F. PERRIN

I. Characteristics and Taxonomy

The scientific name of the South American sea lion has been under discussion for many years. Two names were in use until a few years ago: *Otaria flavescens* (Shaw, 1800) and *Otaria byronia* (de Blainville, 1820). More recently, the use of *O. flavescens* has been recommended; this is the name used throughout the distribution area in South America (Rodríguez and Bastida, 1993). The common name changes with location: *lobo marino de un pelo*, *león marino del sur*, *lobo marino del sur*, *lobo comán*, *lobo chusco*, *leão marinho*, or *lobo marinho de um pelo*. "South American sea lion" is preferable to "Southern sea lion," as it prevents confusion with Australian and New Zealand sea lions, species also distributed in the Southern Hemisphere.

This species is one of seven that make up the subfamily Otariinae, part of the family Otariidae, usually called otariids, or pinnipeds with ears (Riedman, 1990). It is one of the largest and most dimorphic otariids (Fig. 1). Adult males are much heavier than females. Differences in size between males and females have also been documented among juveniles, and even newborns (Cappozzo et al., 1991). Adult males reach a maximum length of around 3 m and weigh 300–350 kg; adult females are about 2 m long and weigh up to 150 kg. The newborn sea lion usually weighs between 12 and 15 kg and is 0.75–0.86 m long. Adult males have a characteristic hairy, thick neck. The color is generally brownish, from the very dark brown of adult males to almost yellow in females. Pups are black at birth. After the molt of the embryonic coat (*lanugo*) at 2 months, the first juvenile HAIR is reddish brown, changing in color with age and sex.

II. Distribution and Abundance

South American sea lions are widely distributed along the Atlantic and Pacific coasts of South America: from Torres in southern Brazil to Cape Horn in the extreme south of the Atlantic coastline, and from Cape Horn to Zorritos in northern Peru, on the Pacific (Reyes et al., 1999; Cappozzo and Rosas, 1991). Total population has been estimated at 110,000 for the southwestern Atlantic coast, concentrated mainly on the Patagonian coast and southern islands. The population in southern Argentina was estimated at 22,157 from surveys in 1992–1997 (Schiavini et al., 2004) and is thought to be increasing (Dans et al., 2004). The population at the Falkland Islands (Las Malvinas) is estimated to have reached less than 1.5% of its pre-sealing size by 1990, with 2034 pups produced in 1995 (Thompson et al., 2005). There is no reliable information concerning the Pacific population, but it is considered smaller than that on the Atlantic side.

In Argentina, the species was widely distributed from the La Plata river to Cape Horn, but at present only two subadult male rookeries

Figure 1 South American sea lion.

remain in Buenos Aires Province: at Mar del Plata and Quequén harbors, as well as a breeding rookery at Isla Trinidad, 39°S. To the south, they breed along the Patagonian coast, from Punta Bermeja to Tierra del Fuego. There are 18 breeding and non-breeding colonies between Punta Bermeja and Punta Leon, in Northern Patagonia, for which a flow of individuals showing a seasonal pattern has been reported. There is a gap of about 200–300 km between the northern and the central Patagonian stocks. The main concentration of this species occurs in central and southern Patagonia, where there are more than 53 breeding and non-breeding rookeries.

A study analyzed the genetic variability between two rookeries, Isla de Lobos, Uruguay, and Punta Norte, Península Valdés, Argentina; the results suggested that both rookeries belong to the same population (Szapkievich *et al.*, 1999) and that therefore the overall population of the southwestern Atlantic is apparently homogeneous, with movements between rookeries. However, a later analysis of samples from the Atlantic and Pacific suggest that not only do populations in the oceans represent different ESUs but that differences in haplotype frequencies between the two clusters of colonies in Uruguay and Patagonia indicate that they should be considered as different conservation stocks (Tunez *et al.*, 2007).

Variation of the substrate and weather phenomena affect DISTRIBUTION. For example, the occurrence of El Niño on the Peruvian Pacific coast influences the whole marine ecosystem by a drastic superficial thermal inversion that affects the entire trophic web from the plankton up to the top predators. Every time El Niño occurs, there is a drastic population decrease due to higher death rates and migration. Also, on the coasts of southern Brazil and Buenos Aires, Argentina, there has been a great reduction of habitat because of human use of the zone.

III. Ecology

The South American sea lion eats mainly demersal and benthic species, including fish and squids, but its diet is very variable and it adapts easily to locally abundant prey, including crustaceans and even penguins (Alonso *et al.*, 2000). In central Chile, the prey is mainly pelagic fishes, including jack mackerel (*Trachurus murphyi*) (Hückstadt *et al.*, 2007). Off Peru, a larger diversity of prey species (especially of demersal fishes) was consumed during El Niño, when

achovy and lobster were less abundant (Soto *et al.*, 2006). Satellite tracking in Patagonia has revealed that both sexes forage in the temperate waters of the continental shelf, although males traveled farther than females and came closer to the edge of the shelf (Campagna *et al.*, 2001). Trips lasted a mean of 3.4 days and distance traveled averaged 206 km (maximum 864 km). Depths of dives were in the range of 2–30 m.

In some areas of their distribution along the South American coasts, South American sea lions live sympatrically with South American fur seals, but they do not compete with them for breeding space because their respective breeding seasons are out of synchrony. Killer whales prey on sea lions that are at sea and have been seen at Península Valdés preying on groups at the shore by surging out of the water onto the beach and returning with a sea lion in their jaws. They have also been observed preying on sea lions during jack-mackerel fishing operations in central Chile (Huckstadt and Antezana, 2004). Sharks have also been seen eating sea lions in Uruguay.

IV. Behavior and Physiology

Adult males and females arrive at the breeding rookeries during the first half of December (Campagna, 1985; Campagna and Le Boeuf, 1988a). The males defend a position on the central breeding area, and during the peak of the breeding season they also defend females in ESTRUS. In other rookeries such as Puerto Pirámide (also located at Península Valdés), males defend the territories where females go to mate. In a female-defense polygynous mating system, with males capable of forcing copulation, the female's first priority would be to survive the breeding season and then to mate with high-quality males. Males attempt to mate with as many females as possible. Adult males may maximize their reproductive success through the selective defense of those females that are close to estrus. Adult females develop choice of the male with which they copulate by changing the associated male before giving birth or by mating with more than one male during their maximum sexual receptivity. Thermoregulatory requirements interact with rookery topography to shape mating strategies, variation in mating success, and the mating system type (Campagna and LeBoeuf, 1988b). At Punta Norte, the pebble substrate is homogeneous regarding thermoregulatory advantages. Thus, sites advantageous for THERMOREGULATION

are not a limited resource that can be used to attract females. Consequently, males acquire mates by selective female defense or abduction. However, at the Puerto Pirámide rookery, a variation in the quality of the substrate with respect to reducing thermal stress favors the development of a territorial system where the best territories contain water or are close to the water. Here, the abduction of females or direct defense of females by males is not required, as females preferentially gather in wet territories. Thus, the topography and substrate of the breeding area, along with thermoregulatory requirements, are driving forces that generate adaptive changes in male mating behavior. Substrate has also been shown to be a factor in degree of agonistic behavior among females (Cassini and Fernando-Juricic, 2007).

Males that are sexually mature but cannot compete gather in “bachelor clubs” close to the main breeding area. These subadult or non-territorial males may develop alternative mating strategies: group raids, solitary breeding (single male with a single female or with a small isolated harem), or female interception (keeping females that leave the main breeding area on the way to and from the water) (Campagna *et al.*, 1988).

A cost–benefit model applied to data from a breeding colony of South American sea lions (Cassini and Fernandez-Juricic, 2003) suggests that gregariousness of females reduces the reproductive costs of interacting with males and that this dilution effect may have played an important role in the evolution of this species’ mating system.

There is little information regarding migrations and seasonal movements. To the north of the Uruguayan breeding grounds, in southern Brazil, there are only two non-breeding haul-out rookeries where subadult males predominate, with seasonal movements. Aberrant records for the species have been reported for Rio de Janeiro, Brazil at 23°S, and even to 13°S but these are always solitary individuals.

South American sea lions do not spend long periods away from the coast, as many pinnipeds do, and they gather in groups or colonies. There are both permanent and nonpermanent colonies; the latter are mainly reproductive settlements. At the permanent colonies, during the breeding season, the individuals that do not participate in the reproductive activity stay in the colony segregated in non-reproductive groups.

V. Life History

The sex ratio at birth is 1:1. Males become sexually mature in their sixth year of age, whereas females produce their first offspring about the fifth year or before. The reproductive behavior of marked individuals was studied for 10 years at Punta Norte rookeries in Peninsula Valdés, Argentina.

The breeding and pupping season begins in mid-December and extends to early February (Campagna, 1985). Most of the pups are born during January, usually 2–3 days after the mother’s arrival at the rookery. Copulations occur on land 6 days after parturition, and females spend 2–3 days more with their pups fasting. Mothers begin leaving their pups temporarily and foraging offshore at between 1 and 4 days; each foraging trip is followed by 2 days of nursing bouts on land. Lactation continues for 8–10 months, although it is not unusual to find females with un-weaned yearlings. Lactating females spend around 53% of the time at sea diving, with median and maximum depths ranging from 19 to 62 and from 97 to 175 m, respectively (Werner and Campagna, 1995). The pups wander about and tend to gather in groups; they spend most of the time sleeping or playing. The number of pups in these groups increases as the season goes on. When

the mother returns to the colony, she calls her pup and they recognize each other by sound and smell. Each female nurses only her own pup. In 10 years of study at Punta Norte, Península Valdés, only three cases of true adoption were documented, although it is not infrequent to see pups suckling from females other than their mothers, “stealing” milk.

The death rate of pups is usually high, with main reasons being the separation from their mothers, starvation, being crushed by large males where the ground is hard, abuse from juveniles, or predation by other species. Both pup mortality and timing of birth are effected by prey availability influenced by El Niño (Soto *et al.*, 2004).

The degree of dimorphism of South American sea lion pups is similar to that of other otariids. Newborn males are 9–18% heavier than females at Península Valdés. Assuming that there is no sex difference in energy expenditure by fetuses, sexual dimorphism in the size of newborn pups suggests that South American sea lion mothers invest more energy in sons than in daughters during gestation. Contrary to other otariids, in which males increase in mass faster than females, no sex difference was found in growth rates among South American sea lions. The size dimorphism present at birth in this species persists during the nursing period, suggesting that sons continue to be more costly to their mothers than daughters. It is not known if differences in size found at birth in the South American sea lions of Península Valdés persist until weaning, but there is some evidence suggesting that this may be true.

Six-month-old male pups at the Malvinas (Falkland) Islands are longer than females; the difference in length remains in 18-month-old individuals and is even more marked in older juveniles. Data for other otariids show that sexual dimorphism at birth continues through weaning.

VI. Human Interactions

Human exploitation has been hard on pinnipeds. Some species were hunted down to extinction (Caribbean monk seal, *Monachus monachus*) or barely survive (Mediterranean monk seal, *Monachus schauinslandi*), whereas others were spared thanks to the remoteness of their location, as the Antarctic phocids and the fur seals at Patagonian islands. Pinnipeds in general were killed to obtain oil, fur, and meat either for subsistence or for commercial purposes. The South American sea lion was hunted mainly for oil, as its fur is not as valuable as that of the South American fur seal (*Arctocephalus australis*). In Southern Chile it is still captured by fishermen as bait for the southern king crab. It is also hunted by fishermen who regard it suspiciously, as sea lions are supposed to compete for the same fishes they seek and to damage fishing gear. The South American sea lion endured long periods of exploitation with a severe reduction in ABUNDANCE. Although it is estimated that only 20% of their historical number remains, recent signs of recovery have been reported (Crespo and Pedraza, 1991).

More recently, depredation on fishery catches by sea lions has arisen as a problem in artisanal fisheries in Uruguay (Szteren and Paez, 2002) and Chile (Sepulveda *et al.*, 2007) and commercial purse-seining for jack mackerel off central Chile (Huckstadt and Antezana, 2003; Huckstadt and Krautz, 2004), and attacks on salmon in Chilean fish farms has led to a search for effective mitigation measures (Sepulveda and Oliva, 2005).

Southern Fur Seals

Arctocephalus spp

JOHN P.Y. ARNOULD

Southern fur seals (genus *Arctocephalus*) are generally recognized as comprising eight species and four subspecies. As the name implies, they occur almost exclusively in the Southern Hemisphere with only one species being found north of the equator. They are circumpolar in distribution, occurring in all the Southern Hemisphere oceans. The generic name, *Arctocephalus*, comes from the Greek words *arktos* and *kephale*, meaning “bear headed,” and many of their facial characteristics reflect their terrestrial carnivore ancestry.

The majority of southern fur seals were overexploited during large-scale commercial hunting in the eighteenth and nineteenth centuries, and many species were so depleted in numbers that they were considered extinct. Fortunately, because of the isolated nature of the islands on which many southern fur seal species occur, remnant populations persisted. All known species survived and are now recovering at various rates. Several species have been the focus of extensive research over the last few decades which has greatly improved our understanding of pinniped biology and the influence of environmental variation on the population demography and behavior of top-order marine predators.

I. Characteristics and Taxonomy

The most obvious diagnostic feature separating fur seals from sea lions is the presence of an underfur layer in their pelage. The

TABLE I
Scientific and Common Names of the Southern Fur Seal Species (*Arctocephalus* spp.) with Their Mean Adult Body Mass and Most Recent Estimates of Population Size

Scientific name	Common name	Mean adult mass ^a (kg)		Population size (× 1000)
		Female	Male	
<i>A. townsendi</i> (Merriam, 1897)	Guadalupe fur seal	49	124 ^b	>7
<i>A. galapagoensis</i> (Heller, 1904)	Galapagos fur seal	27	64	12
<i>A. philippii</i> (Peters, 1866)	Juan Fernandez fur seal	48	140	18
<i>A. australis</i> (Zimmerman, 1783)	South American fur seal	35–58 ^c	75–107 ^c	235–285
<i>A. forsteri</i> (Lesson, 1828)	New Zealand fur seal	39	127	135
<i>A. pusillus pusillus</i> (Schreber, 1775)	Cape or South African fur seal	57	247	1700
<i>A. pusillus doriferus</i> (Wood Jones, 1925)	Australian fur seal	76	279	92
<i>A. tropicalis</i> (Gray, 1872)	Subantarctic or Amsterdam Island fur seal	34–36 ^c	88–131 ^c	>310
<i>A. gazella</i> (Peters, 1875)	Antarctic or Kerguelen fur seal	45	188	1600

^b $n = 1$.

^cRange of means from different populations.

density of hair follicles in the underfur of fur seals is approximately 50 times greater than that in terrestrial mammals and this layer plays an important role in their THERMOREGULATION. Fur seals are generally smaller than their sea lion counterparts. Another difference between the two groups can also be found in the baculum (penis bone), the tip of this bone being narrow in fur seals whereas in sea lions it is broad. In addition, fur seals have six pairs of upper post-canine teeth, compared to five in sea lions, and the third upper incisor is less circular in horizontal cross section.

The southern fur seals can be distinguished from the NORTHERN FUR SEAL, *Callorhinus ursinus*, by the extent to which the fur line extends on the fore flippers. In the northern fur seal the fur stops at the base of the flippers in a sharp line, whereas in southern fur seals it extends across part of the flipper, ending in a line over the metacarpals. A more prominent difference between these species is the shape of the SKULL, with the angle of the slope from the top of the nasal bone to the tip of the premaxilla being much greater in the northern fur seal. This gives the head of the northern fur seal a distinctive shortened-snout appearance in comparison to southern fur seals. Recent phylogenetic analyses (Arnason *et al.*, 2006; Deméré *et al.*, 2003) suggest the southern fur seals are more closely related to sea lions than the northern fur seal.

Within the southern fur seals there is a relative uniformity in appearance. This led to some confusion among early researchers about the classification and nomenclature of the various species in the genus. The history surrounding this has been discussed at length by Bonner (1981, 1994) and Gardner and Robbins (1998). The classification used here is taken from Rice (1998), and the scientific and common names for each species are given in Table I. The discreteness of their distributions aids in the identification of the different species, and in the areas where sympatry occurs morphometric, behavioral, vocalization, and habitat-choice differences can be used to separate the species.

Pelage color among southern fur seals is generally uniform dark brown to dark gray on the dorsal surface with a grizzled appearance caused by the tips of the guard hairs (outer fur layer) being white or pale in color. The fur is a lighter color on the ventral surface, especially

Figure 1 Male sub-antarctic fur seal (*A. tropicalis*). Photo courtesy J. Arnould.

around the abdomen. There can be considerable variation between individuals of a species in the shading of the pelage and the degree to which it appears grizzled depending on age and sex. For example, older Australian fur seal (*A. pusillus doriferus*) and ANTARCTIC FUR SEAL (*A. gazella*) females often have a lighter, more grizzled appearance than younger individuals. The time elapsed since the last molt, which occurs annually in late summer–early autumn, also affects the appearance of the pelage due to wear and soiling.

There are two notable exceptions to the general pelage color within southern fur seals. Subantarctic fur seals (*A. tropicalis*) have a distinctive COLORATION: the chest and face (muzzle and around the eyes to just below the ears) are pale yellow or creamy in color while the top of the head and dorsal surface are dark brown–gray (Fig. 1). The demarcation in coloration is more pronounced in males, which also have a conspicuous tuft of dark hair on the forehead that becomes more erect when the animal is excited. In the Antarctic fur seal population

Figure 2 Female Australian fur seals (*A. pusillus doriferus*). Photo courtesy J. Arnould.

on South Georgia, 0.1–0.2%; of individuals have a white pelage. These animals are not albinos and have normal skin and eye pigmentation. This white-phase pelage has not been reported in any of the other Antarctic fur seal populations. Incidences where the fur appears uniform golden or tan, however, have also been reported in several other southern fur seal species, albeit rarely and usually only in pups.

Pups of all the southern fur seal species are born with a black natal coat (lanugo) which, with the exception of Cape and Australian fur seals (*A. pusillus* subsp.) where the ventral surface can vary from gray to pale yellow, develops a grizzled appearance soon after birth. In all species, the natal pelage molts 3–4 months after birth to reveal a silky smooth gray or brown fur.

The Galapagos fur seal (*A. galapagoensis*) is the smallest of the southern fur seals (and the Otariidae) with mean female and male adult mass at 27 and 64 kg, respectively (see Table I). Most of the other species are slightly larger, with mean masses ranging from 34 to 58 kg for females and 75 to 188 kg for males. The exceptions to this pattern are the Cape fur seal (*A. pusillus pusillus*) and the Australian fur seal (*A. p. doriferus*), which have mean masses of 58 and 76 kg for females and 247 and 279 kg for males, respectively (Fig. 2). These two subspecies also differ from the remainder of the genus in having some behavioral traits reminiscent of the sea lions. In particular, *A. pusillus* subsp. display very thigmotactic tendencies (tolerance of physical contact between individuals), behavior not seen in other fur seals but common in sea lions. In addition, the mode of terrestrial locomotion and aspects of their vocal repertoire resemble those of sea lions more than those of other fur seals. This is consistent with phylogenetic analyses placing *A. pusillus* as the stem arctocephaline.

Differences in the shape of the flippers can be used as diagnostic characters between several southern fur seal species, especially when their distributions overlap. For example, the fore-flippers of New Zealand seals have a more triangular shape than those of Australian fur seals, which are more paddle shaped and curved. Similarly, Antarctic fur seals have proportionally longer hind flippers than subantarctic fur seals. Snout lengths in southern fur seals also vary, being longest in the Juan Fernandez fur seal (*A. philippii*) and shortest in the Galapagos fur seal. In addition, the rhinarium (soft tissue of the nostrils) is smooth and inconspicuous in Antarctic and Galapagos fur

seals, whereas it is inflated and bulbous in Juan Fernandez and New Zealand fur seals.

II. Distribution and Abundance

The large-scale HUNTING during the commercial sealing era severely depleted the populations of Southern fur seals and it is known to have reduced the breeding distribution of many species. For several species, the pre-sealing distribution and population size are not accurately known, as sealing ships did not always keep detailed records of the number or species taken. This is particularly so for species which have overlapping ranges such as the New Zealand and Australian fur seals in southern Australia and the Antarctic and subantarctic fur seals on several subantarctic island groups.

The current breeding distributions of southern fur seals are shown in Fig. 3 and their population sizes are given in Table I. The Guadalupe fur seal (*A. townsendi*) is the only Southern fur seal species found in the Northern Hemisphere. Its breeding colonies are currently restricted to Isla Guadalupe, situated off the Pacific coast of Mexico, but it once had a wider distribution, including the Channel Islands (of California) and the San Benito Islands (off Baja California). The most recent (1992) estimate of the Guadalupe fur seal population size is >7000 individuals, making this by far the rarest of the southern fur seals.

The distribution of the Galapagos fur seal is limited to the equatorial Galapagos Islands. The population increased following cessation of the extensive sealing in the nineteenth century and it is currently estimated at 12,000 individuals. Periodic El Niño events, however, have been shown to significantly affect the population size by heavily reducing pup production and reproductive success in this species (Trillmich and Ono, 1991).

Further to the south, off the coast of Chile, the Juan Fernandez fur seal is confined to the islands of the same name. This species was once abundant and is estimated to have numbered over four million prior to exploitation. It was thought to have been hunted to extinction until it was rediscovered in 1966. Currently, the Juan Fernandez fur seal occupies four main breeding colonies and has a population size of approximately 18,000, making it the third rarest of the southern fur seals.

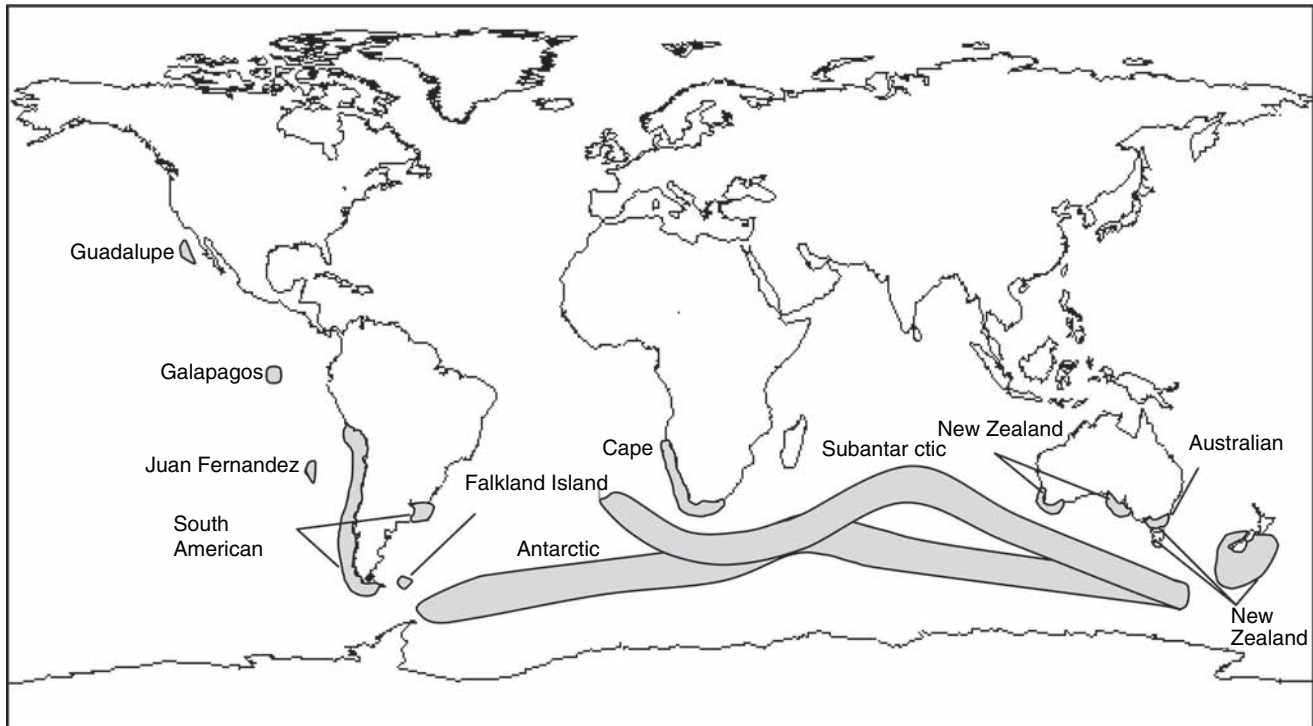

Figure 3 Distribution of southern fur seals.

The South American fur seal (*A. australis gracilis*) is found at many sites along the Pacific coast of South America, from Peru down to the islands west of Tierra del Fuego and in the Straits of Magellan, and on the Atlantic coast in southern Brazil and Uruguay. The colonies in Uruguay were exploited regularly in a small, controlled harvest until as recently as the early 1990s. The majority of colonies occur on offshore islands except in Peru where the dramatic increase in population since the 1960s (from 40 in the 1950s to over 20,000) has occurred mostly on three mainland colonies at Punta San Juan, Paracas Peninsula, and San Fernando. The Falkland Islands subspecies (*A. a. australis*) is found only on the Falkland Islands where its numbers are still greatly reduced as a result of commercial sealing, which continued into the early part of the last century. The total population size for both subspecies is presently estimated at 235,000–285,000 individuals.

In addition to colonies along the coast of the South Island of New Zealand, the breeding distribution of the New Zealand fur seal (Fig. 4) extends eastward as far as the Bounty, Antipodes, and Chatham Islands and southward to the Snares, Auckland, and Campbell Islands. There are also substantial colonies of New Zealand fur seals along the southern coast of Australia. Colonies in the Recherche Archipelago (Western Australia) and Kangaroo Island (South Australia) have been increasing rapidly in size, and there is the potential for competition to develop between them and the sympatrically breeding AUSTRALIAN SEA LION (*Neophoca cinerea*). Small breeding colonies of New Zealand fur seals (<400 individuals each) have also recently been established at three sites in Bass Strait (southeastern Australia), the most easterly extent of the species in Australia, where it breeds in sympatry with Australian fur seals. Historical evidence suggests both species were once found in larger numbers alongside each other throughout Bass Strait. The total New Zealand fur seal population is estimated at 135,000, with approximately 35,000 being found in Australia. Interestingly, molecular studies

Figure 4 Female New Zealand fur seal (*A. forsteri*). Photo courtesy J. Arnould.

have shown significant genetic variation, not only between Australian and New Zealand subpopulations of this species, but also within the latter, suggesting deeply divergent lineages “bordering on species-level distinction” (Lento *et al.*, 1997).

Although separated widely in their distributions, the Cape fur seal and the Australian fur seal show morphological and genetic similarities consistent with their status as subspecies. The Cape fur seal breeds at 25 colonies around the coasts of South Africa and Namibia. It is unique among fur seals in that the four largest colonies are located on mainland sites. The fact these colonies border diamond mining areas, where human access is restricted, and the

Namib Desert, which is devoid of large predators, may explain their location. The Cape fur seal has been subject to controlled harvests for over a century, yet the population continued to increase until the early 1990s. The most recent survey (2004) suggests the population has stabilized at around 2 million individuals. In contrast, the Australian fur seal has not been subject to commercial harvesting since 1923, but the population is currently estimated at only 92,000 individuals and breeding colonies are restricted to ten islands in Bass Strait. While the colonies are currently experiencing annual increases of 6–15%, the population size is still well below the estimated 175,000–225,000 individuals present prior to the commercial sealing era. The slower recovery, and smaller pre-exploitation size, of the Australian fur seal population in comparison to the Cape fur seal is thought to be attributed to differences in food availability. Australian fur seal colonies are situated in the nutrient-poor waters of Bass Strait, whereas Cape fur seals forage in the highly productive waters of the Benguela Current.

The subantarctic fur seal has a total population of >310,000 and a widely dispersed breeding distribution with colonies on several subantarctic and subtemperate island groups located north of the Antarctic polar front. The main focus for the species is on Gough Island in the South Atlantic Ocean where colonies total over 200,000 seals. A small population (250) is located to the west at nearby Tristan da Cunha. To the east, in the southern Indian Ocean, substantial colonies exist on the Prince Edward Islands (75,000), the Iles Crozet (1000), and Amsterdam Islands (50,000). A small population also exists to the southeast of Australia on Macquarie Island (<200) where the species breeds sympatrically with the Antarctic fur seal and some hybridization has occurred (Goldsworthy *et al.*, 1999). Hybridization between subantarctic fur seals and Antarctic fur seals has also been recorded at Marion Island (Prince Edward Islands) where the latter is greatly outnumbered (only 1200). These two species also breed sympatrically on Iles Crozet.

The ANTARCTIC FUR SEAL also has a very large breeding range and is the most southerly breeding of the *Arctocephalus* species. With the total population in 1990 estimated at over 1.6 million and growing at an annual rate of 9.8%, the Antarctic fur seal is now likely to be the most numerous of the southern fur seals. Over 95% of the population breeds on South Georgia in the South Atlantic Ocean, but colonies are found on numerous island groups spreading eastward as far as Macquarie Island. All colonies are located south of, or on, the Antarctic polar front with the exception of those at Marion Island, Iles Crozet, and Macquarie Island. The species was considered extinct until a small remnant population of 1000–3000 individuals was discovered in 1950 on Bird Island (northwest tip of South Georgia). From this colony emanated the phenomenal recovery of the species with the recolonization of many sites being attributed to emigration from the expanding South Georgia population. The rapid recovery of the South Georgia population is thought to have been facilitated by its predominant prey, Antarctic krill (*Euphausia superba*), being found in super-abundance in the surrounding waters.

The nonbreeding range of most southern fur seal species is often much greater than the breeding distribution and is determined by the movements of males and juveniles. These segments of the population are not restricted in the same way as adult females, which must return regularly to the natal colony in order to suckle their pup. Males of most species undertake some form of seasonal movement after the breeding season or during the winter months when local food availability is reduced. Whether such movements constitute structured migrations or reflect individual dispersal patterns may vary between species and different age classes.

III. Ecology

Southern fur seals feed on a variety of prey species, including fish, cephalopods (octopus, squid, and cuttlefish), crustaceans (krill, shrimp, rock lobster), and even penguins and other seabirds. Studies of several species have shown great temporal variation in diet composition, with seals exploiting seasonally abundant prey items such as spawning squid or schools of migrating fish. In addition, substantial differences in diet can be found between populations of the same species. For example, the Antarctic fur seal population at South Georgia feeds almost exclusively on Antarctic krill, whereas at Heard and Kerguelen Islands (southern Indian Ocean), seals of this species feed primarily on myctophid fishes. The majority of detailed studies, however, have concentrated on the diet of adult females because natal colonies have been the easiest to sample for feces (the most commonly used technique for determining diet). Consequently, for most species, there is relatively little information on the diet of adult males or how it varies seasonally. Nonetheless, studies of New Zealand, Juan Fernandez, and Antarctic fur seals have shown significant differences between the sexes in diet which is thought to reflect resource partitioning, differences in nutritional requirements, and physiological diving abilities.

Over the last decade, the foraging zones of several southern fur seal species have been determined through the use of satellite telemetry. Studies of lactating female Cape, Antarctic, subantarctic, and New Zealand fur seals have found that most foraging activity occurs in upwelling zones, oceanic frontal systems, or continental shelf-edge regions, areas generally high in primary productivity. An exception to this trend is the Australian fur seal, which has been found to forage exclusively over the shallow continental shelf region of Bass Strait and surrounding areas in south-eastern Australia. Sex differences in foraging areas have also been observed in New Zealand, Antarctic and Australian fur seals with males generally tending to forage in areas of greater depth. There is little information about the foraging locations for other age and sex classes in southern fur seals.

IV. Behavior and Physiology

As with diet studies, the majority of research on foraging behavior in southern fur seals has involved lactating females due to their relative ease of handling and recapture in comparison to adult males. Although they are known to be able to dive to much greater depths, it has been shown in most species that foraging activity occurs mainly in the surface mixed layer (<50–60 m) at night. The larger body size of males would be expected to enable them to dive deeper than females, and studies of New Zealand and Antarctic fur seals support this with foraging depths >200 m regularly observed. In most species studied, diving depths change throughout the night, generally reflecting the diel vertical migration of the main prey. The exception to this is the Australian fur seal, the largest of the fur seal species, which has been shown to forage almost exclusively in benthic habitats to depths of up to 200 m during both day and night. This trait, more akin to sea lion foraging behavior, is considered the result of their large body size and the relatively low productivity of their marine habitat.

Like in all otariid seals, female southern fur seals have a lactation pattern characterized by regular nursing periods ashore alternating with foraging trips to sea during which the pup remains on land fasting. However, whereas female sea lions generally only leave their pups for short durations (1–2 days), maternal foraging trips in southern fur seals can be much longer. While in most southern fur seals species maternal foraging trips are 4–6 days long, females of subantarctic, Juan Fernandez, and Australian fur seals have been recorded

as regularly undertaking trips of >20 days (Francis *et al.*, 1998; Kirkman *et al.*, 2002). Because of these long separations between mother and pup, lactating southern fur seal females have the longest inter-suckling intervals of any mammal, yet are able to maintain mammary gland function, and their pups endure the longest repeated fasts of any developing mammal. The physiological mechanisms by which these feats are achieved are still poorly understood.

V. Life History

While definitive data are lacking for some species, southern fur seal females generally reach sexual maturity at 3–5 years of age and thereafter have pregnancy rates of 70–80%. Males reach sexual maturity around the same age but do not attain territorial status and the ability to mate until 7–10 years old. Longevity in the wild has been documented for few species but ranges from 20–23 years for females and 10–18 for males in Australian, subantarctic and Antarctic fur seals.

The breeding biology of the southern fur seals is similar to that of other otariid seals (sea lions). Females give birth to a single pup each year, and the reproductive cycle consists of a perinatal attendance period of 6–10 days, culminating in estrus and copulation; an embryonic diapause lasting 3–4 months; and an active gestation of 8–12 months. Females have two pairs of mammary glands and lactate for 8–12 months, but several species may suckle their pup into part of the second or even third year. The exceptions to this are the Antarctic fur seal, which has a lactation period lasting only 4 months, and the Galapagos fur seal in which weaning may occur at >3 years of age and females can suckle successive offspring at the same time. Differences in food availability and seasonal predictability may explain these divergent strategies.

Timing of the pupping season is fairly consistent, occurring between October and December in the Southern Hemisphere species and in the corresponding late spring–early summer period of June–July in the Northern Hemisphere for the Guadalupe fur seal (Boyd, 1991). Estrus synchrony, measured as the period over which 90% of births occur, varies from 21 days in the Antarctic fur seal to 70 days in the Galapagos fur seal and is negatively related to latitude (Boness, 1991). High estrus synchrony is considered a prerequisite for polygyny, and resource defense polygyny has been demonstrated clearly in New Zealand, Antarctic, and Australian fur seals. As is common in polygynous species, Southern fur seals are sexually dimorphic and have some of the most extreme male:female mass ratios of any mammal. In addition, the operational sex ratio, defined as the average ratio of fertilizable females to sexually active males at any given time, has been shown to be correlated positively to the degree of SEXUAL DIMORPHISM in southern fur seals.

VI. Interactions with Humans

In addition to experiencing severe population declines during the eighteenth and nineteenth centuries as a result of the commercial sealing era, several southern fur seal species have been subject to culls and harvests, both legal and illegal, at various times since then. The majority of these have been related to commercial fisheries concerns of competition with increasing seal populations. Indeed, as populations continue to recover, and human exploitation of the oceans increases, interaction with commercial fisheries is becoming more prevalent. Currently, only the Cape fur seal in Namibia is legally harvested (>60,000 annually, most which are pups) ostensibly for protecting the Namibian fisheries stocks. However, in addition to

competition for resources, direct negative interactions (e.g., entanglement in gear, drowning in nets) can lead to high levels of mortality in some species.

In contrast to the generally negative impacts of interactions with fisheries, populations of several southern fur seal species have enjoyed positive attention in recent decades through eco-tourism activities. The popularity of viewing (and in some locations swimming with) fur seals in their natural habitat has proved to make ecotours focused on these animals important to local economies in numerous places throughout the southern hemisphere. Recent estimates place the annual value of tickets sale alone at >US\$8 million.

Species

WILLIAM F. PERRIN

I. What is a Species?

Although the term “species” is widely used, there is no agreement on exactly what it means beyond the general conception of a basic taxonomic or evolutionary unit. It is important

to make progress in our understanding of species and how to define them, not least because much of the legal machinery of international conventions, national legislations, and regulations dealing with wildlife and the conservation of biodiversity uses the term in specifying what they seek to protect. If we cannot agree on what constitutes a wild species, we may not be able to agree on how to conserve and protect it.

There are a number of species concepts in use for vertebrates (Claridge *et al.*, 1997). In the *biological species concept* (BSC) (Mayr, 1963), a species is a group of interbreeding or potentially interbreeding individuals separated from other such groups by intrinsic (genetically fixed) barriers to gene flow. In cases of sympatry or parapatry, direct evidence of non-interbreeding may be available, but more commonly morphological separation has been used as a proxy to indicate the lack of gene flow; in this case the definition works fairly well. In the case of allopatry, however, there is difficulty. While the same operational criterion has been used, in nearly all such cases we do not know whether the groups would interbreed if the chance arose. The barrier to interbreeding may be a broad gap in range or simply a purely physical geographic one such as an isthmus or a climatic zone.

In the more recently developed *phylogenetic species concept* (PSC), a species is “the smallest population or group of populations within which there is a parental pattern of ancestry and descent and which is diagnosable by unique combinations of character states” (Cracraft, 1997), with no inference about potential interbreeding. Indeed, interbreeding is considered a shared primitive character and, as such, is not able to diagnose a lineage, which the PSC requires. In the case of sympatry, this concept does not differ materially from the BSC. Both have difficulties with allopatric populations (biological subspecies under the BSC may equate to phylogenetic species under the PSC) and with paraphyly. Phylogenetic taxonomists insist on reciprocal monophyly (having diagnostic unique characteristics, a single common ancestor, and no reticulation) between most closely related (sister) species, but this may be violated by the real phenomenon of incomplete lineage sorting in the case of some newly evolved but widely recognized species, e.g., because polar bears evolved from brown bears relatively recently, some brown bears are still related more closely genetically to polar bears than they are to other brown bears. In practice, adherents to the biological species concept use morphological characters in exactly the same way as phylogenetic taxonomists, albeit as proxy indicators of reproductive isolation. One difficulty faced by strict phylogenetic species-level taxonomy is that different genes or sequences may have different phylogenies due to differential modes of inheritance or introgression; a gene tree may not equal a species tree.

The two species concepts are actually complementary perspectives on evolution and can reinforce each other. To quote Avise and Wollenberg (1997), “Historical descent and reproductive ties are related aspects of phylogeny and jointly illuminate discontinuity.” Furthermore, more important is not the process of specifying units to fit into the simplifying Linnaean binomial system, but rather describing and understanding in detail the coalescent genealogy and demography of discontinuous populations. Where did they come from, how are they different, and where are they likely to go? Whether they are called species (always, under the phylogenetic species concept) or subspecies (sometimes, under the biological species concept) is little more than semantics rooted in perspective. This is generally true also in the conservation of diversity. For example, named subspecies are accorded the same legal protection as species in the U.S. Endangered Species Act and Marine Mammal Protection Act.

There are additional species concepts, e.g., the *cohesion species concept* (Templeton, 1989), under which a species is “the most

inclusive group of organisms having the potential for genetic and/or demographic exchangeability.” Some pairs or groups of sympatric or parapatric species, such as wolves (*Canis lupus*) and coyotes (*Canis latrans*), may make up *syngameons* (Templeton’s term) of species that are fully interfertile and may at times interbreed extensively but nonetheless have persisted separately for geological periods of time. Some of the species of southern fur seals (*Arctocephalus* spp.) may fall into this category (discussed later). Despite sporadic or scattered interbreeding, they would qualify as full species under the cohesion species concept.

It is clear that the current trend is toward pragmatism in addressing species concepts. Agapov and Sluys (2005) noted, “Species are complex things, their identity resting on the methodologies used to diagnose them and on the many different ways that organisms have of belonging to a species. We would do well to embrace plurality, using different species concepts in different circumstances rather than searching for a platonic ideal.”

While the various species concepts are necessary (because of the legal need to define units for conservation) and laudable attempts to model the results of actual evolutionary processes, they are human constructs (Hey, 2001), and as for all such constructs, in certain circumstances even the most commonly accepted species concepts fray at the edges. One problem of the biological species concept in its application (mentioned earlier) is that of closely related allopatric species, whether they be defined by morphological or genetic characters. If at some point they became sympatric or parapatric because of some geological or climatic change, would they then freely and effectively interbreed (be one species)? Are they a little different from each other only because of inconsequential genetic drift due to physical separation, or are their differences the result of important differential ecological selection that has led to a permanent parting of their evolutionary paths? Even if their morphological differences are great, the question remains of whether this is due to large genetic differences, or of pleiotrophic effects of a small difference unassociated with genetic differences that would prevent interbreeding. For the most part, of course, answers to these questions will remain unobtainable. However, we can deduce what might happen from looking at the results of some “natural experiments.” In one possible example, a zone of hybridization/intergradation between two subspecies of spinner dolphins, *Stenella longirostris*, in the eastern tropical Pacific is thought to perhaps be the result of recontact after separation during an earlier cooler climatic period (Perrin *et al.*, 1991). HYBRIDIZATION in the putative zone of re-contact is evidenced by greater variance in body size and color pattern. The two subspecies, the eastern spinner (*S. l. orientalis*) and Gray’s spinner (*S. l. longirostris*), are morphologically so dissimilar that they were once thought to belong to different species (eastern spinners were identified as *S. microps* and Gray’s spinners in Hawaii as *S. roseiventris*).

Thus, some of our present allopatric species may be transient taxa that will be absorbed or blended back into a pooled line of descent; i.e., they were never really “good” species at all.

Antitropical species seem especially good candidates for potential recontact and subsequent reticulation; sporadic movement of cool-water forms across the equator during cooler geological periods is thought to have played an important role in speciation, e.g., in the porpoises, including the formation of antitropical pairs of putative species. Species pairs that potentially represent such transient situations include the vaquita (*Phocoena sinus*) and Burmeister’s porpoise (*P. spinipinnis*), northern and southern right whale dolphins (*Lissodelphis borealis* and *L. peronii*), the Pacific white-sided dolphin (*Lagenorhynchus obliquidens*) and the dusky dolphin

(*L. obscurus*), the North Pacific and southern right whales (*Eubalaena japonica* and *E. australis*), Baird's and Arnoux's beaked whales (*Berardius bairdii* and *B. arnuxii*), North Atlantic and southern bottlenose whales (*Hyperoodon ampullatus* and *H. planifrons*), and the northern and southern elephant seals (*Mirounga angustirostris* and *M. leonina*).

Examples of non-antitropical allopatric species complexes include the four *Cephalorhynchus* species *C. hectori*, *C. commersonii*, *C. eutropia*, and *C. heavisidii*; they are sharply distinct morphologically but undoubtedly closely related. The Ganges and Indus river dolphins (formerly *Platanista gangetica* and *P. minor*) are presently separated geographically but are thought to have been in contact in Recent, perhaps historical, time, and Rice (1998) recognized the likely inconsequential nature of any differences by downgrading them to subspecies in *P. gangetica*. Among pinnipeds, the eight currently recognized species of southern fur seals, *Arctocephalus* spp., are almost entirely allopatric, but there are at least four breeding sites where two species (*A. gazella* and *A. tropicalis*) have begun to cooccur as populations have recovered from severe depletion by sealing in the last century (Rice, 1998). At two of these (Marion Island and Heard Island), limited hybridization has occurred, but at the others (Îles Crozet and Bass Strait) it has not been observed. In the North Pacific, there are two allopatric species of sea lions in the genus *Zalophus* (formerly three; the Japanese sea lion *Z. japonicus* is almost certainly extinct). The three seals in the genus *Pusa* are allopatric, albeit strongly differentiated. The allopatric Mediterranean monk seal (*Monachus monachus*) and Caribbean monk seal (*M. tropicalis*) are very similar morphologically (the latter is extinct). The three very similar manatee species *Trichechus manatus*, *T. senegalensis*, and *T. inunguis* are largely allopatric.

All of these are potential cases of geographical forms within a species being perceived as evolutionary species because of allopatry. In some cases, of course, the question is entirely moot. For example, while the Orinoco and Amazon drainages could merge in the future (bringing *T. manatus* and *T. inunguis* into contact and possible full interbreeding—beyond the occasional marine interbreeding now observed around the mouth of the Amazon—(Vianna *et al.*, 2006), the same could not happen for the Amazon and Congo drainages (inhabited by *T. inunguis* and *T. senegalensis*) under any conceivable geological scenario short of reversal of continental drift; thus the latter two forms are “good” species *perforce* under any species concept.

All of the marine mammal species recognized today, with one exception, were described on morphological grounds, although for the cryptic pairs *Delphinus delphis*/*D. capensis*, *Orcaella brevirostris*/*O. heinsohmi* and *Sotalia guianensis*/*S. fluviatilis*, genetic data provided part of the basis for recognition of more than one species where previously there had been thought to be only one. The exception is Perrin's beaked whale *Mesoplodon perrini*. It was discovered and described primarily based on genetic distinctness, although subsequent research uncovered divergent morphological characters (Dalebout *et al.*, 2002).

The operational criterion of at least one absolutely differentiating character that is commonly used to indicate species-level difference in morphologically based taxonomy has been extended by some to genetic characters. An example of such a potential application concerns Hector's dolphins, *Cephalorhynchus hectori*. Dolphins from east and west sides of the South Island of New Zealand were found to have no mtDNA control-region sequence haplotypes in common (Pichler *et al.*, 1998). They are thus fully diagnosable and reciprocally monophyletic terminal taxa, qualifying as species under the phylogenetic species concept (Cracraft, 1997), if such a decision were

to be based on this single genetic character. Very few would agree with such a decision, although most would probably accept designation of the two populations as *evolutionarily significant units* (ESUs, something worth saving because of unique genetic or morphological diversity) (Ryder, 1986) and agree that they should be managed separately. More recently, the trend has been toward the use of a suite of fixed genetic differences (preferably unlinked) as a criterion for specieshood; this parallels the practice of most morphological taxonomists of not recognizing a species based on a single point of difference but rather on the basis of multiple concordant characters (Avice and Wollenberg, 1997).

In a recent international workshop on cetacean taxonomy (Reeves *et al.*, 2004), it was agreed that a species is a populational entity on an independent evolutionary trajectory and that “the different approaches to species delimitation should be employed in a flexible and pragmatic way, with the basic aim of using proxies to identify irreversible divergence.” It was further agreed that multiple lines of evidence are essential. Such kinds of data could include morphological together with genetic data, or data from multiple independent genetic loci.

De Queiroz clarified the “species problem” by pointing out three separate issues subsumed under that rubric: (1) The necessary properties of species, i.e., what is a species? (2) How species come about (the process). (3) How to delimit a species. He suggested that the most reasonable answer to the first question is that a species is a “separately evolving metapopulation lineage,” much the same conclusion arrived at by the 2004 cetacean workshop. On the question of the process leading to formation of a species, he proposed that the species category is a cluster concept and that “no single process or set of processes be considered necessary for the existence of species.” He concluded that separating out the methodological question of how to delimit a species from the two other more theoretical questions would help to focus research on the important applied problems of estimating the numbers and boundaries of species.

Figure 1 The “Great Victorian Radiation” of described (nominal) species of delphinoid cetaceans.

II. The Future

The 2004 workshop also emphasized that taxa, including species, are best viewed as hypotheses about evolutionary history rather than rigidly fixed or sacrosanct entities. Thus, while Rice's (1998) classification recognized 127 species of marine mammals, the status of many of these is open to question. For example, Rice "lumped" the northern right whale (*Balaena glacialis*) and the southern right whale (*B. australis*) into a single species *B. glacialis*, but some authors have preferred to continue recognition of two species (under the genus *Eubalena*), one reason being the existence of fixed genetic differences between the forms (but see discussion earlier of allopatric species). The most recent usage is to recognize three species, including the North Pacific *E. japonica* (see Species List). In another example, Rice (1998) provisionally listed three species of humpbacked dolphins, *Sousa teuszii*, *S. plumbea*, and *S. chinensis*, but he discussed the results of taxonomic work in progress that indicate that there likely is only one species, with pronounced geographical variation. In still another example, the number of recognized species of southern fur seals (*Arctocephalus*) may decrease from eight. These and many other examples demonstrate that the *alpha* (species-level) taxonomy of marine mammals is still very much in flux: new species are almost certainly yet to be discovered, some species will be lumped (Fig. 1), and others may be split. There is still ample work for the taxonomists.

Spectacled Porpoise

Phocoena dioptrica

R. NATALIE P. GOODALL

I. Characteristics and Taxonomy

The spectacled porpoise is known from a large number of skeletons, mostly from Tierra del Fuego, but from few fresh specimens. As late as 1976, the species was known from only 10 occurrences (nine specimens) all off southeastern South America.

Phocoena dioptrica was first described by F. Lahille of Argentina in 1912 from a live, pregnant female stranded near Buenos Aires. A second female and an adult male with an improbably large dorsal fin were examined fresh by Bruch (1916); casts and mounted skeletons of these two animals are in exhibition in the Museo de La Plata. The only synonym is *P. storni*, based on a cranium from Tierra del Fuego. *Phocaena obtusata* Philippi, 1893, sometimes thought to be of this species, has been shown to be a synonym of *Cephalorhynchus eutropia*. In a revision of the taxonomy of the Phocoenidae, *P. dioptrica* was put in a new monotypic genus, *Australophocaena*, but later studies of phocoenid mitochondrial DNA returned it to the genus *Phocoena*. The specific name, *dioptrica*, refers to the double eye patch seen in most specimens. The common name in Spanish is *mar-sopa de anteojos*.

The spectacled porpoise is a robust animal with a rounded head and no beak (Fig. 1). The gape is short, and the flippers are small and situated well forward on the body. The dorsal fin is broadly triangular and shows strong sexual dimorphism, being much larger and more rounded in adult males. The rather small flukes have rounded tips with a fairly straight posterior border (illustrated in Goodall and Schiavini, 1995). At least some external measurements are available for 29 specimens from Tierra del Fuego. Eleven females ranged from 124.6 (a calf) to 203.5 cm in length. Eleven animals of unknown sex were from 94 cm, the smallest animal found, to 201 cm. Seven males measured from 109 (a neonate) to 224 cm, the largest animal known. This probably does not represent the maximum size for the species. Weights range from a fetus at 1.6 kg, to an 85-kg female, and a 115-kg male. A 135-cm male live-stranded in New Zealand; two juvenile females of 119 cm (17.5 kg) and 127 cm (21.3 kg) stranded in southern Australia (Evans et al., 2001).

The spectacled porpoise is highly distinctive with its unusual pigmentation, small head and facial features, and the large male dorsal

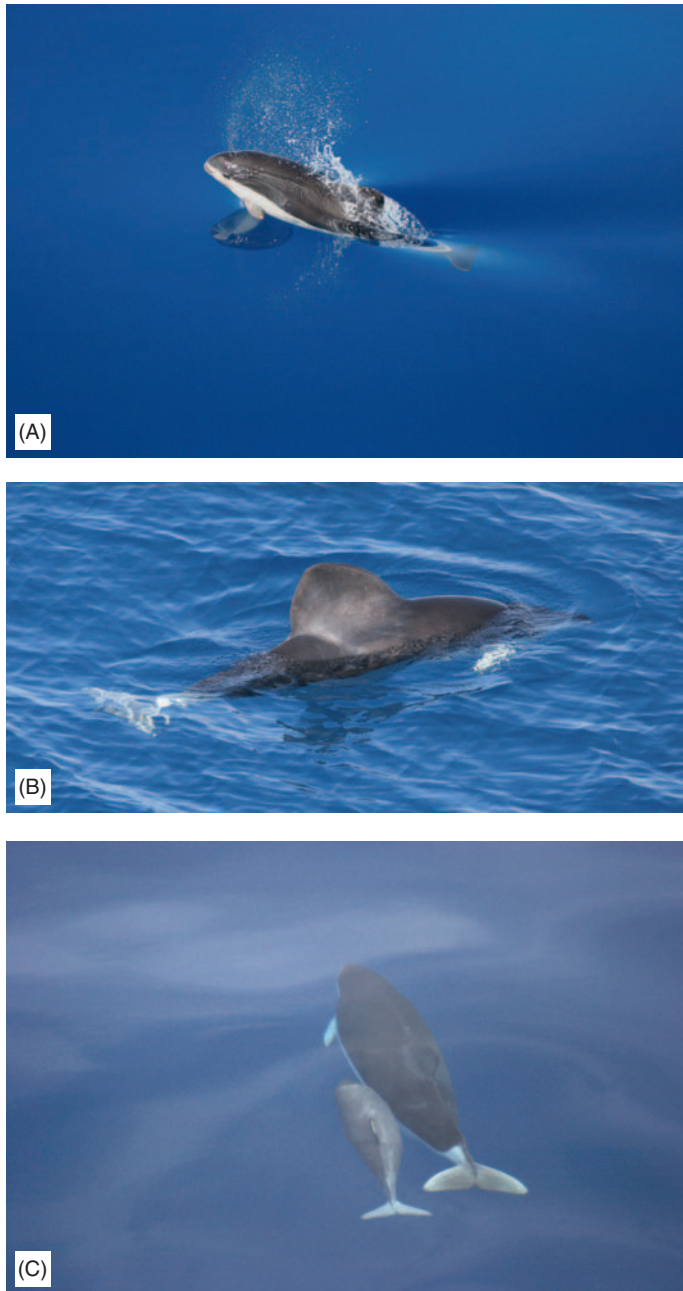

Figure 1 Spectacled porpoise (A) Surfacing female or juvenile, (B) adult male showing large dorsal fin typical of males, and (C) presumed adult female with calf. Photographs by Paula Olson, Southwest Fisheries Science Center, NOAA.

fin. Color patterns have been depicted for few animals. Young animals are dark gray dorsally and light gray ventrally with darker gray or brownish streaks, including a well-defined mouth-to-flipper stripe and gray flippers. This pigmentation changes in the adult to shining black on the dorsal surface, sharply separated on the sides from the pure white ventral region, although there is feathering on some specimens. Live animals seen at sea appear lighter (Fig. 1). Some may have a dark patch around the blowhole (Evans *et al.*, 2001) and a paler saddle around the dorsal fin. Females and juveniles appeared lighter in color than adult males; one animal had two lighter stripes

or “bridle” from the blowhole to the apex of the melon (Sekiguchi *et al.*, 2006).

The juvenile flipper stripe seems to disappear with growth. Both young and adults have dark lips surrounded by white; the eye patch is a dark circle, variably outlined by a lighter or white ring. Most animals had a dark upper tail stock and flukes, which are lighter below. The dorsal surface of the flipper varies from white or mottled gray to black, usually ending in a sharp line at the base of the flipper. The pigmentation is illustrated in detail by Goodall and Schiavini (1995) and Sekiguchi *et al.* (2006).

The large dorsal fin of the male is striking. Those from the southern South Pacific may have more pointed fins (Sekiguchi *et al.*, 2006) than those from Tierra del Fuego (Goodall and Schiavini, 1995). The young female from South Australia had 26 small tubercles on the leading edge of the dorsal fin, as do some other phocoenids (Evans *et al.*, 2001). In spite of taking tracings of all dorsal fins, we have not noticed this in Tierra del Fuego animals. The flippers of the two animals from South Australia seemed longer than those from Tierra del Fuego.

The skull has been illustrated and described in several works. Condylbasal lengths of 54 adult skulls ranged from 276 to 424 mm. The rostrum of a specimen from the Auckland Islands was relatively smaller than those of other regions (Perrin *et al.*, 2000). The teeth vary from spade- to peg-shaped and are often hidden in the gums. The posterior teeth are situated in a groove without noticeable alveoli. Tooth counts range from 16 to 26 upper and 17 to 23 lower teeth per side. The vertebral count is C7, T14, L14–16, and Ca 32–33 (66–70). From three to six cervical vertebrae may be fused. There are 13–14 ribs per side, the first 9 bicipital and 8 sternal ribs. The phalangeal count of one specimen was I = 2, II = 7, III = 4, IV = 3, and V = 4. The facial complex system has been studied (A. Purgue, personal communication), but little else is known of the internal anatomy.

II. Distribution and Abundance

The spectacled porpoise is circumpolar in cool temperate, subantarctic, and Antarctic waters. Specimens are known from southern Brazil (33°S) (Pinedo *et al.*, 2002), Uruguay, and Buenos Aires south to Tierra del Fuego, the Falklands (Malvinas) and South Georgia in the southwestern South Atlantic, Auckland and Macquarie Islands in the southwestern South Pacific; Heard and Kerguelen in the southern Indian Ocean, Burney Island, Tasmania and South Australia (Fig. 2). It is associated with the Falkland (Malvinas) current and the West Wind Drift on both sides of the Antarctic Circumpolar Front.

Sightings are rare but widely distributed: off Uruguay, Patagonia, South Georgia, Kerguelen, the Auckland Islands, south and southeast of New Zealand, Tasmania, and Heard Island. The southernmost sighting was at 64°33.5'S, 176°19'E; there are now nine sightings in Antarctic waters south of 60°S (Sekiguchi *et al.*, 2006). Surface water temperature records to date range from 0.9 to 10.3°C, with most sightings in waters of 4.9–6.2°C. The degree of contact among populations in the different oceans is unknown. Sekiguchi *et al.* (2006) reported 28 live sightings—five of them formerly reported by Kasamatsu and Joyce (1995) and Goodall and Schiavini (1995). Two more recent sightings are from the Drake Passage and east of the Falklands (Malvinas) (A. Walley personal communication).

Since it was known mainly from strandings, this species was once thought to be an inshore animal. Offshore sightings show it to be oceanic in cool temperate, subantarctic and Antarctic waters. Although sighted in deep waters far from land, spectacled porpoises

Figure 2 Known distribution of the spectacled porpoise. Open circles represent sightings, closed circles are single strandings, and the large closed circle represents over 298 specimens.

sometimes enter river estuaries and channels. We do not know why so many specimens are found on the beaches of Tierra del Fuego (298 specimens to date) and so few in other areas.

Nothing is known about the abundance of this species. It is the second-most frequent species found stranded in beach SURVEYS in eastern Tierra del Fuego but is uncommon elsewhere.

III. Ecology

There are no observations of feeding behavior. Only a few stomachs have been examined (stranded animals are soon flensed by birds). One contained a small piece of algae and another meager amounts of anchovy (*Eugraulis* sp.) and stomatopods. The stomach of a 210-cm male from southern Brazil contained remains of Ascidiaceae (Tunicata) (Pinedo *et al.*, 2002). The stomach of the 119-cm juvenile female from Tasmania contained a milk-like liquid (probably still suckling) and two sets of cephalopod beaks (*Sepia* sp.), and a partly digested ornate cowfish (*Aracana ornata*) was found in

the esophagus (Evans *et al.*, 2001). Both young animals from southern Australia were emaciated.

Killer whales (*Orcinus orca*), leopard seals (*Hydrurga leptonyx*), and sharks are possible predators of this species. The stomach of a killer whale stranded in Brazil (33°45'S) contained partial remains of two porpoises, possibly this species, but more probably *P. spinipinnis*. The small animal from Tasmania had fine, incisor-like tooth marks on its side, thought to be caused by a small shark which mouthed the porpoise after death (Evans *et al.*, 2001).

This is mainly an oceanic animal which occasionally comes near shore. Next to nothing is known of its life at sea.

The taphonomy of this species is interesting. Its “yummy factor” is very high. Predators and scavengers, especially birds such as kelp gulls and giant petrels, seem to prefer the flesh of this species; they attack dead animals immediately and nearly skeletonize them within an hour or two. The flippers, being small, are soon lost. Organs and muscle are rapidly consumed and the areas with little flesh soon become dry and hard (head, tail stock, flukes, and dorsal fin) and are

Figure 3 The spectacled porpoise can be sexed by the size of the dorsal fin.

then ignored. The probable sex of the animal can be determined by the shape and size of the dried dorsal fin (Fig. 3).

IV. Behavior and Physiology

All sightings to date have been of one–five animals. Mother–calf pairs were recorded stranded twice, but there have been no mass strandings. Five of the seven fresh specimens came ashore alive. Nothing is known of the social behavior, sounds, or associations of this species.

Group size of sightings was small, averaging 2.0 animals. Six cow–calf pairs were accompanied by one–two other animals, including an adult male (Sekiguchi *et al.*, 2006).

Spectacled porpoises are difficult to sight at sea. Swimming behavior has been described as “unobtrusive” and “inconspicuous”. Two animals circling in a small bay at South Georgia in March 1995 reacted to boat noise by STRANDING and were pushed back to deeper water. The swimming before stranding was reported as “slow and steady, with dorsal fins breaking the surface together” (A. Martin, personal communication). A re-floated calf had a respiration rate of four to seven breaths a minute. It swam with a slow, rolling motion, arching its back strongly on each dive. Most sightings described “swimming with a slow rolling motion, without any splash.” When the vessel approached, the animals swam fast, submerged just under the sea surface, producing almost continuous fluke prints on the surface. There is only one record of porpoising and none of bow-riding (Sekiguchi *et al.*, 2006).

Nothing is known of migrations or seasonal movements of this species. Most sightings have been pelagic, but some animals must move inshore off Tierra del Fuego, where they either strand due to the gently sloping beaches and high tides or die in shore-based nets.

V. Life History

Twenty-six Tierra del Fuego animals have been aged. The youngest animal that was physically mature (all epiphyses fused) had three growth-layer groups (GLGs), while one animal with five GLGs was not yet mature. Animals of over 189 cm were physically mature. The maximum age to date was 16 GLGs. The smallest neonates examined measured 94 and 109 cm. Teeth were beginning to erupt in two females of 125 (Tierra del Fuego) and 127 cm (South Australia).

One hundred sixty-five Tierra del Fuego animals were classified by physical maturity. Of these, 10 were neonates, 9 were juveniles, 99 subadults, and 47 physically adult.

Little reproductive information is available. Gonads were examined for one male, which at 205 cm and 6 GLGs was sexually mature. Males of 189–224 cm and 4–5 GLGs were physically mature. No ovaries have been examined. Three females of 183–186 cm had calves or fetuses. Female teeth show a change in layering after the second or third GLG, suggesting an early sexual maturation, as found in harbor porpoises.

Calves of 125–163 cm with unerupted teeth stranded from February to May; birth is probably in the late southern spring or summer (November–February). A calf was seen in December off Heard Island. During IWC IDCR and SOWER cruises, six small calves accompanied by a cow were seen from late December to mid-February, confirming the above (Sekiguchi *et al.*, 2006). There is no information on pregnancy rates, gestation, or lactation periods.

No ectoparasites have been reported. Nematodes were found in the blowhole and nasal sacs of the Lahille specimen and in the stomachs of three animals from Tierra del Fuego. The stomach of a 210-cm male from southern Brazil contained fragments of *Anisakis simplex* (Pinedo *et al.*, 2002). No parasites were found in the organs, body cavities, or passages of two young animals from southern Australia. Nothing else is known of parasites or disease.

VI. Interactions with Humans

One small, emaciated 127-cm female, probably still nursing, which live-stranded on March 24, 1997, at Horseshoe Bay, off Port Elliot, South Australia, was kept in captivity at the RSPCA marine rescue unit, Adelaide. Although it was medicated and force-fed, the animal died early on March 29 (Evans *et al.*, 2001).

The 119-cm female from Tasmania had lacerations near the dorsal fin which may have been from a boat propeller.

Remains of spectacled porpoises were found in 6000- and 1400-year-old kitchen middens of the canoe people in Tierra del Fuego, who harpooned cetaceans for food (Piana *et al.*, 1985). In the twentieth century, whaling captains off South Georgia and fishermen off Uruguay also hunted spectacled porpoises for food. The first four specimens known came ashore alive and were collected by fishermen. There is no known deliberate exploitation of this species at present. At least some (and possibly most) of the specimens found in Tierra del Fuego were taken incidentally in coastal gillnets; the location of the dead animals coincides with that of fishing areas (Goodall *et al.*, 1994; Goodall and Schiavini, 1995). At least one animal died in offshore bottom or mid-water trawls off Patagonia.

None of the biological information needed for conservation and management is available.

Sperm Whale

Physeter macrocephalus

HAL WHITEHEAD

Sperm whales (*Physeter macrocephalus*) are animals of extremes. They have unusually large body sizes, sexual dimorphism, brain sizes, home ranges, dive depths, and dive times; they have an ecological role that may be unrivaled in the ocean; and their vocalizations, social structure, and historical relationship with humans are all remarkable. The likelihood of evolutionary or ecological links between these extreme attributes forms one of the scientific attractions of this animal (Whitehead, 2003).

A potential key to the sperm whale's simultaneous possession of a wide range of extreme biological attributes lies in a series of remarkable parallels with the African elephant (*Loxodonta africana*). These include large body sizes, brain sizes, substantial sexual dimorphism, similar life history variables, large ranges, remarkably congruent matrilineally based social systems, and breeding systems in which males roam between groups of females and generally only mate successfully when in their late twenties or older. The highly evolved spermaceti organ may have

paralleled the trunk (another extreme nose) in allowing the animals efficient access to a wide range of resources. Meanwhile, in these animals, large sizes and cooperative societies gave efficient defense against predators, allowing long lives. Long, safe lives, in turn, promote the formation of significant long-term relationships among animals. Thus elephants and sperm whales evolved in highly social populations, near carrying capacity, and become dominant members of their ecological guilds. However, such animals are not well adapted to recovering from sudden depletion. Both the elephant and the sperm whale have been heavily hit, and, because their social structures are so important, exploitation has had consequences beyond animals killed directly.

I. Characteristics and Taxonomy

In 1758, Linnaeus described four sperm whales in the genus *Physeter*. It soon became clear that all refer to the same species, but there has been a long, and sometimes contentious, debate as to whether *P. catodon* or *P. macrocephalus* has precedence. Currently, most, but not all, authorities prefer *P. macrocephalus*.

The common name, “sperm whale,” may have resulted from whalers misinterpreting the function of the spermaceti oil found in the massive forehead of the whale, or the fact that the cooled spermaceti has some physical resemblance to mammalian sperm.

The closest living relatives of the sperm whale are the much smaller dwarf and pygmy sperm whales (*Kogia breviceps* and *K. sima*). Sperm whales seem to have separated from other odontocetes early in modern cetacean evolution, about 20–30 million years ago. See SPERM WHALES: EVOLUTION for more information.

Sperm whales are the largest of the odontocetes (Fig. 1), and the most SEXUALLY DIMORPHIC cetaceans in body length and weight. While adult females reach about 11 m in length and 15 tons, a physically mature male is approximately 16 m and 45 tons (Rice, 1989).

The most distinctive feature of the sperm whale is a massive nasal complex, one quarter to one-third of the length of the animal, situated above the lower jaw and in front of the skull. It principally contains the spermaceti organ, which is enclosed in a muscular “case” (Fig. 2). This is a roughly ellipsoidal-shaped structure made of spongy tissue filled with spermaceti oil and bounded at both ends by air sacs. Between the spermaceti organ and the upper jaws is the “junk,” a complex arrangement of spermaceti oil and connective tissue. Spermaceti oil, which has the properties of a wax, differs chemically from the oils found in the “melons” of most other odontocetes.

There is considerable asymmetry in the parts of the skull and air passages that surround the spermaceti organ. This is externally manifested most clearly by a blow which is pointed forward and to the left from the tip of the snout. Compared with the blows of similar-sized baleen whales, the blow of a sperm whale is comparatively weak, low, and hard to see.

Behind the sperm whale's skull lies the largest BRAIN of any animal (mean of 7.8 kg in mature males). However, as a proportion of body size, the sperm whale's brain is not remarkable, and we have no direct information on the sperm whale's cognitive abilities, although its complex social system is consonant with those found in other cognitively advanced mammals.

The sperm whale has 20–26 large conical teeth in each rodlike lower jaw. These teeth do not seem to be necessary for feeding, as they do not erupt until near puberty, and well-nourished sperm whales have been caught that lack teeth, or even lower jaws. The teeth in the upper jaw seem to be vestigial and rarely erupt.

Large corrugations cover most of the body behind the eye, but the surface of the head and the flukes are smooth. The majority

Figure 1 Young male sperm whale (*Physeter macrocephalus*) off Kaikoura, New Zealand. Photo courtesy B. Würsig.

Figure 2 A diagram of the head of a sperm whale (*Physeter macrocephalus*). From Ellis (1980).

S of the body is dark gray in most sperm whales, but there is often a bright white lining to the mouth and sometimes white patches on the belly. The occasional sperm whale has larger white patches, especially in mature males, around the head. The flippers are relatively small and paddle shaped, and the flukes are fairly flat and triangular shaped. The dorsal fin is low, thick, and usually rounded. Especially in mature females, it may be topped by a white or yellowish rough callus. The dorsal ridge, behind the dorsal fin, consists of a series of large crenulations.

II. Distribution and Abundance

With the exception of humans and killer whales (*Orcinus orca*), few animals on EARTH are as widely distributed as the sperm whale.

They can be seen near the ice-edge in both hemispheres and are also common along the equator, especially in the Pacific. As with so many aspects of sperm whale biology, the sexes have very different distributions.

Although sperm whales have been sighted in most regions of deep water, there are some areas which the whalers called “grounds,” where they are more abundant. Many of the grounds coincide with areas of generally higher primary productivity, usually resulting from upwelling, although there are grounds in apparently unproductive waters, such as the Sargasso Sea (Jaquet, 1996).

Concentrations of a few hundred to a few thousand sperm whales can be found in areas a few hundred kilometers across characterized by a relatively high deep water biomass and usually situated within

Figure 3 Worldwide distribution of sperm whales (*Physeter macrocephalus*): Females and males in green and just adult males in red.

grounds. Sometimes aggregations of 50 or more sperm whales can be found within a few kilometers, presumably the result of concentrations of food.

Female sperm whales almost always inhabit water deeper than 1000 m and at latitudes less than 40° (except 50°N in the North Pacific), corresponding roughly to sea surface temperatures greater than 15°C (Fig. 3) (Rice, 1989). Although sometimes seen close to oceanic islands rising from deep ocean floors, most female sperm whales are far from land.

Young male sperm whales accompany the females in tropical and subtropical waters. On leaving their female relatives, sometime between 4 and 21 years of age, the males gradually move to higher latitudes: the larger and older the male, the higher the average latitude. Large males may be found near the edge of pack ice in both hemispheres, although they return to the warm water breeding grounds on an unknown schedule.

The large males of high latitudes can be found over almost any ice-free deep water, but, like the low latitude females, they are more likely to be sighted in productive waters, such as those along the edges of continental shelves. However, in some areas, such as off New York and Nova Scotia, the large males are sighted regularly in waters less than 300 m deep.

Extrapolation from surveys of sperm whale density that covered 24% of their global habitat suggests a current population of about 360,000 animals (CV = 0.36), down from a pre-whaling population of about 1,110,000 whales (Whitehead, 2002).

Information on stock structure in sperm whales is confused, but rather few differences have been found between animals in different ocean areas (Dufault *et al.*, 1999). Genetic studies have been unable to find clearly distinct stocks at geographical scales of less than an ocean basin (Lyrholm *et al.*, 1999). Sperm whales worldwide are remarkably homogeneous in the mitochondrial, maternally transmitted, genome. Explanations for this unexpected result (also found in pilot, *Globicephala* spp., and killer whales) include a historical population bottleneck, a demographic consequence of the result of these whales' matrilineal social system, increased selection on the mitochondrial

genome, or the indirect effects of selection of matrilineally transmitted cultural traits (see CULTURE IN WHALES AND DOLPHINS).

III. Ecology

The sperm whale has a most catholic DIET consisting of many of the larger organisms that inhabit the deeper regions of the oceans. Females appear to principally eat squids weighing between 0.1 and 10 kg. Favored taxa include Ommastrephidae, Onychoteuthidae, Gonatidae, Pholidoteuthidae, Octopoteuthidae, Histioteuthidae, and Cranchiidae (Kawakami, 1980). Of these, the histioteuthids, mesopelagic gelatinous pelagic cephalopods weighing about 0.1–1 kg, have featured at or near the top of the list of preferred food items in several studies of sperm whales. Females also eat larger prey, such as the giant squid (*Architeuthis* spp.) and the jumbo squid (*Dosidicus* spp.), as well as noncephalopod prey, especially demersal and mesopelagic fish.

Males use the same squid taxa as females, but tend to eat larger individuals. In addition, they eat species that are largely restricted to higher latitudes such as the colossal squid (*Mesonychoteuthis hamiltoni*) of Antarctic waters (Clarke, 1987) and are also more likely to eat demersal fish (including sharks, rays, and gadoids) than females. Off Iceland and in the northern Gulf of Alaska, their primary food is fish.

Sperm whales have competitors for many of these food items—beaked whale (Ziphiidae) and elephant seals (*Mirounga* spp.) also eat mesopelagic squid—and there may be important nonmammal predators of the species that the sperm whales use. For instance, the jumbo squid eats the smaller histioteuthid squids. Although we know virtually nothing of the quantitative ecology of the deep ocean, sperm whales, because of their size and numbers, seem to dominate this trophic level in terms of biomass removed (Clarke, 1987; Whitehead, 2003). Rough estimates of the worldwide consumption of prey by the world's sperm whale population, about 100 million metric tons per year, are comparable with the current annual catch by all human marine fisheries.

Killer whales have been observed attacking sperm whales. They were usually unsuccessful, although at least one sperm whale was

killed during a well-documented encounter off California (Pitman *et al.*, 2001), and sperm whale remains have, very occasionally, been found in the stomachs of killer whales. Pilot whales have been seen harassing sperm whales on a number of occasions (Fig. 4), but whether they are any real threat to the much larger sperms is uncertain. Large sharks are also potential predators, especially of young animals (Best *et al.*, 1984).

IV. Life History

The sperm whale is the epitome of the “K-selected” mammal, one presumed to have evolved in an environment of competition for resources with members of its own species. It has a very low birth rate, slow growth, slow maturation, and high survival.

Young are born, almost always singly and with an equal sex ratio, following an approximately 14–16-month gestation (Best *et al.*, 1984). Although sperm whales may eat solid food before their first birthday, they continue suckling for several years. The females reach sexual maturity at about age 9 when roughly 9 m long, at which age growth starts to slow (Best *et al.*, 1984). They give birth roughly once every 5 years, although pregnancy rates have been found to vary between areas and in the same area at different stages of exploitation by humans. Female reproductive rates decline with age, and very few give birth after age 40. Females reach physical maturity when growth ceases, at about 30 years old and 10.6 m long.

Males, which are slightly larger than females during the first 10 years of life, continue to grow at a substantial rate until well into their 30s, finally reaching physical maturity at about 16 m long when roughly 50 years old. In males, puberty is prolonged, lasting approximately between ages 10 and 20 years old. However, males seem not to generally take much of an active role in breeding before their late 20s (Best, 1979).

Rates and causes of natural mortality are not well known. Longevity can be at least 50 years. Groups occasionally mass strand on shorelines, usually with fatal results for all members.

V. Behavior and Physiology

A. Vocalizations

The principal function of the spermaceti organ and its associated structures (the junk, air sacs and passages, and the *museau de singe*

clapper system at the front of the organ) (Fig. 2) is to form, and focus, the sperm whale’s click, making an extremely powerful communication and ECHOLOCATION system (Cranford, 1999; Møhl *et al.*, 2000). The vocalizations of sperm whales consist almost entirely of clicks, although a few relatively quiet “squeals” and “trumpets” are made. However, these clicks are used both for foraging (see below) as well as social signals.

“Codas,” stereotyped series of 3–20 clicks lasting 0.2–2 sec, are heard in social situations. Groups of females have distinctive repertoires of codas. In the Pacific, groups are delineated clearly into clans by distinctive coda repertoires (Rendell and Whitehead, 2003). Coda repertoire is probably acquired culturally from within family units.

Whereas codas are heard principally from social females, another form of click, the “slow click” or “clang,” in which distinctively ringing clicks are repeated every 6–8 sec, is largely or entirely produced by large males (Weilgart and Whitehead, 1988). The function of slow clicks is not clear, but they may attract females, repel other males, or be used to ECHOLocate off other whales.

B. Movement

Scientists have studied the movements of sperm whales using photoidentification, satellite tags, and artificial marks, as well as by following groups over periods of a few days. Sperm whales usually move through the water at about 4 km/h. When feeding conditions are poor, their tracks are straight, resulting in daily displacements of about 90 km/day. However, when food is plentiful, the animals stay in much smaller areas 10–20 km across. Female home ranges seem to be generally of the order of 2000 km across. Some males roam more widely, but others are found quite consistently over several years in restricted coastal waters.

Migrations of the sperm whale are not as regular or as well understood as those of most baleen whales. In some midlatitudes there appears to be a general seasonal north–south migration, with whales moving poleward in summer, but, in equatorial and some temperate areas, there is no clear seasonal migration (Whitehead, 2003).

C. Social Structure

The life of a female sperm whale is overwhelmingly social. She is always in the company of other females, some of whom are her

Figure 4 Sperm whales (*Physeter macrocephalus*) being harassed by a school of several dozen short-finned pilot whales, *Globicephala macrorhynchus*, in the northern Gulf of Mexico. Photo courtesy B. Würsig.

relatives. The basic element of sperm whale society is a family unit, consisting of about 12 females and their young (Whitehead, 2003). Most females spend their lives in the same unit, with their close female relatives. However, units may contain two or more matrilineal and there are recorded instances of females switching units. Two or more units may travel together for a few days as a cohesive group of about 20 animals.

Within the social units there is communal care for the young, with evidence for females suckling calves who are not their own offspring (e.g., Best *et al.*, 1984). Young sperm whale calves do not seem to be able to dive to foraging depths for as long as their mothers. Instead they remain at or near the surface, moving between the members of their group while they are breathing. This babysitting begins soon after birth. Members of groups with young calves seem to intentionally stagger their dives, thus providing better babysitting for the young.

When faced with predators, particularly killer whales, female sperm whales quickly cluster. Two defensive patterns have been described. In the “marguerite” or “wagon wheel” formation, the members of the group place their heads together at the hub, with the bodies radiating out like spokes. In contrast, when adopting the “heads-out” formation, the sperm whales face their attackers, tightly aligned in a rank, and seem to principally use their jaws for defense. Young calves stay toward the center of whichever defensive formation is adopted. Females have been observed risking themselves to assist unit members in peril during a killer whale attack (Pitman *et al.*, 2001).

Young males leave their natal unit when between 4 and 21 years old and then are found in loose aggregations, sometimes called “bachelor schools,” with other males of approximately the same size and age (Best, 1979). As the males age and grow they move to generally higher latitudes and the aggregation sizes become smaller, until the largest males are usually alone. Repeat association between males on more than 1 day are rarely observed (Letteval *et al.*, 2002). However, mature and maturing males do strand on beaches together, suggesting significant social relationships on a scale not readily apparent to human boat-based observers.

The large mature males, in their late 20s and older, return to the tropical breeding grounds to mate, although the timing of such visits is largely unknown. When on the breeding grounds, the large males roam between groups of females, usually spending just a few minutes or hours with each (Whitehead, 2003). They are presumably searching

for receptive females. There are no clear descriptions of mating itself. The breeding males seem to roam independently and generally avoid one another, although they are sometimes observed within the same group of females, and occasionally fight. These fights are rarely observed, but many large males have deep scars made by the teeth of other males.

D. Behavioral Modes

Sperm whales possess two quite distinct behavioral modes: foraging and social/resting (Whitehead and Weilgart, 1991). While foraging, the animals make repeated deep dives. Modal dives are about 600 m and for about 45 min (Watwood *et al.*, 2006), but dives can be much deeper (to over 1000 m), shallower (e.g., when in shelf waters 200 m deep), or longer. Between dives the whales come to the surface to breathe for about 9 min. The dive is usually signaled by the raising of flukes out of the water. The descent to depth, as well as the return to the surface, can be nearly vertical.

While foraging, sperm whales generally make regularly spaced clicks at intervals of 0.5–1.0 sec, a searching sonar (Watwood *et al.*, 2006). These are interrupted by creaks, consisting of clicks with accelerating rates, which are assumed to indicate short-range sonar during prey capture events. Small gelatinous squid, such as histioteuthids, are usually both relatively inactive and bioluminescent, so these can be captured using visual or acoustic cues. Larger, more muscular animals may need active chasing.

Groups of females and immatures spread out over 1 km or more of ocean when foraging, often forming a rank aligned perpendicular to the direction of travel. In contrast, males seem generally to forage independently.

Female and young sperm whales spend approximately 75% of their time foraging (Whitehead and Weilgart, 1991). However, during periods of several hours, often in the afternoon, they gather at or near the surface. At these times, their behavior is highly variable. Sometimes the animals may lie still and quiet, closely clustered, for hours at a time, apparently resting (Fig. 5). Particularly at the start or end of non-foraging periods their behavior may be much more active, with breaches, lobtails, animals rolling, maneuvering and touching one another, and codas and creaks being emitted. Large males also lie quietly at the surface for long periods, but they are usually alone unless accompanying a group of females.

Figure 6 Open-boat sperm whaling. From Beale (1839).

VI. Interactions with Humans

In the early eighteenth century, New Englanders began to hunt sperm whales for commercial purposes off their own shores. Over the next two centuries, sperm whaling grew to be a major worldwide industry. By the 1830s, about 5000 sperm whales were being killed each year by whalers from several countries, especially the United States, and the oil produced was a vital element of the burgeoning industrial revolution (Starbuck, 1878). The whalers sailed all oceans of the world in their square-rigged ships. On sighting sperms, open whaleboats were lowered and rowed or sailed to the whales. The whalers threw harpoons into the animals, and then killed them using lances (Fig. 6). Dead animals were towed to the whale ship, where the oil was baled from the spermaceti organ, the BLUBBER stripped from the body and boiled to render the oil, and virtually all the remainder of the carcass discarded. In the nineteenth century, sperm whaling had become such a significant enterprise that it had important effects on fields as diverse as literature (Herman Melville's great novel "Moby Dick") and ocean exploration. The open-boat hunt declined during the latter half of the nineteenth century because of the development of petroleum products as alternatives for sperm oil, an apparent decline in the sperm whale population, and for other reasons.

After about 50 years of relative peace, sperm whale populations were again hit hard following World War II. The whalers of the twentieth century chased sperm whales using mechanized catcher vessels equipped with sonar and killed them using explosive harpoons shot from harpoon guns. This whaling was also widely distributed and took a large number of sperms (up to 30,000 per year). However, unlike their earlier counterparts, the modern whalers used almost all of the whale, and preferentially targeted males. Much, but not all, of this whaling was carried out under the auspices of the International Whaling Commission (IWC). Sperm whale populations, particularly the male portions, were reduced substantially. Commercial sperm whaling declined in the 1970s and 1980s and virtually ceased with the IWC moratorium in 1988. Currently there is a small catch of sperm whales in Lamalera, Indonesia, using primitive methods, and a "scientific" hunt for sperm whales by Japan.

Nowadays, most interactions between sperm whales and humans are more benign. Sperm whales are the principal subjects of WHALE-WATCHING operations in several locations, including

Kaikoura (New Zealand), Andenes (Norway), the Azores (Portugal), and Dominica (West Indies). Scientists study their behavior from small vessels in these and a few other locations.

The sperm whale has survived the onslaught of the whalers better than most other large whales. There are still a few hundred thousand sperm whales left in the ocean, sperm whale food is of little interest to human fishers, and their deep water home is further from most sources of pollution than the preferred habitat of most other marine mammals. However, the effects of whaling seem to be lingering. In the southeast Pacific, where modern whaling on males was particularly severe, large breeding males are still scarce and calving seems depressed below the replacement rate (Whitehead *et al.*, 1997). In other parts of the world, the picture appears brighter. For instance, in the northwest Atlantic, where sperm whales were hit hard by whaling in the eighteenth and nineteenth centuries but largely spared by modern whalers, the population appears relatively healthy. However, sperm whales have very low reproductive rates even in the best of times—they do not recover quickly when depleted. They are also killed inadvertently in a range of ways, including entrapment in fishing gear, choking on plastic bags, and collision with ships. The chemical POLLUTION levels in their blubber are generally higher than that of baleen whales, but lower than in inshore odontocetes.

Sperm Whales, Evolution

GURAM A. MCHEDLIDZE

Sperm whales include the cetacean families Physeteridae (the modern sperm whale) and Kogiidae (the modern pygmy and dwarf sperm whales). Modern sperm whales are represented by two genera only, but sperm whales were much more diverse in past times. Phylogenetically, sperm whales are usually thought to be close to the root of the odontocetes, and they retain many characters that are primitive for odontocetes. They do, however, also have some highly derived features and are not very similar to the primitive Eocene cetaceans (archaeocetes) that they are descended from.

Physeterids and kogiids may be subsequent branches of the basal odontocete phylogenetic tree, or both may be derived from a common sperm whale ancestor, such as *Ferecetoherium* (see Evolution of Marine Mammals).

I. Physeteridae

Physeterids (including the modern sperm whale *Physeter macrocephalus*) are highly specialized for teutophagy (eating cephalopods such as squid) at great depths, and many parts of sperm whale anatomy show adaptations for this behavior. Some specialized morphologies are already present in the oldest known physeterid, *Ferecetoherium kelloggi* (Mchedlidze, 1984), from the late Oligocene of Azerbaijan, but many fossil sperm whales were probably fisheaters.

The earliest physeterid, *Ferecetoherium*, was small (approximately 5 m long) and had a small head. An increase in size and head size occurred in the Miocene, and modern *Physeter* has a body length of 16 m in females and 21 m in males. The head of *P. macrocephalus* is approximately one-third the size of the body. An increase in body size happened throughout physeterid evolution (Fig. 1).

Ferecetoherium had a relatively narrow rostrum. Miocene sperm whales are characterized by the widening of the rostrum. This widening took different paths in different species. In some clades, widening occurred in the maxillae and premaxillae, whereas in other clades only one of these elements enlarged. In the Miocene *Diaphorocetus* and *Orycterocetus*, the premaxilla and maxilla are nearly equal in width near the base of the rostrum, but the tip of the rostrum consists entirely of the premaxillae. In contrast, in *Physeter* the maxillae make up nearly all of the rostrum, and the premaxillae are only exposed near the tip of the rostrum. Widening of the rostrum was probably the result of the enlargement of the spermaceti organ, a large structure housed in a depression (the supracranial basin) on the forehead. The supracranial basin is characteristic of sperm whales, although it is relatively small in older forms. Posteriorly, this basin is bounded by the supraoccipital and the posterior plate of the right premaxilla, and laterally vertical plates of the frontals bound the basin. In modern *Physeter*, the lateral walls of the supraoccipital basin are formed by the maxillae. All physeterids, including *Ferecetoherium*, are also characterized by strong asymmetry of the rostrum, particularly the premaxillae and nasals.

Macroevolutionary changes also occurred in the mandible. In modern sperm whales, the maxilla (upper jaw) is much wider than the mandible as a result of the widening of the rostrum and a narrowing of the mandible. These give the lower jaw a peculiar undersized image. This mismatch evolved gradually in physeterids. *Ferecetoherium* has a primitive mandible, not unlike that of archaeocetes. In late Eocene archaeocetes, the lower margin of the mandible is horizontal, but the mandibular depth increases posteriorly and teeth are present on the ascending ramus. Physeterid specializations in the mandible of *Ferecetoherium* include the parallel edges of the ramus, the superior displacement of the mandibular condyle, and the reduced coronoid process.

As a rule, modern *Physeter* only has teeth in the lower jaw, although occasionally an individual is found with upper teeth. Upper teeth are still present in physeterids from Oligocene through middle Miocene. Teeth in *Physeter* are positioned in the upper edge of the mandible. In *Ferecetoherium*, posterior teeth are rooted in the upper edge of the mandible, but anterior teeth (except the first tooth) are implanted more laterally. The latter condition occurs in all teeth of *Kogia*. All physeterids have homodont and polydont teeth, as do most extant odontocetes. The tooth crowns of physeterids are small, and their roots are more shallow than those of archaeocetes.

Figure 1 The skeleton of the modern sperm whale (*Physeter macrocephalus*). The concave area on the snout and forehead is the supracranial basin.

In physeterid evolution, the length of mandibular symphysis increased from one-twelfth of the length of the mandible in the Oligocene to one-fourth in the Miocene, and one-half in *Physeter*. The mandible of *Ferecetotherium* has 27 teeth, whereas that of *Diaphorocetus* has 14. In the middle Miocene *Aulophyseter morricei*, upper teeth, if present at all, were only lodged in the gums, and all upper teeth were lost in the upper Miocene *Placoziphius duboisii*.

The great differences in the shape of the face and jaws between early physeterids and modern ones suggest that the teutophagic specializations of *Physeter* may not have been present in extinct relatives. It is possible that Oligocene and Miocene physeterids were ichthyophagous (fish-eating), as were most cetaceans. Modern sperm whales feed on deep-sea squid, and it is likely early physeterids were not deep-sea animals.

The forelimb of physeterids is very different from that of Eocene cetaceans, but similar to that of other odontocetes. The humerus is shortened and the elbow is immobile. The hand forms a flat, smooth surface with no differentiation of individual fingers, causing the entire limb to be an effective rudder. In early physeterids, the head of the humerus changed considerably. The humeral head of *Ferecetotherium* is deviated externally and faces caudally, but the tubercles are situated anteriorly, as in archaic cetaceans. Whereas *Ferecetotherium* retains a greater and lesser tubercle of the humerus, the lesser tubercle of Miocene physeterids is enlarged greatly and the greater tubercle reduced. *Physeter* has a weak lesser tubercle, set medially on the humerus.

II. Kogiidae

One genus with two modern species constitutes the Kogiidae (*Kogia brevipeps* and *K. sima*). *Kogia* is similar to *Physeter* but the body of *Kogia* is much smaller (body length approximately 4 m) and the head is smaller (one-sixth to one-eighth of the body). The spermaceti organ is smaller than in *Physeter*, the blowhole more posterior, and the rostrum shorter. Proportions of the head in *Physeter* embryos are similar to those of adult *Kogia*. This suggests that these cetaceans are closely related and that *Physeter* has a more derived facial morphology.

Kogiids are poorly represented in the fossil record, and most specimens are incomplete, although some localities have yielded good material. The genus *Kogiopsis* is known from a single mandible, and fragmentary skulls are known for Miocene *Scaphokogia* and Pliocene *Praekogia*. Another trend in the evolution of kogiids is the reduction of dental enamel. This trend started in the Miocene. In modern *Kogia* some enamel covers the tips of the teeth, whereas Miocene kogiids lack all enamel.

Phylogenetically, *Scaphokogia* is a basal branch of kogiids, retaining primitive morphologies of rostrum, premaxillae, and intermaxillary groove. It is, however, more derived than other kogiids in having a well-developed supracranial basin. *Scaphokogia* may represent an

early, specialized branch of kogiids, the subfamily Scaphokogiidae. These went extinct near the end of the Miocene. *Praekogia* is closely related to *Kogia* in that both the nasal passages are anterior due to poorly developed telescoping. The new genus *Aprixokogia* from the late Tertiary of North Carolina is known from a well-preserved skull (Whitmore and Kaltenback, 2008).

Spermaceti

DALE W. RICE

Spermaceti is the term given to the liquid waxes present in the head of the sperm whale (*Physeter macrocephalus*). The word comes from the late Latin *sperma*, "sperm" or "semen," and the classical Latin *ceti*, genitive singular of *cetus*, "sea monster" or "whale"—literally "semen of whale." It was bestowed because of the superficial resemblance of these waxes to semen. The vernacular name "sperm whale" is a contraction of "spermaceti whale."

Spermaceti is present in greatest abundance in the spermaceti organ, or "case," and in the "junk." The case is an elongated barrel-shaped organ, which makes up much of the bulk of the sperm whale's huge head. It consists of soft, white, spongy tissue that is saturated with spermaceti. The junk lies below the case and above the rostrum of the skull; it is also white, but it is more solid than the case and is faintly divided into segments by a series of transverse septa composed of denser tissue. It is also heavily saturated with spermaceti (Clarke, 1978; Rice, 1989). At body temperature, the spermaceti will flow freely as a clear, almost watery, fluid from the case and junk when the latter are slashed with a knife. As soon as it cools to about room temperature, however, it solidifies to a whitish wax similar to

paraffin but not as hard. The different fractions may be separated by pressing at various temperatures between 10 and 35°C.

The oils of sperm whales and the other toothed whales (suborder Odontoceti) differ in composition from those of the baleen whales (suborder Mysticeti) (Gilmore, 1951). Those of the baleen whales consist exclusively of triglycerides. Triglycerides are esters compounded from one molecule of the tribasic alcohol glycerol ($\text{CH}_2\text{OH}\cdot\text{CHOH}\cdot\text{CH}_2\text{OH}$) and three molecules of various fatty acids. Lipids of the toothed whales, however, consist of a mixture of triglyceridic oils and wax esters, together with a small proportion ($\geq 2\%$) of diacyl glyceryl ethers in some species. These waxes are compounds formed from one molecule of a higher monobasic alcohol, mostly cetyl ($\text{C}_{16}\text{H}_{33}\text{OH}$) or oleyl ($\text{C}_{18}\text{H}_{35}\text{OH}$), and one molecule of a fatty acid.

Although wax esters are present in all odontocetes, only in the giant sperm whale and the Amazon river dolphin (*Inia geoffrensis*) (family Iniidae) do they comprise a majority of the lipids present. In sperm whales the ratio of waxes to triglycerides varies with position in the body. An early study (Hilditch and Lovern, 1928) found that wax esters comprised 74% of the spermaceti in the head, but only 66% of the BLUBBER oil. More detailed studies revealed that even within the head, the proportion of wax esters varies with sex and age as well as position. In the spermaceti case this proportion ranged from 38 to 51% in a calf, 58 to 87% in an adult female, and 71 to 94% in an adult male. Proportions in the junk of the same three whales were 41–62, 65–94, and 91–98%, respectively (Morris, 1975).

Both the triglycerides and the waxes of the sperm whale are characterized by the virtual absence ($< 2\%$) of isovaleric acid, a branched, short chain (C_5), unsaturated fatty acid. This trait is shared with pygmy sperm whales (*Kogia breviceps*) (family Kogiidae), beaked whales (family Ziphiidae), and some river dolphins (families Platanistidae and Iniidae). This contrasts with the high proportion of isovalerate lipids in delphinoid cetaceans (families Monodontidae, Delphinidae, and Phocoenidae) (Litchfield *et al.*, 1975).

Wax esters of the sperm whale differ from those of all other toothed whales except the Amazon dolphin (family Iniidae) in that they consist predominantly of relatively long chain ($\text{C}_{10}\text{--}\text{C}_{22}$) fatty acids (Litchfield *et al.*, 1975). The fatty acid composition of wax esters in the case is mainly shorter chained, saturated acids at the center, with longer chained, more unsaturated acids at the periphery. In the junk, the anterior portion is mainly shorter chained saturated acids, whereas the posterior portion consists of longer chained, more unsaturated acids. The specific proportions of 25 fatty acid moieties in wax esters from the head of an adult female sperm whale were tabulated by Morris (1975).

Because of its heterogeneous lipid composition, and possible internal temperature gradients, the velocity of SOUND through the spermaceti organ varies in a way that could collimate or focus sound waves (Flewellen and Morris, 1978). This accords with the prevailing hypothesis that this organ functions as an acoustic lens to channel acoustic emissions.

In the nineteenth century when the old-style open-boat whale fishery was flourishing, the oil in the head of the sperm whale (the spermaceti proper) was simply ladled from the case and junk, and was kept separate from the oil that was rendered from the blubber (the remainder of each carcass was discarded). Spermaceti was favored for making candles, and the liquid blubber oil was used as a lamp fuel. In the years from 1804 to 1925, a total of 164,073,918 gallons of sperm oil (including spermaceti) was landed at US ports. This quantity was the product of an estimated 262,134 sperm whales killed around the globe. Lesser quantities were taken by vessels out of British, French, and other foreign ports. In the peak year of 1837,

American landings totaled 5,349,138 gallons, representing an estimated kill of 7472 sperm whales, and were worth \$4,413,039 at the average going price of 82.5 cents per gallon. Discovery of the first commercially recoverable reserves of petroleum in 1859 triggered the phenomenal growth of the oil industry, so the demand for sperm oil plummeted. The last old-style American sperm-whaling voyage was made in 1925.

In the twentieth century the modern harpoon-cannon whaling industry was carried out from factory ships and shore stations around the world. Oil was rendered from the entire carcass (minus the meat) of each whale, and that from sperm whales (“sperm oil”) was kept separate from the oil of baleen whales (“whale oil”). In the early decades of this fishery, whalers took few sperm whales because the edible oil of baleen whales brought higher returns. By the end of World War II, however, baleen whale populations had been severely depleted, and new uses were being discovered for sperm oil. Because of its unique properties, it was in great demand as a high-pressure lubricant, but it also had a diverse array of other specialized industrial uses, such as an ingredient in hydraulic fluids, inks, detergents, and cosmetics, as a plasticizer, and as an agent in the tanning of leathers and the degreasing of wool (Anonymous, 1957). The rising demand led to rapid increases in sperm whale catches, which reached a peak in 1964, when 29,255 animals were killed, yielding 898,257 barrels (=152,703,690 kg) of sperm oil. The International Whaling Commission shut down the entire whale fishery after the 1984 season. Since the cessation of whaling, substitutes for sperm oil have been found—most notably the oil from the seeds of jojoba (*Simmondsia chinensis* of the family Buxaceae), a shrub indigenous to the Sonoran Desert. Jojoba oil has chemical and physical properties similar to those of sperm oil (Harris *et al.*, 1975).

Spinner Dolphin

Stenella longirostris

WILLIAM F. PERRIN

I. Characteristics and Taxonomy

The spinner dolphin, described by Gray in 1828, is the most common small cetacean in most tropical pelagic waters. It can be seen at a great distance as it spins high in the air and lands in the water with a great splash. It can be identified externally by its

relatively long slender beak, color pattern, and dorsal fin (Fig. 1) (Perrin, 1998). The color pattern in most regions is three-part, consisting of a dark-gray cape, light-gray lateral field, and white ventral field. A dark band of even width runs from the eye to the flipper, bordered above by a thin light line. The rostrum is tipped with black or dark gray. Four subspecies are currently recognized: the globally distributed *S. l. longirostris* (Gray's spinner), the eastern tropical Pacific (ETP) endemic *S. l. orientalis* (eastern spinner) and *S. l. centroamericana* (Central American spinner), and *S. l. roseiventris*, the dwarf spinner of central Southeast Asia (Perrin, 1990; Perrin *et al.*, 1999). An additional morphologically different form has been identified off northern Mexico with aerial photogrammetry (Perryman and Westlake, 1998). In the eastern and Central American subspecies (Fig. 2), contrast between

Figure 1 A Gray's spinner dolphin (*Stenella longirostris longirostris*) in the Maldives Islands in the Indian Ocean. Photograph by Robert L. Pitman.

Figure 2 The eastern spinner dolphin (*Stenella longirostris orientalis*) lacks a bold pattern. This adult male has a forward-canted dorsal fin, unique to this subspecies and the parapatric Central American spinner (*S. l. centroamericana*). Photograph by Robert L. Pitman.

the cape and the lateral field is very faint to absent, and the ventral field may be restricted to discontinuous axillary and genital-region patches. Various intermediate color patterns are exhibited by “white-belly” spinners in a broad zone of HYBRIDIZATION between the eastern form and the more typically patterned Gray’s spinner dolphin, *S. l. longirostris*, in the Central and South Pacific. The dorsal fin in adults in all regions is basically triangular, varying from a slightly falcate right triangle to an erect isosceles triangle. In the adult male of the eastern and Central American subspecies the dorsal fin may lean slightly forward, appearing to “be on backwards.” This is correlated with the presence of a large post-anal ventral hump. Both the dorsal fin and the hump appear to be sexual displays, probably important in male–male or male–female communication or both. In calves and juveniles in all regions, the dorsal fin is on average more falcate than in adults.

Sexually mature adults examined ranged from 129 to 235 cm ($n = 1824$) and weighed 23–80 kg ($n > 33$) (Perrin, 1998; Perrin *et al.*, 2005). Males are on average slightly larger than females in body size and most skull characters.

The spinner dolphin may be confused in the tropical Atlantic with the endemic CLYMENE DOLPHIN, *S. clymene*, which is very similar in appearance and has been observed to spin, although not as

acrobatically as the spinner dolphin. In the Clymene dolphin, the beak is relatively shorter, the flipper band narrows anteriorly, the lower margin of the cape dips lower toward the ventral field (in the spinner the cape and ventral-field margins are parallel), and there is usually a dark “moustache” mark on the upper side of the beak that has only rarely been observed in spinner dolphins.

The skull (Fig. 3) can be confused with those of *S. coeruleoalba*, *S. clymene*, and *Delphinus* spp.; all have a relatively long and narrow dorsoventrally flattened rostrum, a large number of small slender teeth (about 40–60 in each row), and medially convergent premaxillae and sigmoid ramus (Perrin, 1998). It differs from the skull of *Delphinus* in lacking strongly defined palatal grooves. The rostrum is narrower at the base than in *S. coeruleoalba* (57–84 mm vs. 93–120 mm). It overlaps *S. clymene* in all skull measurements and tooth counts, but the skull (335–464 mm long in 112 adults) is proportionately longer and narrower. The vertebral count is 69–77 ($n = 90$).

The spinner dolphin is a member of the subfamily Delphininae *sensu stricto* (LeDuc *et al.*, 1999). Morphologically and behaviorally it is most similar to the Clymene dolphin, but in a cladistic phylogenetic analysis based on cytochrome *b* mtDNA sequences it was not closely linked to that species, which was the sister species of

Figure 3 The skull of *Stenella longirostris longirostris*; adult male from Florida. From Perrin and Gilpatrick (1994).

the striped dolphin, *Stenella coeruleoalba*. The morphological similarity between spinner and Clymene dolphins could be an instance of synplesiomorphy (similarity through retention of primitive characters), but the correlated spinning behavior would seem to be highly derived, a probable synapomorphy (shared derived character). This puzzling discordance between molecular and morphological/behavioral characters shows the need for further molecular and morphological investigation; a hybrid origin of *S. clymene* has been suggested as one possible explanation.

II. Distribution and Abundance

The spinner dolphin is pantropical, occurring in all tropical and most subtropical waters around the world between roughly 30–40°N and 20–40°S (Jefferson *et al.*, 2007). It is typically thought of as a high-seas species, but coastal populations and races/subspecies exist in the eastern Pacific, Indian Ocean, Southeast Asia, and likely elsewhere (Perrin, 1998; Perrin *et al.*, 1999).

Estimates of abundance exist for several regions (IUCN, 2008): whitebelly spinners in the ETP, about 800,000; eastern spinners in the ETP, about 600,000 (reduced by more than half from original size; see below); northern Gulf of Mexico, about 12,000; Hawaii, about 3,000; southern Sulu Sea, about 4,000; and southeastern Sulu Sea, about 31,000. Many other populations that exist in the Pacific, Atlantic, and Indian Oceans have not been surveyed.

III. Ecology

In the ETP, the habitats of the pelagic eastern subspecies and the eastern/Gray's intergrade/hybrid or "whitebelly spinner" are similar to that of the pantropical spotted dolphin: tropical surface water characterized by a shallow mixed layer, shoal and sharp thermocline, and relatively small annual variation in surface temperature (Ballance *et al.*, 2006). In other tropical waters, spinner dolphins are usually associated with islands and coasts, venturing out to deeper water at night to feed (Benoit-Bird and Au, 2003; Dolar *et al.*, 2003; Karczmarski *et al.*, 2005). Small and semi-isolated island populations scattered across an archipelago may comprise a metapopulation (Karczmarski *et al.*, 2005; Oremus *et al.*, 2007). The Central American spinner inhabits shallower inshore water.

In the eastern and western Pacific, the pelagic form has been shown to prey mainly on small mesopelagic fishes and squids, diving to 600 m or deeper (Perrin and Gilpatrick, 1994; Dolar *et al.*, 2003), but a dwarf subspecies in inner Southeast Asia, *S. l. roseiventris*, inhabits shallow waters in the Gulf of Thailand, Timor Sea, and Arafura Sea and consumes mainly benthic and reef fishes and invertebrates (Perrin *et al.*, 1999). Spinner dolphins are time- and efficiency-limited in their foraging, rather than being limited by available prey; they need to consume 1.25 large prey items per minute during their foraging bouts while the deep scattering layer is close to the surface (Benoit-Bird, 2004). While resting in shallow reef areas during the day, their feces may constitute an important resource for reef fishes (Silva-JR *et al.*, 2005).

Predators include sharks, probably killer whales (*Orcinus orca*) and possibly false killer whales (*Pseudorca crassidens*), pygmy killer whales (*Feresa attenuata*) and short-finned pilot whales (*Globicephala macrorhynchus*). Parasites may cause direct or indirect mortality.

IV. Behavior and Physiology

Why the spinner spins is unknown. One animal may spin as many as 14 times in quick succession. It has been suggested that the large

underwater bubble plume created by the violent spin and reentry may serve as an ECHOLLOCATION target for communication across a widely dispersed school (Norris *et al.*, 1994). It is also probable that spinning is an outgrowth of an alert state and as such has a social facilitation function. It could also—at least at times—represent PLAY. Another function proposed is to dislodge remoras; the rotation rates and orientation of the dolphin's body during reentry into the water could produce enough force to accomplish this (Fish *et al.*, 2006).

School size varies greatly, from just a few dolphins to a thousand or more. Spinner dolphins commonly school together with pantropical spotted dolphins, *S. attenuata*, and dolphins and small toothed whales of other species, and sometimes even dugongs (Psarakos *et al.*, 2003; Kiszka, 2007). Social organization in Hawaiian waters is fluid, with schools composed of more or less temporary associations of family units; the associations may vary over days or weeks (Norris *et al.*, 1994). Mating appears to be promiscuous. Adult males form coalitions of up to about a dozen individuals; the function of these is unknown. Maximum recorded movements of individuals are 113 km (over 1220 days) in Hawaii and 275 nmi (over 395 h) in the eastern Pacific (Perrin, 1998).

The whistles and burst pulses produced by spinner dolphins have been intensively studied in several areas (Lammers *et al.*, 2006); they vary in complexity geographically and with activity, serving functions that are only beginning to be understood.

The dwarf spinner dolphin as recently photographed (Perrin *et al.*, 2007) has a pink belly. This accords with the Latin name (*roseiventris*) given to it by its discoverer; however, the COLORATION is not likely a permanent characteristic but may indicate a need to dump excess heat (by dilation of blood vessels near the surface of the skin) generated by its living in very warm shallow reef waters.

V. Life History

Gestation is about 10 months. Average length at birth is about 75–80 cm. Length of nursing is 1–2 years. Calving interval is about 3 years. Females attain sexual maturity at 4–7 years and males at 7–10 years. Ovulation may be spontaneous. Breeding is seasonal, more sharply so in some regions than in others. The mating system may vary among populations. This is indicated by geographic variation in morphology and testis size. For example, in the ETP eastern spinners are more sexually dimorphic and have smaller testes than whitebelly spinners, likely indicating a greater tendency toward polygyny as opposed to polygynandry (promiscuous mating) (Perrin and Mesnick, 2003).

VI. Interactions with Humans

Large numbers have been killed incidentally since the early 1960s by tuna purse seiners in the eastern tropical Pacific; the population of *S. l. orientalis* is estimated to have been reduced to less than one-half of its original size, and since reduction of reported purse-seine mortality more than a decade ago it has grown at annual rate of less than 2%, less than the rate expected of about 4% (Gerrodette and Forcada, 2005; Wade *et al.*, 2007). Continued chase and capture in the fishery may adversely affect fecundity or survivorship (Archer *et al.*, 2001; Moore, 2004; Weihs, 2004; Cramer and Gerrodette, 2007; Noren and Edwards, 2007). Bycatches that are also likely unsustainably high occur in drift nets and purse seines in the Philippines (Dolar, 1994, 1999). As is the case for other small cetaceans caught in fishing nets, local human consumption of bycaught animals in several regions has led to the development of markets and large directed catches from unassessed populations (Perrin, 1999; IUCN, 2008), boding ill for CONSERVATION of the species in these regions.

Spinner dolphins have been kept in CAPTIVITY only in Hawaii, where some have lived for several years.

Harassment by dolphin-watching boats is emerging as a new threat to spinner dolphins at several localities in Oceania and Southeast Asia (IUCN, 2008).

Steller's Sea Cow *Hydrodamalis gigas*

PAUL K. ANDERSON AND DARYL P. DOMNING

A very large sirenian once grazed on algae along the shores of the cold North Pacific Ocean. Shipwrecked with Vitus Bering's expedition on Bering Island, the larger of the Kommandorskiye (Commander) Islands, George Wilhelm Steller (1709–1746), the only biologist to observe the species alive before its extinction around

Figure 1 A reconstruction of Steller's sea cow. Outstanding features are the relatively small head, bulky body, rough skin, whale-like flukes, and blunt unflipper-like pectoral appendages.

Figure 2 Skulls of the two recent dugongids drawn to the same scale. The *Hydrodamalis gigas* skull (left) shows the lack of teeth and the relatively undeflected rostrum compared with the downwardly deflected rostrum of *Dugong dugon* (right). The dugong's tusks and molar teeth are indicated by arrows. The Steller's sea cow's head was relatively small compared with its body and that of the dugong relatively large so that the size of the two skulls does not reflect relative body size.

1768, observed and described the sea cow and recorded his observations on external and internal anatomy, natural history, and hunting as seen during his forced stay on the island between November 1741 and August 1742.

I. Characteristics and Taxonomy

Two other common names for Steller's sea cow are the German "Borkentier," referring to its rough bark-like hide, and the Russian "kapustnik" (cabbage eater), which Steller attributed to inhabitants of Kamchatka, where dead sea cows reportedly washed ashore after storms. Because Steller's posthumously published observations (1751) predated Linnean taxonomy, the sea cow was given its formal scientific name by later authors on the basis of Steller's description (no type specimen has ever been designated). Among numerous synonyms, the generic and species names now recognized as correct are *Hydrodamalis* (Retzius, 1794); and *Hydrodamalis gigas* (Zimmerman, 1780). The latter combination was authored by Palmer (1895). The generic synonym used most commonly in the nineteenth century was *Rytina* (Illiger, 1811), improperly emended to *Rhytina*. For full synonymy and comprehensive references, see Domning (1978, 1996).

Hydrodamalis gigas (Fig. 1) was a very large toothless sirenian, a member of an order (Sirenia) consisting of completely aquatic, vegetarian, mammals. *H. gigas* was the only sirenian adapted to cool-temperate or cold climates and an algal diet. It differed from all other mammals in feeding predominantly or exclusively on algae and in having a manus composed only of carpals and metacarpals, with the

phalanges vestigial or absent. Its pectoral limb had a densely bristled blunt termination that Steller described as claw-like or hoof-like. It differed from its predecessor, *Hydrodamalis cuestae*, in lacking teeth and from most fossil and living sirenians other than manatees in having a reduced deflection of the rostrum from the occlusal plane (Fig. 2). This characteristic correlated with feeding in the water column above the bottom. Its uniquely large size may have been a factor in its ability to tolerate cold. Surface water temperatures around the Kommandorskiy range from 0°C in winter to 10°C in summer.

There is no evidence for geographic variation. The northernmost Pacific was likely marginal habitat as members of the Kommandorskiye population may have been stunted. Adults at Bering Island had a body length approximately 750 cm (25 ft.) and a weight of 4500–5900 kg (10,000–13,000 lbs.). Fossil material from farther south suggests maximum body lengths may have reached 9–10 m.

Like other sirenians, Steller's sea cow had paired nostrils, abdominal testes, a pair of axillary mammae, no hindlimbs, horny plates on the occlusal surfaces of the rostrum and mandibular symphysis for macerating vegetation, and ribs and other bones that were swollen (pachyostotic) and completely compact (osteosclerotic). It swam by dorsoventral undulation of the body and its horizontally expanded triangular caudal fluke, resembling those of dugongs and cetaceans. See Domning (1978, 1994) for more detailed morphological diagnoses.

The order Sirenia is agreed to be monophyletic and has been placed in the superorder Tethytheria, which includes the Proboscidea (elephants) as well as an extinct group of marine hippo-like herbivores, the Desmostylia. The cladistic analysis by Domning (1994), based

on morphological characters of skull, mandible, and dentition, supports the conclusion that *H. gigas* was the last of two species in the genus *Hydrodamalis*, sharing the subfamily Hydrodamalinae with its ancestral genus *Dusisiren*. The Hydrodamalinae, Dugonginae, and Halitheriinae constitute the family Dugongidae. The Sirenia also include three other families: the extant Trichechidae (manatees) and the extinct Prorastomidae and Protosirenidae.

Hydrodamalis evolved from tropical and subtropical, seagrass-eating dugongid ancestors that shifted from bottom feeding to surface feeding and from a seagrass in warm protected waters to an algal diet and a high-energy, low-temperature environment. Seagrasses, which have a large part of their biomass below ground in the form of roots and rhizomatous storage organs, are the preferred forage of the extant dugong (*Dugong dugon*) and apparently of the ancestral dugongid line. Kelps have no belowground biomass. Their softer, more edible, growing portions (the bulk of nutritious biomass of the taller kelps) are at or near the surface, suspended by floats. Fossils record this transition from bottom rooting to surface foraging. *Hydrodamalis* descended from the widely distributed tropical genus *Metaxytherium*, a small-tusked, seagrass-eating Miocene halitherine dugongid. At the time a diversity of herbivorous marine mammals foraging along the east-central Pacific shorelines was presumably supported by a diverse flora of tropical and subtropical seagrasses, as well as algae (perhaps including kelps in cooler, more exposed microhabitats). The sister group and apparent immediate ancestor of hydrodamalines was the species *M. arctodites*, living in southern California and Baja California by about 14–15 Ma. Probably already present were the earliest members of its descendant genus *Dusisiren*, as well as a dugongine, *Dioplotherium allisoni*. These three sympatric sirenians, representing the three dugongid subfamilies, probably occupied distinct feeding niches. The large-tusked *Dioplotherium* with its strongly deflected rostrum was likely a bottom feeder, rooting for rhizomes of the larger seagrasses. The small-tusked *Metaxytherium* probably depended on the smaller rhizomes and leaves of seagrasses. *Dusisiren* and later hydrodamalines, in contrast, progressively gave up bottom and rhizome feeding, specializing on kelps growing higher in the water column, reducing their rostral deflections, and losing their tusks. Also present with these Miocene sirenians were three or more genera of desmostylians, hippopotamus-like bottom feeders, presumably also herbivorous and feeding on intertidal and subtidal seagrasses and kelps.

As the climate cooled after the Middle Miocene, and tectonic uplift rendered the western North American coastline more emergent (replacing protected embayments with more exposed, higher energy habitats), the cold-water plants increased their dominance in the marine flora, and the tropical seagrasses finally disappeared altogether. With them went *Dioplotherium*, *Metaxytherium*, and all the desmostylians. By the Late Miocene, *Dusisiren*, having earlier thrown in its lot with the kelps, had increased its cold tolerance and its morphological specialization for kelp eating (passing through the successive evolutionary stages *D. jordani* and *D. dewana*) and had extended its range to the northwestern Pacific. By the end of the Miocene it had evolved into *Hydrodamalis cuestae*, which gave rise in the Pleistocene to *H. gigas*.

The prehistoric distribution of sea cows and sea otters (*E. lutris*) was coterminous. Anderson (1995) speculated on the evolution of a sea cow–sea otter relationship and sea cow morphology as follows: “As the hydrodamaline range shifted northwards, the adoption of a kelp diet may have contributed (along with the thermoregulatory demands of a cooling environment) to selection for large adult body size, high birth weight, prolonged parental care, and low reproductive rate. At

the same time, the more effective chemical defenses of kelps growing below the sea otter foraging zone might have favored the sea cow's specialization for surface feeding and its loss of diving ability.”

II. Distribution

Historically, Steller's sea cow was known only from Bering and Medney (Copper) Islands at the western terminus of the Aleutians, 200 miles to the west of Attu Island and 150 miles east of the Kamchatka Peninsula. Pliocene and Pleistocene fossils demonstrate that the distribution originally extended around the North Pacific from Baja California, Mexico (30° N), along the coast of North America to the Aleutian chain and south in the western Pacific to Honshu, Japan (37° N). Recent evidence implies possible persistence for a few more years in the central Aleutians (Mattioli and Domning, 2006).

III. Ecology

Bering Island is approximately 50 miles in length and Medney Island 35 miles long. Both are narrow, high, and rocky. Sea cows foraged on softer parts of large marine algae (“kelp”) on open coasts in rocky subtidal and intertidal waters. Steller referred to four types of macroalgae (all still undescribed in his day) as preferred foods; these have been variously identified but probably include such forms as *Agarum* spp., *Alaria praelonga*, *Halosaccion glandiforme*, *Laminaria saccharina*, *Nereocystis luetkeana*, and *Thalassiphyllum clathrus*. Tougher stems and holdfasts were not eaten, washing up in heaps on the shore where sea cows fed. Seagrasses have also been suggested as elements of the diet, but this is doubtful. Of the two available forms, *Phyllospadix* spp. are among the toughest seagrasses and *Zostera marina* grows on soft bottoms in protected waters. In any case, *H. gigas* was probably dependent on a small number of forage species. Feeding along the shoreline, with backs above water, the sea cows were not observed to submerge; they moved about using their flukes and maintaining position on the rocks with their bristle-tipped pectoral limbs. Algae growing on rock faces were bitten off or pawed free with the forelimbs, and the softer parts were separated by the bristly lips as if “cut off with a dull knife.” If the animals were indeed unable to submerge, they could access food only to depths of about a meter below low tide level. Steller wrote that they fed “in herds,” keeping the young in the center of the group. He did not specify herd size but referred to family groups as consisting of a pair with their offspring. In addition to rocky shorelines, Steller stated that sea cows were “fond of shallow sandy places along the seashore, but they like especially to live around the mouths of river and creeks, for they love fresh running water.”

As an algivore, *Hydrodamalis* may have been dependent on an ecosystem in which the carnivorous sea otter (*Enhydra lutris*) suppressed invertebrate herbivory in shallow coastal waters. Like Steller's sea cow, the sea otter is confined to the shallows within 1 km of shore where it forages for urchins and other invertebrate herbivores, usually to a maximum depth of about 130 ft. (40 m). Within this zone, otters keep sea urchins and other invertebrate algivores in check. *Hydrodamalis* was dependent on fast-growing kelps on rock faces and on the kelp canopy in deeper waters. Where sea otters are extirpated, grazing by urchins results in “kelp barrens.” Thus sea cows depended on sea otter predation that maintained the shallow-water kelp community.

Steller reported both external and internal PARASITES. The crustaceans that he described as infesting the sea cows' skin have been interpreted as cyamids or caprellids, but identification will probably remain uncertain. The only specimens purported to exist

are ones attached to alleged sea cow skin fragments, but these latter are likely to pertain instead to whales. "White worms half a foot long," observed by Steller in the stomach and intestine of the sea cow, were probably ascarid nematodes; both these and the ectoparasites probably went extinct with the sea cow itself. *Hydrodamalis*, at least the young, may occasionally have been prey for killer whales (*Orcinus orca*) and large sharks.

IV. Life History

Steller suspected that the animals were monogamous. Mating apparently involved only a pair, with the male following or herding the female during prolonged "amorous preludes." Copulation involved mutual clasping with the pectorals, the female in an inverted position and the male above.

Steller's views as to the annual reproductive cycle present some enigmas. He observed mating behavior and copulation in the early spring, and deduced that gestation was more than 12 months, but stated that young were born "at any time of the year, but most frequently in autumn." Fall births would seem likely to put the young at a disadvantage, especially in view of his observations that "during the winter they are often suffocated by the ice that floats about the shore" and "in the winter the animals become so thin that, besides the bones of the spine, all the ribs show." As Steller did not arrive on the island until late November and left the following August, he could not have had direct knowledge of a concentration of births in the fall. He never saw more than one very small calf with a female, implying that births were single.

V. Interactions with Humans

These magnificent animals would have been at least as vulnerable to healthy and skilled Pleistocene hunters along mainland shores as they were to the weakened Russians on the Kommandorskiyes. Domning (1978) has suggested that human hunting may have extirpated sea cows from areas within reach of aboriginal hunters, leaving only the population around the remote Kommandorskiyes. Over most of its range the sea cow may have been the only marine mammal to succumb to "Pleistocene overkill."

Steller's sea cows had no fear of humans. Feeding with the head submerged and half of the back above water they were easily approached and could be touched or speared from the rocks. One method of capture was for a swimmer or a boat crew to approach the intended victim with a large hook attached to a line to the shore. When the hook had been driven into the animal's body, a shore crew would attempt to drag it toward the beach. Steller reported that sea cows made no sounds even when wounded by hunters. Of particular interest are the descriptions of both helping behavior and evident pair bonding in this context. Steller reported that while an animal was being dragged ashore other sea cows would attempt to dislodge the hook and/or break the rope. When one female had been dragged ashore, the accompanying male kept station offshore at the site for at least 2 days.

On the basis of his observation of "family groups" and the evidence of strong pair bonds, the vulnerability of the sea cows in their last stronghold made it possible for the weak and scurvy-ridden castaways of Bering's expedition to secure an abundant supply of food and to escape to the mainland in the summer of 1742. Having found ways to capture the sea cows, the survivors were able to divert manpower to salvage materials from the wreck of their ship and build a smaller vessel in which to reach Kamchatka. That voyage, made possible by sea cow vulnerability, carried with it the news of fortunes to be made in hunting sea otters and fur seals. A fur rush followed,

fueled by sea cow meat. The first hunting expedition wintered on Bering Island in 1743–1744. By 1763 several parties had spent up to 9 months on the islands, living almost exclusively on sea cows and salting down barrels of meat to provision the 2–3-year expeditions to the Aleutian chain and the north Asian and North American coasts in search of furs. Sea cow hides were also used to make large skin boats (baidarkas or umiaks). In 1754–1755 a fur-hunting expedition was forced to winter on Bering Island because the sea cows had been extirpated on Medney Island. The last specimen on Bering Island was reported killed in 1766. Steller's biographer, Leonard Stejneger, summarized accounts of the unrestrained killing by the fur hunters and attributed the extinction of the sea cows to ruthless slaughter. Their persistence in the central Aleutians (Domning *et al.*, in press) may have been due to the remoteness, smaller sizes of these islands, and fewer visits by Russian otter hunters.

The drama played out on Bering and Medney Islands suggests a complementary and more complex and instructive story. Anderson (1995), following a suggestion by Delphine Haley, proposed that the final extinction of the sea cow resulted not solely from ruthless harvesting, but from a cascade of events beginning with extirpation of the local sea otter population around the islands in the first rush for furs. Decimation of the otters in all probability triggered a sea urchin population explosion and the disappearance of chemically defended shallow water kelps that were the sea cows' main food supply. Invasion of the shallow waters by chemically defended deep-water kelps left the hunted remnant of the sea cow population with kelp that was likely toxic. Anderson proposed that this may have been a reenactment of events when North Pacific coastlines were first colonized by humans in the waning Pleistocene.

Steller Sea Lion

Eumetopias jubatus

THOMAS R. LOUGHLIN

I. Characteristics and Taxonomy

The Steller sea lion (or northern sea lion), *Eumetopias jubatus*, is the largest otariid pinniped and one of the more aesthetically appealing sea lions (Loughlin *et al.*, 1987). In Greek, *Eumetopias* means having a well-developed, broad forehead; in Latin *jubatus* means having a mane, as in the male. It is called *qawax* (pronounced ka-wa; *qawan*, plural) by Aleut natives, *sivuch* (*sivuchi*, plural) in Russian, and *todo* in Japanese (*ashika* being the Japanese word for all sea lion species). It exhibits significant sexual dimorphism with males larger (Fig. 1). Average standard length of males is 282cm and of females 228cm (maximum of about 325cm and 290cm, respectively). Estimated average weight of males is 566kg and of females 263kg (maximum of about 1120kg and 350kg, respectively). Pup weight at birth is 16–23kg and may be slightly larger in the western part of their range. Taxonomically the species belongs to the Order Carnivora, Suborder Pinnipedia, Family Otariidae. It can be distinguished from other pinnipeds by a conspicuous diastema between the upper fourth and fifth postcanines. The range overlaps with the California sea lion (*Zalophus californianus*) which is darker color and smaller in size.

The upper postcanine number 5 is double rooted, with the crown directed backward, and does not occlude with lower postcanine 5; all other postcanines are single rooted, slant somewhat forward, and have irregular conical pointed crowns. The diagnostic diastema between upper postcanines 4 and 5 may be caused by rapid growth and extension of the skull rather than by suppression of the 5th and 6th postcanines. Annual growth layers exist in the dentin and cementum with dark layers corresponding to winter and light layers to summer. Dental formula for permanent teeth is $i\ 3/2, c\ 1/1, pc\ 5/5$, total 34. *E. jubatus* has a double alveolar capillary supply, as in the Cetacea, unique among the pinnipeds.

These are attractive animals. Pups (Fig. 2) are born with a wavy, chocolate brown fur that molts after 3–6 months of age. Adult fur color varies between a light buff to reddish brown with most of the under parts and flippers a dark brown to black; naked parts of the skin are black (Fig. 1). Both sexes become blonder with age. Adult males have long, coarse hair on the chest, neck, and shoulders, which are massive and muscular.

Otariids probably arose in North Pacific temperate waters from the Enaliarctidae; the earliest known otariid, *Pithanotaria starri*, is between 10 and 12 million years old (Mitchell, 1968). The earliest large otariid with most cheek teeth single rooted is from 2 mya Pliocene deposits in Japan and is assigned to the extant genus *Eumetopias*, although probably a different species from *E. jubatus*. A skull, teeth, vertebrae, and other parts of a postcranial skeleton of *E. jubatus* were recovered in California from Pleistocene deposits.

The Steller sea lion has 30 metacentric or submetacentric chromosomes and 4 acrocentric chromosomes; the X chromosome is submetacentric and the Y is acrocentric ($2n = 36$).

Studies of mitochondrial DNA from throughout the range suggest that at least two stocks exist, an eastern stock (California through southeastern Alaska), and a western stock (Prince William Sound, Alaska, and westward through Russia) (Loughlin, 1997). Designation of a third stock in Russia is equivocal based on examination of nuclear

DNA. Population declines in western Alaska resulted in the western population being listed as “endangered” in 1997. The eastern population is listed as “threatened”, but increases in population numbers in Southeast Alaska and population stability in British Columbia and Oregon may warrant removal from the threatened list for this stock.

II. Distribution and Abundance

The species was described by the German physician/theologian George Wilhelm Steller based on a specimen that he obtained from the Russian Commander Islands while serving as naturalist on Vitus Bering’s fateful voyage to Alaska in 1741–1742. It was also during this voyage that Steller described the northern fur seal (*Callorhinus ursinus*) and THE STELLER’S SEA COW (*Hydrodamalis gigas*, now extinct).

Steller sea lions occur throughout the North Pacific Ocean rim from Japan to southern California (Fig. 3). They abound on numerous breeding sites (rookeries) in the Russian Far East, Alaska, and British Columbia, with lower numbers in Oregon and California. Washington is the only western coastal state that does not contain a Steller sea lion rookery, although pups were observed at one haul-out site in 1997 and 1998. Seal Rocks in Prince William Sound, Alaska, is the northernmost (60°09’ N) rookery, and Año Nuevo Island, California, the

southernmost (37°06' N). Unlike their more gregarious cousin the California sea lion, Steller sea lions tend to avoid people and prefer isolated offshore rocks and islands to breed and rest. Although rookeries and rest sites occur in many areas, principally on exposed rocky shorelines and wave-cut platforms, the locations used are specific and change little from year to year. Steller sea lions tend to return to their birth island as adults to breed, but they range widely (some yearlings have been seen >1000km from their birth rookery) during their first few years and during the nonbreeding season.

Population numbers have declined during the last 30 years by over 90% in most of western Alaska and southern California, while populations in Oregon, British Columbia, and southeastern Alaska have remained stable or increased slightly (Fig. 4). The worst declines occurred in the Aleutian Islands and Gulf of Alaska, areas

that historically were the centers of abundance (Loughlin *et al.*, 1992; Trites and Larkin, 1996). Causes for these declines have not been identified but may be related to direct mortality caused by shooting or incidental take in fisheries, disease, and contaminants, or indirectly by reduced food availability through natural changes in the ocean or by fishing pressure and the synergistic effects of commercial fishing and climate change. Studies of blood chemistry and body condition of females and pups during the breeding season are within normal ranges for pinnipeds, but similar studies on juveniles, the age class most likely suffering higher mortality rates, have produced equivocal results. The large population declines resulted in the species being listed as “threatened” by the United States in 1992. A survey in 1989 provided a total estimate of about 116,000 Steller sea lions range-wide, and another in 1994 resulted in about

100,000 of which about 9% of the total was in Russia (Burkanov and Loughlin, 2005), 70% in Alaska, 12% in British Columbia, 8% in Oregon and California, and 1% in Washington. The decline continued throughout the 1990s but seems to have ameliorated in the early 2000s with increases approaching 12% during 2000–2004 in parts of the Aleutian Islands and Gulf of Alaska.

III. Ecology

Steller sea lions eat a variety of fishes and invertebrates (Calkins, 1998; Merrick *et al.*, 1997; Sinclair and Zeppelin, 2002). In Alaska, the principal prey is walleye pollock (*Theragra chalcogramma*); Pacific cod (*Gadus macrocephalus*), Atka mackerel (*Pleurogrammus monopterygius*), octopus, squid, herring (*Clupea harengus*), flatfishes, sculpins, and a wide variety of other fishes and invertebrates are also consumed. At specific times of the year other prey may be eaten when plentiful (e.g., Pacific salmon, *Onchorynchus* sp.). During the breeding season, females with pups generally feed at night; territorial males eat very little or not at all while on territory. Feeding occurs during all hours of the day once the breeding season ends.

The variety of the sea lion diet has been correlated with population dynamics. In some Alaskan areas where the diet is diverse, sea lion numbers have been stable or increasing slightly. In areas where sea lions primarily depend on one prey item, the sea lion population has declined. Whether population trends are closely associated with diet diversity is still equivocal, but the availability of a variety of prey is optimal for pinnipeds. Steller sea lions are eaten by killer whales (*Orcinus orca*) and sharks, but the possible impact of these predators is unknown.

A cacophony of noise engulfs rookeries and haul-out sites, with animals of both sexes and all ages vocalizing throughout the day and night. Territorial males use low-frequency roars to signal threats to other males and to court females. Females vocalize frequently, calling to their pups and squabbling with other sea lions of all ages. Pups have a bleating, sheep-like cry; their voice deepens with age.

Grooming is performed by bending the head and neck backward and scratching with the claws of the hind flipper. Sea lions also rub themselves on rocks or other animals. While swimming, the fore flippers are used primarily for movement and the rear flippers for braking and turning.

III. Behavior and Physiology

Observations at sea suggest that large groups usually consist of females of all ages and subadult males; adult males sometimes occur in those groups but are usually found individually. On land, all ages and both sexes occur in large aggregations during the nonbreeding season. Breeding season aggregations are segregated by sexual/territorial status. Steller sea lions are not known to migrate, but they do disperse widely at times of the year other than the breeding season. For example, sea lions marked as pups in the Kuril Islands (Russia) have been sighted near Yokohama, Japan (more than 350 km away) and in China's Yellow Sea (over 750 km away), and pups marked near Kodiak, Alaska, have been sighted in British Columbia, Canada (about 1700 km distant). Generally, animals up to about 4 years of age tend to disperse farther than adults. As they approach breeding age, they have a propensity to stay in the general vicinity of the breeding islands, and, as a general rule, return to their island of birth to breed as adults.

The foraging patterns of adult females vary seasonally. Trip duration for females with young pups in summer is approximately 18–25 h, trip length averages 17 km, and they dive approximately 4.7 h/day.

In winter, females may still have a dependent pup, but a mean trip duration is about 200 h, with a mean trip length of about 130 km, and they dive about 5.3 h/day. Yearling sea lions in winter exhibit foraging patterns intermediate between summer and winter females in trip distance (mean of 30 km) but shorter in duration (mean of 15 h) and with less effort devoted to diving (mean of 1.9 h/day). Estimated home ranges are 320 km² for adult females in summer, about 47,600 km² (with large variation) for adult females, and 9200 km² for winter yearlings in winter. Immature Steller sea lions exhibit long-range trips (>15 km), short-range trips (<15 km), and transits to other sites. Long-range trips start at around 9 months of age and likely occur around the time of weaning, while short-range trips occur almost daily. Transits begin as early as 2.5–3 months of age but occur more often after 9 months of age. Overall, Steller sea lions tend to display two types of distribution when at sea: (1) less than 20 km from rookeries and haul-out sites for adult females with pups, pups, and juveniles, and (2) much larger areas (greater than 20 km) where these and other animals may range to find optimal foraging conditions once they are no longer tied to rookeries and haul-out sites for nursing and reproduction. Large seasonal differences in foraging ranges may be associated with seasonal movements of prey, and seasonal changes in home range are likely related to prey availability.

Compared to some other pinnipeds, Steller sea lions tend to make relatively shallow dives, with few dives recorded to depths greater than 250 m. Maximum depths recorded for individual adult females in summer are in the range from 100 to 250 m; maximum depth in winter is greater than 250 m. The maximum depth measured for yearlings in winter was 72 m and average depths are near 18 m and in shallow near-shore waters.

IV. Life History

Like most pinnipeds, female Steller sea lions ovulate once a year, and most give birth to a single pup each year; twinning is rare (Pitcher and Calkins, 1981). Males establish territories in May in anticipation of the arrival of females. Viable births begin in late May and continue through early July. The sex ratio at birth is slightly in favor of males. Females breed about two weeks after giving birth. Copulations may occur in the water but most are on land. The mother nurses the pup during the day and after staying with her pup for the first week she goes to sea on nightly feeding trips. Pups generally are weaned before the next breeding season, but it is not unusual for a female to nurse her offspring for a year or more.

Females reach sexual maturity between 3 and 8 years of age and may breed into their early 20s. Females can have a pup every year but may skip years as they get older or when nutritionally stressed. Males reach sexual maturity at about the same age but do not have the physical size or skill to obtain and keep a breeding territory until they are 9 years old or older. Males may return to the same territory from 1 to 7 years, but rarely more than 3 years. While on the territory during the breeding season males may not eat for 1–2 months. The rigors of fighting to obtain and hold a territory and the physiological stress over time during the mating season reduce the life expectancy of these animals. They rarely live beyond their mid-teens, while females may live as long as 30 years.

V. Interactions with Humans

Steller sea lions are rarely seen in aquaria because of their large size and pugnacious nature. Those in captivity include about 8 in the United States, 12 in Canada, about 4 in Denmark, and about 15 in

Japan. The 12 in British Columbia at the Vancouver Aquarium and 3 at the Alaska SeaLife Center in Alaska are held for both research and exhibit.

The species is an important subsistence resource for Alaskan natives, who hunt sea lions for food and other uses. Two hundred or more may be taken a year in Alaska.

Steller sea lions may be affected by commercial fishing directly through incidental catch in nets, by entanglement in derelict debris, by shooting, or indirectly through competition for prey, disturbance, or disruption of prey schools (Alverson, 1992). The number of sea lions caught in trawl nets was high during the 1960s and 1970s but has declined since and is presently at very low levels. Incidental entanglement probably contributed to population declines in the Aleutian Islands and western Gulf of Alaska in the 1970s and 1980s, but it is not presently considered an important component in the decline. Entanglement in derelict gear is rare and unlikely to have contributed to the decline. In some areas, Steller sea lions were killed deliberately by fishermen, but it is unclear how such killing affected the world population, especially since declines have occurred in areas uncommonly used by commercial fleets (central and western Aleutian Islands) or where fishermen rarely have guns (Russia). Commercial fisheries target on several of the most important prey eaten by Steller sea lions. In combination, these fisheries remove millions of metric tons of fish. However, the complexity of ecosystem interactions and limitations of data and models make it difficult to determine whether fishery removals, directly or indirectly, have negatively impacted the populations (e.g., see Rosen and Trites, 2000; Fritz and Hinckley, 2005) of Steller sea lions.

The U.S. government has implemented numerous measures for the conservation. These include prohibitions on shooting, reductions on allowable incidental take in fisheries, placement of zones around rookeries to restrict commercial fishing, designation of critical habitat, development of a Steller Sea Lion Recovery Plan, and other measures. Research activities have intensified as scientific findings, litigation, and new legislation focused increasing attention on the species' population decline and concerns over possible impacts by commercial fisheries in Alaskan waters. Additional restrictions were placed on these commercial fisheries, resulting in the U.S. congress allocating a seven-fold increase in research funding beginning in 2000 with over 125 individual projects planned or implemented. These studies have provided over 750 primary citations, journal articles, progress and technical reports, contract reports, proceedings of conferences and symposia, books, thesis and other manuscripts. More than 50% of the articles were written since 2004 with the majority pertaining to Steller sea lion life history, foraging ecology and vital rates.

Stock Assessment

JEFFREY M. BREIWK AND ANNE E. YORK

A marine mammal stock assessment is a process that seeks to estimate the productivity or growth potential of a stock and predict the future growth in conjunction with management objectives and conditions, which often includes removals due to incidental catches, directed harvests or natural causes. It also seeks to measure the capacity of the stock to recover from these removals. The assessment usually encompasses the status of the stock with

respect to some reference level, such as the unexploited population size, and the evaluation of the consequences of various management actions. For stocks that are subject to a harvest or experience mortality incidental to fishing operations, a goal is to determine allowable removal levels (e.g., harvests that will allow the population to recover to some desired level during some time frame). A concise definition of a fisheries stock assessment, equally applicable to marine mammals, is that given by Hilborn and Walters (1992): “Stock assessment involves the use of various statistical and mathematical calculations to make quantitative predictions about the reactions of fish populations to alternative management choices.”

The components of a stock assessment will vary with the species considered, its stock identification, the quantity and quality of data available, and the methods and mathematical models employed. It is a process whose steps typically include the following: (1) the definition of the geographic and biological extent of the stock, (2) collection of appropriate data, (3) choice of assessment model(s) and parameters, (4) specification of performance criteria and evaluation of alternative actions, (5) estimation of model and other parameters, and (6) presentation of results. While these steps were originally formulated for fisheries stock assessments, they are equally applicable to marine mammal stock assessments.

Marine mammal stock assessments are often carried out to determine what level of mortality a stock can sustain. Several type of information are usually required: current as well as historical abundance, trends in abundance and estimates of biological parameters (such as age at sexual maturity, natural mortality rate, sex ratio, and pregnancy rate), historical harvests, age distribution, maximum sustainable yield level (MSYL), age-specific harvest mortality, sustainable or replacement yield, spatial distribution of the stock in question, and other relevant factors that may vary by species and population (see Population Dynamics). In addition to estimates of these quantities, a measure of parameter uncertainty, such as variance or coefficient of variation, is also necessary.

I. Productivity

The productivity of a stock is determined by a number of factors, including abundance, rate of increase, population age structure, sex ratio, and the manner in which density-dependence (see Population Dynamics) operates. The productivity is the amount by which the stock increases over a time interval (usually a year) and is the difference between the number of animals added (by reproduction and immigration) and the number that are lost (due to emigration and from natural causes—all causes not due to harvest). Ideally, immigration and emigration are zero or equal, so their effects cancel each other. The amount by which the population increases each year (in the absence of a harvest) is the net production or the replacement yield, and this amount, if harvested, results in the population size at the end of the time period (usually a year) remaining the same size as at the beginning of the year. A related quantity, the sustainable yield, is the productivity when the stock is stable. This occurs when the various population rates (such as natural mortality and reproduction) have remained constant for sufficient time and the environment does not change. Fisheries stock assessments generally determine productivity in terms of biomass, whereas marine mammal stock assessments most often determine productivity in terms of number of animals. This is not only because marine mammals are difficult to weigh but also because they stop growing after reaching physical maturity, whereas most fish grow throughout their life. It thus becomes increasingly difficult to associate age and size for older animals, especially for cetaceans.

II. Models

Most stock assessments employ a mathematical model of the population to predict the historical trends in abundance as well as future trends under various removal scenarios and choice of model parameters. This approach usually assumes constant environmental conditions and model parameters, and these assumptions are often difficult to evaluate. The model parameters are estimated from the available data or fixed at various plausible values. The more reliable the basic data, the more reliable will be the assessment. A simple population model often used for modeling the dynamics of a population is the discrete, generalized logistic model:

$$N_{t+1} = N_t + R_{\max} N_t [1 - (N_t/K)^z] - h_t \quad (1)$$

where N_t is the population size (in numbers) at the start of year t , R_{\max} is the maximum per capita growth rate, K is the carrying capacity or pre-exploitation abundance of the population, h_t is the harvest in year t , and z is a density-dependent exponent which determines at what population level (between 0 and K) the productivity is maximum. Equation (1) is a difference equation, with the population size at time $t + 1$ being a function of the population size at time t .

The population level at which the productivity curve is maximum, the maximum net productivity level or MNPL, is considered to be greater than 50% of K for marine mammals. When the harvest is random with respect to age and sex, MSYL and MNPL are often used interchangeably. The International Whaling Commission (IWC) has usually adopted a value of 60% for the MSYL, which corresponds to a z of 2.39. A value of $z = 1$ results in a symmetric productivity curve with MSYL at 50% of K . This also corresponds to a linear density-dependence relationship between the per capita rate of growth and population density.

This model is simple in that it combines males and females, it ignores age structure and it assumes constant environmental conditions and model parameters. It does, however, capture the basic dynamics of the population, including harvesting or other known removals. It has the desirable feature that the recruitment rate is density dependent; it is greatest at small population sizes and decreases as the population increases toward K . The sustainable yield as a function of N for the model shown earlier is given by

$$SY(N) = R_{\max} N [1 - (N/K)^z] \quad (2)$$

Productivity, therefore, increases as the population size increases, reaches a maximum when N is equal to the MSYL, a level intermediate between 0 and K , and then declines to 0 at K . This can be seen in Fig. 1, which shows the sustainable yield curves for $z = 1$ (linear density-dependence with MSYL = 50% of K) and $z = 2.39$ (nonlinear density dependence with MSYL = 60% of K). By solving for the population size when the productivity is maximum, the MSYL can be shown to be equal to $K(1 + z)^{-1/z}$. Thus, if $z = 1$, MSYL = $K/2$ or 50% of K (see also Population Dynamics).

Equation (1) and similar models, often modified to include sex, age, and spatial structure, have been used to model cetacean, pinniped, and other marine mammal populations. If estimates of R_{\max} , z , and K are available, along with a time series of removals, then the model can be used to project an initial abundance, N_0 , forward to any particular year. This procedure can be programmed to find an N_0 such that the population trajectory “hits” a current abundance estimate. This is a simplification of a technique employed to assess many marine mammal populations. Parameters of the model can be

Figure 1 A plot showing sustainable yield as a function of population size [see Eq. (2)] for a hypothetical marine mammal population with $R_{max} = 0.05$, $K = 10,000$ and two values for the density-dependent exponent, z .

estimated by minimizing a measure of discrepancy between observed and model-predicted abundance.

III. Population Status

The IWC and the US Government (US Marine Mammal Protection Act of 1972: MMPA) have based assessments on classifying stocks by their depletion level with respect to pre-exploitation population size and MNPL. The IWC New Management Procedure (NMP) was based on classifying stocks as Initial Management (IM), Sustained Management (SM), and Protected (P), based on the MSYL and the current depletion level with respect to K . However, for stocks classified as IM or SM, the quota required knowledge of the MSY. The MSY, in turn, depends on, among other things, the level of density-dependence (see Fig. 1). The Revised Management Procedure (RMP) addresses shortcomings in the NMP such as the difficulty of determining MSY for a stock and relies primarily on estimates of abundance and their uncertainty and a simple population model such as Eq. (1) requiring few biological parameters.

The US MMPA called for marine mammal populations to be maintained at an “optimum sustainable population” (OSP) level. The US National Marine Fisheries Service defined OSP as a population level between the MNPL and the carrying capacity. The application of this requires the determination of the current population status with respect to the MNPL. In some cases a range of MNPL was used, while in other cases an estimate was made whether the abundance was either less than or greater than the MNPL. The 1994 amendments to the MMPA required that a Potential Biological Removal (PBR) be determined for marine mammal stocks. The PBR is equal to the maximum number of animals that can safely be removed from the population annually. It is calculated as the product of the minimum population estimate of the stock, one-half the maximum theoretical or estimated net productivity rate and a recovery

factor between 0.1 and 1. The assessment of allowable removals therefore hinges on estimation of abundance and the productivity rate. The PBR is a conservative approach whose goal is to allow stocks to reach or maintain their OSP without having to estimate quantities such as MNPL or K (see Management) which can be difficult to estimate.

IV. Uncertainty and Other Considerations

Uncertainty and how to deal with it is a feature of all stock assessments. The environment and the genetic structure of stocks, as well as the levels of competition and predation may change over time. There is also uncertainty in the underlying population dynamics (termed process error), in the measurement of abundance or indices of abundance (termed measurement error), in the model structure (i.e., is the model correct?), and in the model parameters. Common methods for dealing with some forms of uncertainty include bootstrapping (a method of resampling the data to estimate variability), maximum likelihood (a method for obtaining parameter estimates and their associated variability), model averaging, and Bayesian statistical methods.

Bayesian statistical methods are increasingly being used to deal with uncertainty in stock assessments. Bayesian estimation involves integrating the product of the likelihood of the observed data and the prior probability distribution for parameters of interest to obtain what is termed the posterior distribution for the quantity of interest. Due to the complexity involved in integrating this product it must often be estimated numerically by Monte Carlo methods (based on computer simulations using random numbers). The advantage of the Bayesian methodology is that various sources of information on parameters, including observations from other stocks or species, can be incorporated into the assessment. The end result is not just a simple estimate of the growth rate, for example, but a probability

distribution, showing the probability of different values of the parameter. Disadvantages of the Bayesian method are that it is often difficult to construct and obtain agreement on a prior distribution to use in an assessment and the difficulty of detecting inadmissible combinations of parameters that arise in the prior distributions (Borel's Paradox).

Most stock assessments deal with uncertainty in model parameter estimates and management-related quantities, but for the most part they are still based on single-species population models. Some progress has been made in considering marine mammal stocks as part of a larger ecosystem that includes food webs, spatial distribution, and interacting (e.g., competing) species. While it would be preferable to consider a host of interacting factors that influence marine mammal stocks, the paucity of available data often precludes the estimation of the parameters necessary to model the various population interactions. It is likely, however, that future stock assessments will increasingly take into account ecosystem considerations.

Environmental factors are an issue that is becoming more important in fisheries and marine mammal stock assessment. In the North Pacific, for example, decadal oscillations in climate can affect the distribution and abundance of fish and marine mammals (by affecting the distribution and abundance of prey species). Large amounts of long-term data are required to be able to assess the effects of climate on marine mammals. Without these data it is very difficult to determine whether changes in stock abundance are due to climate, harvesting, or a combination of the two.

V. Examples

A. Cetaceans

Recent stock assessments carried out for both the eastern North Pacific gray whale (*Eschrichtius robustus*) stock and the Bering-Chukchi-Beaufort Seas stock of bowhead whales (*Balaena mysticetus*) have used Bayesian assessment methods (Wade, 2002; Punt, 2006). Stock definition is not considered an issue for these two stocks, as there is little evidence for sub-stock structure (sub-stock structure has been raised recently with respect to bowhead whales, but the evidence for this is not compelling).

Whales of both of these stocks migrate along the coast where they are counted by shore-based observers. Data collected include counts and sighting distance, which are analyzed to give abundance estimates along with standard errors (measure of uncertainty), and numbers of young and immature animals. Acoustic data are also collected for bowhead whales and integrated with the visual location data to estimate the number of whales passing. Several different assessment models have been used, but all are age- and sex-structured models that incorporate density-dependence in the reproductive rate. A method often used to estimate the posterior probability distribution of management-related parameters (such as MSYL and RY) involves projecting the population model forwards using as inputs parameter values that are randomly chosen from their prior probability distributions (Punt and Hilborn, 1997). A measure of the discrepancy between the observed abundance estimates and the abundances predicted by the population model, the likelihood, is then computed. This is repeated a large number of times, and management-related parameters are calculated for each case. These include historic abundance, current abundance, growth rate, MSYL, and RY. From these repeated model runs, a smaller sample is taken with probability proportional to the total likelihood computed for each trajectory. This second sample is an estimate of the posterior probability distribution of the management-related parameters. From these distributions the median or mean value can

be obtained as well as other statistics of interest, including the answer to questions such as "What is the probability that the RY is less than 100?" or "What is the probability that the current abundance is greater than the MSYL?" In practice, a conservative approach has often been adopted by computing such quantities as the lower 5th or 10th percentile of the RY and other quantities of interest in determining allowable quotas.

Both the US National Marine Fisheries Service and the International Whaling Commission have assessed these two stocks. A Bayesian analysis using an age- and sex-structured model for gray whales resulted in a lower 10th percentile for R_{\max} of 0.047. This, coupled with a minimum population estimate of 17,752 [lower 20th percentile of the mean of the 2000/01 and 2001/02 abundance estimates (not significantly different)], and a recovery factor of 1.0, resulted in a potential biological removal (PBR) of 417 animals (Angliss and Outlaw, 2005), well above the average current annual take of less than 180. An assessment based on Bayesian analyses using two different age-structured models (Wade, 2002) resulted in estimates of K of 19,058 and 21,740; N_{2002}/K of 1.04 and 1.00; and Q_1 , a quantity considered by the IWC to be a more appropriate than RY to use for management advice for populations thought to be above MSYL, of 626 and 669 (Q_1 is defined as 0.9MSY for populations above the MSYL, as the minimum of 0.9MSY and the product N_t^*MSYR for populations below MSYL, and as zero for populations below P_{\min} , the population size below which no catches are allowed). These numbers represent medians, but for management advice the IWC used the lower 5th percentile of Q_1 , 463. This number of whales per year was agreed to be sustainable for at least the medium term (~30 years).

The PBR for the Western Arctic bowhead whale population was based on a minimum population estimate of 9472, a rate of increase of 3.3% (with a harvest, so an R_{\max} of 4% was used), and a recovery factor of 0.5 (because the population is increasing in the presence of a known take) (Angliss and Outlaw, 2005). These result in a PBR of 95 animals ($9472 \times 0.02 \times 0.5$). The development of a PBR for this stock is required by the MMPA even though the Alaska Eskimo subsistence harvest is managed under the authority of the IWC. Thus, the IWC quota takes precedence over the PBR estimate. An assessment submitted to the IWC Scientific Committee was based on a Bayesian estimation method to fit a density-dependent, age-structured population model to available data on abundance (Punt, 2006). The maximum population growth rate, R_{\max} , was estimated to be 0.042. The posterior median for K was 11,120 and for N_{2002}/K was 0.86. The posterior distribution for replacement yield (RY) was 172 and for Q_1 , 243. The difference between these two quantities occurs because the model estimates that the population is above MSYL and close to K .

In the future, gray whale and bowhead whale quotas will be determined by use of a Strike Limit Algorithm (SLA) that has been developed by the IWC Aboriginal Whaling Management Procedure GROUP. The SLA relies mainly on abundance estimates and their variance as well as historic catches. The SLAs for the two species are different, but both of them were developed after a number of years of extensive testing via computer simulations and are robust to uncertainties in abundance, catch, and other factors.

B. Pinnipeds

The population of Steller sea lions (*Eumetopias jubatus*) in western Alaska has declined sharply since the mid-1970s. No single cause has been implicated in the decline, but human-induced mortality (shootings, incidental takes in fisheries, small directed harvests) and

predators (killer whales) are known to have caused sea lion mortality (Loughlin and York, 2000).

A series of modeling papers has attempted to determine the demographic causes of the decline and how they may have changed over time. York (1994) using two age-structure samples with their estimated survival and fecundity rates and counts of Steller sea lions from aerial surveys suggested that the early decline was mostly caused by a decline in juvenile survival. Holmes and York (2003) and Holmes *et al.* (2007) extended this model by additionally using counts of pups and an index of the number of juveniles developed from photographs using pup counts. The later papers estimated time-varying vital rates that were consistent with the non-pup and pup counts and juvenile index data, assuming that the known vital rates were from the sampled animals at time 0. The later models suggested that over the course of the decline, the demographic causes of the decline have changed from low juvenile survival to a combination of low juvenile survival and low adult survival to an increase in survival now in combination with low fecundity.

Commercial harvests of subadult male northern fur seals (*Callorhinus ursinus*) took place on the Pribilof Islands from the time of their discovery in 1786 until 1984. After 1918, the harvest was conducted under the auspices of the Treaty on the Conservation of the Northern Fur Seal (see Northern Fur Seal). The renegotiated Treaty of 1957 provided a vehicle for cooperative research among scientists of the party nations and specified that the population was to be managed to obtain “maximum sustained productivity.” Attempts were made to fit spawner-recruit models to fur seal data and to use them to set the harvest, but these methods largely failed, probably due to high variability in year class survival. Using numbers of young of the year (pups) counted earlier in the century and the pattern of harvests, it was estimated that the harvests, on average, took about 30% of the number of male seals born, or about 15% of the total seals born. When managers of the Pribilof herd learned that age at first reproduction of the Russian herd was, on average, 1 year younger than in the Pribilof herd, they justified a large reduction of females in the Pribilof population with the idea that with a lower herd density age at first reproduction would decrease to the level of the Western Pacific population, and a sustainable harvest of the same size would be obtained from a reduced population. That idea was tried and failed, perhaps because the harvesting regime preferentially killed those females that tended to reproduce at a younger age. At present, there is no commercial harvest, but a subsistence take for food is permitted. The maximum size of the subsistence take is set by the PBR approach at about 15,000 animals, well above the mean annual take from 2000 to 2004 of 750 animals.

The Northwest Atlantic harp seal (*Pagophilus groenlandicus*) population in Canada and Greenland is currently subject to a harvest. The current estimate of the population is 5.4 million (Hammill and Stenson, 2007); approximately 18–20% of the population is young of the year. The population model takes into account catches in Canada and Greenland, bycatch in fishing gear and animals struck and lost in the harvests.

Canada uses a management scheme referred to as “Objective Based Fisheries Management.” They have identified upper and lower reference points of 30 and 70% of the historical maximum population. The present management objectives are to maximize economic return while maintaining the population over the 70% reference level, with an estimated probability of at least 80%.

The current catches in Canada have averaged 312,000 for the past 5 years. In 2007, the catch was 225,000 (more than 95% are young of the year). An additional 90,000 are taken by Greenland from the

same population. The current catch level is about 4–5% of the total population or about 20–25% of the young of year population.

Stock Identity

JOHN Y. WANG

I. Importance of Stock Identity

Determining how a species is divided into stocks (the term “stocks” is used here to refer to biological stocks rather than management stocks; see later) is fundamental to the conservation of marine mammals. Because evolutionary processes act at the intraspecific level, genetic differences and locally adaptive characters will accumulate in stocks over time. This reservoir of genetic and phenotypic diversity increases a species’ ability to persist through environmental changes. Thus, one of the main goals in conservation is to preserve the evolutionary potential of species by maintaining the diversity found in stocks. Another important goal is to maintain species as functioning elements in their ecosystem by preventing regional overexploitation and depletion. Consequently, knowledge of stock structure of species is integral for developing effective management programs to achieve these goals.

The greatest threats to the survival of marine mammals are human activities. Marine mammals experience various levels and kinds of anthropogenic threats in different regions, and all exhibit life history characteristics (i.e., long-lived, low fecundity, late age of maturity) that make them susceptible to these threats. In order to assess the impact of human activities on marine mammals, it is crucial to identify stocks accurately, establish where the stock boundaries exist, and determine the permeability of the boundaries to genetic exchange with other stocks. This information will influence how the biological data needed for assessments are collected and interpreted and how management plans are designed. Inaccurate stock designations can lead to either unnecessary regulation(s) of fisheries or fallacious management that may result in the depletion of a stock and its accompanying genetic material. For example, if stock structure goes unrecognized and two distinct stocks are incorrectly managed as one, one may inadvertently become depleted.

Understanding stock structure can also help in streamlining the design of other studies, providing insights into evolution and monitoring illegal activities [e.g., DNA analysis of cetacean meat products from Japanese markets found stocks that were prohibited from sale (Baker *et al.*, 2000)]. Therefore, much effort has been directed toward identifying stocks of marine mammals. However, the task remains problematic, with two major difficulties: (1) semantic uncertainty and disagreement in the definition of “stock” and (2) studying stock identity with incomplete biological knowledge.

II. Definition of Stock

The term “stock” has been used to refer to both biological and management entities (although in many cases, they are combined or inseparable). A management stock is a group of conspecific individuals that are managed separately. The delineation of these stocks is very much dependent on the goals of managers and may not be based on biological discontinuities (e.g., International Whaling Commission management stock designations for baleen whales). With the exception of the definition by Moritz (1994), who described a “management unit” (MU) (which he synonymized with “stock” and appears to be equivalent to management stock) as having significant differences in allele frequencies at nuclear or mitochondrial DNA loci, the criteria for determining management stocks may have little or no biological rationale or consistency and may be influenced greatly by political interests. Nevertheless, management stocks have been used widely due to the paucity of biological information and will likely continue to play an important role in conservation. Developments in management strategies for situations with incomplete biological information should improve the success of conservation programs (Taylor, 1997). Although management stocks offer more flexibility in the sense that they can still be the focus of management programs without evidence of biological distinctiveness, conservation goals (e.g., maintaining genetic diversity) are more likely to be achieved if stocks are based on biological data. Therefore, this article focuses mainly on biological stocks.

Biological stocks are characterized by no or low levels of genetic exchange (which means that members of a biological stock tend to interbreed with each other more often than with other individuals). An entity with this property has also been called a population, subpopulation, evolutionary significant unit (ESU), deme, and subspecies (the only intraspecific taxon recognized by the International Commission on Zoological Nomenclature). When gene flow between two groups is absent, there is usually no disagreement that they represent separate biological stocks. However, it is more typical that some level of genetic exchange exists. Even low levels of genetic exchange can obscure stock boundaries and complicate the task of discriminating biological stocks. Although there is no consensus on the threshold level of gene flow above which stock status is no longer recognized, several approaches have been developed to make the identification of biological stocks more objective and explicit.

III. Stock Identification Approaches

Defining stocks is linked inextricably with defining species. There are many concepts that propose species definitions, but those advocated most commonly today include biological, evolutionary, and phylogenetic species concepts [for a detailed overview of these and other concepts, see Sites and Crandall (1997) and King (1993)]. However, because these concepts all have major limitations, agreement on the best species definition still eludes biologists. Like the species concepts, each approach to stock identification has limitations and weaknesses. In addition, defining stocks can be influenced, and therefore complicated further, by the goals of conservation and legislation. For example, one of the goals of the U.S. Endangered Species Act (ESA) is to decrease the loss of genetic variation. Thus, for this purpose, defining stocks using genetic criteria [e.g., the ESU of Moritz (1994)] is a reasonable proposal [however, see Pennock and Dimmick (1997) and Dimmick *et al.* (1999)]. Unlike the ESA, the US Marine Mammal Protection Act (MMPA) endeavors to keep biological stocks at or beyond their optimum sustainable levels and functioning in their ecological roles. To accomplish the intent of this

legislation, defining conservation units also requires demographic information.

There are several operational approaches to stock identification. Whereas some approaches are clear extensions of certain species concepts, the theoretical basis of others may be less explicit or embedded within the methodology. Brief descriptions of the approaches used most commonly are presented here.

Morphological characters have been the main evidence for delineating species. Because differences between stocks are generally less obvious than between species, examination of a large series of specimens is recommended for the identification of stocks using morphology. However, for most marine mammal species, it is difficult, if not impossible, to obtain a large number of specimens for analysis.

The “phylogeographic” approach proposed by Dizon *et al.* (1992) determines the likelihood that a group of organisms is an ESU. The determination is based on distribution, population response (including demography, behavior, vocalizations), and phenotypic and genotypic information, all of which serve as proxies for reproductive isolation (the essence of the biological species concept). Groups most likely to be ESUs have clear geographic and genetic separation and are assigned to “category I.” “Category II” units are characterized by clear genetic separation but little to no geographic partitioning. Units with little genetic differentiation but isolated geographically from other conspecifics define “category III.” “Category IV” units are least likely to be ESUs because they are separated neither geographically nor genetically from other units. This approach has been described as being unwieldy, but it is explicit, transparent, and has performed well. It also seems to provide the most flexibility in stock delineation, because several kinds of evidence are used and it offers more than a simple dichotomy for the mosaic of variation present. In addition, by considering information on distribution and population responses, it is much better than the other approaches at detecting recently diverged stocks.

Moritz (1994) proposed definitions for ESU and MU that differ from those of the phylogeographic approach. His definition of an ESU requires these entities to exhibit reciprocal monophyly (i.e., to have diagnostic differences) in the mitochondrial DNA (mtDNA) and significant divergence in nuclear DNA allele frequencies, whereas MUs are defined by significant divergence in either mtDNA or nuclear DNA allele frequencies (irrespective of the distinctiveness of the alleles). Because these definitions are based solely on DNA patterns, they cannot be realized with nonmolecular characters and therefore have limited application. Although DNA information may be more direct for determining whether genetic differences exist (some phenotypic characters can be plastic and influenced by environmental factors), it is not always available, and differences in phenotypic characters may be established more rapidly after divergence (e.g., demographic response).

The “phylogenetic” approach for defining ESU was advocated by Vogler and DeSalle (1994). Their procedure for recognizing ESUs is similar to how species are delimited under the phylogenetic species concept. Only heritable genetic, morphological, ecological, or behavioral characters are analyzed. An entity is deemed an ESU if it differs from all other entities in having a unique character or a diagnostic combination of characters. However, it is unclear how the definitions of ESU and species differ with this approach, and the process of determining useful characters may require expert knowledge and can be operationally complex.

The “character concordance” approach (Awise and Ball, 1990; Grady and Quattro, 1999) suggests that a group of individuals sharing a common evolutionary history should share characters that are unique

to the group, and the level of concordance among independent, shared characters should increase with increasing divergence time. Thus, high concordance would be strong support for distinctiveness. When concordance is incomplete, the weight of the evidence governs the decision on stock status. Because there are no clear procedural guidelines for interpreting discordant evidence, decisions may be complicated and subjective. Furthermore, many independent characters evolve at different rates, so a lack of concordance may be expected for groups that diverged recently. Therefore this approach may not be effective in identifying recently separated stocks.

A recent workshop on cetacean taxonomy recommended a definition for what should be recognized as a subspecies, the highest category of what could be considered a stock (Reeves *et al.*, 2004): a group of organisms that appear to have been on an independent evolutionary trajectory (with minor continuing flow with other groups) as demonstrated by morphological evidence or at least one line of genetic evidence, with the notes that geographical or behavioral differences can complement morphological and genetic evidence and that subspecies could be geographical forms, incipient species, or even actual species for which data are currently too poor to support elevation to the species level. However, quantitative criteria for determining adequate levels of difference were not specified; it was felt that individual researchers should have the responsibility of convincing their peers of the force of distinctions drawn.

Regardless of the approach one decides to use, it is important that clear hypotheses are stated so that interpretation of the results can be objective and divorced from philosophical or conceptual issues. It is also important that the interpretation of data is within the limitations of the hypotheses being tested. For example, if the results of a study do not support distinct units, then the statistical ability (or power) of the study to detect separate units should be examined. With inadequate power, the appropriate conclusion would be that differences in the characters examined were not detected rather than differences do not exist between the units being studied. Without sufficient power, conclusions regarding stock structure would be premature and should not be made. Finally, it may be tempting to combine units when evidence for separating the units is not found; however, this is neither correct nor does such grouping keep to the precautionary principle.

In situations where essentially no biological stock information exists, the participants of a workshop on the genetics of marine mammals recommended that the smallest area where exploitation occurs be recognized as a stock (management stock). However, they also cautioned that in certain circumstances (e.g., migratory stocks that experience exploitation in several fisheries in different areas or seasons), this strategy may not be precautionary (Dizon *et al.*, 1997). Therefore, the suitability of this approach should be assessed for each case and used only temporarily while immediate attention is directed at studying biological stock structure.

IV. Analytical Techniques

Several types of information have contributed to our understanding of marine mammal stocks. Which analytical techniques are adopted depends on which stock definition and identification approach are followed. The types of information that have been used in understanding marine mammal stock structure include phenotypic, genetic, distributional, demographic, and ecological information.

Analyses of phenotypic characters have dominated this task. Comparisons of osteology, morphology, and pigmentation have contributed the most to stock identification because these characters provide tangible evidence of distinctness. Also, increased computing

capabilities have made multivariate analyses of large data sets simple and quick. However, there are few species (and even fewer stocks) for which data from a large series of specimens can be examined, because specimens are difficult and expensive to obtain, prepare, and store and some characters can be affected greatly by the condition of the specimen (e.g., decomposition and external morphology; postmortem changes in pigmentation).

Increasingly, attention has been shifting toward molecular characters. Protein analyses were important for stock identification but have become obsolete with the development of more efficient DNA technology. Presently, most conclusions regarding stock status are not accepted fully until DNA has been analyzed as well.

Because the properties of mammalian mtDNA are fairly well understood, analyses of mtDNA have dominated molecular studies of marine mammal stocks. For many marine mammal conservation goals, mtDNA evidence is sufficient for designating management stocks [for more details, see Dizon *et al.* (1997)]. For biological stocks, evidence from characters that are heritable from both parents would provide more details about contemporary gene flow and be more convincing. This is because the majority of criteria for interpreting mtDNA data assume that mutation, drift and migration have reached an equilibrium, which can take a long time (particularly in species with long life spans and generation times) so this assumption may not be always valid. Direct analyses of nuclear DNA, especially microsatellites and SNPs (single nucleotide polymorphisms), which is inherited from both parents, are becoming more common.

Most marine mammal species do not have uniform distributions. Areas of high density are usually separated by areas with low or no concentration. Thus, distribution can provide a first approximation of where stock boundaries may exist. Based on heterogeneous distributions, seasonality of occurrence, oceanographic features (e.g., barriers, water currents, temperature), and geographic distance between areas of high abundance, provisional stocks can be proposed for further studies to test. However, distributional data should always be interpreted in conjunction with additional biological knowledge (e.g., daily and seasonal movement patterns, philopatric behavior).

Most distinct stocks are separated geographically or temporally. Therefore, each stock experiences unique ambient conditions (e.g., differential environmental stresses, food quality or availability, exploitation). Adaptations to different conditions may be expressed demographically or ecologically. Different demographic profiles in two groups would be strong evidence of non-interbreeding stocks. Also, demographic differences can reveal recently isolated stocks that have yet to develop genetic or phenotypic distinctiveness. However, to obtain accurate demographic information, a large data set must be analyzed. Because other techniques can address stock identity more directly and efficiently, few studies employ demographic analysis for delineating stocks. If available, demographic information should also be analyzed, especially if stock status, based on molecular and phenotypic evidence, is uncertain.

Many studies have proposed stocks using analyses of ecological differences. Prey preference, parasitology, pollutant loads, stable isotope ratios, and fatty acid signatures are some of the ecological information used most commonly. Although ecological studies provide another line of evidence for understanding stocks, they act only as proxies for genetic and demographic separation.

V. Study Design and Sampling

Often the people performing analyses of stock structure and identification are distant from the sample collection and may lack

knowledge of the local situation. As a result, they are dependent on those collecting the specimens for information, which sometimes may be incomplete. Thus, it is important for studies (and hypotheses) to be designed with a requirement for a set of standard, *a priori* information (e.g., sex, morphology, demography, ecology, oceanography, etc.).

Selection of samples to be analyzed is a critical part of study design, but researchers are commonly handcuffed by the limited availability of samples. As a result, it is common to include samples with limited or no information about their origin, so assumptions are made, often implicitly (e.g., stranded individuals are commonly assumed to be from a local or nearby "population" or designated as being from a certain body of water or area). Inclusion of such specimens and assumptions can unknowingly further complicate or obscure our understanding of stock structure and identity or lead to erroneous conclusions. In addition, political borders can often affect the scope of sampling. Because man-made boundaries are often unconnected with biology, they should not be used for grouping specimens in analyses.

In general, samples of coastal species (e.g., harbor porpoise, franciscana, etc.) are easier to obtain than for offshore species. However, some coastal species have small populations (e.g., *Sousa*, *Orcaella*, etc.) so specimens may be extremely rare. Also, industrial offshore fisheries may result in the capture of large numbers of oceanic species (e.g., the infamous eastern tropical Pacific tuna purse-seine fishery). For coastal species, assuming that stranded specimens are from local or nearby waters is often fairly reasonable, especially if other information exists such as local fauna composition, freshness of carcass, evidence of entanglement in local fisheries, etc.). However, the same assumption is highly questionable for offshore species, which may be less tied to land masses or fixed geographic locations but more related to highly dynamic water masses with boundaries that can vary greatly seasonally or annually. Dead or dying oceanic animals may also be carried by water currents for long distances before stranding. Therefore, great caution must be exercised when attempting to understand stock structure of oceanic species with analyses that include stranded specimens. It is also often assumed implicitly that stranded animals (which are often all that may be available) are representative of a population or stock rather than a specific part of the group.

More and more studies are employing *in situ* sampling (e.g., biopsy darting). Even with such direct sampling methods, it is crucial that extensive information accompany each sample. Standard data such as date, time and geographic location, while vital, are insufficient for species that may be relating to fluid boundaries. Sampling from the same geographical position may result in the sampling of different stocks at different times when water masses shift (Fig. 1). Recording data that can help to characterize water masses from which samples were collected (e.g., water temperature, salinity, turbidity, etc.) will help greatly in understanding stock structure. Photographs of animals sampled may also allow recognition of slight differences in morphology (e.g., pigmentation, etc.) that may help to set *a priori* groupings for tests. Although some analyses do not require *a priori* grouping (e.g., cluster analyses, STRUCTURE for nuclear genetic data), taking a more holistic approach and incorporating ecological, oceanographic and other information into study design and interpretation of results will produce more powerful and convincing conclusions.

V. Other Complications

Even if there were agreement on a single stock definition and multiple techniques were used, defining stocks would still not be a trivial task. Many situations can obscure and complicate our attempts

Figure 1 Different possible scenarios of shifts in water masses (dark and light blue and green) past a nearby land mass (brown) and through the sampling area (crossed circle) are shown. The sizes of the arrows represent the strength of the currents.

to delineate stocks, including taxonomic uncertainty; various levels of genetic exchange between stocks; clinal variation; differences between sexes in dispersal and philopatric behavior; diversity in mating strategies; habitat shifts (e.g., occasional environmental fluctuations may bring stocks that are usually separated geographically into contact and allow interbreeding); fragmentation and genetic bottlenecks resulting from exploitation; mixed stocks; social structure; and short-term and seasonal movements, sometimes across international boundaries. Without knowledge of, and consideration for these (and other) attributes, conclusions about stock structure can be compromised. With so many complications, it is not surprising that the biological stock structure of most marine mammal species (even those that were exploited heavily by commercial harvesting) remains uncertain. However, multidisciplinary techniques, technological advancements, and continued attention should allow us to make rapid progress in identifying biological stocks of marine mammals and to design more effective management programs in the absence of essential biological information.

Stranding

WILLIAM F. PERRIN AND JOSEPH R. GERACI

Stranded whales have fascinated us through history (Fig. 1). Why do marine mammals strand, what can we learn from their misfortune, and what can we do about it?

I. Why Do Marine Mammals Strand?

Animals that die or become enfeebled at sea of course may be brought passively to shore by wind and wave action. More intriguing are those cases where marine mammals in distress purposely come ashore. A stranded animal when returned to the water may deliberately strand again. This is very frustrating to those who are trying to “rescue” it. It must be understood that an animal may have stranded because it has decided that it cannot keep itself afloat and survive at sea. Thus, deliberate stranding may represent an effort to keep breathing, whatever the ultimate cost. While this may not be adaptive behavior in evolutionary terms, because nearly all stranded animals die if unassisted, given the alternative of equally certain but earlier death the consideration may be moot. A will to survive is adaptive in general, even if not effective in this circumstance.

Figure 1 A sei whale (*Balaenoptera borealis*) stranded in Argentina in 1940. From Leatherwood et al. (1982).

The natural and unnatural causes of death and disablement leading to single strandings are many: environmental conditions such as anomalously low sea temperature or ice entrapment, parasites, disease, biotoxins, ENTANGLEMENT associated with fisheries, starvation due to decreased food supply, collisions with vessels (Laist *et al.*, 2001), contaminants, oil spills, and death or direct injury inflicted by predators, other marine mammals, or at the hands of humans (Geraci and Lounsbury, 2005). The majority of live strandings of pinnipeds are caused by disease or malnutrition (Greig *et al.*, 2005; Colegrove *et al.*, 2005). Determining the cause of a stranding of either a cetacean or a pinniped can be very difficult, even when one is not dealing with a decomposed carcass; symptoms and pathology may be obscure, and two or more factors may be operating simultaneously. Animals that strand in a cluster over a period of a few days may be victims of poisoning, infectious diseases, intensive local fisheries operations (Silva and Sequiera, 2003), or unusual environmental events. By the time the strandings are investigated, the ultimate cause may no longer be evident.

Certain patterns are exhibited in the strandings of particular species related to their distribution, migrations, and reproduction (Geraci and Lounsbury, 2005). For example, newborn gray whales, *Eschrichtius robustus*, are likely to come ashore in the lagoons of Baja California only during the winter calving season. For all cetaceans, the mother-calf bond is very strong and may continue after lactation ceases. If they come ashore together, it may be impossible to determine who led the way. Young juvenile males of highly social pelagic species may strand after being lost or displaced from bachelor schools; this is thought to happen to young Atlantic white-sided dolphins, *Lagenorhynchus acutus*, along the US northeast coast during the fall. Some species follow the migrations of prey. Long-finned pilot whales, *Globicephala melas*, for example, pursue squid into shallow waters of Cape Cod Bay during the autumn and early winter and can be expected to strand at these times.

Mass strandings have always been a puzzle. A large number of whales or dolphins of pelagic species such as sperm whales (*Physeter macrocephalus*), pilot whales (*Globicephala* spp.), false killer whales (*Pseudorca crassidens*), or rough-toothed dolphins (*Steno bredanensis*), may come ashore together for no apparent reason and in seeming good health (Fig. 2). While there undoubtedly is more than one cause

Figure 2 A mass stranding of sperm whales in Oregon in 1979. Photo by Robert L. Pitman.

of mass stranding in these animals, evidence is accumulating that caregiving behavior engendered by tight social bonds may be involved in at least some cases. For example, a herd of 30 false killer whales that semi-stranded in very shallow water in the Dry Tortugas in 1977 included a large male that was moribund due to illness or injury (Connor, 2000). The other whales clustered around this male and did not return to deep water until he died 3 days later. The whales became agitated when would-be rescuers tried to separate them and insisted on remaining in a tight group around the large male. Similar behavior has been reported for other mass strandings, with rescued individuals deliberately rejoining a group on the beach containing one or more severely ill or injured animals (Geraci *et al.*, 1999) or simply joining apparently healthy animals that stranded earlier (Evans *et al.*, 2002). In most cases, in the absence of human intervention, the entire group perishes, victims of a social cohesion that must be highly adaptive in other circumstances. Death may be due to physiological stress or shock, a consequence of lying or struggling on dry land. On a population basis, mass stranding must be a rare event, or it could not persist evolutionarily. Suicidal mass stranding has been suggested

as a possible mechanism for population regulation (Sergeant, 1982), but this smacks of the group selection hypothesis of Wynne-Edwards (1962), now largely discredited.

In some other instances of mass stranding, careful investigation has uncovered pathological evidence of widespread disease or parasitism that may have been causal or contributory. For example, about half of the mature females in a large stranded group of Atlantic white-sided dolphins were severely infected with a nematode to the extent that reproductive success was likely affected (Geraci *et al.*, 1978). In a stranding of 33 or more short-finned pilot whales, *Globicephala macrorhynchus*, in Florida, all live individuals examined were clinically ill, exhibiting an increased respiratory rate, difficulty in breathing, an elevated heart rate, and a wide range of metabolic and hematological abnormalities (Walsh *et al.*, 1991). As Walsh and colleagues noted: "In such a case, the actual etiology of the stranding event may be unknown because the original inciting factor, such as a virus, may have occurred days or even weeks before."

A number of additional causes for mass stranding have been posited (Geraci and Lounsbury, 2005). Areas with broad tidal flats, strong or unusual currents, or extreme tidal volume may lead to errors of navigation or judgment that result in stranding. It has been suggested that pelagic animals may run aground in shallow water because their echolocation is impaired, or because they encounter acoustical dead zones (Sundaram *et al.*, 2006). Others believe that cetaceans use the earth's magnetic field for navigation and are led astray by magnetic anomalies or disturbances. Links to large-scale climate events (Evans *et al.*, 2005), seasonally changing environmental parameters (Walker *et al.*, 2005), and solar activity (Vanselow and Ricklefs, 2005) have also been suggested. However, the only apparent common factor is strong social cohesion, strong enough that when a single animal comes ashore, for whatever reason, others in the group are likely to follow.

Mass strandings may be increasing in frequency, due possibly to anthropogenic causes. For example, during the period 1981 to 1991, there were 20 mass strandings of long-finned pilot whales on 32 miles of beach in Cape Cod, Massachusetts, whereas only 1 had been reported in the previous 20 years, and epidemiological evidence suggests a possible link with recent morbillivirus outbreaks affecting a number of marine mammal species in the North Atlantic and Mediterranean (Geraci and Lounsbury, 2005; Duignan *et al.*, 1995). The impact of a viral outbreak may be potentiated by organochlorine pollutants that weaken the immune system.

Military sonar can cause whales and dolphins to strand and die singly or *en masse*. Some may die and sink at sea and not wind up on a beach. This has been a controversial issue since a mass stranding of beaked whales in the Bahamas in close conjunction with a nearby naval exercise in 2000 (Balcomb and Claridge, 2001). Use of tactical mid-range-frequency sonar in combination with local oceanographic and topographic conditions was identified as the cause of the stranding event (US Department of Commerce and Secretary of the Navy, 2001). The likely proximate cause of death in sonar-related strandings as determined from necropsies of beaked whales in another mass stranding in the Canary Islands is gas embolic syndrome, similar to decompression sickness ("the bends"), caused by nitrogen coming out of supersaturated blood precipitously, perhaps as the whales are frightened into surfacing faster than usual from a deep dive (Fernández *et al.*, 2005). Other effects may include physical damage to ears and other organs (Wang and Yang, 2006). Another source of loud sounds that may have similar effects is seismic survey operations prospecting for and assessing petroleum deposits (National Research Council, 2003; U.S. Marine Mammal Commission, 2007).

II. What Can Be Learned From Strandings?

All we know about many species of cetaceans is only what we have learned from strandings. This is true for many of the BEAKED WHALES, the *Mesoplodon* species for example. They are not kept in captivity for exhibit, are hunted only rarely and in remote parts of the world, and are relatively rare, elusive, and notoriously difficult to observe at sea. A rotting carcass on the beach can yield invaluable information on such things as anatomy, life history, genetics, disease, parasites, predators, contaminants, and feeding ecology. A live stranding transported to a holding facility can inform us about physiology, behavior, and cognition. A mass stranding offers a population sample (albeit potentially biased), opening to view parameters such as sex ratio, age structure, pregnancy rate, lactation rate, and relatedness within a group. A released stranding that has been tagged with a transmitter can yield invaluable data on movements, migration, and diving behavior; animals successfully released and tracked have included a pygmy sperm whale (*Kogia breviceps*), common bottlenose dolphins (*Tursiops truncatus*), and long-finned pilot whales (*Globicephala melas*) (Scott *et al.*, 2001; Nawojchik *et al.*, 2003). Every stranding event should be considered a potentially unique opportunity to learn something that cannot be learned any other way.

III. Stranding Programs and Networks

In order to take full advantage of the scientific opportunities offered by stranded marine mammals, formal stranding response programs have started up in many parts of the world. One of the first was begun by Frederick True, the noted cetologist and one of the first curators of the U.S. National Museum of Natural History (Smithsonian Institution) in Washington, DC, and resulted in the beginnings of the largest collection of marine mammal specimens in the world. The stranding program has continued to the present (Fig. 3) and is a world model for stranding-response procedures and data and specimen collection and curation (Geraci and Lounsbury, 2005). Another early stranding program began in Britain when the board of trade instructed receivers of wrecks to send telegraphic reports of the stranding of whales to the British Museum (Harmer, 1914). As "Royal Fishe," stranded cetaceans are property of the Crown and thus receive special attention and care. This has resulted in a long series of detailed data reports on Cetacea stranded on British coasts and basic knowledge of many North Atlantic species, as well as an immense and irreplaceable collection of specimens (Fraser, 1974; Sheldrick *et al.*, 1994). Perhaps the oldest stranding program, although not scientifically based or motivated, is in Vietnam, where cetaceans are revered as sea-going friends and souls, and those washing ashore have been collected and their skeletons preserved in Buddhist temples for centuries; these accumulations are now yielding information on the cetacean fauna of the region (Smith *et al.*, 1997).

In recent years, formal stranding programs and networks have been established in many countries, including Australia, Japan, New Zealand, Canada, France, Italy, Argentina, Brazil, Thailand, the Philippines, and others. In the United States, a national stranding alert network and officially mandated regional stranding programs arose after passage of the Marine Mammal Protection Act in 1972. These new programs around the world are motivated not only by scientific considerations, but by the desire to achieve humane treatment of live-stranded animals, rescuing them if possible. The goals of these programs are well established, provide for the welfare of live animals, minimize risk to public health and safety, support scientific investigation, and advance public education.

Figure 3 Stranding poster issued by the Smithsonian Institution in the 1970s.

IV. What Should Be Done With Live-Stranded Marine Mammals?

First, it must be recognized that marine mammals are under legal protection in many countries, and anyone who interferes with them, even though well meaning, may be breaking the law. The first response should be to notify the relevant authorities so that if there is a formal stranding network in the area it can go into action. A telephone call to the nearest natural history MUSEUM, oceanarium, fisheries laboratory, rehabilitation center, or marine wildlife agency will help the information get to the right place. In some areas, hotlines have been established for this purpose and the telephone numbers posted at lifeguard stations, fishery monitoring and landing sites, and other locations.

Not every live animal on the beach needs help. Pinnipeds and sea otters spend time out of the water in the course of their normal affairs. Even some cetaceans may come into very shallow water or ashore for brief periods, e.g., a killer whale to snatch a seal or a bottlenose dolphin to ride a wave. However, certain conditions are unambiguous and do demand attention: a live dolphin obviously in distress on a beach, a sea otter coated with oil, a fur seal too feeble to move, or a porpoise trapped in a fishing weir. Although it is not always possible to judge the health of a cetacean by its outward appearance, coastal animals such as bottlenose dolphins, *Tursiops truncatus*, usually strand singly only when ill and likely will need rehabilitation to survive. Many pelagic cetaceans come ashore in apparent good health, or at least free

Figure 4 A stranded pygmy killer whale, *Feresa attenuata*, brought into the Miami Seaquarium. From Leatherwood et al., 1982

of recognizable disease, and have a reasonable chance of withstanding the rigors of being returned to sea, although their long-term survival is undocumented.

Once a decision is made to do something about a live-stranded animal, there are three options: return it to the sea, euthanize it, or transport it to a care facility (oceanarium or marine mammal rescue center) for rehabilitation (Fig. 4). The basic consideration should be to take no action that will only prolong suffering. The basic criteria for making a decision are the following: (1) whether logistical support is available (e.g., a large dolphin or whale cannot be transported without a truck and means to put the animal on it), (2) the number of animals involved (a mass stranding may be a logistical nightmare), (3) the environmental conditions (rough seas, harsh terrain, darkness, or simply a rising tide can increase the risk to the animal and the team, or extremes of heat or cold may affect the animal's ability to thermoregulate), (4) condition of the animal (a healthy animal is resilient, whereas one that is ailing may not survive the ordeal associated with a rescue), (5) risk to wild populations (because of a pathogen), (6) risk to human safety, (7) ease of handling (a very large or struggling animal may be impossible to rescue), and (8) whether care facilities and resources are available.

Immediate return to the sea is an option when the animal is manageable, healthy, and able to function normally; logistical and environmental conditions are favorable; social obligations (e.g., maternal care for the young) can be met; and the area of release is within the normal range of the animal, suitable and navigable. Single-stranded odontocetes, and sea otters or pinnipeds unable to leave the shore, are usually poor candidates for immediate release. Before an animal is released, a plan should be made for monitoring it after release.

Rehabilitation is an option when there is a good chance the animal can be restored to health, facilities are available and equipped for the species and number of animals involved, arrangements can be made for safe and quick transport, the animal is manageable, and, very importantly, there are sufficient funds and staff to provide care for a reasonable period. It should be noted that even where care facilities are increasing in number, more animals come ashore than can be taken into the existing facilities.

Euthanasia is an option when it is necessary to end the suffering of an animal in irreversibly poor condition, no rehabilitation facility is available for orphaned dependent young, rescue is impossible and no care facility is available, animals persistently re-strand, or a distressed cetacean ashore is likely to attract others milling nearby

to mass strand. The procedure should be carried out humanely by an experienced qualified person and only if essential equipment and materials are available. A clumsy attempt to euthanize an animal without adequate equipment or expertise can cause more suffering than a natural death.

The time between discovery of a stranded cetacean and arrival of a stranding response team can be used by volunteers to relieve stress and improve the animal's chance of recovery. The key is to prevent further injury and keep the animal comfortable while minimizing handling and disturbance. The animal should be protected from blowing sand and kept moist with clean fresh or salt water. Care should be taken to keep water and sand out of the blowhole. In the summer, shade should be provided against the sun. If small, the animal can be positioned on its belly and holes dug to accommodate its flippers. The animal should be out of the surf and protected against lacerations by sharp rocks and seashells.

Moving, release, tagging, transport, rehabilitation, or euthanasia should only be done by qualified, experienced personnel. Detailed guidelines are available in various manuals and government publications.

Mass strandings present a special challenge and can only be coped with effectively by an organized stranding response team backed up with adequate resources. One person, the stranding coordinator or "Incident Commander," must be in charge of all on-site activities. The best procedure is to organize a response team in advance of need to attend to a mass stranding. Volunteers are often indispensable, but their activities must be closely overseen by the coordinator. The most qualified people available should be recruited to the team, including safety officers, veterinarians, and other experienced professionals from aquariums, research stations, veterinary clinics, academic institutions, and wildlife and conservation groups. A list of the kinds of equipment needed to respond effectively to a mass stranding is given in stranding manuals (Geraci and Lounsbury, 2005). The goal should be the swift release of the largest manageable number of animals that have the best chance of surviving. Live animals should be dealt with first. The animals judged to have the greatest prospect of survival should be given priority, not those near death. The integrity of the group may be important to survival of the released animals. A proven approach is to relocate as many animals as possible to a safe place in shallow water where they can rest and become reoriented among their fellows. After tagging and monitoring of condition, the animals can be released together into open water. Because mass-stranded animals returned to sea may re-strand, sometimes immediately but often days or even weeks later, released whales or dolphins should be monitored on a long-term basis, through direct observation (by cooperating fishermen, Coast Guard, sailing clubs, etc.) or telemetry.

V. What Should Be Collected From a Stranded Carcass?

The condition of a carcass determines much about what can be collected from it and should be specified in field notes. Standard condition codes are (1) alive, (2) freshly dead (i.e., edible), (3) decomposed, but organs basically intact, (4) advanced decomposition (i.e., organs not recognizable, carcass intact), and (5) mummified or skeletal remains only. The quality of information that can be obtained depends on a number of additional factors, including location; size, skills, organization, interests, and morale of the team; adherence to clear, detailed protocols; availability of equipment and supplies; number of animals to be examined; amount of time available; and care maintained in packaging, labeling, shipping, and storing samples. It is well recognized

that it is not possible or practical to collect maximal samples and data in all cases; the effort must be tailored to the conditions. As a rough guide, three levels of collection have been described (modified slightly from Geraci and Lounsbury, 2005):

Level A Data: Basic Minimum Data

1. Name and institutional address of investigator.
2. Reporting source.
3. Species (including preliminary identification and voucher material in the form of photographs in several views, teeth, skulls, and other specimens).
4. Field number.
5. Number of animals, including total and subgroups.
6. Location (preliminary description, plus longitude and latitude and closest named cartographic feature).
7. Date and time of discovery and of specimen recovery.
8. Length (and girth and weight if possible).
9. Condition, using codes above (at time of discovery and at time of recovery).
10. Sex.

Level B Data: Supplementary On-Site Information and Samples

1. Weather and tide conditions.
2. Offshore human/predator activity.
3. Presence of prey species.
4. Behavior before and during stranding, and after return to sea. Also note tag color and number and location of tagging.
5. Samples collected for life history studies (teeth, earplugs, or bone for age determination, reproductive tracts, stomach contents).
6. Samples collected for blood studies.
7. Disposition of carcass.

Level C Data: Necropsy Examination and Parasite Collection

1. Collection of tissues for toxicology, microbiology, and gross histopathology.
2. Collection of parasites.

Detailed protocols for collection of data and specimens are contained in stranding and dissection manuals (Geraci and Lounsbury, 2005). It must be stressed that information has scientific value only when documented carefully. In the case of a mass stranding, it is better, after collecting the minimal basic data for all, to obtain good samples and perform thorough examinations with accurate documentation on a small number of animals than to do a hasty job on many. However, Level-A data should be collected for all animals before moving on successively to Levels B and C.

Streamlining

FRANK E. FISH

Streamlining has a major impact on the ecological performance of marine mammals. Because swimming is an integral behavior of marine mammals that forage, mate, escape predation, disperse, and migrate in water, constraints on performance promoted adaptations for effective locomotion by aquatic mammals. To propel itself through the water at a constant swimming speed, a marine mammal needs to generate a forward force (thrust) at the expense of metabolic energy that is equal and opposite to the sum of resistive forces (drag) (Williams, 1987).

I. Drag

Two major types of drag are experienced by a marine mammal as it swims submerged. These include the pressure or form drag and the viscous or skin friction drag (Williams, 1987). The pressure drag results from the pressure distribution around the body. As water flows about a body, a high pressure is generated at the upstream face and a lower pressure is generated at the downstream face. This difference in pressure produces a force, pressure drag, which opposes forward movement. Viscous drag is a function of the viscosity or stickiness of the water around the body. Water particles adhere to the body surface within a thin layer of water adjacent to the body, called the boundary layer. Friction within the boundary layer and between the boundary layer and the body create a force in the drag direction. The magnitude of the viscous drag will depend on the wetted surface area of the body and the flow conditions within the boundary layer. Boundary flow can be laminar, turbulent, or transitional. A boundary layer with laminar flow produces the lowest viscous drag.

Figure 1 A sketch of dolphin and body contours by Cayley.

Drag is minimized primarily by streamlining the shape of the body and the appendages (Hertel, 1966; Fish, 2006). The streamlined profile of these structures has a fusiform design resembling an elongate teardrop with a rounded leading edge extending to a maximum thickness and a slowly tapering tail. This shape was first investigated in the dolphin by Sir George Cayley (circa 1800) as a solid of least resistance design (Fig. 1). As shown in Fig. 2, marine mammals display a streamlined, fusiform, design. This fusiform shape is sculpted by the distribution of blubber and/or fur covering the body. Modern submarines utilize a fusiform design analogous to the body shape of marine mammals. In addition, the appendages, such as the flukes, flippers, and dorsal fin, have a cross-sectional shape with a fusiform design similar to conventional aircraft wings and hydrofoils.

Streamlining minimizes drag by reducing the magnitude of the pressure difference over the body (Fish, 2006). This reduced pressure difference allows water in the boundary layer to flow without separation from the body surface until near the trailing edge. As separation occurs, a wake is generated downstream. The wake behind the body is narrow, indicating little distortion to the flow and a small pressure drag. Premature separation of the boundary layer occurs because of instabilities in the flow. A laminar boundary flow is inherently less stable and more prone to premature separation than turbulent flow. An animal may pay a higher energetic cost in frictional drag by allowing the development of a turbulent boundary layer, but the pressure and total drags will be substantially lower than with laminar flow where separation transpires.

II. Body Shape

The bodies of marine mammals are well streamlined (Hertel, 1966; Fish and Hui, 1991). An indicator of the degree of streamlining is the fineness ratio ($FR = \text{body length} / \text{maximum diameter}$). The FR value of 4.5 is considered to provide the least drag and surface area for the maximum volume, although only a 10% increase in drag is realized in the FR range of 3–7 (Fig. 3). However, analysis of streamlined bodies demonstrated minimum drag at FR of 7. In general, cetaceans, pinnipeds, and sirenians have body shapes with FR between 3.3 and 8.0 (Fig. 3). The notable exception for cetaceans is the northern right whale dolphin (*Lissodelphis borealis*) or “snake porpoise” that can have a FR up to 10.9. Despite their bulk and specialization of the head

for filter feeding, the mysticete whales are well streamlined. FR for the Balaenopteridae ranges from 4.8 to 8.1 and Balaenidae ranges from 3.3 to 8.0.

FR is however a crude indicator of the streamlining of the body, because it does not provide information on changes in body contour. Another indicator of body streamlining is the position of the maximum thickness, called the shoulder. Shoulder position is important because this is where transition from laminar to turbulent flow and boundary layer separation are likely to occur. Anterior of the shoulder the pressure distribution favors maintenance of a laminar boundary layer. The position of the shoulder in the most rapidly swimming aquatic mammals is displaced posteriorly which is similar to engineered wings with “laminar” profiles, which reduce drag through maintenance of laminar boundary flow. The shoulder position for dolphins is 34–45% of the body length from the beak.

The shoulder position is located at 40% of body length for otariid seals and 50–60% of body length for phocid seals from the nose. The position can be varied in pinnipeds, because the neck is capable of being retracted and extended. Extension of the neck during rapid swimming could modify the flow over the anterior of the seal and reduce drag by extending the region of laminar flow. Such a drag reduction could aid seals in catching fast swimming, elusive prey.

Experiments on flow visualization using a fluorescent dye applied to a dolphin’s melon showed the flow to be laminar over the anterior 32% of the dolphin. Transition began before the dorsal fin with turbulence aft of the fin. Separation of the boundary flow occurred smoothly near the base of the flukes. Flow visualization using bioluminescence within the boundary layer of dolphins and seals similarly indicated a lack of separation from the body surface (Fish, 2006). Flow separation is restricted to the tips of the flukes, flippers, and dorsal fin. The flow separation has been observed as bioluminescent “contrails” (Fig. 4).

The contrails are vortices generated at the tips of the appendages. A tip vortex is generated from pressure differences along the two surfaces of the appendage. The pressure difference produces a lift force similar to the lift produced by airplane wings. Marine mammals utilize lift generated from the appendages to propel the body, increase stability, regulate depth, and maneuver (Fish and Hui, 1991). A consequence of the tip vortices is the loss of energy from the generation of lift, which is referred to as an induced drag.

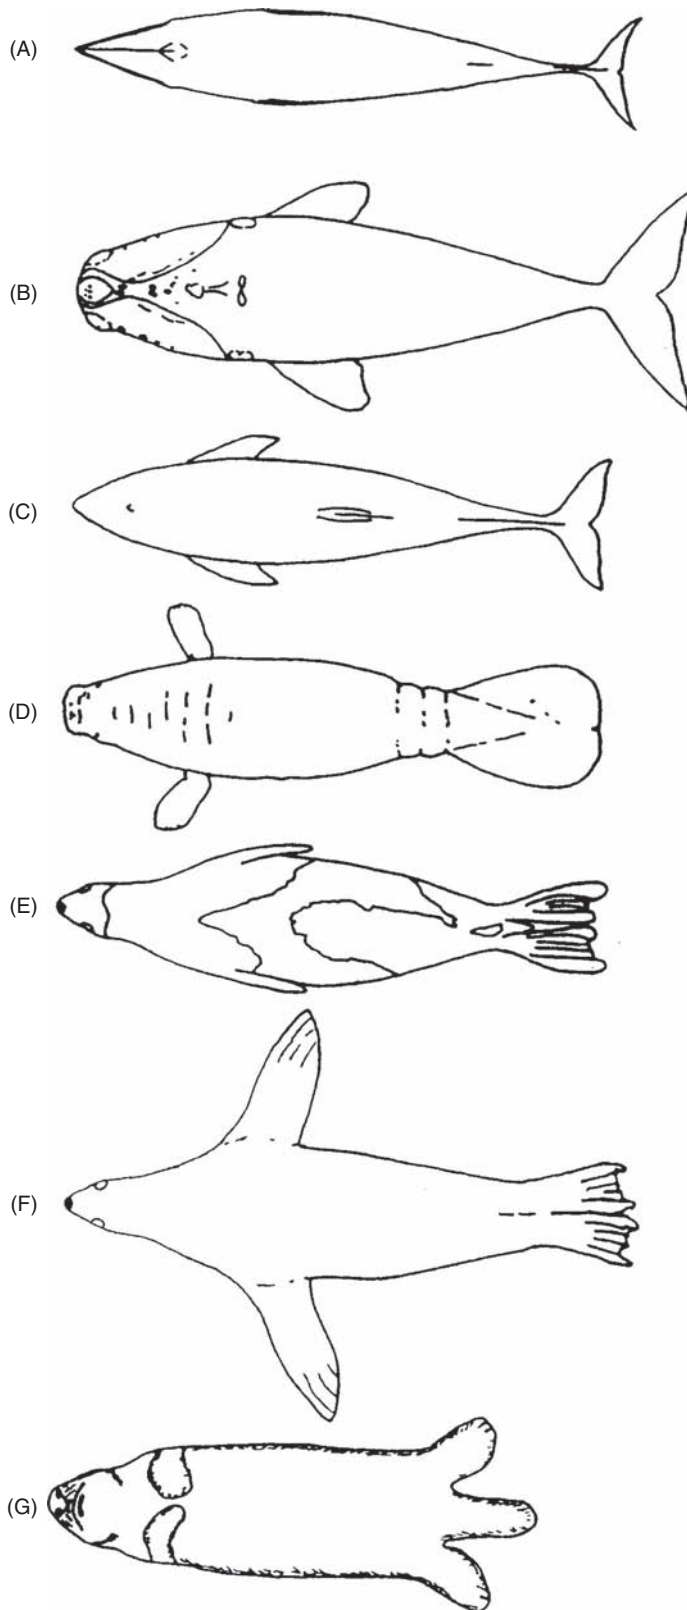

Figure 2 Fusiform body shape of marine mammals represented by (A) minke whale, *Balaenoptera acutorostrata*, (B) North Atlantic right whale *Eubalaena glacialis*, (C) harbor porpoise, *Phocoena phocoena*, (D) West Indian manatee, *Trichechus manatus*, (E) harp seal, *Phoca groenlandica*, (F) California sea lion, *Zalophus californianus*, and (G) sea otter *Enhydra lutris*.

Figure 3 A comparison of ranges of Fineness Ratio (FR) for various marine mammal families. The dashed lines indicate FR of 4.5 and 7.0. Minimum drag for streamlined bodies occurs at FR of 7. Silhouettes show the difference in shape in reference to FR from a circular shape (FR = 1) to an elongated form (FR = 7).

The induced drag and interference to the flow over the body due to the addition of the appendages can affect streamlining. The dorsal fin, pectoral flippers, and flukes comprised only 2.6, 4.2, and 5.6% of the total surface area of the harbor porpoise (*Phocoena phocoena*), respectively; however, these appendages are responsible for 35.7% of the total drag (4.3, 18.0 and 13.4%, respectively). Induced drag is reduced by appendages with a long narrow shape and tips that taper sharply to a point (Fig. 5).

Streamlining also is fostered through buoyancy control. Compared to the center of gravity, the center of buoyancy is closer to the head for terrestrial mammals in water. This relationship produces a torque that causes the body to float at an angle to the horizontal. This orientation would decrease streamlining. Internal and external modifications for buoyancy control provide aquatic mammals with longitudinal trim for better streamlining by presenting a smaller body area to the oncoming flow. For sea otters (*Enhydra lutris*), non-wettable fur provides buoyancy by an entrapped layer of air to maintain a horizontal body orientation when swimming at the surface. The elongate shape of the lungs of marine mammals helps to displace the center of buoyancy posteriorly. This arrangement is possible because the diaphragm of marine mammals is oriented obliquely to almost parallel to the spine.

III. Drag reduction mechanisms

High swimming speeds attained by many marine mammals have focused attention toward specialized drag reduction mechanisms.

Figure 4 Bioluminescent image of a gliding bottlenose dolphin (*Tursiops truncatus*) showing lack of separation from the body surface.

Figure 5 False killer whale (*Pseudorca crassidens*) displaying highly tapered and elongated appendages.

In what is known as Gray's Paradox, hydrodynamic estimates of dolphin power output at high speeds were inferred to be greater than the power that could be developed for the mass of muscle available for swimming (Gray, 1936). Resolution of the paradox was believed only possible if the drag was reduced by maintaining laminar flow within the boundary layer, despite a high swimming speed dictating a turbulent boundary flow with increased viscous drag.

While the idea of a special drag reduction mechanism in dolphins has been irresistible, direct evidence of its existence has been elusive. To date, no conclusive evidence has been found of laminar boundary flow over the entire body surface of fast-swimming dolphins (Fish, 2006). The mechanisms examined included compliant skin dampening, secretions, skin cell sloughing, infusion of long-chain polymers into the boundary layer, boundary-layer heating, skin folds, and boundary layer acceleration (Fish and Hui, 1991). Special drag reduction mechanisms are unnecessary to explain Gray's Paradox, which is reconciled when one considers that the calculations of power output were based on burst swimming (10 m/sec for 7 sec) and muscle power output was underestimated, because it was based on sustained performance of dogs and humans.

The naked skin of cetaceans is regarded as a means to maintain a smooth flow with an attached boundary layer over the surface of the body. In addition, the cells of epidermis are produced rapidly, which promotes a high rate of skin sloughing. This increased skin sloughing deters organisms, such as barnacles, from attaching to the skin and thus minimizes drag. The large bumps or tubercles along the leading edge of the flippers of humpback whales (*Megaptera novaeangliae*) produce large vortices, which aid in stabilizing the boundary layer, preventing separation and minimizing drag (Miklosovic *et al.*, 2004). The flippers can then be used to generate large lift forces for maneuvering. The properties of the hair of aquatic mammals are noted to reduce drag by aiding in streamlining of the body. The lack of arrector pili muscles in seals and sea otter permits the pelage to lie flat in water, minimizing resistance to swimming.

Behavioral mechanisms are used also to minimize the drag. Porpoising, which is performed by the fastest swimmers, is a series of rhythmic leaps. By traveling through the air for a given distance, the animal reduces its drag compared to swimming over an equivalent distance underwater (Au and Weihs, 1980). This reduction in drag

is due to the lower density and viscosity of air compared to water. In addition, swimming near the water surface to facilitate breathing incurs a large drag increment due to the energy lost for the animal in the formation of surface waves. Porpoising becomes economical only at high swimming speeds when the cost of leaping from the water becomes smaller than the drag on the animal in water. In addition, porpoising is associated with the need to increase ventilation time resulting from greater energetic demands of rapid swimming (Fish and Hui, 1991).

Many dolphins utilize free-riding behaviors to reduce the energy cost of swimming (Williams *et al.*, 1992). In this behavior, the dolphin takes advantage of the pressure field generated by another body and moves along with little or no energetic input. Dolphins have been observed to ride the pressure waves of ships and large whales. By situating itself on the bow wave, the small cetacean can be pushed along or surf down the front slope of the wave (Lang, 1966). This latter mechanism is analogous to human surfing. Sea lions will surf on breakers to get up onto beaches. Even large whales may reduce swimming effort by using the energy of large oceanic waves.

Formation swimming influences the water flow around adjacent individuals. Drafting is the beneficial use of the water flow to reduce drag with a concomitant decrease in the energy cost of locomotion (Weihs, 2004). Large groups of dolphins will organize into side-by-side and echelon formations. Drafting becomes particularly important to young whales to maintain speed with their mothers. A calf swims next to the maximum diameter or near the genital region of the mother. At these locations, the calf is in a hydrodynamically favorable position arising from the interaction of its pressure field with that of the mother's. The calf experiences a thrust component pulling it along with the mother, who experiences increased drag.

Striped Dolphin

Stenella coeruleoalba

FREDERICK I. ARCHER, II

I. Characteristics and Taxonomy

The striped dolphin (*Stenella coeruleoalba*) is a pelagic small delphinid common in warm-temperate to tropical waters around the world. The specific name, *coeruleoalba*, refers to the diagnostic pattern of blue and white stripes and blazes along the lateral and dorsal sides of their bodies. These dolphins have been well studied in several regions where they occur, such as the western north Pacific, eastern tropical Pacific, and the Mediterranean.

The most striking characteristic of striped dolphins is their bold gray and white color pattern (Fig. 1). The primary features are an eye-to-anus and an eye-to-flipper stripe that are dark gray or bluish black. The dorsal cape is a muted gray or bluish-gray, usually invaded by a white to light-gray spinal blaze that flows from the lateral field. The lateral field is usually darker than the ventral field. A dark stripe branching from the eye-to-anus stripe and continuing into the ventral field is usually present. A faint secondary stripe may also be present in the ventral field.

Striped dolphins, also referred to as "streakers," are similar to most other small oceanic dolphins, having a long beak (well-demarcated from the melon) and falcate dorsal fin. In the field they are most likely to be confused with common dolphins (*Delphinus delphis*), Fraser's dolphin (*Lagenodelphis hosei*), spinner dolphins (*S. longirostris*), or Clymene dolphins (*S. clymene*) but can be easily distinguished by their robust body and coloration. The longest recorded specimen was 2.56 m long and the heaviest specimen weighed 156 kg. Mean maximum body length in the western Pacific is 2.4 m for males and 2.2 m for females (Archer and Perrin, 1999).

Variation in skull and body size has been documented among several geographical regions, and there is genetic evidence that further population subdivision may occur within some of these regions (Bourret *et al.*, 2007). Cranially, *S. coeruleoalba* most closely resembles *S. clymene*, but is significantly larger (Perrin *et al.*, 1981). Sequence analysis of the cytochrome-*b* mitochondrial gene supports a sister species relationship between these two species. The two share an unresolved polytomic clade with *Delphinus* spp., *S. frontalis* and *Tursiops aduncus* (LeDuc *et al.*, 1999). However, as the genus *Stenella* was found to be paraphyletic in this study, the final taxonomic resolution for striped dolphins awaits further work.

II. Distribution and Abundance

The range is well documented in the western and eastern North and Tropical Pacific, where most records are below about 43°N. Total abundance in this region is estimated to be approximately 570,000 in the western North Pacific and 1.5 million in the eastern North and Tropical Pacific. The species has been recorded from the Atlantic coast of northern South America up to the eastern seaboard of North America, with the northern limit a function of the meanderings of the Gulf Stream. It is found in the eastern North Atlantic south of the United Kingdom and is the most frequently occurring dolphin in the Mediterranean Sea. Abundance in the western Mediterranean Sea has been estimated at approximately 118,000. A recent estimate for the southern Tyrrhenian Sea is 4030 (CV = 0.30) (Fortuna *et al.*,

Figure 1 A leaping striped dolphin in the Mediterranean Sea. Photo courtesy of F. Fossa, Delfini Metropolitan, Acquario di Genova.

2007). It has also been documented from the coast of several countries bordering the Indian Ocean, but its full range in this region is unknown.

III. Ecology

Striped dolphins can usually be found outside the continental shelf, typically over the continental slope out to oceanic waters and often associated with convergence zones and waters influenced by upwelling (Ballance *et al.*, 2006). The species has been reported in waters from 10–26°C, although most records are from about 18–22°C (Archer and Perrin, 1999).

The species feeds on a variety of pelagic or benthopelagic fish and squid. Off the coast of Japan, South Africa, and in the oceanic waters of the northeast Atlantic, lantern fish (family Myctophidae) are the dominant prey items. In coastal waters in the Northeast Atlantic, their diet shifts more to cod and anchovy, while they primarily feed on squid more in the Mediterranean (Perrin *et al.*, 1994; Ringelstein *et al.*, 2006). To reach potential prey, striped dolphins may be diving from 200 to 700 m. However, analyses of stomach contents suggest that foraging occurs around dusk or early night when prey migrate closer to the surface. Attacks by both sharks and killer whales (*Orcinus orca*) have been reported for this species (Archer and Perrin, 1999).

As a result of a large number of specimens available from the Japanese drive fishery and a morbillivirus epizootic in the western Mediterranean, contaminants and parasites have been studied more intensively in this species than in any other cetacean. High organochlorine loads in the western Mediterranean population have been hypothesized to have caused an immunodepressive state, thus decreasing resistance to infection which in turn led to the deaths of thousands of dolphins from 1990 to 1992. Blubber PCB levels from animals affected by the epizootic may be among the highest recorded values for any mammal (Archer and Perrin, 1999; Aguilar, 2000).

IV. Behavior and Physiology

Striped dolphins perform a variety of aerial behaviors such as breaching, chin slaps, and a unique behavior termed “roto-tailing,” in which they make high arcing jumps while rapidly rotating their tail before reentering the water. They do not commonly ride the bow. School sizes vary between regions, ranging from 10 to 30 to several hundred individuals, but rarely greater than 500 (Archer and Perrin,

1999). In the western Pacific, a complex schooling system has been documented in which individuals move between juvenile, adult, and mixed schools (Miyazaki and Nishiwaki, 1978). The adult and mixed schools are further divided into breeding and nonbreeding schools in what is likely to be a polygynous mating system.

V. Life History

Mating is seasonal, with gestation lasting from 12 to 13 months. Body length at birth has been estimated to be between 93 and 100 cm. Males enter sexual maturity between 7 and 15 years of age, while females become sexually mature between 5 and 13 years of age. Mean length at sexual maturity is 2.1–2.2 m. Density-dependent changes in several life history parameters have been reported for the western Pacific population, probably a result of large fishery kills. Maximum estimated age for both males and females is 57.5 years (Archer and Perrin, 1999).

VI. Interactions with Humans

The western north Pacific population(s) of striped dolphins has experienced its heaviest mortality from Japanese drive and hand-harpoon fisheries. Annual catches in one region during the 1940s and 1950s were approximately 8000–9000 animals, reaching as high as 21,000 in some years. However, self-imposed quotas, lower encounter rates, and the dissolution of a fishery cooperative caused annual catches to drop to below ca. 1000 in the early–mid-1980s (Kishiro and Kasuya, 1993). Other directed takes of the species have also occurred in St. Vincent and the Mediterranean for human consumption and protection of fishing gear. Incidental catches have also occurred in the eastern Tropical Pacific tuna purse-seine fishery, pelagic driftnets in the western Mediterranean and northeastern Atlantic, as well as in a variety of gear in fisheries across their range (Archer and Perrin, 1999; Aguilar, 2000). Striped dolphins have not been successfully maintained in captivity, where most have died within 1–2 weeks after not feeding well (Archer and Perrin, 1999).

Surveys

KARIN A. FORNEY

Surveys are used to address many different marine mammal research questions, including distribution, abundance, trends, and habitat associations. Equipment and methodology vary depending on the species of interest, financial resources, availability of research platforms, and survey objective. Marine mammals at sea are most commonly surveyed aboard ships or large boats (Øien, 1991; Wade and Gerrodette, 1993; Barlow, 1995), or from fixed-wing aircraft (Heide-Jørgensen *et al.*, 1993; Forney *et al.* 1995; Garner *et al.*, 1999). Small boats, helicopters, airships, and land-based viewing stations are also used when appropriate (Kraus, *et al.*, 1983; Rathbun, 1988). Line-transect methods (Buckland *et al.*, 2001) are often the most effective for estimating the abundance of marine mammals at sea, although other survey techniques are also used (Hiby and Hammond, 1989; Garner *et al.*, 1999). Marine mammals on or near land, such as pinnipeds, sea otters or walrus, are more commonly counted from land-based viewing points or using aerial photography (Lowry, 1999).

I. Vessel Surveys

Large oceanographic research vessels (Fig. 1), are the most versatile platform for at-sea surveys of marine mammals. They can carry a dozen or more researchers and remain at sea for weeks at a time, providing the ability to cover extensive marine areas. Search efficiency is greatest aboard these large vessels, because observers can search from a greater height above the water (on the flying bridge, bridge, or in a crow's nest) and use high-power, deck-mounted binoculars ("big eyes") (Fig. 2) when searching for and identifying marine mammals. Large research vessels usually also have equipment for collecting oceanographic data for marine mammal habitat studies (Fiedler and Reilly, 1994), and they may be able to tow hydrophones to detect marine mammals acoustically. Auxiliary studies including photography, biopsy sampling, diving behavior, and prey sampling are also often possible during vessel surveys. A significant disadvantage to large research vessels, however, is their great operating cost: approximately US \$10,000 per day. Small- or medium-sized vessels (Fig. 3), including a variety of fishing boats and sail boats, have successfully been used for surveys at a significantly reduced cost (Vidal *et al.*, 1997). This is the most feasible option in many parts of the world, particularly in developing countries (Aragones *et al.*, 1997). On these smaller vessels, searching is usually conducted with hand-held binoculars or by naked eye, from the highest stable deck or platform on the ship. In some shallow bays and rivers, even smaller boats (e.g., rigid-hull inflatable boats, whalers) may be required for safe navigation.

Figure 2 "Big eyes" used to search for marine mammals on large survey vessels. (Photo courtesy of Protected Resources Division, Southwest Fisheries Science Center, NOAA).

II. Aircraft Surveys

The main advantages of aerial surveys are the ability to cover large areas quickly and the lower cost of aircraft compared to large ships. They are particularly useful for rapid assessments and preliminary studies to determine the relative distribution and abundance of species in a particular region. Using strip or line-transect methods, aerial survey can be used to estimate abundance and monitor trends. Aircraft with high wings and bubble windows (Fig. 4) are best suited, because they allow lateral viewing as well as some downward visibility. An additional downward-viewing ("belly") window enhances sighting efficiency considerably, because marine mammals are most easily seen from the air when viewing perpendicular to the water surface. A typical aerial survey observer team consists of two observers searching through the two side windows, one data recorder, and, if possible, a belly observer. Aircraft can also be outfitted with downward viewing instrumentation (e.g., radiometer, hyperspectral imager) to measure ocean surface properties, such as sea surface temperature and ocean color, to provide habitat information during surveys.

Figure 3 Small survey vessel used in the Philippines (Photo: W. Perrin).

Figure 4 NOAA Twin Otter survey aircraft with bubble window (under propeller) and belly window port (above tire) (Photo: K. Forney).

III. Land-Based Surveys

A few populations of whales reliably migrate close to shore and have successfully been surveyed from land-based stations. These include bowhead whales, *Balaena mysticetus*, at Point Barrow, Alaska, and gray whales, *Eschrichtius robustus*, along the California coast (Buckland *et al.*, 1993). During these surveys, visual and acoustic means may be used to record all whales that travel past the observation point during the migratory period. Adjustments are made for unobservable periods, such as night-time and times of poor weather conditions. Pinnipeds are most commonly counted from land-based

viewing stations, such as cliff-tops, although aerial photographs can provide an excellent alternative means of surveying these animals along the coastline (Lowry, 1999).

IV. Methodological Considerations

Detectability of marine mammals is a key factor in deciding what type of survey platform to use (Hiby and Hammond, 1989; Buckland *et al.*, 2001; Garner *et al.*, 1999). Animals that dive for prolonged periods, such as sperm whales (*Physeter macrocephalus*) and beaked whales (Ziphiidae), will be missed much more frequently during

aerial surveys than from ships, because the aircraft travels much faster. For some species, correction factors have been developed to correct for the proportion of animals missed from airplanes or ships. Vessel attraction or avoidance is another concern when designing shipboard marine mammal surveys. For example, harbor porpoise are known to avoid vessels, and if animals are not detected before they react, resulting abundance estimates may be too low. The opposite problem exists for species that are attracted to vessels to “ride the bow”; in these cases abundance estimates may be too high. Both of these problems can be minimized by using a larger vessel that allows viewing from a greater height and with high-power binoculars; animals can then be detected at a greater distance before they react to the vessel.

There is increasing recognition that marine mammal surveys are most effectively interpreted in the context of the habitat conditions at the time of the survey. Marine ecosystems are very dynamic, and the concurrent collection of real-time ecosystem data during surveys provides an ecological context for the observed patterns in marine mammal distribution and abundance. Physical oceanographic measurements and indices of biological productivity can readily be obtained through shipboard sampling, aerial instrumentation, or satellite data. Biological measurements generally require shipboard sampling, such as net tows and hydroacoustic measurements. With the addition of such ecosystem data, survey results can be used to model ecological relationships and evaluate the effect of environmental variability on marine mammal species (Hedley *et al.*, 1999; Forney, 2000; Ferguson *et al.*, 2006).

Sustainability

CHARLES W. FOWLER AND MICHAEL A. ETNIER

Sustainability has been elusive in spite of its ubiquitous appearance in the goals for management. Human impacts need to be sustainable, whether they are the harvest of a marine mammal population, the harvest of finfishes in the marine environment, our production of CO₂, or the genetic effects we have on other species. Sustainable human interactions with other systems must be established in ways that account for the suite of factors involved in ecosystems and the complexity of the biosphere to include both our direct effects and our indirect effects on such systems. It is unlikely that historical harvests of marine mammal populations are sustainable, partly because of their low productivity levels (Perrin, 1999). Thus, defining sustainability, whether it involves our interactions with marine mammals, fisheries resources, or ecosystems, remains an important objective.

Historically, the concept of Maximum Sustainable Yield (MSY) has played a major role in the management of our utilization of natural resources. This approach has yet to be assessed in its contribution to worldwide problems such as over-harvested fish populations (Rosenberg *et al.*, 1993; Committee on Ecosystem Management for Sustainable Marine Fisheries, 1999). Commercial whaling and sealing have also involved concepts derived from the MSY approach.

The inadequacies of management based on MSY have been recognized [e.g., it is illogical (Fowler and Smith, 2004)]; such approaches are not sustainable. Progress in understanding such problems involve the development of other methodologies, e.g., the Catch Limit Algorithm of the International Whaling Commission (Slooten, 1998) and the Potential Biological Removal approach being used by the National Marine Fisheries Service in the United

States (Wade, 1998). These alternatives, however, have not escaped the weaknesses of being applicable only to individual species and they do not account for complexity. The ecosystem effects of fishing (Hall, 1999), whaling, or sealing are not adequately considered in current management strategies. The challenges currently facing management are not being met.

It is therefore extremely important to find alternatives that will work. One approach is systemic management (Fowler, 2003) in which empirical examples are used to define and measure sustainability and set sustainable goals. Along with other species, marine mammals are sources of information about sustainability that is broadly applicable and meets the demands being made of management. Using empirical examples of sustainability, the abnormal or pathological can be avoided.

Marine mammals serve as empirical examples of sustainable roles, or niches, within marine ecosystems; they have persisted as parts of such systems to integrate the various factors contributing to their evolution. Resource consumption is an example of an ecosystem relationship for which we need measures of sustainability. Both marine mammals and fisheries consume biomass from resource/prey species, making part of their interaction competitive. The rates of predation by marine mammals exemplify variation in sustainable levels of consumption. The size selectivity of their feeding habits exemplifies sustainability involving genetic impact. Importantly, there are limits to variation in such interspecific interactions as there are with all ecological interactions (Fowler and Hobbs, 2002). The failures of conventional management can be overcome by replacing such management with processes that mimic empirical examples of sustainability (Fowler, 2003). Such management ensures that fisheries catches or selectivity are not abnormal, in comparison to the consumption and selectivity observed among other consumer species. Thus, observed examples of sustainable consumption rates, and size selectivity can be used to regulate the catches taken by fisheries while simultaneously conserving resources and habitat for other species. As such, marine mammals, like other species, are empirical examples of sustainability that provide guiding information. Use of such information prevents the bias of human limitations in converting scientific information to objective management advice (Fowler, 2003).

I. Management Questions, Empirical Answers

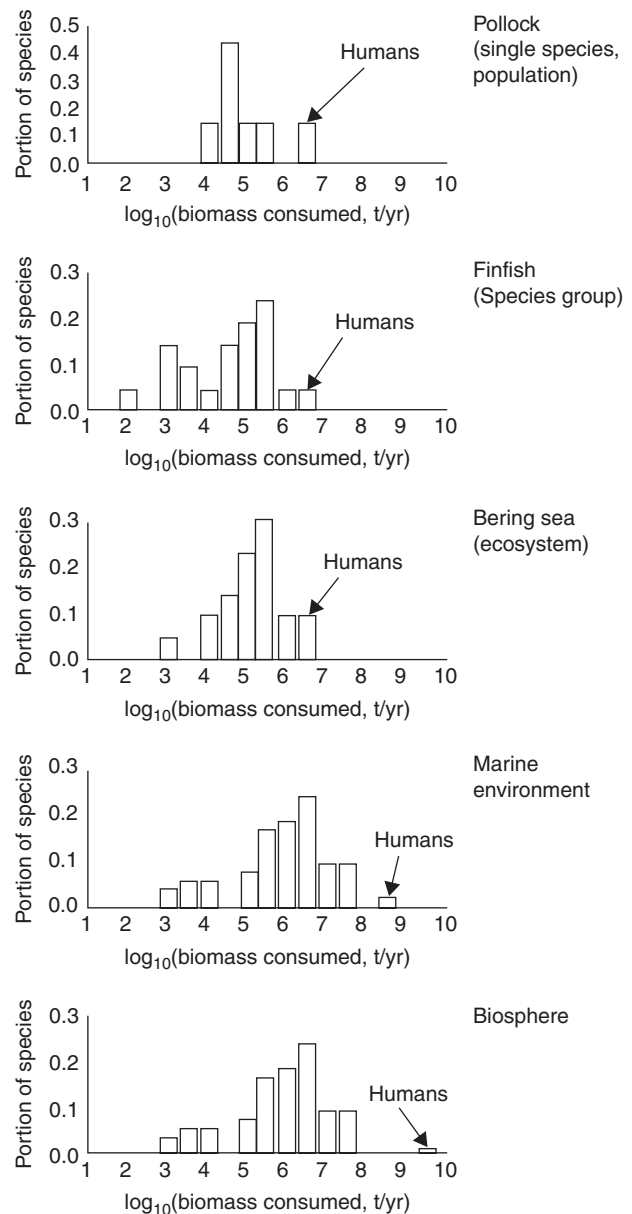

How many tons of whales, seals, fish, cephalopods, or other resources should we harvest each year? What is the appropriate or optimal rate at which to harvest biomass, and when and where should it be harvested? What is an advisable size selectivity for commercial fishing, to deal with one of the many aspects of the genetic effects of harvesting? Such questions can be asked with regard to a single resource species, or with respect to any area of the oceans, an ecosystem, a group of resource species, a season, or the biosphere. How do we answer all such questions so that the answer for one case will not be in conflict with the answer for another? Empirical information is key to answering such questions consistently, and marine mammals are key elements in providing such information for management in marine environments (Fowler, 1999; Fowler, 2003).

Fig. 1 shows frequency distributions (empirical probability distributions) for consumption rates exhibited by various marine mammals. Also shown, for comparison in each case, is the harvest rate for fisheries—the rate at which humans consume biomass. The top panel illustrates consumption from a population of an individual species and the bottom panel total consumption within the biosphere. Intermediate panels depict consumption from a group of resource

species, an ecosystem, and the marine environment. Thus, Fig. 1 represents information for a telescoped series of increasing complexity. In this case, the biosphere contains the marine environment which, in turn, includes the ecosystem (Bering Sea). Within the ecosystem we find populations of resource species (the finfish) among which is the population of walleye pollock (*Theragra chalcogramma*, one species).

Figure 2 is a comparison of the mean size of Atlantic cod (*Gadus morhua*) taken by 19 species of marine mammals with that of commercial fisheries. This represents one measure of the abnormality of commercial fishing in regard to the size composition of catches and its related genetic effects on the resource species compared to the situation normally experienced in the ecosystem (Etnier and Fowler, 2005). The intensity of this selectivity is directly related to the abnormally high harvest rates shown in Fig. 1.

Various requirements are placed on management (e.g., the tenets of management) (Fowler, 2003). It has been made clear that management should avoid abnormality in the components, processes,

and characteristics of systems (Christensen *et al.*, 1996; Mangel *et al.*, 1996) [see the review of Fowler and Hobbs (2002)]. These include the components and processes that constitute individuals, species, ecosystems, and the biosphere. Humans (through commercial fishing) are, or have been, obvious outliers relative to the natural variation illustrated in Figs. 1 and 2 (Fowler and Hobbs, 2003).

There are things management can not do. The other species within these distributions are largely beyond our control, but not our influence, especially the collective aggregate of species in each distribution. Individual species can undergo change opposite to our intentions if we act to influence them directly. In fact, changes we stimulate in these species may result in unwanted reactions in the rest of the system, whether we purposely manipulate them individually or as a group. These changes include repercussions throughout the food web (e.g., predator/prey dynamics) and domino-effects of genetic consequences in the underlying coevolutionary web. Such reactions cannot be avoided.

Management can move forward, however, by focusing on reducing consumption by humans, or harvesting smaller fish, thus avoiding the abnormal by falling within the range of the variation exhibited by other species. Nonhuman species exhibit predator–prey interactions that occur within the context of complexity—all the things that influence these species to result in what we observe (all the explanatory factors) (Fowler and Crawford, 2004). That is, all the things that have contributed to the observed rates of consumption such as those shown in Fig. 1, or the size selectivity shown in Fig. 2, are taken into account. These factors include all anthropogenic factors to include

Figure 2 The frequency distribution of the mean size of Atlantic cod (*Gadus morhua*) taken by 19 species of marine mammals (1983–1996) compared to that in the take of cod by commercial fisheries prior to their collapse in the Northwest Atlantic. From Etnier and Fowler (2005), with permission.

the effects of global warming, toxic chemicals, overfishing, introduced species, and oceanic acidification. This complexity is inherent to the patterns we observe.

Figures 1 and 2, then, serve to guide the management of our use of fisheries resources when achieving sustainability is the ultimate goal. The empirical data exemplify what works in the face of the complete suite of factors that set limits on the consumption of resources. Better options are found among the more numerous examples toward the centers of the distributions compared to the lack of examples beyond the tails (Figs. 1 and 2). The risks and constraints that prevent the accumulation of species in such regions are to be avoided. How, then, can we carry out sustainable management?

II. Management to Achieve Sustainability

It has long been recognized that we need a form of management that applies to ecosystems (Christensen *et al.*, 1996). To develop sustainable management strategies, humans must manage by having sustainable influence on ecosystems. This includes consuming biomass from ecosystems at rates that are sustainable. Sustainable management requires change. For example, reducing consumption by humans to 10% of current harvest rates of fish would place our species squarely within the range of variation shown in relevant ecosystems (third panel of Fig. 1). Such change will require time to accomplish. Maintenance of reduced levels, once achieved, would lead to further challenges for management. These would include responding to changes within ecosystems over seasons, with shifts in climate, or in response to our management.

It has been recognized for some time, in the world of commercial fisheries management, that the historical focus on managing harvests from the individual species point of view has been insufficient, partly because of the need to consider ecosystems. However, management restricted to ecosystems would be similarly insufficient because of the need to account for both the broader marine environment and the biosphere, in addition to individual species.

Management based on empirical examples is an integrated approach that simultaneously helps to define sustainable harvests at the level of individual species and the biosphere. For example, reducing harvests to between 1 and 10% of recent harvest levels would be required for the species represented in the top panel of Fig. 1. We can similarly account for multi-species groups and the entire marine environment (second and fourth panels, respectively, Fig. 1). The biosphere can be involved by reducing human consumption to about 0.1% of current consumption levels (Fig. 1, panel 5). Not only would this account for food-web effects, but it would also deal with the intensity of any selectivity resulting in genetic effects. Selectivity *per se* can also be dealt with directly as a distinct management issue (Fig. 2).

Figure 1 The frequency distribution of consumption rates (biomass consumed per year, in \log_{10} scale) for marine mammals showing optimal consumption rates where most species are concentrated. The rate at which humans harvest biomass is shown for comparison. The top panel shows the natural variation in consumption of walleye Pollock (*Theragra chalcogramma*) as observed for six species of marine mammals in the Bering Sea in comparison to recent takes of pollock by commercial fisheries (Livingston, 1993). The second panel shows consumption of finfish in the Bering Sea by 20 species of marine mammals compared to fisheries takes (predominantly pollock) (Fowler and Perez, 1999). Total biomass consumption is shown for 20 species of marine mammals in the Bering Sea in the third panel, again compared to the commercial take which is predominantly pollock (Fowler and Perez, 1999). Total biomass consumption for the entire marine environment (all oceans combined) is shown in the fourth panel for 55 species of marine mammals, here compared to the take of about 110 million metric tons estimated as the harvest of biomass for human use in the late 1990s (Committee on Ecosystem Management for Sustainable Marine Fisheries, 1999). Worldwide consumption of biomass by humans is compared to that of 55 species of marine mammals in the bottom panel. The last two panels are based on indirect estimates (Fowler and Perez, 1999) using population and body size data from the marine mammal series by Ridgway and Harrison (1981–1999) and equations representing ingestion rates as a function of body size in Peters (1983).

In all cases shown in Figs. 1 and 2, management would involve change, often measured in orders-of-magnitude, to avoid human abnormality. If the distributions themselves change in response to the reduction of harvested biomass by humans (or other management to deal with factors such as habitat modification, and the production of CO₂ and toxic chemicals), then sustainable management would need to respond to the new information. This requires continuous monitoring through concerted scientific effort to observe such changes.

III. Accounting for Complexity

In management, the list of things to be considered seems endless. For example, we need to account for the effects of all forms of selectivity (evolution), endangered species, and multiple complex processes such as nutrient flow within ecosystems. It is often said that management needs to be interdisciplinary, or an integrated accounting of everything science can study. But we also need to account for the things we do not, or cannot, study or know about. This is accomplished in two ways when we take advantage of empirical examples provided by species such as marine mammals.

First, every species reflects the effects of everything that influences it. These factors are integrated in (inherent to) the distributions shown in Fig. 1 (Fowler and Crawford, 2004). For example, evolution is taken into account through its influence on the position of every species within each distribution. Each species represents a composite of balances among various opposing forces (e.g., those involved in predation, population growth, evolution, or extinction). Each species reflects the constraints of the system—constraints such as competition for the limited availability of energy in its path through the various trophic levels. The relative importance of each factor compared to every other factor is accounted for implicitly. They are integral to what we observe.

Second, we must address other management questions. Distributions similar to those of Fig. 1 can be developed for the allocation of biomass consumption over alternative resource species, seasons, and geographic space. Marine mammals can be used as empirical examples in such an endeavor and through such species we account for the unknowns that influence the position of each species in distributions like those of Fig. 1. For marine mammals themselves, finding the rates at which they can be harvested sustainably would involve information regarding consumption by their predators—including other marine mammals!

IV. Consistency

An important aspect of empirical examples is their representation of a system that is internally consistent. Advice for management at the ecosystem level (Fig. 1, panel 3) will be consistent with advice at the individual species level (panel 1) when applied simultaneously. Collective application at the individual species level must be constrained to the limits set by application at the ecosystem level. Nutrients, energy, biomass, and species involved in this systemic consistency guarantee freedom of conflict because the conflicting forces of nature result in what we see in distributions derived empirically.

Marine mammals can serve as empirical sources of information about how species fit into marine ecosystems. Through information about nonhuman species, such as marine mammals, we are provided with guidance about sustainable harvest rates, size selectivity, allocation over size, allocation of harvests over time and space, allocation across resource species, and the variety of other management questions left largely unaddressed in current management practices.

Susu and Bhulan

Platanista gangetica gangetica and *P. g. minor*

BRIAN D. SMITH AND GILLIAN T. BRAULIK

I. Characteristics and Taxonomy

The susu and bhulan are two river dolphins of the South Asian subcontinent. Some scientists dispute the existence of one species and consider them to be separate, *P. gangetica* and *P. minor* (Pilleri *et al.*, 1982).

A variety of vernacular names are used for the susu and bhulan, mostly connoting the sound made during respiration. For susu, these include *swongsu* and *sus matsya* (*matsya* = fish) in Nepali, *soonse* and *sunsar* in Hindi, *hiho* and *shihu* in Assamese, and *shushuk* and *sishu-*, *foo-*, or *hungmaach* (*maach* = fish) in Bengali. For bhulan these include *bhoolun* in Suraiki and Sindhi and *dolphin muchli* (the name for dolphins generally) in Urdu.

Both subspecies are nearly identical in external appearance (Fig. 1). Their body is supple and robust, attenuating behind the dorsal fin to a narrow tailstock. Coloration is gray or light brown overall, becoming blotchy with age. Bellies of young animals are lighter and often have a pinkish hue. The dolphins have a long snout that becomes thicker at the tip. Mature females generally have a longer rostrum,

which sometimes curves upward and to one side at the tip when particularly long. Their numerous narrow pointed teeth (26–39 in each upper jaw and 26–35 in each lower jaw) are curved inward and become longer toward the distal end of the rostrum, sometimes protruding outside the mouth. Teeth become broad, flat, and peg-like in older animals from wear and accumulation of the cement layer. The eyes are extremely small and visible as pin-hole openings slightly above the upturned mouth. The external auditory meatus is larger than the eye opening and located slightly above it, a unique arrangement among odontocetes. The blowhole is a small slit oriented longitudinally, which is a rare but not unique configuration among cetaceans. A distinct median ridge begins anterior of the blowhole and bisects a convex melon, which becomes less rounded as the dolphin approaches adulthood. The dorsal fin is a low triangular hump with a slightly defined knob at the apex located about two-thirds of the body length posterior of the melon. Large, broad flippers sometimes are squared-off at the end with a crenellated margin, and the arm and hand bones are visible beneath the taut dorsal surface. Flukes are broad with a concave margin and distinct median notch. The opening for male genitals is located much closer to the umbilicus in relation to the anus compared with most other cetaceans.

An extraordinary feature of the skull is the projection of a maxillary crest, upward and forward, covering an air sinus that leads to the tympanic cavity. The crest slants to the left, which makes the skull among the most asymmetric of all odontocete skulls. Other skull features unique to *Platanista* include that the palatine is found in the nasal tube and that the pterygoids are external on the palate and enter the temporal fossa (Reeves and Brownell, 1989). The

(A)

(B)

Figure 1 Generic appearance of susu and bhulan (top, C. Brett Jarrett) and susu surfacing in the Sundarbans mangrove forest, Bangladesh (bottom; photo by Mougliz).

mandibular symphysis is laterally compressed, slightly upturned toward the end, and constitutes as much as two-thirds the mandible length of adult females and a little more than half in adult males (Reeves and Brownell, 1989). Cervical vertebrae are unfused, allowing considerable neck movement. Postcranial skeletal features unique to *Platanista* include the location of costal facets of the thoracic vertebrae on the posterior margin of the centrum, a thicker ulna than radius, and the absence of ulnare and pisiform bones in the flippers.

The presence of a cecum between the large and small intestines, a penis with erectile side lobes, nasolaryngeal air sacs that form a diverticulum of the eustachian tube, and a primitive and relatively unlobulated kidney distinguish *Platanista* from all other odontocetes. The length of the intestine is 4–5 times the body length, which is the shortest among the river dolphins (Yamasaki and Kito, 1984). Compared to other dolphins, the brain is small and neocortical development is low; however, sub-cortical components associated with acoustical functions are well developed. Their small eyes have a flat, thick cornea and lack a crystalline lens, giving the dolphins a reputation for being blind. Although the optic nerve is extremely reduced and light can only enter through a pin-hole muscle-controlled sphincter, the retina has densely packed light gathering receptors (Herald *et al.*, 1969).

Fossil and genetic evidence indicates that *Platanista gangetica* is a relict species, the sole surviving member of a primitive and once widespread taxon of archaic cetaceans (Cassens *et al.*, 2000). Although the superfamily Platanistoidea was previously considered to include three other monotypic genera—*Pontoporia*, *Lipototes*, and *Inia* (Kasuya, 1973; Zhou, 1982), the genus *Platanista* is now recognized as the only extant member of the taxon (Rice, 1998). Pilleri *et al.* (1982) recognized two species of *Platanista* based on differences in the prominence of the nasal crests, caudal height of the maxillary crests, length of the lower transverse processes of the sixth and seventh cervical vertebrae, blood protein composition, and free-esterified cholestrin ratio in the lipids. Their arguments were unconvincing, due to the small sample of adult specimens examined and the absence of statistical analyses (Reeves and Brownell, 1989). Based on differences in tail lengths, Kasuya (1972) proposed that the susu and bhulan be considered subspecies; this was followed by Rice (1998).

II. Distribution and Abundance

A map of historical distribution, charted by the nineteenth-century British naturalist John Anderson (Anderson, 1879), shows the susu occurring throughout the Ganges-Brahmaputra-Megna and Karnaphuli river systems in Nepal, India, and Bangladesh, and the bhulan occurring throughout the Indus River mainstem, and in the Sutlej, Ravi, Chenab, and Jhelum tributaries. Anderson (1879) stated that the range of both species was only limited downstream by increasing salinity in deltas and upstream by rocky barriers or insufficient water. Their distribution has shrunk considerably since then, largely due to water development, which has blocked dolphin movements and degraded their habitat.

With the exception of a few vagrants, bhulans currently occupy less than 700 km of the Indus mainstem (about one-fifth of their historic range), fragmented into three subpopulations by the Chashma, Taunsa, Guddu, and Sukkur barrages (Fig. 2) (Reeves and Chaudhry, 1998). The subspecies has been extirpated from the Sutlej, Ravi, Chenab, and Jhelum Rivers, and from downstream of the Kotri Barrage and upstream of the Jinnah Barrage in the Indus mainstem. The largest subpopulation is located at the downstream end of the dolphins' range, between Guddu and Sukkur barrages, with a reported count of 602 dolphins (3.60/km). Numbers decline progressively in

upstream segments, despite their progressively larger geographical size, with counts of 259 (0.74/km) and 84 (0.28/km) individuals between the Guddu and Taunsa, and Taunsa and Chasma barrages, respectively. Correcting for missed animals and extrapolating for un-surveyed channels, the metapopulation was estimated in 2001 to be about 1200 individuals (Brauk, 2006).

Historically, susus were found in the Ganges River as far upstream as Haridwar, about 100 km above their current range, and in the Yamuna River year round as far upstream as Delhi, probably about 400 km above their current low-water range (Fig. 3) (Sinha *et al.*, 2000). In the Ganges mainstem, there are four extant subpopulations isolated between barrages. In the northern tributaries of the Ganges, three of the six subpopulations that have been isolated above or between barrages have been extirpated (Gandak River above the Gandak Barrage and Sarda River above the upper and lower Sarda barrages) (Sinha *et al.*, 2000) and one reduced to insignificant numbers (Kosi River above the Kosi Barrage) (Smith *et al.*, 1994). In the Son River, a southern tributary of the Ganges, a small population of susus has been isolated above the Indrapuri Barrage, and the dolphins no longer occur during the dry season for about 100 km below the barrage until the Ganges confluence (Sinha *et al.*, 2000).

Although no rigorous range-wide surveys of susus have been conducted, the aggregate population is believed to number in the low- to mid-thousands (Smith and Reeves, 2000). In the approximate center of the Ganges mainstem, about 120 susus (1.8/km) occur in the Vikramshila Gangetic Dolphin Sanctuary (Choudhary *et al.*, 2006). In southern Bangladesh, at least 125 susus occur in the Karnaphuli and Sangu Rivers and connecting Sikalbaha-Chandkhali canal. This river system is unconnected to the much larger Ganges-Brahmaputra-Meghna system, and dolphins in the two systems are probably demographically isolated from each other, although it may be possible for there to be movement between them during the high-water season when salinity is low in the coastal area in between. There are occasional reports of dolphins remaining in a reservoir behind Kaptai Dam in the Karnaphuli, but a survey in 1999 produced no sightings (Smith *et al.*, 2001). At the far downstream end of their range in the Sundarbans of Bangladesh, a Huggins conditional likelihood model of double concurrent counts estimated that the population inhabiting waterways of the mangrove forest was 225 individuals (CV = 12.6%) and overlapped the range of Irrawaddy dolphins *Orcaella brevirostris* (Smith *et al.*, 2006).

III. Ecology

The susu and bhulan are patchily distributed throughout their range, generally occurring in counter-currents and deep pools located downstream of channel confluences and sharp meanders, and upstream and downstream of mid-channel islands. They also occasionally occur in counter-currents induced by engineering structures such as bridge pilings and groynes. The affinity of the species for counter-currents is probably greatest in upstream tributaries where productivity is especially clumped and strong downstream currents restrict occupancy to the hydraulic refuge these areas provide (Smith, 1993; Smith *et al.*, 1998). During the dry season, dolphins are occasionally sighted in secondary braided channels of the Indus River but encounter rates are 62–85% lower compared to the main channel (Brauk, 2006).

IV. Behavior and Physiology

Captive studies of susus and bhulans have revealed exceptional aspects of their behavior and sensory abilities. The dolphins vocalize

Figure 2 Map of the Indus river system of Pakistan showing dams and barrages that have fragmented the population of bhulan and degraded their habitat.

almost constantly and swim on their sides. The dolphins continuously emit trains of high frequency (15–150 kHz) echolocation clicks, interrupted by short pauses of 1–60 sec (Herald *et al.*, 1969). The click trains are focused in two highly directional fields, the dorsal one emitted directly from the melon and the ventral one reflected downward by the maxillary crest, with an acoustic “scotoma” in front of the rostrum (Pilleri *et al.*, 1976). During a dive, the dolphins spin 90° on their lateral axis and position their head down, sweeping it

back and forth in a scanning motion, while trailing one flipper along or slightly above the bottom. Shortly before surfacing, the dolphins reverse their spin and surface close to their original position and orientation.

In the wild, susus and bhulans are observed alone or in clusters of 2–3, but occasionally as many as 25, individuals. With the exception of mother–young pairs, the attracting force for these clusters may be more related to the patchy distribution of prey and the availability

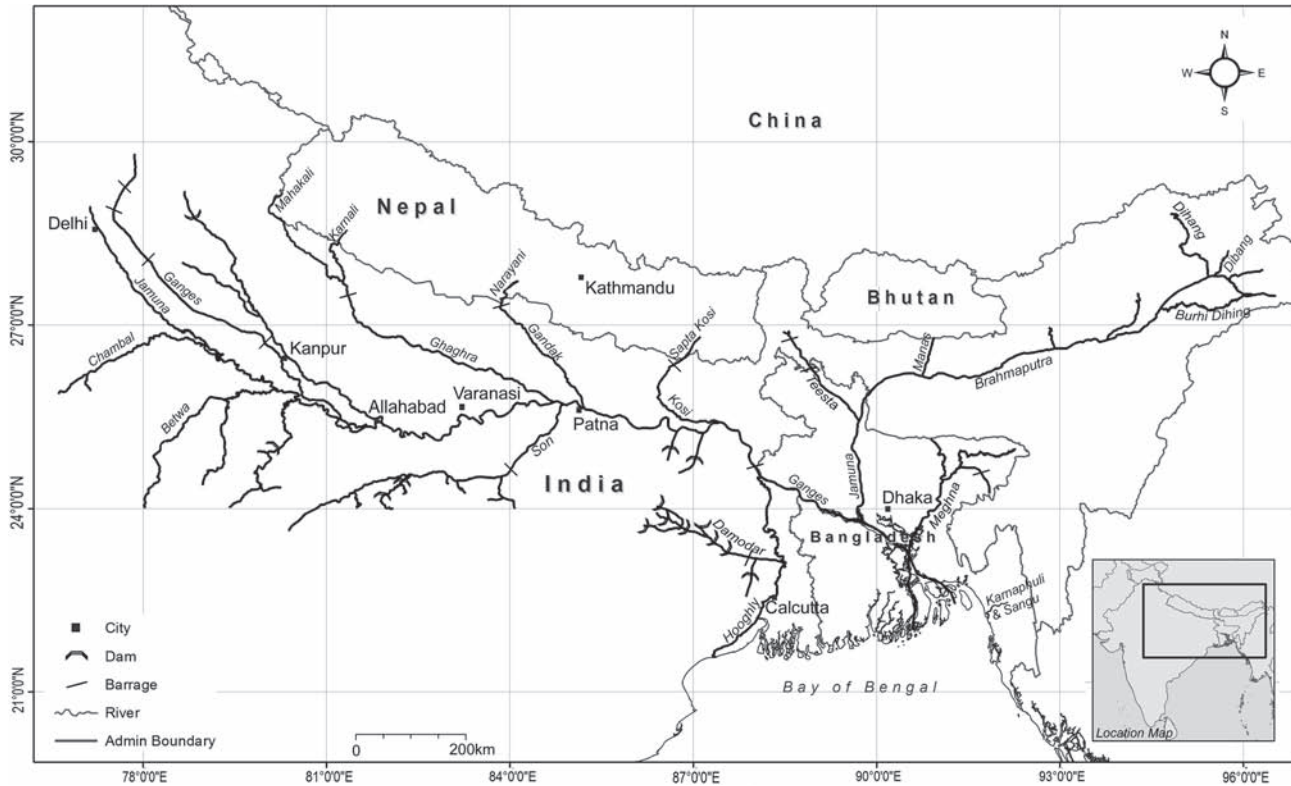

Figure 3 Map of the Ganges-Brahmaputra-Megna and Karnaphuli-Sangu river systems of Nepal, India, and Bangladesh showing dams and barrages that have fragmented the population of susu and degraded their habitat.

of hydraulic refuge and deep pools than to survival or reproductive advantages gained by close social affiliations. Susus have been observed surfacing just inside of the upstream end of counter-current boundaries where the eddies become aligned with main flow. Surfacing at this location may allow the dolphins to minimize energy outputs while monitoring foraging opportunities in the mainstream flow and center pool of the counter-current (Smith, 1993).

V. Life History

Males attain sexual maturity at a body length of about 170 cm and physical maturity at 200–210 cm. Females attain sexual maturity at similar or slightly larger body lengths but physical maturity at about 250 cm. The generally larger rostrum of females accounts for this sexual dimorphism, which becomes evident at a body length of about 150 cm. Length at birth is estimated to be about 70 cm. Gestation lasts approximately 1 year, with possible peak birthing seasons in early winter and early summer. Young begin feeding on small prey at about 1 or 2 months and are weaned within a year (Kasuya, 1972).

VI. Interactions with Humans

The susu and bhulan are both classified by the IUCN as endangered due to declines in their range and population size. The most significant threat to their survival is probably the existence of numerous dams and barrages that have severely fragmented populations and reduced the amount and quality of suitable habitat. Dams are absolute barriers to dolphin movements. Subpopulations trapped

above barrages could lose dolphins when they move downstream during high water while the barrage gates are open and probably cannot return due to strong hydraulic forces between the gates (Reeves *et al.*, 1991)—although if flow velocity is sufficiently reduced when discharge approaches its maximum capacity in the downstream channel and there is no head behind the barrage (i.e., water elevations on both sides are equal) it may be possible for there to be upstream movement through the gates. Involuntary attrition due to downstream movement below barrages would exacerbate normal biological problems faced by small isolated populations. Dolphins are also sometimes lost to their metapopulation when they become stranded in irrigation canals where they can apparently survive for long periods before the canals are drained for maintenance. Water diverted by barrages, generally for irrigation and flood control, and abstracted by surface pumps and tube wells also results in dolphins competing with humans for the actual substance of their environment: freshwater. During the low-water season, the Indus and Ganges rivers become virtually dry downstream of the Sukkur and Farakka barrages, respectively. The long-term effects of global climate change will almost certainly hasten the decline of dry season flows as snowmelt from the Himalayan and Karakoram ranges (which feed the Ganges-Brahmaputra-Meghna and Indus River systems, respectively) becomes progressively reduced. An additional threat comes from embankments constructed for flood control. These structures simplify hydraulic complexity and eliminate or reduce the size of counter-current pools where the dolphins most often congregate. The range of the South Asian river dolphins will probably continue to decline as smaller upstream subpopulations are extirpated due to habitat loss related to the combined impacts of escalating water

demands, construction of large engineering structures, and long-term climate changes.

Deliberate killing of the bhulan for meat and oil was a traditional practice until at least the early 1970s. Hunting is now banned and no longer common (Pilleri and Zbinden, 1973–1974; Reeves and Chaudhry, 1998). Susus are killed by indigenous people in the upper Brahmaputra for their meat and by fishermen in the middle reaches of the Ganges for their oil, which is used as a fish attractant (Motwani and Srivastava, 1961). Similar to all cetaceans, the susu and bhulan are threatened by entanglement in fishing gear and vessel collisions. Their preferred habitat is often in the same location as primary fishing grounds and ferry crossings, which puts the dolphins at increased risk. The problem of accidental killing in fisheries will undoubtedly worsen as the demand for fish and fishing employment increases. Pollution may also be affecting the survival of both species, especially considering the decline in the flushing benefits of abundant water, the aggregate distribution of river dolphins in areas of intensive human use, and the occurrence of major portions of both subspecies' populations downstream of large cities. As top predators, the dolphins are particularly vulnerable to persistent contaminants (e.g., PCBs and DDTs), some of which are banned or strictly regulated in more developed countries but widely used in industry and agriculture of South Asia.

In 1974, the government of Sindh declared the Indus River between the Sukkur and Guddu barrages a dolphin reserve and the government of Punjab prohibited deliberate killing (Reeves *et al.*, 1991). Enforcement of these measures seems to have stopped the rapid decline of the bhulan between Guddu and Sukkur barrages reported by Pilleri and Zbinden (1973–74), and there is evidence that the population in this segment has been increasing (Braulik, 2006). The susu was perhaps the first cetacean to receive official protection from hunting when it was listed as a protected species in the Moral Edicts of King Asoka in India more than 2000 years ago. Susus currently receive legal protection from deliberate killing in all range states. The Vikramshila Gangetic Dolphin Sanctuary, Bihar, India, located in a ~60 linear kilometer of the Ganges River between Sultanganj and Kahalgaon, was declared a protected area for dolphins in August 1991 and some measures have been taken there to conserve the animals (Choudhury *et al.*, 2006). In a few smaller tributaries, susus receive nominal protection by virtue of small portions of their habitat being included in or adjacent to national parks and sanctuaries.

Swimming

TERRIE M. WILLIAMS

I. Introduction

The primary mode of locomotion for marine mammals with the possible exception of polar bears (*Ursus maritimus*) is swimming. For dolphins, porpoises and whales, it is the only form of locomotion. The duration of swimming among these mammals may be as short as several seconds when moving between prey patches or as long as several months during seasonal migrations across entire ocean basins. Although swimming by marine mammals often appears effortless, it is in reality a delicate balance between precise body streamlining, exceptional thrust production by specialized propulsive surfaces, and locomotor efficiency (Fig. 1).

II. Hydrodynamics and body streamlining

One of the most characteristic features of marine mammals is a streamlined body shape. This is not surprising when one considers the forces that the animal has to overcome in order to move through water. When a swimmer moves through water a force, termed drag, acts backward on it, resisting its forward motion. The equation describing total body drag is given by

$$\text{Total Drag} = 1/2\rho V^2 ACd \quad (1)$$

where ρ is the density of the fluid, V is the velocity of the fluid relative to the body, A is a characteristic area of the body, and Cd is the drag coefficient (a factor that takes into account the shape of the swimmer). There are four primary types of drag that contribute to total body drag: (1) skin friction drag which is a tangential force resulting from shear stresses in the water sliding by the body, (2) pressure drag which is a perpendicular force on the body associated with the pressure of the surrounding fluid, (3) wave drag that occurs when a swimmer moves on or near the water surface, and (4) induced drag that is associated with water deflection off hydrofoil surfaces such as fins, flukes, or flippers. Of these, pressure drag is the component most influenced by body streamlining in marine mammals. The more streamlined a body, the lower the pressure drag and consequently the lower the total body drag of the swimmer.

Mammals whose lifestyles or foraging habits involve prolonged periods of swimming have streamlined body shapes. In contrast to the lanky appearance and appendages of terrestrial mammals, marine mammals tend to have a reduced appendicular skeleton and characteristic tear drop body profile. External features that may disrupt water flow across the body are also reduced or absent in many species of marine mammal. These features include the pinnae (external ears), limbs, and long fur. In highly specialized swimmers such as dolphins the skin contains microscopic ridges that help to direct the flow of water in a controlled manner down the body. All of these adaptations prevent the onset of turbulence in the water surrounding the swimmer and thereby reduce total body drag.

Hydrodynamic theory describes the streamlined body shape as one in which a rounded leading edge slowly tapers to the tail, and total length is 3–7 times maximum body diameter. The ratio of these

Figure 1 A bottlenose dolphin (*Tursiops truncatus*) swimming at high speed on the water surface. The generation of waves by the dolphin's movements leads to increases in body drag and elevated energetic costs during surface swimming.

morphological measurements, termed the Fineness Ratio, can be written as

$$\text{Fineness Ratio} = \frac{\text{maximum body length}}{\text{maximum body diameter}} \quad (2)$$

The optimum fineness ratio that results in minimum drag with maximum accommodation for volume is 4.5. Calculations of the fineness ratio for a wide variety of marine mammals show that many species have body shapes that conform to the ideal hydrodynamic range (Fig. 2). A review paper by Fish (1993) showed that many cetaceans, pinnipeds, and sirenians have body shapes with Fineness Ratios that range from 3.0 to 8.0. The species examined included seals, sea lions, and odontocete whales that are considered by many to typify a streamlined body profile. Even mysticete whales with enlarged heads and jaws specialized for filter feeding maintain a streamlined body profile when swimming (Fig. 2). However, the loss of this hydrodynamic profile when the animals open their mouths quickly results in a marked increase in drag, a reduction in forward speed, and a concomitant elevation in energetic costs (Acevedo-Gutierrez *et al.*, 2002; Goldbogen *et al.*, 2006).

Despite nearly ideal body streamlining, all marine mammals must contend with drag forces when moving through the water. These forces can be a considerable challenge for the swimmer and will influence how quickly the animal will be able to move. It is apparent from Eq. (1) that the velocity of the swimmer will have a large impact on total body drag. As the swimmer moves faster, body drag increases

Figure 2 Body shapes and fineness ratios for cetaceans. Shapes can range from the robust bowhead whale, *Balaena mysticetus* (A) to the long thin tapered body of the rorqual whales (B) and beaked whales (D). The killer whale (*Orcinus orca*) (C) has the optimum shape in terms of fineness ratio and streamlining. From Berta and Sumich (1999), "Marine Mammals: Evolutionary Biology," Academic Press.

exponentially. An example of the relationship between total body drag and velocity is presented in Fig. 3 for the sea otter (*Enhydra lutris*) (Williams, 1989). Whether the sea otter swims on the water surface or submerged, body drag increases with velocity. However, body position clearly affects the level of total body drag encountered by the sea otter. At all comparable swimming speeds, body drag is higher for the otter moving on the water surface than when it is swimming submerged. The same results have been found for other swimmers, including humans and harbor seals (*Phoca vitulina*). In general, body drag for a swimmer moving on or near the water surface is 4–5 times higher than the level of drag encountered by the submerged swimmer moving at the same speed (Hertel, 1966). Much of this increase in drag at the water surface is due to energy wasted in the formation waves. This can be avoided if the swimmer is able to submerge to a depth equivalent to three body diameters. For a seal or small whale with a maximum body diameter of 1 m, this would mean changing swimming position to at least three meters in depth to avoid wave drag and the consequent elevation in total body drag. This is one of the reasons that swimming is comparatively difficult for humans—our entire performance takes place on the water surface where wave drag, and hence total body drag, is the highest.

The ability to swim submerged for prolonged periods is one of the most important adaptations for increasing swimming efficiency and performance in marine mammals. The sea otter provides an excellent example of the advantage provided by this adaptation. Sea otters restrict prolonged periods of surface swimming to speeds less than $0.8 \text{ m} \cdot \text{sec}^{-1}$ and to a maximum body drag of 4.2 N (Fig. 3). For high-speed swimming, sea otters change to a submerged mode of locomotion. In doing so, drag is reduced by 3.5 times and the sea

Figure 3 A comparison of body drag for surface and submerged sea otters (*Enhydra lutris*) in relation to swimming speed. Note that at all comparable speeds, body drag of the sea otter on the water surface is higher than when the otter is submerged. The dashed line denotes the preferred swimming speeds of surface and submerged sea otters.

otter is able to reach speeds of $1.4 \text{ m} \cdot \text{sec}^{-1}$ before body drag once again exceeds 4.0 N . Thus, behavioral changes by the sea otter takes into account the differences in drag associated with body position in the water and allows the animal to extend its range of swimming speeds. Several other behavioral strategies, such as porpoising and

Figure 4 Swimming modes for semiaquatic and marine mammals. The muskrat (A) is a semiaquatic mammal that uses drag-based propulsion by paddling its hind feet. Otariids (B), phocid seals (C), and cetaceans (D) use lift-based propulsion that may involve fore flippers (sea lion), lateral body undulation (seal), or dorsoventral undulation (dolphin). Major forces on the animals and propulsive surfaces are shown. T denotes thrust, and D shows the direction of body drag on the animals. L and d illustrate lift and drag forces on the appendages, respectively. From Fish (1993), with permission.

wave-riding, are also used by marine mammals to avoid elevated body drag while swimming and will be discussed below in Swimming Speed and Behavior.

III. Kinematics

A hallmark of marine mammal swimming is the use of lift-based propulsion that allows thrust to be generated through the entire stroke cycle. This capability is found in highly adapted marine species such as pinnipeds and cetaceans. It contributes to an increase in locomotor efficiency in marine mammals, especially when compared to the inefficient drag-based swimming styles of humans and terrestrial mammals (Fig. 4).

Marine mammals use a wide variety of swimming styles to move through the water (Table I). The most terrestrial species of this group, the polar bear and sea otter, swim by alternate strokes of the

forelimbs or hind limbs, respectively. Polar bears use a dog style of forelimb paddling with the hind limbs dragged passively behind or used as an aid to steering. Sea otters are unique among marine mammals in their ability to lie on their backs during surface swimming. Propulsion is provided by either the simultaneous or alternate strokes of the hind limbs. When on the surface, sea otters can also swim ventral surface (belly) down using the hind paws for propulsion. The front paws are held against the submerged chest and do not play a role in propulsion during this mode of swimming. Stroke frequency has been measured for swimming sea otters and ranges from approximately 30 to 80 strokes per minute while swimming on the water surface (Williams, 1989).

Polar bears and sea otters are the only marine mammals that rely primarily on drag-based modes of swimming. These modes of swimming have two distinct phases during the stroke cycle, a power phase when thrust is produced, and a recovery phase when the foot or paw is repositioned for the next stroke. During the power phase, the foot is moved backward relative to the body. Drag created by this motion is subsequently translated into thrust and the animal moves forward through the water. The enlarged hind flippers of sea otters and fore paws of polar bears enable the animals to increase propulsive efficiency by moving a large mass of water during this power phase. The recovery phase of the stroke is only used to bring the limb back to its starting position, and occurs without the generation of thrust. Because thrust is produced only during part of the stroke cycle, drag-based modes of swimming are comparatively inefficient.

When sea otters want to move quickly through the water, they switch to an undulatory mode of swimming involving dorsoventral body flexion and simultaneous movements of paired hind flippers. The tail and hind flippers are held straight back and trail the undulatory movements of the trunk. Stroke frequency of sea otters remains relatively constant at 55 strokes per minute during submerged undulatory swimming, which suggests that underwater speed is elevated by increasing stroke amplitude.

As observed for submerged swimming sea otters, dolphins and whales use undulatory modes of propulsion. The primary propulsive movements of all cetaceans occur in the vertical plane with the posterior third of the body undulating in a dorsoventral direction. Termed, thunniform swimming or carangiform swimming with a semi-lunate tail, this mode of locomotion is characterized by an undulatory wave that travels with increasing amplitude down the body, caudal peduncle, and finally the flukes (Fig. 5). "Semi-lunate" refers to the crescent shape of the flukes. This mode of propulsion is shared by other fast swimming vertebrates including tuna, hence the name "thunniform." Undulatory propulsion in cetaceans is considered highly efficient and can generate high levels of thrust on both the upstroke and downstroke. There is no recovery phase and propulsion can be produced throughout the stroke cycle. Stroke frequency using this mode of swimming varies with the speed and size of the cetacean. The range of stroke frequencies for bottlenose dolphins (*Tursiops* spp.) swimming in a pool is 60–180 strokes.min⁻¹. Stroke frequency decreases with increasing body size among the cetaceans. Thus, we find that the largest species of swimming mammal, the 100 ton blue whale (*Balaenoptera musculus*), uses stroke frequencies that are only one-tenth of the range observed for bottlenose dolphins. A measurement of the stroke frequency of blue whales ascending during a dive was 6–10 strokes.min⁻¹ (Williams *et al.*, 2000).

Swimming by pinnipeds differs markedly between the eared seals, the otariids, and the true seals, the phocids. Otariids use pectoral appendages to generate propulsive forces during swimming, with the hind flippers trailing passively or occasionally used for steering.

TABLE I
A Comparison of Swimming Characteristics for Four Major Classes of Marine Mammals

	<i>Sea Otter</i>	<i>Otariid</i>	<i>Phocid</i>	<i>Small Cetacean</i>
Routine Speed (m/sec)	<0.8 (surface)	2.0–3.0	1.2–2.0	2.0–4.0
	<1.4 (submerged)		sprints to 4.0	sprints to 10.0
Hydrodynamics	Surface/Submerged	Submerged	Submerged	Submerged
Kinematics				
Mode	Paddle, Row (surface) Undulate (submerged)	Pectoral	Lateral Carangiform	Dorso-ventral Thunniform
Energetics				
(COT measured)	12.0 (surface)			
COT predicted	6.0 (submerged)	2.3–4.0	2.3–4.0	2.1–2.9

Note: The energetic Cost of Transport (COT) was measured for animals swimming in a flume or freely swimming in open water. The ratio of these values and the predicted values for fish of similar body mass are presented.

Figure 5 Video image (A) and range of movement (B) of four anatomical sites during a single stroke for a swimming bottlenose dolphin (*Tursiops truncatus*). Colored squares in the picture correspond to the line colors illustrating the movements for each site. Note the traveling wave as it passes from the dorsal fin (dark blue) to the peduncle (red), fluke hinge (green) and finally the fluke tip (pink). From Skrovan et al. (1999), with permission.

In this way, sea lions and fur seals resemble penguins and sea turtles during swimming. Detailed kinematic analyses have been conducted for California sea lions (*Zalophus californianus*) swimming in a flume (Feldkamp, 1987). These studies revealed three distinct phases to the stroke: (1) the power phase, (2) a paddle phase, and (3) a recovery phase. The majority of thrust is produced during the paddle phase when the fore flippers are quickly and forcibly moved from the water flow to the sides of the animal's body. Stroke frequency for these sea lions increased with swimming speed, and ranged from 15 to 50 strokes.min⁻¹ as the animals increased speed from 0.5 to 3.0 m.sec⁻¹. In addition to stroke frequency, sea lions increase the amplitude of the fore flipper stroke during high-speed swimming.

When viewed in cross section, the fore flipper of the sea lion resembles a hydrofoil. This specialized shape allows the flipper to produce thrust during both the power and recovery phases of the stroke cycle. As found for cetaceans, the specialized flipper movements of otariids result in thrust production throughout the stroke cycle and contribute to overall locomotor efficiency. Several other advantages are provided by fore flipper propulsion. These include stability at slow speeds and maneuverability at high speeds. Consequently, otariids are champion underwater acrobats and are capable of rapid changes in direction and acceleration.

Phocid seals and walrus (*Odobenus rosmarus*) differ from the otariids in terms of swimming style, and rely on alternate sweeps of the hind flippers for propulsion. In addition to the flippers, the posterior half of the body flexes during each stroke, with the result that body flexion provides nearly 90% of the change in amplitude during the stroke cycle. In phocid seals both hind flippers are swept in the same direction as the posterior portion of the body during each half of the stroke cycle. The leading flipper remains closed and the trailing flipper maximally expands during the sweep to one side. Once the flippers have moved to the maximum lateral position, the flippers switch their open and closed positions in preparation for the reverse lateral sweep. By reversing the role of each flipper during lateral sweeps, one flipper is able to provide thrust while the other flipper recovers. The result, once again, is the ability to produce propulsive thrust during the entire stroke cycle. Stroke frequency in phocids increases linearly with swimming speed. For harbor seals trained to swim at 1.0–1.4 m.sec⁻¹ in a water flume stroke frequency ranged from 60 to 78 strokes.min⁻¹.

IV. Energetics

The energetic cost of swimming has been measured for numerous species of semi-aquatic and marine mammals using a wide variety of techniques. Smaller swimmers such as sea otters, seals, and sea lions have been studied while they swam against a current in water flumes. Similar to placing a human on a treadmill, flume studies have enabled scientists to measure how much energy a swimmer expends while moving at different speeds. Often oxygen consumption is measured during these tests by using a face mask or metabolic hood connected to an oxygen gas analyzer. By training animals to breathe into a metabolic hood, expired respiratory gases can be collected and analyzed for oxygen content. For larger, more powerful swimmers like dolphins and whales, most flumes are not adequate in terms of size or challenging water speeds. Instead, investigators have relied on a variety of novel techniques for determining the energetic cost of swimming in cetaceans. Techniques have included using trained dolphins that match their swimming speed to that of a moving boat in open water (Williams *et al.*, 1992) or having whales swim to metabolic stations where expired gases can be collected for analysis (Worthy *et al.*, 1987).

To compare swimmers of different size, it is useful to convert the metabolic measurements into a cost of transport. Defined as the amount of fuel it takes to transport one unit of body weight over a unit distance, the cost of transport is analogous to the fuel rating of an automobile. In this case, the cost of transport indicates the “gas per mile” used by the swimmer rather than the “miles per gas” achieved by automobiles. The total cost of transport is calculated from the following equation:

$$\text{Total Cost of Transport} = \frac{\text{Oxygen Consumption}}{\text{Swimming Speed}} \quad (3)$$

where oxygen consumption is in $\text{mLO}_2 \cdot \text{kg}^{-1} \cdot \text{sec}^{-1}$ and speed is in $\text{m} \cdot \text{sec}^{-1}$ which results in a cost of transport in $\text{mLO}_2 \cdot \text{kg}^{-1} \cdot \text{m}^{-1}$. These values are usually converted to an energetic term and expressed as Joules expended per kilogram of body mass per meter traveled ($\text{J} \cdot \text{kg}^{-1} \cdot \text{m}^{-1}$). The conversion calculation assumes a caloric equivalent of 4.8 kcal per liter of oxygen consumed and a conversion factor of $4.187 \times 10^3 \text{ J per kcal}$.

Comparisons of the cost of transport for a wide variety of mammalian swimmers indicate that swimming is energetically expensive for mammals compared to fish. The total cost of transport for swimming mammals can also be divided into two distinct groups, the semi-aquatic mammals and the marine mammals (Williams, 1999) (Fig. 6). Swimming costs for semiaquatic mammals such as minks (*Mustela* spp.), muskrats (*Ondatra zibethicus*), and humans are 2–5 times higher than observed for marine mammals. These high energetic swimming costs are attributed to a wide variety of factors including elevated body drag associated with a surface swimming position (Fig. 3) and low propulsive efficiency associated with drag-based propulsion.

Mammals specialized for swimming demonstrate comparatively lower energetic costs. Total cost of transport in relation to body mass for swimming marine mammals ranging in size from a 21 kg California sea lion to a 15,000 kg gray whale (*Eschrichtius robustus*) is described by

$$\text{Total Cost of Transport} = 7.79 \text{ mass}^{-0.29} \quad (4)$$

where the cost of transport is in $\text{J} \cdot \text{kg}^{-1} \cdot \text{m}^{-1}$ and body mass is in kilograms. Interestingly, the style of swimming used by marine mammals

Figure 6 Total energetic cost of transport in relation to body mass for different classes of swimmers. Marine mammals include gray seals (*Haliocoerus grypus*) and harbor seals (*Phoca vitulina*) (filled circles), California sea lions (*Zalophus californianus*) (open circles), bottlenose dolphins (*Tursiops truncatus*) (triangle), killer whales (*Orcinus orca*) (squares), and a gray whale (*Eschrichtius robustus*) (downward-pointing triangle). The least squares regression through the data points for marine mammals is presented in the text. This regression is compared to the regressions for swimming semiaquatic mammals (upper solid line), and the predicted regression for salmonid fish (lower solid line). From Williams (1999), with permission.

did not affect the cost of transport relationship. Species and swimming styles represented in this equation include sea lions using pectoral fins for propulsion, phocid seals using lateral undulation of paired hind flippers, and odontocete and mysticete whales using dorso-ventral undulation of flukes.

As illustrated in Fig. 6, the energetic cost of swimming for marine mammals is greater than predicted for salmonid fish of similar body size. Despite specialization of the body and propulsive surfaces for aquatic locomotion, the cost of transport for swimming by seals and sea lions is 2.3–4.0 times higher than predicted for swimming fish. Values for cetaceans are somewhat lower, and range from 2.1 to 2.9 times values predicted for fish. Differences in the total cost of transport between marine mammals and fish are due in part to the amount of energy expended for maintenance functions, particularly thermoregulation and the support of a high core body temperature. As endotherms, mammals expend more energy to support the production of endogenous heat than ectothermic fish. In addition, many marine mammals show exceptionally high metabolic rates while resting in water in comparison to terrestrial mammals resting in air. A consequence of these high maintenance costs is an overall increase in the total energy expended during swimming, especially when compared to fish.

V. Swimming Speeds and Behavior

Although body size varies considerably among marine mammals from the 20 kg sea otter to the 122,000 kg blue whale, routine swimming is limited to a surprisingly narrow range of speeds. Many species

Figure 7 Swimming speeds for marine mammals. Routine speeds of phocid seals, otariids, mysticetes, odontocetes, humans and autonomous underwater vehicles (AUVs) are shown by the bars. Filled circles above the bars denote the sprinting speeds recorded for each species. Note the similar range of routine speeds for these marine mammals regardless of body size.

of marine mammal routinely swim between approximately 1.0 and $3.6\text{ m}\cdot\text{sec}^{-1}$ regardless of body size (Fig. 7). Within this range, pinnipeds generally select slower routine traveling speeds than cetaceans, and mysticete whales swim slower than odontocetes. For example, average swimming speeds for a wide variety of otariids and phocids range from 1.3 to $2.0\text{ m}\cdot\text{sec}^{-1}$. The massive mysticete whales are only slightly faster; routine speeds for this group of marine mammals ranges from 2.1 to $2.6\text{ m}\cdot\text{sec}^{-1}$. Although they are not the largest marine mammals, odontocetes tend to move the fastest during routine travel. The slowest of the odontocetes represented in Fig. 7 was the beluga whale (*Delphinapterus leucas*) with a routine speed of $1.8\text{ m}\cdot\text{sec}^{-1}$. In comparison, the killer whale (*Orcinus orca*) demonstrates the fastest routine speed of the marine mammals measured to date and averages $3.6\text{ m}\cdot\text{sec}^{-1}$ during casual swimming. These speeds are even more remarkable when compared to the efforts of humans. The routine speed of humans during freestyle swimming is approximately $1.0\text{ m}\cdot\text{sec}^{-1}$, about the same speed as a sea otter swimming under water.

As would be expected, the sprinting speeds of marine mammals are considerably faster than routine speeds, and show much variation among the species measured. Most of the information regarding sprint swimming performance in marine mammals is for cetaceans. However, the speed of adult Weddell seals (*Leptonychotes weddellii*) chasing fish beneath the Antarctic sea ice has been measured and was found to exceed $4.0\text{ m}\cdot\text{sec}^{-1}$ during the hunt. Among cetaceans, sprint speeds are even higher. The range of sprinting speeds measured for mysticete whales is $4.1\text{--}13.3\text{ m}\cdot\text{sec}^{-1}$ (Fig. 7); sprint swimming by odontocetes is within the upper end of this range and averages $6.1\text{--}12.5\text{ m}\cdot\text{sec}^{-1}$. Killer whales remain the fastest of the

odontocetes measured and can sprint at $12.5\text{ m}\cdot\text{sec}^{-1}$. This is nearly six times faster than the maximum performance of human swimmers in Olympic sprint competition.

Because marine mammals must periodically surface to breathe, they are subject to high levels of drag associated with the effects of wave formation and splashing especially during high speed swimming. To help minimize body drag and energetic costs during these surface intervals, marine mammals have developed a number of unique behavioral strategies to accommodate breathing while swimming fast. Porpoising is one such highly visible behavioral strategy used by small cetaceans and some pinnipeds moving at high speed near the water surface (Au and Weihs, 1980). Rather than stroke continuously, the animals leap into the air and simply avoid the elevated wave drag that occurs when swimming near the water surface to breathe. Theoretically, this behavior results in an energetic savings to the animal, although the cost of surface swimming versus leaping has yet to be measured. Wave-riding is another strategy that enables the swimmer to avoid the work of continuous stroking while moving near the water surface. In a study involving bottlenose dolphins trained to swim freely or wave-ride next to a moving boat, investigators found that heart rate, respiration rate and energetic cost were reduced for animals riding the bow wave of the boat (Williams *et al.*, 1992). This behavior enabled the dolphins to nearly double their forward traveling speed with only a 13% increase in energetic cost. Consequently, it is not surprising that marine mammals routinely ride waves generated by the wind, surf, the wake of boats and even large whales. What appears to be an amusing activity also provides an energetic benefit to the swimmer.

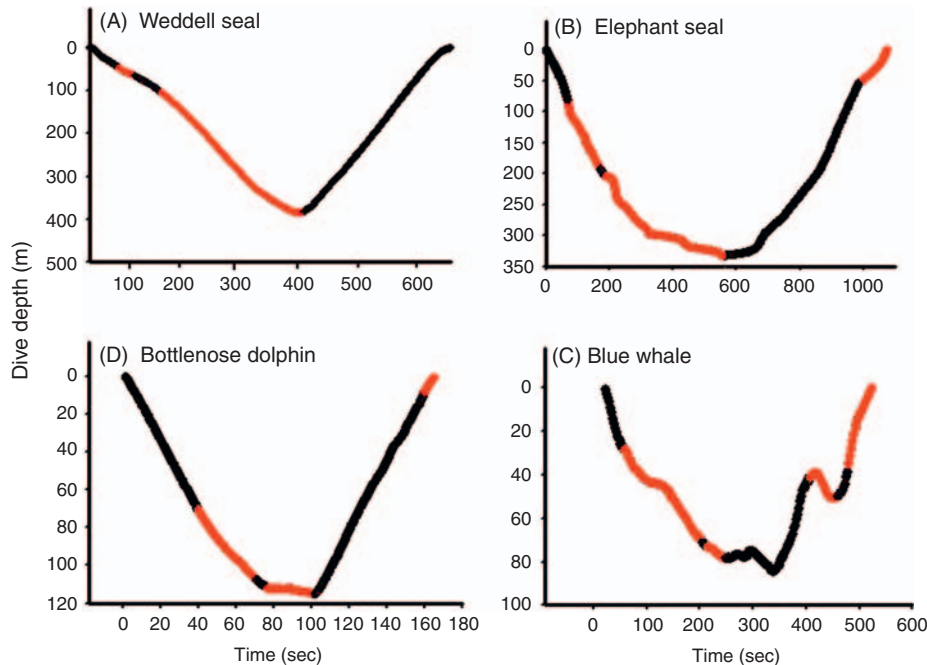

Figure 8 Swimming and gliding activity of four species of diving marine mammal. Representative deep dives are presented for the Weddell seal (*Leptonychotes weddellii*) (A), elephant seal (*Mirounga* spp.) (B), bottlenose dolphin (*Tursiops* spp.) (C), and blue whale (*Balaenoptera musculus*) (D). Each curve shows dive depth in relation to time elapsed during the dive. The color of the line corresponds to stroking (black) and gliding (red) periods. For each species the descent was characterized by prolonged periods of gliding. From Williams *et al.* (2000), with permission.

Although energetically advantageous when swimming near the water surface, both wave-riding and porpoising have been described for only a limited number of marine mammal species moving at high speeds. These locomotor strategies are not possible during slow transit, in large marine mammals such as elephant seals (*Mirounga* spp.) and whales, or in polar regions where ice covers the water surface. Instead, transit swimming is often accomplished by a sawtooth series of sequential dives that allows the animals to remain submerged except for brief surface intervals to breathe (Davis *et al.*, 2001).

VI. The Special Case of Swimming at Depth

Most of our information about swimming in marine mammals is from animals moving near the water surface. However, the majority of swimming by these animals occurs at depth in conjunction with diving. When descending or ascending during a dive, marine mammals must contend with changes in buoyant forces, hydrostatic pressure, as well as body drag. As discussed above, drag forces resist both forward progression and limb movements of the swimmer. In contrast, buoyant forces act in a vertical direction in the water column and result from the weight, volume, and compressibility of the tissues and air spaces of the animal's body. Hydrostatic pressure results from the weight of the water column above the marine mammal.

The magnitude of buoyant forces and hydrostatic pressure on the swimming marine mammal will depend on where in the water column activity takes place. Hydrostatic pressure progressively increases by 1 ATM for every 10.1 m an animal descends in the water column. This will have a profound effect on compressible spaces or tissues, and hence buoyancy of the animal, especially for marine mammals

that may descend and ascend hundreds of meters during the course of a dive. In addition, seasonal changes in blubber content, pregnancy and lactation will have an effect on the overall buoyancy of the marine mammal.

A consequence of the interrelationships between depth, buoyancy, hydrostatic pressure and body drag is that the physical forces influencing the animal swimming horizontally near the water surface are very different from those encountered by the diving animal moving vertically through the water column. Detailed studies on diving bottlenose dolphins and elephant seals have shown that the animals are positively buoyant near the water surface, and that buoyancy decreases as the animal descends during the dive. For example, the buoyancy of a bottlenose dolphin changes from positive when near the water surface to negative once the animal exceeds 70 m in depth (Skrovan *et al.*, 1999).

These changes in buoyancy are associated with changes in lung compression due to the increase in hydrostatic pressure as marine mammals descend on a dive. Thus, as dolphins, whales and seals dive, hydrostatic pressure increases, the lungs progressively collapse with the result that overall buoyancy is changed. These marked changes in physical forces with depth affect both the locomotor behavior and energetics of the marine mammal as it descends and ascends during a dive (Fig. 8).

Until recently, it was not possible to observe the swimming modes of marine mammals during deep dives. With the development of miniaturized video cameras and instrumentation worn by free-ranging marine mammals, new information about swimming at depth has been obtained (Fig. 9). The videos revealed that bottlenose dolphins, elephant seals, Weddell seals and blue whales switch between different modes of swimming during the dive, much like terrestrial mammals switch between gaits (Williams *et al.*, 2000). Dive descents

Figure 9 A bottlenose dolphin (*Tursiops sp.*) carries a video camera to record its swimming movements during deep dives. (Courtesy of Kevin McDonnell.)

usually began with a period of continuous stroking. Once the marine mammals reached 70–80 m in depth they changed to a passive glide for the remainder of the descent. For deep divers such as phocid seals, these gliding periods can be quite long. For example, prolonged gliding periods exceeded 6 min for Northern elephant seals (*Mirounga angustirostris*) traveling to nearly 400 m and Weddell seals descending to 540 m beneath the Antarctic sea ice. Nearly 80% of the descent of diving seals was spent passively gliding rather than actively swimming on dives exceeding 200 m in depth.

The ascent portion of a dive requires more effort by these marine mammals when compared to the descent. The beginning of the ascent represents the period of greatest swimming effort for many mammalian divers. During this period, many species of pinniped and cetacean use sequential, large amplitude strokes to begin moving upward. As the ascent continues, the physical forces impacting the diver are once again altered as they move through the water column. Hydrostatic pressure decreases on ascent. Consequently, the lungs are able to reinflate and the buoyancy of the marine mammal increases. Swimming behavior reflects these changes with the result that the continuous stroking phase is followed by a stroke and glide mode of swimming, and finally a brief glide to the water surface.

An interesting contrast to the seals, dolphins, and blue whales is the right whale (*Eubalaena spp.*). This species, considered the “right” whale to hunt because their carcasses tended to float, are comparatively buoyant. As a result, the right whale displays some of its most powerful fluke strokes at the beginning of descent as it counteracts large positive buoyant forces at the start of a dive (Nowacek *et al.*, 2001). The advantage of this positive buoyancy subsequently occurs during the ascent, when the animals are able to glide to the surface and reduce the number of energetically costly strokes.

By altering the mode of swimming to account for changes in the physical forces that occur during a dive, marine mammals are able to conserve limited oxygen reserves during submergence. Studies investigating the metabolic rates of Weddell seals diving from an ice hole found that the incorporation of prolonged glides enabled seals

to reduce the energetic cost of individual dives by 9–60 % (Williams *et al.*, 2000, 2004). Such an energetic savings could make the difference between completing the dive aerobically or anaerobically, and can increase the time available for hunting or avoiding predators.

In summary, these studies demonstrate that swimming can be energetically expensive for mammals. Marine adapted species including sea otters, pinnipeds, and cetaceans have undergone marked morphological, physiological, and behavioral changes to increase their swimming efficiency. An especially important adaptation that distinguishes marine mammals from semi-aquatic mammals is the ability to remain submerged for prolonged periods when swimming. However, prolonged submergence also requires specialized physiological responses associated with oxygen loading and utilization as described in the chapter “Diving.” A major benefit of these adaptations is a capacity for aquatic performance by marine mammals that far exceeds those of semi-aquatic mammals and the best Olympic efforts of humans.

Systematics

ANNALISA BERTA

Systematics is the study of biological diversity that has as its primary goal the reconstruction of phylogeny, the evolutionary or genealogical history of particular group of organisms (e.g., species). Because of its emphasis on phylogeny, this discipline is often referred to as phylogenetic systematics or cladistics. Other related goals of systematics include determination of the times at which species originated and became extinct and the origin and rate of change in their characters. An important component of systematics is taxonomy that involves the identification, description, nomenclature, and classification of organisms. Systematics provides a framework for interpreting patterns and processes in evolution using explicit, testable hypotheses.

The rapid pace of research on marine mammals has resulted in renewed interest in their systematics. Phylogenetic systematic methodology as introduced here has gained near universal acceptance. [For a general introduction see Maddison and Maddison (2000) and for more detailed discussion of methods see Felsenstein (2004).] In addition to their use in elucidating evolutionary relationships, phylogenies are now recognized as powerful tools for unveiling evolutionary patterns of biodiversity in ecological and behavioral settings (Brooks and McLennan, 2002).

I. Basic Tenets of Phylogenetic Systematics

The recognition of patterns of relationship among species is founded on the concept of evolution. Patterns of relationship among species are based on changes in the characters of an organism. Characters are diverse, heritable attributes of organisms that include DNA base pairs, anatomical and physiological features, and behavioral traits. Two or more forms of a given character are termed the character states. For example, among pinnipeds the character, contact between the maxillary and frontal bones consists of three character states: (1) V-shaped (in bears, extinct desmatophocids, *Enaliarctos*, and phocids), (2) W-shaped (in otariids), and (3) transverse (walruses). In the determination of relationships among groups of organisms phylogenetic systematics emphasizes evolutionary novelties (derived characters) in contrast to ancestral similarities (primitive characters). If derived characters are unique to a particular taxon rather than showing relationships among taxa they are termed autapomorphies. An example of an autapomorphy is the straight contact between the maxillary and frontal bones seen only in walruses among pinnipedimorphs (living pinnipeds and their fossil relatives).

The evolutionary history of a group of organisms can be inferred by sequentially linking species together based on their common possession of derived characters, also known as synapomorphies. These derived characters are considered to be homologous, a similarity that results from common ancestry. For example, the flipper of a seal and that of a walrus are homologous because their common ancestor had flippers. In contrast to homology, a similarity not due to homology is homoplasy. For example the flipper of a pinniped and that of a whale are homoplasious as flippers because their common ancestor lacked flippers. Homoplasy may arise in one of two ways convergence (parallelism) or reversal. Convergence is the independent evolution of a similar feature in two or more lineages. Thus seal flippers and whale flippers evolved independently as swimming appendages,

their similarity is homoplasious by convergent evolution. Reversal is the loss of a derived feature coupled with the reestablishment of an ancestral feature. For example, in phocine seals (e.g., bearded seal, hooded seal, and the Phocini) the development of strong claws, lengthening of the third digit of the foot, and de-emphasis of the first digit of the hand are character reversals because none of them characterize phocids ancestrally but are present in terrestrial arctoid carnivores, common ancestors of pinnipeds.

Relationships among organismal groups are commonly represented in the form of a cladogram, a branching diagram that conceptually represents the best estimate of phylogeny (Fig. 1). Derived characters are used to link monophyletic groups, groups of taxa that consist of a common ancestor plus all descendants of that ancestor (referred to as a clade). For example, currently the best supported hypothesis of relationships among pinnipedimorphs based on both morphologic and molecular characters proposes that phocid seals (Phocidae) and an extinct lineage (Desmatophocidae) are more closely related to each other than either is to other pinnipeds. Fur seals and sea lions (Otariidae) together with their sister taxon walruses (Odobenidae) are positioned as the next closest relatives to this clade with the fossil taxon *Enaliarctos* recognized as the most basal lineage (Fig. 1). According to this hypothesis, relationships among pinnipedimorphs are depicted as sets of nested hierarchies. In this case, four monophyletic groups can be recognized. The most exclusive monophyletic group is that formed by phocid seals and desmatophocids since this clade shares derived synapomorphies not also exhibited by walruses, otariids or *Enaliarctos*. At the other extreme, the most inclusive monophyletic group is that formed by *Enaliarctos* (Otariidae + Odobenidae) (Desmatophocidae + Phocidae).

The task in inferring a phylogeny for a group of organisms is to determine which characters are derived and which are ancestral. If the ancestral condition of a character or character state is established, then the direction of evolution from ancestral to derived, can be inferred, and synapomorphies can be recognized. The methodology for inferring direction of character evolution is critical to cladistic analysis. Outgroup comparison is the most widely used procedure. It relies on the argument that a character state found in close relatives of a group (the outgroup) is likely to be the ancestral or primitive state for the group of organisms in question (the ingroup). Usually more than one outgroup is used in an analysis, the most important being the first or genealogically closest outgroup to the ingroup called the sister group. For example, among pinnipedimorphs the ingroup includes Phocidae (seals), Desmatophocidae (extinct seal relatives), Otariidae (fur seals and sea lions), Odobenidae (walruses), and the fossil taxon *Enaliarctos*. Phocidae is hypothesized as the sister group of Desmatophocidae and these taxa together form the sister taxon to Odobenidae + Otariidae. *Enaliarctos* is positioned as the earliest diverging lineage. Ursids (bears) are hypothesized as the closest pinniped outgroup (Fig. 2) although there is evidence to support an alternative arrangement, an ursid-mustelid ancestry.

II. Phylogeny Reconstruction

The first step in the reconstruction of phylogeny of a group of organisms is selection and definition of characters and character states for each taxon (e.g., species). Next, the characters and their states are arranged in a data matrix (Table I). Characters can be further distinguished; those with two states are binary, whereas characters with three or more states are multistate. For each character, ancestral and derived states are determined. The determination of character state, whether ancestral or derived (also called polarity

assessment) is done using outgroup comparison. For example, if the distribution of character 1, condition of the lacrimal bone, is considered, two character states are recognized, the presence versus the absence (or fusion of the lacrimal such that it does not contact the jugal). The outgroup bears possess a lacrimal bone condition which is the ancestral state (Table I). The ingroup taxa lack the lacrimal bone which is the derived condition. Since this derived state unites pinnipedimorphs to the exclusion of bears it is considered a synapomorphy.

A final step in phylogeny reconstruction is the construction of a cladogram or phylogenetic tree by sequentially grouping taxa based on the common possession of one or more shared derived character states (Fig. 3 A-C) (three possible pinnipedimorph cladograms). An important aspect of phylogeny reconstruction is the principle of

parsimony. The basic tenet of parsimony is that the cladogram that contains the fewest number of evolutionary steps, or changes between character states of a given character summed for all characters, is accepted as being the best estimate of phylogeny. However, multiple equally parsimonious solutions are possible and should be examined as well as suboptimal topologies (i.e., less parsimonious trees). In this example, Fig. 3B is the most parsimonious cladogram. Note that an alternative cladogram for the data set (Fig. 3C) showing a different relationship among the five taxa, requires eight characters state changes, two more than the most parsimonious cladogram (Fig. 3B). It should be noted that this alternative view, an alliance between the walrus and otariids, although less parsimonious on the basis of morphologic characters in the data set employed herein, is consistently and robustly supported by molecular data and total evidence analysis. It also should be pointed out

Figure 1 Hypothesis of pinnipedimorph relationships modified from Berta et al., 2006. † = extinct taxa.

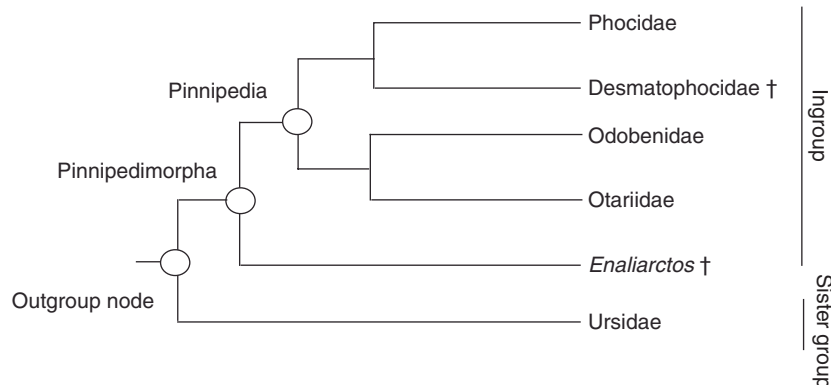

Figure 2 Pinniped relationships with ingroup and outgroups identified. † = extinct taxa. Although ursids are hypothesized as the closest outgroup there is evidence to support an ursid-mustelid ancestry for pinnipeds.

TABLE I
Data Set for Analysis of Pinnipedimorphs Plus an Outgroup Showing Five Characters and Their Character States

Taxon	Character/character states				
	Lacrimal bone	Middle ear bones	Orbital/maxilla	Maxilla/frontal	Squamosal/jugal
Outgroup					
Ursids	Present	Small	No	V shape	Overlapping
Ingroup					
<i>Enaliarctos</i>	Absent	Small	No	V shape	Overlapping
Otariidae	Absent	Small	Yes	W shape	Overlapping
Desmatophocidae	Absent	Large	Yes	V shape	Interlocking
Phocidae	Absent	Large	Yes	V shape	Interlocking
Odobenidae	Absent	Large	Yes	Straight	Overlapping

Figure 3 Three possible cladograms (A–C) of relationships and character-state distributions for the ingroups listed in Table I. Convergence is denoted by circled C. “C” is the currently best accepted hypothesis (Note: morphologic characters used here do not support this arrangement although it is supported by molecular data and total evidence analysis).

that parsimony is only one of several methods for reconstructing phylogenetic relationship. Other methods such as maximum likelihood and Bayesian approaches are most often used with molecular or combined data, and perform especially well with large data sets (Felsenstein, 2004).

The methods used to search for the most parsimonious tree depend on the size and complexity of the data matrix. These methods are available in several computer programs, e.g., PAUP (Swofford, 2000) and MacClade (Maddison and Maddison, 2000). The latter is particularly useful in assessing the evolution of characters. Systematists are concerned about the relative accuracy of phylogenetic trees (i.e., how much confidence can be placed in a particular phylogenetic reconstruction). Various measures (e.g., tree length) and indices (e.g., consistency index, rescaled consistency index) have been devised to address this concern (Swofford, 2000). Another approach that is often used to estimate the value of a particular cladogram with respect to the data places confidence limits on the individual branches,

techniques known as bootstrapping and Bremer support. Another concern stems from the realization that increase in size of the data sets results in a greater chance of the analysis resulting in more than one equally parsimonious trees. A method of working with multiple trees involves the implementation of consensus trees that are useful in identifying the areas of agreement and conflict among competing trees. A related issue in systematics is how to evaluate different data sets (e.g., morphology, behavior, and DNA sequences) particularly how they should be combined (also referred to as “total evidence” or supermatrix approach) (de Queiroz and Gatesy, 2006). The results of “total evidence” or simultaneous analysis of all character data can then be compared with the results of the separate analyses. Before data sets can be combined, it is necessary to determine if they are congruent, that is the order of branching is not contradictory. Several statistical tests have been developed to test for significant incongruencies among data sets. In summary, many factors should be considered in evaluating phylogenetic hypotheses, among the most important is taxonomic sampling, rigorous analysis including the underlying assumptions of various methods, and computer capabilities.

TABLE 2
Classification of Major Lineages of Pinnipeds

Pinnipedimorpha (including <i>Enaliarctos</i> and all other pinnipeds)
Pinnipedia (fur seals, sea lions, seals, walruses, and their extinct relatives)
Otarioidea (walruses, fur seals, sea lions and their extinct relatives)
Otariidae (fur seals and sea lions)
Phocomorpha (walruses, seals, and their extinct relatives)
Phocoidea (including <i>Allodesmus</i> , <i>Desmatophoca</i> , seals and walruses)
Phocidae (seals)
Odobenidae (walruses)

III. Phylogenetic Classification

Taxonomy is the language of biology. One aspect of taxonomy is the classification of organisms which allows us to organize and communicate information about life's diversity. Phylogenetic systematists contend that classification should be based on phylogeny and should include only monophyletic groups. In contrast to monophyletic groups, a paraphyletic group (designated by quotation marks) is one that includes a common ancestor and some but not all of the descendants of that ancestor. An example of a paraphyletic taxon is the “Otarioidea,” traditionally recognized as group that includes walruses, otariid seals, and their extinct relatives to the exclusion of

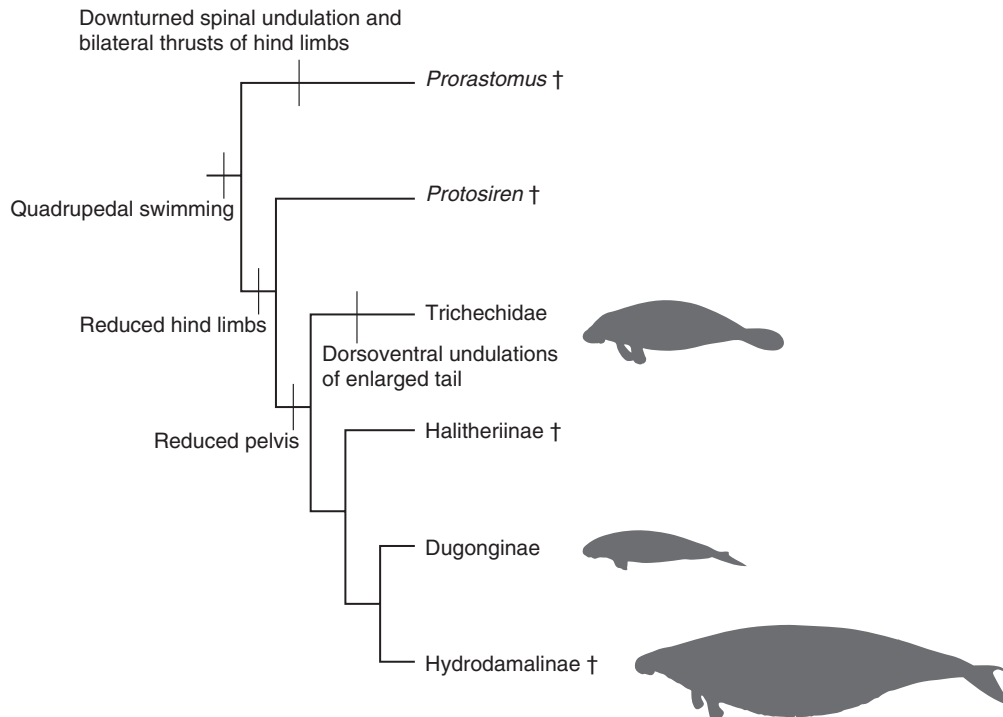

Figure 4 Evolution of locomotion among sirenians † = extinct taxa. Based on Domning (2000).

phocid seals (Fig. 1). The recognition of paraphyletic taxa is to be avoided since by doing so we risk misinterpreting the evolutionary relationships of taxa and their classification. One result of the use of phylogenetic methodology is that traditionally accepted ranks (e.g., phylum, class, order, family, genus, and species) often do not correspond to new information about evolutionary relationships among taxa thus rendering their classification misleading. One method is the elimination of rank altogether and the indication of relative rank by subordination as shown by indentation. An example, the classification of major lineages of pinnipedimorphs, is shown in Table II.

IV. Uses of a Phylogeny

Once a phylogenetic framework is produced, one of its most interesting uses is to elucidate questions which integrate evolution, behavior, and ecology. One technique used to facilitate such evolutionary studies is optimization or mapping. Once a cladogram is constructed, a feature or condition is selected to be examined in light of the phylogeny of the group. Among several computer programs recently available for reconstruction of ancestral states and character mapping is Mesquite (Maddison and Maddison, 2006). Examples using marine mammals are becoming more numerous. One of these studies, the evolution of locomotion among sirenians, is briefly reviewed here. A cladogram of relationships among sirenians was first established based on morphologic data. Next, using this phylogenetic framework Domning (2000) (Fig. 4) mapped locomotor characters onto the tree. Sirenians passed through three locomotor stages from a terrestrial quadrupedal ancestry. In the first stage exemplified by archaic sirenians, the prorastomids, swimming was accomplished by alternate

thrusts of the hind limbs. This was followed by a second stage seen in the extinct taxon *Protosiren* which employed dorsoventral spinal undulation and bilateral thrusts of the hindlimb in swimming. In a final stage, seen in modern sea cows and manatees, sirenians have evolved into completely aquatic animals swimming with the tail only.

T

Telemetry

ANDREW J. READ

Telemetry is the process of obtaining data remotely, by transmitting information from a marine mammal or by storing it for later retrieval. The field of telemetry includes a number of research approaches, from simple radio tags that allow researchers to relocate a tagged animal, to complex systems that record and transmit data from multiple environmental sensors. Recent advances in computing power, microprocessors, and global telecommunication systems have led to extraordinary insights into the behavior, ecology, and physiology of many marine animals including mammals (Block, 2005). It is now possible to follow the fine-scale behavior of marine mammals for months at a time and from the most remote regions of the world's oceans, from the comfort of one's office. It is also possible to visualize and listen to what a marine mammal sees and hears as it swims through the water column. These and other advances allow researchers to investigate how marine mammals use their three-dimensional world, quantify important physical and biological aspects of their environments, and test potential conservation measures designed to mitigate the effects of adverse human activities. The field continues to develop rapidly, fueled by continuing advances in technology, miniaturization, and data processing.

There are two primary approaches to collect data with telemetry systems. In the first approach, an archival data logger is attached to a marine mammal, records data for a predetermined period, and then it is recovered, allowing researchers to download the information stored in the package. In the second approach, information is transmitted from a marine mammal via radio or acoustic signals.

I. Archival Tags

The earliest data loggers were simple time-depth recorders that used smoked glass disks rotating past recording needles attached to pressure transducers. These devices were first employed in 1963 by Gerry Kooyman to study the diving behavior of Weddell seals (*Leptonychotes weddellii*; Kooyman, 2006). To record time in these devices, Kooyman incorporated simple kitchen timers. This ingenuity is typical of the field of marine telemetry, which is too small to support much of its own commercial research and development. Instead, biologists have adopted, modified and refined technology developed for other purposes.

Modern data loggers are sophisticated digital devices that are capable of storing large quantities of information. Data are collected from one or more sensors that measure parameters such as depth,

water temperature, light intensity, or swimming velocity. The location of a tagged animal can be determined by several methods, but the most common approach is to record light levels and times of dawn and dusk, and to back-calculate latitude and longitude after the tag is recovered. It is also possible to record physiological data, such as heart rate and body temperature. Researchers routinely record feeding events by transmitting temperature changes in the stomach to external data loggers and jaw movement. A small transmitter, equipped with a temperature sensor, is introduced into the stomach of an animal and transmits data to a data logger mounted on its external surface. Most prey are heterothermic, or cold-blooded, so when the transmitter is swallowed, the temperature of the stomach drops abruptly. Eventually, the transmitter is passed or regurgitated.

One archival tag in particular has yielded considerable new insights into the behavior of marine mammals. This device, known as a digital acoustic tag (or DTAG), was developed by Mark Johnson and Peter Tyack at the Woods Hole Oceanographic Institution. The DTAG records the acoustic environment of the tagged animal, as well as fine-scale data on its three-dimensional orientation (Johnson and Tyack, 2003). The DTAG records sound (at sampling rates up to 200kHz), depth, temperature, and orientation. In addition to the vocalizations of the animals themselves and the sound of nearby vessels, the loggers have provided unexpectedly rich data on swimming stroke and heart rate.

DTAGs have been used to study the acoustic behavior of marine mammals and to examine their response to anthropogenic sounds. For example, attachment of DTAGs to beaked whales (*Ziphius* and *Mesoplodon*) demonstrated that these deep-diving animals are highly vocal, producing high-frequency echolocation clicks, but only when they are at depths greater than 200m (Johnson *et al.*, 2004). In addition, the DTAGs were able to detect echoes from prey during foraging events. Such rich detail allows us to understand the behavior of these enigmatic animals, even as they forage near the sea floor in depths of more than 1000m. Researchers have also used DTAGs to examine the response of North Atlantic right whales (*Eubalaena glacialis*) to alert signals designed to make the animals aware of approaching ships (Nowacek *et al.*, 2004). The whales reacted strongly to the alerting signal by swimming rapidly to the surface, a response likely to increase rather than decrease the risk of collision. This work made it clear that mitigation measures other than alerting sounds will be required to solve the problem of ship strikes with right whales.

Data loggers have several advantages over other types of telemetry systems. First, data storage requires considerably less power than data transmission, so fewer and/or smaller batteries are required. In turn, this means that recoverable loggers can be smaller than transmitting tags. Second, the storage of large quantities of data is possible, particularly with modern digital technology. As noted in Section II, transmitting systems limit the quantity of data that can be relayed from the animal to a receiver.

The primary disadvantage of these systems is the need to recover the data loggers to retrieve stored information. The use of data loggers in studies of pinnipeds is fairly straightforward, because these animals haul out at predictable times and locations. Researchers studying elephant seals (*Mirounga* spp.), for example, are able to recover up to 95% of their loggers because of the strong fidelity of these animals to their rookeries. The use of data loggers with cetaceans, however, is considerably more challenging, as researchers must first attach the package to a dolphin or whale and then recover the tag after it is jettisoned. One solution is to attach the loggers with suction cups using a hand pole or other remote method, and then to recover the buoyant packages after release by homing in on a radio

signal emitted by a tag in the package. Several research groups have employed this technique with considerable success, although this is possible for only short deployments. The logistics of such field work, in which researchers follow tagged animals at sea, are considerably more complex than the deployment and retrieval of data loggers on pinnipeds.

II. Transmitting Systems

Transmitting systems have also undergone an extraordinarily rapid development over the past several decades. The earliest transmitters were omnidirectional radio or acoustic transmitters that allowed researchers to relocate a tagged animal but did not provide information on its behavior or physiology. These simple systems have evolved into sophisticated systems in which large quantities of data can be recorded, compressed, and transmitted via orbiting satellite.

Some of the earliest radio transmitters used with marine mammals were developed by Bill Watkins and W.E. Schevill from the Woods Hole Oceanographic Institution. In the 1960s, these researchers developed implantable radio tags fired into the blubber of large whales. Similar tags are still used today to study the movements and behavior of baleen whales. Radio tags have also been attached to the dorsal fins of dolphins and porpoises or glued to the fur of pinnipeds. These tags allow researchers to follow marine mammals at sea and gain insight into their behavior and short-term movements. This labor-intensive field work requires the use of directional receiving antennas to home in the radio signal produced by the transmitter.

The utility of these simple transmitting systems is limited by several factors. First, the high-frequency signals emitted by radio tags attenuate rapidly in salt water, so it is possible to receive signals only when the antenna is above the surface. This complicates the tracking of animals because only a few signals are heard at each surfacing. Acoustic signals propagate for much greater distances underwater, but often overlap with the hearing range of marine mammals, limiting their applicability. Even under ideal circumstances, radio transmitters have effective ranges of only a few tens of kilometers, so researchers are forced to stay in close proximity to tagged animals. Finally, the large size and cumbersome design of many early radio tags created significant hydrodynamic drag and resulted in the premature detachment of the packages and possible harm to the animals wearing them.

Today, there are a wide variety of transmitting systems available to researchers. The most significant advance has been the development of satellite-linked radio transmitters that allow biologists to track the movements and behavior of marine mammals from their offices. The principle underlying these systems is straightforward. Each transmitter emits a stable radio signal to receivers aboard orbiting weather satellites. As a satellite moves across the horizon, the received frequency of the tag changes due to the Doppler shift, allowing estimation of the position of the transmitter. Each transmission also includes the identity of the transmitter and any associated sensor data. Data are processed and relayed to the user by e-mail or made available over the web. This technological advance obviates the need for researchers to follow animals in the field, thus allowing insight into the movements and behavior of marine mammals in the most remote and challenging environments.

Satellite-linked radio transmitters have been coupled with data logging systems, to allow the collection of detailed behavioral or environmental data from marine mammals via satellite. This coupling of data logging and transmitting systems has proven to be very successful, because it precludes the need to recover the logger package to obtain sensor data. Typical data collected by these systems include depth and

swim speed, although in principle any sensor system can be employed. Recent developments in sensor design and data handling have allowed development of a new generation of tags that are deployed as oceanographic sensors on marine mammals (Block, 2005). Thus, marine mammals now collect and transmit large quantities of data on the physical and biological attributes of their environments, greatly facilitating our understanding of their ecology. Marine mammals are adept at exploiting fine-scale oceanographic features that concentrate prey, such as frontal systems, and animals instrumented with appropriate sensors provide considerable information about the location and dynamics of such processes. These marine mammal sentinels are providing a rich picture of the physical structure of their environment to oceanographers in areas where research cruises or the deployment of oceanographic drifters is difficult and prohibitively expensive. It is likely that marine mammals will contribute significantly in this manner to future ocean observing systems (Fedak, 2004).

Satellite-linked data loggers are extremely powerful data acquisition systems, but they do have limitations. Their signals can be received only when the transmitter is above the surface and a satellite receiver is overhead. Energy for signal transmission is a significant limitation with current battery technology, although battery life may be conserved by using a salt-water switch, which suppresses transmissions when the tag is submerged. In addition, the current satellite system limits each transmission to 256 bits, so algorithms are required to compress complex data, such as records of individual dive profiles, prior to transmission. Nevertheless, these tags have revolutionized our understanding of the ecology, behavior, and environments of marine mammals.

III. Biological Insights

Advances in the field of telemetry have revolutionized our view of marine mammals. As terrestrial observers, we are limited in our ability to study marine mammals and, in the past, have been limited to collecting data from animals at the surface or ashore. While at sea, most marine mammals spend more than 90% of the time submerged, often in remote or harsh environments in which field research is difficult or impossible. Telemetry allows us to peer into the lives of whales, dolphins, sirenians, and pinnipeds as they go about their daily activities of feeding, finding mates, and avoiding predators. We can ask how a beaked whale hunts for food at a depth of 1000 m, or how an elephant seal is capable of such long, repeated submergences, or where blue whales (*Balaenoptera musculus*) go in the winter months. The insights provided by this technology will continue to challenge our thinking about these animals; particularly, as new technological developments improve our ability to collect data at sea.

Elephant seals have proven to be particularly amenable to study with telemetry. These are large animals that haul out to breed and molt at predictable times and locations, but which spend the majority of the year far from shore. Thus it is possible to equip individual elephant seals with fairly large telemetry packages and be confident that most packages will be recovered. Researchers in both hemispheres have equipped a large number of elephant seals with recoverable data loggers and, more recently, satellite-linked data loggers. From this research, we now know that elephant seals in the North Pacific make two long-distance feeding migrations each year, one after breeding and the second after the molt. For example, adult male elephant seals travel from central California to the Gulf of Alaska on each migration, a distance of more than 10,000 km in each round trip. Individuals appear to return to the same feeding area each year and, once on the feeding grounds, forage almost continuously. While

feeding, individual elephant seals dive repeatedly, spending more than 90% of their time at sea submerged, and sometimes diving to depths of more than 1500 m. Such behavior is consistent with what we know about diet of these animals; elephant seals feed primarily on mesopelagic squid found at depths of 200–1000 m. These prolonged and continuous dives have raised many physiological questions, particularly with regard to the oxygen storage capacity of these animals (discussed later). The prodigious diving behavior of elephant seal behavior has led some biologists to refer to them as mesopelagic mammals.

Elephant seals are not alone in possessing an impressive diving capacity. Sperm whales (*Physeter macrocephalus*) have been tracked using telemetry to depths of more than 2000 m during dives that may last for more than an hour. Beaked whales are also capable of long, deep dives. Northern bottlenose whales (*Hyperoodon ampullatus*), for example, equipped with time-depth recorders attached with suction cups, have made dives to 1500 m and for over an hour in duration. Studies using satellite-linked data loggers attached to smaller whales, such as belugas (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*), indicate that these species are also capable of prolonged, deep dives under the Arctic ice.

Recent studies with data recorders equipped with video cameras, or crittercams, have provided dramatic findings regarding the behavior of marine mammals. Weddell seals have been videotaped flushing prey from crevices in the ice by blowing bubbles and researchers have watched Hawaiian monk seals (*Monachus schauinslandi*) sleep and forage on the sea floor. This type of research has particular relevance to conservation because it is believed that monk seals may be endangered, in part, due to conflicts with commercial fisheries.

Documenting the availability of prey and the success rate of capture attempts allow us to test such ideas directly for the first time. Backward-mounted crittercams have been used to study the diving behavior of a variety of marine mammals and, in particular, to investigate how whales and seals can make such long dives without exceeding their aerobic capacities. It now appears, for example, that elephant seals and other marine mammals conserve oxygen by gliding extensively during descent. These animals take advantage of the changes in buoyancy brought about by increased pressure at depth and can effectively descend with little extra expenditure of energy or oxygen.

IV. Challenges and Future Developments

It is difficult to anticipate what surprises the field of telemetry has in hold, but it is clear that these techniques will be an integral component of the toolbox of future marine mammal researchers. In particular, it is likely that more sophisticated sensors will be developed to take advantage of the success of recoverable and satellite-linked data loggers. Such novel sensors will monitor physiological parameters, such as blood oxygen concentration, hormone levels, and blubber thickness (some of these advances have already been tested with other marine vertebrates). Current advances in wireless technology hold great promise for our ability to telemeter data from marine mammals, because many current applications in acoustic and video telemetry are limited by bandwidth—the amount of information that can be transmitted from the animal to a receiver. New telemetry systems based on Global System for Mobile Communications (mobile phone, GSM) technology have been deployed with great success on several species of pinnipeds in Europe and North America. Seals wearing these mobile phone tags send text messages to researchers when they are in areas of GSM coverage, providing information on location and behavior (McConnell *et al.*, 2004). A new generation of low-orbit satellite systems would improve our ability to collect more

data from a larger sample of animals. Future readers will, no doubt, find our current suite of data loggers and satellite-based telemetry systems quaint and outdated.

Despite the great promise of telemetry for our understanding of the biology of marine mammals, some significant challenges lie ahead. As the cost of tags has been reduced, and their availability and sophistication increased, the number of individual animals studied has increased exponentially. It is not uncommon for very large samples (hundreds) of tags to be deployed in some of the largest telemetry programs such as the Tagging of Pacific Pelagics (Block, 2005). Our ability to analyze such large data sets has not kept up with the availability of information and new analytical methods are required to gain maximum insight from these large (and costly) field projects. Problems continue to exist with uncertainty in position estimates (although a new generation of GPS tags is helping to resolve some of these issues) and incorporating this uncertainty into an appropriate analytical framework. In particular, it is critical to integrate movement and behavioral data obtained via telemetry with observations of the environment conditions available to the animals (Shaffer and Costa, 2006). Making telemetry information available through publicly available data commons, such as the OBIS-SEAMAP project (Halpin *et al.*, 2006), will facilitate innovative approaches to analysis and integration with environmental data.

Finally, the ready availability of off-the-shelf electronic tags has greatly increased the number of animals instrumented each year. Despite this rapid growth in the field, there have been few attempts to determine what behavioral or physiological effects are caused by carrying a transmitter or archival data logger. Such effects could include mechanical artifacts of the attachment method used, increased energy expenditure caused by elevated rates of hydrodynamic drag, or changes to the thermal biology due to decreased heat flow across the integument. The maturation of the field will, without doubt, bring an evaluation of such potential effects on a variety of marine mammal species.

Territorial Behavior

EDWARD H. MILLER

I. Territoriality in Marine Mammals

“Territoriality” refers to the exclusive use of fixed space, which entails obtaining, defending, or advertising occupancy of the space. All agonistic social interactions occur within a spatial framework, but by themselves do not constitute territorial behavior. “Home range” refers to the space used by an individual or group (whether or not it is used exclusively), without attendant behavior in defense or advertisement (Fig. 1). As in other animals, territoriality in marine mammals can evolve if space is defensible, enabling monopolization of resources within that space. Territoriality is absent in most marine mammal species simply because no whales are territorial; the polar bear (*Ursus maritimus*), marine otter (*Lontra felina*), and most Sirenia also are not territorial. The best known examples of territoriality are breeding males in: one population of dugong (*Dugong dugon*; in Shark Bay, Western Australia; Anderson, 2002); sea otter (*Enhydra lutris*); and many pinnipeds. Superficially, territoriality appears to characterize the land-breeding elephant seals (*Mirounga* spp.) and gray seal (*Halichoerus grypus*; some populations also breed on ice), because males are fairly sedentary when hauled out (Fig. 2). All marine mammals that are territorial when breeding are polygynous; polygyny is most extreme in land-breeding pinnipeds, because density of breeding females can be very high (Fig. 3; Boness, 1991; Boness *et al.*, 2002). Territoriality is expressed differently even between closely related species, is rigid or invariant in any species, and varies intraspecifically through short-term opportunistic behavior, throughout development, seasonally, and geographically. Territoriality away from the breeding site and outside the breeding period occurs but has been studied little. Key papers are Bartholomew (1970), Stirling (1983), Boness (1991), Miller (1991), Boness *et al.* (2002), and Tyack and Miller (2002).

II. Development of Territorial Behavior

Territoriality involves complex behavioral patterns used repeatedly in interaction and communication, which emerge in play early in life. The complex underwater vocal displays of territorial male bearded seals (*Erignathus barbatus*) appeared at 4–5 years of age in several captive males, but not in females. Sexual differences in behavioral development have been documented in most detail for fur seals and sea lions (Otariidae), in which pups segregate by sex, male pups are more aggressive than females, and male pups engage in more play-fighting and territorial displays (Gentry, 1974). Those social interactions occur even in the appropriate topographical context for breeding territoriality; e.g., in the Steller’s sea lion (*Eumetopias jubatus*), “Pups located themselves on opposite sides of any available ridge and used boundary display postures, open mouth

lunges, and other ... behavior characteristic of boundary defense in adult males” (Gentry, 1974, p. 402). Young male otariids and walrus (*Odobenus rosmarus*) of all ages engage extensively in play-fighting (and for walruses, other display forms as well) throughout the year.

Territorial male otariids appear to try to influence females to stay on their territories by “herding” (Section VIII). Such behavior appears early in life, and male pups preferentially direct this behavior toward female pups (e.g., New Zealand fur seal, *Arctocephalus forsteri*). Herding is expressed also by non-territorial or peripheral males during the breeding season; for example when they encounter females outside breeding aggregations. In all otariid species, non-territorial males (including sub-adults) may rush simultaneously into (“raid”) breeding aggregations, and herd or interact with females in various ways before they are chased away by territorial males (Peterson, 1968; Campagna *et al.*, 1988a; Section VIII). Outside the breeding season, juvenile and sub-adult male otariids occasionally herd pups or young juveniles, at wintering haulout sites or colony sites (e.g., New Zealand fur seal). An extreme form of this behavior has been noted in several otariid species, in which non-territorial (generally sub-adult) males carry pups away in their mouths following raids on breeding sites (Campagna *et al.*, 1988b; Kiyota and Okamura, 2005). In the southern sea lion (*Otaria flavescens*), males may carry pups to the ocean, and then to non-breeding areas where the males herd and mount them, sometimes over several days; about 6% of pups treated in this manner die as a result (Campagna *et al.*, 1988b).

Breeding territoriality in otariids develops within the context of strong colony and natal-site fidelity (Section V), which become increasingly precise with age [e.g., for male northern fur seals (*Callorhinus ursinus*) aged 2–6 years]. Male northern fur seals start to haul out near the breeding site when they are 2-years old, and hold their first territories at about 7 years of age; first territories tend to be located peripherally, and are occupied late in the breeding season (Gentry, 1998; Kiyota, 2005). Over successive breeding seasons, territories become stabilized in location and size, and are established progressively earlier in the season.

III. Territorial Functions

Non-breeding territoriality is poorly documented and understood. Male otariid territoriality occurs at some non-pupping sites during the breeding season (Miller, 1991). Many minor disputes over space take place throughout the year at both breeding colonies and non-breeding haulout sites, where individuals of various classes tend to use and interact agonistically repeatedly at the same sites. Non-breeding (winter) territoriality in some individuals of some seal (Phocidae) species may provide exclusive (or priority) access to breath holes in stable ice. The function of another form of territoriality also is not known: mature male otariids may return to occupy their territorial sites for several days in the fall, weeks after abandon them (Section V).

The best known, most dramatic, and most interpretable forms of territoriality in marine mammals are shown by breeding adult males, which establish territories seasonally where females copulate. The ultimate function of male territoriality in all cases is to gain access to estrous females; proximate functions that mediate male reproductive success are more difficult to identify and are both varied and variable. For example, male pinnipeds may change locations in response to female movements, attend and defend isolated lone females, or even defend and copulate with female carcasses.

In many otariids, males hold territories where females give birth and remain on land until they enter estrus; in such cases, male

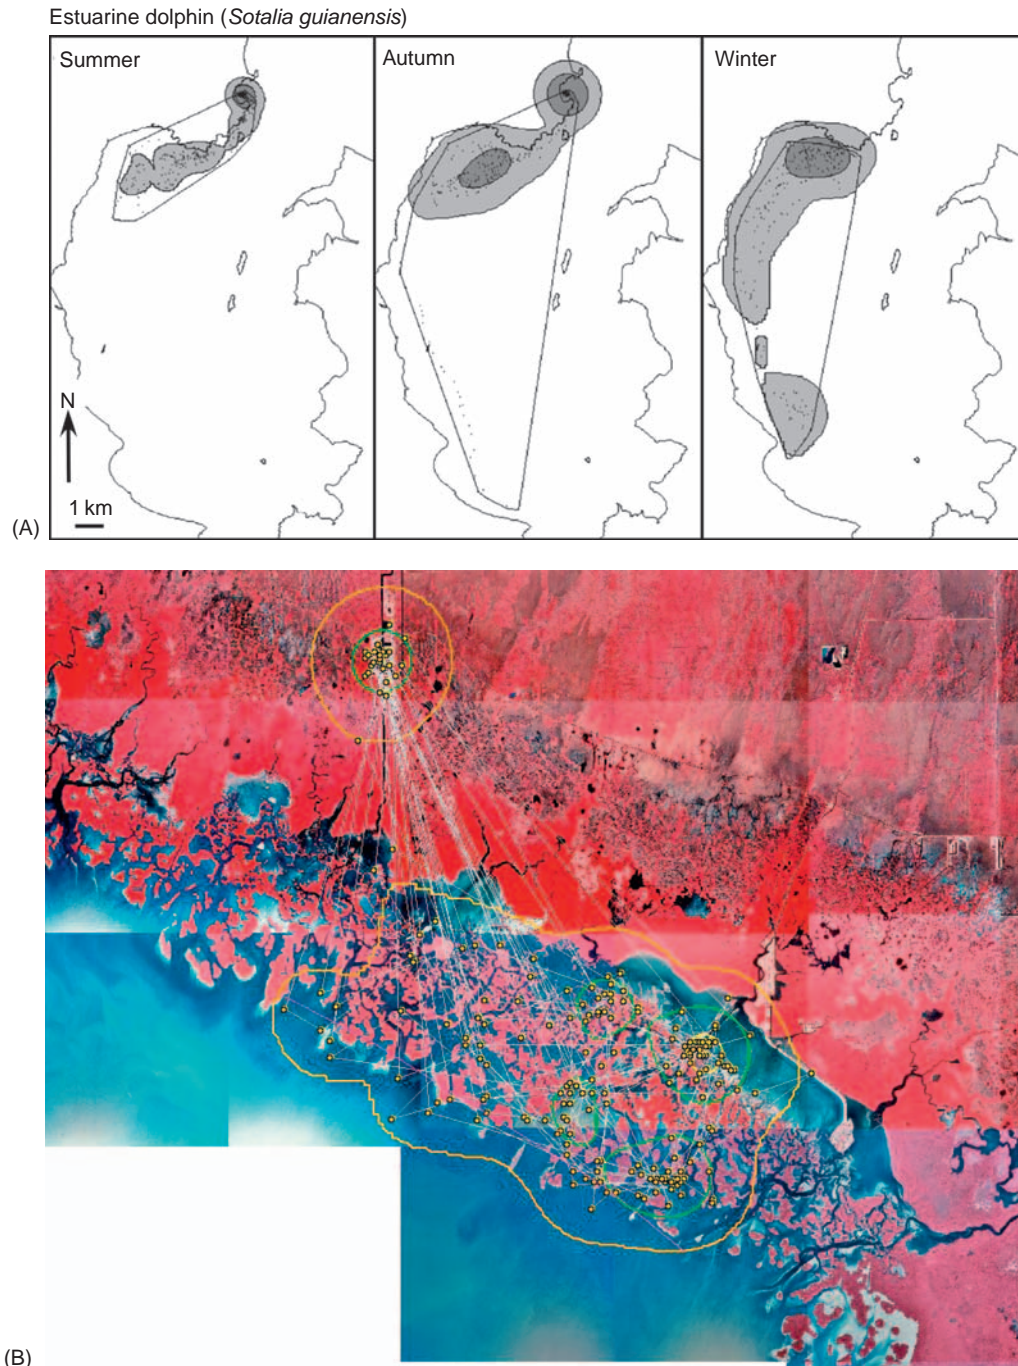

Figure 1 Most marine mammal species are not territorial: they occupy undefended home ranges, which typically incorporate systematic seasonal movements and regular smaller-scale movements between habitats. (A) Group home ranges of estuarine dolphins (*Sotalia guianensis*) in Norte Bay, southern Brazil in 2002, illustrating size, shape, and seasonal changes in home range. Home ranges were estimated by: (i) the minimum convex polygon method; and (ii) fixed kernel analysis, with dark and light gray areas representing 50% and 95% levels, respectively. (B) Home range of one adult female West Indian manatee (*Trichechus manatus*) in southern Florida in a dry period (March 2 to May 31, 2001), when it made many trips between marine-coastal feeding areas (seagrass beds), and freshwater rivers and creeks (the species needs regular access to freshwater for drinking and osmoregulation). White lines connect successive high-quality fixes by Argos satellite; colored lines reflect fixed kernel analysis, and depict 95% (orange), 50% (green), and 10% (yellow) levels. (A) After figure 3 of Wedekin et al. (2007); (B) after figure 56 of Stith et al. (2006).

Figure 2 The spacing system of breeding male gray seals (*Halichoerus grypus*) on land resembles territoriality but is structured on attendance (“consortship”) of females, but not defense of space *per se*. This figure shows areas used by adult males attending females in a study area on Sable Island, Nova Scotia, in the 1975–1976 breeding season. After figure 9 of Boness and James (1979).

Figure 3 Female fur seals and sea lions (*Otariidae*) return seasonally to particular terrestrial sites on islands free from predation, to give birth and raise offspring. These factors have enabled the evolution of male territoriality and polygyny; the tendency of females to aggregate when ashore increases polygyny levels further (see text). This photograph illustrates a breeding aggregation of northern fur seals (*Callorhinus ursinus*) at the Little Polovina rookery, Pribilof Islands, Alaska, in July 1948. Photograph by Edward C. Johnston, Fish and Wildlife Service, U.S. Department of the Interior. Photograph courtesy National Marine Mammal Laboratory (NOAA, National Marine Fisheries Service).

territories hold resources that are needed by females (sites for pupping, reuniting with pups between foraging trips, and nursing). However, territoriality is fluid in many populations, because breeding animals must move regularly for thermoregulatory reasons or

due to tide levels, or because the breeding substrate is homogeneous and hence territorial boundaries are ill defined (Section IV; Boness, 1991; Miller, 1991; Boness *et al.*, 2002). In the Juan Fernández fur seal (*Arctocephalus philippii*), females move to the sea when it is

Figure 4 Territories are small and fairly fixed in size, shape, and location in many species of fur seals and sea lions (Otariidae). This figure depicts territories (in outlines) and some territorial behavioral events of male northern fur seals (*Callorhinus ursinus*) at Kitovi rookery, Pribilof Islands, Alaska, in 1962. “HUT” is the point of observation. After figure 11 of Peterson (1968).

hot but remain close to the colony; males may hold inland, shoreline, or completely aquatic territories in this species. The most reproductively successful male southern sea lions hold territories where females can thermoregulate: within tidepools, or along the high water mark where the substrate remains wet. Resource-based territoriality is expressed clearly in sea otters. Adult male sea otters establish territories seasonally in or near areas of high female density. Male territories hold multiple resources used by females, including prey, resting areas, protection from wind and waves, and protection from harassment by other males (Garshelis *et al.*, 1984).

The distinction between territories with and without resources needed by females blurs in many cases. In the Weddell seal (*Leptonychotes weddellii*), mature males set up and defend territories seasonally in traditional areas of stable ice where females congregate, give birth, and later enter estrus; females need access to water for foraging, so these access points can be considered as the key defensible resource on which male territoriality is based (Harcourt *et al.*, 2007). Similarly, male ring seals (*Pusa hispida*) hold underwater territories that are near or encompass the birth lairs of several females (Stirling, 1983; Stirling and Thomas, 2003). Male harbor seals (*Phoca vitulina*) establish territories near female haulouts, or on access routes to and from those haulouts (Boness *et al.*, 2006). At an extreme, male territories may hold no resources needed by females, and male reproductive success depends solely on female visitation for purposes of copulation (e.g., Shark Bay dugongs; walrus; bearded seal). In some situations (e.g., walrus), the presence of males near a small number of females can be construed as defense of females, rather than of space (Sjare and Stirling, 1996).

IV. Spatial Aspects of Territoriality

Discrete, clearly defined territories are most apparent on small temporal scales, in situations of crowding, in species that have good locomotory abilities so can efficiently patrol or defend their territories, and where environmental features (e.g., topographical irregularities)

occur that can be used by the animals to demarcate territories. Such conditions are lacking in the lives of cetaceans, especially open-ocean species, so territoriality does not occur in that group. River dolphins, with their spatially restricted distributions, or species that feed on concentrated prey that are sedentary or spatially predictable, may prove to be territorial, but this is not known at present. In Scotland’s Moray Firth, year-round resident bottlenose dolphins (*Tursiops truncatus*) may be territorial and exclude seasonal (winter) visitors from deep waters, which are most favorable for feeding; group territoriality also has been suggested for this species in Ecuador.

Most species of otariids breed on crowded colony sites and hold small territories; territories of male Hooker’s sea lions (*Phocarctos hookeri*) are often no more than 3 m in diameter, for example, and some northern fur seals hold territories that are little larger in diameter than a male’s body length (Figs 3 and 4). Larger territories occur in related species (e.g., about 200 m² in male Steller’s sea lions). Small aquatic territories are held by Juan Fernández fur seals adjacent to breeding aggregations on land, and by walrus adjacent to mixed herds on ice (Miller, 1991; Sjare and Stirling, 1996). In general however, aquatic territories are large: more than 100 m in length in some male Weddell seals, up to 1 km across in male sea otters (Pearson *et al.*, 2006), and up to 10 km across in some male harbor seals. Many aquatic territories are non-contiguous, but contiguous territories invariably overlap some extent, both in linear and in more complex spatial arrangements (Fig. 5; Boness *et al.*, 2006).

Phocids are specialized for aquatic locomotion, so their locomotion on land is slow and energetically costly. The poor locomotory abilities and large size of the two species of elephant seal usually preclude territoriality, although in small confined areas or rough terrain, defense of space and of females amount to the same thing. In contrast, fur seals and sea lions can move quickly and efficiently on land, so offer many clear examples of terrestrial territoriality.

Precise delimitation of territories occurs at many breeding sites of otariids, because rocks, fracture lines, and other natural features are present; in these situations, territorial boundaries may be stable within and across years. On featureless terrain (e.g., sandy beaches), territories are less clearly defined. Territories of northern fur seals are smaller in exposed terrain, and larger in protected terrain (Peterson, 1968). Aquatic territories also are influenced by physical environmental structures. In species that breed in association with ice, underwater features of ice or fractures or leads in ice may be important in determining territorial density, size, and shape. In the walrus, male territories are established in the water adjacent to mixed herds on ice, which may be stable land-fast ice (e.g., in the Canadian Arctic) or unstable drifting pack ice (e.g., Bering Sea).

V. Temporal Aspects of Territoriality

Territories of fur seals and sea lions are most clearly defined at the peak of breeding, when territorial density is highest and territorial size is smallest (Figs 3, 4, and 6).

Absence of females from their territories sometimes leads to territorial desertion by male otariids, but more commonly males attempt to acquire a new territory where females are present. In the Hooker’s sea lion, males establish territories several times during the breeding season in response to movement of the female aggregation down the beach. Southern sea lion males defend territories early in the breeding season but gradually change to defense of females as the season progresses (Campagna and Le Boeuf, 1988).

Male otariids may haul out at the site of their future territory before territorial behavior begins and, in many species, males

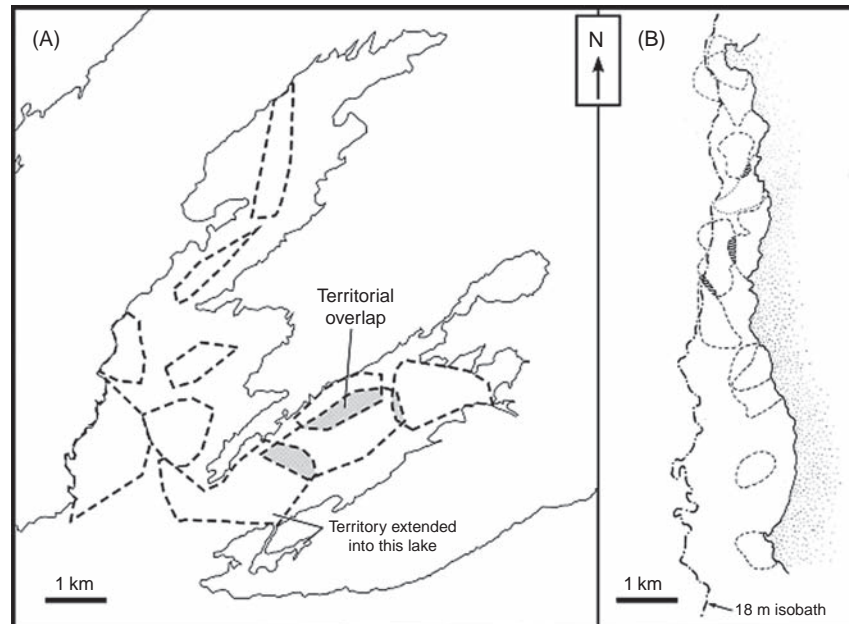

Figure 5 Size, shape, and configuration of marine mammal territories are influenced by the physical environment. Aquatic territories held by adult male sea otters (*Enhydra lutris*) hold multiple resources needed by females. They are large, overlap, and exhibit more complex spatial arrangements in enclosed waters [(A) Prince William Sound, Alaska, 2003; “lake” is a tidal lagoon] than along coasts [(B) central California, 1978–1982; overlapping territories held in different years are shown with areas of overlap not cross-hatched]. (A) After figure 1 of Pearson *et al.* (2006); (B) after figure 2 of Jameson (1989).

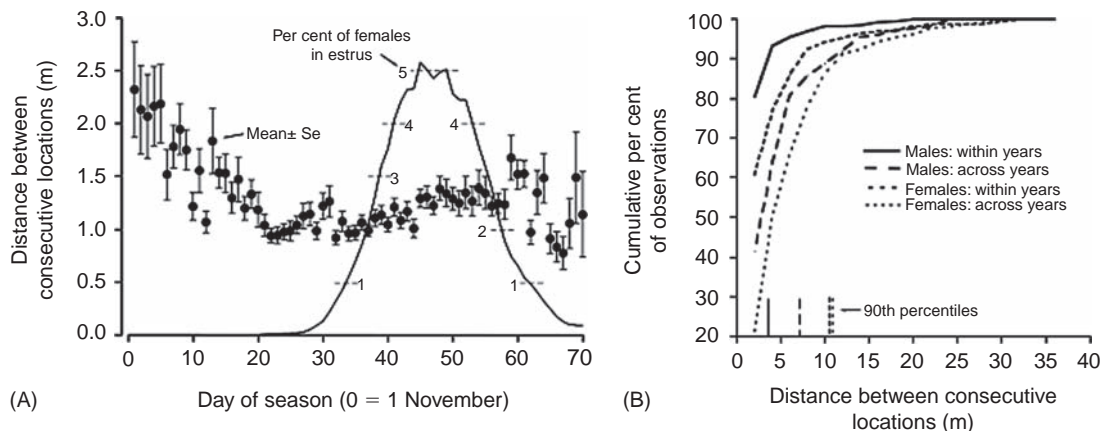

Figure 6 Territories are smallest and males move least at the peak of breeding in fur seals and sea lions (*otariidae*), and males tend to return to the same sites every year, as illustrated by the Antarctic fur seal (*Arctocephalus gazella*). (A) Movements of territorial males become increasingly localized within a breeding season. (B) Males have high site fidelity both within and across years, and their site fidelity is greater than that of females on both temporal scales. After figures 2 and 1 (respectively) of Hoffman *et al.* (2006).

also return to their territories after the breeding season has ended (Fig. 7A). Territorial occupancy may be continuous for weeks or months, or males may leave the territory for periods for thermoregulatory or other reasons, and then return (Fig. 7B; Gentry, 1998). Territorial occupancy is highly variable in the Hooker’s sea lion, and males move extensively within and between breeding sites (Fig. 7C);

this is similar to behavior of breeding males in the non-territorial gray seal on Sable Island, Nova Scotia.

Male otariids habituate to neighboring males and engage in fewer and less aggressive interactions with neighbors over time. A similar effect occurs even across years between returning territorial neighbors (e.g., Steller’s sea lion; Miller, 1991).

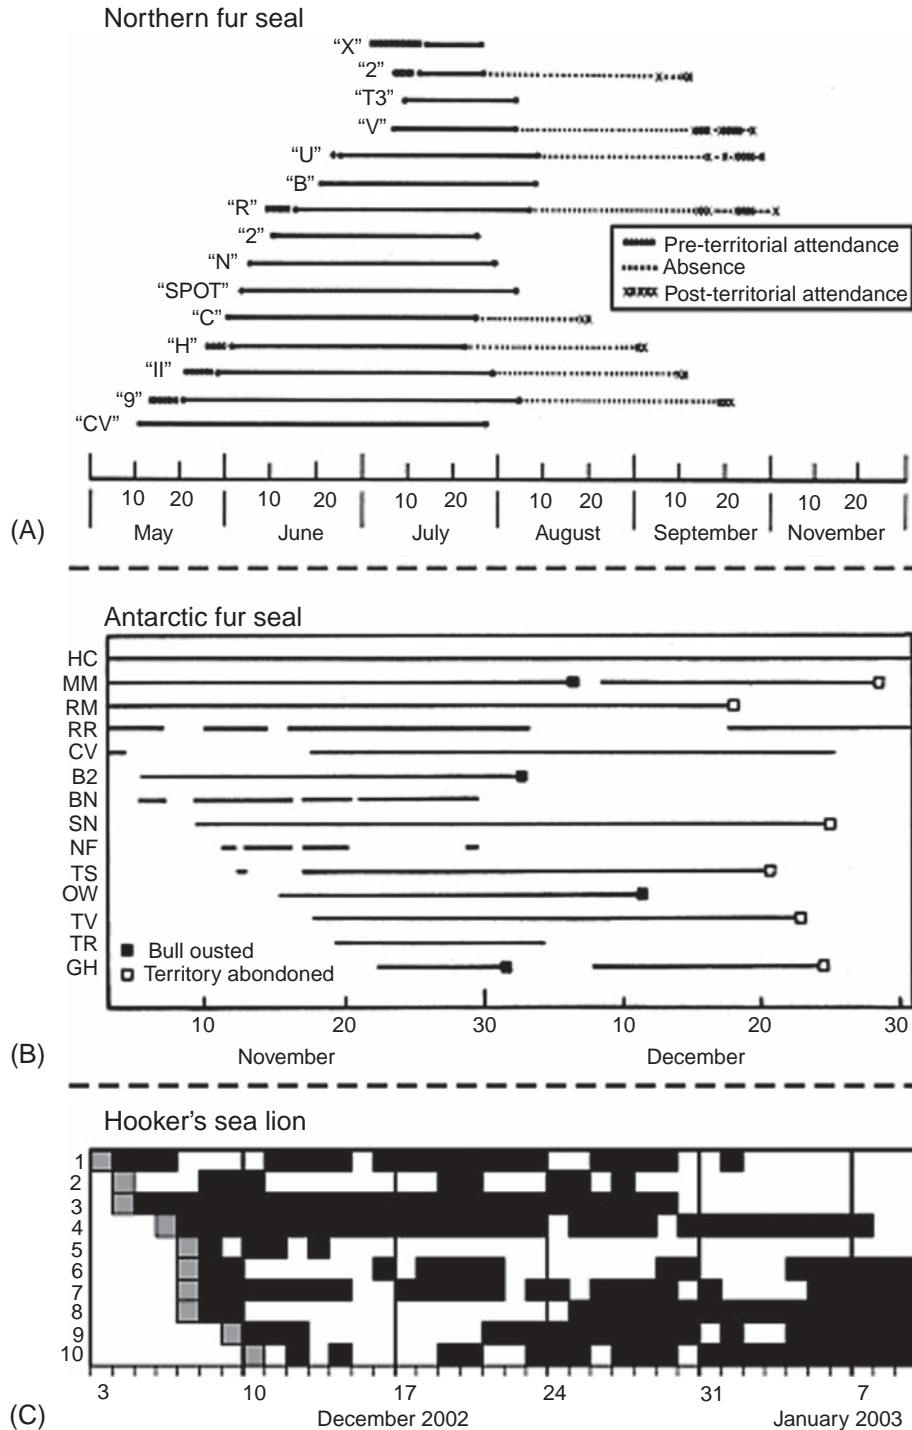

Figure 7 Attendance patterns of territorial male fur seals and sea lions (*Otariidae*) vary within and across species. Territorial attendance patterns are shown for: (A) 15 northern fur seals (*Callorhinus ursinus*) at Kitovi rookery, Pribilof Islands, Alaska, in 1962; (B) 14 Antarctic fur seals (*Arctocephalus gazella*) on Bird Island, South Georgia, in 1975–1976; and (C) 10 Hooker's sea lions (*Phocartos hookeri*) at Enderby Island, Auckland Islands, in 2002–2003 (shaded squares represent days when males were marked). (A) After figure 12 of Peterson (1968); (B) after figure 2 of McCann (1980); (C) after figure 3 of Robertson et al. (2006), respectively.

Long-term fidelity (philopatry) to territorial locations has two components. First, there is a tendency for males to return to breed near the site of their birth (natal philopatry). Second, males tend to return in successive years to where they first established a territory. Both forms of site fidelity are well documented in otariids; e.g., about 50% of returning male antarctic fur seals (*Arctocephalus gazella*) occupy a territory that is within half a body length of the territorial site held in the previous year (Fig. 6B). Site fidelity by breeding males occurs also in species that breed in association with land-fast ice (e.g., ring seal, Weddell seal; Harcourt *et al.*, 2007), or near land (e.g., harbor seal, sea otter); male sea otters hold territories in the same location for up to 7 successive years. Site fidelity even occurs in aquatically territorial phocids that display away from land or land-fast ice: some individual male bearded seals returned seasonally to the same territorial display areas every year of the 16-year-long study by Van Parijs and Clark (2006). The extremely strong natal- and territorial-site fidelity shown by otariids, coupled with their high breeding densities, results in kin breeding in proximity to one another.

VI. Territoriality, Mating Strategies, and Mate Selection

Land-breeding pinnipeds were central to Bartholomew's (1970) model of pinniped polygyny. His model remains as the core paradigm to explain otariid polygyny and territoriality, which assumes lengthy uninterrupted male territoriality, when males fast and expend much energy in territorial display and defense. However, many variations occur in territorial behavior, as noted earlier: thermoregulatory factors influence movements of males and females, and males may hold aquatic or semiaquatic territories (Juan Fernández fur seal, southern sea lion, California sea lion *Zalophus californianus*, etc.); males may vacate their territories for periods ranging from hours to days, even in classically territorial species like the northern and antarctic fur seals (Fig. 7); males may change from territoriality to female defense later in the season (southern sea lion); and so on. Variation in territoriality is paralleled by variation in male mating behavior and success.

Especially in otariids, male reproductive success is closely tied to possession of territory, and territorial males (a) account for most fertilizations and (b) fertilize most females that pup on their territories (Hoffman *et al.*, 2003; Kiyota *et al.*, 2007). Scattered observations over many years have pointed to mating in other situations, however: young male northern fur seals mate with females late in the breeding season, after the main period of reproduction; some mating occurs before pupping in the Cape fur seal (*Arctocephalus pusillus pusillus*) and New Zealand fur seal; and males mature sexually (i.e., physiologically) years before they are large enough to compete for territories. Recent molecular evidence has confirmed that fertilizations occur regularly outside the territorial structure, and involve non-territorial males (Hoffman *et al.*, 2003; Kiyota *et al.*, 2007); furthermore, female antarctic fur seals actively seek and mate with territory holders that are heterozygous and unrelated to them (Hoffman *et al.*, 2007).

Male behavior varies in other territorial species, but its relationship to mating success is not known. Some male bearded seals in Alaska change from being territorial in 1 year to non-territorial in another (Van Parijs and Clark, 2006); in Svalbard, most males are territorial when land-fast ice is extensive. It is not known whether such variability in territorial and mating behavior (a) reflects distinctly different strategies or a continuum, (b) represents evolved adaptations or behavioral plasticity, or (c) is related to male age or other characteristics (e.g., phenotype; in the non-territorial gray seal, males of different body sizes adopt different mating tactics).

VII. Obtaining, Defending, and Advertising Territories

Dramatic and potentially injurious fights between males occur in all territorial species, particularly when new males attempt to establish themselves. Severe injuries or even death can result, so fighting is uncommon, and most interactions between territorial males instead take the form of display (Peterson, 1968; Miller, 1991; Gentry, 1998).

Territorial male dugongs in Shark Bay repeatedly patrol the margins of their territories along fixed routes (Anderson, 2002). Acoustic displays can travel long distances (especially under water) and are energetically cheap to produce, but long-distance sounds are lacking from the diverse vocal repertoire of this species. Patrolling males perform various distinctive behaviors, e.g., they may swim upside-down or rear high out of the water; fights also occur. Male sea otters likewise patrol their large territories, and announce their presence by exaggerated kicking, splashing, and grooming (Garshelis *et al.*, 1984); males interacting near territorial boundaries may engage in mutual porpoising, and they sometimes fight. Like dugongs, sea otters have a rich vocal repertoire, but also lack sounds for long-distance communication (Miller, 1991). In contrast, walrus and aquatically territorial phocids possess acoustic signals that travel under water for long distances (Fig. 8).

Long-distance underwater sounds of territorial pinnipeds tend to be stereotyped, and to convey little behavioral information; nevertheless, they must be informative to several classes of receiver (e.g., non-territorial males, females), not just other territory holders (Miller, 1991; Tyack and Miller, 2002). Long-distance sounds are not universal in aquatically territorial species; for example, high vocal activity and long-distance sounds probably have been selected against in the ring seal, to minimize detection by polar bears (Stirling, 1983; Stirling and Thomas, 2003). Otariids are highly vocal and have rich vocal repertoires (Phillips and Stirling, 2001). Vocalizations of territorial male otariids are transmitted over medium to short distances; the stereotyped "full-threat call" (Phillips and Stirling, 2001, p. 423) is the loudest, and carries the farthest. Many male calls have been interpreted simply as communication of "threat" but carry much richer behavioral information. Most call types of male otariids are variable, have complicated syntactical arrangements, and are used in multiple social contexts (Miller, 1991; Tyack and Miller, 2002). Many morphological specializations for sound production occur in marine mammals but have evolved to serve general communicative functions, not functions related to territoriality *per se* (discussed later).

Optical signaling, likewise, is complex in territorial marine mammals and involves numerous morphological features. The distinctive appearance of adult male otariids is communicatively important in the context of territoriality. For example, in contrast to females or young males, adult male Hooker's and California sea lions are much darker than females or young males, and adult male southern sea lions have especially distinctive manes (Fig. 10B; Miller, 1991). Many other morphological adaptations for communication occur in marine mammals, including optical patterns of the pelage, sound-producing structures, and weapons (Miller, 1991; Tyack and Miller, 2002). Some structures may have become enlarged, strengthened, or otherwise modified for use in fights (e.g., claws of bearded seal; lower canines of otariids; Miller, 1991), and tusks (upper incisors) have evolved as optical display structures in the walrus. However, no morphological features have evolved specifically to serve territorial functions, as such features (e.g., tusks) have evolved independently in marine mammals with diverse non-territorial systems (Fig. 9A, B).

Figure 8 Adult males of some species of seals (*Phocidae*) utter sounds that travel for long distances under water, and function to advertise territorial occupancy. Spectrograms are shown for vocalizations of: (A) wintering territorial male Weddell seal (*Leptonychotes weddellii*), at McMurdo Sound, Antarctica; and (B) breeding male bearded seal (*Erignathus barbatus*), at Scalbard. (A) Courtesy of J.M. Terhune; see Rouget et al. (2007); (B) courtesy of C.M. Lydersen and K.M. Kovacs.

Some optical displays of otariids are relatively passive and undirected (e.g., the distinctive nose-up upright resting posture of otariids), but most optical displays are active and directed toward specific individuals. In otariids, these involve motor patterns such as distinctive head-and-neck swinging in locomotion, or rapid and complex sequences of feints, oblique stares, sprawls, facial expressions, etc., in displays between neighbors across territorial boundaries (Fig. 10A,B).

Chemical communication is probably important in all land-breeding territorial species of marine mammals but is virtually unstudied. Facial glands are unknown in sea otters, but the species has well developed anatomical (neural) characteristics for olfaction, and individuals often actively smell the air. Facial glands (many associated with vibrissae) occur in walruses, phocids, and otariids, and are known to vary seasonally in size and secretory activity in some species. Male otariids emit distinctive odors during boundary displays between neighbors, apparently from the oral cavity, and have distinctive body odors during the breeding season, but the anatomical source and functions of the smell are unknown. Breeding male ring seals hold underwater territories that are near or overlap with areas used by breeding females. During the breeding season, adult males of this species acquire a strong odor which is the origin of terms like “tiggak” (“stinker”) among Inuit, and “gasoline seal” among trappers. Male ring seals may actively deposit secretions from facial glands on entrances to their breathing holes and sub-nivean (“below-snow”) resting lairs, as well as within the latter.

The roles of taste or use of the vomeronasal organ (VNO) in marine mammal communication are unknown, although the VNO is absent in Sirenia but present and well developed in pinnipeds (see SENSORY BIOLOGY, OVERVIEW). Otariids commonly exhibit slow, repeated, tongue extrusion following agonistic displays (e.g., boundary displays or fights involving males; females, juveniles, and even pups also express the behavior), suggestive of behavior of other mammals that are known to use the VNO in chemical communication (at the very least, tongue extrusion is a conspicuous optical signal and likely has become ritualized as an optical display).

Tactile communication in marine mammals likewise is important but essentially unstudied (Miller 1991). Breeding males of all species engage physically and contact one another extensively in biting, wrestling, or pushing. Male sea otters and Weddell seals often try to bite the opponent’s penis, and fractured bacula (penis bones) of mature male sea otters are relatively common (see “Baculum” article). In phocid species that fight aquatically, the rear flippers (necessary for aquatic locomotion) are frequently bitten and injured in fights; walruses use the tusks in fights at and below the water surface (all sex and age classes of the walrus use tusks in numerous other agonistic contexts, of course).

VIII. Costs of Territoriality

Territoriality carries benefits and costs. In dispersed aquatically territorial species, most costs fall on territory holders, which must expend energy and time to establish, maintain, and advertise a territory, and must occasionally fight with other males. In fur seals and sea lions, some costs fall also on pups and on breeding females.

Territorial males must balance needs to be vigilant, advertise and defend territories, and signal about their own behavioral and physical attributes. Male sea otters hold large territories, and do not use long-distance advertisement, so must spend much time patrolling; on average, territory holders spent 17% of their time in this activity in Prince William Sound, Alaska (Pearson and Davis, 2005). In one long-term study, territorial male northern fur seals spent 1.5% of their time in overt interactions with neighbors; however, other types of activities also serve territorial functions, such as simply moving around the territory (1.7%), or resting in an upright position (21.1%; Gentry 1998). In the New Zealand fur seal, males spend about 14% of their time upright, compared with 5% for females (Miller, 1991).

The impact on males of time and energy spent in territorial activities is compounded by other factors: effects of fasting or reduced food intake; and time spent as a territory holder. On average, territorial male northern fur seals fast and do not drink for about a month (maximum 87 days), and decline in body mass by about one third

Figure 9 Specialized morphology has evolved in marine mammals to serve communication and other social functions, but occurs in diverse social systems and is not restricted to territoriality. (A) Male dugongs (*Dugong dugon*) possess tusks (upper incisors) that are used in fights between territorial males in Shark Bay, Western Australia, and between males elsewhere in the species' range, where the species is non-territorial (hp, horny pad on upper jaw; lj, lower jaw; m, mouth opening; od, oral disc, pulled forward to expose tusks; t, tusk). (B) Adult male walrus (*Odobenus rosmarus*; Alaska), which are territorial in parts of the range, develop conspicuous tubercles on the forequarters with age, which may act as an optical signal of male quality (as suggested for scarring in odontocetes by Macleod (1998)). (A) photograph by P.K. Anderson, from figure 4 of Domning and Beatty (2007); (B) photograph by Bill Hickey, courtesy of U.S. Fish and Wildlife Service.

over that time. This loss in body mass is equivalent to about 0.7% of initial body mass per day, similar to some other species: about 0.8% in the antarctic fur seal and the aquatically territorial Weddell seal. Breeding male harbor seals do not fast completely, and body mass declines more slowly (about 0.4% per day), but overall costs can be high (one male lost 30% of his initial body mass over the breeding season).

Costs and risks of territoriality include the danger of suffering severe physical injury. Most (80–90%) of antarctic fur seals found dead in a study on South Georgia had died as a direct or secondary consequence of fighting injuries, especially to the foreflippers or dorsal surface of the forequarters. Fitness of adult female and pup fur seals and sea lions also is affected by male behavior. For otariids, it is believed that female aggregation on land has been selected for, to reduce harassment by males and to protect pups from males (Chilvers *et al.*, 2005; Kiyota and Okamura, 2005). The significance of harassment is evident in the incidence of injuries and deaths in adult female Hooker's sea lions: greater than 80% of females have permanent scars inflicted by males, and annual mortality of adult females is about 0.5% due to male attacks (Chilvers *et al.*, 2005); infanticide by males also occurs (Wilkinson *et al.*, 2000).

Mortality rates of males are similar to those of females until social maturity is attained and males begin territorial activity. Male mortality increases at that time, and thereafter remains much higher than for adult females: 32% vs 15% in Galápagos fur seals (*Arctocephalus galapagoensis*); 30% vs 10–15% in northern fur seal; 30% vs 12% in Cape fur seals; and 50% vs 8% in Antarctic fur seals. This pattern

is presumed to be due largely to direct and indirect effects of male territoriality.

Thermoregulation

MICHAEL CASTELLINI

T Marine mammals have developed methods to retain heat in cold seas using a suite of physiological, biochemical, anatomical, and behavioral methods. Yet, they must be able to lose excess heat when they are on land or extremely active in the water. If the problem was one of solely evolving methods to stay warm in a cold ocean, it would be easier to wrap themselves in deep blubber and fur or to stay very active and not to have deal with the consequences of heat loading. However, the difficulty of that solution is that the animal would get too warm, which in turn would cause problems with metabolic regulation, reproductive chemistry and neural function. Thus, the thermoregulatory mechanisms that have evolved in marine mammals function not only to conserve heat, but also to dump it when necessary. As poorly insulated humans, we

must bring our artificial insulation with us and use exposure suits, wet suits and a variety of human-made insulative materials if we are to spend any significant time in the sea. For marine mammals, the insulation (blubber or fur) is already on board and serves multiple purposes beyond just thermoregulation.

I. The Physics of Heat and Temperature

The terms "heat" and "temperature" are often incorrectly exchanged for one another, yet they have very different physical aspects. "Heat" is the energy that reflects the molecular motion of atoms and molecules. As energy, heat can flow from an area where the energy is high (an object that is "hot") to an area where the energy is low (something that is "cold"). We quantify how hot something is by using a variety of temperature scales (Kelvin, Celsius, and Fahrenheit). Thus, the temperature of an object is our definition of the level of heat energy contained by that object. The unit of heat energy is the calorie, and a single calorie is defined as the amount of heat necessary to raise 1g of water by 1°C. In common usage in the United States, the calorie associated with food and dieting is actually the kilocalorie (kcal; 1000 calories). In strict scientific terms, a single calorie is defined as 4.184 Joules (J).

As with any energy that flows, there is resistance that impedes the flow of that energy. In the field of thermoregulation, that resistance is insulation (the inverse of insulation is thermal conductance). Thus, poor conductors are excellent insulators. Blubber, for example, makes an excellent insulator and conducts heat poorly. Materials such as silver are poor insulators and thus conduct heat very well. Relatively, water is a better insulator than silver by 1000x. The point that is relevant to marine mammals is that air is a better insulator than water by 25x. In other words, water conducts heat away from a warm body 25x more effectively than air. This becomes an important point for the discussion of how fur works to help keep some marine mammals warm.

One final physics description is the definition of how heat flows from a warm to a cold object. Heat will flow when there is a temperature gradient between two sides of a conducting material in relation to the magnitude of the temperature gradient, the thickness of the material, the inherent thermal conductance of the material and the area that is exposed to the gradient. In biological terms, this means that heat would flow from the interior of a warm blooded mammal through the fat and skin to the cold outside air or water. Since water conducts heat 25x times more effectively than air, this means that heat flows out of a warm object in cold water much more efficiently than it does when that same object is in air. Thus, as humans, we can easily stand around outside in 70°F air, but would find being in 70°F water very cold after a while. This principle states that the thicker the insulator, the less heat flow and the larger the temperature gradient, the greater the driving force. Therefore, to stay warm, an animal would want an effective insulator, a small surface area (reduced appendage size, rolling up into a ball, etc.), a low temperature gradient (seek a warmer area or allow the body temperature to fall, i.e., hibernators) and have a thick insulator. An excellent general discussion of the physics of heat and energy transfer can be found in Schmidt-Nielsen (1997) and in Kooyman (1981) and Pabst *et al.* (1999) for marine mammals.

II. What Is "Thermoregulation"?

Having discussed the physics of heat, the next step is to define the act of regulating temperature (thermoregulation) in the biological realm. In the broadest sense, animals can be classified as either *endotherms* or *ectotherms*, although some animals cross between

those two stages. An endotherm is an animal that generates and controls its internal heat so that its body core temperature can be regulated at a level different than the ambient temperature. Birds and mammals are the most commonly cited examples of endotherms. By contrast, an ectotherm is an animal that allows its body temperature to mimic and follow the ambient temperature. Most fish and invertebrates are ectotherms. All marine mammals are endotherms and regulate their normal body temperature at about 37°C. Animals that hold their body temperature constant are called *homeotherms* while those that vary body temperature are called *heterotherms*. Most mammals are therefore homeothermic endotherms.

What is the importance of 37°C to a mammal? Perhaps the most critical point is that the actual value of 37°C is not as important as the constancy of that value. There are no biochemical or physical requirements about 37°C that make it the perfect temperature for a mammal, and most isolated biochemical reactions still work above and below that temperature. However, the mammalian body has evolved to balance its myriad of biochemical reactions at 37°C. If an animal gets much warmer or colder, the system comes out of equilibrium and there can be significant failures in metabolic regulation.

The goal of thermoregulation then, is to maintain a constancy of temperature by adjusting all the properties discussed earlier (the temperature gradient, the conductance, the surface area, etc.). Of course, for an endotherm, there is the additional factor that the animal is generating heat through metabolic processes. To maintain a constant body temperature for an endotherm, the produced heat must equal the heat lost to the environment. Put on too much of an insulator and the core temperature goes up if metabolic heat production stays constant. The good example of this concept is a human in Alaska wearing a thick, down jacket outside in the winter to stay warm but getting much too hot on cross country skis wearing that same down jacket. The analogy to marine mammals is straightforward: a whale or a seal may put on large amounts of blubber but as a consequence, overheat when extremely active. A human can simply take off the down jacket while exercising. A whale, however, does not have the option of taking off its blubber layer; it must be able to dump heat and therefore to thermoregulate using other methods.

There are several ways in which heat is transferred to the environment from a warm body. Evaporation is the process of dumping enough heat into a liquid to turn it into a gas. This is the process of cooling down by sweating. Radiation is the movement of heat through the release of electromagnetic energy from the warm body to the cold environment without physical contact (heat energy from the sun traveling through space and warming the earth). Conduction refers to the transfer of heat energy (calories) by physical contact between the warm body and the cold environment (putting your hand into cold water). Finally, convection is a specialized case of conduction where the heat that is transferred from the warm body is moved away from the area by a current of air or water. Thus, the environment provides an infinite sink for the heat (wind chill is the example in air or moving through very cold water as opposed to staying still in the water).

On the whole then, in order to maintain a constant body temperature, the heat that is generated in an endothermic mammal must be balanced by the heat lost or gained through radiation, evaporation, conduction, and convection. This is the fundamental equation of thermoregulatory biology.

There is a long and fascinating history to the study of thermoregulation in mammals. In the modern era, the study of arctic mammals and birds under cold conditions and the definition of the “thermoneutral zone (TNZ)” came about largely from the work of Laurence Irving and Per Scholander (Scholander *et al.*, 1950). The

thermoneutral zone is the range of temperature over which an endotherm does not need to regulate its metabolism in order to maintain its body temperature constant. At the lower critical temperature, for example, a mammal would need to increase its heat production by shivering or increasing its activity in order to stay warm. The TNZ can be measured in marine mammals (Rutishauser *et al.*, 2004), but most of this theory was built on detailed studies of the thermal properties of terrestrial mammals (Hammel, 1955).

III. Thermoregulation in Marine Mammals

So far, most of this discussion could be applied to any biological system, not just marine mammals. Is there anything unique about thermoregulation in this group of marine endotherms? King (1983), Riedman (1990), and Pabst *et al.* (1999) provide excellent summaries of the broad field of thermoregulation in this group of mammals.

A unifying characteristic of most marine mammals is that they spend a great portion of their lives, if not their entire lives, in a liquid environment that is significantly colder than their core temperature of 37°C. Based on the discussion earlier about the fundamental aspects of thermoregulation, it should be clear that this aquatic life represents a significant thermal challenge to these mammals. While radiation and evaporation are probably insignificant sources of heat loss while in the water, conduction and convection are massive. Yet, in the Antarctic, seals will move to relatively warm polar water (at -1.8°C) when the real or wind chill temperature outside falls below about -40°C. Clearly, there is a balance where the extreme cold of the ice covered water, even with its higher thermal conductance, represents less of a thermal challenge than being outside on the surface.

Marine mammals use either fur or blubber for insulation, and like all endotherms, balance their metabolic heat production with various pathways of heat loss. However, the uses of blubber or fur have their own biological costs. Although blubber is used for thermoregulation, it is also a primary source of metabolic fuel for a marine mammal and plays a role in buoyancy regulation. Blubber is a fairly unique tissue for marine mammals and not found outside of that group except for a similar tissue in polar bears (*Ursus maritimus*) and some penguins. Fur, however, is found in both terrestrial and marine mammals, and the highest quality (density) fur is found in the sea otter. Because fur traps air in its hairs, it is a very good insulator as long as it is carefully maintained, groomed, and kept dry on the layer next to the skin. Fur seals and sea otters will spend up to 12% of the daily energy use maintaining their fur coats.

A. Heat Conservation and Generation

Marine mammals have no unusual heat generating mechanisms or tissues that are not seen in any other mammal. For example, while some large warm-bodied fishes have specialized heat generating tissues behind their eyes, no such organs or tissues exist in marine mammals. Some old data suggest that marine mammals may have an elevated metabolic rate for their mass, but this theory is not generally currently accepted (Lavigne and Kovacs, 1988) with the possible exception of the sea otter. The only heat generating specialized tissue that has ever been found in marine mammals is brown fat in harp seal (*Pagophilus groenlandicus*) pups (Blix *et al.*, 1979). This tissue is thermogenically active via oxidation of lipid compounds, but only for about the first 3 days after birth. This is an important source of heat for these young pups, but not unique since brown fat is found in other terrestrial mammals where it serves the same purpose. As

noted earlier, marine mammals also have a typical mammalian body core temperature. In fact, upon close examination of the data, there appears to be nothing special about marine mammals that would distinguish them from terrestrial mammals when it comes to heat generating mechanisms or abilities.

Given the particularly nondescript aspects of marine mammal heat generation, there must be something that is different about them since they can live in an extremely cold liquid environment that would be fatal to all terrestrial mammals. Again, given the fundamental balance equation of thermoregulation, this suggests that they must have adapted significant ways to alter the heat loss through reduced conduction and convection. They have done this through the use of blubber, fur, and vascular adaptations.

B. Blubber

Blubber is often incorrectly assumed to an inert fat layer beneath the skin. However, it actually is a complex, active tissue that consists of a loose, spongy material where the matrix of the sponge is made up of collagen fibers and the volume is made of adipocytes (fat or lipid cells). As the blubber layer increases or decreases, the collagen matrix remains the same and it is the movement of lipid in and out of that matrix which accounts for the change in blubber quality and characteristics. However, all blubber is not the same and it varies from species to species in terms of the ratio of collagen to lipid and it can even vary within the same animal from location to location or with depth. Blubber depth can range from just a millimeter or two in newborn pinniped pups to 50-cm thick in large whales. The key issue here is that blubber, by itself, is a good insulator since it can be up to 93% lipid with very little water content and has roughly the thermal conductance of asbestos. Because lipid has a conductance of only about one-third that of water, it acts as a relatively good insulator. Because blubber is deposited below the skin, it acts as an internal insulator for marine mammals. Therefore, the skin layer itself will be only marginally warmer than the surrounding water. In polar waters for example, the skin of a whale or a seal would be just a degree or two above freezing while the core temperature would remain about 37°C.

In addition to varying between species and with location, blubber quality or thickness can also vary across time in the same animal. This can be seen in the significant seasonal variation in blubber thickness in a seal as it moves between the breeding season (where it is fattest) and the leaner periods associated with molting and mating. For example, northern elephant seals (*Mirounga angustirostris*) can range between 50% and less than 20% body fat depending on the season. Clearly, this temporal change in blubber impacts not only thermoregulation, but also buoyancy and energy reserves during periods of fasting or lactation. Consequently, the role of blubber and its relative thickness as an indicator of nutritional condition has been followed quite closely in studies that seek to address the population health of marine mammals. If a population of marine mammals is nutritionally compromised, one would hypothesize that the blubber layer should be reduced due to consumption of the blubber as a fuel source.

Blubber should be thought of as a very dynamic tissue with multiple stressors and pressures on its biology. Because it is a critical tissue for several different processes in marine mammals, it cannot be modeled in a strictly thermal scenario. For example, during a time of fasting, the animal will be utilizing blubber heavily, which would be inconsistent if it was also being challenged with an increasing thermal demand. Hence, fasting periods associated with breeding occur in warmer months or in warmer water for most marine mammals.

Rosen and Renouf (1997) and Ryg *et al.* (1988) have written about the relationships between blubber seasonal distribution and thermal problems in seals.

C. Fur

As with terrestrial mammals, fur in marine mammals functions by trapping dry air next to the skin and keeping water (or cold air for a land mammal) away from the skin surface. Thus, the temperature gradient is from the skin outwards with a warm skin surface and cold outer layers of the fur (Boyd, 2000). The most cited example of the use of fur by a marine mammal is that of the sea otter and it provides an excellent example of how this animal lives in a cold environment (Williams *et al.*, 1992). The sea otter is faced with a major thermal challenge, as it is a small mammal (large surface area to volume ratio through which to lose heat). It utilizes a dense fur with a series of guard hairs and under furs to keep its skin warm. However, the cost of this luxurious fur coat is a tremendous amount of maintenance with up to 12% of daily energy expenditure being spent on grooming the coat.

Many species of seals utilize blubber for thermal protection as adults but will use a specialized fur, called lanugo, as newborns. Lanugo, or pup fur, is a very effective insulator in the air and is usually both long and very “fluffy.” On newborn pups, it functions as protection against the cold air during the time that they are on land or ice for nursing. Lanugo is useless in water and allows the skin to chill to essentially water temperature. A pup must shed its lanugo and develop a significant blubber layer before it can enter the water and be an effective swimmer and diver. Not all species of seal or sea lion pups are born with lanugo, but its purpose is well documented in many cases. Lavigne and Kovacs (1988) provide an excellent description of the first few days of life for harp seals as they adapt from the warm temperature inside the womb to the icy cold of being born on the ice. McCafferty *et al.* (2005) discuss the thermoregulatory problems faced by gray seal (*Halichoerus grypus*) pups while still at their nursing age and Dunkin *et al.* (2005) examined the thermal properties of blubber during development in dolphin calves.

It is the reliance on a high-quality fur in the sea otter and fur seals that makes these mammals particularly vulnerable to oil spills. Oil permeates the fur and destroys the air pockets that provide the thermal insulation for the animal. After the *Exxon Valdez* oil spill (EVOS) in Alaska, there was a massive clean-up operation on the hundreds of sea otters that were brought to rescue and rehabilitation centers. The goal was to clean the fur to restore its thermal insulation properties. However, cleaning the fur of human-made oils also cleans the fur of the natural oils (primarily squalene) that help make the fur water resistant. Therefore, small amounts of lipid had to be added and groomed back into the fur of the otters after they were cleaned of the heavy oil. For a general summary of the impact of the EVOS event on marine mammals, see Loughlin (1994); and for a detailed discussion on otters, see Williams and Davis (1995).

D. Vascular Adaptations

It is in the area of vascular thermoregulation that marine mammals have evolved several unusual adaptations. The first of these is termed the *rete mirabile*, which is Latin for a “wonderful net.” This net, which is a counter-current heat exchanger (Scholander and Schevill, 1955) involves an intertwined network of veins and arteries such that the cold blood returning from the extremities in the veins

runs next to the warm blood going out to extremities in the arteries. From the previous discussion on heat flow, it is easy to see how the heat flows from the arteries to the close-by veins thus tending to conserve the heat in the interior and cool the arterial blood going out to the colder regions of the body. Marine mammals have exquisite control of blood flow in their body not only for thermoregulation but also for diving. However, these two demands are themselves inter-related, and the control of one impacts the control of the other. For example, it would do no good for a diving seal to be closely controlling blood flow for oxygen conservation but then to over-ride that control to dump or gain heat. In fact, Elsner and Gooden (1983) discussed some experiments with seals where the diving response inhibited thermoregulatory-driven circulatory adjustments. In another innovative study, divers were able to apply heat flow probes to the skin of dolphins while both divers and dolphins were underwater. The results show that the animals tend to defer heat regulation and favor oxygen conservation vascular adjustments when both must coincide (Noren *et al.*, 1999; Williams *et al.*, 1999).

These circulatory retes are found in several locations in marine mammals (and in some cold adapted birds), with the most cited examples being in the flukes of whales and the flippers of pinnipeds (Tarasoff and Fisher, 1970; Kvadsheim and Folkow, 1997; Meagher *et al.*, 2002). There has been the fascinating description of another rete, but in this case, the rete is used to cool down the reproductive organs of dolphins and seals by bringing in cold blood from the extremities (Rommel *et al.*, 1995).

Another important vascular adjustment seen in marine mammals deals with those mammals that utilize thick blubber as an insulating material. As mentioned several times earlier, having thick blubber is a good technique for staying warm, but can cause serious problems if trying to cool. In fact, the large whales have such a tremendous thermal mass and a low surface area to volume ratio that they may have a much more serious problem dumping heat than conserving it (Hokkanen, 1990). While some fur-bearing marine mammals have been shown to have sweat glands (Rotherham *et al.*, 2005) as a method of dumping heat, these would not be functional underwater. Of greater significance for thermoregulation is that the blubber is not just an inert organic blanket surrounding the animal but is instead vascularized with a series of anastomoses or blood flow shunts. These shunts control the amount of blood moving through the blubber and reaching the skin, thereby controlling the amount of heat lost to the environment. If a seal needs to dump heat, the anastomoses open and warm blood can reach the surface of the skin. When Weddell seals (*Leptonychotes weddellii*) in the Antarctic dump excess heat in this manner, clouds of steam come off the animal as the blood reaches the surface of their skin. In some cases, the seals get so warm that they partially melt their way into the ice and leave perfect "seal shadows." Conversely, when these circulatory shunts are closed, the same seals will be completely covered in snow with no signs of melting at any location except near the eyes and nose.

As mentioned earlier, the balance of blood flow throughout the body of marine mammals can be complex and is controlled by multiple demands: diving, exercise, and heat regulation. Diving requires limited blood circulation, simultaneous underwater exercise requires increased circulation and thermoregulation can require both. How these animals balance those conflicting demands is an area where much more work needs to be done. This can be seen in even simple manipulations of seals and sea lions. When taking blood samples from the flippers of pinnipeds, the flippers must be warm or there is no blood flow out to the periphery. However, if anesthesia or sedation is required to work with the animal, those procedures may also

cause a series of vascular adjustments and can dump great amounts of heat quickly. Under these conditions, externally generated heat needs to be added to the animal to keep the core temperature up and blood flow open to the flippers.

The balance between diving and thermoregulation has another interesting aspect if one looks at it from the point of view of diving physiology. One of the central demands for diving is that oxygen must be conserved in order to extend the dive. This can be done by a variety of means and one of those means is to reduce the demand for oxygen by reducing metabolic rate. If a marine mammal were to reduce its body temperature while diving, it would decrease the demand for oxygen, thus extending dive time. There is some evidence from freely diving pinnipeds suggesting that the animals can drop their core temperatures during diving and would thus gain some diving time by reducing metabolic rate. The exact mechanisms by which this is done are not yet known, but temperature drops have been described in freely diving Weddell seals (Kooyman *et al.*, 1980; Hill *et al.*, 1987) and northern elephant seals (Andrews, 1999).

Advances in instrumentation that measure heat flux in free-ranging marine mammals have allowed a suite of experiments on regional measurements of heat flow across the body of the animal under experimental or field conditions. These include studies on body spatial variation in heat flux (Willis *et al.*, 2005), the use of remote infrared thermography to test how instrument attachment to animals may alter heat flow (Mauck *et al.*, 2003; McCafferty *et al.*, 2007) and novel methods for the attachment of heat sensors to marine mammals (Willis and Horning, 2005).

E. Behavioral Thermoregulation

Most of the mechanisms discussed earlier are biochemical, anatomical, or physiological mechanisms for regulating heat production or loss in a marine mammal. Of course, a marine mammal is not a static system and the animal can alter the demands placed upon it with behavioral modification. For example, sea otters are often seen floating with all four paws out of the water. The paws are highly vascularized but not well insulated with fur. Thus, they would be a tremendous source of heat loss if in contact with the water. The otters keep their paws away from the water if they are trying to stay warm. Similarly, it is not unusual to see rafts of California sea lions (*Zalophus californianus*) floating on the ocean surface with their large fore-flippers extended out of the water. On the beach, both seals and sea lions will move up or down the tidal zone area to either cool off or warm up. When too hot, sea lions will maximize their surface area by spreading out their flippers while if too cold, they will lie on top of their flippers (Beenijes, 2006). As discussed earlier, Weddell seals will head to the water if the actual or convective temperature drops below about -40°C . However, elephant seals will flip cool sand onto their backs to help keep their body temperature down on sunny days and Hawaiian monk seals (*Monachus schauinslandi*) will find shade under bushes or in small ravines out on hot, sandy atolls. These behavioral mechanisms are not unique to marine mammals, except that they have the ability to use the sea to cool down as necessary. A good example of both feeding and thermoregulation are the humpback whales (*Megaptera novaeangliae*) that come into cool Alaskan waters during the summer for feeding, but head south to warm, Hawaiian waters for breeding. Similarly, it has been suggested that thermoregulatory constraints may influence the timing of pupping for seals (Hind and Gurney, 1998). A review of many of these behavior patterns for pinnipeds is found in King (1983).

IV. Summary

What are the essential elements of thermoregulation in marine mammals? Like all endotherms, these mammals must obey the physics of heat balance when holding body temperature constant. The methods for producing heat (resting metabolism and exercise) must balance the windows for heat loss (primarily conduction and convection) (Whittow, 1987). Because marine mammals do not appear to have any special adaptations for producing excess heat, most of their ability to thermoregulate comes with their ability to control heat loss. Control of these heat loss mechanisms are via biochemical, anatomical, physiological, and behavioral means. However, as in all levels of adaptation to the environment, systems cannot be considered or modeled in isolation. For example, balancing blood flow for thermoregulation while also controlling blood flow for diving is an excellent example of multiple demands being put on this system.

It is easiest to observe the behavioral means that marine mammals use to stay warm or to cool down: the movement up or down a beach with the tide, the use of shade, flipping of sand, swimming to warmer or colder water, exposing flippers, and so on. Behind all of these behavioral patterns are the physiological or anatomical mechanisms that make the behavioral patterns effective. Counter-current heat exchangers, blood shunts under the blubber, and even the chemistry of the blubber and the microstructure of the fur are all part of the thermoregulatory system. Ultimately, however, we are still left with the paradox of heat balance in marine mammals: they live in a cold, thermally challenging environment that no terrestrial mammal could survive. However, the very means they have utilized to stay warm in cold seas have come at a cost: for many species, they have had to also evolve the means to get rid of the excess heat. The exquisite balance between all these competing demands and systems is what makes the study of thermoregulatory biology in these mammals such a rewarding experience.

Tool-Use in Wild Bottlenose Dolphins

JANET MANN AND BROOKE SARGEANT

Tool-use is generally defined as the exertion of control over a freely manipulateable external object (the tool) with the goal of (1) altering the physical properties of another object, substance, surface, or medium (the target, which may be the tool user or another organism) via a dynamic mechanical interaction, or (2) mediating the flow of information between the tool user and the environment or other organisms in the environment (*sensu* Beck, 1980). Once considered the defining feature of hominids, tool-use is rare in wild animals. Although 10 primate species (van Schaik *et al.*, 1999; Breuer *et al.*, 2005) and 30 bird species (Lefebvre *et al.*, 2002) are known to use tools, only 0.01% of non-primate mammalian species have been documented using tools in the wild (Chevalier-Skolnikoff and Liska, 1993). In Shark Bay, Australia, a subset (11% of adult females) of the Indian Ocean bottlenose dolphin (*Tursiops aduncus*) population uses marine sponges as foraging tools (Mann and Sargeant, 2003). This itself is remarkable because tool-use is typically common to all or none of the individuals within a population. Thus, despite interaction between tool-users and non-tool-users in Shark Bay, only specific individuals adopt tool-use as a foraging method, indicating individual specialization (*sensu* Bolnick *et al.*, 2003) in the use of foraging tactics and probably prey species. Shark Bay is unlikely to be the only place where wild dolphins use tools. There are definitive anecdotal accounts of Indo-Pacific humpback dolphins (*Sousa chinensis*) carrying sponges in other parts of coastal Australia.

I. History of Research on Dolphin Tool-Use

Rachel Smolker first discovered sponge carrying in 1984, when a dolphin named “Halfflake” was observed with a marine sponge on her rostrum (Smolker *et al.*, 1997). Subsequently several other adult

Figure 1 Grand-daughter of “Halfflake” with a sponge. Photograph by J. Mann.

females were observed carrying sponges on a regular basis (referred to as “spongers”). The cone-shaped sponges, identified as *Echinodictyum mesenterinum*, fit over the dolphin’s beak (Smolker *et al.*, 1997). In 1989, Halfflake’s 2-year-old daughter, Demi, was observed carrying a small sponge, which she would drop when she moved into “infant position” under her mother (Smolker *et al.*, 1997). Thus, we suspected that the behavior was passed down from mother to offspring, particularly daughters, a pattern later confirmed through extensive behavioral observation (Mann and Sargeant, 2003) and mitochondrial DNA (Krützen *et al.*, 2005). Since 1984, we have been documented over 37 regular spongers in the Eastern Gulf of Shark Bay. Strong vertical transmission of sponging is an evident and has thus been characterized as a tradition (Mann and Sargeant, 2003; Sargeant *et al.*, 2007) or a culture (Krützen *et al.*, 2005). Although we argue that sponging is socially learned, there are strong ecological correlates, including use of deep water channels with high conical sponge density. Such areas are rarely used as much by non-sponging females (Sargeant *et al.*, 2007). Although the transmission mechanism is not known, local enhancement, where mothers provide sponge-habitat, qualifies as some form of social learning, and this is obviously the case for sponging. No individuals are known to develop the tactic unless their mother is also a sponger. Sponge carrying has also been documented in the Western Gulf of Shark Bay, quite far from the Eastern Gulf site. To date, those females are of different maternal lineage than the females in the Eastern Gulf (Krützen and van Schaik, 2007), suggesting at least two independent innovations of the behavior.

II. Description of the Behavior

In several 100 hours of focal observation of spongers and over 1000 focal hours of non-sponging females, the pattern has proved to be remarkably consistent. Spongers tend to be more solitary than other females in the population. This is largely because they spend more time foraging than other females and over 95% of that foraging time involves sponges (Mann and Sargeant, 2003). Thus, spongers are clearly specialists because it occupies the majority of their foraging budget. Females have only been observed finding sponges in deeper water (>7m, deep for Shark Bay), and they change sponges approximately every 2–3h. Typically the base of the sponge, which grows out of rock or shell to anchor it, is left on the sea floor. The sponge is torn from the base, and this usually takes less

than 2 min. Searching for sponges (slow swimming with repeated U-turns before diving to the bottom) typically lasts fewer than 20 min. Sponges range in size from about 10–25 cm from base to top and cup the jaw completely when worn (Fig. 1).

When foraging with sponges, dolphins travel in a meandering, undirected manner and nearly all dives are tail-out (fluke-up), reflecting relatively deep dives. Our observations clearly indicate that females are gently disturbing the sandy bottom with the sponge. When dolphins sponge, long dives with multiple breaths at the surface are interspersed with rapid single breaths or leaps, typically without the sponge, when prey chases appear to be underway. Dolphins surfaced with sponges after 76.2% of all dives while foraging with sponges. But, during rapid single-breath surfacings (typically leaps, always lasting less than 3 sec at surface; 10.3% of all surfacing bouts), females wore sponges only 28.2% of the time. During longer surfacings, dolphins carried sponges approximately 80% of the time. Thus, the sponge was used in the search phase and typically not during the chase. Since the sponge cups over the rostrum, it cannot be worn during capture or consumption. In detailed observations of three foraging spongers when water clarity was exceptional, individuals swam slowly along the sandy-bottom habitats with the sponge on, slightly and intermittently disturbing the seafloor. When prey were detected, the dolphin dropped the sponge, accelerated about 5–10 m and then probed the seafloor with her beak. Consistent with all other observations, rapid single breaths or leaps without the sponge were observed before returning to the same spot, indicating that prey may burrow in the sand. Occasionally we have seen spongers with fish at the surface. Fish are always swallowed quickly. Subsequently, the dolphin retrieves the sponge and begins the search process again. Field observations, photographs, and sponging by human divers (with the sponge cupped over one hand) suggest that the prey are small bottom-dwelling fish. Dolphins also transport sponges to foraging areas, and occasionally carry sponges into social groups for use after leaving the group. This indicates “intelligent tool-use” (Beck, 1980; Chevalier-Skolnikoff and Liska, 1993; van Schaik *et al.*, 1999), characterized by planning and social transmission. Chimpanzees (*Pan troglodytes*), for example, carry sticks to termite mounds, transport nuts to areas with appropriate stones to hammer them, and learn socially, particularly by vertical transmission from mother to offspring (Whiten *et al.*, 1999; Lonsdorf *et al.*, 2004). Based on our knowledge of the behavior and substrate where it occurs, sponges are a foraging tool that likely both protects the rostrum from the gritty sand and shell and expands the surface area that can be searched. Fish are probably partially buried in sand and cannot be detected easily any other way, although underwater recordings indicate that echolocation is used intermittently during sponging.

III. Sex Differences in the Development of Sponging

We documented recurrent sponging in 37 bottlenose dolphins: 26 females (including eight daughters of spongers), five males (four of unknown parentage, one son of a sponger), and six of unknown sex (four born to spongers, two with unknown parentage). Thus, 13 regular spongers (8 females, 1 male, 4 of unknown sex) were definitely born to regular spongers. Critically, no regular sponger is known to have a non-sponging mother. Eighty percent of daughters and 17% of sons born to sponger mothers became regular spongers, but only daughters have been observed using sponges before weaning. From long-term data on all 37 spongers, only two daughters, born to one sponger, failed to follow their mother's tradition. Although most males

did not adopt sponging, the age of onset for those that do is not known. Of offspring born to spongers that were observed in detail during focal follows (216 h, 23 calves: 7 females, 4 males, and 12 unknown sex), all seven daughters carried sponges as calves, typically by their second or third year, but no sons did. Of those not sexed, four carried sponges, one did not, four died too early to assess, and three were not observed enough to classify. Clearly, the explanation for why adult males rarely carry sponges cannot be that males adopt it as calves, but the behavior dwindles with age. With a 3–6 year period of dependency (Mann *et al.*, 2000), social learning likely plays a role in the development of tool-use, but like chimpanzees (Lonsdorf *et al.*, 2004), sex-biased learning is apparent.

It is likely that males do not adopt sponging because of the habitat and time-budget constraints. Male spongers have not been observed in detail, but all female spongers use this foraging technique exclusively and maintain a solitary lifestyle (>80% time alone or with dependent offspring). Adult males form long-term alliances essential for reproductive competition (Connor *et al.*, 1999), with social demands seemingly inconsistent with the solitary demands of sponging. Males would have difficulty finding other sponging males to ally with, and even if they did, they would have little time available to search for females and compete with other male alliances. Further, the habitat constraints of sponging would limit them to consortships in sponging areas (deep water with high sponge density) where there are few females other than spongers. Genetic data suggest that most spongers in the Eastern Gulf are closely related (Kritzen *et al.*, 2005), and extreme assortative mating (incest) with female spongers would be problematic. Thus, sponging is unlikely to be advantageous to males. The sex bias in the development of foraging tactics is not limited to sponging. Females exhibit a far wider range of foraging tactics than males and daughters appear to maintain these behaviors long after weaning. How males know not to do what the mother does is not understood.

To date, Shark Bay bottlenose dolphins and sea otters (*Enhydra lutris*) appear to be the only marine mammals that engage in tool-use in the wild. Similarities between dolphins and sea otters include strong matrilineal transmission from mothers to daughters and individual specialization. However, sea otters also develop individual specializations in tool-use itself, with individuals using different tools (e.g., rocks or shells), techniques, and prey (Estes *et al.*, 2003). Although Shark Bay dolphins have individually distinctive foraging profiles and vertical transmission of foraging behaviors appears to be widespread (Mann and Sargeant, 2003), when it comes to tool-use, only sponges have been used and we suspect that they all use sponges in similar ways to capture the same types of prey. In future research, we hope to identify more precisely the mechanisms of transmission, what prey they are eating, and whether this technique confers an adaptive advantage over other foraging tactics.

Toothed Whales, Overview

SASCHA K. HOOKER

The toothed whales comprise the suborder Odontoceti of the order Cetacea. This suborder includes 10 diverse families, 2 of which contain large numbers of species. There are at least 71 species in all, including the true dolphins, monodontids, river dolphins, porpoises, beaked whales, and sperm whales (Table I). These species occur in three primary clades, the superfamilies Delphinoidea (true dolphins, monodontids, and porpoises), Ziphoidea (beaked

whales), and Physeteroidea (sperm whales), whereas the affinities of the river dolphins remain uncertain. With the exception of the sperm whale (males of which reach up to 18m) and the larger beaked whale species (*Berardius* and *Hyperoodon* spp.), most odontocetes are small to medium-sized cetaceans, ranging in size from the Hector’s dolphin (1.5m) to the killer whale (8.5m). These species show a range of distributions, with some such as river dolphins, found only in quite specific areas, whereas others such as sperm whales or killer whales show a global distribution.

I. Diagnostic Characters and Taxonomy

Odontocetes and mysticetes differ fundamentally in three major ways: the way that the bones of the skull have become telescoped, the specialized echolocation system (and associated anatomy) of odontocetes, and the specialized filter-feeding mechanism of the baleen whales (Table II). The name Odontoceti derives from the Greek *odous* or *odontos* for “tooth,” and *ketos* for “sea-monster,” hence “toothed sea-monster,” referring to the presence of teeth (Rice, 1998). In contrast, mysticetes do not possess teeth, but instead have baleen plates, which hang from the upper jaw and are used to filter small prey items from the water. However, although all odontocetes possess teeth, in some species (or sexes) these teeth are much reduced and may not erupt.

Other distinctive features include the possession of a single nares or blowhole, whereas mysticetes have two blowholes. Most odontocetes show some degree of dorsal asymmetry in their skull and facial soft tissue, whereas all mysticetes have a symmetrical skull and facial soft tissue. Odontocetes possess a large ovoid melon in the anterior part of the facial region. This fatty tissue is thought to be an important component of the echolocation system. Although mysticetes possess a fatty structure just anterior to the nasal passages, which may represent a vestigial melon, this is only a fraction of the size of that present in odontocetes.

Odontocetes (with the notable exception of the sperm whale) tend to be smaller in size than mysticetes, although there is some overlap. Odontocetes also show variation in sexual dimorphism. In some species, males are much larger than females (e.g., sperm whale and killer whale), whereas in others there may be reverse sexual dimorphism, in which females are larger than males (e.g., harbor porpoises and Baird’s beaked whale). Among mysticetes, adult females are always slightly larger than adult males.

The skull and jawbone of odontocetes also contain a number of diagnostic characteristics. The odontocete mandible is symphyseal (the two jawbones lock together in a bony symphysis anteriorly) and each jawbone spreads into a fat-filled hollow pan at the posterior, non tooth-bearing section, whereas mysticete mandibles are non-symphyseal and are solid. When viewed from above, the odontocete jawbone is relatively straight, whereas the mysticete jawbone curves laterally. The maxilla of both odontocetes and mysticetes has “telescoped,” migrating posteriorly to form the long rostrum and dorsal nasal openings. In the odontocetes, the maxillae have extended outwards over the orbits to form an expanded bony supraorbital process of the frontal bone. This process forms an anchoring point for the facial musculature associated with sound production (discussed later). In contrast, the maxillae of mysticetes project under the eye orbit and have developed a bony protuberance on the maxilla anterior to the eye orbit. Odontocetes lack this antorbital process of the maxilla. The earbone of odontocetes is also quite different from that of mysticetes. In odontocetes, the tympanic bulla and periotic bone are fused together, equal size, and not fused to the skull. The

TABLE I
Odontocete Families

Family	Common names	No. of species
Kogiidae	Pygmy and dwarf sperm whales	2
Physeteridae	Sperm whale	1
Ziphiidae	Beaked whales	21
Delphinidae	True dolphins	36
Monodontidae	Narwhal and beluga	2
Phocoenidae	Porpoises	6
Iniidae	Boto (Amazon river dolphin)	1
Pontoporiidae	Fransiscana	1
Lipotidae	Baiji (Chinese river dolphin)	1
Platanistidae	South Asian river dolphin	1
	Total	72

TABLE II
Major Differences between Odontocete and Mysticete Suborders of Cetaceans

Odontocetes	Mysticetes
Teeth	Baleen plates
Single blowhole	Two blowholes
Dorsally asymmetric skull and facial tissue	Symmetrical skull and facial tissue
Presence of a melon	No melon
Variable size	Always large
Variation in sexual dimorphism	Always reverse sexually dimorphic
Symphyseal mandible	Nonsymphyseal mandible
Hollow pan bone of lower jaw	Lower jawbones solid, no pan bone
Maxillae project outward over expanded supraorbital processes	Maxillae project under the eye orbit, and possess bony protuberance anterior to the eye orbit
Tympanic and periotic fused and equal sized	Tympanic bulla much larger than periotic from which it separates

odontocete tympanic is thin-walled and conical, tapering anteriorly. In mysticetes, the tympanic bulla is much larger (nearly twice the volume of the periotic bone) and is thick-walled and spherical. Bony flanges of the periotic wedge it against the skull, such that only the large bulla can be removed.

The clear morphological differences between odontocetes and mysticetes suggest monophyly of the odontocetes. There has been some disagreement about this issue, based on some molecular sequence data that supported a closer relationship between the sperm whales and the baleen whales than between the sperm whales and the other toothed whales. However reanalysis of these data and more recent work on both morphologic and molecular data continue to support odontocete monophyly (see CETACEAN EVOLUTION

Figure 1 Generally accepted phylogeny extant odontocete families, with mysticetes as sister group.

sections for further details). Relationships among extant odontocetes are somewhat controversial, but there is a consensus as to the order of branching of the phylogenetic tree, despite controversies over smaller scale relationships (Fig. 1; see RIVER DOLPHINS, EVOLUTIONARY HISTORY).

Odontocetes first appeared in the fossil record in the late Oligocene, approximately 25 Mya (Rice, 1998). Odontocete diversity increased during the warm temperatures of the early Miocene, during which time the earliest ziphiids and platanistids appeared in the eastern North Pacific (see Chapter Cetacean Fossil Record for further details). Middle Miocene diversity was also high and included diversification of these families, together with extensive radiation of the delphinoids, while the platanistoids progressively declined. Modern odontocete families are known from the late Miocene of the eastern North Pacific (monodontids and phocoenids) and western South Atlantic (pontoporiids). Evolutionary trends among odontocetes included the expansion and increase in size of the face, shortening of the intertemporal region, elevation of the cranial vertex posterior to the nasals, increased facial asymmetry and isolation of the earbones from the skull resulting in the diagnostic features described earlier. There has also been a trend toward either long, slender jaws with increased number of teeth, or short, robust jaws and reduced number of teeth.

II. Distribution and Range

Different odontocete species can be found across a wide range of habitats in all oceans of the world. The cyclical changes in sea level over the Quaternary (Pleistocene to Recent) period are thought to be responsible for much of the recent speciation within odontocete families. Sea-level drops associated with cooling are suggested to have isolated populations which then speciated allopatrically. The distributions of modern odontocetes range from species found globally, such as sperm whales and killer whales, to those with more restricted coastal distributions, such as harbor porpoises. Some species are found only in polar regions, including the narwhal and beluga, others only in tropical waters, such as Fraser's dolphin (Jefferson *et al.*, 1993). Segregation by warm tropical waters created antitropical distributions of some species pairs now found only in the Northern and Southern Hemispheres respectively (e.g., the northern and southern right whale dolphin, northern and southern bottlenose whale).

Few odontocetes show the kind of long distance seasonal migration that is found among mysticetes. The only odontocete species

which is known to show a large (ocean-basin) scale of movement is the sperm whale. At approximately 10 years of age, male sperm whales will leave their natal group in the tropics and subtropics and migrate to cold temperate and sub-polar waters where they feed. Once physically mature they return to the tropics to breed. Other odontocetes may show much smaller migrations as they follow their prey movements (e.g., long-finned pilot whales in the North Atlantic will move from shelf edge up onto shallower banks in response to changes in squid distribution). Other species (e.g., killer whales) show negligible seasonal changes in distribution.

Many odontocete species show variation across their ranges, leading to the definition of several subspecies or races. With increasing scrutiny of both genetic and morphological differences, subspecies and population level differences are continually being identified. In some cases, this is leading to revision of the currently established species (Rice, 1998).

III. External Appearance

In general, many odontocete species tend to have darker coloration on the dorsal surface (back and cape) and lighter pigmentation on the ventral surface (Fig. 2). Such countershading is relatively common in the marine environment and functions essentially as camouflage, such that when viewed from above the dark dorsal surface is seen against the darker depths, and when viewed from below the lighter ventral surface is seen against the brighter downwelling light from the surface (e.g., harbor porpoise). Exceptions to this include the beluga, which has a uniform color pattern, although this is thought to be related to the bright ice-covered habitat that it lives in. The general tendency toward countershading has become quite elaborate in some species, which also have striped and saddle patterns (e.g., striped dolphins, short-beaked common dolphins), and has become radically modified in others (e.g., killer whale, Dall's porpoise). It has also been suggested that these color patterns may function in signaling between individuals in a group (Norris *et al.*, 1994), in addition to their function in concealment (from both predators and prey).

Odontocetes tend to show greater body flexibility than mysticetes. This is presumably due to differences in prey capture strategies

between odontocetes, which chase fast, mobile, single prey, and mysticetes which engulf less mobile prey schools. This flexibility is quite pronounced in some odontocete species (e.g., belugas).

IV. Diet and Feeding Strategies

Different odontocete species feed on fish, squid, large crustaceans, birds, and occasionally other marine mammals. They differ from mysticetes in that they generally chase, capture, and swallow single relatively large prey items, rather than filtering and swallowing large quantities of small prey items. This more generalized and more adaptable feeding method is thought to account for much of the diversity of odontocete species and their range of habitats. Many odontocetes also feed on much deeper prey than the surface water plankton diet of many species of mysticetes. Additionally, whereas the diet of baleen whales is highly seasonal due to the seasonal nature of zooplankton biomass and production, that of odontocetes is generally more constant year-round.

Unlike the heterodont condition of most terrestrial mammals, the teeth of odontocetes are uniformly shaped (homodont). There is a wide variation between (and some variation within) species in tooth number, size, and shape (see Dental Morphology). The teeth of most odontocete species tend to be peg-shaped with single, open roots. Exceptions to this include the porpoises, which have spade-shaped teeth, and the beaked whales, which show great variation in size, shape, and location of teeth in the jaw.

Narwhals have only two teeth, both in the upper jaw. In females, these teeth usually remain embedded in the upper jawbones, but in males the left tooth grows out through the front of the head into a tusk up to 3-m long. These tusks are thought to be involved in male-male competition. These are used primarily as a display, although males have been seen sparring with their tusks above the water. The teeth of beaked whales have similarly become adapted for use in male-male competition and generally erupt only in males. In some species, such as the dense-beaked whale (*Mesoplodon densirostris*), these teeth form large structures which protrude above the upper jaw. In the strap-toothed whale (*Mesoplodon layardii*), the teeth, which emerge from the middle of the lower jaw, curl backward and inward, extending over the upper jaw, often preventing it from opening more than a few centimeters.

The diet of a particular species is generally reflected in the morphology of the jaw, and the type and number of teeth. For example, species which feed primarily on fish tend to have more teeth (e.g., spotted dolphin, *Stenella attenuata*), and use these teeth for grasping single prey. Species which feed primarily on squid tend to show reduced dentition (e.g., sperm whales, beaked whales, narwhals, and Risso's dolphin), and are thought to feed by suction. This suction is achieved by using the tongue as a piston in combination with a small gape. The suction feeding mechanism of beaked whales was investigated in detail by Heyning and Mead (1996), and involves distension of the floor of the mouth by expanding the throat grooves together with retraction of the tongue by the styloglossus and hyoglossus muscles. Additionally, it has been suggested that some species may debilitate prey by directing high-intensity sounds at them, prior to capturing them (Norris and Mohl, 1983). Such feeding methods are thought to explain the occasional observation of healthy animals with severe deformity of the jaws (as has been noted in sperm whales).

Notable specializations associated with odontocete feeding are shown by several bottlenose dolphin populations. In Shark Bay, Western Australia, a small number of Indian Ocean bottlenose dolphin females have been observed carrying sponges (Mann *et al.*, 2000).

Figure 2 Short-beaked common dolphin (*Delphinus delphis*) pigmentation, shows countershading with dark pigmentation on dorsal surface and light pigmentation on the ventral surface, common to most odontocetes. Photograph by Sascha K. Hooker.

These are thought to function as “tools” to protect the dolphin’s rostrum as it roots in bottom coralline sediments in order to flush bottom-dwelling fish out. Another bottlenose dolphin population, in North Carolina, USA, has been observed beaching themselves and the fish they were pursuing up onto the surrounding mudbanks, thus immobilizing their fish prey which they can easily catch, and then slide or wriggle back down into the water (Reynolds and Rommel, 1999). The same behavior has also been observed in killer whales in Patagonia and the Crozet Archipelago in their pursuit of seals up onto steeply shelving beaches.

Foraging specializations of killer whales in British Columbia, Canada, and Washington State, USA, waters, have resulted in two separate forms, “transients” which feed on marine mammals, and “residents” which feed on fish. These two forms are thought to potentially represent a case of incipient speciation. The primary difference between these two forms is in their dietary specialization, which has resulted in their social separation and behavioral, morphological, and genetic differences.

Many odontocetes appear to feed throughout the day and the night (e.g., sperm whales and northern bottlenose whales), but many smaller delphinids show marked diurnal differences in feeding (e.g., spinner dolphin and pantropical spotted dolphin). Since many prey species rise to shallower depths during the darkness of night, it is energetically more efficient for some species to conduct the majority of foraging behavior at night.

As mentioned previously, odontocetes tend to feed at greater depths than mysticetes. In general, however, detailed data on diving and foraging patterns of most species of odontocetes is not yet available. The use of novel technologies such as the attachment of time-depth recorders to monitor dive profiles of these species have lagged behind work done on pinnipeds or mysticetes, primarily due to difficulties in deployment, attachment and recovery (Hooker and Baird, 2001). However, new developments in these technologies and attachment mechanisms are increasingly resulting in the initiation of new studies.

V. Sound Production and Reception

Toothed whales have developed specialized sound production and reception mechanisms for the use of biosonar. All modern odontocetes are thought to use echolocation, in the same manner as bats, to gain an “image” of their environment. Although only a few species of odontocete are unequivocally known to echolocate, all odontocetes known to produce pulse-like sounds in the wild are assumed to be able to echolocate.

The sound production mechanism of odontocetes consists of a sound generator located in the “monkey lips”/dorsal bursae (MLDB complex) associated with the upper nasal passages. In most odontocetes, there are two bilaterally placed MLDB complexes, but sperm whales have only a single complex. The central components of the MLDB complex are the fatty dorsal bursae, the monkey lips, the bursal cartilages, and the blowhole ligament (Cranford *et al.*, 1996). Sounds are generated as air is forced between the monkey lips, setting the MLDB complex into vibration. Sound is propagated into the water by the melon, a low-density lipid filled structure which acts as an acoustic lens to focus a directional sound beam ahead of the animal (Au, 1993; see ECHOLOGATION). The short-duration clicks produced as a result of this are used primarily for echolocation, although some species appear to use these clicks in a social context (e.g., Hector’s dolphin).

Most odontocete species produce broadband echolocation clicks in the ultrasonic sound range, well above the range of human hearing. The pulse duration, frequency, inter-click interval, and source

level are adjusted by the animal for optimal performance according to the prevailing conditions of ambient noise, reverberation, target distance, and target characteristics (Au, 1993). With low ambient noise, bottlenose dolphins, belugas, and false killer whales often echolocate using frequencies from 20 to 60kHz, although at higher noise levels, they emit stronger pulses at 100–130kHz. Echolocation clicks of porpoises and many small dolphins are greater than 100kHz, while those of the sperm whale range from less than 100Hz to 30kHz, with most energy from 2–4kHz to 10–16kHz (Richardson *et al.*, 1995).

In addition to echolocation clicks and loud impulse sounds, many toothed whales also produce other sounds, usually described as whistles, squeals, or less distinct pulsed sounds such as cries, grunts, or barks (Richardson *et al.*, 1995). These tend to be narrow band (sometimes pure tone), frequency modulated sounds, often with a harmonic structure. Most whistles tend to have most of their energy below 20kHz. These whistles can show a variety of patterns of frequency and amplitude over the duration of the whistle. For many species, the frequency, duration, and level may vary. Observations of captive bottlenose dolphins have shown that individual animals can be identified from the contour of the whistle on a sonogram (a representation of the whistle as sound frequency plotted against time). The distinctive character of a whistle is thought to function in identifying the sound producer to other animals. These whistles are therefore known as signature whistles. Recent evidence also suggests that there may be population or group-level distinctions between whistles of bottlenose dolphins.

Group-specific sounds have also been found among killer whales and sperm whales. Among killer whales, groups appear to have a repertoire of approximately 10 calls. Different groups may share some but not all of the calls within their repertoire, and relationships between groups can be established based on the similarities in their repertoires. In a similar fashion, the codas (rhythmic patterns of clicks) produced by sperm whales also appear to be characteristic of the social group (Whitehead, 2003).

The high-frequency hearing of odontocetes is reflected in the structures of the jaw and ear. The lower jaw of odontocetes is flared out in a thin hollow pan bone at the rear. This is filled with a fat body that directly connects with the bulla of the middle ear. These fat bodies act as low-density sound channels to conduct sounds to the ears. Within the ear, the tympanic bulla is separated from adjacent bones of the skull by peritympanic sinuses filled with an insulating emulsion of mucus, oil, and air. The bulla is suspended in this emulsion

TABLE III
Social Strategies Employed by Odontocete Species
Known from Long-Term Studies of Wild Animals

	<i>Social groups</i>	<i>Mating system</i>
Bottlenose dolphin	Male coalitions Female groups	“Capture” of females by a coalition of males
“Resident” killer whales	Matrilineal groups of females and descendents	Inter-group mating thought to occur when groups meet
Sperm whale	Matrilineal groups of females and juvenile males; Solitary adult males	Males rove between groups in search of estrus females

by connective tissue, so that the middle ear functions as a sound receiver isolated from the skull to better localize sound signals. The tympanic bulla membrane of odontocetes is also stiffened with bony ligaments, which appear to be associated with ultrasonic hearing (Reynolds and Rommel, 1999).

VI. Social Organization and Culture

Toothed whales are particularly well known for their brain size and rich social lives (Mann *et al.*, 2000). The absolute brain size of odontocetes ranges from 840 g in common dolphins to 7820 g in sperm whales (Berta *et al.*, 2006). However, a more useful way to compare brain sizes is to use the ratio of brain size to body size, the encephalization quotient (EQ). The relative brain sizes of odontocetes (ranging from EQ 0.02% for the sperm whale to EQ 1% for the bottlenose dolphin) are much larger than most terrestrial mammals but are similar to those of anthropoid primates (EQ 0.3% in the gorilla). Captive studies of bottlenose dolphins have shown that dolphins may have a “pecking order” similar to that of chimpanzees, in which both males and females have a social hierarchy, but that generally males are dominant to females.

The social systems of only a few odontocete species are known from long-term studies of wild animals, but these suggest some novel adaptations to standard mammalian patterns (Table III; Connor *et al.*, 1998). In Shark Bay, Western Australia, male Indian Ocean bottlenose dolphins form tight associations with one or two other males with whom they co-operate to form aggressively maintained consortships with individual females. These alliances further appear to form moderately strong associations with one or two other alliances and will defend each other in competition over females. A completely different strategy is found among the fish-eating “resident” killer whales living along the coast of British Columbia, Canada, and Washington State, USA. Here, neither males nor females disperse at maturity, but instead they remain with their mothers in stable matrilineal groups. Genetic data suggest that a similar pattern of natal philopatry may exist among long-finned pilot whales. Sperm whales appear to have a different social structure again. Groups of females and immature males are found in the tropical lower latitudes. Juvenile males remain in these natal groups until they reach puberty, at which stage they depart to lead more solitary lives in colder temperate and polar waters. They later return to the tropics when fully mature and search for estrus females with which to mate. Long-term studies of sperm whales have demonstrated strong co-operative bonds between individuals in groups of females and immature males (Fig. 3). These groups were thought to be composed of matrilineally related individuals, however recent evidence suggests that they are not purely matrilineal in structure but are comprised mainly of clusters of related individuals but also of some animals with no close relations. Baird's beaked whales may have one of the most unusual social systems among odontocetes, although this is inferred only from studies of dead animals. It appears that males mature an average of 4 years earlier than females and may live up to 30 years longer (Kasuya *et al.*, 1997). This has led to speculation that males may be providing significant parental care.

An interesting congruence between low levels of mitochondrial diversity and the presence of matrilineal social systems in four species of odontocete may suggest the cultural transmission of matrilineally inherited traits (Whitehead, 1998). Apparent culture in cetaceans includes the learning of particular feeding techniques from the mother or members of the matrilineal group. In fact, many attributes of cetaceans (and odontocetes in particular) favor the evolution of social learning and culture. These include their long lives (~60–90 years),

Figure 3 Group of female and immature sperm whales in the Galápagos Islands. Photograph by Sascha K. Hooker.

advanced cognitive abilities, prolonged parental care, permanent and cohesive groups, and an environment that varies substantially over large spatial and temporal scales (such that individual learning would be costly) (Rendell and Whitehead, 2001). However, claims of animal culture are argued to be subject to weaknesses, in that behavioral differences thought to be cultural may in many cases result from a combination of genetic, ecological, and cultural variation (Laland and Janik, 2006).

A potential offshoot of the advanced sociality observed in some species of odontocetes is the presence of postreproductive care, i.e., “menopause.” Pilot whales, killer whales, and sperm whales show similar attributes to human females, with reproduction ceasing at approximately 40 years of age although females live on for several more decades. Short-finned pilot whales (*Globicephala macrorhynchus*) show a decreasing pregnancy rate with increasing maternal age, and a parallel age-related decline in the ovulation rate. Up to 25% of adult females may be postreproductive, ceasing to ovulate after age 40 even though the maximum lifespan exceeds 60 years (Marsh and Kasuya, 1991). However, lactation may continue for up to 15 years after the birth of their last calf. It is unclear whether communal nursing exists.

Another apparent consequence of the strong social bonds found among odontocetes is the phenomenon of mass strandings (Sergeant, 1982; see STRANDING). This tendency for animals to come ashore in groups to die is found only among the most highly social odontocete families. Several explanations for this behavior have been suggested. These include disorientation due to geomagnetic anomalies, panic flight responses from predators or underwater noise, morbillivirus infections, parasitic infections of the respiratory system, brain, or middle ear, or the strong social bonds of a group causing the entire group to follow one intentional strander. It has also been noted that many locations in which mass strandings occur share certain structural characteristics. These sites are often composed of a sandy peninsula or promontory, which extends perpendicular to the coastline and appears to form a “whale-trap,” potentially due to the loss of echolocation abilities in the shallow sandy environment.

VII. Mating System, Reproduction, and Life History

Many odontocete species have promiscuous mating systems, in which several adult males may mate with a female. However, other

species such as the bottlenose dolphins in Shark Bay, and Dall's porpoises in the eastern Pacific appear to show a form of mate guarding. Among many beaked whale species males compete, suggesting that there may be a hierarchical nature to their social organization, probably for access to females. However, detailed comparative data on the mating systems of odontocete species will await genetic analyses to determine paternity from offspring within groups.

Gestation periods of odontocetes range between 7 and 17 months and almost all species have interbirth intervals of greater than 1 year (Reynolds and Rommel, 1999; Berta *et al.*, 2006). Length of gestation and fetal growth rate are related to calf size at birth such that larger species tend to require longer periods of gestation. Odontocetes produce a single offspring which is physically well developed (able to swim and surface to breathe), but socially undeveloped. As a result, odontocete species have characteristically long lactation periods, averaging between 32 and 100 weeks (Berta *et al.*, 2006). Females continue to feed throughout this long lactation period.

Odontocetes tend to show extended maternal care, resulting in a strong mother–calf bond. For most species, calves will remain with their mothers for a few years, but for some they will remain in close family groups for their lives (e.g., some killer whale populations, possibly long-finned pilot whales). This high level of investment needed to successfully raise calves may have led to the need to practise mothering behavior. Association between infants and non-mothers, termed allomaternal behavior, has been described for a variety of odontocete cetaceans (Mann *et al.*, 2000). Among bottlenose dolphins, such behavior appears to primarily benefit the non-mother, providing experience in parenting. Similar babysitting has also been documented in sperm whale groups, which stagger their deep-diving behavior such that calves are almost always accompanied by an adult at the surface. However, the function of this behavior in these circumstances appears to relate to increasing calf survival and defense against predation rather than to practise mothering (Mann *et al.*, 2000).

Much of the life history data available for odontocetes has come from studies of dead animals (either from those taken in whaling operations, as bycatch to other fisheries, or from strandings). The age of an odontocetes can be estimated from its teeth using much the same technique as counting the growth rings of a tree trunk. As an individual grows, incremental growth layers are deposited in the teeth and bones. In order to determine the age, the tooth is usually thinly sliced and polished and may often be etched or stained to better resolve the growth layer groups. In most species, each growth layer group is thought to represent an annual increment, but this needs to be independently verified in order to use this method for each species. By establishing the ages of animals, researchers are able to investigate the age-structure of the population, to look at ages at which animals mature, reproduce, the lifespan, etc. Long-term studies of odontocete species in the wild (e.g., those listed in Table III) are gradually allowing life history parameters to be recorded from living animals. In some cases, particularly in establishing lifespan, these are providing records of lifespan to a much greater age than were estimated from catch records.

The life histories recorded in this manner show large differences between different odontocete species. Harbor porpoises have a maximum longevity of 12 years (although some may live up to 17 years); they reproduce at age 3 and become pregnant every year thereafter. In contrast, killer whales have a maximum longevity of about 80 years and first give birth at approximately 15 years of age, with a 5-year interbirth interval. Many species also show sex-specific differences in life history parameters. For example, sperm whale females

become sexually mature at approximately age 9–10, whereas sperm whale males do not appear to become sexually mature until approximately age 26–27.

VIII. Human Interaction and Conservation Status

In the past, the majority of human interaction with odontocetes involved the capture of animals from the wild, either for consumption as part of the whaling industry, or more recently to obtain animals for captive display purposes. Only a few odontocete species were hunted to the same scale as the fisheries for baleen whales in the last two centuries. The main odontocete species taken historically were the sperm whale, some beaked whale species (northern bottlenose whales and Baird's beaked whales), and pilot whales. However, although the moratorium on large whale hunting essentially put an end to the hunting of myticetes, the only odontocete species included in this moratorium was the sperm whale. Thus today, many odontocete species are still taken in large numbers primarily in aboriginal subsistence hunts. Unfortunately, many of these go unmonitored, and so the exact numbers taken are unknown, although they are suspected to be high (Bown, 2000).

Several odontocete species are or have been maintained in captivity for display, research, or conservation purposes (Twiss and Reeves, 1999). Some species are maintained in captivity for research or public display (e.g., bottlenose dolphin, killer whale, and beluga) whereas others have only rarely been kept in captivity following live stranding (e.g., sperm whales and beaked whales). Some species are successfully bred in captivity, including bottlenose dolphins, Commerson's dolphins, and killer whales, but most other odontocete species do not appear to fare so well in captive situations.

Humans are also increasingly attempting to interact with odontocetes in the wild. Whale-watching operations are increasing in number worldwide. In the San Juan Island area between British Columbia, Canada, and Washington State, USA, the number of whale-watching vessels has increased dramatically over the last two decades. There is currently a good deal of concern about the impact of whale watching on the animals involved. Although there has been little documentation to date of immediate adverse impacts, there has been little investigation of the long-term stresses and consequences for the viability of the populations concerned. Swim-with-dolphin programs are also increasing in frequency. There is also concern about the effect of these, although one of the most pressing concerns is the potential to misinform the public. As a result, of these activities, the public may form the perception that association with wild animals is endorsed. Currently in Florida, many people continue to solicit interactions with wild dolphins, and, despite legislation against it, often encourage this by provisioning.

Lone animals of several odontocete species have, at times, been recorded to solicit associations with humans. This behavior has been recorded a number of times all over the world. In all cases, animals have become resident in a small area, where they approach and interact with boats or people in the water. In many cases, the animals involved have been bottlenose dolphins, but this behavior has also been recorded from belugas and rough-toothed dolphins.

Today, conservation problems exist for nearly all odontocete species. In fact, since the International Whaling Commission moratorium on catching large whale species, many of the current conservation threats faced by cetaceans are likely greater for odontocete species than for mysticetes. Their typically smaller size means they are less likely to be able to free themselves when trapped in nets,

leading to high incidence of bycatch. The squid diet of many species renders them prone to plastic ingestion and their higher trophic levels magnify their pollutant load. Additionally, the habitat specificity shown by many species means that they have little recourse in the face of habitat destruction (for more details, see Conservation section).

Other less direct threats to odontocetes include noise and disturbance, pollution, and habitat loss, and degradation. In general, noise is thought to be less of a problem for many odontocete species than for mysticetes, since much oceanic anthropogenic noise is low frequency. However, higher frequency noise (such as that created by fishfinder units) is likely to coincide with the hearing range of many odontocetes (Twiss and Reeves, 1999). Additionally, some odontocete species (particularly beaked whales) appear to be highly susceptible to disturbance from mid-frequency sonar, although the mechanism by which this causes mass strandings and death remains unknown (Cox *et al.*, 2006).

Training and Behavior Management

TED TURNER, TODD FEUCHT AND TYLER TURNER

I. Introduction

Marine mammal training is a relatively new field that gained formal recognition in the late 1940s. One of the first institutions to successfully maintain a breeding colony of bottlenose dolphins (*Tursiops* spp.), Marineland of Florida, also became the first institution to begin a formal training program for bottlenose dolphins. As behavioral observations of these animals began to generate questions unanswerable through scientific observation alone, it seemed that further exploration involving dolphin learning abilities could only be facilitated through training. Early training methods were considered industry secrets; yet those techniques were primitive and lacking in their full understanding of current behavior modification principles and procedures. Although the methods used at that time were limited, often consisting of trial and error, the marine mammal training field now employs a range of specific animal learning principles, including operant conditioning, as a means to provide better care, manage breeding groups, and shape specific behaviors to individual animals.

Although the use of operant conditioning is not exclusively the only mechanism used to train marine mammals, it is arguably the most direct. Therefore, the fundamentals of this science, as a minimum, must be assimilated for those who train, or wish to train, marine mammals (Pryor, 1995). Because the field of marine mammal training strongly discourages the use of aversive techniques, it is also highly productive and continues to stand as a model for ethical animal training. This philosophy of focusing on positive proactive behavior management and eliminating aversive and punishing practices has also created much safer environments for both the trainers and the animals by greatly reducing incidents of aggression, between animals and humans as well as within social groups.

The high exposure and excitement that is created when animals perform in shows for the general public have focused attention on

Figure 1 Marine mammal training and show performances generate public interest in marine mammals and related issues. Here Pacific white-sided dolphins, *Lagenorhynchus obliquidens*, perform for a crowd.

the cognitive abilities of these animals (Fig. 1). Though some criticize the use of marine mammals in show performances and other public programs, many who experience these interactions are fascinated by the level of complexity, coordination, and consistency in behavior. Still others are amazed at the degree of cooperation between animal and trainer. The vast majority of guests who participate in controlled swim-with-the-dolphin programs experience a greater sense of appreciation, conservation awareness, and concern for marine mammals (Marine Mammal Poll, 2005). Magical to some and practical to others, it is the training process itself that creates the medium for “communication” between marine mammal behaviorists and the animals with which they closely interact. In most cases, public performances, shows, presentations, and interactions have provided the animals with stimulating enrichment, and the general public with the motivation for further education. As a result, public interest in marine mammals is growing, and quality programs are expanding the use of marine mammal training. In turn, visitors to marine mammal facilities continue to develop a stronger sense of interest, empathy, and awareness, especially when they can interact and observe the results of marine mammal training and behavior management in a variety of contexts. In this and other areas, marine mammal training is making a significant impact on the conservation of these species.

II. Animal Learning and Behavior

At a fundamental level, learning is a biological process necessary for the survival of an animal. The expression or suppression of certain behaviors enables animals to respond to their environment and adapt to ever-present social and environmental changes. An animal’s ability to learn is directly related to its survival.

The study of animal learning involves not only biological processes, but also detailed aspects of psychology such as memory, developmental learning, classical conditioning, operant conditioning, behavior modification, cognition, and other information processing disciplines (Spear and Riccio, 1994). The field of psychology is now experiencing a stronger appreciation for its role in understanding marine mammals,

and although a number of important learning principles have been excluded from this chapter due to their current limited applications for marine mammal training and behavior management, we have attempted to include some of the most widely utilized principles, or principles having significant future impact (Domjan, 1993). When describing the main components of current marine mammal training, three primary learning modes become salient:

A. Observational Learning

Also known as *modeling*, this vicarious process is defined as learning by observing another (model) engage in a behavior. During observational learning, the animal (observer) need not emit the behavior, experience direct consequences, or receive applied reinforcement for learning to occur. Mimicry seems to be a by-product of observational learning. It is a primary learning element for young animals raised in a complex social environment, and appears to be of significance in developing socialization skills.

The expression of these mimicked behaviors is not relegated to social behaviors only. Young marine mammals attempt to mimic trained behaviors, and often accompany adults in show performances or training sessions (Fig 2.). It is common practice for marine mammal behaviorists to “capture” (reinforce) mimicked behaviors in order to rapidly develop and accelerate the learning process for young animals. However, regression often occurs when the model (adult) is no longer present, a phenomenon that must be considered when zoological exchange, reintroduction programs, or environmental changes occur. Under conditions such as these, expressed behavior (observed while in the presence of the model), may not occur in a changed environment. This may impact behavioral acclimation, foraging skills, socialization patterns, predator avoidance, and other behaviors that may have health or survival ramifications. Training programs that rely on observational learning must often re-train these animals using direct operant conditioning and behavior shaping with individual training sessions. Nonetheless, observational learning plays a critical role in the lives of marine mammals.

B. Classical Conditioning

Past understanding of Ivan Pavlov’s early work investigating anticipatory salivation in dogs led to a restricted view that classical conditioning [the pairing of a conditioned stimulus (CS) in conjunction with an unconditioned stimulus (UCS)], only produced a conditioned response (CR) involving reflex systems. In recent years, groundbreaking research in experimental psychology has replaced this view with a more dynamic understanding of Pavlovian learning. Associations between conditioned and unconditioned stimuli have been linked to learning phenomena such as *sign tracking* (movement towards a stimulus that signals the availability of a positive reinforcer such as food), *conditioned emotional response* (anxiety/fear), and *conditioned taste aversion* (food preference/avoidance) (Cole *et al.*, 1996). These seemingly insignificant components have a measurable and often profound impact on subsequent learning during the training process.

The accidental or deliberate pairing of events, which often occur in any given environment (both wild and zoological); can create learning via classical conditioning that can influence the training of marine mammals. Associating food with a loud noise for example, can eventually diminish the startle effect the noise might otherwise evoke and reduce the likelihood of a negative reaction (such as escape or aggression). However, pairing the same loud noise with a painful medical procedure can exacerbate the negative reaction to that same noise in

Figure 2 A killer whale, *Orcinus orca*, calf accompanies its mother during a training session.

the future, and increase the probability of that negative reaction. A minor avoidance response by the animal could intensify into a severe aggressive or panic response, causing injury to the animal or the animal handlers. In another applied example, pairing food with an aversive medical procedure can cause an animal to avoid eating, leading to weight loss, even though no illness is present. A conditioned food aversion can be an unintended by-product of seemingly unrelated events.

Pavlovian conditioning can be used to help modify behaviors needed for the long-term care of marine mammals, such as introducing new animals into established social groups during animal acclimation procedures. An experienced marine mammal behaviorist understands the principles of Pavlovian conditioning and will manage environmental conditions with behavior to prevent problems, while assisting the animal in the beneficial acquisition of behaviors commensurate to the long-term goals.

C. Operant Conditioning

Commonly defined as behavior which is modified by consequences, operant conditioning is currently recognized as the most widely employed training program for marine mammals (Ramirez, 1999). The three basic components of instrumental learning (learning that occurs as a result of operant conditioning), however, must occur in precise order for learning to be achieved. These three components are the *antecedent* (a stimulus, cue or hand signal which precedes the behavior), the *behavior* (the resultant observed response emitted by the animal which immediately follows the antecedent), and the *consequence* (a stimulus or applied reinforcement that immediately follows the response and acts to increase or decrease the preceding behavior) (Honig and Staddon, 1977).

Consequences play a key role in operant conditioning as they will cause a behavior to become more or less frequent in the future, and influence the way antecedents set the occasion for repeating or not repeating a behavior (Baldwin, 1998). Reinforcers will strengthen a behavior and increase the likelihood of it occurring in the future, whereas punishers will decrease the frequency of a behavior. The terms “positive” and “negative” are used to indicate if a stimulus is being applied (onset of a stimulus) or removed (termination of a stimulus). Therefore, positive reinforcement would consist of applying a “good” or rewarding stimulus as a consequence of a behavior, whereas negative reinforcement would consist of removing or

terminating a “bad” or aversive stimulus. In both cases, the preceding behavior will have been strengthened. Conversely, positive punishment is the application of a “bad” or aversive stimulus as a consequence of a behavior; while negative punishment is the removal or subtraction of a “good” or rewarding stimulus. In either case, the preceding behavior will decrease in frequency. As previously mentioned, the marine mammal industry concentrates its efforts on the use of positive reinforcement for behavior management plans; however, it is still critical to understand how all consequences affect behavior so one can be fully prepared to manage and understand the many different scenarios that will undoubtedly occur when caring for any animal or group of animals.

During a typical marine mammal training session, a hand signal (antecedent) is usually presented to the animal, followed by the animal’s response (behavior). If correct, the behavior is usually reinforced (consequence) by the trainer with either primary reinforcement (food) or secondary reinforcement (touch, toys, play, and activities). Common in marine mammal training, incorrect, or undesired behaviors are usually ignored with minimal or no consequence applied. Again, punishment and negative reinforcement is avoided or eliminated. In the operant process, each behavior is best described as a learning cycle representing three critical elements (Fig. 3). Within a series of behaviors, typical of a formal training session, this cycle is repeated multiple times.

Principles supporting the successful training sessions must be understood by the behaviorist and include *stimulus consistency*, *stimulus fading*, *behavioral criterion*, *behavioral development*, *delay of reinforcement*, *schedule of reinforcement*, *magnitude of reinforcement*, and many others (Kazdin, 1994). Experienced marine mammal trainers understand the implications of precise application. Like other forms of learning, operant conditioning should not be characterized as a “technique” or “system” of training that can be switched on and off conveniently; instead, it is a dynamic and ever-present environmental learning phenomenon that is in continuous action and influences the acquisition, intensity, or extinction of specific behaviors. Behaviors are in the constant process of strengthening or diminishing as a result of the consequences that follow. Not all of the antecedents and consequences experienced by each animal are applied by the marine mammal trainers. Behaviorism views the environment in its’ entirety, with many such antecedent stimuli being processed by the animals in context. Even in the most productive marine mammal training programs, it is rare that more than 3h per day, on average, are devoted to actual training sessions, leaving many hours each day to other environmental learning influences.

For large institutions with formal marine mammal training programs, certain principles, and techniques have been refined and “operationalized” to facilitate staff development and expertise, resulting in efficient animal training. Expertise is often gained through practical hands-on application and supplemented with coursework, seminars, and testing. Other mediums such as conference attendance and trade groups provide additional sources of information. The International Marine Animal Trainers Association (IMATA) is an established trade group that offers opportunities to formally exchange specialized marine animal training information. Many marine mammal training programs emphasize the following:

1. *Optimal Learning Conditions* Naïve animals (animals without prior training experience or limited behavior repertoire) often seem cautious and wary of their surroundings. This apprehension can be reduced by minimizing or eliminating those elements that can create anxiety and avoidance such as aversive procedures, unstable environment,

Figure 3 A typical operant conditioning cycle where the signal (antecedent) precedes the response (behavior), followed by the reinforcement (consequence). A single training session includes many such cycles.

incompatible conspecifics, or unfamiliar sounds, to name just a few. The process of extinguishing avoidance behavior is aided by the cumulative positive effect of daily feedings and time spent with the animal, allowing both desensitization and familiarity to influence a more comfortable learning environment. Marine mammals will readily take food from a familiar caregiver and generally allow some calm touching during feeding times. This provides the foundation for positive reinforcement (a stimulus that is applied as a consequence and increases the frequency, intensity, and duration of the preceding behavior). Regression can be minimized if aversive events can be delayed or eliminated. As a reinforcement history develops, unavoidable aversive events (such as routine medical treatment) have less impact and cause minimal regression. The opposite appears to be true as well. Repeated aversive procedures early in the process can have a profound negative effect and will delay the positive response to the trainer.

2. Conditioned Reinforcers We have already discussed briefly and given examples of unconditioned (primary) reinforcers and conditioned (secondary) reinforcers; however, it warrants some additional information. Unconditioned reinforcers satisfy a biological need and therefore are effective without having to be learned or conditioned. Food is a common example of an unconditioned reinforcer.

Conditioned reinforcers are those stimuli that were once neutral but have gained reinforcing properties by repeatedly preceding or predicting other reinforcers (Baldwin, 1998). Some examples of conditioned or secondary reinforcers could include the toys or a rubdown from a trainer. The consistent delivery of an *unconditioned reinforcer* (such as food) as an immediate consequence to a desired behavior establishes the foundation for training a *conditioned reinforcer* (a stimulus that has acquired reinforcing properties through learning) (Chance, 1994). These conditioned reinforcers are an important tool for a marine mammal behaviorist, as they allow a much greater variety of positive consequences to motivate and shape behavior.

Most marine mammal training facilities also use audible whistles called a “bridging” stimulus. This bridging stimulus acts as a cue that signals the imminent application of reinforcement. It is referred to as

a “bridge” because it acts to bridge the time delay between the precise behavior targeted for increase, and delivery of a positive consequence, such as food, toys, play, a favorite activity or another reinforcing behavior. Marine mammal trainers and behaviorists use a variety of tools that act as a bridge. Typically, a high-frequency whistle is used for cetaceans (due in most part to higher hearing ranges), whereas a verbal cue or clicker sound is used for pinnipeds. This bridging stimulus, when consistently followed by the offering of food, quickly becomes recognized by the animal. Within a few training sessions the sound itself evokes a response from the animal and subsequent orientation back to the trainer.

3. Increasing the Attention Threshold In order to maintain the animal’s attention sufficient to advance learning and develop a repertoire of beneficial behaviors, an early emphasis on *attention threshold* (the duration that a stimulus will control behavior) is necessary. This is done by systematically increasing the amount of time the animal will continue to watch the trainer prior to bridging and reinforcement delivery. Increments of a few seconds are literally counted by the trainer when shaping an increased attention span. This is particularly important in the training of species such as Commerson’s dolphins (*Cephalorhynchus commersonii*), young animals, or animals in high stimulus environments. Eventually, within a few days or weeks, an attention span of several minutes can be conditioned if bridging and reinforcement is precise. Conversely, a lack of precision can interfere with or delay the acquisition of new behaviors. Inexperienced or impatient marine mammal trainers often overlook this critical element.

4. Following a Target Pole If the pairing of food with the bridge has been well timed and effective, the animal will quickly learn to touch a hand prior to the bridge and food delivery. By holding the hand close to the animal, the animal will readily touch the hand. The behavior of touching is then reinforced. Eventually, the hand can be moved back and forth to shape and strengthen the hand-touch response. In time, the animal will move to the hand wherever it is placed. Target poles (a long pole with a small round float, or “target” attached to the end) are often introduced at this stage to simulate an extended reach. Using this target pole, touching and following the target can be reinforced and various high-energy behaviors can now be safely shaped through *successive approximations*.

5. Achieving Stimulus Control As animals begin to learn the relationship between their emitted response (behavior) and the delivery of reinforcement by the trainer (consequence), they also begin to learn which specific behavior will likely lead to reinforcement. Discrimination between learning events occurs when animals respond differently to separate antecedent signals or cues. The trainer offers reinforcement only for specific responses and thereby facilitates discrimination learning. This process is aided with specific hand signals (*discriminative stimuli*) that precede each behavior. When trainers selectively reinforce only desired behaviors, animals learn to recognize the signals and respond appropriately. This is referred to as *stimulus control* where behaviors are reinforced in the presence of a particular signal (or stimulus). *Random sampling* (emitting several behaviors in an attempt to gain access to reinforcement) is a common phenomenon early in the training process. Trainers will ignore all but the requested behavior, thereby aiding the process of stimulus control and discrimination learning.

6. Successive Approximations The most effective trainers break each behavior down into small easily understood and planned steps. Each small step, or approximation, is reinforced until the animal consistently responds to the antecedent cue. Once consistency

is established, the trainer will continue in sequence to each new (usually more complex or difficult) step. For example, a high jump begins with the lifting of the head in order to touch the target and receive reinforcement. With each successive approximation, the target is raised slightly until the desired height is achieved. In effect, each behavior can be visualized by the trainer as a systematic process. All behaviors including complex behaviors involved in medical procedures can be broken down in such a manner, creating an easier learning process for the animal.

7. Schedules of Reinforcement A schedule of reinforcement refers to the timing and frequency of reinforcement. Any behavioral plan without regard to the precise schedule of reinforcement can lead to training and subsequent learning problems. Specific *schedules of reinforcement* have been empirically derived in learning laboratories and applied in marine mammal training programs. Through practical application, many facilities are beginning to recognize the importance of *variable schedules of reinforcement* including reinforcement variety. This type of reinforcement delivery provides reinforcement and enrichment intermittently and unpredictably. It more closely replicates the type of reinforcement schedule most often associated with the wild environment, helps maintain motivation and interest, and provides enrichment opportunities for each animal while it shapes extended thresholds and increases the number of attempts made.

Only certain components of animal learning disciplines have been described for the purpose of identifying those elements most commonly used to influence the acquisition of trained behaviors, but it is also helpful to recognize that these principles continue to influence animal behavior, whether formally applied or not. The process of “training” through observational, instrumental, or Pavlovian learning is constantly shaping behavior independent of the presence of “trainers” or the existence of a formal training program. Even the normal daily cleaning, feeding, and operational activities in any animal facility can effectively act to shape and modify behaviors. The appearance of the staff veterinarian, for example, might inadvertently act to suppress courtship behavior depending on the timing of appearance. In another example, the appearance of the staff veterinarian could also act as a reinforcer in a different scenario, depending on prior learning experiences, thereby increasing certain behaviors. As many zoological facilities have experienced, the principles of learning and the effects of timing can even affect stereotypic patterns such as anticipatory pacing prior to feeding time, creating an opportunity for *adventitious reinforcement* (coincidental cause and effect reinforcement causing an inadvertent increase in the unwanted behavior). This is why, in addition to animal training objectives, comprehensive behavior management programs are being incorporated into progressive zoological institutions. The Animal Behavior Management Association (ABMA) is a trade group, formed in the United States, to promote the understanding and use of broad-ranged behavior management by zoological professionals. It promotes the systematic use of animal training, environmental enrichment, behavior medicine, exhibit design, and other natural-history behaviors to achieve desired and measurable goals.

As we continue to learn about information processing and marine mammal training, additional learning principles will add to our knowledge of these animals. Investigations into memory retrieval, short and long-term memory capacities, context specific learning (learning in one environment that does not necessarily transfer to another environment), and other principles, may help us understand and predict the success of future reintroduction projects. Awareness of these learning principles enables caretakers, behaviorists, veterinarians, scientists, and trainers to better understand environmental factors influencing

the expression of appropriate or inappropriate behaviors. Further investigations into animal emotion, cognition, and stage developmental learning will improve our ability to manage the behavior of marine mammals to their benefit.

III. Early Development and Learning

For newborn marine mammals, motor skill development occurs rapidly and within a few weeks. Observations of increasing independence (time and distance away from the mother) begin to emerge as motor skill, buoyancy control, visual acuity, echolocation, and auditory learning strengthen. Observational learning becomes evident and mimicry increases until the young animal learns to directly manipulate its environment.

In some cetaceans between 4 and 7 months of age, when teeth begin to erupt and grow, the mother (dam) initiates a weaning process through food sharing (both partially digested and regurgitated or with food that has been ripped into small pieces). This seems to coincide with accelerated learning and may signal the beginning of a *sensitive learning phase* or *critical period* (a developmental stage where rapid acquisition of behaviors occurs). For marine mammals born in zoological facilities, most formal training begins during this stage.

IV. An Emphasis on Positive Reinforcement

Marine mammals respond readily to operant conditioning and possess a strong aptitude for instrumental learning. The rapid acquisition of behaviors has done little to refute the notion that marine mammals are unusually “intelligent.” However, other marine and terrestrial animals trained via operant conditioning sometimes show an equal or superior aptitude and learning curve. Therefore, comparative intelligence remains difficult to define and quantify. Regardless, empirical evidence suggests that positive reinforcement has a strong motivating influence on learning, and this has certainly contributed to the notion that marine mammals can learn quickly.

Positive reinforcement-based training creates an environment that is non-threatening and therefore facilitates learning for marine mammals, although maintaining a strong desire to interact with their trainers. Significantly, the most effective training programs develop a foundation of voluntary cooperation as opposed to compliance. With voluntary cooperation as a prime goal of most marine mammal programs, behaviors once thought impossible to train have been achieved, and positive reinforcement has been the common element for many of the breakthroughs in marine mammal training. These programs emphasize *positive reinforcement* and discount the use of *negative reinforcement* (an increase in a response that causes the removal of an aversive stimulus) and *punishment* (a decrease in a response that is followed by an aversive stimulus). Marine mammal facilities licensed in the United States are regulated by the US Department of Agriculture and abide by the provisions of the Animal Welfare Act. These institutions consider the use of negative techniques as unethical. This philosophy has been a model for other animal management programs and has been drawn acclaim and interest from a variety of sectors. Behavioral consistency and using strictly positive reinforcement may prove to be the marine mammal training industry’s most profound contribution to the social sciences.

V. Enrichment and Variety

Just as we recognize the importance of play in the development of young animals, we also recognize how crucial other physical and

cognitive challenges are for optimal animal health. An emphasis on behavioral enrichment programs that produce beneficial changes in behavior as well as health and well-being has gained wide acceptance in zoos and aquariums (Shepherdson *et al.*, 1998). In the past, this aspect was considered superfluous to well-designed facilities. It was believed that “natural” behaviors would be an automatic by-product of a naturalistic exhibit. It was soon recognized that these behaviors required more prompting than just high quality food, health care, and naturalistic environments.

A focus on *environmental enrichment* (the application of environmental complexity to stimulate beneficial activity), has become a fixture in the behavior management of mammal species. The goals of environmental enrichment programs clearly fit within the animal training model (i.e., behaviors can be shaped, maintained, and modified using animal learning and training principles). In fact, most successful enrichment programs are now managed by experienced animal trainers and behaviorists. They coordinate environmental change, food placement, toys, games, and other behavioral prompts and reinforcers that target specific behaviors and patterns. When used properly and applied as a consequence of desired behaviors, environmental enrichment devices offer important physical and mental stimulation, while simultaneously maintaining a repertoire of “healthy” behaviors. Daily variety and reinforcement of appropriate behaviors help reduce other inappropriate, destructive, or agonistic behaviors.

VI. Animal Acclimation

The assumption that animals immediately behave towards a new member with acceptance or at best indifference, is often erroneous. Animals use aggression as a means to acquire and establish territories, food sources, breeding rights, sleeping space, and more. Without employment of simple learning principles, the possibility of any new member being aggressively challenged is highly likely. The use of a reinforcement schedule known as *differential reinforcement* provides selective reinforcement to the group when pro-social behaviors are observed. Through the use of differential reinforcement, inappropriate behaviors are reduced while appropriate behaviors are strengthened.

Differential reinforcement modifies behavior using four main procedures known as; DRO (*Differential Reinforcement of Other behavior*), DRI (*Differential Reinforcement of Incompatible behavior*), DRH (*Differential Reinforcement of High rates of response*), and DRL (*Differential Reinforcement of Low rates of response*) (Kazdin, 1994). Although each differential reinforcement schedule targets specific aspects of behavior, the general procedure is quite simple. Trainers are directed to observe social interactions, and apply reinforcement only when appropriate behaviors are observed. These procedures are commonly used to accelerate acclimation to a new social group, which maintains long-term compatibility quite effectively.

VII. Behavior Medicine

Achievements in veterinary care, treatments, and procedures have been possible through the training of specific husbandry or medical behaviors. These behaviors provide marine mammal specialists, researchers, and medical personnel access to treatments, procedures, and biological sampling once thought only obtainable through forced restraint, sedation, or anesthesia. Optimal animal health is achieved via routine examinations. For untrained marine mammals however, simple procedures and check-ups can become a risk to both people and animals. Untrained animals usually express fear,

Figure 4 Trainers at the Dolphin Research Center collect a voluntary blood sample from a bottlenose dolphin, *Tursiops truncatus*.

apprehension, and a “fight or flight” response (*activation syndrome*) that can be dangerous for all involved.

A variety of procedures has been routinely trained through operant conditioning, approximation training, and positive reinforcement. Marine mammal facilities now require the training of behaviors specific to health maintenance for each animal. Commonly referred to as “husbandry behaviors,” the effort to begin training medical procedures gained momentum in the early 1980s. Aware of the risks associated with forced restraint or anesthesia, coupled with the need to obtain ongoing biological sampling, marine mammal training took a new direction. Simple procedures, such as allowing a veterinarian to touch a trained animal without restraint, conduct up-close visual examinations, or inspect an open mouth, were the first behaviors trained for health purposes. Within a few years, routine blood sampling (Fig. 4) was trained to dolphins, killer whales (*Orcinus orca*), sea lions, and walrus (*Odobenus rosmarus*), providing valuable data, serum banks, and unprecedented research opportunities. Soon thereafter, trainers began conditioning voluntary urine samples, milk samples, x-rays, sonography, weights and measurements, endoscopy, intubation, and even tooth drilling, all without restraint, sedation, or anesthesia. Marine mammal veterinarians were able to access healthy animals using procedures unimaginable to small animal practitioners, equine, and zoo vets.

Today, these procedures have evolved into comprehensive *behavior medicine* programs. Behavior medicine employs the use of behavior modification to treat chronic and acute medical conditions or to promote and maintain good health through behavior management. A well-known field in psychology, behavior medicine combines traditional medicine and behavior modification techniques to diagnose and successfully treat such complex medical issues as chronic regurgitation, stereotypies, kidney function, eating disorders, conditioned food aversions, osmoregulation, and more. In addition, behavior medicine programs also incorporate the training of behaviors that help maintain optimal health such as exercise, pre/post parturition examinations, dentistry, sonography and EKG, to name a few. Behavior medicine for marine mammals is growing in both understanding and in effective use. Pre-treatment baseline data are normally gathered prior to the onset of behavioral change (treatment) to monitor effectiveness and subsequent health improvement.

Chronic medical conditions can also be treated by engineering a behavioral training program that targets a specific behavioral goal. Acute medical conditions can be treated if prior training was completed. Through training, marine mammal medicine is reaping tremendous benefits from behavioral management. It is no coincidence that dolphins housed in quality aquariums live as long as or longer than their wild counterparts, and that neonate mortality is lower in zoological facilities than in the wild. In fact, the oldest known bottlenose dolphin still lives a productive and healthy life at Marineland in Florida, where she has surpassed her 54th birthday. In addition, recent research by Willis (2007) reports that the life expectancy for dolphins living in accredited facilities of the Alliance of Marine Mammal Parks and Aquariums (AMMPA) exceeds that of the wild. Many zoos are now emulating the success of marine mammal husbandry training and are beginning to experience those same benefits with endangered species. Curators wisely understand that a good animal health program utilizes all available expertise including animal training and behavior management.

VIII. Research via Training

Research scientists must often be opportunistic when gathering data while investigating marine mammals, since access to these data can be limited. Using a creative approach, scientists can gather information such as food intake, metabolism, respiration, activity levels, and other data during the normal course of operations at marine life facilities. This opportunistic approach has been very useful in producing valuable and factual information. However, the ability to gather data using trained animals has accelerated this process for some investigators, opening up new avenues for researchers and experimental scientists.

New training procedures have given many investigators opportunities for direct experimentation, using non-invasive, reliable, and replicable methodology. Physiological studies using trained animals were pioneered by the US Navy's marine mammal program. This research provided a foundation for understanding the deep diving reflex. Cognitive studies conducted at Kewalo Basin Marine Mammal Laboratory were only possible using trained dolphins. These studies have enhanced our awareness of language use and information processing in animals. More recently, marine mammal energetic studies at West Chester University use trained animals in cooperation with marine mammal programs to measure acceleration and maneuverability in multiple species. Marine mammal training also facilitated signature whistle research for Woods Hole Oceanographic Institution, using a routine pool separation procedure to evoke signature whistle production in bottlenose dolphin calves.

Animals trained to allow voluntary blood samples provided comparative data and titer analysis that helped investigators at the National Marine Fisheries Service identify *morbillivirus* spp., a disease that has devastated some populations of wild marine mammals. In addition, voluntary blood sampling by trained killer whales at SeaWorld enabled scientists to precisely identify gestation in this species. Prior to this, it was speculated that the killer whale gestation period lasted 12 months; but because of this significant research, it is now known to be much longer, at approximately 17 months. Accurate information about reproduction, gestation, and inter-calf interval is vital when calculating the recovery of wild stock. This new information, discovered in the 1980s, had an important impact on stock assessment. These institutions and others, in partnership with marine mammal programs, are providing unprecedented volumes of important information. The utility of marine mammal training continues to have a strong impact on science.

IX. Interactive Programs

In the early years of keeping marine mammals at oceanaria, scheduled feeding times were billed as a main event that piqued the interest of the visitors. As training advanced, small routines evolved into highly complex behavioral sequences and dramatic shows that featured choreographed behavior, multiple species, and special effects. The significance of marine mammal training became evident as attendance in some marine parks exceeded 5 million guests annually, driven in large part by behavioral programs.

Marine mammal training had become "big business" as the impact of these productions changed marine parks dramatically by generating funds for new and improved exhibits, stadiums, water systems, medical programs, animal rescue, rehabilitation, and research. The most successful marine parks also had the highest quality shows. As new facilities were built, facility design centered on training programs for show production; and attendance at marine parks in the United States soared to over 60 million annual visitors. Millions of park visitors became more interested in marine life than at any other time in history. Vicariously, and from a distance, they were able to experience the excitement of interacting with dolphins, whales, sea lions, and other marine life.

During the early 1980s, Dolphin Research Center in the Florida Keys began a new training program that allowed some guests a hands-on, in-water experience with dolphins (Fig. 5). As with most pioneering efforts, this new program was strongly criticized by anti-captivity groups and even other marine parks, yet they prevailed in developing the first guest interaction program. These early educational programs had a profound impact on the participants, generating a renewed interest in marine life conservation, concern for the oceans and empathy for marine mammals. Just as the early dolphin shows changed public attitudes about these animals in the 1970s by helping to develop a sense of value in protecting wild marine mammals, interactive programs are doing the same. Today, the popularity of these programs once again is dramatically changing marine mammal facility design, animal training programs and public opinion. Since 1999, innovative new facilities have recently been built in Florida, the Bahamas, and the United Arab Emirates, with more large-scale marine mammal training facilities being planned worldwide.

Figure 5 Interactive programs are providing a new generation with unique educational experiences.

In addition, new marine mammal legislation has recently been passed in the Bahamas and is being developed in other countries, once again recognizing that marine life facilities and the value of their training programs directly support wildlife conservation. Just as dolphin shows helped in developing and ratifying the US Marine Mammal Protection Act, interactive programs and facilities are the catalyst for new marine mammal legislation that supports professionally supervised interactive programs. At the same time, this particular legislation is beginning to incorporate regulations of wild dolphin interactions. US legislation makes wild dolphin interaction illegal due to the inherent risks involved when attempting to interact with any large, wild mammal. Wild dolphin interactions lack behavioral supervision, pose potential health and safety hazards to animals and people, and adversely affect natural behavior patterns (Spradlin *et al.*, 1999). Supervised programs with trained animals have proven to be a safe and educational alternative.

As well-managed programs in quality institutions continue to evolve, opportunities to interact with species such as beluga whales (*Delphinapterus leucas*), sea lions, false killer whales (*Pseudorca crassidens*), and more species will help shape a future generation of ocean stewardship.

X. Other Uses for Marine Mammal Training

Marine mammal training and behavior management has always been a fixture in marine mammal programs. With its use in an ever-growing list of projects and applications, this field is rapidly expanding and becoming increasingly sophisticated due to the complexities of each project. In some cases, animal training supplements the project, in others it is of paramount importance.

A. Military Programs

Marine mammal training has been employed successfully in open-ocean work. The US Navy's marine mammal program has trained mammals a variety of behaviors involved in rescue and recovery, deep diving physiology, echolocation, boat following, harbor security, and object retrievals, to name just a few. Some of these programs actually save human lives. These early and ongoing programs continue to generate enormous benefit to scientists in understanding marine mammal learning capabilities, physiology, and motivation. A number of research institutions now use open-ocean training for interaction programs, research, and reintroduction training.

B. Rescue and Rehabilitation

Training techniques have also been employed in the rehabilitation process for sick and injured wild animals. Classical conditioning has been successfully used to help condition orienting response, suckling, and bottle feeding for orphaned cetacean calves (Fig. 6) and pinniped pups. The ability to respond, locate, and move toward animal caretakers is not only vital to the survival of the animal, but also becomes a developmental indicator that aids in the diagnosis of neurological disease or injury.

C. Social Compatibility

The use of body weight maintenance, through trained daily body weights combined with differential reinforcement aids in weight maintenance, avoids radical weight fluctuations and aggression

associated with breeding seasons. Through these procedures, social compatibility increases whereas agonistic behaviors are decreased in male California sea lions (*Zalophus californianus*) (Turner and Stafford, 2000). This management strategy has been successfully used in captive bottlenose dolphin populations as well.

D. Epimeletic Behavior

Epimeletic or care-giving behavior is being investigated as an opportunity to apply training and behavior management to increase the probability of calf survival. During the first few hours of life, the primary challenge for marine mammal newborns is maternal acceptance (vs rejection), followed closely by the need for protection and nutrition. It seems that a dam's natural care-giving behavior should automatically engage, yet healthy newborns are sometimes rejected for reasons not fully understood. Though rare, this phenomenon has been observed in many species (both wild and captive), including humans. It seems evident that many of the skills required for early calf/pup survival and care-giving are acquired through a learning process. In some facilities, training has been applied to this scenario, and although definitive results are not yet available, progress has been made in understanding the process of training to prompt nursing behavior (presentation of the mammary to the soliciting calf), especially for first-time mothers, those without observational models, or those without prior experience raising offspring.

Work has been carried out to apply marine mammal training to accelerate the acquisition of other epimeletic behaviors such as parallel swimming, calf protection, calf retrieval, and other behaviors. Behavioral management is also practiced that encourages calm behaviors and avoids accidental or *adventitious* reinforcement of calf rejection. Fortunately, the majority of newborns calves, *are* accepted (some immediately after birth and some within a few hours) and their dams usually allow them to nurse within 24h. Within a few days, the calf or pup rapidly acquires the motor skills necessary to coordinate successful nursing, while its mother is also acquiring and strengthening her own repertoire of care-giving behaviors, thereby increasing survivability in subsequent offspring. When these young

Figure 6 Members of the Texas Marine Mammal Stranding Network bottle feed a beached dwarf sperm whale, *Kogia sima*. Photograph supplied by Adrian Dahood.

survive, opportunities to collect valuable data help scientists better understand the biological and learning developmental processes in wild environments, where observations are difficult or sometimes impossible. These data also act as comparative models for some species, providing like parameters for understanding their development. In some cases, like that of a beached or orphaned killer whale calf, comparing these data can influence the course of treatment, types of supplemental formula, or other behavior management decisions necessary to improve the odds of survival. Having at least some understanding of calf development is particularly critical for other endangered species such as Hector's dolphin (*Cephalorhynchus hectori*) and Vaquita (*Phocoena sinus*).

E. Feeding and Foraging

An unprecedented opportunity to apply operant conditioning during rehabilitation in a juvenile gray whale calf (*Eschrichtius robustus*) proved successful. In 1997, SeaWorld San Diego assisted in the rescue and managed the recovery and release of this orphaned calf. After initially stabilizing the young animal's health, blood indicators suggested that the animal's level of activity was in need of improvement. This particular animal was placed on a behavioral management plan; and using positive reinforcement the calf was conditioned to move through gates, increase its activity level, and adjust its eating patterns to more closely match the bottom feeding strategies of wild gray whales. Upon reintroduction after a 14 month rehabilitation, the animal had gained over 18,000 pounds (an average of 40 pounds per day), and grew in length from 14 to 30 ft (SeaWorld, 2006). The information gathered during this process has contributed invaluable information on growth rates and may help future beached calves to survive.

F. Breeding and Reproduction

The training of voluntary blood and urine sampling has enhanced captive breeding programs by providing science with information about progesterone levels and the estrus cycle in cetaceans. Success in conditioning voluntary semen collection in male cetaceans (dolphins and killer whales), and voluntary artificial insemination in females, has resulted in the first successful pregnancies for both species. Artificial insemination using trained procedures is becoming increasingly common. Sonographic evaluations were also trained using positive reinforcement, providing scientific proof of the effectiveness of this training program. The first successful birth of a killer whale calf using artificial insemination training occurred recently at SeaWorld; and a cooperative effort between Miami Seaquarium and Dolphin Research Center resulted in a live birth of a bottlenose dolphin calf in late 2006. This technology provides science with encouraging news for the preservation of endangered marine mammals.

G. Reintroduction Programs

The translocation of wild animals and the release of marine mammals held for short periods (usually for research or rehabilitation purposes), has provided many opportunities for behavioral management and in some cases, animal training during the holding process. If managed correctly, the success rate of these relatively short-term research projects can be an effective means of gathering data. However, the release of animals born or housed long-term in zoological facilities, should be approached carefully, and include specific behavioral plans as well as health screening and scientific monitoring

of released animals to ensure their well-being and success of the reintroduction.

There have been instances where marine mammal releases have been over-simplified by extremist and anti-captivity groups. Although emotionalizing their concept of "freedom," these groups generally discount the biological need of such experiments, especially for non-endangered species, while often disregarding the very real and complex survival obstacles an animal must confront successfully. Therefore, thorough and unbiased scientific review must be completed before any such permit can be granted in the United States. Attempts to release animals without scientific review and permit authorizations are in violation of the US Marine Mammal Protection Act. Past attempts to do this in the United States has resulted in the needless suffering and death of animals. In one well-publicized case in Florida (1996), this violation led to the prosecution and conviction of those involved (US Department of Commerce, 1999). Unfortunately, not all governments have laws protecting marine mammals from the naive actions of some individuals and claims of success have been reported without proper conditioning, scientific verification, or follow-up, and in most cases it is likely that these animals succumbed to the challenges of life in the wild. However, reintroducing captive-born animals is not without success.

A number of captive-born terrestrial mammal species have been released into historical home ranges with success. Endangered animals such as red wolves (*Canis rufus*), golden lion tamarins (*Leontopithecus rosalia*), and black-footed Ferrets (*Mustela nigripes*) are some examples of well-managed and scientifically sound protocols that are helping in the recovery of wild populations. Due to their endangered status and the biological necessity to make their genetic material available to the wild population, the risks of such programs are deemed acceptable. These animals are carefully managed at reputable facilities, candidate animals are selected based upon specific criteria, population and environmental dynamics carefully reviewed, behavioral repertoires (such as predator avoidance and foraging skills) are strengthened, tracking and follow-up protocols scrutinized, unbiased scientific review completed, and legal permits obtained before such an undertaking begins. Research into the release of captive-born marine mammals, or animals housed long-term, must include an analysis of behavior, a strict behavioral management plan, and the measurable observation of behaviors that enhance survivability in the wild.

In addition, in order for this program to fulfill a biological imperative, the candidate animal must be assimilated into a social group so that breeding and reproduction completes the conservation objective. If a future opportunity to collect endangered marine mammals for captive breeding finds strong support, then using non-endangered marine mammals such as bottlenose dolphins as a concept model for successful captive breeding and reintroduction of endangered species is certainly prudent. Animal training and behavior management will undoubtedly play a role in the future of reintroductions.

XI. Conservation

Clearly recognizing the valuable contributions made by zoos and aquariums in the conservation of marine mammal species, the US Marine Mammal Protection Act (MMPA) specifically authorizes (and periodically re-authorizes) qualified institutions to collect wild marine mammals for the purpose of public display, education and research (Marine Mammal Permits and Authorizations, 2006). Advances in marine mammal training are contributing to a new wave of public interest among marine life parks. Each year, worldwide attendance

continues to grow and in the United States, public support stands firmly behind both the MMPA and marine mammal facilities. More people are now enjoying the benefits of new and exciting training programs, shows, presentations, interaction opportunities, and scientific discoveries, all facilitated through behavior management.

By maintaining a healthy captive population of various marine mammal species, comparative data are generated to assist in understanding wild animals, and these facilities continue to give material support to important research and conservation initiatives. In addition, these facilities act as part of the Marine Mammal Stranding Network, assisting NOAA/NMFS in the rescue, housing, and care of stranded wild animals where expertise in medical care can be applied. These facilities also develop animal management and husbandry skills in staff members who are also able to assist in health assessment studies or during mass strandings, as directed by NMFS. Captive marine mammals and the facilities in which they live provide a template for handling highly endangered animals, or the establishment of a controlled breeding group, when the need arises. Finally, these facilities maintain a living repository of genetic material accessible through behavior management, where candidate animals can be carefully and scientifically selected and trained for introduction into the wild if needed. This successful model has been pioneered in zoological parks, saving numerous species from extinction, including the black-footed ferret and California condor (*Gymnogyps californianus*) (Top 10 Wildlife Conservation Success Stories, 2006). Behavior management plans are an intricate and important part of these programs, helping to generate public interest through fascinating presentations, dynamic behaviors, and invaluable research. These contributions are undoubtedly saving the lives of wild marine mammals.

XII. Conclusion

As formal behavior management gains wider application, wildlife managers will continue to increase their knowledge and application of animal learning principles, particularly as they relate to the conservation of highly endangered species, shrinking populations, and population recovery. Solutions to man/animal encounters, fisheries depletion, survival skill acquisition, translocation, reintroduction, and relocation efforts will require a specialized understanding of the learning and training processes, pioneered in the learning laboratories, and applied in the field of marine mammal training and behavior management.

Acknowledgments

We wish to express our sincere gratitude to all the professionals who dedicate their careers to advancements in the care, training, and research of marine mammals. We are especially grateful to Mr. Tom Sanders for his professional input, behavioral review and suggestions for content, as well as his efforts to coordinate file transfers and author communications between Gavutu, Nadi, Los Angeles, Columbus and Cleveland...welcome back.

Tucuxi and Guiana Dolphin

Sotalia fluviatilis and *S. guianensis*

PAULO A.C. FLORES AND VERA M.F. DA SILVA

I. Characteristics and Taxonomy

The genus *Sotalia* of the family Delphinidae was once considered to comprise five species, but in the twentieth century, this was reduced to two, the riverine *Sotalia fluviatilis* and the marine *Sotalia guianensis*. Later these were further lumped into a single species

(*S. fluviatilis*), with marine and riverine ecotypes. Recent morphological and genetic studies, however, concluded that marine and riverine *Sotalia* are different species (Cunha *et al.*, 2005; Caballero *et al.*, 2007). Based on priority criteria, the name *Sotalia guianensis* (Van Bénédén 1864) was assigned to the marine animals, whereas riverine dolphins retained the oldest species name *Sotalia fluviatilis* (Gervais 1853). No fossil record is known.

The common name tucuxi comes from *tucuchi-una* after the Tupi language of the Mayanas Indians from the Amazon region of Brazil, where it is called *boto-tucuxi*, *boto-cinza*, or simply *boto*. In the other Amazon countries it is usually called *delfin* or *bufeo gris del rio*. *S. guianensis* is also known simply as *boto* or *golfinho* and as *boto comum* and *golfinho cinza* along the Brazilian coast; *bufeo gris*, *bufeo blanco*, or *bufeo negro* in Colombia and Peru; *tonina de rio*, *delfin blanco*, or *soplón* in the Venezuela Amazon, *tonina del lago* in Lake Maracaibo, and *bufeo negro*, *bufete*, or *soplón* in the Orinoco River basin in Venezuela; *lam* in Nicaragua; Guyana dolphin or Guiana white dolphin in Guyana; and *profuso* or *dolfijn* in Surinam. There is some controversy about a definitive international common name for *S. guianensis* in English. Various names have been used in the literature, most frequently marine tucuxi, gray dolphin, estuarine dolphin, and recently costero. We avoid the controversy here by using “Guiana dolphin,” based on the Scientific name.

The two *Sotalia* species are very similar in coloration, differing mainly in body size and number of teeth, and somewhat resembling a small bottlenose dolphin, *Tursiops* (Fig. 1). They are light gray to bluish gray on the back and pinkish to light gray ventrally, with a distinct line from the mouth gape to the flipper's leading edge. There is a lighter area on the flank between the flippers and the dorsal fin and

another mid-body at the level of the anus. The marine species has another light gray rounded streak on both sides of the caudal peduncle. In both species, the eyes are large, and there is black countershading around the eyes. A case of atypical white coloration was recently reported, although it was not confirmed whether it was albinism or another type of anomalously light pigmentation. The dorsal fin is triangular and sometimes slightly hooked on the tip. The tucuxi has a moderately slender beak, a rounded melon and 26–36 teeth in each mandibular ramus. The Guiana dolphin has more upper teeth and is larger than the tucuxi, with a maximum total length of 220 cm and about 80 kg body mass vs a maximum length of around 152 cm and mass of 55 kg.

II. Distribution and Abundance

The tucuxi occurs in the main tributaries of the Amazon/Solimões River basin in Brazil as far inland as southeastern Colombia, eastern Ecuador, and northeastern Peru, with records in all three types of water that occur in this region. Several rivers contain impassable falls, rapids, and shallow waters. On the tributaries of the right side of the Amazon basin, the Teotônio and Santo Antônio Falls on the Madeira River, the Santa Isabel Falls on the R. Xingú, and S. Luis Falls on the Tapajós river are impassable barriers, whereas on the left side the falls on the Rio Negro and Raudal La Libertad on the Caquetá River (Colombia) are also important. The tucuxi does not occur in the Beni/Mamoré River basin in Bolivia and is not known in the upper Rio Negro. The presence of the species in the Orinoco River basin is still controversial, since a stretch of rapids and falls in the Negro River and the 354 km of numerous rapids and outcrops of

Figure 1 Guiana dolphins. (Photo by P.A.C. Flores).

the Cassiquiare Channel block the species' movements. Its distribution is influenced by seasonal river level fluctuations, with channels and lakes occupied during rising and high waters but avoided at low water. The tucuxi is abundant in the Solimões and Japurá Rivers as well as in large black water lakes such as Tefé Lake (Brazil) and the El Correo lakes system (Colombia). Tucuxis do not go into flooded forest as does the sympatric boto, *Inia geoffrensis*, but these species share a preference for areas with reduced current and waterway junctions. Mean density along the margins of main rivers in the central Amazon, Brazil within 150 m survey strip of 1,319.7 km was 3.2 individuals per km², with 54% of the individuals occurring within 50 m of the edge (Martin *et al.*, 2004). At the border of Colombia, Brazil, and Peru, Vidal *et al.* (1997) found along about 120 km of the Amazon River a density of 8.6/km² in lakes, 2.8 along main banks and 2.0 around islands (Fig. 2).

The Guiana dolphin is found in the Western Atlantic coastal waters of South and Central America from southern Brazil (27°35'S, 48°35'W) to Nicaragua (14°35'N, 83°14'W), including Colombia, Costa Rica, French Guyana, Guyana, Panama, Suriname, Trinidad, Venezuela, and possibly Honduras (15°58'N, 79°54'W). In the Orinoco River dolphins seen as far up as Ciudad Bolívar may be of this species. The Guiana dolphin is found mostly in estuaries, bays, and other protected shallow coastal waters, although it has also been recorded at the Abrolhos Archipelago, around 70 km off the coast of Bahia State, Brazil. The species' southernmost limit is influenced by the cold waters of the Malvinas current in South Brazil. It is notably recorded throughout the year in many coastal locations such as Baía Norte in Santa Catarina State, Cananéia Estuary and Baía de Guanabara (both in southeastern Brazil), Baía de Todos os Santos and around Fortaleza (northeastern Brazil), Bahía Cispatá and Golfo de Morrosquillo (Colombia), as well as on the Cayos Miskito Coast in Nicaragua. Standard abundance estimates are scarce for the Guiana dolphin, but the species seems to be abundant in various locations along its distribution, mainly in South-Southern Brazil outside of

Guanabara Bay. Stocks or significant evolutionary units are evident from residency, site fidelity, genetic and acoustical data.

III. Ecology

The Guiana dolphin feeds on neritic prey distributed through the water column, mainly on neritic fishes such as clupeids and sciaenids, but cephalopods, shrimps, crabs, and flounders are occasionally taken. Usually young specimens of these teleost fishes, including over 20 species, are the most important diet items. Tucuxis feed mainly on schooling pelagic fish such as characiforms, freshwater clupeids, and sciaenids, no larger than 35 cm. Feeding may occur in pairs, usually mother and calf, and in larger groups or subgroups when different strategies and cooperation among individuals are employed. During feeding activities, Guiana dolphins often associate with birds such as the brown booby (*Sula leucogaster*), terns (*Sterna* spp.), frigate bird (*Fregata magnificens*), and kelp gull (*Larus dominicanus*). Mixed-species flocks of up to a hundred birds can be seen in such associations. In the Amazon, tucuxis may feed occasionally in association with terns (*Phaetusa simplex*). These associations are initiated by the birds and have no impact on the dolphins.

There are no known predators for either species, although bites from sharks of unidentified species have been seen on Guiana dolphins.

Because of the huge regional differences in habitats from temperate waters in the south to the tropical waters, including estuaries such as the Amazon estuary, Guiana dolphins are found in a wide range of water depth, temperature, salinity, and turbidity.

No mass stranding has been reported. Individuals often wash ashore, sometimes due to incidental catch in fisheries in both marine and freshwater environments.

IV. Behavior and Physiology

Sotalia dolphins show a variety of aerial behaviors such as full leaps, somersaults, fluke-ups, spy-hopping, surface rolling, and porpoising. In coastal areas, feeding and traveling are by far the most common behaviors, although resting and milling are rare. Socializing involves various tactile contacts, and herding of females by males has been occasionally seen in southern Brazil. Bow-riding has not been recorded, but Guiana dolphins may surf in waves and wakes produced by passing boats.

Spontaneous swimming interactions with domestic dogs (*Canis familiaris*) and a lone wild Guiana dolphin sociable toward humans were recorded in southeastern Brazil. Epimeletic behavior and hand feeding were also recorded in the same area (Santos *et al.*, 2000). Apparent mating behavior with bottlenose dolphins was recorded off Costa Rica in Baía Norte, South Brazil, at the southernmost distributional limit, Guiana dolphins do not associate with bottlenose dolphins, and rare encounters even result in aggression by bottlenose dolphins or escape behavior by the Guiana dolphins (Flores and Fontoura, 2006). Epimeletic behavior toward an offspring was recorded at that locality.

Dives for Guiana dolphins last about 30–120 sec with shorter dives of 5–10 sec in between. Tucuxis are fast swimmers, spending less than a second at the surface, with an average dive time of about 2 min.

The *Sotalia* species are social dolphins, almost always in cohesive groups engaged in the same activities. Tucuxis are often found in groups of one to six individuals, although larger groups up to 20 individuals are also recorded (Faustino and da Silva, 2006). Groups of up to 50 or 60 Guiana dolphins are common, whereas the average group size is two to six. Large aggregations of up to 200 are reported at Baía de Sepetiba and around 400 individuals in Baía da Ilha Grande on the

Figure 2 Distribution of the tucuxi *Sotalia fluviatilis* and the Guiana dolphin *S. guianensis*.

southeastern Brazilian coast, where these larger aggregations are usually engaged in cooperative feeding. Apparently, larger groups are more common in the south and southeastern Brazilian coast. Mixed groups of adults and calves are common. Individual associations are known only for the Cananéia Estuary population in Brazil; these are weak to moderate, except for a few pairs of individuals with apparently stronger associations, suggesting a relatively fluid society with individuals in fission–fusion (Santos and Rosso, in press).

Photo-identification studies have shown that Guiana dolphins may be resident within and between years for up to 10 consecutive years (e.g., Flores 1999; Flores and Bazzalo, 2004). Home ranges are poorly known and apparently among the smallest for small cetaceans with a mean of about 15 km² in southern Brazil and up to 265 km² in another location. Movement patterns vary among warm and cold seasons in the temperate region, whereas no variation was found in warm waters. In any case, daily movements are small. Freeze-branded tucuxis in Central Amazon were recorded for several years in the same area, suggesting residency and seasonal use of areas.

Comparative analysis of the whistles of Guiana dolphins in different areas along the Brazilian coast revealed significant effects of geographical location. However, it is difficult to discriminate between adjacent populations. Guiana dolphins produce mainly upsweep whistles, shorter and less complex in shape than for other species of dolphins. The range of whistle fundamental frequencies recorded was 0.21–24 kHz and durations 38–1064 ms (Azevedo and Van Sluys, 2005).

Research with acoustic pingers in Fortaleza, Brazil, during 345 h of experiment showed that Guiana dolphins avoided areas where pingers were active (Monteiro-Neto *et al.*, 2004).

V. Life History

Calving is year-round and gestation is estimated to be around 11–12 months for the Guiana dolphin, with calves ranging in size from 90 to 100 cm of total length. Calving interval is believed to be 22–24 months based on photo-identification data. Tucuxi calving occurs between September and November, during low water season, after a gestation time estimated at 11 months, with calves at birth measuring from 71 to 83 cm (da Silva and Best, 1994).

According to tooth growth layer groups (GLGs), life span can reach 30 and 35 years for the Guiana dolphin and tucuxi, respectively. Natural mortality rates are unknown for both species.

VI. Interactions with Humans

Historically, these species have not been exploited commercially, although incidental mortality in local and commercial fisheries such as those using gillnets and seines are a direct threat to *Sotalia* dolphins. Bottom-set nets for lobsters also occasionally capture Guiana dolphins. On the coasts of Amapá, Maranhão, and Pará States, northern Brazil, Guiana dolphins are killed for shark bait, although they have some protection from myths and legends. This is especially true for the tucuxis in the Amazon (Gravena *et al.*, in press). There, their genital organs and eyes have a local market as love charms, and teeth and bones are used for arts and crafts. Guiana dolphins in some parts of their distribution, mainly on the northern and northeastern coasts of Brazil, may also be used for human consumption. Although these dolphins are fully protected by Federal laws in Brazil, forbidding the harassment, hunting, fishing, or capture of tucuxis and all cetaceans, pinnipeds, and sirenians in national waters, law enforcement may not be effective. In other countries such as Colombia, Ecuador, Peru, and Venezuela, tucuxis are not clearly protected by laws.

Acoustic pingers attached to gill nets may successfully reduce or prevent by catch of Guiana dolphins as suggested by a single study conducted with free ranging dolphins in northeastern Brazil (Monteiro-Neto *et al.*, 2004).

Dams and hydroelectric power facilities in the Amazon region interrupt fish migration, reducing fish abundance, and consequently prey availability for dolphins. Mercury from gold mining, water pollution, seismic activities, oil spills, and boat traffic are other potential threats to tucuxis in the Amazon, while the same factors, except gold mining, plus marine culture farms and destruction of habitats, mainly mangroves and salt marshes, strongly affect the Guiana dolphins. Hand feeding and the behavioral effects caused by boat activities also deserve concern, as these may affect at least populations off the coasts. Bioaccumulation of contaminants and growing pollution outfalls are also concerns.

Sotalia dolphins are susceptible to capture stress, quickly become entangled and sometimes suffocate in nets, and are not robust to long periods of transportation or handling after capture. However, Guiana dolphins captured off the coast of Panamá in the late 1970s were kept in captivity in Europe for more than 20 years, and one animal is still alive today. A few Guiana dolphins are still kept in Colombian facilities, although since 2005 it has been illegal to maintain them in captivity.

The separation of the two species is too recent to appear in any of the Species Conservation Status lists, although both *Sotalia* species should be listed as “insufficiently known” by the World Conservation Union (IUCN) as was the status of the unified species. Because of its coastal habits, aggregating in estuaries and bays, and in river channels and lakes, *Sotalia* dolphins are vulnerable to almost all human activities throughout their range. A large proportion of the distributional area of the two species is close to human habitation. Consequently, these habitats are subject to intense fisheries, boat traffic and sewage, industrial waste, and high levels of contaminants. Examples are the Santos and Rio de Janeiro harbors in southeast Brazil, Recife and Rio Grande do Norte in the northeast Brazil, Maracaibo in Venezuela, Golfo de Morrosquillo in Colombia, and Belém, Santarém and Manaus in the Brazilian Amazon.

The Tuna-Dolphin Issue

TIM GERRODETTE

I. The Problem

In the tropical waters of the Pacific Ocean west of Mexico and Central America, large yellowfin tuna (*Thunnus albacares*) swim together with several species of dolphins: pantropical spotted (*Stenella attenuata*), spinner (*S. longirostris*), and common (*Delphinus delphis* and *D. capensis*) dolphins. This ecological association of tuna and dolphins is not clearly understood, but it has had two important practical consequences: it has formed the basis of a successful tuna fishery, and it has resulted in the deaths of a large number of dolphins. This is the heart of the tuna-dolphin issue.

The bycatch of dolphins in the eastern tropical Pacific (ETP) purse-seine tuna fishery stands apart from marine mammal bycatch in other fisheries, not only in scale but also in the way the dolphins interact with the fishery. Marine mammals interact with most fishing

gear only incidentally, but in the ETP tuna fishery the dolphins are an intrinsic part of the fishing operation (Perrin, 1969). The fishermen intentionally capture both tuna and dolphins together, then release the dolphins from the net (National Research Council, 1992). Further, unlike in most other fisheries, the vast majority of dolphins captured by the ETP tuna fishery are released alive; thus, an individual dolphin may be chased, captured, and released many times during its lifetime.

The number of dolphins killed since the fishery began in the late 1950s is estimated to be over 6 million animals, the highest known for any fishery. For comparison, the total number of whales of all species killed during commercial whaling in the twentieth century was about 2 million. The bycatch of dolphins in the ETP tuna fishery has now been successfully reduced by more than 99%, but even at the present level of 1500 dolphins/year, it remains among the largest documented cetacean bycatches in the world.

II. Purse-Seining for Tuna

Prior to the development of modern purse seines, tropical tuna were caught one at a time using pole-and-line methods. In the late 1950s, the twin technological developments of synthetic netting that would not rot in tropical water and a hydraulically driven power-block to haul the net made it possible to deploy very large purse-seine nets around entire schools of tuna, and thus to catch many tons of fish at a time. Purse-seining for tuna in the ETP can be conducted in one of three ways: the net may be set around schools of tuna associated with dolphins (“dolphin sets,” which catch large yellowfin tuna), around schools of tuna associated with logs or other floating objects (“log sets,” which catch mainly skipjack but also bigeye and small yellowfin tuna), or around unassociated schools of tuna (“school sets,” which catch small yellowfin and skipjack tuna). The proportions of different set types have varied over the history of the fishery, but in recent years, about half have been dolphin sets, one quarter log sets and one-quarter school sets.

Dolphins are killed almost exclusively in dolphin sets. During “porpoise fishing” (the fishermen’s term), schools of tuna are located by first spotting the dolphins or the seabird flocks which are also associated with the fish. Speedboats are used to chase down the dolphins and herd them into a tight group; then the net is set around them (Fig. 1). The tuna-dolphin bond is so strong that the tuna stay with the dolphins during this process, and tuna and dolphins are captured together in the net (Fig. 2). Dolphins are released from the net during the backdown procedure (Fig. 3). If all goes well, the dolphins are released alive, but the process requires skill by the captain and crew, proper operation of gear, and conducive wind and sea conditions. As with any complicated procedure at sea, things can go wrong, and when they do, dolphins may be killed.

From an ecosystem perspective, management of the ETP purse-seine tuna fishery poses interesting challenges. The three methods of purse-seining for tuna, log-, school- and dolphin-fishing, catch different mixes of tuna species and sizes, and in addition have different amounts and composition of bycatch. Dolphin sets result in dolphin mortality, but dolphin sets have the least bycatch overall. Log sets have about 30 times the bycatch of school sets by weight per set, which in turn have about 3 times the bycatch of dolphin sets. Most of the bycatch, though, even on dolphin sets, is fish, primarily tuna, marlin, and dorado. These fish have much higher reproductive rates than dolphins, sea turtles, sharks and rays, so the effect of the bycatch is smaller. Although the effects of the fishery on dolphin populations have been strong and are relatively well known, the effects on other marine populations of concern, such as sharks and sea turtles, are mostly unknown.

Figure 1 Purse-seine being set on tuna and dolphins in the eastern tropical Pacific Ocean. The net is not yet closed, and four speedboats are driving in tight circles near the opening to keep the dolphins from escaping.

Figure 2 Spotted dolphins in the purse-seine net. The submerged corkline is being pulled out from beneath them as the boat tows the net in reverse to release the animals.

Figure 3 Backdown procedure in progress. As the tuna vessel moves backwards, the net is drawn into a long channel. The corkline at the far end is pulled under water slightly, and the dolphins escape. Speedboats are positioned along the corkline to help keep the net open.

III. Actions to Reduce the Dolphin Bycatch

The magnitude of dolphin mortality in the ETP tuna fishery first came to widespread attention in the mid-1960s. The dolphin kill at that time is not known with precision, but without question was very high (Fig. 4). When the US Marine Mammal Protection Act was passed in 1972, it included provisions for reducing the bycatch to “insignificant levels approaching zero” after a 2-year moratorium on regulation during which the tuna industry was expected to solve the problem through development of improved fishing methods. Under this law, scientific studies were initiated, observers were placed on fishing boats, fishing gear was inspected, and boat captains with high dolphin mortality

rates were reviewed. Modifications of fishing gear and procedures were developed to reduce dolphin kill. After much litigation, the first regulations to reduce the dolphin kill on US vessels were promulgated (Gosliner, 1999). By the end of the 1970s, the kill had declined from about 500,000 to about 20,000 dolphins per year (Fig. 4).

As the US tuna fleet decreased in size and the fleets of Mexico, Venezuela, Ecuador, and other Latin American countries increased, the dolphin kill began to grow again, and actions to monitor and reduce the dolphin bycatch became international. The Inter-American Tropical Tuna Commission began a dolphin conservation program in 1979 modeled on the US effort. By 1986, an international

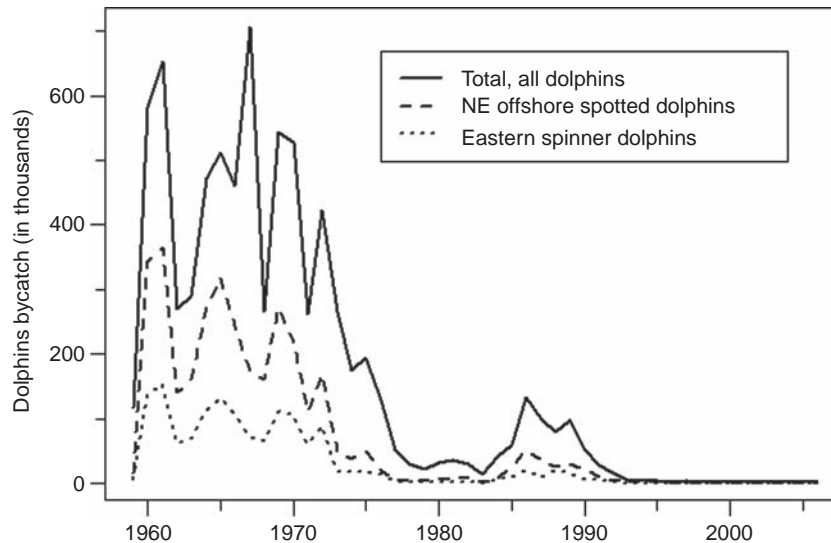

Figure 4 Estimated annual number of dolphins killed in the eastern tropical Pacific purse-seine tuna fishery, total for all dolphins and separately for the two dolphin stocks with the highest number killed.

observer program with all countries participating showed that total dolphin mortality had increased to 133,000/year (Fig. 4). Because US boats operated under restrictions that did not apply to boats of other countries, the United States began requiring that imported tuna be caught at dolphin mortality rates comparable to US boats (Gosliner 1999). The concept of Dolphin-Safe tuna—tuna caught without setting on dolphins (i.e., in log and school sets)—became popular, and by 1994, only Dolphin-Safe tuna could be sold in the United States. These trade actions were important because the United States is the largest market for the canned tuna product of the fishery.

The dolphin kill declined between 1986 and 1993 due to these various political and economic pressures (Fig. 4). Starting in 1993, the ETP fishing countries decided to increase observer coverage, institute skipper review panels, and meet a schedule of decreasing dolphin quotas on an individual boat basis (the La Jolla Agreement). The Declaration of Panama of 1995 carried these ideas further, proposing observers on every boat over 400 tons and strict by-stock dolphin mortality limits. These features became part of the International Dolphin Conservation Program Agreement (Hedley, 2001), a binding document among the major fishing countries that went into force in 1999. By this time total reported dolphin mortality had fallen to fewer than 3000 dolphins/year.

The Declaration of Panama also called for the United States to change its definition of Dolphin-Safe tuna to include tuna caught by setting on dolphins, as long as no dolphins were observed killed or seriously injured *on that set*. Before changing the Dolphin-Safe label, however, the US undertook studies to determine if the process of chasing and encircling dolphins was having a significant adverse impact on depleted dolphin populations. At the conclusion of the studies in 2002, the US National Marine Fisheries Service decided that the fishery was not significantly affecting the dolphin populations, which would have allowed the less restrictive definition of Dolphin-Safe to take effect. The decision was immediately challenged in court by environmental groups, and overturned because the decision was based on “political meddling,” not science. Therefore, the original definition of Dolphin-Safe applies to all canned tuna sold in the United States. Tuna caught by setting on dolphins may also be sold but may not be labeled

Dolphin-Safe. The Inter-American Tropical Tuna Commission certifies tuna as Dolphin-Safe under the Declaration of Panama definition, and such tuna is sold in parts of Europe and throughout Latin America.

IV. Status of the Dolphin Populations

The status of ETP dolphin stocks (management units) is based on two time-series of data: estimates of the number of dolphins killed, based on data from observers on tuna vessels (Fig. 4), and estimates of abundance, based on data from research vessel surveys (Gerrodette and Forcada, 2005; Fig. 5). Combining these data in a population model has indicated that the stocks most affected by the tuna fishery are the northeastern stock of the offshore pantropical spotted dolphin (*S. attenuata attenuata*) and the ETP endemic subspecies, the eastern spinner dolphin (*S. longirostris orientalis*). Both populations declined between 1960 and 1975 during the period of high mortality on US boats but have remained approximately constant since then (Fig. 5). As of 2002, northeastern spotted and eastern spinner dolphins were estimated to be at 19% and 29%, respectively, of population sizes when the fishery began (Wade *et al.*, 2007). Other stocks have apparently been less affected, although little is known of the small populations of coastal forms of spotted and spinner dolphins.

Since the early 1990s, reported dolphin mortality has been low enough that the dolphin populations should have started to recover. As of 2002, however, neither dolphin population was recovering at expected rates (Wade *et al.*, 2007). Hypotheses to explain the lack of recovery (Gerrodette and Forcada, 2005) have included underreporting of kill by observers, cryptic effects of the fishery not detectable by observers, such as stress, induced abortion or separation of mothers and calves (Archer *et al.*, 2004; Noren and Edwards, 2007), long-term ecosystem changes, and a lag in recovery due to interactions with other species. In years with a high number of dolphin sets, there are fewer calves in the spotted dolphin population. Reproduction in both dolphin populations declined between 1993 and 2003, which is at least one reason why recovery has been at a lower-than-expected rate. On the other hand, perhaps pelagic dolphins inherently have low reproductive rates, and our expectation for rate of recovery needs to be

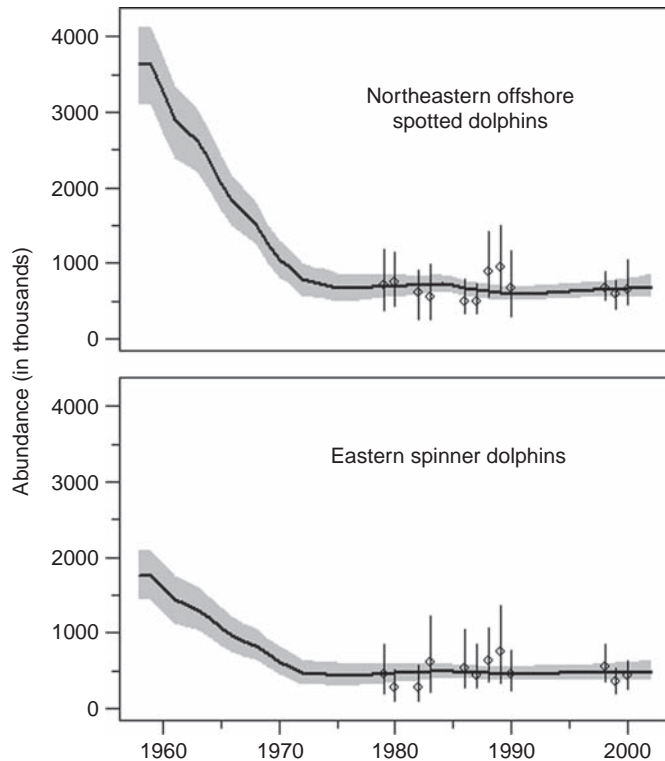

Figure 5 Estimated population trajectories of the two dolphin stocks most affected by tuna purse-seine fishing in the eastern tropical Pacific. Estimates of abundance between 1979 and 2000 are shown as points with 95% confidence intervals. The populations declined due to high numbers of dolphins killed in the tuna fishery from 1960 to 1975, as shown in Fig. 4.

revised. Research is continuing, but until there are clear recoveries of the affected dolphin stocks, the tuna-dolphin issue is likely to remain highly controversial.

Vaquita

Phocoena sinus

LORENZO ROJAS-BRACHO, ARMANDO M. AND
JARAMILLO-LEGORRETTA

The Vaquita (*phocoena Sinus*), or Gulf of California harbor porpoise, is endemic to the upper Gulf of California, Mexico. The Vaquita was first discovered and described in 1958 (Norris and McFarland, 1958), however it was not until the past decades that important advances were made in the knowledge of this porpoise. It is the most critically endangered cetacean species, taken incidentally in fishing nets at an unsustainable rate. Without help it will soon be gone. Currently the Mexican Government is putting into action a recovery plan including provision for alternative livelihoods for the fishermen.

I. Characteristics and Taxonomy

The vaquita is the smallest of all the porpoises (family Phocoenidae). The mean length for females is 140.6 cm; males are slightly smaller (134.9 cm). The vaquita differs from other phocoenids not only in total length, but also in that the flippers of the vaquita are proportionately larger and the dorsal fin is taller and more falcate. Generally, the pigmentation pattern consists of a dark gray cape, pale gray lateral field, and white ventral field. The most conspicuous features of the pigmentation are the relatively large black eye rings and lip patches (Fig. 1). Skulls of adult vaquitas are smaller and have relatively much broader and shorter rostra than those of other members of the genus. The number of teeth in each upper and lower jaw is 16–22 and 17–20, respectively (Brownell *et al.*, 1987; Vidal *et al.*, 1999). Norris and McFarland (1958) suggested that the vaquita had a recent common ancestor with the South American Burmeister's porpoise, *P. spinipinnis*, rather than with the harbor porpoise, *Phocoena phocoena*, its closest phocoenid geographic neighbor. This hypothesis was corroborated almost 37 years later by Rosel *et al.* (1995) using molecular techniques.

II. Distribution and Abundance

The limited abundance, distribution, and narrow habitat specificity of vaquita makes it one of the rarest marine mammal species (Rojas-Bracho *et al.*, 2006). The most recent estimated population size (Jaramillo-Legorreta *et al.*, 1999) was 567 individuals during the summer of 1997 (CV: 0.51, 95% CI 177–1073). All sightings from systematic ship surveys indicate that its distribution is limited to an area north of 30°45'N (Silber *et al.*, 1994; Gerrodette *et al.*, 1995; Vidal, 1995; Jaramillo-Legorreta *et al.*, 1999) specifically to a small portion of the upper Gulf of California (Fig. 2). Since 1997, acoustic surveys have been carried out as an alternative to the expensive traditional

Figure 1 Morphology of the vaquita: (A,B) lateral view (note proportionally large dorsal and pectoral fins), (C) lateral view of the head, showing the dark patches surrounding the eye and lips, (D) ventral view of the mouth, showing the palate and the spade-shaped crowns of teeth.

sighting surveys (Jaramillo-Legorreta *et al.*, 2005). The vaquita emits high frequency narrow clicks (Silber, 1991; Kamminga *et al.*, 1996) that can be automatically detected by specifically designed equipment (Chappell *et al.*, 1996; Gillespie and Chappell, 2002). Using this equipment it has been confirmed that the distribution is very limited, year-round. The core distribution area of acoustic encounters is approximately 1652 km², which must coincide with its optimal habitat and which overlaps that of the highest concentration of fishing effort with gill and mesh nets defined by Cudney-Bueno and Turk-Boyer (1998, fig. 2). This represents a very high risk for vaquita survival. In a worst-case scenario, having all or the majority of vaquitas in a small area makes the remaining population more vulnerable to a large by-catch event in an area of intense fishing (Rojas-Bracho and Taylor, 1999). The continued increase of fishing effort in the area allowed Jaramillo-Legorreta *et al.* (in press) to estimate that the current population level is, very probably, less than 40% of that estimated in 1997.

III. Ecology

The vaquita inhabits an area of approximately 4000 km² (Rojas-Bracho *et al.*, 2006). This area is located toward the west coast of the Upper Gulf of California, where the most turbid waters of the region are encountered (Alvarez and Jones, 2004). The extent of this distribution area is so small that according to measured swimming speeds a vaquita can nearly traverse it in a single tidal cycle (Jaramillo-Legorreta *et al.*, 2005). The acoustic encounters with vaquitas have been constrained to the most turbid zone of the distribution area, which could be part of a *quiet strategy* to avoid predators in clearer waters.

Analysis of stomach contents of 34 vaquitas reveals them to be non-selective feeders (Findley *et al.*, 1995; Pérez-Cortés-Moreno, 1996). Prey consisted of a wide variety of demersal/benthic fishes (21 species), squid (2 species), and crustaceans (1 species, plus 2 that were fish parasites). Several of the fish prey species (such as croakers, family Scianidae) are known to be sound producers so it is possible that vaquitas are in part using passive sound rather than echolocation to find their prey.

Morphological abnormalities in the vertebrate, unusual number of digits (six), and pathological condition of the ovaries (calcification of corpora albicantia) have been reported (Ortega-Ortiz *et al.*, 2000; Torre-Cosio, 1995; Hohn *et al.*, 1996). Taylor and Rojas-Bracho (1999) and Munguia-Vega *et al.* (2007) discounted these and other pathologies as a threat to the survival of the species (endogamic depression) due to a small population size.

IV. Behavior and Physiology

Little is known of social organization. Mean school size is 2, but groups as large as 8 or 10 individuals have been reported. An important aspect is loose aggregating behavior. The dynamics of these group aggregations are not clear, however it seems that either their duration is short or they shift locations in short periods of time. For example, Jaramillo-Legorreta *et al.* (1999) reported 41 vaquita groups loosely aggregated over several hundred square meters. During the next few days and some weeks later a similar pattern occurred, with several survey days without sightings and few survey days with this kind of aggregations sighted. There are also indications that suggest that shrimp trawlers are related at some extent with this aggregating behavior (Jaramillo-Legorreta *et al.*, 1999), however data on acoustic detection reveals this behavior also in the absence of the trawler fleet (Jaramillo-Legorreta *et al.*, 2005).

As compared with the other phocoenid members, the vaquita has on average relatively larger dorsal fin, flippers, and flukes. It has been

confirmed by histological examination that the dorsal fin is highly vascularized. Large arteriole vessels are surrounded with a plexus of thin walled veins (Pérez-Cortés-Moreno, 1996). Some researchers have suggested that these characteristics may be the result of evolutionary adaptations to cope with the extreme water temperatures that prevail in the Upper Gulf of California.

V. Life History

Hohn *et al.* (1996) noted an unusual age distribution. Most individuals (62%) were found to be between 0 and 2 years of age. The remainder (31%) were between 11 and 16 years of age, with few specimens between 3 and 10 years. There was a complete absence of specimens between the ages of 3 and 6 years. The sample of animals may be biased due to spatial segregation of different age classes or the susceptibility of various ages to be captured in nets. Alternatively, if this were the true age distribution of the population, it would represent a complete recruitment failure in recent years. Demographic models favor the hypothesis of a biased sample.

Like other porpoises, the vaquita is a seasonal reproducer, with most births occurring around March. There are not enough data for a precise estimate, but gestation is probably 10–11 months, as with other porpoises. The maximum observed life span is 21 years, which is higher than the maximum life span known for the harbor porpoise (*Phocoena phocoena*). Age at sexual maturity is difficult to estimate because of the lack of juvenile animals in the sample, but all females less than 3 years were immature and all females older than 6 years were mature. Most female harbor porpoises mature at age 3 and give birth for first time at age 4, which is consistent with observations for the vaquita. Unlike harbor porpoises in the Gulf of Maine, female vaquitas are probably not annual reproducers.

VI. Interactions with Humans

The vaquita is classified in the most critical conservation categories by the International Union for the Conservation of Nature (IUCN, 2007), the Convention on International Trade in the Endangered Species of Wild Fauna and Flora (UNEP-WCMC, 2007), and the Mexican Government (SEMARNAT, 2002). In 1996, the IUCN concluded that the extinction of the vaquita is likely unless conservation efforts are increased substantially.

To protect the vaquita and other endangered species, the Mexican government created the Upper Gulf of California and Colorado River Delta Biosphere Reserve on June 10, 1993. However, as new knowledge of the vaquita has been gained, it is clear that this measure is insufficient. Results of surveys in 1993 and 1997 indicate that the boundaries of this biosphere reserve do not correspond well to the distribution of vaquitas. A large percentage of the sightings (40%) lie outside the reserve boundary (Fig. 2). Further, no sightings were within the nuclear zone of the reserve, which is the area where all fishing is prohibited (Gerrodette *et al.*, 1995; Jaramillo-Legorreta *et al.*, 1999).

A more specific action has been the creation of the International Committee for the Recovery of the Vaquita (CIRVA) by the Mexican government. Recognized scientists from the United Kingdom, Norway, Canada, the United States, and Mexico make up CIRVA. The mandate of this group is to propose a recovery plan based on the best available scientific information. The plan should also contemplate and consider the socioeconomic impacts of any required regulations on the resource users in the affected areas.

During their first meeting, CIRVA concluded that in the short term, gill nets are the greatest risk to the survival of the vaquita. Estimated incidental mortality in gill nets is 39–84 vaquitas per year (D'Agrosa *et al.*, 2000). This represents from 6% to 14% of the

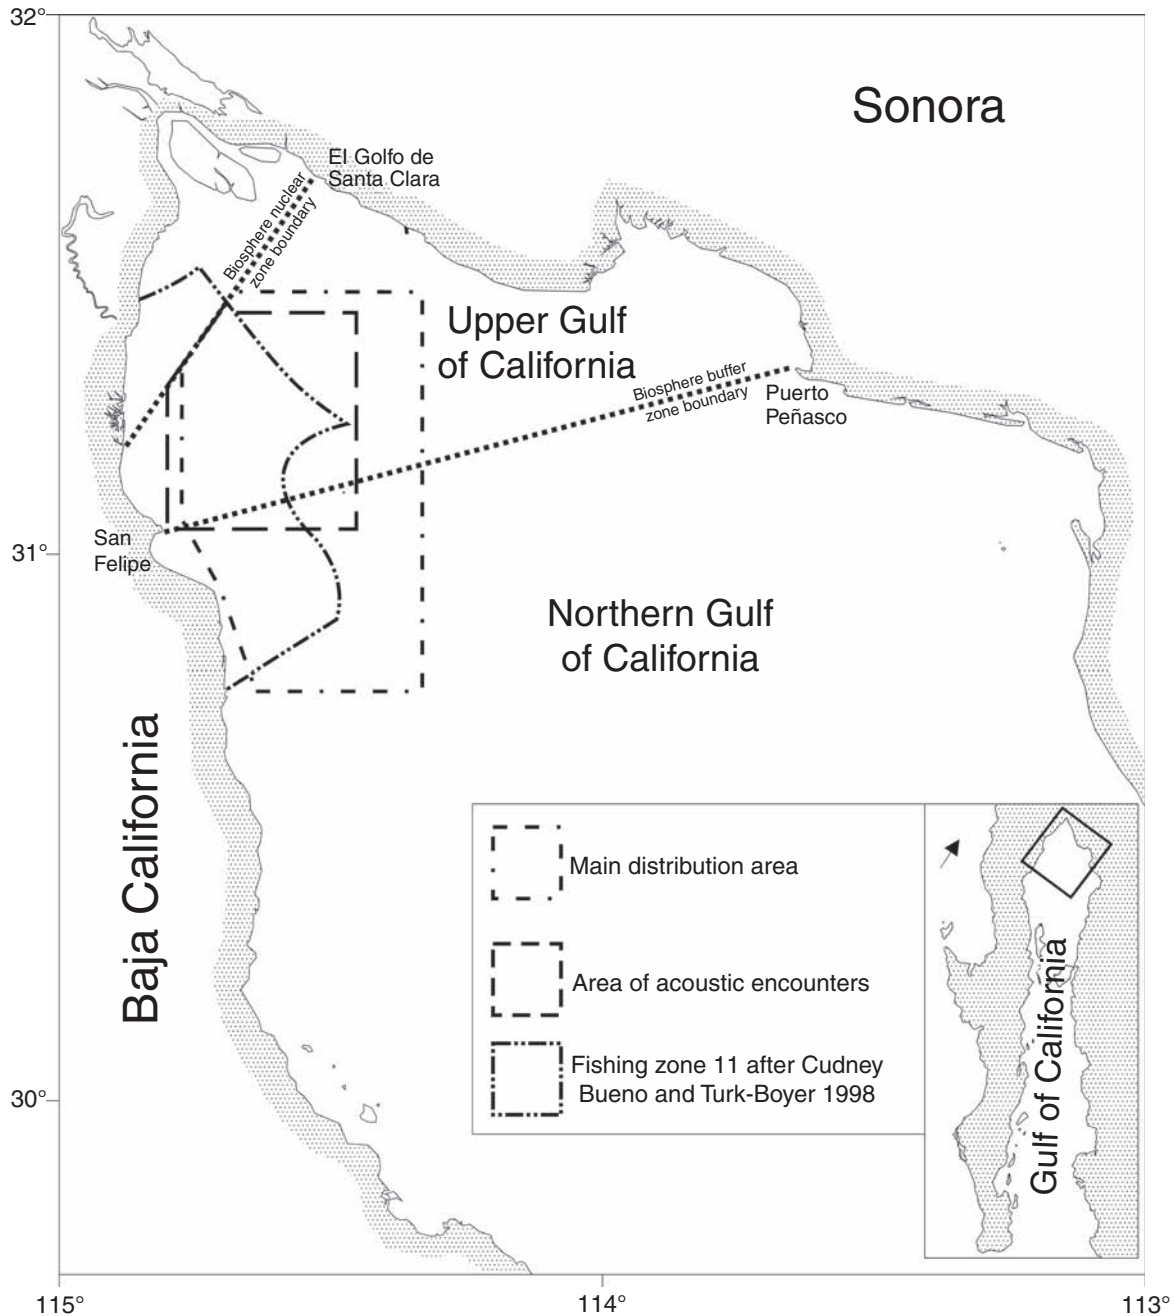

Figure 2 Distribution of the vaquita. Main distribution area from sightings data; most of the sightings are from near the coast. Approximately 40% of this area lies outside the Biosphere Reserve. A major portion of the area of acoustic encounters overlaps that of the fishing zone 11 defined by Cudney-Bueno and Turk-Boyer (1998).

current population size estimate and is from only one fishing port. The committee agreed that inbreeding depression, chlorinated pesticide concentrations in the upper Gulf, and reduced flow from the only freshwater input (the Colorado River) are not risk factors at present (Rojas-Bracho and Taylor, 1999; Taylor and Rojas-Bracho, 1999). It also agreed that, in the long term, changes in vaquita habitat due to reduction of the Colorado River flow are matters of concern and must be investigated. During its second meeting, CIRVA evaluated potential mitigation measures (seasonal closures of specific areas, gear restriction, acoustic deterrents, and marine-protected

areas) and strongly recommended that vaquita by-catch should be reduced to zero as soon as possible, the southern boundary of the biosphere reserve be expanded to include the entire range of the vaquita, and gill net and trawlers should be banned in the enlarged biosphere reserve. CIRVA recognized that these protective measures would have significant impacts on the resource users of the upper Gulf of California and therefore it is not possible to implement full protection immediately. Considering this, it was recommended that gill net fishing in the areas inhabited by vaquitas be removed in three stages, starting with large-mesh gill nets. CIRVA also strongly

recommended investigating the development of strategies to offset economic hardship imposed by these regulations. Other recommendations were that fishing regulations be effectively enforced; acoustic surveys be started immediately to begin monitoring an index of abundance and to gather data on seasonal movements of vaquitas; development and testing of alternate gear types to replace gill nets be carried out; the design and development of community involvement, education, and public awareness programs go forward; and a description of the critical habitat of vaquita be developed.

Recently, the Scientific Committee of the International Whaling Commission indicated that more science is not required to conserve this species. Instead, the Committee *strongly recommended* that resources be found to design and implement a comprehensive programme to eliminate entangling nets from the range of the vaquita (IWC, 2007).

Recently the President of Mexico announced the Conservation Program for Endangered Species (Programa de Conservación de Especies en Riesgo-PROCER) which will instrument specific Species Conservation Action Programs (Programas de Acción para la Conservación de Especies- PACE) for a list of selected species. The vaquita is listed among the top five species. The specific conservation actions will be announced shortly. Mention should be made that an intense effort by the Federal Government is taking place; which includes a coordinated program by the Ministry of Environment, the Ministry of Agriculture and Fisheries (SAGARPA) and all stakeholders, including fishermen (artisanal and industrial), NGOs and NAFTA's Commission for Environmental Cooperation (CEC).

In the absence or ineffectiveness of these kinds of measures the vaquita is very probably doomed to extinction in the near future.

Vision

ALLA M. MASS AND ALEXANDER YA. SUPIN

The vision of marine mammals has a number of specific features associated with its ability to function in both water and air. Although many marine mammals (cetaceans, sirenians) spend their entire life in water, their aerial breathing confines them to a near-surface layer of water. Other marine mammals (pinnipeds, sea otters) spend a significant part of their life on land. As a result, the organization of their visual system fits requirements of both these different media. Although some aspects of organization of the visual system of marine mammals still remain unstudied, many features of their vision are known already.

I. Visual Abilities of Marine Mammals

A. Cetaceans

It was long believed that dolphins—animals with excellent hearing and echolocation—have a poorly developed visual system playing a minor role in their life. However, observations of the visual activity of dolphins have demonstrated the opposite. The ability to catch fish in air, perform precisely aimed jumps to reach targets above the water, and recognize their trainers all show that vision in dolphins is well developed. In conditions of keeping in captivity, dolphins decrease their use of echolocation and, as their interest in events above the water increases, vision takes on a leading role.

Reviews of Madsen and Herman (1980) and Mobley and Helweg (1990) summarize observations of dolphins in captivity and experimental studies which provide a basis for regarding the vision of dolphins as playing an important role in various aspects of their life: in social interactions, discrimination between individuals and species based on their colors and individual marks, the search and discrimination of prey, orientation, reproductive activity, and defense. Only vision provides the ability for rapid and precise assessment of distances to objects in air where echolocation does not operate.

Apart from numerous observations, good visual abilities of cetaceans were demonstrated in behavioral experiments for assessing their visual acuity. Precise behavioral measurements performed by Herman and colleagues (Madsen and Herman, 1980) on the bottlenose dolphin resulted in an estimate of underwater visual acuity of 8.2 arcmin (at the best distance of 1 m) and aerial visual acuity of 12.5 arcmin (at distances of 2.5 m and longer). In general, estimates of visual acuity in dolphins varied from 8 to 27 arcmin in water and from 12 to 18 arcmin in air.

Studies of color vision in cetaceans are very few in number. Only one cone type was found in the bottlenose dolphin, with the best sensitivity at 525 nm; rods are best sensitive to 488 nm. These sensitivity peaks are considerably blue-shifted as compared to those of

many terrestrial mammals (Jacobs, 1993). Therefore, the dolphin lacks the common dichromatic vision typical of many terrestrial mammals, which is based on two cone types with different chromatic sensitivity. If color vision is present in dolphins (based on comparison of signals from rods and cones), it is poorly developed and limited to a blue–green region of the spectrum.

In all cetaceans, the eyes are positioned laterally, thus providing a visual field as wide as 120–130° and panoramic vision. Although positioned laterally, the eyes are directed somewhat forward and downward (ventronasally). On viewing visual objects in air, the dolphin eyes can move forward by 10–15 mm, so that the visual fields of the two eyes overlap by 20–30° in the frontal sector, giving a basis for binocular vision. However, uncrossed optic fibers have not yet been demonstrated in dolphins. Therefore, the existence of true binocular (stereoscopic) vision (based on interaction of crossed and uncrossed optic fibers) in dolphins still remains under question.

Dolphins are equally capable of the perception of complex configurations of objects using both vision and echolocation. Besides, there is also a possibility of intermodal transfer between these two modalities: objects known for a dolphin only by visual appearance can be discriminated and recognized by echolocation, and vice versa. The intermodal transfer is equally successful when visual experience is used for echolocation discrimination and when echolocation experience is used for visual discrimination.

Even in riverine cetaceans inhabiting turbid and low-transparent water (the Amazon river dolphin *Inia geoffrensis*, the tucuxi dolphin *Sotalia fluviatilis*), the visual system does not exhibit a significant regression. The only exception is the Indian river dolphin, *Platanista gangetica*, in which the visual system is reduced markedly.

B. Pinnipeds

Because pinnipeds spend their life partially in water and partially on land, they use both underwater and aerial vision. On land, vision plays an important role during the reproductive period, during birth and feeding of pups, and for maintaining intrapopulation relationships, as well as for orientation. In water, vision is used for prey detection and recognition, avoiding predators, and spatial orientation during migrations.

Because of a great diversity of pinniped species in terms of systematic position and ecology, the role of vision diverges widely as well. Walrus (*Odobenus rosmarus*) rely mainly on their vibrissal sensitivity to identify objects during benthic foraging. Other pinnipeds also have a well-developed vibrissal apparatus; however, in aquatic conditions, most seals use both visual and tactile modalities to search for food. Experiments demonstrated that seals are capable to distinguish rather small objects visually, recognize the shape of figures, and perform a complex analysis of visual images. Data summarized by Fobes and Smock (1981) shows that both otariids and phocids are capable of discriminating objects differing in size from 9% to 24%.

Most pinnipeds (both otariids and phocids) have maximum spectral sensitivity within a range of 496–500 nm. An exception is the southern elephant seal (*Mirounga leonina*), which is sensitive to a shorter wavelength (486 nm).

A possibility of limited color discrimination in a few pinniped species (*Pagophilus groenlandicus*, *Phoca largha*, *Arctocephalus pusillus*, *A. australis*, *Zalophus californianus*) is indicated by their capability to discriminate blue and green objects from gray ones, although they cannot discriminate red and gray objects. The best rod sensitivity in the harbor seal (*Phoca vitulina*) was found at 496 nm, and cone sensitivity at 510 nm; i.e., similarly to dolphins, the spectral sensitivity is

blue-shifted as compared to terrestrial mammals. No indication was obtained of more than one cone type in pinnipeds (see Section IV.A).

Measurements of visual acuity based on the use of grids as test stimuli have demonstrated that visual acuity in both water and air is 5–8 arcmin in a few otariid species: *Zalophus californianus*, *Eumetopias jubatus*, *Arctocephalus pusillus*, and *A. australis*, *Phoca vitulina*.

C. Other Marine Mammals

1. *Sirenians* Little is known of the visual capabilities in sirenians. A few observations summarized by Piggins *et al.* (1983) showed that the Amazon manatee (*Trichechus inunguis*) is capable of visually driven behavior, in particular, visual tracking of underwater objects. Recently underwater visual acuity was assessed in the Caribbean manatee *Trichechus manatus* as rather poor—from 24 to 56 min of arc, depending on the test gain orientation and media. A capability of this species for dichromatic (blue–green) color vision has been shown. It remains unknown whether the manatee has an ability of good aerial vision.

2. *Sea Otters* Very little is known of the visual abilities of sea otters (*Enhydra lutris*). Inhabiting the coastal zone and feeding under water, sea otters need to have good vision in both air and water. Observations showed that they actively use vision, and experiments have shown their capability to discriminate objects of different sizes. However, quantitative behavioral measurements of their visual abilities are absent.

II. Eye Anatomy and Optics

A. Cetaceans

Ocular anatomy in cetaceans is markedly different from that in terrestrial mammals by being adjusted to optical properties of water and to a number of other factors: possibility of eye damage because of high density of water and presence of suspended particles, low temperature and low illumination deep in water, significant light scatter, and so on. Characteristic examples of eye structure in cetaceans are shown in Fig. 1. Remarkable features are a thick sclera (especially so in whales, Fig. 1B), a thickened cornea, a highly developed vascular network forming a typical vascular *rete mirabilia* which fills a significant part of the orbit behind the eyeball, and massive ocular muscles. All these structures take part in protecting the eye from underwater cooling and mechanical damage.

Although in terrestrial mammals the eyeball is almost spherical, in cetaceans its anterior part is flattened, so as the anterior chamber is small and the eyecup is of almost a hemispherical shape. More precisely, the eyecup shape approximates a segment of a sphere of about 150° of arc (Fig. 1A,B), and its naso-temporal diameter slightly exceeds the dorsoventral one.

In terrestrial mammals, the convex outer surface of the cornea is the major refractive element of the eye because it separates media with different refractive indices: air with a refractive index of about 1 and the corneal tissue with a refractive index of more than 1.35. However, the refractive index of water is 1.33–1.34, which is very close to that of the cornea and the intraocular media. As a result, the

Figure 1 Schematic presentation of eye anatomy and optics in some cetaceans: (A) the bottlenose dolphin, (B) the gray whale, and (C) the Amazon river dolphin. Co, cornea; L, lens; Ir, iris; O, operculum; S, sclera; Ch, choroids; R, retina; ON, optic nerve; OD, optic disc; VB, vitreous body. Arrows 1 and 2 delimit a part of the eyecup, which can be approximated by a spherical segment of about 150°. Arrows 3 and 4 show directions of light rays passing through the nasal and temporal holes of the pupil and through the lens center to the high-resolution parts of the retina.

corneal surface plays very little part in underwater light refraction. Therefore, in cetaceans, light refraction and focusing of an image on the retina are almost entirely performed by the lens. This is why the lens in cetaceans is almost spherical or slightly elliptical. The large curvature of the lens surface provides a sufficiently high refractive power of the lens and well-focused images on the retina, despite very weak refractive power of the corneal surface in water. These optics are similar to those in fish, which is not surprising given that in both cases the eye is adjusted to optical properties of the same medium.

A strongly convex (spherical) lens consisting of homogeneous material have a very strong spherical aberration. The cetacean lens is free of this disadvantage due to a heterogeneous structure: outer layers have a lower refractive index than the inner core.

In the cetacean eye, the spherical lens is located in such a way that its center almost coincides with the center of the spherical segment of the eyecup; so light rays coming from any direction are focused almost identically on the retina. This is significantly different from the case in terrestrial mammals, which provides the best focusing on the eye axis.

In terrestrial mammal eyes, accommodation (refraction adjustment to the distance to the object) is performed by change in the shape of the lens due to contraction and relaxation of ciliary muscles. In cetaceans, spherical lens shape and center-symmetric optics of the eye led to loss of this accommodatory mechanism. The ciliary muscles are poorly developed in dolphins and are absent from most whales suggesting that accommodation cannot be achieved by changing the lens shape. It has been suggested that accommodation in cetaceans is performed by another mechanism, namely by axial displacement of the lens due to changes in intraocular pressure. Intraocular pressure can change because of contraction of the massive the massive retractor muscle (*m. retractor bulbi*) which produces axial displacements of the eye in the orbit. When the eye is pulled back into the orbit, intraocular pressure increases, thus shifting the lens forward; when the eye is moved forward, the pressure decreases shifting the lens backward.

The cornea in cetaceans is thicker than in many terrestrial mammals, and this thickness is not uniform: the cornea is thinner in the center and thicker in the periphery. Although major refraction in the cetacean eye is performed by the lens, the refractive role of the cornea is not negligible. Its outer surface is of lower curvature than the inner one; i.e., the cornea has a shape of a divergent lens. Under water, this lens makes minor contribution to the total refraction power, as the media on both sides of the cornea (water outside and the anterior chamber liquid inside) have refractive indices rather close to that of the cornea. However, some difference between the refractive indices of water (1.33) and the cornea (from 1.37 in the central part to 1.53 in the periphery) does exist. Thus, the cornea acts as a weak but nonetheless divergent lens. The total refraction of the cornea and lens makes the cetacean eye well emmetropic within a range of ± 1 diopters under water.

Adaptation to underwater vision also affects the cetacean iris and pupil. The cetacean vision functions in conditions of wide and rapid changes of illumination when the animal dives from the well-illuminated water surface into the depth where illumination is very low. This requires the pupil to react in a wide range of illuminations and to have a wide range of sizes. The cetacean pupil is of an unusual shape. The upper part of the iris has a characteristic protuberance, the operculum. At low illumination, the operculum is contracted (raised), so the pupil, similarly to other mammals, is of a round or slightly oval shape; its horizontal diameter in dolphins is of about 10 mm (Fig. 2A). With illumination increase, the operculum advances downward, turning the pupil into a U-shaped slit (Fig. 2B). At high illumination, the

Figure 2 Shape of the pupil in the bottlenose dolphin at various levels of illumination: (A) low illumination, nonconstricted oval pupil; (B) moderate illumination, partially constricted U-shaped pupil; and (C) high illumination, strongly constricted pupil reduced to two pinholes.

operculum advances so far that the slit becomes closed, leaving only two narrow holes in the temporal and nasal parts of the iris (Fig. 2C). This pupil shape is characteristic for many dolphins, including the bottlenose dolphin *Tursiops truncatus*, harbor porpoise *Phocoena phocoena*, common dolphin *Delphinus* spp., tucuxi dolphin *Sotalia fluviatilis*, and also for a number of whales, although in some whales the operculum is small. A known exception is the Amazon river dolphin which has a round pupil even when it is constricted.

The cetacean eye is well emmetropic in water; however, in air refraction on the outer convex corneal surface adds to the lens refraction. The difference of refractive indices of air and the cornea results in significant refractive power of the central, the most convex part of the corneal surface: about 20 diopters. The addition of this refraction to the emmetropic lens refraction should make the cetacean eye catastrophically myopic (near-seeing) in air. Nonetheless, dolphins have good visual acuity in both water and air.

The solution of the problem is in the presence of flattened (low-curvature) regions of the cornea. A flat corneal surface does not produce additional refraction in air. Even if the surface is not truly flat but a little convex, its refractive power becomes low enough and may be compensated by some additional mechanisms. Keratoscopic studies in common bottlenose dolphins showed a “spoon” shape of the cornea with lower curvature in its nasal and temporal regions.

Aerial myopia can be partially compensated by accommodatory displacements of the lens. For aerial vision, the dolphin eye moves forward thus producing decrease of intraocular pressure; this results in shifting the lens backward and reduced myopia. Additionally, reduction of intraocular pressure decrease the curvature of the cornea. Under water, the eye is retracted into the orbit, which results in increased intraocular pressure and a shift of the lens forward to a position providing underwater emmetropia.

An additional mechanism for the correction of aerial myopia is pupil constriction. Above water, high illumination results in strong pupil constriction; the latter corrects all errors of refraction, including aerial myopia, and provides fairly good depth of field.

Another adaptation of the cetacean eye to low underwater illumination is the well-developed reflective layer, the tapetum (*tapetum lucidum*). It lies behind the retinal pigment epithelium within the choroid. In cetacean, the tapetum is formed with extracellular collagen fibrils (*tapetum fibrosum*). Multiple reflection of light from 50–70 layers of fibrils results in significant light reflection back to the retina, thus increasing visual sensitivity in scotopic conditions.

The tapetum is present in all cetaceans. In most of the investigated cetaceans, particularly in mysticete whales, it covers all of the fundus (although varies in coloration), or at least it covers a large dorsal part of the fundus. Complete coverage of the fundus by the tapetum is

Figure 3 Schematic presentation of eye anatomy and optics in some representatives of pinnipeds, sirenians, and otters: (A) the northern fur seal; (B) the manatee; (C) the sea otter. Co, cornea; FC, flattened region of the cornea; L, lens; Ir, iris; S, sclera; Ch, choroids; R, retina; ON, optic nerve; OD, optic disc; P, lens protuberance; VB, vitreous body.

unique among vertebrates: in terrestrial mammals, the tapetum usually does not extend lower than the horizontal equator of the eyecup.

B. Pinnipeds

In all pinnipeds (except walruses), both the absolute and the relative sizes of the eyeball are large. Eye structure in pinnipeds (Fig. 3A), despite significant differences from cetaceans, has some common features arising from adaptation to underwater vision (Jamieson and Fisher, 1972). In particular, a characteristic feature is an almost spherical or slightly elliptical lens. Although the eyeball does not appear as shortened in the axial direction, a major part of the eyecup has a shape close to a hemisphere, so a significant part of the retina is almost constantly distant from the lens center. Thus, the eye optics, like in cetaceans, is almost centrally symmetrical. The difference between the eyeball shape in cetaceans and pinnipeds (shorter axial length in cetaceans and longer in pinnipeds) is mainly due to larger size of the anterior chamber in pinnipeds.

Iris in pinnipeds is very muscular and heavily vascularized. The dilator is well developed. Most pinnipeds have a pupil which being constricted becomes pear-shaped. Pupil size can change over a very wide range; at bright illumination, it constricts to a very small hole. In shallow-diving species, the range of pupillary area variation is rather small: 26–70.5 times. In a deep diver, the northern elephant seal, *Mirounga angustirostris*, the pupil area varied within an extremely wide range, from 422 mm² in dark-adapted conditions to a pinhole of 0.9 mm² in light-adapted conditions, i.e., almost 470 times.

The ciliary muscle in pinnipeds is well developed, although accommodation is either absent or very weak.

Unlike cetaceans, the central part of the cornea has a clearly delimited region (6–10 mm in diameter) of almost a flat surface. It is located near the center of the cornea, slightly shifted to the nasal direction (FC region in Fig. 3A). Such a flat region of the cornea was found in a number of both otariids and phocids and was demonstrated by precise measurements on the Californian sea lion (*Zalophus californianus*). The flat region of the cornea serves as an emmetropic “window” in which refraction remains almost equal in both water and air. In another pinniped, the hooded seal (*Cystophora cristata*), the flattened part of the cornea does not look like a delimited region but arises because of low curvature of the cornea of the extremely large eyeball.

The existence of a flat region in the central part of the cornea indicates a very specific principle of eye construction in pinnipeds. Indeed, the convex shape of the cornea in most animals is a consequence of excessive intraocular pressure, which is necessary for maintaining the shape and size of the eyeball. Direct data on intraocular pressure in pinnipeds are absent, but their flat cornea suggests that this pressure is very low, perhaps about zero. Anatomical observations on the northern fur seal (*Callorhinus ursinus*) showed that its vitreous body is of a rigid rather than a gelatinous consistency, thus taking a part in maintenance of the eyeball shape and dimensions. This way of maintaining the eye shape is evidently used in a number of pinniped species.

The pinniped tapetum is one of the best developed among both terrestrial and aquatic mammals. Contrary to the tapetum fibrosum

in cetacean, the tapetum in pinnipeds is formed with intracellular reflective rodlets (tapetum cellulosum). It consists of a large number (20–30 or more) of cell layers and covers all the fundus.

C. Other Marine Mammals

1. *Sirenians* Among other marine mammals, the eye anatomy of the manatee (*Trichechus manatus* and *T. inunguis*) is of interest as an example of the order Sirenia, which, apart of cetaceans, is the only group of completely aquatic mammals.

Both in *Trichechus manatus* and in *T. inunguis* the eye is rather small (13–19 mm diameter) and is set deeply within the ocular fascia. Its general morphology resembles more that of terrestrial mammals than the cetacean eye (Fig. 3B). The eyeball is almost spherical (the axial length differs little from the equatorial diameter), the anterior chamber is shallow, and the lens is set forward and is not true spherical: its axial dimension is markedly shorter than the diameter. The sclera is rather thin. Thus, despite of completely aquatic mode of life of the manatee, its eye anatomy exhibits a number of conservative features (Piggins *et al.*, 1983). Underwater, the eye is almost emmetropic or slightly hyperopic, but in air it is strongly myopic. It remains unknown whether the manatee has some mechanisms to compensate aerial myopia; thus, its capability to aerial vision remains unknown.

A distinctive feature of the manatee's eye is the vascularized cornea which in all other mammals is pathology.

2. *Sea otters* To a large extent, the eyeball of the sea otter (*Enhydra lutris*) is similar to those of terrestrial mammals (Fig. 3C): it is almost spherical, axial length is only a little shorter than the diameter. Contrary to spherical lenses of cetaceans and pinnipeds, the lens of sea otter is lenticular. However, the front surface of the lens has a protuberance of increased curvature. A characteristic feature of the eye anatomy is that the iris is fastened to the frontal lens surface. Therefore, contraction of iris muscles influence the curvature of the frontal lens surface. This mechanism is capable of providing an accommodation range of up to 60 diopters, thus compensating for the appearance of refraction at the corneal surface in air and its disappearance in water. This accommodation mechanism in the sea otter eye is able to preserve emmetropia in both air and water.

III. Eye Movements

All dolphins and whales have mobile eyes. However, measurements in the bottlenose dolphin indicated that eye mobility is less than in humans, and eye movements are more slow.

Oculomotor muscles are well developed in dolphins and whales; an exception is the Ganges river dolphin (*Platanista gangetica*), which has reduced eyes and no oculomotor muscles. Other cetaceans have a complete set of muscles known in mammals: four straight and two oblique muscles. These muscles allow eye movements in both the horizontal and the vertical directions. In addition, unlike terrestrial mammals, cetaceans have retractor muscle (*m. retractor bulbi*), which produce axial (in/out) movements of the eye in the orbit. The bottlenose dolphin is capable of moving its eye forward to 10–15 mm and pulling it back. As a rule, forward eye movements (protraction) appear when the dolphin examines an object in air visually. These eye movements may be used for binocular examination of objects. As mentioned earlier, the eye protraction in air can also provide accommodation to avoid the aerial myopia.

Another intriguing feature of oculomotor activity in dolphins is the ability to move the left and right eyes independently. Quantitative

measurements in dolphins have shown that correlation of movements of the left and the right eyes are very low; i.e., independent eye movements in dolphins are a rule rather than exception.

In addition to independent eye movements, cetaceans have rather independent pupil reflexes of the two eyes. Moreover, eyelids of the left and the right eyes can also function independently, so one eye can be open while the other is closed. Such observations were made during sleep in dolphins, although similar behavior is also possible in wakefulness: dolphins can swim for long periods with one eye open and the other one closed, with the left and the right eye alternating.

As to pinnipeds and sea otters, there is no significant difference from terrestrial mammals in their oculomotor muscle anatomy and the character of eye movements.

IV. The Retina and Optic Nerve

A. Features of the Retina in Cetaceans

The histological structure of the retina has been investigated in a number of cetacean species: the common bottlenose dolphin, short-beaked common dolphin (*Delphinus delphis*), Dall's porpoise (*Phocoenoides dalli*), dwarf sperm whale (*Kogia sima*), Amazon river dolphin (*Inia geoffrensis*), fin whale (*Balaenoptera physalus*), and common minke whale (*B. acutorostrata*). All of these studies have shown that the laminal structure of the cetacean retina is basically similar to that in terrestrial mammals. The retina consists of typical layers as follows (Fig. 4A). The receptor layer (the nearest to the pigment epithelium) is composed of densely packed outer segments of photoreceptors. The outer nuclear layer is composed of receptor pericaria arranged in a multilevel manner. The outer plexiform layer contains cell processes establishing connections between receptors and first-order neurons, bipolar cells. The inner nuclear layer is composed mostly of pericaria of bipolar cells; in addition, this layer contains horizontal and amacrine cells, which establish horizontal connections within the outer and inner plexiform layers. The inner plexiform layer contains processes establishing connections between bipolar and ganglion cells. The ganglion layer contains ganglion cells sending their axons to the optic nerve. Finally, the nerve fiber layer (nearest to the vitreous body) contains optic fibers (axons of ganglion cells), which spread along the inner retinal surface until they reach the optic disk and enter the optic nerve. This laminal structure of the retina is fully developed in all cetaceans. Even in the Ganges river dolphin with strongly reduced eyes, the retina contains all the layers. Being basically similar in cetaceans and terrestrial mammals, the retina has a number of specific features in cetaceans. It is markedly thicker than in terrestrial mammals, ranging from 370 to 425 μm (in terrestrial mammals, the retina is 110–240 μm thick).

The most detailed description of the retina is available for the common bottlenose dolphin (Dral, 1977; Dawson, 1980). Its retinal receptor layer consists predominantly of rods (receptors for achromatic vision). The question of the existence of cones (chromatic-vision receptors) in cetaceans remained debatable for some time. Recent studies of visual pigments have shown that the cetacean retina does contain cone receptors, however rods dominate: cone proportion is in the range of 1–2% (Peichl *et al.*, 2001).

Contrary to the majority of terrestrial mammals which have two types of cones with different pigments providing color vision (short-wave sensitive S-opsin and middle-to-long-wave sensitive L-opsin), only L-opsin containing cones were found in 10 species of odontocetes the cetacean retina. S-opsin have not been reported (Peichl *et al.*, 2001). This corresponds to behavioral data showing poor color

vision in dolphins (see Section I.A). As to amacrine, bipolar, and horizontal cells in the cetacean retina, they are generally similar to those in terrestrial mammals.

A marked difference from terrestrial mammals is in the inner plexiform layer and the ganglion layer of the cetacean retina. The ganglion layer looks like a single row of large, sparsely distributed neurons separated by large intercellular spaces. These neurons have large cell bodies with a clearly defined cell membrane, large amount of cytoplasm, a well visible nucleus up to $15\mu\text{m}$ in diameter, and clearly defined nucleolus $4\text{--}5\mu\text{m}$ in diameter. Cell bodies contain clearly visible, well stained Nissl granules.

A remarkable feature of the cetacean retina is large size of ganglion cells, particularly, the presence of giant ganglion cells. Bodies of such cells reach $75\text{--}80\mu\text{m}$, sometimes more. Giant ganglion cells were described in a number of odontocete species and in a few mysticete whales. In some dolphins, however, retinal ganglion cells do not reach giant sizes: in the Amazon river dolphin and the Indian river dolphin they do not exceed $40\text{--}42$ and $20\mu\text{m}$, respectively. However, even these cells are as large as compared to those in many other mammals. The smallest ganglion cells in cetaceans are as large as $10\mu\text{m}$.

Figure 5A,B present ganglion cell size distributions in the retina of the common bottlenose dolphin. The histograms represent samples in different parts of the retina: with high and low concentration of ganglion cells. Despite some difference between the samples (in the area of high cell concentration, cells are a little smaller than in the area of low concentration), both samples demonstrate large cell sizes: the most common size is $20\text{--}35\mu\text{m}$, but cells as large as $50\text{--}60\mu\text{m}$ are also present; there are no cells smaller than $10\mu\text{m}$.

Large cells are not characteristic of all levels of the visual system in cetaceans (the lateral geniculate body, visual cortex); they are typical only in the retina. The largest pyramidal cells in the visual area of the dolphin cerebral cortex are not more than $20\text{--}30\mu\text{m}$. In other parts of the dolphin brain, cells do not exceed $20\text{--}45\mu\text{m}$ either. There is presently no satisfactory explanation why ganglion cells in the cetacean retina are so large. One of possible explanations is that large ganglion cells have thick axons with high velocity of conduction; in a large body, it may be helpful for fast transmission of signals. However, large terrestrial mammals (e.g., the bull or the elephant) have ganglion cells not larger than $25\text{--}30\mu\text{m}$.

Apart from large cell sizes, a characteristic feature of the retinal ganglion layer in cetaceans is low cell density. The large neurons are separated by large intercellular spaces.

The question of separation of retinal ganglion cells into different morphological types has not been solved for cetaceans. Large-size ganglion cells in cetaceans resemble large Y-neurons in the visual system of terrestrial mammals, as opposed to smaller X-neurons. However, Y-neurons in terrestrial mammals constitute no more than 1% of ganglion cells, whereas in cetaceans, large ganglion cells predominate.

B. Optic Nerve Structure in Cetaceans

Retinal ganglion cells send their axons into the optic nerve. Consistent with the large sizes of ganglion cell bodies, the axon diameters in cetaceans are also greater than in terrestrial mammals. In a variety of dolphin species, a significant proportion of optic fibers exceed $15\mu\text{m}$ in diameter. For comparison, the maximum fiber diameter in cats and in monkeys, is no more than $8\mu\text{m}$. The only exception is the Chinese river dolphin *Lipotes vexillifer*, which has thin optic fibers, although its retina contains ganglion cells as large as $75\mu\text{m}$.

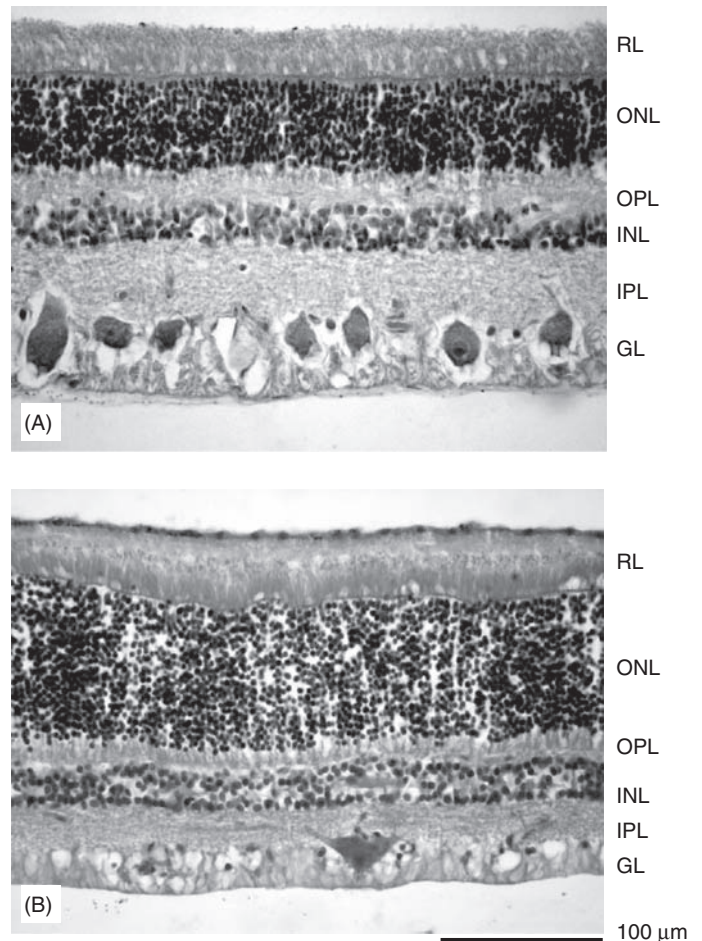

Figure 4 Microphotographs of a transverse section of the retina of a bottlenose dolphin (A) and a Steller sea lion (B). RL, receptor layer; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GL, ganglion layer.

The low density of ganglion cells in the retina of cetaceans corresponds to the low density of fibers in the optic nerve. In cross sections of the optic nerve of dolphins, the density of fibers is less than $50,000/\text{mm}^2$, whereas in monkeys it exceeds $220,000/\text{mm}^2$. Thus, although the optic nerve in cetaceans is of a large diameter, the total number of optic fibers does not exceed that in many terrestrial mammals. More than 50% of the cross-section area of the cetacean optic nerve is occupied by intercellular space (contrary to 12–20% in terrestrial mammals), not by glia.

The total number of optic fibers varies among cetacean species. The smallest number of fibers (14,000–16,000) was found in the Indian river dolphin, *Platanista gangetica*, and the Amazon river dolphin, *Inia geoffrensis*; the number of optic fibers in the Chinese river dolphin, *Lipotes vexillifer*, is a little higher, more than 20,000. In the common bottlenose dolphin, the number of optic fibers is 150,000–180,000. Other odontocetes have an optic fiber number similar to that in the bottlenose dolphin. In mysticetes, the number of optic fibers is within a range of 250,000–420,000.

C. Features of the Retina in Pinnipeds

In general, the retinal structure in pinnipeds is the same as in terrestrial mammals (Fig. 4B). All layers are present in the pinniped

Figure 5 Histograms showing size distributions of ganglion cells in the retina of cetaceans and pinnipeds. Abscissa axis, cell size; ordinate axis, number of cells of the present size. (A,B) Data from a common bottlenose dolphin; samples from areas of high (A) and low (B) cell densities. (C,D) The same for a northern fur seal.

retina, although there are a number of specific features, mainly of the outer nuclear, inner nuclear, and ganglion layers (Jamieson and Fisher, 1972). The very thick outer nuclear layer is characteristic of many pinnipeds. The inner nuclear layer does not have clear margins, in contrast to terrestrial mammals, where this layer is strictly ordered. There are large horizontal cells with very long processes within this layer. The giant horizontal cells are located irregularly among bipolar and amacrine cells, which are also distributed chaotically. Bipolar cells are located mostly in the outer part of the inner nuclear layer while large amacrine cells are located close to the inner plexiform layer.

The ganglion layer in pinnipeds consists of a single row of ganglion cells separated by wide intercellular distances. Ganglion cells have large pericaria, a large amount of Nissl substance in the cytoplasm and long dendrites. Most of these cells are of intermediate size (10–30 μm), although large cells (up to 50 μm) are also encountered (Fig. 5C,D). These sizes are larger than in terrestrial mammals.

All pinnipeds have a predominately rod retina. The question of existence of cones has been a matter of discussion for a long time. However, light and electron microscopy have shown the presence of cones in the harbor seal and harp seal, although photoreceptors of this type are not numerous. Moreover, recently, immunochemical studies in a few pinniped species demonstrated that their retinæ contained sparse populations of cones, consisting about 1–2% of photoreceptors (Peichl *et al.*, 2001). However, these studies revealed only one opsin type in the cone receptors, the middle-to-long-wave sensitive L-opsin and did not revealed the short-wave sensitive S-opsin. This feature is common with cetaceans (in spite of the quite different phylogeny of cetaceans and pinnipeds) and distinguishes pinnipeds from majority of terrestrial mammals that have at least two spectrally sensitive cone types (middle- and short-wave sensitive) or three cone types in primates. The existence of some amount of cones corresponds to behavioral data showing a limited capability of color discrimination in pinnipeds (see Section I.B).

D. The Retina of Other Marine Mammals

1. *Sirenians* The retina of the manatees also features the common laminar organization. Receptors are presented mostly by rods; cones are less numerous. Among specific features, the large size of ganglion cells can be mentioned: up to 60 μm, mostly 15–30 μm, and not less than 10 μm. Thus, the large size of ganglion cells seems to be a common feature of different groups of marine mammals.

2. *Sea Otters* In the sea otter, the retina has many features similar to those in terrestrial rather than in aquatic mammals. The majority of ganglion cells are not of large size: 7–30 μm, mostly 11–15 μm. They can be subdivided into three size groups: large, medium, and small. The retina of the sea otter contains a large number of small amacrine and neuroglial cells.

V. Retinal Topography and Visual Field Organization

A. Cetaceans

Ganglion cells are distributed nonuniformly in the mammalian retina: ganglion cell density (number of cells per area unit) is high in some areas and much lower in the remainder of the retina. Regions of ganglion cell concentration (high density) provide the most detailed analysis of visual images. Characteristics of retinal topography in a variety of mammals are presented in a review by Hughes (1977).

In terrestrial mammals, there are two main types of organization of a region with high cell density. In mammals with frontal vision, highest density is in the fovea or area centralis located in the center of the visual field. This retinal area is little vascularized to avoid its shadowing by blood vessels. In mammals with laterally located eyes, the region of high cell density is shaped as a narrow horizontal strip, the visual streak. All terrestrial mammals studied until now have only one, if any, region of the highest ganglion cell density.

The cetacean retina does not have avascular areas that would indicate the presence of fovea or area centralis. Therefore, visual examinations of the eye fundus are not capable of revealing such regions. Data on topography of ganglion cell distribution in the cetacean retina were obtained using retinal whole mounts. Whole mounts are preparation of a total retina flattened on a slide, ganglion layer upward, and stained appropriately. Retinal whole mounts allow to count ganglion cells systematically across all the retina surface, thus constructing a topographic map of ganglion cell distribution. Studies of retinal whole mounts have shown that different regions of the cetacean retina have a very different density of ganglion cells (Fig. 6A,B). Beginning from the pioneering studies of Dral (1977), studies of cetacean retinal whole mounts were performed in a number of dolphin species, particularly, the common dolphin, bottlenose dolphin, harbor porpoise, Dall's porpoise, and Pacific white-sided dolphin (*Lagenorhynchus obliquidens*) (see detail in Supin *et al.*, 2001).

The most characteristic feature of these species is that, unlike terrestrial mammals, all of these marine dolphins do not have a single area of high ganglion cell density but two such areas. They are located near the horizontal diameter of the retina, one in the nasal and the other in the temporal sector (Fig. 7A). In the bottlenose dolphin, both these areas are located at a distance of 15–16 mm from the optic disk, which corresponds to 50–55° of the visual field. Ganglion cell density in each of these areas reaches 700–800 cells/mm², which corresponds to 40–50 cells per squared degree of the visual field (cells/deg²). The two high-density areas are connected by an elongated zone

Figure 6 Microphotographs of the ganglion layer in retinal whole mounts. (A,B) A bottlenose dolphin, (A) an area of high cell density and (B) an area of low cell density. (C,D) A harp seal, (C) an area of high cell density and (D) an area of low cell density.

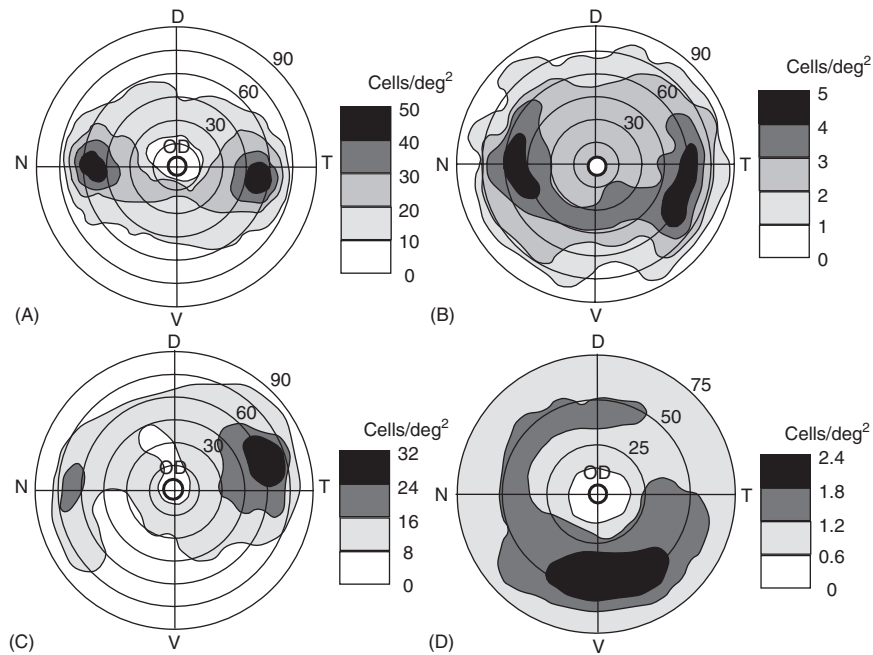

Figure 7 Topographic distribution of ganglion cell density in the retina of some cetaceans: (A) the bottlenose dolphin, (B) the tucuxi dolphin, (C) the gray whale, (D) the Amazon river dolphin. Cell density is expressed as a number of cells per squared degree of the visual field and is shown by various shadowing, according to the scales. Concentric circles show angular coordinates on a retinal hemisphere centered on the lens. D, V, N, T, dorsal, ventral, nasal, and temporal poles of the retina, respectively.

of increased, although somewhat lower, cell density, which runs below the optic disk; this zone looks like a visual streak.

In other dolphin species, the retinal topography is basically similar to that described earlier: there are two areas of high ganglion cell density. Even at low cell density in some cetaceans inhabiting turbid and low-transparent water (e.g., the tucuxi) the retinal topography looks the same (Fig. 7B). However, some quantitative differences do exist. In the bottlenose dolphin, the ganglion cell density is almost equal in the two areas, the nasal and the temporal areas, whereas in the harbor porpoise, the cell density in the temporal area (i.e., the region serving the frontal visual field) is higher than in the nasal region: 28 and 20 cells/deg², respectively.

The retinal topography of ganglion cells was studied in two mysticete species: the gray whale (*Eschrichtius robustus*) and common minke whale (*Balaenoptera acutorostrata*). Both of them also have ganglion cell distributions with two areas of high cell density, in the nasal and temporal sectors (Fig. 7C). Again, the cell density in the temporal area is higher than in the nasal one: 28 and 21 cells/deg² in the gray whale.

The significance of the two areas of high ganglion cell density (i.e., of high retinal resolution) is probably associated with the cetacean's capability of good vision both above and under water, in particular, with preventing the aerial myopia. Indeed, the high-resolution areas are located just opposite the two small pupil holes formed when the pupil is constricted in air (see Fig. 1A). Because of the centrally symmetric optics of the cetacean eye, light falls onto each of these areas through the opposite hole of the pupil. The areas of the cornea with minimal curvature are located across from these narrow pupil holes. Both the pinhole pupils and the low cornea curvature are devices

to prevent aerial myopia. Thus, images are projected onto the high-resolution areas of the retina with minimal distortions.

The two high-resolution retinal areas in cetaceans may be used differently for the underwater and aerial vision (Supin *et al.*, 2001). When a dolphin looks at an underwater objects, it takes a position lateral to the object; i.e., the object is placed into the posterolateral part of the visual field, which projects onto the nasal high-resolution area of the retina. On the contrary, when a dolphins looks at an object above water, it places the object into the ventronasal part of the visual field, which projects onto the temporal high-resolution area of the retina (Fig. 8). Of course, the temporal high-resolution area of the retina also participates in underwater vision. This area serves the frontal part of the visual field, which is very important for forward-moving animals. The existence of two high-resolution areas of the retina can also compensate for limited head mobility in many cetaceans. At low head mobility, even at high mobility of the eyes, a single high-resolution area allows the animal to inspect only a limited part of the surrounding space, whereas two such areas can provide almost panoramic vision.

The retina of the Amazon river dolphin is a special case. The visual system of this species is adapted to inhabiting low-transparent turbid water where vision is possible only at short distances. Contrary to all other investigated cetaceans, the retina of the Amazon river dolphin has only one area of higher ganglion cell density. However, this single area is located not in the center or temporal sector, but in the lower part of the retina, i.e., in the region responsible for the upper part of the visual field (Fig. 7D). In turbid low-transparent water, significant illumination exists only near the water surface, i.e., in the upper part of the visual field of a normally oriented animal. Just this part of the visual field is served by the ventral part of the retina where the Amazon river dolphin has higher retinal resolution. The density of ganglion cells in this region reaches 500 cells/mm²; with the small size of the eyeball, this corresponds to a cell density of about 2 cells/deg².

B. Pinnipeds

Few otariids has been subjects of study of the ganglion cell topography in retinal whole mounts (Supin *et al.*, 2001). All of them have a typical area centralis, well-defined area of high concentration of ganglion cells (Fig. 6C,D). It is located at a distance of 35–40° from the visual field center (Fig. 9A); taking into account the position of the eye in orbit, this place may be at the projection of the vertical meridian of the visual field. Thus, the position of this area is similar to that in terrestrial carnivores. Cell density in this area reaches 1000 cells/mm², which corresponds to more than 160 cells/deg².

Quite different is the retinal topography in the walrus. The area of increased ganglion cell density is not defined as clearly as in the northern fur seal. It looks like a horizontally extended oval, resembling the visual streak of terrestrial mammals (Fig. 9B). Within this streak, the highest cell density in its temporal part exceeds 1000 cells/mm²; because of the smaller size of the walrus eye, this cell density corresponds to only about 50 cells/deg². No phocid seals have been studied successfully yet with respect of their retinal topography.

C. Other Marine Mammals

1. *Sirenians* Ganglion cell distribution in the manatee retina presents an example of low specialization. There is no sharply restricted spot of cell concentration. Ganglion cell distribution is not

Figure 8 Characteristic positions of the dolphin body relative to visually inspected objects: (A) dorsal view (for both underwater and aerial vision) and (B) lateral view (for aerial vision). 1, an above water object; 2, an underwater object. Arrows show directions of light rays from an object to the corresponding high-resolution area of the retina.

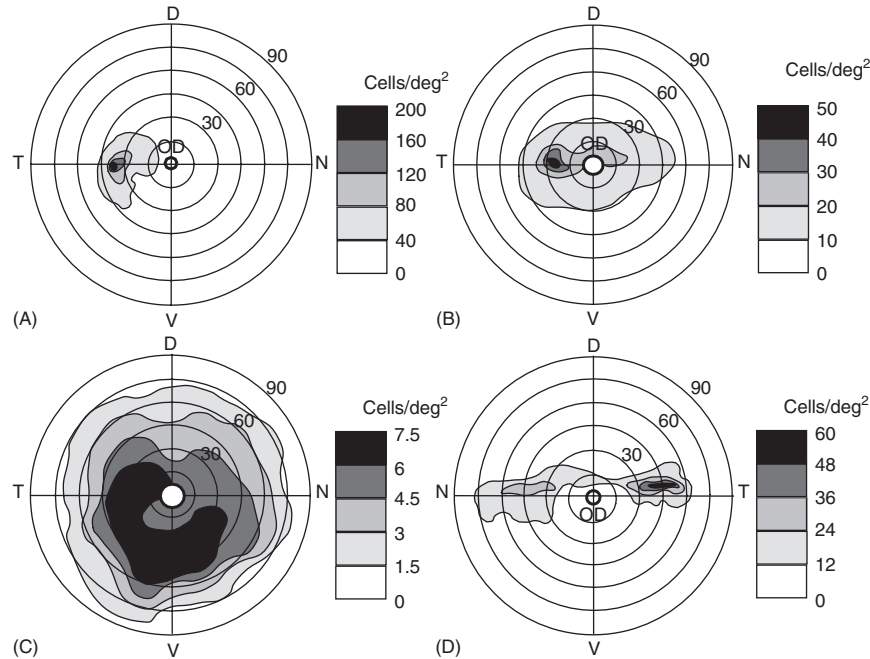

Figure 9 Topographic distribution of ganglion cell density in the retina of some pinnipeds, sirenians, and sea otters: (A) the northern fur seal; (B) the walrus; (C) the Caribbean manatee; (D) the sea otter. Cell density is expressed as a number of cells per squared degree of the visual field and is shown by various shadowing, according to the scales. Concentric circles show angular coordinates on a retinal hemisphere centered on the lens. D, V, N, T, dorsal, ventral, nasal, and temporal poles of the retina, respectively.

uniform but varies smoothly across the retina: cell density is higher in a large center part of the retina (except in the nearest vicinity of the optic disk) and diminishes toward edges (Fig. 9C). The highest cell density is about 250–300 cells/mm²; for a rather small manatee eye, this corresponds to 6–7 cells/deg².

2. *Sea otters* In the sea otter retina ganglion cell topography (Fig. 9D) has a number of features similar to that of terrestrial mammals. The high-density area resembles naso-temporal streak. Within this streak, in its temporal part, there is a narrow and well-defined spot of the highest cells density which is similar to the area centralis in terrestrial mammals. The highest ganglion cell density in the sea otter exceeds 4000 cells/mm²; in the rather small eye of the sea otter, this corresponds to 50–60 cells/deg².

D. Estimations of Visual Acuity from Ganglion Cell Density

Visual acuity is determined by two factors: quality of the eye optics and the retinal resolution. In normal eyes, these two values are in agreement. Therefore, retinal resolution can be used as a first-order estimate of the visual acuity. The retinal resolution depends on the density of ganglion cells (not of other retinal cells, e.g., photoreceptors, as ganglion cells transmit visual information to the brain). Thus, data on ganglion cell topography can be used to estimate the visual acuity of investigated species. When it is possible to compare estimates of visual acuity obtained by behavioral (psychophysical) methods and those based on ganglion cell topography, these estimates are in good agreement.

Retinal resolution (hence, visual acuity) is defined as the mean angular distance between neighboring ganglion cells; i.e., as $s = 1/\sqrt{D}$, where s is the angular distance between cells and D is the cell density per square degree. The estimation of retinal resolution is different in air and water: if the corneal surface is flat, the retinal image of an object in water is 1.33 times larger than in air (because the ratio of refraction indices of water and air is 1.33). Therefore, retinal resolution in water is 1.33 times better than in air. If the retinal surface is a little convex, this factor is less than 1.33 but still more than 1.

Retinal resolution in the areas of the highest concentration of ganglion cells (i.e., visual acuity in the best-vision areas of the visual field) was estimated in a number of marine mammal species (Table 1). In many cetaceans (except for river dolphins) it varies from 8 to 12 arcmin in water, correspondingly from 11 to 15 arcmin in air. For the bottlenose dolphin, the estimation of visual acuity obtained from the retinal topography almost coincides with that obtained in behavioral experiments. In general, the visual acuity of cetaceans is within a range of visual acuities of many terrestrial mammals, except the foveal vision of primates, where the visual acuity is around 1 arcmin. The Amazon river dolphin has much worse visual acuity: 40–50 arcmin in water; however, this value is adequate for vision in turbid water where objects are visible at best at a few tens of centimeters.

Among pinnipeds, rather acute vision is characteristic for the northern fur seal: better than 5 arcmin in water and better than 7 arcmin in air. This is close to estimates obtained in behavioral experiments in a number of both otariids and phocids: 5–8 arcmin (Schusterman, 1972). In the walrus, the visual acuity is worse than in seals: around 8 arcmin in water and 10 arcmin in air (Table 1).

TABLE I
Visual Acuity of Some Aquatic Mammals

<i>Species</i>	<i>Water</i>	<i>Air</i>	<i>Mode of measurement</i>
Odontoceti			
Bottlenose dolphin (<i>Tursiops truncatus</i>)	8–9	11–12	BR
Short-beaked common dolphin (<i>Delphinus delphis</i>)	8		R
Harbor porpoise (<i>Phocoena phocoena</i>)	11	15	R
Tucuxi dolphin (<i>Sotalia fluviatilis</i>)	25	33	R
Amazon river dolphin (<i>Inia geoffrensis</i>)	40	53	R
Dall's porpoise (<i>Phocoenoides dalli</i>)	11		R
False killer whale (<i>Pseudorca crassidens</i>)	9		R
Pacific white-sided dolphin (<i>Lagenorhynchus obliquidens</i>)	11		R
Beluga whale (<i>Delphinapterus leucas</i>)	12		R
Mysticetes			
Common minke whale (<i>Balaenoptera acutorostrata</i>)	7		R
Gray whale (<i>Eschrichtius robustus</i>)	11		R
Phocid and Odobenids			
Harbor seal (<i>Phoca vitulina</i>)	8		B
Harp seal (<i>Pagophilus groenlandicus</i>)	4	3	R
Otariids			
Northern fur seal (<i>Callorhinus ursinus</i>)	4–5	5–7	R
Steller sea lion (<i>Eumetopias jubatus</i>)	6–7		B
California sea lion (<i>Zalophus californianus</i>)	5–6	5–7	B
Cape fur seal (<i>Arctocephalus pusillus</i>)		6–7	B
Southern fur seal (<i>A. australis</i>)		7	B
Walrus (<i>Odobenus rosmarus</i>)	8	10	R
Sirenia			
Caribbean manatee (<i>Trichechus manatus</i>)	20–24		BR
Lutrinae			
Sea otter (<i>Enhydra lutris</i>)	7		R

Visual acuity is presented as minimal resolvable distance in minutes of arc, rounded to a whole number of minutes. In some cases, a range of variation is indicated (e.g., 11–12 arc min). Estimates of visual acuity are given for underwater (*Water*) and aerial (*air*) vision. In the column *air*, data are not presented when none of the authors attempted to interpret their results in terms of aerial visual acuity. When several estimates of visual acuity in different conditions are available (e.g., in the nasal and temporal best-vision areas in cetaceans, at various illumination conditions, etc.), the best estimate (i.e., the minimal resolvable distance) is selected. Mode of measurement: B, behavioral data; R, data on retinal resolution.

In the manatee, underwater visual acuity is around 20 arcmin (it remains unknown whether the manatee has good aerial vision). In the sea otter, the visual acuity is around 7 arcmin in water.

VI. Cerebral Visual Centers

In dolphins, the visual system is well represented in the midbrain (the superior colliculus), thalamus (the lateral geniculate body), and in the cerebral cortex. However, the visual centers (both the superior colliculus and the lateral geniculate body) are several times less in

volume than corresponding parts of the auditory system (the inferior colliculus and the medial geniculate body).

In the cerebral cortex of dolphins, visual representation was found by the evoked potential method. This area occupies a part of the cortex named the lateral gyrus (Fig. 10A). The cortical representation of the visual system in dolphins also is not as large as that of the auditory system; nevertheless, it occupies a significant cortical area. There is a differentiation within this area: it contains a zone generating short latency evoked potentials (i.e., the primary projection zone) and another zone generating evoked potentials of longer latency (a nonprimary

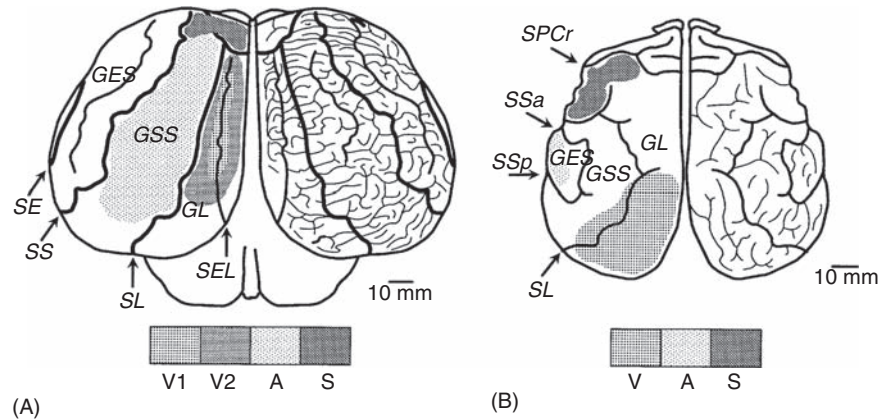

Figure 10 Position of projection sensory areas (visual, auditory, and somatosensory) in the cerebral cortex of cetaceans and pinnipeds: (A) the bottlenose dolphin and (B) the northern fur seal. Dorsal view of the cerebral cortex. On the right hemisphere, the pattern of cortical sulci and gyri is shown in more detail. On the left hemisphere, only main cortical sulci are shown and the positions of the visual, auditory, and somatosensory areas are indicated. The main sulci (labeled by arrows at their ends): SE, sulcus ectosylvius; SS, sulcus suprasylvius; SL, sulcus lateralis; SEL, sulcus endolateralis; SSa, sulcus suprasylvius anterior; SSp, sulcus suprasylvius posterior; SPCr, sulcus posterocruciat. The main gyri (labeled on their surface): GES, gyrus ectosylvius; GSS, gyrus suprasylvius; GL, gyrus lateralis; V, visual area (V1, primary projection zone; V2, nonprimary zone); A, auditory area (only a part of this area is visible in B); S, somatosensory area.

zone). The first of them is located in the depth of the entolateral sulcus (a second-order sulcus within the lateral gyrus); the latter occupies the remainder of the lateral gyrus. These two zones differ in cytoarchitectonic features: the primary projection zone contains an incipient layer IV (the layer where visual thalamocortical afferent fibers end), whereas this layer is absent in the nonprimary zone.

In mysticetes, which do not have echolocation, the sizes of visual and auditory structures in the midbrain and thalamus are comparable. Their cortical sensory areas were not investigated.

Among pinnipeds, the visual representation in the cerebral cortex was found by evoked potential method in one otariid species—the northern fur seal (Fig. 10B), and one phocid species—the Caspian seal, *Pusa caspica*. The location of this area is very similar to that in carnivores: the projection occupies the caudal part of the lateral gyrus.

VII. Conclusions

In general, the visual system of marine mammals demonstrates a rather high degree of development and performance, in particular, good visual acuity, capabilities to precisely aim visually driven behavior and intermodal transfer, and well-developed visual brain centers. This system also exhibits a number of specific features associated with adaptation to both aquatic and aerial environment, in particular, specific retinal topography (positions of best-vision areas) along with pupil and cornea structure which provide emmetropia in both air and water.

Walrus

Odobenus rosmarus

RONALD A. KASTELEIN

The walrus (Fig. 1; Fay, 1982) is the single species of the pinniped family Odobenidae and is distinguished from other pinnipeds by the upper canines in both sexes being prolonged as tusks. Walruses feed mainly on small organisms on the ocean floor, whereas almost all other pinnipeds feed primarily on highly mobile fish and crustaceans. For an animal of such a large size, this predator consumes organisms that are relatively low in the food chain. The diet of the walrus influences its biology: compared to other pinnipeds the walrus has a less streamlined body, swims more slowly, and dives less deep. Its sensory systems are adapted to its benthic foraging technique.

I. Characteristics and Taxonomy

The latin name *Odobenus rosmarus* means “tooth walking sea horse.” The genus *Odobenus* consists of only one species: *O. rosmarus*. Two sub-species are recognized based on morphological characteristics and on mitochondrial DNA divergence: the Pacific walrus (*Odobenus rosmarus divergens* Illiger 1815) and the Atlantic walrus (*Odobenus rosmarus rosmarus* Linnaeus 1758). A potential third sub-species, the Laptev walrus (*Odobenus rosmarus laptevi* Chapski 1940), is dubiously distinct from *Odobenus rosmarus divergens*.

The walrus is the largest pinniped except for the male elephant seal (*Mirounga* spp). The body is rotund; the girth at axilla is almost equal to body length. Males are larger than females of the same age. Adult Pacific walruses are on average slightly larger than adult Atlantic walruses of the same gender. Adult male walruses have an average body length of around 320 cm and weigh 1200–1500 kg; whereas adult females have a body length of around 270 cm and weigh 600–850 kg. Regional differences in body size per gender and age class exist.

Walruses are easily distinguished from other pinnipeds by their flat noses and enlarged upper canines that form huge tusks. Males have longer and thicker tusks than females. The tusks grow throughout life but growth is usually balanced by tooth wear. The large whiskers on the upper lips are translucent and yellowish and are directed forward. The eyes are small relative to body size compared to other pinniped species. They are positioned high on the head and can be protruded and retracted. There are no external pinnae. The color of the skin varies from gray when the walrus has just left cold water to yellowish brown when it is warm and dry. The fur is very short and is absent in some areas of the body. Although much variation exists, walruses generally

molt inconspicuously between May and June and grow new pelage in July and August. The appendages are hairless and the palms and soles are rough. The skin is 2–4 cm thick and very tough. It is thickest around the neck (about 4 cm) and in the area above the whiskers which is used for plowing through the ocean floor. The skin on the neck of adult males is thicker than that of females and is covered with fibrous tubercles. These tubercles are 1 cm thicker than the surrounding skin and protect the underlying tissues against tusk attacks by other males, and are an important visual sexual characteristic (Fig. 2). The blubber layer thickness varies depending on the part of the body and season, and can be up to 10 cm.

The skull (Kastelein and Gerrits, 1990) has some distinct features that relate to the ecology of the walrus. It is very thick and strong, as an adaptation to breaking through ice to make breathing holes. The front of the skull of an adult walrus is much higher and broader than that of other pinnipeds, to accommodate the large tusks. Males, which have thicker tusks than females, also have broader skulls. The tusks are composed of dentine covered with a thin layer of cementum. The ivory of walruses can be distinguished from that of other mammals by its central globular dentine. The heavy weight of the lower jaw probably serves to increase the impact of the tusks. The walrus is able to use its tusks to haul its body upward onto land or ice, because of the strong neck muscles attached to the large mastoid processes and the hinge between these processes: the condyle of the occipital bone. The zygomatic arch below the orbital cavity contains a strip of cartilage, probably to dampen shocks from the tusks to the brain case. In contrast to most pinnipeds, the orbital cavity is not closed on the dorsal side of the head, allowing the walrus to look in the direction it is moving upward during plowing through the substrate at 45°.

The spinal column consists of 7 cervical, 14 thoracic (occasionally 15), 6 lumbar (occasionally 5), 4 sacral, and 8 or 9 caudal vertebrae. There are 14–15 pairs of ribs. The hind flippers of the walrus rotate forward like those of otariids for locomotion on ice and land. The females have a 1- to 2-cm long clitoris bone. The penis bone (baculum) of adult males is up to 62 cm long.

Many of the muscles in the upper lip of the walrus are used to erect the whiskers in unison, although whiskers can be moved individually. The tongue muscles are very strong, and are used to create a low pressure in the mouth to extract the soft parts from clams. The mastication muscles are not very large, as the walrus usually does not chew its prey, but swallows it whole. The cheek muscles are strong, so that the walrus can produce powerful water jets from its mouth to wash sediment away from its prey.

The muscles in the hind limbs are similar to those in otariids. The adult walrus is so heavy and rotund that it does not lift its belly off the substrate when it moves on land or ice. Only calves can walk with just their flippers touching the substrate. In the water, the hind flippers are used for propulsion, and the front flippers mainly for steering.

The trachea is supported by cartilaginous rings throughout its length. It passes between the lungs for a third of their length, before bifurcating into bronchi. The lateral walls of the pharynx of sub-adult and adult males are extremely elastic and, when inflated, form air sacs (pharyngeal pouches). These sacs are used as resonance chambers for the production of the bell-like sounds underwater, and also for floatation when resting in the water.

The mouth is narrow and bordered by the tusks. The roof of the mouth is very concave, allowing room for the large tongue that acts as a piston when retracted quickly. The force (of up to 119 kPa) generated by this piston is used to extract the soft parts of clams from their shells. The non-tusk teeth are worn down to the gums in wild animals, perhaps by sand moving in the mouth during feeding. The

Figure 1 Adult male, adult female, and pup walrus (C. Brett Jarrett).

teeth are pointed in captive walrus that are fed on fish. The dental formula of the Pacific walrus' permanent dentition is as follows:

$$\begin{array}{l} \text{Incisors } \frac{(1) - (2) - 3}{(1) - (2) - (3)} \quad \text{Canines } \frac{1}{1} \quad \text{Premolar } \frac{1 - 2 - 3 - (4)}{2 - 3 - 4} \\ \text{Molar } \frac{(1) - (2)}{(1) - (2)} \times 2 = 18 \text{ to } 38 \text{ teeth} \end{array}$$

The teeth in parentheses are present in less than 50% of the adult specimens.

The tip of the tongue may be rounded or bifid. The stomach consists of one J-shaped cavity. The intestines are 10–15 times the length of the animal.

A conspicuous aortic bulb is present at the base of the aortic arch. The arteries to the fore limbs are larger than those to the hind limbs. This is related to the division of the muscle masses for the limbs; the muscles of the neck and shoulders are more developed than those of the pelvis area. The testes are situated between the skin and the muscles. The penis is normally retracted into an opening posterior

to the umbilicus. The uterus is bicornate and each horn opens separately into the vagina. Walrus usually have four nipples.

II. Distribution and Abundance

The Pacific walrus is principally found in the Bering Sea south to Bristol Bay and Kamchatka, and in the Chukchi Sea, although in summer it may enter the Beaufort Sea and East Siberian Sea (Fig. 3). Breeding occurs in late winter in the marginal ice zone of the Bering Sea. The location of the main breeding sites varies depending on the state of the ice, but is generally southwest of Nunivak Island and southwest of St. Lawrence Island. Pacific walrus move north in spring with the receding and drifting ice; females give birth on ice floes which drift north. They move south in autumn, following the movement of the pack ice. Their swimming speed is approximately 10 km/h. For most of the year, sexes and age classes live separately. The population presently is estimated at around 200,000 animals.

The Atlantic walrus is found in the western and eastern Atlantic Arctic (Fig. 3; Born *et al.*, 1997). Within their range Atlantic walrus

Figure 2 An adult male Pacific Walrus. Note the large diameter of its tusks, the bulging eye, and the pronounced tubercles of the skin on the neck. The latter feature is only seen in adult males. Photo: Ron Kastelein.

occur in several (perhaps eight) more or less well defined sub-populations—five to the west and three to the east of Greenland. In the western Atlantic Arctic walrus range from the East Canadian Arctic to West Greenland, including the Davis Strait, Baffin Bay, the archipelago in the Canadian high-Arctic, and Foxe Basin. The western Atlantic population is estimated now at more than 10,000. In the eastern Atlantic Arctic, walrus range from eastern Greenland to Svalbard (Norway), Franz Josef Land (Russia), and the Barents and Kara Seas. The eastern Atlantic population is estimated to be in the low thousands. Movement studies have shown a connection between walrus at Franz Josef Land and Svalbard and between the latter area and eastern Greenland.

The Laptev walrus (if this population is recognized as a sub-species) is found only in the Laptev Sea. The population has been estimated at 4000–5000 animals.

III. Ecology

The walrus is found in the Arctic, where its distribution is limited by the availability of shallow water foraging grounds and thickness of ice. Walrus prefer relatively shallow water over continental shelves, because they feed on invertebrates which occur on the ocean floor up to a depth of about 80m. Walrus can break through ice up to about 20cm thick, but when the ice is thicker than this, they retreat to areas with drift ice. Thus, in winter walrus inhabit those regions of the drifting ice where leads and polynyas (irregular areas of open water surrounded by sea ice) are numerous and where the ice is thick enough to support their weight.

Male Pacific walrus rest in traditional terrestrial haul-out sites (sand, cobble, or boulder beaches), whereas females and calves prefer to haul out on pack ice or ice floes. In summer, males rest and molt while hauled on land out close to their feeding grounds. Females molt when hauled out on ice. Atlantic walrus also molt in the summer and during that time both males and females (sometimes in the same groups) haul out on both land and ice.

The diet of walrus consists mainly of benthic invertebrates. By far the most commonly eaten are bivalve mollusks, which are found buried in the sediment in high-density beds. How walrus find these beds is unknown. When they find a mollusk bed, they plow through the sediment with their snouts, while swimming with their

bodies at a 45° angle to the ocean floor, to find prey items. When foraging by plowing through the sea bed with its snout in search of invertebrates, the walrus uses its tusks and fore flippers as sleds while swimming with its hind flippers. Long furrows in the sediment have been observed in walrus feeding areas.

Once the walrus encounters a potential food item, it is quickly identified by the sensitive whiskers. If it is a bivalve mollusk, the foot or siphon is taken between the mobile lips, and by means of retraction of the large tongue, the soft parts are sucked from the shells and swallowed. The empty shells are discarded and can be found on the ocean floor near the furrows. The walrus can produce strong water jets with its mouth to excavate its prey, but can also remove sediment by producing strong water currents with movements of its fore flippers. The whiskers can be moved individually and are probably used as a tool to manipulate clams so that the foot is directed toward the walrus' mouth. Once a prey item is in front of the mouth, the tongue probably takes over as a touch and manipulation organ.

Compared to most other pinnipeds, walrus consume organisms that are small and low in the food chain. The large walrus has to consume many small organisms and must have a very efficient feeding method. In fact, walrus dive for up to 24 min (average around 5 min), usually spend 80% of that time on the bottom, and generally obtain 40–60 clams per dive. Dive times probably vary depending on water depth, prey type, and prey density. Adult walrus require on average about 25kg of soft clam parts per day and a walrus has been found with 6000 prey items in its stomach. In captivity, Pacific walrus sometimes eat up to 50kg of fish per day. Walrus probably store extra fat during summer when they can exploit their inshore foraging grounds, and use this during migration when they swim in waters that are too deep to contain their main prey.

Unusually, individual walrus may take a vertebrate diet. These animals usually kill seals and cetaceans as well as scavenge on their carcasses, from which they suck the blubber and internal organs. Seal-eating walrus thus consume organisms that are higher in the food chain than those consumed by mollusk-eating walrus and therefore carry a relatively high concentration of heavy metals and PCBs. Walrus sometimes also capture and eat sea birds.

IV. Behavior and Physiology

The walrus has well-developed extrinsic eye muscles. The orbital cavity is not closed on the dorsal side. This allows the walrus binocular vision in the frontal and dorsal direction, as it can protrude its eyes, and does so mostly when excited. The lack of a roof of the orbital cavity suggests that the eyes are vulnerable to mechanical injury. However, the walrus eye has strong retractor muscles. The eyes can be pulled deep into the orbital cavity for protection, and the eye opening can be closed with thick eyelids. Blood vessels and surrounding fat probably serve to keep the eyes warm and functional in cold temperatures. Under high light conditions, the pupil is a vertical slit, during moderate light levels key-hole shaped, and under low light conditions circular. Retinal anatomy suggests that the walrus has color vision, but no psychophysical tests have been carried out, so that is unclear which part of the spectrum it can detect. Visual acuity appears to be less than in other pinnipeds so far investigated, and the eyes of the walrus seem to be specialized for short-range vision.

Because walrus dive up to 130m and also at night, they often cannot always use vision to detect and process their prey. Instead, they use their sensitive mystacial vibrissae (whiskers). Each walrus has about 450 whiskers, which are highly innervated by sensory and motor nerves. The main sensory nerve of the face (Trigeminal nerve) is well

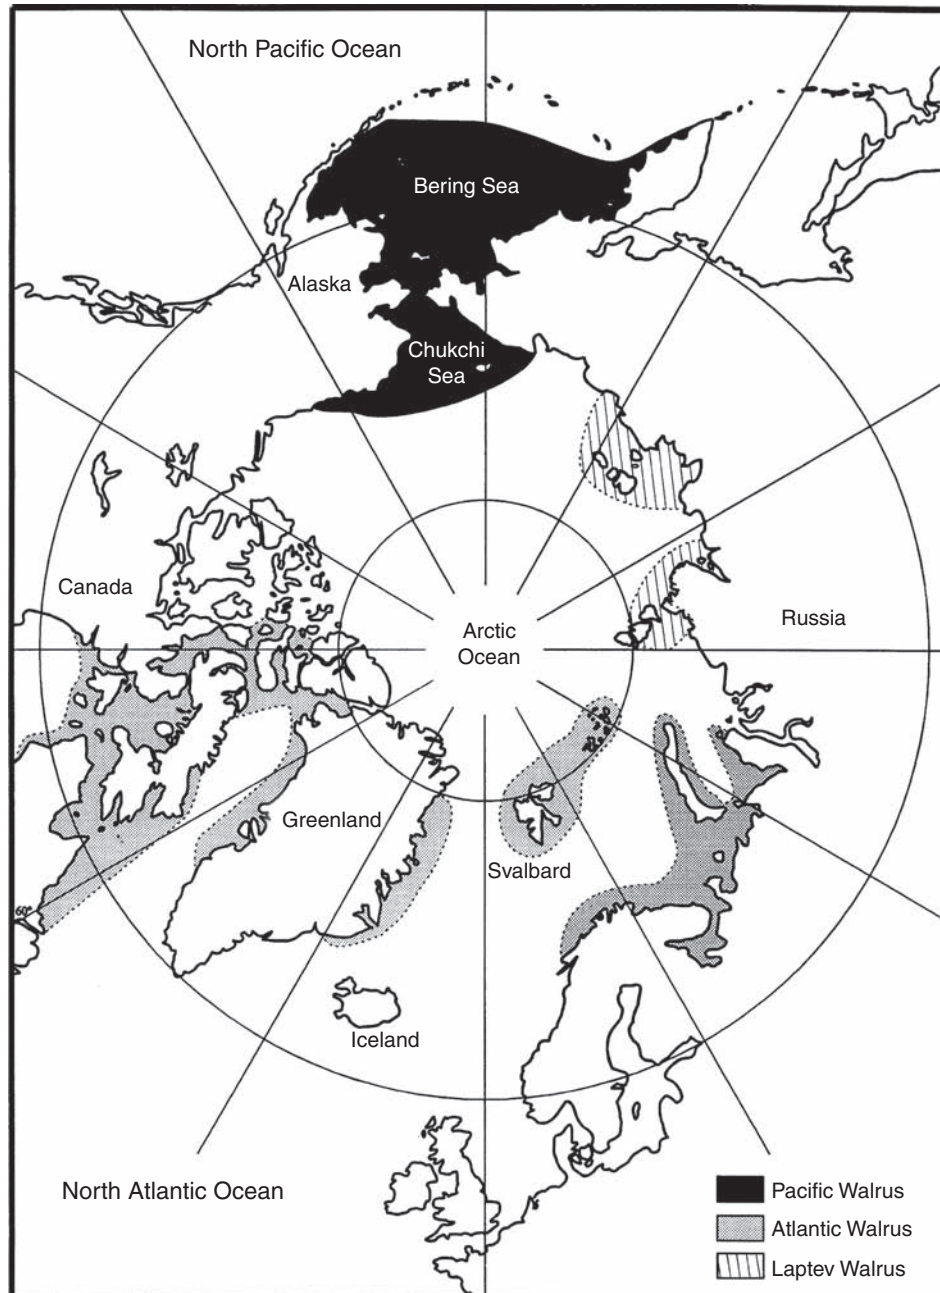

Figure 3 The distribution of the three walrus subspecies (the recognition of the Laptev walrus as a subspecies is controversial).

developed and the infraorbital foramen in the skull is proportionally large to accommodate it. In contrast to most other pinnipeds, which probably use their whiskers to detect vibrations in the water, walruses use their whiskers to examine and manipulate small objects. In a psychophysical test, a captive walrus could distinguish a circle and a triangle which each had a surface area of 0.4cm^2 . The longer and thicker lateral whiskers are mainly used for the detection of objects, whereas the shorter and thinner ones near the mouth opening are primarily used for identification. The tip of the tongue also contains many mechano-receptors, and can be used to identify or reposition prey.

The behavior of the walrus on land and on ice suggests that it probably relies to a high degree on its sense of smell to obtain information about its surroundings. Anatomical evidence also suggests the

importance of olfaction to walruses. They have large nares that can be closed during dives, and the nasal passage is highly vascularized so that air that passes through it can be heated. However, no conclusive psychophysical tests have been conducted on the olfactory sensitivity of the walrus. Compared to many terrestrial mammals, the walrus has relatively few, but large taste buds. However, not much is known about the taste abilities and discrimination in walruses. Anecdotal information on captive animals suggests that they are not very sensitive to (bitter) flavors that are disgusting to most terrestrial mammals.

The walrus has limited ability to locate the source of sounds, as evidenced by its lack of pinnae. When the walrus is in air, sound reaches the tympanic membrane via a large cartilaginous outer ear tube. The aerial hearing has been tested, and is less acute than that of humans in

the frequency range tested (125 Hz to 8 kHz). When diving, the walrus closes its auditory meatus, and hears by tissue conduction, probably mainly via the vascular lining of the outer ear tube. The underwater hearing range of the walrus has an upper limit of 16 kHz.

Male and female walruses usually do not have contact with each other for most of the year, but animals of each sex congregate in large numbers both in winter and in summer.

Walruses seem to prefer being in groups. Walruses literally pile on top of each other (probably to conserve heat) in dense aggregations, and spend most of their haul-out time resting. On land, they are usually in deep sleep and are difficult to wake up. They often lie up-side-down, perhaps to reduce the pressure on their lungs. In this position their tusks point upward, they can stretch their necks, and surplus ear wax can drain from their ears. Body size and tusk length play important roles in establishing the hierarchy at haul-out sites. The tusks are used for display and as weapons in fights between walruses, as weapons against polar bears and killer whales (which may prey on walrus calves). They also aid in hauling out on ice floes and shores and serve to enlarge and keep open breathing holes in the ice. In addition, they function to hold heads above water by resting at the edges of ice floes.

Several aerial acoustic signals are used in a social context: barking, coughing and roaring when excited, whistling by males during the reproductive period (source levels of around 120 dB re 1 pW have been recorded), and soft calls from the females toward their calves. Alarm calls and other calls of calves have been described. Underwater, bell-like sounds are produced by the air sacs of adult males. Walruses have well-developed facial muscles and can make many facial expressions, which probably play a role in short-range communication.

V. Life History

Females generally begin to ovulate at around 7 years of age (but some ovulate at the age of 5 years), and usually give birth for the first time at the age of 9 years. Males become sexually mature between 7 and 10 years of age, but become physically and socially mature, and therefore able to mate, at the age of 15 years. Walruses can reach an age of 30 to 40 years.

Adult male and female walruses congregate during the mating season (January–April). Walruses are polygynous. In the mating season adult males fight intensively in the water, evidently in competition for display sites near females. During courtship, the male walrus emits a stereotyped sequence of underwater sounds consisting of taps, knocks, pulses, and bell-like sounds. This acoustic display probably serves as an advertisement to females and as a warning to other males. Females choose a mate from among the displaying males. Copulation usually occurs in the water, but has been observed to occur on land in captivity, although a pool was available.

After a gestation period of about 15 months (including a period of delayed implantation of 4–5 months), a single calf of around 60 kg and 120 cm in length is born in spring (April–early June). Calves can swim immediately and may sometimes be carried on their mothers' backs for a while. The coat of the calves is slate gray. They are suckled for at least a year (on land, on ice, and in the water), and are usually gradually weaned during their second year, when they begin to forage for invertebrates. Reproductive females can produce about one calf in 3 years. The calves remain near their mothers, in groups of adult females, for several years. Most calves are weaned by the age of 3 years, when juvenile males tend to join male herds. The high degree of maternal care and low predation rate result in low natural mortality in walrus calves. This probably allows the walrus to have fewer offspring than other pinnipeds, most of which produce a calf every year.

VI. Interactions with Humans

Atlantic walrus stocks were greatly reduced by intense exploitation in the eighteenth and nineteenth centuries by European whalers and sealers (for ivory, oil, and hides), and appear at present not to have recovered fully. The Pacific walrus population recovered from intense hunting, but, for unknown reasons, may have started to decline again.

Atlantic walruses are still hunted for subsistence by native people of Canada and Greenland. For the same purpose, Pacific walruses are taken by indigenous peoples of Russia and the USA (Alaska). Atlantic walruses are fully protected at Svalbard (since 1952) and in the western Russian Arctic (since 1956). Potential threats to walrus populations are: over-hunting, competition with shellfish fisheries, accidental bycatch by trawlers, pollution (PCBs, heavy metals, nuclear radiation), water borne noise at their foraging areas, aerial acoustic disturbances at their resting places (snow mobiles, aircraft, ships, oil and gas exploration), and habitat destruction by bottom trawling.

The first walruses in captivity were in Denmark and Germany. Later, zoological parks in The Netherlands, USA, and Russia began to keep this species. Captive walruses often ingest foreign objects that they cannot digest. A walrus can even die from consuming too many dead leaves that drop in pools in autumn. Another problem is the wearing down of tusks on the pool floor and walls, which, in severe cases, can cause root infections of the tusk.

When properly cared for, walruses are friendly and easily trained. They can perform for the public as well as in psychophysical research projects. Occasionally, males become difficult to handle after they reach maturity. Walruses can be kept in good health on diet of whole fish, which they swallow without chewing. Reproduction in parks and zoos has improved since the mid-90s, but only a few calves have been raised by their mothers, as walrus mothers are very protective of their calves toward both conspecifics and humans. This causes the mother to neglect her calf (she spends more time defending the calf than nursing it) or reduces the production of milk. The main problem in the early years of husbandry was the lack of a good formula to raise calves without milk-producing mothers. This problem has been overcome and calves from the wild or captive born ones can be hand-raised without nutritional deficiencies.

Weddell seals are black with grayish silver streaks, with individual variations (Fig. 1). The adult pelt does not have underfur. In pups, the light gray lanugo is longer and thicker than adult hair and is shed by 44 days of age. There is no dramatic SEXUAL DIMORPHISM in body size; males reach 2.5–2.9 m and females are 2.6–3.3 m in length. Weights range from 400 to 500 kg, with pregnant females being the heaviest. At birth, pups weigh 22–29 kg and are about 1.5 m in length.

As with other phocids, the Weddell seal has a fusiform body shape and laboriously crawls on its belly or rolls to move on ice. It is not capable of upright stance or moving the hind limbs forward. Under water, the Weddell seal propels itself by moving the hind flippers in a horizontal plane. The manus is a flipper and the pes fully webbed. The first metacarpal is noticeably larger than the others. Black claws on the front flippers are large and useful for gripping the ice or scratching. Claws on the hind flipper are reduced in size. The tail is distinct and free.

The large brown eyes often have wet circles around them because of no lacrimal duct. A tapetum on the back surface of the retina assists in seeing in low-light levels, especially during the austral winter and deep dives. A nictitating membrane protects its eyes from blowing snow and allows its eyes to be open in salt water. The species has excellent VISION under water.

The external ear is absent; the cochlea is about 10 mm high and forms about two and a half turns. The organ of Corti contains one row of inner and three rows of outer hair cells. Microscopic examination of the ear did not reveal obvious specializations for high-frequency hearing. A preliminary attempt was made to measure the in-air hearing of a Weddell seal using auditory evoked potentials and auditory brainstem responses on immobilized Weddell seals, but difficulties in the field precluded completion of an audiogram.

The nostrils are oriented vertically and normally are closed, but open when the seal needs to respire. There are seven rows of mystacial vibrissae and superciliary whiskers that are smooth, not beaded as in some pinnipeds. The tip of the tongue is notched. Testes are abdominal, the penis is retractable, and there is a baculum. The uterus is bipartite. Two mammary glands are present and the milk is exceptionally high in fat and protein content.

The seal has a simple stomach and eats whole fish, heads down first. There are 34 chromosome pairs in this species.

The dental formula is 2/2, 1/1, 4/4, 1/1. The milk teeth disappear before or soon after birth. Cheek teeth have three points and are homodont, but are not the exaggerated tricuspid structure of the crabeater and leopard seals. The outer incisors are larger and procumbent or project forward. The canines also are procumbent and, along with the last incisor, are used in "ice-sawing" behavior. The seal maintains circular breathing holes in the fast ice by turning within the hole and raking ice off the rim of the hole with its teeth. Such behavior allows the seals to maintain holes for breathing and hauling out throughout the year.

Weddell Seal

Leptonychotes weddellii

JEANETTE A. THOMAS AND JACK TERHUNE

I. Characteristics and Taxonomy

The Weddell seal belongs to the family Phocidae, subfamily Monacinae, and tribe Lobodontini (Bertram, 1940; Kooyman, 1981; Nowak, 1991 for general reviews). There is a single species within the genus *Leptonychotes*. The closest relatives are the other Antarctic seals in the tribe Lobodontini, i.e., crabeater, *Lobodon carcinophaga*; leopard, *Hydrurga leptonyx*; and Ross seals, *Ommatophoca rossii*; and the monk seals in the tribe Monachini, i.e., Caribbean, Mediterranean, and Hawaiian monk seals, *Monachus* spp. The subfamily Monachinae evolved in the North Atlantic during the Miocene. A fossil, *Homiphoca*, found off the South African coast could be the intermediate form between monk seals and Antarctic seals.

II. Distribution and Abundance

The Weddell seal has a circumpolar distribution around Antarctica, preferring land-fast ice habitats, but the proximity to open water and pack ice also influences the distribution of haul-out sites in fast-ice areas. In the winter, the propensity for the fast ice to crack is the major determinant of Weddell seal distribution. The seals haul out through cracks in the fast ice formed from tidal action. This fast ice provides a stable platform for giving birth to pups, nursing pups, hauling out to avoid predators, and resting. There is no predictable migration in this species, and both males and females exhibit breeding site fidelity

Figure 1 Weddell seal.

(Cameron *et al.*, 2007). Some seals maintain holes in coastal land-fast ice throughout the dark austral winter while others frequent the offshore pack ice or move back and forth, presumably to forage offshore and return to rest on the stable fast ice. Occasionally, seals are seen at subantarctic islands, including South Shetlands, the South Orkneys, and South Georgia. Single wandering Weddell seals have been found in remote locations such as Heard, Kerguelen, Macquarie, Auckland, Juan Fernandez, and Falkland/Malvinas Islands, as well as Australia, New Zealand, Patagonia, and Uruguay.

No systematic, large-scale population census studies have been conducted, so estimates in the literature are approximate. The Weddell seal is abundant; the estimated range is from 500,000 to 1 million seals. However, population studies following a recent calving of a glacier in McMurdo Sound demonstrate the ability of the species to shift their distribution and adapt to new haul-out sites. Several studies of population dynamics have been carried out (Stirling, 1971; Siniff *et al.*, 1977; Testa, 1987; Testa and Siniff, 1987; Testa *et al.*, 1990; Cameron and Siniff, 2004).

III. Ecology

The diet includes the large Antarctic cod (*Dissotichus mawsoni*), and smaller fish (*Pleurogramma antarcticum*, *Pagothenia borchgrevinki*, and *Trematomus* spp.). The seals sometimes startle fish by blowing bubbles at them and erect their vibrissae when near a fish (Davis *et al.*, 1999; Plötz *et al.*, 2001).

Weddell seals do not exhibit the scars from leopard seal predation that are seen on crabeater seals. However, killer whales (*Orcinus orca*) are known to take Weddell seals of all ages. When killer whales and leopard seals move into areas of Weddell seals, *Leptonychotes* suddenly and dramatically stops calling underwater, perhaps to avoid detection (Thomas and Kuechle, 1982; Thomas *et al.*, 1983).

IV. Behavior and Physiology

Weddell seals are extremely good divers, commonly diving to about 600 m for up to 82 min, although shallower dives of <20 min are typical (Elsner *et al.*, 1970; Kooyman, 1981; Wartzok *et al.*, 1992; Harcourt *et al.*, 2000). Some seals range out to 5 km from a breathing hole and returning on a single dive. A great deal about their DIVING BEHAVIOR has been documented using satellite tags with time-depth recorders and video cameras attached to the seal's back. Before a dive, the seal exhales slightly and the nostrils and mouth are closed. Seals usually make a series of short shallow dives before commencing on a longer dive. In one study in the dark of February, the seals foraged almost exclusively in the upper water column at night but often dove to 340–450 m during the day for benthic feeding. Typical swim speed is 8–12 km/h and the descent rate for a dive is 35 m/min, whereas a foraging seal has a swim speed of 0.7–1.8 m/sec. Sometimes the ascending

dive retraces the path of the descending dive. During a dive, the lungs collapse, the trachea compresses, blood is shunted to the extremities, the metabolic rate drops to about 20% of the resting rate, and the heart rate undergoes bradycardia, dropping from about 85 to 16 beats/min. The blood and muscles have a 3–5 times greater oxygen-carrying capacity than those of humans.

Males patrol using loud (up to 193 dB re 1 μ Pa) trills to advertise and defend their underwater territories, which cover an area 15–50 m wide by 50–400 m long. Sometimes bloody fights occur between males underwater and even continue onto the ice, with the loser evicted from the territory. Territorial males are rarely found more than 1 km from the colony. The underwater repertoire of Weddell seals is elaborate, including over 30 sound types, and many repeated call types have up to seven rhythm patterns. Some researchers suggest the species has song. Their sounds are some of the longest among marine mammals, ranging up to 70 sec. Over 100 calls/min have been recorded at a colony in darkness in the winter and during the height of the breeding season. GEOGRAPHIC VARIATIONS in the repertoire have been documented among McMurdo Sound, Palmer Peninsula, and Davis Station and Mawson Station seals.

The seals stay warm with a thick layer of subcutaneous fat, often remaining hauled out on the ice covered with snow. On warm Antarctic days, steam can be seen rising from their bodies and heat dissipation may be necessary. Weddell seals can dilate blood vessels in the skin to dissipate heat or constrict them to conserve body heat. During winter, however, few seals haul out.

Water is obtained metabolically through the diet; sometimes the seals eat snow. The KIDNEYS are reniculate, adapted for conserving water and removing high salt loads.

V. Life History

The mating system is likely a variation of harem defense polygamy in which dominant males fight to establish territories at breeding sites, but the territory is underwater (Bartsch *et al.*, 1992). Adult males are not tolerated on the ice in maternal colonies. Occasionally a non-breeding, adult male is seen at the periphery of the colony. Some males establish underwater territories around breathing holes that freeze up in early winter and others arrive and compete for territories after the females give birth. Subadult seals are rarely seen in breeding colonies. They tend to congregate in large groups near the ice edge.

The mother Weddell seals return to tidal cracks each austral spring and give birth to pups from late September to early November, depending on the location (Lugg, 1966; Gelatt *et al.*, 2000; general reviews). Typically, a single pup is born, but twins have been observed and even an albino pup was reported. A few mothers have pups in isolation from other seals, but most give birth in colonies of up to 50 mothers with pups. Mothers and pups maintain

individual spacing when hauled out on ice. When disturbed, mothers vocalize to intruders. Pups nurse for a 7- to 8-week period, gaining almost 2 kg per day. At weaning, pups weigh about 125 kg and mothers have lost nearly twice that amount of weight because they do not forage during the nursing period. Pups are first enticed into the water by their mother's calling at 10 to 14 days of age. Pups struggle to swim and stay under the water, popping to the surface. Some pups die in the breathing holes, not being able to crawl out of the slippery, steep hole. Mothers and older pups go into the water progressively more often as the pup grows. They exhibit a distinct diel pattern of haul-out, with most seals hauling out in the colony for several hours around midday.

Mating takes place in the water, with about 80% of females becoming pregnant, at least in the McMurdo Sound area. Once the pups wean, the mother enters the water to feed and mating occurs within a male's territory. Adult seals molt after mating. Implantation of the blastocyst is delayed until mid-January. Because of delayed implantation, pups are born the following spring at approximately the same time of year. Delayed implantation allows the mother to molt, feed, and recover from the dramatic weight loss associated with lactation before another fetus starts to develop.

About the time the last pup in the colony weans in mid-December, the fast ice begins to break up, adults disperse, and newly weaned pups are left to fend for themselves. Some data taken from pups with transmitters indicated pups feed near shore on small fish such as *Pleurogramma* spp. This may be a vulnerable period for Weddell seals because the breakup of the fast ice provides access for predators, like killer whales and leopard seals, to the colonies.

VI. Interactions with Humans

This species is the most studied of all Antarctic pinnipeds because the seals can be found reliably in breeding colonies at traditional sites. The use of traditional haul-out sites has facilitated research on this species since the early 1960s. Several investigators have maintained research programs near the US bases at McMurdo Sound and Palmer Peninsula, the New Zealand Scott Base, the Australian bases, Davis and Mawson in Eastern Antarctica and the German bases in the Weddell Sea. The seals have little fear of humans because there are no natural land predators like the Arctic polar bears (*Ursus maritimus*).

In 1957, the International Geophysical Year established the importance of conservation and research in the Antarctic. The Antarctic treaty was signed in 1961, establishing the protection of the species and its habitat. During the 1970s and 1980s, inhabitants of the New Zealand station in McMurdo Sound took Weddell seals to feed their sled dogs over the winter. This practice has stopped. Otherwise, there is no record of extensive harvest of this species. Today, Weddell seals encounter humans as various ships resupply research stations and occasionally as passengers on ecotourism vessels disembark on the ice.

Whale Lice

CARL J. PFEIFFER

Whale lice (cyamids) are crustacean ectoparasites living on the skin of some species of cetaceans. Whale lice remain among some of the world's biologically most specialized but least understood crustaceans. The current lack of knowledge about these animals undoubtedly stems from the fact that their natural habitat is limited to the skin surface of primarily slow-moving baleen whales, which themselves are difficult to study because they are generally submerged and constantly moving. Accordingly, it is very difficult for scientists to observe, in their natural setting and over extended periods of time, the behavior and biologic processes of whale lice. Some features have been learned, however, by a small number of scientists who have studied these interesting crustaceans for over a century, and the following brief account reviews these data.

I. Classification

Whale lice are actually not lice but perhaps they acquired this nickname in the 1800s from whalers who noticed that they crawled, presumably as parasites, on the surface of the whale's skin and that their size, in proportion to that of a great whale, was comparable to the size of louse on a human or dog. Whale lice are arthropods of the subphylum Crustacea, class Malacostraca, order Amphipoda, family Cyamidae, and genus *Cyamus*. As such they are closely related to other more commonly observed amphipods such as sand hoppers and caprellids, i.e., common marine peracarids. Altogether there are more than 5000 crustacean species, but only 23 known species of whale lice or cyamids. At least 15 of these comprise the genus *Cyamus*. Because the practice of WHALING has such a long history, cyamids were historically documented early, including *Cyamus ceti* by Linné in 1758, a genus described further by Latreille in 1796. A number of species were classified in the 1800s, including *C. ovalis* in 1834, *C. delphini* in 1836, *C. boopis* in 1870, and *C. scammoni* in 1872, and these cyamids were found on southern right whales (*Eubalaena australis*), humpback (*Megaptera novaeangliae*), gray (*Eschrichtius robustus*), and other large whales. Species names have occasionally been revised for cyamids and new species were discovered even late in the twentieth century, such as the two new cyamids reported on one of the large beaked whales, the Baird's beaked whale *Berardius bairdii* (Waller, 1989). Genus names for cyamids have also been changed over time and the earlier genus *Paracyamus* is no longer considered valid.

Figure 1 The life stages of humpback whale cyamids (*Cyamus boopis*).

II. General Ecology and Morphology of Cyamids

Although information does not exist on the early development of cyamids, their evolution has undoubtedly been closely coupled with the long evolution of cetaceans, which first began around 55 million years ago when terrestrial species returned to the marine environment as precursors of the modern whales. Thus, modern cyamids show little resemblance to other crustaceans and have become greatly specialized for their parasitic and lifelong relationship to whales. They have a high degree of host specificity to whales, and one species, *C. boopis*, is found only on humpback whales (Fig. 1) and another species, *C. scammoni*, only occurs on the gray whale. Some other species of whale lice overlap their residence on two to four species of whales. The two isolated Arctic odontocetes, beluga whales (*Delphinapterus leucas*) and narwhals (*Monodon monoceros*), each share the same two cyamids, *C. monodontis* and *C. nodosus*. Table I summarizes the cetacean distribution of cyamids. Cyamids are unable to swim freely in the sea or from whale to whale at any of their developmental stages. Accordingly, they die if they lose their foothold on their host, but can be transferred from cetacean mother to calf or during cetacean mating. Although details on the number of juvenile stages that occur prior to adulthood are not yet established for cyamids, Leung (1976) has estimated that at least seven to eight instar stages exist for *C. scammoni* of the gray whale.

Although the general gross body structure of cyamids has been described elsewhere (Margolis, 1955; Leung, 1967; Berzin and Vlasova, 1982), very few studies have been directed toward the microscopic anatomy of cyamids. Early work on the musculature and very recent work (Levin and Pfeiffer, 1999) on cyamid ocular structure have been reported. Their small, paired eyes appear almost rudimentary. However, ultrastructural analysis of these photoreceptors for *C. ceti* has revealed well-developed sensory organs with each eye containing about 50 visual ommatidial units and an overall organization similar to other amphipod compound eyes. The exoskeleton of cyamids consists of a chitinous cuticle that is similar to that typically observed for other crustaceans. It has an exocuticle with multiple microfibrillar lamellae and an endocuticle traversed by both pore canals and dense fibers, as revealed by electron microscopy (Pfeiffer and Viers, 1998).

Cyamids are SEXUALLY DIMORPHIC. The males are larger and, depending on species, adult cyamids usually range from approximately 6 to 19mm in length. The most striking features of their appearance are their marked degree of segmentation and prominent gnathopods,

TABLE I
Distribution of Cyamid Species on Cetaceans^a

Host	Whale lice
Mysticeti	
Bowhead whale, <i>Balaena mysticetus</i>	<i>Cyamus ceti</i>
Right whales, <i>Eubalaena</i> spp.	<i>C. ceti</i> , <i>C. erraticus</i> , <i>C. gracilis</i> , <i>C. ovalis</i> , <i>C. catadontis</i>

Figure 2 Two specimens of *Cyamus ovalis*. The head region faces the top. Note segmented body and antennae.

or legs, with large dactyli, or hooks, that assure firm attachment to the host. The body is flattened and divided into a small cephalic-cephalon or head with paired, minute eyes, and segmented pereion or body to which are attached two pairs of gills and four pairs of gnathopod-type appendages. Fig. 2 illustrates the general body structure for *C. ovalis*.

Cyamids are mostly found on those areas of the whale surface most protected from the turbulence of water flow, which on baleen whales include regions around barnacles, skin folds or ventral grooves of the head, protected zones around the blowholes, eyes, and flippers, margins of the lips, on callosities, wounds, and genital slit (Fig. 3). In those species of whales that serve as host to several species of cyamids, there may be differences in the spatial distributions of the different species of whale lice, and within one species of cyamid the reproductive status and sex of the cyamid may alter the spatial distribution (Rice and Wolman, 1971; Balbuena and Raga, 1991; Rowntree, 1996). Whale lice do move around on their cetacean hosts; in the case of *C. boopis* of the humpback whale, the larger males may carry their smaller female mates and, in an artificial aquarium setting, were observed to walk at a rate of 4.5 m/h (Rowntree, 1996).

Whale lice breathe by means of two pairs of external gills, which are much reduced in size in early juvenile stages. It has been reported that they can live for up to 3 days out of an aquatic environment, such as on a stranded whale, suggesting that they can also rely on integumentary respiration (Leung, 1976).

III. Feeding Habits of Cyamids

It was speculated for a long time that whale lice fed on whale skin and hence they were deemed ectoparasites. Some workers suggested that they might be omnivorous and ingest algal filaments or suspended materials or plankton in the water near their attachment

Figure 3 Aerial survey photo of mother and calf right whale (*Eubalaena* spp.) pair showing orange genital slit cyamids (*Cyamus erraticus*) covering the calf's head and *C. ovalis* (white cyamids) on the mother's callosities. Photo by J. Atkinson.

site. However, their mouth parts are very small compared to their body size and they do not possess claws such as some other crustaceans or food-gathering cirri such as some predatory, sessile crustacean barnacles (Pfeiffer and Lowe, 1989). Cyamids have poorly developed paired mandibles and incisor processes with strong chitinous teeth that appear well suited for piercing and scraping skin. Rowntree (1983) showed that the color of intestinal contents of cyamids from humpback whales matched the skin color (black or white) from which the cyamids were collected. More recent conclusive evidence has proven that whale skin is a principal dietary material of cyamids. Both electron microscopic proof of whale skin keratinocytes within the upper digestive tract of cyamids and stable isotope evidence have shown that the dietary staple of whale lice is whale skin. Analysis of stable carbon and nitrogen isotope ratios from cyamids and skin from six species of whales have shown that the cyamid stable isotope ratios closely matched those of whale skin, but not those of zooplankton from the sea where the cyamids and whales reside (Schell *et al.*, 2000). Also supporting this conclusion is the evidence of direct damage to the skin by whale lice (Leung, 1976). Thus, cyamids have evolved into the only obligate parasites among the amphipods in distinction to other amphipods, such as caprellids, which are predatory and feed on diatoms, other crustaceans, and so on.

IV. Reproduction in Cyamids

Reproductive and mating behavior has been less studied in cyamids than in other amphipods and, indeed, has not been investigated in most cyamid species. The males practice mate guarding and consorts are formed, but there appears to be less aggressive territorialism than is evident with some other amphipods. Little is known about cyamid copulation. There is morphological evidence of a secretory product being released on the cuticular surface of amphipods (Pfeiffer and Viers, 1998), but it is not known if this serves as a pheromone-type attractant for mates or serves some other function. Electron microscopic evidence has shown many tactile sensillae on the antennae and head regions of cyamids, some of which are also likely chemoreceptors. One can question if they always sit on their sole food source, why they have evolved so many sensillae. Female cyamids have a brood pouch (four-plated) or marsupium on their ventral surface, and both unhatched eggs and juvenile whale lice are retained in this cavity (Fig. 4). A clutch of 1078 eggs was observed in the marsupium of one female *C. scammoni* (Leung, 1976). The young cyamids measure only about 0.5mm in length and crawl in and out of the marsupium during development and remain there for at least 2–3 months, when they become about 1.5 mm in length for *C. scammoni*. Several workers have proposed a seasonality for cyamid reproduction, but partly due to the migratory

Figure 4 Sperm whale cyamid with its marsupium full of young. The marsupium is a pouch that is an important adaptation for animals living in a flowing world. Photo by Jon Seger.

habits of whales, detailed data are not yet available on potential seasonal changes.

V. Genetic Diversity in Relation to Host Populations

Whale-lice populations are closely coupled to those of their hosts, especially in species that live on only one whale species. The three named species of *Cyamus* found on right whales (*Eubalaena* spp.) occur regularly on no other cetaceans. Their mitochondrial DNA sequence variation shows clearly that the North Atlantic, North Pacific, and southern ocean populations separated roughly 5 mya, near the Miocene–Pliocene boundary (Kaliszewska *et al.*, 2005). This finding supports previous evidence (from the whales' own genes) that right whales themselves speciated at about that time. Because whale lice have been riding on whales for millions of years, have no alternative hosts or free-living life stages, and usually have population sizes that are orders of magnitude larger than those of their hosts, they may be able to teach us about some aspects of whale population history that could not be discerned using other sources of information.

Whale Watching

ERICH HOYT

Whale watching is the human activity of encountering cetaceans in their natural habitat. It can be for scientific, educational, and/or recreational purposes (sometimes all three). Mostly, whale watching refers to a commercial enterprise, although it is sometimes undertaken privately. The wide variety of whale watching activities includes tours lasting from 1h to 2 weeks, using platforms ranging from kayaks to cruise ships, from land points including cliffs and beaches, from sea planes and helicopters in the air, as well as swimming and diving activities in which the whale watcher enters the water with cetaceans. Whale watching grew out of the traditions of bird watching and, to a lesser extent, other forms of land-based wildlife watching. To this day, the better whale and dolphin trips include sea birds, seals, turtles, and other marine fauna to appeal to more people as well as to give a well-rounded ecological interpretation.

I. The Birth of Whale Watching

The species originally responsible for the development of whale watching was the gray whale (*Eschrichtius robustus*). Beginning in

the mid-1940s, students from Scripps Institution of Oceanography, led by Carl L. Hubbs, began participating in annual gray whale counts from university buildings such as Ritter Hall and from coastal headlands and lighthouses. In 1950, the Cabrillo National Monument in San Diego was converted into a public land-based whale watch lookout, attracting 10,000 people the first winter. Year after year, more and more people came to watch whales.

In 1955, the first commercial whale watch operation charged \$1 US to see gray whales on their winter migration off San Diego. Although the gray whales passed close to shore, the boat tours sometimes allowed a closer look. By 1959, Raymond M. Gilmore, a US Fish and Wildlife Service biologist who had taken over the gray whale counting chores from Carl Hubbs, began serving as the first naturalist on whale watch trips out of San Diego. Through the 1960s and early 1970s, boat tours and land-based whale watching spread slowly up the coast of California to Oregon and Washington, and the first long-range commercial whale watch trip to the Mexican calving lagoons was organized out of San Diego.

In 1971, the Montreal Zoological Society began offering whale watch tours to go down the St. Lawrence River in Canada to see mainly fin (*Balaenoptera physalus*) and minke whales (*Balaenoptera acutorostrata*), and belugas (*Delphinapterus leucas*). This was the first commercial trip on the east coast of North America. These trips became an annual event.

It was the humpback whale (*Megaptera novaeangliae*), however, that turned commercial whale watching into a big industry. Humpback whales tend to be more active at the surface than gray or other whales, frequently breaching clear of the water—ideal for whale watchers wanting photographs. Added to this is the phenomenon of “friendly” behavior—the tendency of certain individual humpback whales to habituate to the presence of whale watch boats and to approach them regularly. This behavior, first observed commonly in humpback whales, has now also been found in gray whales, particularly in the mating and calving lagoons of Baja California, Mexico; in certain minke whales; and in killer whales, or orcas (*Orcinus orca*), and bottlenose dolphins (*Tursiops truncatus*), among others.

In New England and Hawaii, tours to see humpbacks began in 1975. For more than a decade before, the Wailupe Whale Watchers, a local club on Oahu, sponsored loosely organized, infrequent tours, but when whale watching began in earnest from Lahaina on Maui, where the humpbacks were more numerous and accessible, it immediately became the center of the humpback whale watch industry in the Pacific. Most of the Hawaiian tours were strictly commercial.

In New England, however, operators established their own brand of commercial whale watching with strong scientific and educational components—naturalists on every trip who were often working researchers. Educational programs to introduce school children to wild cetaceans—began in southern California by such groups as the American Cetacean Society—were expanded in New England. Within a decade, the New England industry would attract even more participants than Californian and Hawaiian whale watching. New England was fortunate to have humpback whales on the feeding grounds centered on Stellwagen Bank, 10km north of the tip of Cape Cod, as well as North Atlantic right (*Eubalaena glacialis*), fin, minke, and sometimes long-finned pilot whales (*Globicephala melas*), and Atlantic white-sided dolphins (*Lagenorhynchus acutus*). From a commercial point of view, Stellwagen Bank was ideally located close to the large population centers of the US east coast.

II. Scientific Whale Watching

Whale watching for the purposes of research can be traced back to Aristotle, who spent time on boats and with fishermen in the Aegean Sea. In “Historia Animalium,” Aristotle noted that the fishermen would nick the tails of the dolphins and that they could tell them apart. This practice foreshadows the studying of animals by watching them, a key feature of the ethology approach for studying birds and land animals pioneered by Konrad Lorenz, Niko Tinbergen, and others (Hoyt, 1984). It took longer to attempt such research with cetaceans because of the greater difficulties of approaching close and conducting research at sea. The photographic identification (photo-ID) research of cetaceans began in the early 1970s with humpback whales in the North Pacific and North Atlantic, gray whales and killer whales in the eastern North Pacific, and southern right whales (*E. australis*) and bottlenose dolphins off Argentina.

A successful partnership between science and commercial whale watching began in Provincetown, Massachusetts, in 1975, when Al Avellar of the *Dolphin* fleet asked Charles “Stormy” Mayo to be his naturalist. Mayo soon saw the possibilities for using the boat as a platform for studying whales. He set up the Center for Coastal Studies as a research and educational institution, and the close ties with commercial whale watching have been maintained ever since.

The arrangement works as follows: The Center provides naturalist guides for the *Dolphin* fleet. They are paid to help direct the boat to the whales, presenting an informal educational lecture, and answering questions. The Center sells T-shirts and other merchandise on board. Most important, Center researchers can conduct their own photo-ID research, and often collect other data. Sometimes more than one researcher will come aboard to ensure the maximum use of boat time.

This key partnership between science and commerce has determined the course of whale watching, as well as the practice of whale research, throughout southern New England. As of 1995, 18 of the 21 whale watching operators that mainly go to the Stellwagen Bank area had naturalists guiding boats and lecturing whale watchers, while 10 operations were taking and contributing ID photos. Despite the competitive atmosphere of commercial whale watching in New England, the researchers and their representative institutions have cooperated in setting up the North Atlantic Humpback Whale Catalog—a photo catalog and data-base covering more than 10,000 individual whales. As a measure of the scientific value of whale watching, at least 30 published papers in refereed journals have come largely from research aboard whale watching boats on Stellwagen Bank (Hoyt, 1995).

The New England model of successful whale watching and research, like Yankee whaling from an earlier century, has had an impact on the development of whale watching in locales as diverse as the Gulf of St. Lawrence in Quebec, northern Norway, and Dominica in the eastern Caribbean. Of course, a large part of scientific research on cetaceans does not lend itself to being conducted from commercial whale watch trips (such as transect surveys, biopsy darting, and collecting skin and fecal samples). In some cases the research and commercial enterprise operate separately, using different boats and personnel, but the commercial operation supports or contributes to the research. In several areas, whale watch operations have discovered new populations of cetaceans, accessible for study. In all, whale watching worldwide has led to at least 50 cetacean photo-ID programs supported in part or conducted aboard commercial whale watch boats. This has contributed to considerable public support for research through greater familiarity with research programs.

III. The Growth of Commercial Whale Watching

The value of whale watching in 1981 was estimated to be \$4.1 million US in direct revenue and \$14 million in total revenues (including travel, accommodation, food, and souvenirs), based on approximately 400,000 boat-based whale watchers. By 1988, these numbers had expanded by more than 3 times, with the industry still based largely in New England and California as well as a small amount in Canada, Mexico, and the US Northwest (Table I).

In the late 1980s, whale watching began to spread rapidly to other parts of the world. Between 1987 and 1991, new whale watch industries started up in the Canary Islands, the Azores, Belize, Costa Rica, Dominica, Italy, Madagascar, and New Zealand, whereas existing industries expanded rapidly in Argentina, Australia, South Africa, and in parts of Canada. The diverse opportunities for whale watching included boat tours to view rare species (Heaviside's dolphins, *Cephalorhynchus heavisidii*, in South Africa), observing sperm whales, *Physeter macrocephalus*, from the air (New Zealand), land-based whale watching of southern right whales (South Africa, Australia, Brazil), and glimpsing various beaked whales in the Azores and the Bahamas. However, by the 1990s whale watching meant for the most part going to sea on large, comfortable, purpose-built ships that could take 150 to 400 people to see the whales and return to the dock in 2–4h.

During this same period, whale watching became important in Norway and Japan, two countries with strong whaling interests. In both countries, the number of whale watchers increased steadily year by year until, in 1998, Norway had more than 21,000 whale watchers spending \$6.9 million US, whereas more than 102,000 whale watchers in 20 Japanese communities spent \$32.4 million US (Hoyt, 2001). Norway's whale watching industry has about a dozen operators working from four communities and offering sperm and other whales (May–September) or killer whales (October–December); whale watchers (visitors) primarily come from other European countries. Japan's whale watching industry, however, is a 99% domestic industry with diverse attractions including Bryde's whales (*Balaenoptera edeni*) and sperm whales at several warm-water locations from Shikoku Island and adjacent Honshu; humpback whales and tropical dolphins in Okinawa and Ogasawara, both island groups off southern Japan; and minke whales, Dall's porpoises (*Phocoenoides dalli*), and Pacific white-sided dolphins (*Lagenorhynchus obliquidens*) from Hokkaido in the north, as well as multiple locations for watching bottlenose and other dolphins off southern and eastern central Japan.

The compatibility of whaling and whale watching has been debated by whaling and non-whaling countries within the International Whaling Commission (IWC). Whaling can reduce the number of whales available for watching, change whale behavior, diminish the conservation value of whale watching, and potentially affect the larger tourism industry (Hoyt and Hvenegaard, 1999). Despite evidence of such impacts, following a return to whaling in 2003, Iceland has become one of the fastest growing whale watch destinations in the world, with five communities hosting more than 89,000 whale watchers in 2006 and receiving total expenditure of more than \$23 million US. Whale watching remains much more popular in non-whaling countries. As of 2006, four countries attracted more than 1 million whale watchers per year: the USA, Canada, Australia, and Spain (including the Canary Islands). According to the most recent worldwide figures (1998), more than 9 million people are going whale watching in 87 countries and overseas territories and spending more than \$1 billion US (Hoyt, 2001) (Table I). However, based on the substantial growth (1998–2006) noted in Australia, New Zealand, Iceland, the USA, and certain other countries, it is possible to make a minimum world estimate

for 2006 of 12 million whale watchers with total expenditure of \$1.5 billion US (IFAW, 2004; IFAW, 2005; Hoyt, 2007).

IV. Whale Watching Conflicts and Regulations

Such explosive whale watching growth has led to management problems. Typical scenarios include too many boats on the water in a limited area, too many close approaches and sometimes collisions with cetaceans, strain on the infrastructure of local communities from too many visitors, and a lack of guidelines and regulations and/or enforcement of them.

Some operators have formed associations to devise self-imposed guidelines, but most have waited for researchers or NGOs to suggest guidelines or for government to try to impose regulations (Carlson, 2004). Yet even where regulations do exist, enforcement tends to be minimal or absent. In the USA, however, cases have been prosecuted with substantial fines levied against boat operators, as well as researchers and photographers, who approach too close or too aggressively to whales or who operate without a permit. In Hawaii, a film maker was fined for harassing whales when his close-up underwater video of a short-finned pilot whale (*Globicephala macrorhynchus*) mouthing a woman researcher was sold to television.

In 1983, the first whale watch fatality occurred when a mature gray whale overturned a small boat in Laguna Ojo de Liebre (Scammon's Lagoon), Mexico, killing two tourists. Until 1995, this was the only fatal whale watch accident. Then, all in the space of a year, in the Dominican Republic, the upper deck of a crowded boat collapsed after being hit by a wave, killing one tourist and injuring others, and in Kaikoura, New Zealand, a boat overturned, fatally trapping a person underneath. In the same period, on a sightseeing trip near Baffin Island in the Canadian Arctic, a surfacing whale overturned a 5.5m boat and four tourists died of exposure. Only their guide survived. He was wearing a survival suit.

The number of injuries and fatalities is small considering the millions of people who go whale watching every year. Whale watching is by and large safe for both people and whales. Still, whale watch boats have struck whales, injuring, or even killing them, whereas other boats have been accidentally overturned by whales. Many more accidents have happened due to problems with the boats themselves or

TABLE I
Estimated Growth of Whale Watching Worldwide

Year	Number of whale watchers	Direct expenditure (million USD) ^a	Total expenditure (million USD) ^b
1981	400,000	\$4.1 million	\$14.0
1988	1,500,000	\$11.0–16.0	\$38.5–56.0
1991	4,046,957	\$77.0	\$317.9
1994	5,425,506	\$122.4	\$504.3
1998	9,020,196	\$299.5	\$1,049.0 million
2006 ^c	12,000,000+	\$450.0+	\$1,500.0+

^aDirect expenditure = Cost of whale watch tour (ticket price).

^bTotal expenditure = The amount spent by tourists going whale watching from point of decision, including transport, food, accommodation, and souvenirs, as well as ticket price, but not including international air fares.

^c2006 figures are minimum estimates only.

with overloading—things that are not specific to whale watching but could happen as part of any type of marine tourism. Indeed, most if not all of the accidents to date could have been avoided with due care and precaution.

Perhaps the greatest concern for safety is for the tours involving swimming or diving with cetaceans. Even these have a good safety record with thousands of encounters with dolphins in such places as New Zealand, the Bahamas, and Japan. Despite the generally strict protocol of no touching and approaching cetaceans, some have suggested that swimming with cetaceans should be banned or at least limited to certain dolphin populations or areas and that experienced researchers should always be present as guides to help interpret behavior and ensure safety. Swimming with whales, such as humpback whales on their mating grounds where there is surface active behavior, is potentially more dangerous to humans; despite criticism it continues in several areas of the world, and it remains controversial.

V. Does Whale Watching Have an Impact on Whale and Dolphin Populations?

Since the late 1990s, researchers have tried to determine whether observed short-term effects on whales and dolphins from whale watching (approaching or avoiding boats, staying down longer, interrupting natural behavior) might be leading to long-term negative impacts (displacement, reduced reproductive success, or reduced survival rate). Concerns have centered around the presence of boats on critical mating, calving, feeding, and resting areas; the amount of time and the number of boats approaching close to the same whales; and the intensive whale watching of certain rare or endangered species. The problems are most evident with small, inshore populations of dolphins living in restricted areas such as Doubtful Sound, New Zealand; eastern Vancouver Island, Canada; and Shark Bay, Australia. In these populations, repeated exposure of individuals to boat-based whale watching is leading to long-term impacts (Report of the Workshop on the Science for Sustainable Whalewatching, 2004; Bejder *et al.*, 2006; Lusseau *et al.*, 2006). These studies highlight the sensitivity of small dolphin populations chronically exposed to whale watching. Yet even large whales sometimes show behavioral changes as a result of whale watching which, for some populations, may represent a threat.

There is much that can be done to manage the development of whale watching to minimize the risk from adverse impacts. In some areas of the world, watching from a large, quiet ship may reduce the pressure exerted by numerous small boats, whereas watching from a land-based lookout can eliminate negative effects on the animals. Well managed whale watching begins with a protective government policy with sensible regulations and an enforcement regime to control the numbers of boats on the water with cetaceans and to limit their approach and the amount of time they spend with cetaceans (IFAW *et al.*, 1995). The Whale and Dolphin Conservation Society has suggested a practical, precautionary plan whereby one-third of every whale and dolphin area and one-third of daylight hours be kept free from any whale watching activity (Hoyt, 2007). Such restrictions on areas and times would also prove useful as controls for researchers doing comparative studies. Equally important for management is the education of whale watch operators, passengers, and other mariners using their boats in whale watch areas. Central to this is the role of the naturalists, or guides, who are the public face of whale watching and marine protected areas, and act as the bridge between the largely urban whale watchers and the sea. Naturalists play an essential conservation role with their ability to shape through their words and actions

TABLE II
Brief, Useful Guidelines for Boat Operators^{a,b}

1. Do not pursue, overtake, head-off or encircle cetaceans or cause groups to separate.
2. Never approach whales/dolphins head on.
3. Avoid sudden changes in noise level (gear shifts and reverse, unless necessary to back away slowly from a surfacing whale or dolphin group).
4. Reduce speeds in areas where whales may be sighted; approach and leave whales cautiously and slowly.
5. Extreme caution is required when any of the following is present: (a) feeding whales, (b) cow/calf pairs and juveniles, (c) resting, (d) breeding or rowdy groups, or (e) socially active groups. Cetaceans engaged in such behavior are particularly sensitive to disturbance and may be vulnerable to collisions.

^aThis is not a complete list covering every situation but is meant to provide some general suggestions and overall direction for the use of operators offering whale watch tours as well as wildlife managers who are establishing guidelines or regulations on whale watching.

^bAdapted from IFAW *et al.* (1997).

the way whales and dolphins and the marine environment are perceived and ultimately respected (IFAW *et al.*, 1997; Hoyt, 1998, 2007).

VI. Whale Watching and Conservation

In 1983, the IWC co-sponsored the “Whales Alive” conference in Boston, Massachusetts, which examined the “non-lethal” uses of whales. Ten years later, in 1993, the IWC adopted a whale watching resolution prepared by the Whale and Dolphin Conservation Society and successfully proposed by the UK at the IWC annual meeting in Kyoto, Japan. The underlying strength of the argument that the IWC should become involved in whale watching was that, since the IWC moratorium on whaling, the most prevalent “use” of cetaceans among IWC members has been whale watching. However, despite majority agreement on the relevance of whale watching to the IWC, delegates from Japan have repeatedly stated that the IWC has “no competence” concerning whale watching matters.

From 1995 to 2000, a series of six international workshops, organized by the International Fund for Animal Welfare (IFAW), with assistance from the Whale and Dolphin Conservation Society, Tethys Research Institute, World Wide Fund for Nature, and others, brought together more than a 100 cetacean experts from some 25 countries to explore the socioeconomic, educational, and legal aspects of whale watching, as well as the scientific aspects of management. The first of these, the seminal Scientific Aspects of Managing Whale Matching workshop, held in Italy, recommended a precautionary approach to management with a periodic review of regulations based on continuing research and monitoring into possible effects on cetaceans (sample guidelines for boat operators are provided in Table II) (IFAW *et al.*, 1995). The overall impact of this and later workshops has been to focus the debate on the status of whale watching, pointing out that better regulations were needed as well as enforcement, that whale watching had substantial unrealized potential in terms of education and science, and that, economically, whale watching was worth far more than had previously been determined, although some values were difficult to measure in terms of dollars alone (Hoyt, 2005, 2007).

TABLE III
Educational Values of Whale Watching^a

1. Whales are emblems for promoting awareness of endangered species and habitat protection.
2. Whale watching provides the opportunity for people across all ages and cultures to become familiar with environmental issues and to become involved in conservation efforts on a personal, local, regional, national and international level.
3. The development of education programs forges links between the whale watch industry and local communities as well as building bridges between the general public and scientific communities.
4. Natural history knowledge gained through whale watching has intrinsic value.
5. Whale watching provides an opportunity to observe animals in the wild, transmitting factual information and dispelling myths.
6. Whale watching is a model for marine educational programs in adventure travel and ecotourism.
7. Whale watching provides the opportunity for appreciation and understanding of local history, culture and the environment.

^aAdapted from IFAW *et al.* (1997).

Perhaps the most valuable legacy of whale watching has been the building of a constituency out of the general public that is interested in and sympathetic to marine mammals, the sea, and marine conservation, including marine protected areas. The designation of Stellwagen Bank as a US National Marine Sanctuary in 1993 was largely the result of public interest in whales in New England and in the northeastern US through whale watching. Several million people encountered whales in the wild between 1975 and 1992, saw the research being conducted on whale watching boats, and learned about the whales and problems of the sea, which led to overwhelming popular support for the sanctuary (Hoyt, 2001).

Since the late 1980s as whale watching has expanded, however, it has become less educational in some areas of the world (Table III). A 1998 world survey of whale watch operations found that only 35% of all operators had enlisted naturalists to guide their trips (Hoyt, 1998). In terms of the scientific content, about 9% of operators worldwide had researchers or naturalists on board who conducted regular photo-ID and other research as part of their trips, whereas 57% never conducted scientific research or even offered information to scientists. Most operations were strictly commercial ventures. Clearly, a great deal more could be done to encourage whale watching tours to offer the maximum benefits to local communities and regions in terms of education, science, and conservation, as well as earning tourism dollars, while at the same time protecting the whales and ensuring that they will remain in coastal waters and accessible to whale watchers for generations to come.

RICHARD ELLIS

I. Man Meets Whale

One of the earliest records of man's interactions with whales can be found in the chronicle of the conquests of Alexander the Great, which took place in the fourth century BC, and was transcribed some 300 years later by the Greek historian Arrian. Because Alexander's empire included the eastern Mediterranean, the northern shore of the Persian Gulf, and the shore of the Indian Ocean from the Strait of Hormuz to the mouth of the Indus River—and also because many of his campaigns were conducted at sea—we can safely assume that he and his army had many opportunities to see whales. The following passage appears in Arrian's description of the officer Nearchus's encounter in the Indian Ocean:

In this foreign sea there lived great whales and other large fish, much bigger than ours in the Mediterranean As we set sail we observed that in the sea to the east of us water was blown aloft, as happens with a strong whirlwind. We were terrified and asked our

pilots what it was and whence it came. They replied that it was caused by whales, which inhabit this sea. Our sailors were so horrified that the oars fell from their hands Then I walked round the fleet and ordered every steersman I met to steer straight at the whales, exactly as if they were going into a naval battle. All the men were to row as hard with as much noise as possible, including yells The whales, which could be seen just in front of the ships, dived terrified into the depths. Not long after that, they surfaced behind the fleet, blowing water into the air as before Now and again a few of these whales come ashore, having been stranded on the flat beaches at ebb tide. Often, too, they are flung up on dry land by a violent storm. Then they die and rot. When the flesh has mouldered away, the skeletons are left, which the inhabitants of these shores use for building their houses. The large bones at the side form the beams of their houses, the smaller ones the laths. From the jawbones they make doors.

From this description, it is not possible to identify the whales, for there seem to be two types discussed simultaneously. The schooling behavior (including the mass stranding) suggests sperm whales (*Physeter macrocephalus*), but the description of the bones found on the beach would better apply to baleen whales. Whatever the species, it is obvious that stories like these were passed down, modified, embellished, and eventually reconstructed as the stuff of fable and fantasy.

When Jonah fled from Joppa rather than obey the word of the Lord that he go to Nineveh, his ship was caught in a “mighty tempest.” To appease the angry God, the mariners cast Jonah into the sea because they knew he had disobeyed the Lord’s commands, and immediately “the sea ceased from her raging,” a “great fish” swallowed Jonah, and he remained in its belly for 3 days and 3 nights. Inside this uncomfortable sanctuary, Jonah repented, and the creature spewed him up again onto dry land.¹

¹This is not the first mention of a whale in the Bible: that distinction is found in *Genesis* 21: “And God created great whales.” It is, however, the first mention anywhere of a man being swallowed by a whale (or a “great fish”). There are very few animals in the sea large enough to swallow a man, and most of them are whales. Of the sharks, only the whale shark (*Rhincodon typus*), the basking shark (*Cetorhinus maximus*), and the great white shark (*Carcharodon carcharias*) are the requisite size, but the whale shark and the basking shark are plankton-eaters, with the equipment, but not the inclination to swallow a man-sized object. That leaves only the great white, the largest carnivorous shark in the world. This fish has a fully-deserved reputation as a man-eater, but it tends to take great bites of its victims, and while there have been survivors of white shark attacks, there is no record of a human victim having been swallowed whole. The only cetacean with the anatomical equipment required to swallow a human being is the sperm whale, which usually feeds on squid. A giant squid (*Architeuthis* spp.) weighing over 400 pounds was found in the stomach of a sperm whale harpooned off Madeira, so there is no question about the ability of the cachalot to swallow Jonah. Throughout the history of the sperm whale fishery, there have been several tales of whalers swallowed by the object of their attentions. There are indeed stories of whalers having been swallowed and recovered alive from the belly of the sperm whale, but under close examination, they begin to resemble the fable of Jonah more than demonstrable fact. An oft-quoted account of a whaler who fell overboard off Newfoundland and was swallowed by a sperm whale is more likely to be true. In this history (published as a letter to the editor of *Natural History* in 1947 by one Edgerton Y. Davis), the man is exhumed from the carcass of the whale, but he is badly crushed, decomposed, and extremely dead. Yes, it is physically possible for a whale to swallow a man, and no, the man would not survive the experience.

In the book of Jonah, there is no mention of a *whale*, but in the book of Job, there are several references to “leviathan,” an animal that has been variously interpreted as a crocodile, a shark, and a whale. (“His teeth are terrible round about. His scales are his pride, shut up together as with a close seal. One is so near to another, that no air can come between them He maketh the deep to boil like a pot: he maketh the sea like a pot of ointment.”) Isaiah 27: “The Lord with his sore and great strong sword shall punish leviathan the piercing serpent, even leviathan that crooked serpent; and he shall slay the dragon that is in the sea.” And finally, Psalms 104:25-26: “So is this great and wide sea, wherein are things creeping innumerable, both small and great beasts. There go the ships; there is that leviathan, whom thou hast made to play therein.” At best the Bible is ambiguous about the whales; creating them, punishing them, watching them at play, and even feeding Jonah to one of them (maybe). When we really want to know about whales, the Bible ignores them altogether.

When Noah was commanded to build the ark, he “admitted aboard every beast after his kind, and all the cattle after their kind, and every creeping thing that creepeth upon the earth after his kind, and every fowl after his kind, every bird of every sort,” but there is no mention of a fish, a dolphin, or a whale. Maybe these creatures were supposed to tag along in the wake of the ark, since they would not be affected by the rains or the “increase in waters.” Or perhaps they were not recognized as creatures worth saving, living as they did in an alien environment.

As early as 350 BC, Aristotle recognized that whales were mammals and not fish. He wrote, “The dolphin, the whale and all the rest of the cetacea, all, that is to say, that are provided with a blow-hole instead of gills, are viviparous ... just as in the case of mankind and the viviparous quadrupeds.” This knowledge, however, was to prove of little use to mankind for 1000 years, because it was based upon random and infrequent examinations of stranded animals. The observation of cetaceans in the wild only occurred when seafarers spotted dolphins at play in the bow waves of their vessels, or when someone like Nearchus encountered and described living whales. Men would not encounter whales until they began to venture out to explore the oceans, which would not take place for another fifteen centuries. In the meantime, what observations of cetaceans were to be made would be made from land, or in the inland waterways in which men felt more or less secure.

Undaunted by the absence of real whales to describe, ancient authors described them anyway. Pliny the Elder (who often relied upon Aristotle and other authors) included whales in his *Naturalis Historia*, written shortly before he was killed at Pompeii in the AD 79 eruption of Vesuvius. A doctor named Philemon Holland (1552–1637) translated Pliny into Elizabethan English in 1601, and in his discussion of “The Whale,” we find the following:

The biggest and most monstrous creature in the Indish Ocean are the whales called Pristis and Balaena. These monstrous Whales named Balaenae, otherwhiles come into our seas also. They say that in the coast of the Spanish Ocean by Gades [Cadiz], they are not seen before midwinter when the daies be shortest: for at their set times they lie close in a certaine calme deepe and large creeke, which they chuse to cast their spanne in, and there delight above all places to breed. The Orcae, other monstrous fishes, know this full well, and deadly enemies they bee unto the foresaid Whales. And verily, if I should portraitt them, I can resemble them to nothing else but a mighty masse and lumpe of flesh without all fashion, armed with most terrible, sharp, and cutting teeth.

When the sixth century Irish monk known as St. Brendan set out on his North Atlantic voyages, the result was one of the earliest mentions of a whale-human interaction in the European literature. According to Samuel Eliot Morison (1971), “Brendan was a real person ... and his *Navigatio* is based on a real voyage or voyages, enhanced by the Celtic imagination.” Brendan’s discovery of Iceland, the Canaries or Madeira, while interesting, does not concern us as much as the delightful tale of his encounter with Jasconius the whale. With his crew of seventeen, Brendan came upon “a bare, treeless black island,” but when they built a cooking fire, the island sank beneath them. Jasconius told them they could return, but only if they refrained from lighting fires on his back. The story appears in the *Physiologus*, and again in von Mengenberg’s translation of Thomas de Cantimpre’s *De natura rerum* (“Of things in nature”):

Some whales are so big that when seen from afar they seem like islands or groves, or resemble great hills. The whale heaps a thick coating of earth upon its back, so that when seamen are driven by the stress of weather upon this earth, they imagine it to be an island and that they have come to land. Rejoiced at this they let down the sails, drop their anchor in the water, build a fire upon the earth and seek to enjoy a little rest. As soon, however, as the whale feels the heat of the fire, it becomes enraged and dives beneath the water, bearing down to the depths both ship and sailors.

It would be another 500 years before men actually went whaling, but whales would continue to inexplicably cast themselves upon the beaches. In his *Historia Animalium* Aristotle wrote, “it is not known for what reason they run themselves aground on dry land, at all events it is said that they do so at times, and for no obvious reason.” Whales and dolphins have been running themselves aground for as long as men can remember, and probably long before that. In the twenty-two centuries that have elapsed since Aristotle made his prescient comment, we have come no closer to solving the mystery of whale strandings than the Greeks. Beached whales represented the first important contact between men and whales, one which would set the tone for the interaction of these two mammals for centuries.

Not all knowledge of whales came from those that beached, of course; seafarers encountered all sorts of cetaceans as they plied their trade routes or began their hesitant explorations of distant coasts. Men sailed from the ports of Europe, Asia, and Africa; for conquest, for trade, or to spread the word of their god, but they did not set sail casually. Discovery as an end in itself, exploration in intellectual pursuit of geographical knowledge, or in the romantic pursuit of unusual adventure, is characteristic of a safer, richer, more comfortable society than that of fifteenth century Europe (Parry, 1974). There was no such thing as science for the sake of science, and if men found whales, they took them for what they believed them to be: huge, mysterious, threatening creatures. On their early maps, they figured them as large, scaly animals with a frightening array of unlikely appendages: horns, fringes, crests, armor, lumps, bumps, ridges, horrific dentition, and often twin pipes gushing water into the air.

It was not the intention of these mapmakers to frighten their fellow men; everyone believed that foreign lands harbored all sorts of mysterious animals and equally strange varieties of men. If this was the case, then surely the ocean, home of rite sea serpent and the *kraken* (a giant cephalopod capable of entangling ships in its tentacles and dragging them to the bottom), could be the home of even more terrifying creatures. For medieval man, these superstitions proved to be true, as the sea spewed forth monsters larger and more terrible than

any creature imaginable. There are indeed giant squid with arms 50 or 60ft long, and there certainly are leviathans. Although they did not have scales, horns or twin blowpipes, the leviathans had equally improbable characteristics: giant flattened tails, strange plates where terrestrial mammals had teeth, gigantic reproductive organs (often grotesquely distended in death), and no legs where proper mammals were supposed to have legs. Who could fault the ancients for suspecting that the sea harbored monsters?

We have no way of knowing when or where the first aborigines encountered the first beached whales, but it is obvious that this encounter would eventually lead to whaling. As soon as the inhabitants of what would become Holland, Norway, or Vancouver realized that they did not have to depend on the uncertain generosity of the sea to provide a bounty of meat or oil, they would take to the sea themselves, to hunt the whale.

Many of the earliest descriptions of cetaceans were based on beached animals, and for the scientists of the sixteenth and seventeenth centuries, they were a boon. How else could landlocked Robert Sibbald of Scotland have described a blue whale (*Balaenoptera musculus*) so accurately in his 1692 discussion of the carcass found at Abercorne on the Firth of Forth? At one time or another, every species of whale has come ashore: fin whales (*B. physalus*), minke (*B. acutorostrata*), right whales (*Eubalaena* spp.), humpbacks (*Megaptera novaeangliae*), gray whales (*Eschrichtius robustus*), and dolphins of every sort. But the most celebrated of all stranders is the sperm whale. With its great square head filled with a mysterious waxy substance, its wrinkled hide and peg-like ivory teeth, a sperm whale appearing on the beach became a *cause célèbre*. In many of the early descriptions of beached whales, the species is open to question, but once you have seen *Physeter*, there is no possibility of confusing it with any other animal on earth, let alone any other whale. (The veneration of the sperm whale reached its apogee in the nineteenth century, when, during the most productive years of the sperm whale fishery, *Moby-Dick* raised the sperm whale to the soaring heights of hyperbole.)

Around 1577, the first engraving of a stranded whale appeared in print. By the turn of the seventeenth century, more whales had stranded on European coasts, and with the heightened interest in popular science, more engravings appeared. Either because the whales preferred the coasts of the Netherlands, or because the Dutch had a particular interest in stranded whales, the majority of the early illustrations of whales were the work of Low Country artists. In these elaborately detailed drawings, the good burghers of Holland are often seen perched upon the carcass, standing around in fashionable attire, or occasionally carrying off a bucket of what may very well have been whale oil.

The North Sea coast of Holland would appear to be one of those places (noteworthy others are in New Zealand and Cape Cod) where whales strand with some degree of regularity. From 1531 to around 1690, some 40 whales of assorted species beached themselves on these shingled coasts. Most of them seem to have been sperm whales, and with their huge heads, a mouthful of ivory teeth, and—in what appear to be a majority of the cases—its male genitalia prominently exposed, the dead whale must have been a wonder of wonders to the Dutchmen who came to view these monsters. It would be another half-century before the whalers of Rotterdam and Delft would head for the icy seas of Spitsbergen, where they would hunt a totally different creature, the Greenland right whale.

One of the best documented of these aliens from the deep was a 54-ft bull sperm whale (*potvisch* to the Dutch) that was discovered floundering helplessly in the shallows of Berckhey in February 1598. When the whale expired, its carcass was sold off for the oil,

but its fame lies more in its portrayal than in its products. Drawn by the artist Hendrick Goltzius, the Berckhey whale has appeared in countless versions, often accompanied by a descriptive text that marvels at its leviathanic dimensions. In later years, more whales would strand on the beaches and be immortalized by Dutch engravers, but the Goltzius illustration, repeated and degenerated for 200 years, has probably been employed more often than any other cetacean depiction, before or since. In 1991, German whaling historians Klaus Barthelmess and Joachim Münzig published a three-volume compendium (Barthelmess and Münzig, 1991; *Horrible Monsters: Whales and Whale Representations in 16th Century Prints, and their Artistic Influence*) of the illustrations of whales, beached and otherwise, known from European archives.

A dead whale on the beach begins to decompose rather quickly, so often the illustration was erroneous in some of its particulars. In the chapter in *Moby-Dick* on “The Monstrous Pictures of Whales,” Melville had the same complaint. He wrote, “Consider! Most of the scientific drawings have been taken from the stranded fish; and these are about as correct as a drawing of a wrecked ship, with broken back, would correctly represent the noble animal itself in all its undashed pride of hull and spars. Though elephants have stood for their full-lengths, the living Leviathan has never yet fairly floated himself for his portrait.” Correct or not, these pictures were the best available, and from them, the civilized world began to learn of gigantic animals that lived in the sea, and occasionally appeared on beaches. However, long before scientists would examine, dissect, illustrate, and classify the whales, people with very little concern for their correct nomenclature would be hunting them in the open seas.

Jenkins (1921) writes, “Although the general opinion is that the Basques were the earliest whalers, Noel de la Moriniere says that this is a misapprehension and that the Northmen were really the first in the field.” He says that a man called “Ochther” hunted whales and walrus beyond the North Cape, but then the notes that “there is no evidence that it developed into a regular fishery such as that of the Basques.”

His “Ochther” was Othere (or Ottar), a Norseman in the service of King Alfred of Wessex around the year AD 890. Alfred (called Alfred the Great) is known for his defense of England against the marauding Danes, and also for the initiation of the *Anglo-Saxon Chronicle*, the first history of England. (Our word “whale” comes from the Anglo-Saxon *hwael* that means “wheel,” and probably refers to the shape of the whale’s back as it rolls in the water.) Alfred translated many Latin texts, including the one that concerns us here, a description of Europe by one Orosius, who lived four centuries before. To the work of Orosius, Alfred added a description of the northern voyage of Othere, wherein was described the whale- and walrus (*Odobenus rosmarus*)-hunting of a northern people known as the Biarmians. From the location (the White Sea in northern Russia), and description of the whales hunted (“50 ells” in length, which by one calculation works out to 187 ft), it would appear that the larger ones—whose size was greatly exaggerated—were bowheads (*Balaena mysticetus*), whereas Othere’s “horsewhales” were walrus. In the history of British *Voyages and Discoveries* compiled in the sixteenth century, Richard Hakluyt, a diplomat and scholar, wrote that the principal purpose of Ochther’s expedition was “to increase the knowledge and discovery of these coasts and countries, for the more commodity of fishing for horse-whales, which have in their teeth bones of great price and excellency: whereof he brought some at his return unto the King. Their skins are also very good to make cables for ships, and so used.”

In medieval Scandinavia, whales were very much a part of the lives of the people, and were therefore incorporated into their literature. A thirteenth century Icelandic account known as *Konung’s skuggsjá* (*Speculum Regale* in Latin; *Konegspiel* in German; “King’s Mirror” in English) describes the whales that are found off Iceland, and includes such mysterious creatures as the horse whale, the red whale, and the pig whale, but also discusses recognizable species, such as the killer whale (*Orcinus orca*), the narwhal (*Monodon monoceros*), and the sperm whale. The right whale is described thus:

People say it does not eat any food except darkness and the rain which falls on the sea. And when it is caught and its intestines opened, nothing unclean is found in its stomach as would be in other fish that eat food, because its stomach is clean and empty. It cannot open its mouth easily, because the baleen that grows there rise up in the mouth when it is opened, and often causes its death because it cannot shut its mouth. It does no harm to ships: it has no teeth, and is a fat fish and edible (Whitaker, 1986.)²

There is an almost complete lack of information on Norse whaling, but the waters in which they sailed were then (and are still) among the whale richest in the world. There are right whales, humpbacks, fin whales, sperm whales, belugas (*Delphinapterus leucas*), narwhals, pilot whales (*Globicephala* spp.), and various species of dolphins in the cold, productive waters of the North Atlantic. The Norse sagas are silent on the subject of whales and whaling, but it would be hard to imagine these hardy seafarers ignoring a plentiful source of food and oil as they plied the otherwise inhospitable seas around Iceland, Greenland, and Labrador. There are references, however, to battles royal between various “families” as they dispute the ownership of whale carcasses, which indicates the importance of whales—at least of dead whales—in the lives of the early Norsemen. They left no tryworks, their settlements provide no trace of harpoons or lances, but there are tantalizing hints of Norse whaling in some of the more recent discussions. In his 1928 *History of Whaling*, Sydney Harmer says, “The Icelanders seem to have engaged in whaling ... and the whale known as “Slettibaka” ... is believed to have been the Biscay whale.” (The modern Icelandic for the right whale is *sletbag*, which means “smooth back.”)

II. Early Icelandic Whaling

Iceland’s early history is to be found in the sagas, tales of the exploits of the island’s early heroes. The Vikings of Norway evidently brought to Iceland knowledge of the techniques employed in driving whales (probably pilot whales) into the fjords for slaughter. There are occasional mentions of disputes over stranded whales in the sagas, but as far as we know, there was no active whale fishery. An Icelandic bestiary from about 1200 describes some of the whales (but not accurately enough for modern cetologists to identify them as to species), and the *Konung’s skuggsjá* lists no fewer than 21 sea creatures, some of which can be referred to living whales, dolphins and pinnipeds, and some of which—mermaids and mermen, for example—are clearly mythological.

²The King’s Mirror was written in Norwegian, probably as a set of instructions for a king’s son. It contains the first description of the ice in the interior of Greenland, a summary of contemporaneous beliefs about the Aurora Borealis, and the most complete inventory of the sea mammals of Greenland and Iceland up to that time.

In a seventeenth century work by an Icelander named Jon Gudmundsson, there is a list of the various whales that might be found in Icelandic waters, including the sperm whale (*Burhvalur*), the narwhal (*Náhvvalur*), the right whale (*Slettbakur*), the fin whale (*Geirreydur*), and the blue whale (*Steypireyður*). With the exception of the right whale, which probably refers to the bowhead and was hunted to extinction after this publication appeared, all these whales can still be seen off Iceland. Also included was something that the author referred to as *Sandloegja*, which has been translated as “sandlier” (i.e., one that lies in the sand). Each of the abovementioned whales is accurately illustrated, so there is little doubt as to its identification. The description of the *Sandloegja* is accompanied by a picture of a whale that has not been seen in the Atlantic since commercial whaling began, and if the interpretation is correct, it depicts the only whale to have become extinct in recent history (Lindquist, 2000).

The California gray whale is well known from the North Pacific, where it makes the celebrated round-trip migration from Alaska to Baja California. It was the object of an intense fishery in the nineteenth century which nearly eliminated the species. Fossil remains of a similar—if not identical—species have been found in western Europe (Sweden, England, and the Netherlands), and on the east coast of North America from New Jersey to South Carolina. From the evidence, it appears that there was also an Atlantic gray whale, which probably maintained similar habits to its Pacific cousin; i.e., it fed in cold northern waters (perhaps Iceland and Greenland), and then moved south (Spain, France, England?) to breed and calve. With the exception of the fossil evidence, the only clues to the identity of this whale are found in the work by Gudmundsson and in a debatable reference in a New England work of 1725, where Paul Dudley describes the “scrag whale” with characteristics that are not applicable to any other species except the gray whale. Whether hunted or occasionally appearing on the beach, the gray whale should probably be listed in the Icelandic cetacean fauna, even though no living Icelander has ever seen one in his own country. (In his analysis of the whales of the *Konung’s skuggsjá*, Ian Whitaker (1986) wrote that “the gray whale was hunted in the Atlantic between 1100 and 1200, although it has not been found there since the 18th Century.” He is unable to correlate this species with any of the thirteenth century Icelandic names, although he indicates that there are two “unallocated” names, which translate as “hog-whale” and “shield-whale.”)

Whales were caught by the Norwegians off the Tromsø coast as early as the ninth or tenth century. The oil was used for lighting and the baleen for jewelry, coopering, and boatbuilding. But, as C. B. Hawes wrote in 1924, “with a lamentable lack of foresight, the earliest whaling captains neglected to enlist the services of scholars and historians,” so much of the story of early Norse whaling has to be left to conjecture.”

One of those who did a lot of conjecturing was Ivan Sanderson. Trained as a zoologist, Sanderson was particularly interested in unusual phenomena, such as the abominable snowman and the Loch Ness monster. He wrote several books on zoological and cryptozoological subjects, but he will probably be best remembered for his *Follow the Whale* (1956). In this book, along with some rather good accounts of the biology of whales and some excellent maps, he re-creates the lives of whalers of the past and the present, “corralling the forgotten and more neglected aspects of whaling history and the new discoveries about the whales themselves, and weaving them into a continuous web of narrative.” One of these “neglected aspects” is Norse whaling history, but despite the lack of documentation, Sanderson devotes a whole chapter to the subject, fictionalizing what could not otherwise be ascertained. He has the Norsemen under “Thorvald the Long” trapping

sei whales in the fjords of Norway at an unspecified time, along with “Biarmi the Yellow standing in the bow holding a trumpet of cow’s (*Bos taurus*) horn in his hand.” He also recounts an Icelandic saga of AD 1100, which contains “a delightful passage in which we are told of the stranding of a large rorqual at Rífsker in Iceland and how all the important people who were able went to it.” The documentation for this is sparse, but there can be no question that the Norsemen, ranging the North Atlantic from Finnmark to Iceland and from Greenland to North America, had to have encountered whales. Whether they killed the whales in an organized fashion or took them incidentally to their viking and settlement forays may never be known. They did hunt walrus for their skin and ivory tusks, and narwhals for their spiraled ivory tooth, which was passed off as the horn of the fabled unicorn.

III. Basque Whaling

As far as we can tell, the first people to hunt large whales in an organized and intentional manner were the Basques. As far back as records go—and even further, perhaps as far back as the Stone Age—these men were hunting whales. In his 1820 *Account of the Arctic Regions*, William Scoresby suggests that “the Biscayans were the first who exercised their courage in waging a war of death with the whales,” but he attributes their motivation to the protection of their fishing nets, which “would naturally suggest the necessity of driving these intruding monsters from their coasts.” Whatever their reasons, the Basques became the paradigms of the whaling industry, establishing the *modus operandi* that would characterize the industry for another 1000 years. “Historians have only recently begun to realize,” wrote Farley Mowat (1984) “that it was the Basques who lit the flame that was eventually to consume the mighty hosts of the whale nations.” They discovered the “resource,” exploited it, and then pursued it so vigorously that it became uneconomical to continue. They probably took their first whales in the shallows, and then, like the bay whalers who were to follow their lead all around the world, realized that it was considerably more expeditious to go after the whales rather than wait for the whales to come to them. The Basques may also have been responsible for the only large cetacean extinction in recorded history.

Somewhere around the year AD 1000, these intrepid hunters of the Bay of Biscay began the slow but systematic eradication of the whales that came into the protected bays in the shadow of the Pyrenees. Obviously, the Basques did not wait for the first millennium to end before beginning their whaling, but most authors cite this as approximately the time they began. Ommanney (1971) wrote: “The industry, founded on the Biscay Right whale, was fully developed by the twelfth century but probably dated from much earlier, possibly from the tenth century when the Basques may have learned the craft from Norse whalers.” The Belgian historian W. M. A. De Smet (1981) searched the literature for references to European whaling *before* the Basques, and wrote, “Only a few authors are aware of the fact that whaling existed in still earlier days in other European seas, and that it was practiced in the North Sea and the English Channel during the Middle Ages, certainly from the 9th century onward.” Although the species of whale in these early instances was rarely recorded, the likelihood is that it was the right whale that was hunted in the North Sea, and perhaps the gray whale, although the precise date of the disappearance of the Atlantic gray is still being debated.

De Smet cites several instances in which whale meat is mentioned in early texts, and suggests that “it is clear from the regularity with which whale meat occurred in these markets that it cannot have come from stranded animals alone and there must have been regular landings.” After providing for themselves, the enterprising

Basques established markets for the meat and blubber, and even had “consulates” in Holland, Denmark, and England to encourage sales. In French, the blubber was known as *lard de carime*, which means “lenten fat,” and Europeans were allowed to eat it on designated meatless calendar days. The oil was used for lighting and the manufacture of soap, wool, leather, and paint; the meat was fed to the poor and to the ships’ crews, and the baleen was put to all sorts of uses (including being shredded into plumes for the decoration of knight’s helmets), the vertebrae were used for seats, and the ribs were employed as fence-pickets, and beams for cheap housing. The tongue was considered a particular delicacy, and was reserved for the clergy and royalty.

In the unregulated (and largely undocumented) confusion of the Middle Ages, small pockets of Basques lived along the shores of the Bay of Biscay, speaking their own language, about which a contemporaneous cleric wrote, “The Basques speak among themselves in a tongue they say they understand but I frankly do not believe it.” In their strongholds in the crook of the elbow of the Iberian peninsula, they were isolated from the turmoil of land wars, fiercely intent upon self-preservation, and coincidentally upon the pursuit of the large black whales (which they called *sarda*) that arrived every autumn in their offshore waters.

It is likely that they also hunted the Atlantic gray whale, although there is no evidence to support this supposition. There is, however, considerable evidence that the Atlantic gray whale (which was called *otta sotta*) was present in the Atlantic during the days of Basque whaling. Remains have been found on both sides of the ocean: in England, Holland, and Sweden in the east; and from New York and New Jersey to North Carolina in the west. An account discovered by Fraser (1970) suggests that a gray whale (called *sandloegja* by the Icelanders) existed as recently as 1640 in the waters off Iceland. With nothing more than the absence of gray whales to substantiate his claim, Mowat (1984) wrote “that by as early as the fourteenth century, the *otta sotta* had been hunted to virtual extinction in European waters.” Mead and Mitchell (1984) recognize only Fraser’s *sandloegja*,³ a 1725 description of the “scrag whale” by Paul Dudley, Esq.,⁴ and the 1611 instructions given by the directors of the Muscovy Company to Thomas Edge⁵ as “reliable records of gray whales in the North Atlantic.” There are no more gray whales in the Atlantic, and while this unfortunate state of affairs might not be directly attributable to the Basques, it is not unreasonable to assign them some part in the disappearance of these whales.

For many years, the most comprehensive study on the subject of Basque whaling was that written by Sir Clements Markham and published in 1881. While working on a study of William Baffin, he learned “that the first English whaling vessels were in the habit of shipping a boat’s crew of Basques to harpoon the whales,” so he began to investi-

gate, and ended up in Spain. He found that King Sancho the Wise of Navarre had granted petitions to the city of San Sebastian in the year 1150 for the warehousing of certain commodities, among which were *boquinas-barbas de ballenas*, plates of whalebone. Markham traced the fishery through the records of various cities and towns (he found the “Casa de Ballenas” in Asturias), and acknowledged that it was the Basques who taught the British how to kill whales. He sums up the Basque contribution as follows: “Of course the English, in due time, learnt to strike the whales themselves; but the Basques were their instructors; and it is therefore to this noble race that we owe the foundations of our whaling trade” (Markham, 1881).

More recently, the Spanish cetologist Alex Aguilar (1981) has been searching the records for written documentation of Basque whaling and has discovered a reference from Bayona, in the Gulf of Biscay, that dates from the year 1059. From the remains of cetaceans examined at some of the settlements on the shore of the Cantabrian Sea (off the northern coast of Spain), it has been suggested that the Basques occasionally hunted sperm whales, but the predominant object of their fishery was the right whale. Ancient whaling bases have been found along the length of this coastline, which encompasses the provinces of Galicia, Asturias, Santander, and the heart of the Spanish Basque country, Guizpuzcoa. From the western tip of northern Spain the sites have Spanish names (Camariñas, Malpica, Antrellusa, Llanes), but as we move eastward, toward the Basque settlements on the Bay of Biscay, the names take on a decidedly Basque flavor: Lequeitio, Ondarroa, Guetaria, Zarauz. Aguilar quotes several sources (including Markham) for the number of whales killed at Lequeitio from 1517 to 1662, and produces a total of some 62 whales, adults and young, from incomplete records, for a provisional average of something less than 2½ whales per year. Occasional records for Guetaria from 1699 to 1789 provide even lower numbers, suggesting that the Biscayan right whales were on the decline by the eighteenth century.

Along the French and Spanish Biscayan coasts, there are several towns and villages whose seals and coats-of-arms depict whale-fishers, including Bermeo, Ondarroa, Motrico, and Fuenterrabia in Spain, and Biarritz, Hendaye, and Guethary in France. Jenkins (1921) wrote, “in this fishery the Bayonnais took part, and it is one of the most interesting features in the ancient records of the town of Bayonne.” For several centuries, the Basques of Biarritz, St. Jean-de-Luz, Bayonne, San Sebastian, and other towns killed the *sarda* in their inshore and offshore waters. This activity did not go unnoticed by the tax collectors. In 1197, King John of England (acting as the Duke of Guienne) collected a tax on the first two whales taken at Biarritz. In 1261, all whales taken at Bayonne were tithed, a continuation of an earlier, voluntary gift of all whales’ tongues to the Church. The kings of Castile and Navarre also extracted taxes from the whalers, often in the form of meat or whalebone. Under a 1324 edict known as *De Praerogativa Regis* (The Royal Prerogative), Edward II of England (1307–1327) collected a duty on every whale captured in British waters, and his successors continued to claim the “royal fish” as Crown property.

To this day, we do not know whence the Basques came, or from whom they were descended. (Their blood type distinguishes them from the French and the Spanish, and biologically as well as linguistically they appear to be distinct from any other people now in existence.) As far as we can ascertain from the scanty records and the ruined stone watchtowers (known as *vigias*) that still stand overlooking the bays, they pursued the right whale. Harmer (1928) wrote, “A watchman who tried to use [the towers] for their original purpose would now have an unprofitable occupation, and he would not be likely to see a single whale of this species during his lifetime.”

³Sandloegja. Good eating. It has whiter baleen plates, which project from the upper jaw instead of teeth, as in all other baleen whales, which will be discussed later. It is very tenacious of life and can come to land to lie as a seal like to rest the whole day, but in sand it never breaks up.

⁴The Scrag whale is near a-kin to the Fin-Back, but instead of a Fin on his Back, the Ridge of the After-part of his back is scragged with a half Dozen Knobs or Knuckles; he is nearest the right Whale in Figure and for Quantity of Oil; his Bone is white, but won’t split.

⁵The fourth sort of whale is called Otta Sotta, and it is of the same color its the Trumpa having finnes in his mouth all white ball white but not above a yard long, being thicker than the Trumpa but not so long. He yeeldes the best oyle but not above 30 heads’ heads.

Even more significantly, the Basques are said to have invented the on-board tryworks, where whales could be processed at sea, avoiding the time-consuming and arduous process of towing the carcass to shore and then winching it up on the beach for rendering. According to Jenkins, this distinction belongs to “a captain of Cibourre named François Sopite,” but surprisingly, in a book heavily footnoted with obscure references, this important fact goes undocumented. In Sanderson’s *Follow the Whale*, however, a whole chapter is devoted to a re-creation of Sopite’s accomplishments, including a description of him standing “silently on the poop with his hands behind his back peering out from under his curious floppy black hat.” Sanderson seems to have consulted many of the same references listed by Jenkins (1921), but he does not tell us where the hat comes from, or how he knows that Sopite was “smiling wryly” at the success of his experiment. Up to that time, whales were flensed and tried-out on shore, which meant that the whalers could never roam too far from their home ports. As we shall see, however, Sopite’s “invention” may have been the invention of some creative authors, since real evidence of the Basque whalers has been uncovered, and there is no indication whatsoever of on-board tryworks.

Even though the hunters never took many whales in a given season, the right whale (known as the Biscayan whale to distinguish it from the Greenland right whale) disappeared from Biscayan waters, and the Basques had to look farther afield for oil and bone. Markham (1881) wrote that each of the whaling villages may have taken no more than a couple of whales per year. This would not be enough to decimate the population, but it is possible that the disturbance caused by the whalers drove the whales to other, less perilous breeding grounds.

From Iberia, Basque fishermen crossed the North Atlantic seeking new grounds. Some evidence indicates that they may have fished the Labrador-Newfoundland grounds as early as the fourteenth century, but were driven off by the local Eskimos. The vessels that they used were not known until recently, when a Canadian archaeologist named Selma Barkham (1984) followed up some vague hints in the historical records of Labrador and with the help of divers located the wrecks of several Basque ships in the area known as Red Bay. Found sitting on the bottom of the bay were the remains of a three-masted, 90-ft galleon which is believed to have sunk in a storm in 1565, and the complete hull of one of the frail chalupas.⁶ On two of Red Bay’s smaller islands, workers found unmistakable evidence of tryworks, where the blubber of the whales was rendered into oil. Since this endeavor took place between the years 1560 and 1570 (ascertained from documents examined in Spanish archives by Barkham), it would appear that Sopite’s “invention” of on-board tryworks was either apocryphal or somehow did not extend to the whaling operation at Red Bay.

As the Basques enlarged the scope of their search for whales to the vicinity of Newfoundland and Labrador, they may well have been the first Europeans to fish the Greenland coasts and the Grand Banks, two of the richest cod-fishing grounds in the world. Upon landing, they predated the “official” discoverers of the land known as Terranova, John Cabot, and Jacques Cartier. In their pursuit of the sea’s bounty, the adventurous Basques visited Ireland, Iceland, Greenland, and evidently sailed as far north as Spitsbergen. They also crossed the Atlantic to find the right whales that inhabited the inshore waters of

Newfoundland and Labrador, but it is unlikely that they made these voyages without island hopping across the perimeter of the Northern Atlantic, much as the Norse had done before them.

Examination of the bones at Red Bay indicate that bowheads were also processed there by the Basques. This location is considerably south of the known range of the bowhead, which includes eastern Arctic waters and the Bering Sea. (It is likely that the Basques took bowheads farther north, and then brought them back for processing, thereby accounting for bowhead bones in a region where bowheads are not known to have lived.) There are no records of Basques hunting humpbacks, but these whales are found off the Canadian Maritime coasts and Greenland.

The rich days of Newfoundland and Labrador whaling ended for the Basques as the sixteenth century was ending. The destruction of the Spanish Armada in 1588 meant that Spanish ships of war could no longer protect fishing fleets so far from home, and the Basque whalers ventured across the Atlantic unprotected. They had established shore stations at Tadoussac and Sept-Iles on the St. Lawrence, where they hunted humpbacks and probably belugas. By 1738, the last Basques had left Canada. Why bother with the transatlantic crossings and hostile North Americans when there were fat Greenland whales for the taking in Spitsbergen? The Basques participated in the early Dutch and British expeditions in Spitsbergen, bringing with them 500 years of whaling experience.

Six Basque harpooners from St. Jean-de-Luz were part of the crew of the first Muscovy Company expedition to Spitsbergen in 1611. In the early years of the Greenland Fishery (Barendsz had named the Spitsbergen islands “Greenland” when he discovered them in 1596, because he believed they were an extension of the island of that name), the Basques sold their services to whoever was willing to pay, but in addition to their participation in the Dutch/British rivalry, the Spanish Basques also sent their own ships to the northern ice in 1613. No sooner had the Spanish tried to join the fishery on their own than James I of England issued the Muscovy Company an exclusive charter to fish the waters of Spitsbergen, to which the Dutch countered in 1614 by forming their own Noordsche Compagnie with the same objectives.

Although the Spanish Basques had the experience and the expertise, they did not have the naval power to back up their claims, and as the Dutch and the British competed for supremacy in Spitsbergen (the Dutch eventually won the battle because of their more effective management and business practices, but in the end, everybody lost because they ran out of whales), the Basques faded into whaling oblivion. As time and progress passed them by, their domestic whaling capabilities diminished accordingly. According to J.-P. Proulx (1986) when a whale stranded at St. Jean-de-Luz in 1764, the hunters could only find old and rusty implements with which to cut it up.

In many respects, the Basques were the advance guard of what would eventually become an all-out war on the whales, but in those relatively uncomplicated times, they were only aware of the nutritional needs that could be fulfilled by the taking of these large, inoffensive animals. They would, however, establish a pattern with regard to the right whale fishery that would serve as an example for virtually every nation that followed their lead: they took the females and calves because they were the most accessible, and by so doing, guaranteed the catastrophic degeneration of the breeding population. In a review of the available data, Aguilar (1981) estimates that during the period 1530–1610, Basque whalers might have taken as many as 40,000 right whales. Medieval Europeans probably did not have much time to ponder the effects of their actions on future generations, however—certainly not on future generations of whales.

⁶A *chalupa* (in French a *chaloûpe* and in the British fishery a *shallop*) was a 25-foot-long whaleboat, rowed by six oarsmen, from which the whale was harpooned and towed to shore.

IV. Aboriginal Whaling

In its early chapters, the story of whaling was a simple one: man against whale. Very infrequently, the whale won. (In *Moby-Dick*, despite the rage of Captain Ahab and the skill of the harpooners, the white whale triumphs.) With the passage of time, the hunters changed the nature of the hunt, and turned it into an industry. The hunted whales remained unevenly matched with their opponents; all they had was the hope of escape in the depth and expanse of the ocean. As the industry grew more economically important, technological innovations were introduced that greatly altered the odds. The introduction of diesel catcher boats, exploding harpoons, spotter planes, sonar and asdic greatly changed the nature of the hunt. No longer remotely equitable, it was not even a hunt any more, but a highly mechanized business. The whale had as much of a fighting chance as a tree had against a chain saw.

There are only a few places in the world where people still *hunt* whales. The Caribbean island of Bequia in the Grenadines, e.g., has a relic humpback whale fishery that the Bequians learned from Yankee whalers in the nineteenth century. The Eskimos of Greenland hunt minke whales and humpbacks (they are given a quota by the International Whaling Commission), as well as belugas and narwhals, which are considered “small cetaceans” and are not under the jurisdiction of the IWC. Alaskan Eskimos “hunt” the bowheads that annually pass their North Slope villages, but because of the complexities of politics and other factors, they have upgraded their weaponry to the point where once again, the whale has hardly any chance of escaping. The only place where whaling takes place in a thoroughly primitive manner (and completely unregulated by the IWC) is in Indonesia.

Lomblen, also known as Lembata, is one of a group of islands that make up the Sunda Archipelago (*Nusa Tenggara Timur* to the Indonesians), which includes the large islands of Timor and Flores, as well as the smaller Solor, Adonara, Pantar, and Alor. Lomblen/Lembata is only one of the 13,000 islands that comprise the 3000 mile long country of Indonesia, but there is something very special about this island. On its southern shore is Lamalarep, one of the few whaling villages in all Indonesia. Lamalarep is the poorest village on the island because it has virtually no industry or agriculture other than whaling, and the success rate of the whalers seems to be rather low. They might capture a whale on 3 trips out of 10; to put it another way, 70% of their trips are unsuccessful. The villagers of Lamalarep do not eat the bulk of the whale meat they take, but dry it in the sun and trade it to other villages for vegetables.

In June of 1979, a research team was sent to Lamalarep by the World Wildlife Fund to investigate the whaling activities there. Unfortunately, on July 17, a giant tsunami inundated Lomblen, causing over 700 casualties and destroying the villages of Wai Teba and Sara Puka. The investigators all survived, however, and remained on Lomblen for 3 weeks. On July 26, on nearby Rote Island, a “giant shark” (species unidentified) was found with the body of what was thought to be a Lomblen fisherman in its stomach. (It is likely that the shark ate one of the victims of the tsunami, rather than taking a swimmer or a fisherman.)

At dawn the Lamalarep fleet sets out for a day’s hunting. They may roam as far as 17 miles offshore, but the whales are usually found closer to the islands. The boats (known as *peledang*) are about 30 ft long and brightly painted, often with vigilant eyes on the bows. No nails are used in their construction, only wooden pegs; and the sails are patchwork rattan, a single gaff-rigged square sail for each boat. A crew of 10 to 15 men rows (or sails, if the winds are favorable) the boat out to the whaling grounds, south of the islands in the Savu Sea. They look for the forward-angled spouts of the largest of

the toothed whales, the sperm, which they call *ikan pails* in Bahasa Indonesia. (In the language of the islands that was employed before the introduction of this *lingua franca* by President Sukarno, the sperm whale was known as *kotan klema*.) During the 10 weeks that the World Wildlife Fund researchers kept records, the whalers of Lamalarep took sperm whales, killer whales, pilot whales and several species of dolphins. Traditionally, the whalers of Lamalarep do not hunt baleen whales. Although the men of Lamalarep are considered whalers, they will also harpoon any large fish, ray or turtle that they encounter, including sharks, marlin, and ocean sunfish (*Mola mola*).

The whalers of the island are divided into hereditary “corporations,” each of which owns a whaling vessel. The vessels—and their names—are passed down from generation to generation, so when a given boat wears out, the next one built by that clan is given the same name.

When a whale is sighted, the *peledang* crews row stealthily upon it, douse the sail, and because they are Christians, they whisper a communal *Pater Noster* for their own protection. The harpooner stands on a narrow platform with his bamboo-shafted harpoon poised. At the critical moment, when he is within striking range of the wrinkled, humped back of the whale, the harpooner launches not only the harpoon, but *himself* through the air, using his strength and his weight to drive the iron deep into the flesh of the whale (Fig. 1).

As the whale is slowed or stopped by the pain of the harpoon in its back, another harpooner throws himself on the whale, and if necessary, another. The iron must be planted in exactly the right place to kill the whale; otherwise the fragile *peledang* will be towed for miles as the whale pulls the whalers on the Indonesian equivalent of the “Nantucket sleigh ride.” There are stories of boats being towed all the way to Timor by a maddened whale. (In fact, there are many tales about maddened whales in the Timor Sea. One of the most notorious of all these was a bull sperm whale named “Timor Jack,” who savaged whaleboats for years until he was taken by setting out a barrel on a line which he attacked, allowing whalers to lance him.) Or the whale will dive, pulling the line out rapidly and unless it is cut, and pulling the boat down with it. If the right spot is pierced (the heart or lungs), the whale will spout blood from its blow-hole and expire quickly. The dead whale is towed back to the village where it is butchered.

There is a complex system for dividing up the meat of a whale, in which the carcass is portioned out according to rank in the clan and the village. The meat is eaten or bartered to other villages; the oil is used for lamps. The men of the village may carve patterns onto the teeth, like scrimshanders everywhere.

The villagers of Lamalarep kill between 30 and 50 sperm whales every year. They do not take the large bulls, because the big males do not visit these waters. They cannot eat all the meat, so they barter it in neighboring villages. This is in direct contravention of the regulations of the International Whaling Commission, but since Indonesia is not a signatory to the Whaling Convention, the IWC regulations are difficult—if not impossible—to apply.

Whaling, Illegal and Pirate

ROBERT L. BROWNELL, JR., AND ALEXEY V. YABLOKOV

Illegal whaling occurs in contravention of national laws or internationally agreed quotas, season, area restrictions, and other limitations, whereas “pirate whaling” refers to unregulated whaling conducted outside the aegis of the International Whaling Commission, usually under a flag of convenience. Such activities can lead directly to depletion of whale populations through overexploitation. Furthermore, the lack of catch data, or the reporting of falsified data, can lead to serious error in assessment of the size and status of populations and erroneous management advice ultimately contributing to their collapse.

I. Illegal Whaling

Known instances of illegal whaling were conducted by several nations. Because the offenses of the USSR were the most egregious, most of this discussion will focus on what is known of Soviet activities. The Soviet Union conducted massive illegal whaling and falsification of data over a period of decades, with catastrophic consequences for whale CONSERVATION and development of the science of whale MANAGEMENT. The USSR commenced pelagic whaling in the North Pacific with the *Aleut* in June 1933 (Tønnessen and Johnsen, 1982). This floating factory operation continued in the North Pacific through the 1967 season. After this date, four additional Soviet factory ships conducted pelagic whaling operations in the North Pacific. The last season was in 1979 when the Soviets stopped whaling in the region. For more than a decade following the end of World War II, the USSR operated a single whaling factory ship (*Slava*) in the Antarctic. Beginning in 1959, the Soviets began expanding their whaling operations, adding one new factory ship in each of the next three Antarctic seasons (*Sovietskaya Ukraina* in 1959/1960, *Yuri Dologorukiy* in 1960/1961, and *Sovietskaya Rossiya* in 1961/1962). This expansion occurred at a time when there was extensive discussion in the IWC about declining stocks and other countries were decreasing their whaling operations. The USSR voted against the drastic reductions in catch quotas required to meet scientific recommendations and against implementation of an International Observer Scheme (IOS), both of which were eventually put in place. After the breakup of the Soviet Union, a number of Russian and Ukrainian biologists who had served aboard Soviet factory ships and knew of the existence of accurate but unreported catch statistics decided to collect them and make them available to the world scientific community. This section summarizes information on Soviet illegal activities during the two major phases of its whaling in the Southern Hemisphere and North Pacific and briefly notes recent information on illegal whaling activities by other nations.

TABLE I
Comparison of Southern Hemisphere USSR Commercial Catch Data (1947–1972)^a

Species	Reported	Actual	Disparity
Blue whale	3,887	3,681	+206
Pygmy blue whale	10	9,215	−9,205
Fin whale	52,860	48,889	+9,971
Sei whale	29,751	53,366	−23,615
Bryde's whale	10	1,457	−1,447
Minke whale	1,246	384	+862
Humpback whale	2,820	42,889	−43,011
Southern right whale	4	3,368	−3.364
Sperm whale	50,715	72,372	−21,657
Killer whale	482	124	+358
Southern bottlenose whale	10	17	−7
"Others"	0	29	−29
Total	141,795	232,733	−90,938

^aReported to the IWC with numbers actually taken. Modified from Yablokov *et al.* (1998) and Tormosov *et al.* (1998).

A. Southern Hemisphere

A summary of the disparity between USSR catch data reported to the IWC and actual takes is given in Table I (modified from Yablokov *et al.*, 1998). These data concern catches made by Soviet fleets working in, or en route to or from Antarctic waters. The period concerned is from the beginning of post-war Soviet whaling in 1947 until the introduction of international observers in the 1972/1973 whaling season, when most illegal activities ceased. During this period, unreported catches totaled 102,335 whales, almost half (44%) of which were humpbacks (*Megaptera novaeangliae*). However, 11,397 animals (primarily fin whales, *Balaenoptera physalus*, which were then an unprotected species) were actually over-reported; this was done to conceal the massive illegal catches of pygmy blue (*B. musculus brevicauda*), sei (*B. borealis*), humpback, and southern right whales (*Eubalaena australis*).

Massive falsification of geographic data began in 1959 and was practiced by all four Soviet Antarctic whaling fleets. The primary areas for illegal catches were numerous sections of the South Atlantic, the Indian Ocean (including as far north as the western Arabian Sea), and the southwestern Pacific (Yablokov, 1994; Zemsky *et al.*, 1995a, b). IWC regulations prohibited the taking of baleen whales (mysticetes) north of latitude 40°S, although the killing of sperm whales (*Physeter macrocephalus*), killer whales (*Orcinus orca*), and bottlenose whales (*Hyperoodon planifrons*) in this region was permissible. Therefore, the Soviets used the pretext of hunting toothed whales to exploit mysticete populations in the prohibited areas. Soviet whaling fleets bound for the Antarctic began search and catcher operations immediately after leaving the Red Sea or after passing either Gibraltar or Portuguese waters.

Virtually all biological data reported to the IWC were "corrected" to disguise the extensive illegal catches. Because of the prohibition on killing mothers and calves, all such cases were either unreported or were concealed with false data. Thus, a fin whale mother and calf might be reported as "two sei whales," whereas a catch of four female sperm whales would be reported as "two males." It has been estimated that at least 80% of all officially reported Soviet data on length, weight, sex ratio, reproduction, and maturational state are false.

The scale of the Soviet catches partly explains the apparent failure to recover that has been evident in some mysticete populations despite their supposedly protected status. The Soviets killed 12,896 blue whales in the Southern Hemisphere, of which more than 9200 were unreported pygmy blues killed after the IWC accorded protected status to both subspecies by the 1965/1966 season. Catches were made over a wide area, including the Indian Ocean north of the equator. Thus, these populations were reduced to much lower levels than the 800–1600 (blue) and 10,000 (pygmy blue) that were estimated at the time. Although recent estimates of 500 and 5000 for current Antarctic populations of blue and pygmy blue whales, respectively, are not statistically robust, it is apparent that the population sizes are smaller than would be expected following three decades of protection.

Humpback whales were even more seriously impacted by illegal catches. In addition to the huge number (45,831) of unreported catches made by the Soviets, it is known that additional illegal takes were made in Antarctic waters by the *Olympic Challenger*, a pirate factory ship owned by Aristotle Onassis (Tønnessen and Johnsen, 1982), discussed later. The Australian biologist Graeme Chittleborough (1965) asserted that large discrepancies in calculated mortality coefficients for humpbacks could be explained only by the occurrence of extensive illegal catches, a view that is now validated by the Soviet catch data reported here. Many of the Soviet catches were made from management division known as Antarctic Area V (Dawbin, 1966), which explains the collapse of shore whaling stations in eastern

Australia and New Zealand in the early 1960s. There is now evidence of strong population growth in some Southern Hemisphere humpback populations (Bannister 1994; Paterson *et al.*, 1994; Findlay and Best, 1996), but the status of other stocks remains unclear.

Additional illegal Soviet pelagic whaling occurred in the Arabian Sea on humpback (Mikhalev, 1997a), blue, Bryde's (*Balaenoptera edeni*), and sperm whales during the 1960s (Mikhalev, 1996, 1997b; personal communication). This whaling occurred while the whaling fleets were en route to the Antarctic whaling grounds. Biological data from humpback catches made in November 1966 off Oman and India have resolved a long-standing issue regarding the identity and boreal breeding cycle of this population, which is unique among humpbacks in that it resides in tropical waters year-around (Mikhalev, 1997a). However, the status of this tropical population of humpbacks remains uncertain.

Southern right whales have always been protected under IWC regulations; this status dates from a League of Nations agreement in 1935. Recovery (increasing populations) is today apparent in only 4 of the 13 putative populations of this species (Best, 1993), although five of the remaining nine stocks are considered impossible to monitor on a regular basis. True data show that the Soviets made large unreported catches (3368) of right whales between 1950 and 1971 (Tormosov *et al.*, 1998). Many of these takes were made around remote islands or in mid-oceanic areas such as Campbell Island, Crozet, Kerguelen, Tristan da Cunha, and the central Indian Ocean.

B. North Pacific

A single Soviet whaling factory operated in the North Pacific between 1933 and 1967, a small vessel named the *Aleut*. Four additional Soviet factory ships later operated there. A new ship, the *Sovietskaya Rossiya* (built as the sister ship to the *Sovietskaya Ukraina*), operated for four seasons (1962–1965) and then again for three more seasons in 1973, 1978, and 1979. The *Slava*, after working for many years in the Southern Hemisphere, worked in the North Pacific for four seasons (1966–1969). Two sister whaling factory ships were built specifically for the North Pacific (the *Vladivostok* and the *Dal'ny Vostok*); both began operations in 1963. The *Vladivostok* operated through 1978 and the *Dal'ny Vostok* through 1979. The main whaling grounds for these two fleets were the Bering Sea, Gulf of Alaska, and other more southerly parts of the North Pacific.

The whales in the North Pacific did not fare any better than those in the Southern Hemisphere. However, the available records of the true catches are not as good. Doroshenko (2000a) and others reported numerous illegal catches of North Pacific right whales (*Eubalaena japonica*) in both the western and the eastern North Pacific, catches which devastated the last of the latter population. Brownell and colleagues (2000) provided some data on massive illegal catches of sperm whales, on the order of 180,000 whales, in the North Pacific. Soviet pelagic whaling operations in the North Pacific also illegally took blue, humpback, bowhead, and gray whales (*Eschrichtius robustus*) (Doroshenko, 2000a). A summary of the inconsistencies between data reported by the USSR to the IWC and actual catches is given in Table II.

It is known that illegal whaling on a similarly large scale was also conducted by the USSR throughout the Northern Hemisphere, although the same details of catch data are not available. In light of these revelations about the true catches in both the Southern Hemisphere and the Northern Hemisphere (North Pacific Ocean), it is clear that current views regarding the status and recovery potential of virtually all affected whale populations worldwide need revision. This

is a long-term project that has been underway by the staff of the IWC and others for over a decade and may continue for another decade.

At the 50th IWC meeting in Oman in 1998, the IWC took action on the Scientific Committee's (SC) concern about the falsified Soviet whaling data, mainly for sperm whales, by adopting the SC recommendation to remove the official Soviet Southern Hemisphere whale catches from the IWC database.

The USSR was not alone in the illegal hunting of whales. Recent evidence on the falsification of catch statistics has been reported for various North Pacific land-based operations conducted by the Japanese (Kasuya, 1999; Kasuya and Brownell, 1999, 2001; Kondo, 2001). Suspicions about illegal reporting in Japanese operations are not new and have been presented in the past (Kasuya and Miyazaki, 1997). The scale of these activities, however, was much smaller and the consequences less severe than in the case of the Soviet whaling. Sperm whale catches between 1954 and 1964 were 1.4 to 3 times greater than the numbers Japan reported to the IWC. The total true catches of Bryde's whales taken during the final years of commercial land-based whaling (1981–1987) off the Bonin Islands were 1.6 times the numbers Japan reported to the IWC. Fin whales were reported taken illegally by the Republic of Korea in the 1980s and minke whales were still reported taken illegally in the early 2000s.

During the 1990s and the following decade, numerous reports appeared regarding the sale of "illegal whale products" from protected whales collected in the Japanese market (Baker *et al.*, 2000). It is argued that Japan's scientific whaling program (since 1989) has acted as a cover for undocumented or illegal products from various protected species (fin, sei, humpback, and gray). While this is possible, there are no available data to support the occurrence of any large-scale illegal whaling during the 1990s. The most parsimonious explanation for the whale products from protected species is that they are from (1) whales killed before the 1986 IWC moratorium on commercial whaling, (2) past scientific hunts by Iceland or Norway, (3) by-catches from Japanese fisheries, and (4) STRANDINGS in Japan.

II. Pirate Whaling

As noted earlier, unregulated whaling conducted under the flags of non-IWC member nations has contributed to the depletion of some whale stocks. The most famous of these operations was that

TABLE II
Comparison of North Pacific Commercial USSR Catch Data (1961–1972)^a

Species	Reported	Actual	Disparity
Blue whale	517	1,205	−688
Fin whale	10,613	8,621	+1,992
Sei whale	9,048	4,177	+4,871
Bryde's whale	775	714	+61
Humpback whale	3,043	6,793	−3,750
Gray whale	0	138	−138
Right whale	0	508	−508
Bowhead whale	0	133	−133
Total	23,996	22,289	+1,707

^aReported to the IWC with numbers actually taken.

conducted by interests in Norway and Japan from 1968 to 1979 in the North and South Atlantic under the flags of Somalia, Cyprus, Curaçao, and Panama. Meat from the whales was shipped to Japan for human consumption. The *Run* operated mainly in the South Atlantic from January 1968 to February 1972. It was renamed the *Sierra* in 1972 and expanded major operations to the North Atlantic in 1975, where it continued taking whales until it was rammed and sunk by the *Sea Shepherd* (a privately operated vessel dedicated to interference with commercial whaling) in 1979 off Portugal (Watson, 1979). The *Tonna* joined the *Sierra* in December 1977 and operated until July 1978, when it foundered during processing of a large whale on deck. The *Cape Fisher*, later renamed the *Astra*, operated briefly as a processing vessel for the *Sierra* in 1979.

The *Sierra* Fishing Agency submitted its catch statistics to the Bureau of International Whaling Statistics in Norway until 1976, when the practice was discontinued because of a perceived lack of credibility of the data. Data for the remaining years of operation were destroyed, but some information was salvaged through interviews with former crew members (Best, 1992). The catches included blue, fin, sei, Bryde's, humpback, and minke (*Balaenoptera acutorostrata* and/or *B. bonaerensis*). Large catches of fin whales totaling hundreds were made off the coasts of Spain and Portugal (the IWC's "Spain-Portugal-British Isle Management Area") after 1976.

Another notorious episode of pirate whaling occurred in the Southern Hemisphere from 1951 to 1956 by the factory ship *Olympic Challenger* and its fleet of 12 catcher boats (Tønnessen and Johnsen, 1982). The Olympic Whaling Company, an affiliate of the Pacific Tankers Co. of New York, was financed by the Greek-born Argentine citizen Aristotle Onassis. The ownership of the vessel, a converted tanker, was later transferred to the Olympic Whaling Company S.A. in Montevideo, Uruguay. The captain was German and the expedition manager Norwegian. The factory ship and some of the catcher vessels flew the Panamanian flag and the remainder of the catchers the Honduran flag. Neither Panama nor Honduras were members of the IWC at the time, so the whaling operations were completely unregulated. The expedition took thousands of whales in the Antarctic South Pacific sector and off Chile, Peru, and Ecuador, including blue, humpback, sei, right, and sperm. Catch data were reported to the International Bureau of Whaling Statistics, but these have been shown to include extensive falsification of number, species, and sizes of whales caught (Barthelmeß *et al.*, 1997). As noted earlier, these unregulated catches in combination with later illegal catches by Soviet fleets contributed in a major way to the catastrophic decline of whales in the Southern Ocean, particularly the humpback.

Whaling, Modern

PHILLIP J. CLAPHAM AND C. SCOTT BAKER

There is no means known to catch the fin whale, or its fast cousins.

So wrote Herman Melville in the year 1851, echoing the common lament of whalers that the fastest (and some of the largest) species of whales, such as the finback (*Balaenoptera physalus*) and the blue (*B. musculus*), lay beyond contemporary means of capture. At the time that Melville wrote *Moby Dick*, the basic technology of whaling had remained essentially unchanged for centuries. Whaling ships plied their trade under sail, and the small boats that they lowered to pursue whales were also powered by wind, or by the brute strength of their crew’s arms at the oars. The killing of whales required men to bring their frail craft alongside the huge quarry, subduing and fastening to it with hand-thrown harpoons. If this dangerous series of actions succeeded, the whale might ultimately be dispatched with a lance thrust deep into some vital organ. Once killed, the whale’s carcass would be either towed to shore, or brought alongside the whaling vessel for the time-consuming process of butchering.

I. The Emergence of Modern Whaling

These methods had been in use in the eleventh century when the Basques began the first sustained commercial whale fishery, on North Atlantic right whales (*Eubalaena glacialis*) in the Bay of Biscay (Ellis, 1991). Although many improvements had been made, the technology available to whalers in the middle of the nineteenth century severely limited the number of animals that could be taken and processed in a working day. Furthermore, as Melville noted, it largely precluded exploitation of the faster species. Blue, fin, sei (*B. borealis*), and Bryde’s (*B. edeni/brydei*) whales, all large and desirable targets, were too swift to allow pursuit by oars or sails. Thus, it was the slower species such as the humpback (*Megaptera novaeangliae*), the right, and the sperm whale (*Physeter macrocephalus*) which had borne the brunt of commercial whaling, and they had done so in some cases for almost a 1,000 years.

By 1860, however, all of this was about to change (Tønnessen and Johnsen, 1982). Two men, the Norwegian Svend Føyn and an American named Thomas Welcome Roys, were independently experimenting with explosive harpoons. As patented by Roys in 1861, this device was initially fired from a shoulder gun; Føyn developed a different approach using a bow-mounted cannon, which was to become the industry standard. The “bomb lance” was an innovation that was to revolutionize the whaling industry by providing a much more efficient means to dispatch whales, both quickly and from a distance.

About the same time, the use of sail was beginning to give way to steam. This was a key innovation: together with the explosive harpoon, it radically changed the industry, and finally allowed the pursuit and capture of any whale. Suddenly, even the fastest rorquals came under the gun as they were chased down by motorized catcher boats.

A further innovation, the compressor, solved a long-standing problem with regard to the many species which did not float when dead: by pumping air into the carcass immediately after death, whalers could secure it before it sank, thus greatly reducing the loss rate.

For the industry, this transition into the mechanized age could not have come at a more opportune time. By 1900, many populations of the traditionally hunted species were commercially exhausted. In some cases, such as the bowhead (*Balaena mysticetus*) and the North Atlantic right whale, this was the result of exploitation spread over centuries. With some other stocks, decimation had been accomplished in a remarkably short time; the first North Pacific right whale (*Eubalaena japonica*) was not killed until 1835, yet 14 years later the population had already been reduced to the point where many whalers switched their focus to the newly established fishery for bowhead whales in the western Arctic. Another quickly depleted stock was that of the eastern North Pacific gray whale (*Eschrichtius robustus*), made vulnerable by its predictable coastal migration and tendency to concentrate for breeding and calving in the lagoons of Baja California.

The new technology opened up all species to whaling, and did so at a time when the industry, spurred on by steam power, was also expanding geographically. By far the most significant development in this regard was the discovery of the vast stocks of whales in the Southern Ocean. In 1904, the Norwegian whaler C.F. Larsen arrived at the South Atlantic island of South Georgia and reported with astonishment, “I see them in hundreds and thousands.” Huge pristine populations of rorquals—notably blues, fin whales, and humpbacks—filled the surrounding waters together with southern right whales and other species. Modern whaling had found its greatest playground, and a slaughter unparalleled in whaling history was about to begin.

Whaling at South Georgia was initially constrained by the need to use land stations for processing of the carcasses. Because of this, spoilage limited the range of the catcher boats; it also left the whaling companies vulnerable to high taxes levied by the British authorities. Despite these difficulties, the industry accomplished the destruction of local stocks of whales with remarkable efficiency. At the height of operations, hundreds of humpback, fin, and blue were taken in a single month. By 1915, the South Georgia population of humpbacks had essentially been extirpated, with a total catch of some 18,557 whales; while occasional catches were made in later years (the largest being one of 238 humpbacks in 1945/1946), the stock had essentially been rendered commercially extinct by the time of the Great War. Blue whales suffered a similar fate; 39,296 were killed at South Georgia between 1904 and 1936, at which point the population had crashed, irretrievably.

The problem of dependence upon land stations was solved, at a stroke, with the introduction of the factory ship. The British vessel *Lansing* was the first such floating factory and began operations in Antarctic waters in 1925. It is difficult to overestimate the importance of this innovation to whaling, or its contribution to the destruction of whale populations in the Antarctic. Factory ships could operate independently far out to sea for months at a time. They maintained round-the-clock processing operations, their huge flensing decks kept constantly supplied by an attendant fleet of catcher boats. Whale carcasses were hauled up the large stern ramp and dismembered with astonishing mechanical efficiency; an adult fin whale of 70 or 80 ft and 100 tons could be rendered

from whole animal down to bone in half an hour. With the factory ship, all of Antarctic waters became open to whalers, their operations limited only by the constant dangers of weather and ice.

Over the six decades following the opening of the Antarctic grounds in 1904, the whaling industry killed more than 2 million whales in the Southern Hemisphere (Table I). This included 360,000 blue whales, some 200,000 humpbacks, 400,000 sperm whales, and a staggering three-quarters of a million fin whales. By the 1930s, it was apparent even to the whaling nations that some kind of regulation was required. In 1931, the Convention for the Regulation of Whaling was

held and adopted worldwide protection for right whales, an action which came into effect in 1935. The Second Convention for the Regulation of Whaling was held in 1937 and provided protection for the much-depleted gray whale. However, neither convention went far enough; among other things, since neither Japan nor the Soviet Union ratified these agreements, both were theoretically free to continue killing the only two species that had been granted protection (Fig. 1).

II. Advent of the International Whaling Commission

In 1946, following the virtual cessation of whaling that occurred during World War II, the International Convention for the Regulation of Whaling was developed and signed by all major whaling nations (including Japan and the USSR). Among other things, this landmark convention created the International Whaling Commission (IWC), established to regulate whaling and to oversee research on whale stocks. The latter task had as its principal objective learning enough about the abundance, population structure, and life history of the great whales to permit the IWC to set quotas that would allow the highest viable level of exploitation, a concept widely known as Maximum Sustainable Yield (MSY).

Unfortunately, the quota system of the IWC was immediately handicapped by an earlier development. In 1932, the whaling nations had developed the "Blue Whale Unit" (bwu). A single bwu was equivalent to one blue whale, two fin whales, two and a half humpbacks, or six sei whales. As such, quotas set in bwu, by permitting whalers to make their own decisions about which whales to take, made no allowance for the conservation status of a particular species,

TABLE I
Southern Hemisphere Catch Totals, 1900–2005.

Blue	362,770
Fin	725,331
Sei	203,843
Humpback	213,245
Bryde's	7,881
Minke	119,415
Right	4,424
Sperm	405,898
Other	11,835
Total	2,054,642

let alone that of a specific population. It was not until 1949 that a species-specific quota (for humpbacks) was established.

The bwu remained in effect until 1972, despite recommendations from IWC scientists as early as 1963 that it be abolished (also in 1963, the same scientists recommended a halt to all humpback and blue whaling; the IWC responded by setting a quota of 10,000 bwu). In some years, the IWC could not agree on a bwu quota, and whaling nations were left to make their own informal agreements on catch levels. Overall, the bwu arguably represents the most ill-conceived and damaging management strategy in IWC history. However, it was far from the only problem in the Commission's management of whale populations.

III. Illegal Whaling

The result of this was that some breeding areas for sperm whales became deserts.

Soviet biologist Alfred A. Berzin

From its inception, the IWC was hampered by the unwillingness of the whaling nations to pay attention to the mounting evidence of decline in whale populations and by the complete lack of any enforcement or independent inspection measures. That the first humpback whale quota promulgated in 1949 was immediately exceeded in the three subsequent Antarctic seasons pointedly highlighted the latter issue. Additional examples followed, but it was not until the 1990s that the true extent of this problem became apparent, and it was more egregious than anyone could have predicted.

In 1993, following the end of the Cold War, former Soviet biologists revealed that the USSR had conducted a massive campaign of illegal whaling beginning shortly after World War II (Yablokov *et al.*, 1998; Ivashchenko *et al.*, 2006). Soviet factory fleets had killed virtually all whales they encountered, irrespective of size, age, or protected status. The scale of this deception was staggering; in all, the difference between the USSR's reported take and its actual catches was close to a 100,000 animals in the Southern Hemisphere alone (Table II). Of these, the humpback whale was the most heavily

impacted; reporting 2710 catches to the IWC, the Soviets had in fact taken more than 48,000. In the Northern Hemisphere, Soviet activities were on a smaller scale, but were nonetheless extremely damaging in some cases. The virtual disappearance of right whales in the eastern North Pacific in the 1960s was recently explained by revelations of Soviet catches of 372 whales from this already small stock between 1963 and 1967.

In retrospect, it is possible to see clues to this unfolding catastrophe. Beginning in 1959, at a time when there was increasing discussion of declining populations and the need for diminished quotas, the Soviets began adding a new factory ship each year to their Antarctic Fleet. These included the *Sovetskaya Ukraina*, the largest floating factory ever built, with an attendant fleet of 25 catcher vessels. In just two seasons (1959/1960 and 1960/1961), *Sovetskaya Ukraina* and a second factory, the *Slava*, killed almost 25,000 humpbacks, mainly from the high-latitude waters south of Australia and western Oceania. In addition, the intransigence of the USSR in its opposition to a proposed International Observer Scheme (IOS, to permit independent inspections of catches at sea) is now easy to interpret.

In the latter part of the 1960s the IWC finally began to respond to the increasing evidence that whale populations had been exploited well beyond MSY. Blue whales were protected in 1965, and quotas for fin and sei whales were reduced in the late 1960s in response to declines in catches. Nonetheless, any enforcement remained absent, and the Soviets secretly continued to kill whales irrespective of quota or protection until adoption and implementation of the IOS was finally accomplished in 1972.

However, it is now known that extensive falsification of catch data also occurred in Japan's coastal fisheries for Bryde's and sperm whales into the 1980s.

IV. The Decline of Commercial Whaling

In the following decade, however, a sea change occurred at the IWC. The composition of the Commission slowly shifted as non-whaling nations joined, whereas others ceased whaling and developed instead into advocates for conservation. A whaling moratorium was proposed by the US and Mexico as early as 1974, but this and later proposals were rejected by the IWC until 1982. In that year, a radically changed Commission finally achieved the necessary votes to pass a 10-year moratorium. Predictably, Japan, Norway, and the Soviet Union all objected. The moratorium went into effect in 1986, with a zero catch quota for both pelagic and coastal whaling.

At this point in time Soviet whaling was coming to an end; with aging capital and the imminent dissolution of the USSR, the nation that had wreaked so much havoc on whale populations (a fact still unknown at this time) slowly removed itself from the business of commercial whaling. Japan, Norway, and Iceland, however, remained active, and in 1987 they effectively circumvented the moratorium by beginning "scientific" whaling. This act exploited a provision in the Convention (Article VIII) which allows member nations to issue themselves permits to conduct whaling for scientific research; it was originally included at a time when the only way in which any information could be gathered about whales was to kill them. As opponents of scientific whaling pointed out, the emergence in the 1970s of long-term studies of living whales (frequently based upon the identification of individual animals) provided a much better means to study the biology and behavior of cetaceans.

The stated reason for the moratorium was to permit world whale stocks to recover from the overexploitation to which they had been subject. In the meantime, the IWC's Scientific Committee was

TABLE II
Reported vs. Actual Catches in the Southern Hemisphere by the USSR

Species	Reported	Actual
Blue	3,651	3,642
Pygmy blue	10	8,439
Fin	52,931	41,184
Sei	33,001	50,034
Humpback	2,710	48,477
Bryde's	19	1,418
Minke	17,079	14,002
Right	4	3,212
Sperm	74,834	89,493
Other	1,539	1,745
Total	185,778	261,646

Note: Some catches were actually over-reported; this was to disguise takes of protected species by over-reporting catches of species which could be legally hunted at the time.

charged with developing a new procedure for future management of stocks and setting of quotas. After considerable debate, the so-called Revised Management Procedure (RMP) was accepted by the Scientific Committee in 1994. However, the scheme by which the RMP would actually be implemented had still not been adopted, and there remains considerable resistance to the idea of the IWC endorsing a program which would effectively permit the resumption of commercial whaling. In 1994, Norway preempted such an agreement by resuming commercial whaling under "objection" to the moratorium, and used the RMP to set its own catch quotas for minke whales (*Balaenoptera acutorostrata*) in the northeastern North Atlantic. Norway has recently announced that it intends to unilaterally amend the RMP because it views the procedure as too conservative.

The reluctance of many nations to implement the RMP stems largely from lingering concerns regarding enforcement and transparency (i.e., independent observation and inspection) in whaling operations. These issues are considered by most nations to be essential components of a Revised Management Scheme (RMS), within which the RMP would operate. At present, however, there is little agreement on the general framework or specific inspection mechanisms of an RMS. The whaling nations maintain that adequate measures are now in place to ensure compliance with quotas set under the RMP. Opponents disagree, pointing to the egregious history of deception in modern whaling and noting more recent evidence that such deception continues to exist. In particular, considerable attention has been focused on the use of forensic genetics to test samples of whale meat in Japanese markets; although the only meat that should be found there is that from minke and Antarctic minke whales (*Balaenoptera bonaerensis*) taken in Japanese scientific catches, numerous other species have been detected (Baker and Palumbi, 1994). Although many of these animals certainly represent bycatch (incidental entrapment in fishing gear), their presence reinforces the fact that there is currently no means to adequately track whale products at every stage from catch to market. A DNA Registry of all animals taken in Japanese and Norwegian hunts has been implemented. However, confidence in this system has been compromised by the whaling nations' refusal to permit independent monitoring of the registry and their insistence that any discussion of trade in whale products is outside the competency of the IWC and lies instead within the purview of the Convention on International Trade in Endangered Species (CITES) or the World Trade Organization.

V. Impact of Whaling on the Stocks of Whales

The impact of modern whaling on the world's stocks of whales has been varied (Clapham *et al.*, 1999). Many species appear to be recovering well in most parts of their range despite exploitation which in many cases may have reduced numbers by 90% or more from pre-exploitation levels (Best, 1993). Humpback whales, which were extensively over-hunted worldwide and which bore the brunt of illegal Soviet catches in the Southern Hemisphere, are showing strong rates of population growth in the North Atlantic, North Pacific and many areas of the Southern Ocean. Eastern gray whales number more than 20,000 animals and in 1994 were removed from the US list of endangered species. Although no reliable estimates of abundance exist, populations of fin and sei whales are assumed to be healthy in the Northern Hemisphere; the status of the extensively exploited Antarctic populations is less clear. Similarly, sperm whales are likely to be generally abundant, although in some areas apparently slow rates of population growth may be attributable to overexploitation of mature males in high latitudes, resulting in insufficient availability of mates

that are "acceptable" to adult females. Furthermore, female sperm whales were extensively exploited in the North Pacific by Soviet illegal whaling, and the status of this population is unknown. Although there is considerable controversy over Japanese and Norwegian minke whaling (and over the associated estimates of abundance), it is generally agreed that the Antarctic minke and some stocks of common minke are abundant. However, serious concern has been expressed by the IWC Scientific Committee about scientific hunting and unregulated bycatch of minke whales from coastal stocks around Japan and Korea.

In contrast, other populations of whales appear to be struggling to recover from the indiscriminate exploitation to which they were subject. In some extreme cases, local populations appear to have been extirpated, with no recovery evident in the intervening years. Humpback and blue whales at South Georgia were commercially extinct by 1915 and 1936, respectively, and are rarely observed there today. Blue whales were wiped out from the coastal waters of Japan by about 1948, and no members of this species have been recorded there in recent years despite often extensive survey effort. Off Gibraltar, a population of fin whales was extirpated with remarkable rapidity between 1921 and 1927. The population of humpbacks that used the coastal waters of New Zealand as a migratory route crashed in 1960, the result of protracted shore whaling and (in particular) the Soviet catches of some 25,000 humpbacks in the feeding grounds to the south; some sightings have been reported off New Zealand in recent years, perhaps suggesting that a slow recovery is underway. In the North Atlantic, right whales were removed from much of their former range largely by historical whaling prior to 1880, and a remnant population in European waters was extirpated by Norwegians using modern techniques at the beginning of the twentieth century. The demise of at least one stock of whales can be attributed exclusively to pre-modern whaling: the bowhead was commercially extinct from Spitsbergen waters by 1900, and the species is only occasionally observed there today.

In all of these cases, whaling essentially extirpated a stock of whales; the lack of recovery over a timescale ranging from four decades in the case of New Zealand humpbacks to almost four centuries for right whales in some parts of the North Atlantic has important implications for modern management of whale populations. Although it is quite likely that the observed lack of recovery was at least partly due to a simultaneous overexploitation of adjacent populations (i.e., those that might otherwise have provided a source for repopulation), these localized extirpations reinforce the belief that management units should be designed carefully on often smaller spatial scales than has often been the case in the past.

Of those populations which survived, several are critically endangered. Right whales persist in low numbers in the western North Atlantic and the western North Pacific; the present size of the eastern North Pacific population is unknown, but is clearly precariously small following the immense damage done by the Soviets in the 1960s. In sharp contrast to the eastern ("California") gray whale, the outlook for the western North Pacific population of this species is bleak. Whaling on this small stock continued in Korean waters into the 1960s, and only a hundred or so animals may remain today. Furthermore, nothing is known of the location of the breeding grounds for this population; if it is reliant on coastal lagoons for calving (as is a major segment of the eastern stock), the impact of coastal development and other human activities may be severe. Among bowhead populations, that in the Bering/Beaufort/Chukchi Seas is recovering strongly despite continued exploitation by a (well-managed) Inuit hunt. In the eastern Arctic, some hundreds of bowheads remain in Canadian waters (principally Hudson Bay/Foxe Basin and Baffin Bay/Davis Strait), whereas the Spitsbergen stock may be functionally extinct.

Finally, blue whales have fared poorly almost everywhere; the only population which appears to be large and healthy is that which feeds off California in summer. Other blue whale stocks, including all of those in the Southern Ocean, remain small and highly endangered.

VI. An Uncertain Future and the Rise of Scientific Whaling

It is not clear what the future holds for whaling. With the Moratorium still in place, Japan continues to substantially increase its self-assigned quotas for scientific whaling in both the North Pacific and Antarctic, taking minke, Antarctic minke, sei, sperm, and Bryde's whales. An expanded scientific whaling program in the Antarctic which began in 2005 doubled the catches of minke whales (to about 900 a year) and also added fin and humpback whales to the list of targeted species. The inclusion of the latter two species, considered threatened or endangered by many nations and conventions, has raised further international concern about the lack of control over scientific whaling programs.

All this has fueled arguments that scientific whaling has strayed far from its original purpose of research and is today being used to circumvent the Moratorium (Gales *et al.*, 2005; Clapham *et al.*, 2006). Indeed, since 1987 (the year after the Moratorium came into effect), Japan has killed more than 10,000 whales in its two scientific whaling programs, a figure which is almost 5 times the total number killed for research (2100 whales) by all other nations combined (including Japan) since 1952.

Ultimately, the future of whaling depends upon the outcome of developing geopolitics: put simply, on whether the emerging world-view of commercial whaling as an anachronism prevails or, if it does not, on whether whaling can learn the lessons of its grim past. For now, the outcome remains hung in the balance.

Whaling, Traditional

RICHARD ELLIS

Beginning with the Basques around 1000 AD, there were many peoples that conducted whale hunts, but until the advent of industrial whaling in the twentieth century, there had never been a whale hunt as organized and systematic as the sperm whale fishery out of New England. Founded in the Massachusetts villages of Nantucket and New Bedford, the technology of sperm whale (*Physeter macrocephalus*) hunting—and the profits to be derived therefrom—spread to many locations in and around New England, including Albany, Long Island, New Jersey, Delaware, and Maine. The whale fishery—immortalized in Herman Melville's (1851) *Moby-Dick*—had an enormous effect on the economy of the recently founded USA, and the whaleships spread American culture and customs around the world. The focus here will be on the well-documented American whale fishery, but similar fisheries were operated by many other nations during the same period.

I. Bowhead (*Balaena mysticetus*) Whaling

The gigantic nose of the sperm whale contains an enormous quantity of valuable oil, and this was the primary object of the sperm whalers. Bowheads are fatter than sperm whales, and their blubber thicker, but it was not so much for the blubber that the bowheads were hunted: their huge, arched mouths contained the longest baleen plates of any whale, and it was this that the whalers were after. It was used for the manufacture of skirt hoops, corset stays, horsewhips, and dozens of other necessities of nineteenth century America.

In July, 1848, Captain Thomas Welcome Roys, a sperm whaler out of Sag Harbor (New York) sailed through Bering Strait, a thousand miles farther north than any whaleship had ever gone in the Pacific, and came upon a thriving population of bowheads that had previously been known only to Eskimos. His crews took 11 bowheads in only 35 days during that eventful summer, and sailed for home with 18,000 barrels of oil, an accomplishment that normally took two or more seasons. According to Bockstoce (1986), the historian of western Arctic whaling, "Roys' cruise was not only the most important whaling discovery of the nineteenth century, it was also one of the most important events in the history of the Pacific More than 2700 whaling voyages were made into Arctic waters at a cost of more than 150 whaleships lost and the near extinction of the bowhead whale, as Roys' whales came to be called." Arctic bowhead whalers also changed the way in which whales were hunted; instead of hand-thrown harpoons, they introduced the efficiency of artillery, shooting at the whales first with shoulder-guns, and later killing them with bomb-lances.

Many New England whaleships had been captured or burned by the Confederate raider *Shenandoah* in 1865, and to revive the flagging industry, 39 ships sailed to the Arctic in April, 1971. By August, 32 of them were trapped in the ice off Point Barrow, Alaska. The seven remaining ships took on 1129 men and brought them back to Honolulu, signaling the beginning of the end of Arctic bowhead whaling.

II. The Beginning of Sperm Whaling

The story of Christopher Hussey's accidental encounter with a school of sperm whales has been told so often that it probably no longer matters whether it really happened. In 1712, Captain Hussey

Figure 1 When a sperm whale (*Physeter macrocephalus*) beached itself at Katwijk in Holland in 1598, Hendrik Goltzius drew it for posterity.

was cruising the Massachusetts coast [there were still right whales (*Eubalaena* spp.) to be caught at that time], when an unexpected storm blew him out to sea. When the clouds cleared, he saw the spouts of whales, but they were forward-angled blows, not the vertical, paired plumes of the right whales. Hussey managed to capture one of these unusual animals and towed it back to Nantucket. Instead of baleen plates, it had ivory teeth in its underslung lower jaw, and in its head was a great reservoir of clear amber oil, which solidified to wax when exposed to the air (Fig. 1).

The first industry practiced by the New England colonists was the export of beaver (*Castor* spp.) pelts and furs to England, but these commodities were quickly exhausted, and given the availability of the easily killed right whales close to their shores, they turned their attention from the forests to the sea. The earliest colonial whaling was practiced in the Indian manner; towers were erected along the shore to enable lookouts to watch for whales, and when one was sighted, the whalers took to the boats. As navigation improved, the whalers began to roam farther offshore, occasionally visiting the rich grounds of Georges Bank, and some vessels even ventured south into the vast oceanic river that would become known as the Gulf Stream. The Yankee whalers also headed north, toward the Gulf of St. Lawrence and the Grand Banks of Newfoundland. By the middle of the eighteenth century, there were some 50 ships bringing oil and bone to England and returning with such things as iron ore, hemp, cloth and other necessities

for the burgeoning new colony. By 1775, Nantucket had a fleet of 150 whalers, which ranged in size from 90 to 180 tons.

The beginning of the sperm whale fishery in 1712 did not automatically spare the remaining right whales. Although sperm oil was enormously desirable for lubrication and candle-making, the need for whalebone had not abated. In the middle of the eighteenth century, European women of fashion still required tight-laced corsets, so the New England whalers captured whatever whales they could find and processed them accordingly. Scammon (1874) tells us that “shore-whaling continued for over fifty years, but eventually it was abandoned, for the same reason that the Spitsbergen and Smeerenburg fisheries were—the scarcity of whales near the coast.”

Regardless of the species being hunted, the primary product of the whale fishery was oil (Fig. 2). Earlier, however, the Dutch and English whalers of Spitsbergen and Greenland had concentrated on the whalebone, to the extent that they sometimes cut the slabs of baleen from the mouth of the whale and discarded the carcass. Much of the commerce of whaling was determined by fashion; by the amount of whalebone that would be required to girdle the ladies. In America, by contrast, there was no court, no royalty, and in the mid-eighteenth century Quaker colony of Nantucket, very little fancy dress.

As practiced in the Greenland fishery (and every other whaling operation until that time), the blubber of the whale was cut off in strips (a process known as “making off”), and packed directly into

Figure 2 Casks of oil line the New Bedford wharf. Photo by Old Dartmouth Historical Society—New Bedford Whaling Museum.

casks for transport to the home port. Scoresby (1820) noted that “in the early ages of the fishery [it was] performed on shore; and even so recently as the middle of the last century, it was customary for ships to proceed into a harbor, and there remain so long as this process was going on.” By the middle of the eighteenth century, an innovation that would change the nature of the entire industry had been introduced: iron caldrons set in a brick furnace enabled the whalers to render the oil from the blubber aboard the ship instead of on shore. This method seems to have evolved around the year 1750, but there is no individual whose name is associated with the invention. Although it is not possible to identify the father of the on-board tryworks, there were many mothers, all of whom had “necessity” as part of their names. Among the reasons for its introduction were the unpleasant odors associated with the onshore boiling of the blubber into oil, and the energetic protests of the people who lived downwind of a noisome blubber-works. (Even on board ship, blubber stored in casks tended to spoil quickly, and the stench was overpowering to the whalers.) On the Spitsbergen and Greenland grounds, the cold climate kept the blubber from turning rancid until the ships could get back to a port, but in New England no such natural refrigeration existed, and the heat often “turned” the oil in the blubber before it could be processed. As long as the whales could be caught within sight—or at most, a couple of days’ sail—of shore, the blubber could be casked and stowed, but when the whales became scarcer in the home waters, and longer voyages were required, some other method of processing and stowage was called for. Scoresby (who never employed on-board tryworks, even though

the idea existed during his whaling days) wrote that it was less efficient to carry home the blubber, since “blubber in bulk, notwithstanding every precaution ... generally loses much of its oil.”

Now that sperm whales were being processed with some regularity, another change was taking place in the whaling industry. Earlier, all whale oil, casked as blubber or tried-out at sea, was considered usable for lighting and lubrication. (It was often referred to as “train oil,” from the Dutch *traan* for “tear” or “drop”). It is a true fat, and impregnates every part of the whale, from the bones to the muscles, but most importantly it is found in the blubber. The fat of right whales and bowheads [and the occasional humpback (*Megaptera novaeangliae*)] provided the whale oil that was extensively used from the tenth century until the middle of the nineteenth for heating, lighting, manufacture of soap and cosmetics, and lubrication of machinery.

Because spermaceti (from the head of the whale) is quite different from train oil, its processing and utilization were also different. Up to the middle of the nineteenth century, candles were the primary source of indoor light. They were usually made out of wax or tallow, and emitted a smelly black smoke as they burned. The head of the sperm whale contained the mysterious fluid which could be used to make a better kind of candle. This wax, which the whale maintains in a liquid form during its lifetime solidifies when exposed to air, and someone realized that it might be employed in the manufacture of candles. From sometime around 1750, it was used to manufacture smokeless, odorless candles, the best candles known before or since.

In addition to the liquid oil contained in the case, the sperm whale produced a spongy material also impregnated with oil, known to the whalers as the “junk.” The liquid oil in the case and the oil that was squeezed from the junk were collectively known as “head matter,” and were used in the finest lamps and candles. The process of manufacture was a fairly complicated one. Upon delivery, the sludge-like substance was heated in a large copper vat and the impurities drawn off. It was left to congeal in casks and then bagged in woolen sacks, to be pressed later in a large screw press. The oil squeezed from the head matter was the highest quality, and was used in lamps. Further processing produced lower qualities of sperm oil, used for candles. Sperm oil candles were particularly popular in Africa and the Caribbean, but as articles of colonial manufacture they could not be imported into England. Both types of oil were considered superior to the train oil of the right whale and were priced accordingly. As the market developed for the finer qualities of oil, colonial entrepreneurs appeared. In 1751, one Benjamin Crabb of Rehoboth, Massachusetts, applied to the state house of representatives for a monopoly on the manufacture and sale of sperm oil candles, which was granted (Kugler, 1980).

As the right whales became scarcer, the tempo picked up for the sperm whale fishery. Starbuck (1878) called the period from 1750 to 1784 “the most eventful era to the whale fishery that it has ever passed through.” New England whaleships were under constant threat of being captured by privateers (the various wars between France and England for control of the North American colonies were going on at the time), and ships that were not commandeered pursued the fishery as far from home as the Grand Banks and the Bahamas. There were also natural disasters attendant upon the nascent whaling industry: ships were lost to storms and occasionally to whales. For reasons of security and increased profitability, the small sloops that had been the mainstay of the fishery were being replaced by larger ships with tryworks aboard; now the whalers could pursue the sperm whale, “the haughty, elusive aristocrat of the high seas.” By this time, the method of lowering boats for whales and fastening to them with harpoons attached to the whaleboats had evolved, and would remain the dominant practice for another century. It was this method of whaling—and the great sperm whale—that Melville would immortalize in *Moby-Dick* (Fig. 3). At this time, the fluctuations in the price of whale oil made for a most uneasy market. Good catches would overload the market and depress the price, while in a bad year, the scarcity of the oil would make it dearer.

The failure of the British whaling industry in the early decades of the nineteenth century left the field wide open to the New Englanders, and they were quick to capitalize on it. When the French and Indian War ended in 1763 and France conceded her claims to Canada, the New England whalers moved in. They sailed from Massachusetts and New York to the Gulf of St. Lawrence and the Strait of Belle Isle, and by 1776 they had discovered the whaling grounds off western Africa (Angola and Walvis Bay), the Falkland Islands, and the River Plate

grounds of the South Atlantic. In many of these regions, the whalers occasionally encountered a right whale, but the major object of the fishery by this time had become the sperm whale. These explorers in the name of oil were canvassing the world and perfecting their techniques, but instead of flourishing, they fell deeply into debt. The British government, still trying to support its own collapsing whaling industry, placed a duty on all oil and bone carried to England by colonials. Relations were becoming increasingly strained between the Crown and her rambunctious colony; in the years that followed, the infamous Stamp Act would be enacted and repealed; the Townshend Duties ditto, and finally, the Tea Act was passed in 1773, leading to the Boston Tea Party in the same year. (The East India Company, planning to sell its tea directly to America without having to first sell it to British merchants, shipped 1253 chests of tea from London to Boston on four whaleships: *Beaver*, *Dartmouth*, *Eleanor*, and *William and Anne*. It was this tea that the rebels, led by John Hancock and Samuel Adams, dumped into Boston Harbor). The next 2 years saw the first shots fired at Concord Bridge, and for the ensuing decade, most Americans became preoccupied with things other than whaling. (In April 1775, the same time that the “shot heard round the world” was fired, the ship *Amazon*, Captain Uriah Bunker, was discovering the whaling grounds known as the Brazil Banks, some 500 miles off that country.)

At approximately the same time that British whalers were depositing their cargoes of convicts and finding themselves in the middle of the rich whaling grounds of Australia and New Zealand, Yankee whalers were cruising almost everywhere in search of sperm whales. It was dangerous work, and sometimes the voyages seemed to last forever, but there were those who saw it as pleasurable and even romantic, the epitome of the wholesome life.

III. Life Aboard a Whaler

In retrospect, however, the voyages were often less than romantic and the weather less than benign. There were indeed fresh breezes, tropical sun, and vast herds of sperm whales, or cachalots, but there was also the tedium of years of sailing (the record seems to be the 11 year voyage made by the ship *Nile*, out of New London: 1858–1869), as well as gales, blizzards, typhoons, hurricanes, mountainous seas, and howling winds. The crew’s quarters were stinking holes; their food was cheap, coarse, and maddeningly monotonous; the work itself was dirty and dangerous. A voyage aboard a New England whaler was not a luxury cruise.

In the nineteenth century, the hierarchy of officers and men, so important to the successful operation of a whaling vessel, was rigidly observed, and nowhere was the distinction more evident than in their respective living quarters. The captain lived in relative luxury; the ship’s officers had smaller cabins; the boatsteerers, the cooper, and the steward occupied the steerage, an irregular compartment fitted with

Figure 3 In this sketch for the 100-foot-long mural in the New Bedford Whaling Museum, *Moby-Dick* is shown with the “harpoons all twisted and wrenched within him.” Credit: Richard Ellis pinxit.

plain bunks. The crew was in the forward section just below the main deck, which followed the shape of the ship: it went from a fairly wide cross-section to a narrow, cramped, triangular warren, where the ship's timbers formed the walls, and the pounding of the waves formed the ambience. The lower portion of the foremast often kept the occupants of the fo'c's'le company, reducing even further their limited space, and the only light that entered this literal and figurative rat hole came from the hatchway cut in the deck for the purpose of giving access to the ladder that allowed the men to climb in and out of their quarters. When the weather turned foul, the hatch was closed, and there was no light but stubby candles, and no ventilation whatever. The number of men that occupied this wretched space often exceeded 20.

No whaleman was ever paid a wage, except in unusual circumstances. If, for instance, a full ship had to take on additional hands on the way home, their share of the profits would be zero (since they had not participated in the whaling), and they were paid a monthly wage. Ordinarily, each man, from the captain to the cabin boy, received a percentage of the profits—called a lay—at the end of the voyage.

The distribution differed from vessel to vessel—larger ships could carry more oil, and therefore the profits to the crew were likely to be proportionately higher—but while a successful voyage could be better for the captain and the officers, it meant precious little indeed to the foremast hands. (On an unsuccessful voyage, where the profits were low or nonexistent, the crew might receive nothing at all.) The captain might earn 1/8 or 1/10 of the net proceeds, whereas a mate could earn 1/15 and a harpooner 1/90. Ordinary seamen could hope at best for 1/150, and there are instances in the records where a green hand signed aboard for 1/350. What did this mean in terms of actual money? On board the *Addison*, First Mate Ebenezer Nickerson, whose lay was 1/18, earned \$845. Robert Baxter, the second mate with 1/35, earned \$554.83, and a boatsteerer named Narcisco Manuel, with 1/90, got \$376.56. Compare these figures to those of the crew: John Martin, at 1/175, earned a total of \$31.95, and Francis Finley, got \$92.08. During six consecutive voyages totaling 1128 days at sea from 1845 to 1868, the average lay per voyage on the Salem whaler *James Maury* was \$321.21, or about 26 cents a day. This compared unfavorably to wages then being paid to unskilled laborers ashore (an average of 90 cents a day), but landlubbers did not get to visit exotic Pacific islands where they might be eaten by cannibals or risk their lives fighting gigantic whales (Hohman, 1928).

Infrequently, the men were paid in the species of whaling; i.e., they received casks of oil that they were then able to sell at the prevailing prices in their port of disembarkation. The cooks often received an added benefit: in addition to their lays, they were permitted to save the grease (known as “slush”) from their galleys and sell it to soap-makers ashore.

The whaleman's food and bunk space were generously provided without charge, but throughout the voyage he was docked for various items that he had to buy from the ship's stores. Additional items of clothing, tobacco, knives, needles, and even thread were charged to each man's account, and if he required spending money in a port of call, this too was deducted from the final reckoning. This was a period where the master's voice was law, and if a man needed a new shirt or a pair of boots, he could “either pay up or go naked.” Although most of the whalemens signed aboard voluntarily, they usually did not know of the dangers and hardships that lay ahead of them, and the “profit-sharing” which at the outset sounded so attractive often deteriorated into an enforced “risk-sharing,” which was invariably uncomfortable, inevitably dirty, and frequently dangerous.

Among the more unusual charges assessed to a whaleman was the cost of desertion. If a man jumped ship, his account included

the cost of recapturing him, an expense that was obviously nullified if he remained at large. However, there were captains who rewarded the lookouts with bonuses for the sighting of whales. This exercise was glorified in *Moby-Dick*, where Ahab nails a gold doubloon to the mainmast and exhorts his crew: “Whosoever of ye raises me a white-headed whale with a wrinkled brow and a crooked jaw; whosoever of ye raises me that white-headed whale, with three holes punctured in his starboard fluke-look ye, whosoever of ye raises me that same white whale, he shall have this gold ounce, my boys!” The “Spanish ounce” that was offered to the crew was a 16-dollar gold piece.

On a 3- or 4-year voyage, a man might earn \$100, but the items billed to him often exceeded this amount, so many hands returned to port not only with no spending money, but in debt. The only thing to do to work off this indebtedness was to sign on for another voyage, thus starting the insidious process all over again. If and when they made it—back to port, the whalemens were set upon by all sorts of “land sharks,” eager to assist them in disposing of their wages by enticing them into taverns, brothels, and other iniquitous dens where they could make up for the pleasures they had been denied for the past several years. In an 1860 issue of *Harper's* magazine, an observer describes the arrival of the whalemens in New Bedford:

A cart rattles by, loaded with recently discharged whalemens—a motley and a savage—looking crew, unkempt and unshaven, capped with the head-gear of various foreign climes and peoples—under the friendly guidance of a land shark, hastening to the sign of the “Mermaid,” the “Whale,” or the “Grampus,” where, in drunkenness and debauchery, they may soonest get rid of their hard-earned wages, and in the shortest space of time arrive at that condition of poverty and disgust of shore life that must induce them to ship for another four years' cruise.

The system of wages aboard a whaler was obviously not conducive to enthusiasm or hard work. In response to the brutal discipline often administered by the captain, there was bound to be apathy, indifference and suspicion on the part of the foremast hands. There was also a profound class distinction between the officers and the men. Despite the abuses, hardships and low earnings which characterized the industry, however, the labor supply was somehow adequate to meet its needs. As Hohman (1928) put it, “The steady stream of men pouring into the forecastles proved sufficient to counteract the continuous labor leakage caused by death, illness, incapacity, discharge and desertion.” It was possible (although uncommon) for a dedicated seaman to work his way up through the ranks, and there are instances where a green hand, or even a cabin boy, raised his lay from 1/150 to 1/15, and after perhaps 20 years at sea (in 4- or 5-year increments), a man might even rise to command a whaling vessel.

The *Benjamin Tucker*, a New Bedford whaler, brought back 73,707 gallons of whale oil, 5348 gallons of sperm oil, and 30,012 pounds of whalebone in a voyage that ended in 1851. At the prevailing prices—43 cents a gallon for whale oil, \$1.25 a gallon for sperm oil, and 31 cents a pound for bone—the gross value of this cargo was \$47,682.73. From this, \$2,362.73 was variously deducted, leaving a net of \$45,320 to be distributed. But before the profits were divided, the owners took a substantial percentage off the top to compensate for their initial outlay and also because these flinty New Englanders were not in the business for the thrill of the chase. In general, the owners took between 60% and 70% of the profits. On the 1805–1807 cruise of the *Lion*, the various oils yielded a total of \$37,661.02. Of this, \$24,252.74 went directly to the owners, leaving \$13,045.53 to be divided among the captain and the crew for 2 years of work (Hohman, 1928).

During its heyday, New Bedford was the richest municipality per capita in America, and Melville described it as “perhaps the dearest place to live in all New England . . . nowhere in America will you find more patrician-like houses, [or] parks and gardens more opulent.”

Of course, profits from the whaling industry were not restricted to the owners. They had to repair, refit, and re-provision their ships, which provided work and income for the shipwrights, chandlers, coopers, rope-makers, carpenters, and blacksmiths, and ready markets for the farmers and greengrocers. The entire township of New Bedford benefited from the outfitting and victualing of the armada of ships that annually departed her wharves, loaded with food, clothing and supplies, most of which were bought from local merchants.

The captain had his own cabin, with a proper bunk, a washstand, a table, and perhaps even a sofa and some extra chairs. The captain’s quarters of the whaleship *Florida* “opened off the after cabin on the starboard side and extended nearly to the end of the forward cabin. A small room and a toilet room were aft of the stateroom. A large swinging bed was in the captain’s cabin instead of the usual fixed berth.” The gimballed bed was a special innovation designed by Captain Thomas Williams, because he was planning to bring Mrs. Williams along.

Occasionally a captain took his wife, and even more infrequently, he took his entire family. Captain Williams, of the ship *Florida* out of New Bedford, was accompanied by his wife for a voyage that lasted from September 1858 to October 1861. During the voyage, Eliza Azelia Williams gave birth to two children, who spent the first year of their lives at sea. She also kept a detailed journal of her adventures, which allows us a most unusual perspective of life aboard a whaleship. The voyage commenced on September 7, 1858, in New Bedford, and on January 12 of the next year, Mrs. Williams gave birth to a baby boy, whom they named William. (William’s arrival might help to explain her seasickness early in the voyage, when she wrote, “it remains rugged and I remain Sea sick. I call it a gale, but my Husband laughs at me and tells me I have not seen a gale yet. If this is not one I know I do not want to see one.”) On August 5, 1859, off the rugged coasts of Sakhalin in the Okhotsk Sea, the *Florida* spoke the *Eliza F. Mason*, and Mrs. Williams visited another “lady ship,” where the captain had brought his wife and child, “a Lady Companion, and a little Girl that they brought from the Bay of Islands, New Zealand.” On February 27, 1860, Mrs. Williams wrote, “We have had an addition to the Florida’s Crew in the form of our little daughter . . .”

It was US maritime law that a logbook be maintained by the mate or the first officer. (The term “logbook” originated with the practice of casting a log overboard affixed to the ship by a knotted line. The speed at which the line played out—measured in knots—determined the speed of the ship, and the daily records were originally kept in a book reserved for that purpose. Later, the term “logbook” was used to designate the book used for the keeping of all the ship’s records). For the most part, logbooks and journals were kept by the masters. Although rarely educated in the classical sense, most of these men could read and write passably well, and their records have given us an enduring picture of life aboard a whaleship. Even though the maintenance of a logbook was mandatory, it obviously served the whalers particularly well, since the appearance of whales at a known latitude and longitude in one season might enable the whalers to predict their reappearance at the same location the following year and thereby avoid aimless wandering.

The more mundane entries consisted of the ship’s position, the number of whales caught, and illness and injury aboard ship, but additional dramatic possibilities were vast. In his introduction to the

catalog of the logbook collection of Paul Nicholson, Sherman (1965) listed “castaways, mutinies, desertions, floggings, women stowaways, drunkenness, illicit shore leave experiences, scurvy, fever, collisions, fire at sea, stove boats, drownings, hurricanes, earthquakes, tidal waves, shipwrecks, ships struck by lightning, men falling from the masthead, hostile natives, barratry, brutal skippers, escape from Confederate raiders, hard luck voyages and ships crushed by ice.” That is not to say that all logbooks read like *Moby-Dick*; dramatic events occurred infrequently, and most of the daily entries—when the ship was not engaged in killing whales—consisted of a remark on the wind direction, the location, and whatever else the keeper of the logbook deemed pertinent.

It is not surprising that few of the foremast hands kept records; their quarters were not conducive to the literary life, and besides, many of them could not write. Francis Olmstead (1841) could. Of the literary aspirations of his fo’c’s’le companions, he wrote

The forecandle of the *North America* is much larger than those of most ships of her tonnage, and is scrubbed out regularly every morning. There is a table and a lamp, so that the men have conveniences for reading and writing if they choose to avail themselves of them; and many of them are practicing writing every day or learning how to write When not otherwise occupied, they draw books from the library in the cabin and read; or if they do not know how, get someone to teach them. We have a good library on board, consisting of about two hundred volumes

J. Ross Browne, a journalist who shipped aboard the New Bedford whaler *Bruce* in 1842, kept a journal of his experiences that was published, with major revisions, as *Etchings of a Whaling Cruise* in 1846. Browne wanted to do for whaling what Richard Henry Dana had done for merchant sailing in 1840, i.e., exaggerate the problems so that necessary changes would be implemented. Although his account may contain a certain amount of propaganda in the form of negative commentary, he was aboard a whaler for more than a year, and because he is regarded as a reporter and not a writer of fiction, much of the material contained in his book can be taken as fact. Here is Browne’s description of the place in which he lived:

The forecandle was black and slimy with filth, very small and hot as an oven. It was filled with a compound of foul air, smoke, sea-chests, soap-kegs, greasy pans, tainted meat, Portuguese ruffians and sea-sick Americans In wet weather, when most of the hands were below, cursing, smoking, singing and spinning yarns, it was a perfect Bedlam. Think of three or four Portuguese, a couple of Irishmen, and five or six tough Americans, in a hole about sixteen feet wide, and as many perhaps, from the bulkheads to the fore-peak; so low that a full-grown person could not stand upright in it, and so wedged with rubbish as to leave scarcely room for a foothold. It contained twelve small berths, and with fourteen chests in the little area around the ladder, seldom admitted of being cleaned. In warm weather it was insufferably close. It would seem like an exaggeration to say, that I have seen Kentucky pig-sties not half so filthy, and in every respect preferable to this miserable hole; such, however, is the fact.

Rats were more numerous on whaleships than on any other vessels, probably because of the profusion of blood and oil that soaked the decks, despite the regular scrubblings. They were more than any ship’s cat could cope with, and then as now, there was nothing that could cope with cockroaches. They were endemic aboard the whalers, and for many seamen, the roaches were a more predominant

aspect of a whaling voyage than whales. Olmstead wrote that they made “a noise like a flush of quails among the dry leaves of the forest.” They are extremely voracious, and destroy almost everything they can find: their teeth are so sharp, the sailors say, that they will eat the edge off a razor.”

In *Nimrod of the Sea* William Davis (1874) described roaches as serving a useful purpose: “His chief recommendation is his insane pursuit of the flea ...,” but then goes on, “it is a horrible experience to awaken at night, in a climate so warm that a finger-ring is the utmost cover you can endure, with the wretched sensation of an army of cockroaches climbing up both legs in search of some Spanish unfortunates! It reminds me of how many times I have placed my tin plate in the overhead nettings of the forecabin, with a liberal lump of duff reserved from dinner, and on taking it down at supper, have found it scraped clean by the same guerrillas. They leave no food alone, and have a nasty odor, which hot water will scarcely remove. But one becomes philosophical at sea in matters of food.”

The crew’s rations aboard a whaleship ranged from bad to disgusting, but, Browne says, “a good appetite makes almost any kind of food palatable.” He describes the usual fare on board the *Bruce* (which he has, for culinary and other reasons, named the *Styx*): “I had seen the time when my fastidious taste revolted at a piece of good wholesome bread without butter, and many a time I had lost a meal by discovering a fly on my plate. I was now glad enough to get a hard biscuit and a piece of greasy pork; and it did not at all affect my appetite to see the mangled bodies of diverse well-fed cockroaches in my molasses; indeed, I sometimes thought they gave it a rich flavor.” Fresh vegetables were taken on at the outset of a voyage, and often picked up when the vessel put in for provisions, but unless they were used quickly, they rotted. (By Browne’s time, the causes of scurvy were known, but if the vegetables were used up and the ship was cruising somewhere off the Aleutian Islands, there was not much anyone could do to prevent the dread disease.) Because of their inability to store much water—and to prevent it from spoiling—the whalers hardly ever drank it. (Scammon tells the story of one captain, who, to preserve the dwindling water supply, had the drinking cup hung from the royal-mast head, requiring any man who wanted a drink to climb all the way up after the cup.) They drank “longlick,” a mixture of tea, coffee, and molasses, and if the cook was imaginative, he prepared something known as “lobscouse” (or simply “scouse”), which was a hash made of hard biscuits that had been soaked in the greasy water left over after boiling the salted meat. The mainstay of the whaler’s diet was salted meat, which was supposed to be pork or beef, but was occasionally horse. In *Omoo* Melville (1847) described the meat on board a whaleship:

When opened, the barrels of pork looked as if preserved in iron rust, and diffused an odor like a stale ragout. The beef was worse yet; a mahogany-colored fibrous substance, so tough and tasteless, that I almost believed the cook’s story of a horse’s hoof with the shoe on having been fished up out of the pickle of one of the casks.

Nordhoff (1856) described the duff made by a certain cook as “that potent breeder of heartburns, indigestion, and dyspepsia ... the very acme of indigestibility,” and Ben-Ezra Ely (1849) wrote, “... no swine that gleans the gutters ever subsisted on viler meat and bread than did our crew.” The rare opportunity to eat something fresh was a blessing. The cook prepared sea birds, whatever fish they could catch, turtles, dolphins [off the African coast, Nordhoff describes the harpooning and subsequent eating of a hippopotamus (*Hippopotamus amphibius*)], and since they were engaged in the capture of 50- or

60-ton mammals whose carcasses they would otherwise leave for the sharks, they often ate the meat of the whales. On the eating of various parts of the whale, usually during the trying-out, Browne wrote:

About the middle of the watch they get up the bread kid [a kid was a wooden tub] and, after dipping a few biscuits in salt water, heave them into a strainer, and boil them in oil. It is difficult to form any idea of the luxury of this delicious mode of cooking on a long night-watch. Sometimes, when on friendly terms with the steward, they make fritters of the brains of the whale mixed with flour and cook them in the oil. These are considered a most sumptuous delicacy. Certain portions of the whale’s flesh are also eaten with relish, though, to my thinking not a very great luxury being coarse and strong

It was a different world above decks. On December 28, 1856, the crew of the New Bedford whaler *Addison* caught a porpoise, and Mary Chipman Lawrence (the captain’s wife) wrote in her journal, “The meat looks very much like beef. The oil is contained in the skin, which they will boil out tomorrow. Had some of the meat fried for dinner and some made into sausage cakes for supper. They are as nice as pork sausages.” If a further demonstration of the disparity between the fare of the men and that of the officers is required, here is Mrs. Lawrence’s description of Christmas dinner for that same year: “roast chickens, stuffed potatoes, turnips, onions, stewed cranberries, pickled beets and cucumbers, and a plum duff. For tea I had a tin of preserved grape opened and cut a loaf of fruitcake.”

Unlike their British counterparts, American whalers rarely carried any sort of medical man. It commonly fell to the captain to cope with whatever illness or accident befell his crew, and given the master’s experience, it was considerably safer to remain healthy. For internal maladies, whaleships were often equipped with medicine chests, which contained various potions and a manual for their dispensation. (Stories were told of masters who, having run out of medication Number 12, simply administered equal amounts of Numbers 5 and 7.)

Physical injuries were not uncommon, considering the number of sharp-edged tools, whistling whale lines, and hostile natives—not to mention shipboard arguments between men who were almost always armed with knives. Here again, the master served in the role of surgeon, with the same amount of training as he had as apothecary. In *Nimrod of the Sea* (1874), Davis tells the gory tale of a whaleman who was yanked from his boat by a kinked line, and dragged some 125 fathoms from the boat. When he was finally picked up, “it was found that a portion of the hand, including four fingers, had been torn away, and the foot sawed through at the ankle, leaving only the great tendon and the heel suspended to the lacerated stump.” Equipped with “his carving knife, carpenter’s saw and a fish-hook,” the captain “amputated the leg and dressed the hand as best he could.”

IV. Whaleships and Whaleboats

As whaling voyages increased in distance and duration, it became expedient to enlarge the ships. In the early days of the fishery (around 1820), the ships averaged around 280-ton burthen, but within two decades, 400-ton vessels were not uncommon. The move toward bigger whaleships contributed to the decline of Nantucket whaling because there was a prominent sandbar across the harbor, and only the smaller, shallower-draft ships could enter. New Bedford, with its excellent harbor facilities, took up the slack.

All whaling vessels were ships—as opposed to *boats*, which were the smaller vessels that the whalers rowed after their quarry. The literature

is replete, however, with references to ships, brigs, brigantines, barks, barkentines, and schooners. These differentiations have to do with the rigging of the masts, and not with the number of masts, although a three-masted, square-rigged vessel was always known as a ship. If the aftermost mast was rigged fore-and-aft, with the sail slung between a gaff and a boom, the vessel was known as a *bark*, the commonest plan, because fewer hands were required to handle the sails, and thus there were more men available for the boats. There were further variations, including the *brig*, where the upper courses of the aftermost mast were rigged with squaresails, but there was also a fore-and-aft sail known as a “spanker.” A *barkentine* was square-rigged only on the foremast; the rest fore-and-aft, and a *brigantine* had only two masts, the foremast square-rigged and the mainmast fore-and-aft. A *schooner* had two or more masts, rigged fore-and-aft.

Whaleships differed from merchantmen of the time in that they usually carried less sail. More canvas meant more men aloft, and the whalers needed as many hands as possible for the boats. One further characteristic of the whaler was the presence of masthead hoops, in which the lookouts stood during the daylight hours to watch for whales.

Square-rigged ships, which gave their name to an era of sailing, ran powerfully before the wind, but were not particularly handy in head- or cross-winds. The whalers did not have to perform any smart sailing maneuvers, nor did they have to sail with great speed. All they had to do was get from one location to another and then lower the boats after the whales. Because of the determined, plodding nature of their craft, the masters rarely sailed at night, preferring instead to furl their sails and wait till dawn before continuing.

It was during the heyday of New England whaling, from 1830 to 1860, that the fabulous clipper ships reached the zenith of sailing-ship design, with their graceful lines, sharply raked bows, and opulence of canvas. In marked contrast to these ocean-going greyhounds, the whalers were sturdy, bluff-bowed, flat-bottomed sailers, designed more for durability and storage than for speed. (The *Lagoda* sailed for 50 years, and the all-time record-holder, the *Charles W. Morgan*, sailed for more than 80 years, and earned over a million dollars for her owners. The *Lagoda* was copied at half-scale for the New Bedford Whaling Museum, and the *Morgan*, the last of her kind, is now the proud centerpiece of Mystic Seaport in Connecticut.)

A typical whaler was 100–150 ft long, and especially broad in the beam to accommodate the fixtures of whaling: heavy brick tryworks on deck, iron caldrons, cooling tanks, davits for the boats, and of course, the space required to perform the trying-out of the whale. Ordinary seamen, whose voyages did not take 4 or 5 years, belittled the whaleships as “built by the mile and cut off in lengths as you want ‘em.” They were usually painted black, and had mock gun ports painted along the sides, supposedly as a deterrent to pirates or hostile savages.

The naval historian Albert Cook Church (1938) wrote: “Whaleships differed materially from any other type of merchant ship or clipper in model and equipment, and in fact, both sides of a whaleship differed from each other above the waterline.” The larger ships were equipped with four boats, one on the starboard quarter, and three on the port (also known as the “larboard”) side. This allowed the cutting stages, which were always on the starboard, to be lowered without interference from davits.

When a whale or a group of whales was sighted, the lookout shouted “She blows!” or “Blows!” and when the captain had ascertained “where away,” the boats were lowered, and the chase began. All the boats might or might not be lowered, depending upon the number of whales sighted. If only a single whale was seen, the captain might designate one boat to chase it. The starboard boat was

reserved for the captain (or the fourth mate, if the captain chose to stay aboard ship during the hunt); the larboard, waist, and bow boats were for the first, second, and third mates, respectively. Each boat contained a regular crew, consisting of five oarsmen, and a boats-teerer/harpooner. Whoever was in command of the whaleboat pulled the steering oar and gave the orders. The boats were double-enders; in case they got turned around in the frenzy of the hunt, they would be able to maneuver, and they were among the most graceful and utilitarian boats ever designed.

All the requisite equipment would be carefully stowed aboard the whaleboats, from the line, which was carefully coiled in a tub so it could be let out rapidly, to the knife that might be required to cut it if a man got his leg entangled. In addition to the six adult men who would be required to man the boat, Scammon lists the contents of a fully equipped whaleboat:

One mast and one yard, one to three sails, five pulling oars, one steering oar, five paddles, three rowlocks, five harpoons, one or two line-tubs, three hand lances, three shortwarps, one boat-spade, three lance-warps, one boat-warp, one boat-hatchet, two boat knives, one boat-waif, one boatcompass, one boat-hook, one drag, one grapnel, one boat-anchor, one sweeping-line, lead, buoy, etc., one boat-keg, one boat-bucket, one piggin, one lantern-keg (containing flint, steel, box of tinder, lantern, candles, bread, tobacco, and pipes), one boat-crotch, one tub-oar crotch, half a dozen chock pins, a roll of canvas, a paper of tacks, two nippers, to which may be added a bomb-gun and four bomb-lances; in all, forty eight articles, and at least eighty-two pieces.

V. Killing and Processing the Whale

The lowering of the boats took place as the ship was underway; the captain did not come about for the comfort or convenience of his crews. Often in high seas, the graceful whaleboats took off after the whales with the men facing the stern; the boatsteerer was the only man who could see the whales. When they had come within range, the harpooner threw the harpoon. It consisted of a wooden shaft, some 6 ft in length, with a forged iron head. The earliest harpoons had simple fluted arrowhead-shaped heads, but as the fishery developed, more sophisticated designs were introduced. Although the two-flued iron pierced the blubber effectively, its razor edges would occasionally pull out as smoothly as they went in. This led to the introduction of the single-flued iron which held much better. Harpooners and blacksmiths had plenty of time, on board the whalers and in port, to work on harpoon design, and all sorts of elaborate heads with toggles, barbs, and swivels were tried. The most successful of these designs was the double-barbed “Temple” iron, invented in 1848 by a New Bedford blacksmith named Lewis Temple. A graceful, practical device, the Temple iron consisted of a pointed head that was held in the forward position by a wooden shear-pin that broke off when withdrawal forces were applied. This rotated the head 90° in the flesh of the whale, forming a T-shaped device that would not pull out, because the flattened surfaces were pulling against the meat or blubber. The iron was fastened to the shaft of the harpoon by a line which was bent to the heavy manila line. The line, which Melville calls the “magical, sometimes horrible whale line,” was originally fashioned of hemp, but was later superseded by manila rope, which was stronger and more elastic. “Hemp is a dusky, dark fellow,” Melville wrote, “a sort of Indian, but Manilla is as a golden haired Circassian to behold.”

Even though tradition demanded that the harpoon and the lance be thrown separately, some creative whalers tried to design an iron that would fasten to and kill the whale simultaneously. A

Scottish toxicologist named Robert Christson invented a poison-headed harpoon, equipped with glass cylinders containing prussic acid, one drop of which is lethal enough to kill a man. There is no evidence that prussic-acid harpoons were used in the American fishery, but they were carried on some vessels. The likelihood is that the American harpooners felt that they had enough problems killing the whale without worrying about killing themselves.

If the iron was well placed—the ideal spot was in the flank, forward of the hump—the boat was fast to the whale, and the injured animal took off. Sometimes the whale sounded, taking out the line at such speed that the line smoked as it ran out, and the loggerhead had to be doused with water to keep it from bursting into flame. More often the whale swam at the surface, towing the boat through the waves at a violent clip. Sperm whales are prodigious divers, and no boat could hold enough line for a dive that could be measured in miles. If the whale sounded, another 200-fathom line might be bent to the first, and then another. Eventually, the wounded whale had to surface to breathe.

The lance, also known as the “killing iron,” was plunged into the “life” of the whale, a vital artery, the lungs, or the heart. The killing iron consisted of a wooden shaft like that of the harpoon, with a scalpel-sharp head. It was not thrown, but rather stabbed repeatedly into the body of the whale. Melville describes the death-throes of a whale:

The red tide now poured from all sides, off the monster like brooks down a hill. His tormented body rolled not in brine but in blood, which bubbled and seethed in furlongs behind in their wake. The slanting sun playing upon this crimson pond in the sea sent back its reflection into every face, so that they all glowed to each other like red men . . . Stubb slowly churned his long sharp lance into the fish and kept it there, carefully churning and churning, as if cautiously seeking to find some gold watch that the whale might have swallowed, and which he was fearful of breaking ere he could hook it out.

The victory did not always go to the whalers. Sperm whales are immensely powerful creatures, and do not take kindly to being stabbed with spears. The most frequent problem occurred when the whale took it into its 20-pound brain to retaliate. A 30-ft whaleboat was no match for an enraged, wounded, 60-ton whale, and the harpooned animal might rise up from the depths and grab the boat in its massive jaws, splintering it into so many matchsticks (Fig. 4). Both ends of a wounded whale are lethal; the triangular flukes, which might measure 20 ft across, could function as a formidable weapon, crashing down upon the whaleboat and dumping the men into the sea. Other perils faced the whalers, where the whistling line might take a turn around a leg or an arm, surgically severing it, or yanking the man into the water. Even if the boat was not destroyed, it might be upended and its occupants dumped into the ocean. Many of them could not swim, so such a plunge often spelled death.

But more often than not, the world’s deadliest predator won the battle, and then faced the problem of bringing whale and ship together. If the conquering whaleboat was downwind of the ship, it was a relatively simple matter to sail the ship to the carcass, but if less propitious conditions prevailed, the tired whalers might have to tow the whale back to the ship, often for miles. And then, after an exhausting chase and a laborious haul with a 50-ton deadweight in tow, the real work began. What had been a free-swimming, powerful sea mammal was effectively reduced to a disparate assortment of its parts, the reduction accomplished by literally tearing it apart.

Figure 4 A painting by Clifford Ashley, the American painter/author/whaleman, showing what happened when the men in a whaleboat got too close to a sperm whale they had harpooned. Credit: New Bedford Whaling Museum.

As in virtually every other aspect of New England whaling, the cutting-in process was described better by Melville than anybody else. (In the Yankee whale fishery, the process of removing the whale from his outer integuments was known as “cutting-in,” and the rendering of the blubber into oil was known as “trying-out.” In the English fishery, these operations were known respectively as “flensing” and “making off”). In *Moby-Dick* there is one chapter devoted to the actual process, and several more to the byproducts, including the “blanket,” the “funeral,” and the “sphinx”—the last referring to the head of the whale after the body and blubber have been separated from it.

The whale was made fast to the ship by lashing heavy chains through its head and around its flukes. The first part of the whale to be brought aboard was the lower jaw, ripped from the head and laid aside to be dealt with later. Then the whale was decapitated, and if it was a small one, the head was brought aboard. But the head of a large whale, often one-third of its 60-ft, 60-ton body, could not be brought on deck (Melville wrote that “even by the immense tackles of the whaler, this were as vain a thing as to attempt weighing a Dutch barn in jeweler’s scales”), and had to be processed in the water. The “head matter” was saved for last, however, because the carcass of the whale alongside the ship was threatening to the ship by its weight, and the longer it remained unprocessed, the longer the sharks could wreak havoc on the very outer layer of blubber that was of so much interest to the whalers.

By the use of a complicated series of tackles—described by Melville as “ponderous things comprising a cluster of blocks generally painted green, and which no single man can possibly lift—the cutting stages were lowered, and the process of removing the blubber commenced. Sitting or standing on the lowered cutting stages, men with razor-sharp cutting spades began to slice into the whale’s rubbery outer covering. A massive iron hook was inserted in the first piece to come off, and this was hoisted high into the air while the men on the scaffold sliced the blubber. The whale was rotated in the water, and its blubber “stripped off from the body precisely as an orange is sometimes stripped by spiralizing it.” The power for this peeling and dismemberment came from the strong backs of the whalers, who turned the windlass located forward of the foremast.

As the thick spiral of blubber was peeled from the whale, it was cut into sections approximately 15 ft long and a ton in weight (the “blanket pieces”). These were dropped through a hatch into the blubber room, where they were stored until the carcass of the whale was completely stripped. (With the removal of the blubber and the head, the remainder of the carcass was left for tile sharks.) Workers in the dark, bloody blubber room further reduced the blanket pieces to smaller, more manageable “horse pieces,” which were then sliced into “Bible leaves,” with cuts almost to the skin making them resemble the splayed pages of a thick-leaved book. (It was believed that the opening of the blubber into “pages” made the oil more accessible). The Bible leaves were then forked back up through the forehatch to the men who would place them in the trypots.

Although the trypot fires were usually started with wood, the unmelted skin of the whale made a wonderful fuel, and the whale was therefore cooked in a fire of its own kindling. As the oil was separated from the blubber, it was carefully ladled into a copper cooling tank, where it rested before being casked. Aside from the obvious danger of a fire spreading, the process was—like almost every aspect of whaling—hard, messy, and dirty. Oil and blood covered the decks and the people, and the smell was often intolerable. J. Ross Browne called the trying-out process “the most stirring part of the whaling business, and certainly the most disagreeable.” He described the nighttime scene aboard the “*Styx*”:

Dense clouds of lurid smoke are curling up to the tops, shrouding the rigging from the view. The oil is hissing in the trypots. Half a dozen of the crew are sitting on the windlass, their rough, weather-beaten faces shining in the red glare of the fires, all clothed in greasy duck, and forming about as savage a looking group as ever was sketched by the pencil of Salvator Rosa. The cooper and one of the mates are raking up the fires with long bars of wood or iron. The decks, bulwarks, railing, try-works, and windlass are covered with oil and slime of black-skin, glistening with the red glare of the try-works. Slowly and doggedly the vessel is pitching her way through the rough seas, looking as if enveloped in flames.

At the end of this description, he wrote, “Of the unpleasant effects of the smoke I scarcely know how any idea can be formed, unless the curious inquirer choose to hold his nose over the smoking wick of a sperm oil lamp, and fancy the disagreeable experiment magnified a 100,000 fold. Such is the romance of life in the whale fishery.”

One of the least romantic aspects of the whale fishery was the prospect of fire. Oil-soaked wooden ships upon whose decks fires are being encouraged do not lend themselves to a feeling of security. Care was taken to avoid conflagrations—water was pumped over the decks to keep the planks wet and cool—but occasionally the sails or rigging were ignited by flying sparks, and sometimes the ships burned to the waterline.

When the oil had cooled, it was ladled into the casks that had been assembled by the cooper. Each barrel held 302 gallons, and the figures for the fishery were almost always recorded in barrels. Starbuck’s (1878) *History of the Whale Fishery*, which contains the records of every American whaling ship, from every American whaling port, “from its earliest inception to 1876” (insofar as these records were known), lists the result of every whaling voyage in sperm oil (barrels), whale oil (barrels), and whalebone (pounds).

A large female sperm whale might yield 35 barrels of oil, whereas the largest bulls gave up 75–90. As with the sometimes questionable

lengths of large bulls, where there were reports of 90 footers. Ashley (1938) wrote, “If these whalemens’ records are accurate, it would appear that the 100-ft Sperm Whale is not an impossibility.” Because the reports were invariably made by men whose reputation would be enhanced by overstating the yield of individual whales, many of the whales in the 100–150 barrel range must be questioned.⁷

The amount of oil that could be taken and stored was enormous, but it did not necessarily reflect the success of a voyage. The profits of a voyage could only be calculated when the ship reached port and sold the oil and bone at the prevailing prices. A 31-gallon cask was about 5 ft high and 4 ft in diameter at its bulging middle (Fig. 2). On her maiden whaling voyage, which lasted from October 1841 to September 1843, the *Lagoda* brought home 600 barrels of sperm oil, 2700 barrels of whale oil, and 17,000 pounds of baleen. (“Sperm oil” was the stuff that was ladled out of the whale’s “case,” and was of a finer quality than “whale oil,” which was rendered out of the blubber. Although they were not averse to taking an occasional right whale or humpback, most of the whales hunted by the Yankees were sperm whales). The *Lagoda* was 108 feet long, with a beam of 27 ft. Hunting concluded when there was no more room for the storage of oil, but the whalers sometimes put into port, offloaded some of their greasy cargo, and set out again for the whaling grounds. Some of these sweaty, iron-bound vats were probably stored in the blubber room, but most were stored in the hold.

It was the mysterious “head matter” of the sperm whale that made it the primary object of this globe-girdling enterprise. Other whales were encased in blubber, and some of them had the long “finnes” that could be converted into milady’s bodices. But the spermaceti was the *ne plus ultra* of this business, the pot of liquid gold that attracted the whalers to the Azores and the Galapagos, to Zanzibar and the Japan Grounds, to Kamchatka and the Okhotsk Sea. The stuff is as poorly understood today as it was when some early beachcomber presumed that this vast reservoir in the whale’s nose was its seminal fluid. Whatever its purpose to the whale (and it certainly is not its seminal fluid), the amber wax that hardened white as it was exposed to air was worth risking life and limb—and sometimes boat and ship—to the whaler. Kept free from contamination by other oils, sperm oil was worth from 3 to 5 times as much as whale oil. In *Nimrod of the Sea*, Davis recorded a whale that yielded 27 barrels of spermaceti from the case, and Ashley’s research indicated that the largest bulls gave up something on the order of 30 barrels. At 31.5 gallons per barrel, that works out to 945 gallons of the mysterious liquid wax in the nose of a single whale.

To extract the spermaceti from the head, a much more direct method was employed than the multi-step process of turning blubber into oil. Since the spermaceti already *was* oil, the whalers only had to remove it from the whale and cask it. A hole was cut in the outer fabric of the whale and a man lowered a bucket into it on a long pole, then turned it over to another man on deck who would

⁷If only the whaler’s stories remained, we would have no way of verifying the size of the largest whales. There is something that they leave behind, however, and Ashley proposes a novel argument for the existence of gigantic bull sperm whales: he examines a particularly large pair of teeth, over 11 in. long, and suggests that “in the days before the Sperm Whale herds were depleted, there must have been exceptional whales, either larger or older than are found today.” Mitchell (1983) finds this argument “well taken, but not conclusive,” but a look at these teeth, which are on display in the New Bedford Whaling Museum, certainly gives one cause to wonder.

empty the bucket into a waiting tub—or as Melville put it, “Tashtego downward guides the bucket into the Tun, till it entirely disappears; then giving the word to the seamen at the whip, up comes the bucket again, all bubbling like a dairy-maid’s pail of new milk.”

When the oil had all been casked and the casks stowed, the decks were scrubbed down with lye, which had been leached from the cinders and ashes of the tryworks, and the oily, smoky clothes of the whalers were also scrubbed down, but the pernicious odor of smoked blubber could never really be removed, and until they could exchange their work clothes for new garments, the whalers usually smelled like disused tryworks.

VI. The “Romance” of Whaling

In the nineteenth century, when so much of the world was still unexplored, the whalers faced even greater hazards than an occasional angry whale. The US Exploring Expedition under Wilkes had visited many of the island groups in the Central Pacific and found that some of the stories of hostile savages, often cannibals, were true. The Fiji Islands were known—more or less accurately—as The Cannibal Isles, and whenever possible the whalers avoided them. In 1835, the whaler *Awashonks*, out of Falmouth, was attacked by the natives of Namarik in the Marshall Islands, and the captain, the first and second mates, and four crew members were killed before an enterprising whaler dynamited the deck where the would-be conquerors were standing, and the ship was retaken. The *Syren* was recaptured from Palauan natives only after a box of tacks was scattered on deck, driving the barefoot raiders howling overboard.

The need for fresh vegetables and water often outweighed the threat of being attacked, and even though many of the captains knew or had heard stories of cannibalism and “cutoffs” (a whaleship captured by natives and its crew massacred), they could not resist the temptations of cheap provisioning. Whaleships hardly ever carried money; the very same “slop-chest” that provided the foremast hands with their replacement items of clothing also served as a trading bank. “Recruiting ship” was the term used to describe the acquisition of provisions, and the captain would trade cotton cloth, powder, tobacco, knives, and beads for fresh food and water. It was sometimes too much for the parsimonious New Englanders to resist: for a couple of pounds of tobacco or some rusted iron hoops, they could trade for pigs, coconuts, water, wood, and women.

The quality of life aboard a whaler was hardly luxurious, but it was often better than life on the farm. Indeed, many whalers deserted on the islands, not because they were unduly harassed or flogged, but because life on a lush, green island, with free food and even freer women, was an economic and sociological step upward. By the middle of the nineteenth century, there may have been as many as 3000 deserters from whaleships scattered throughout the coral archipelagoes of Micronesia and Polynesia.

Hawaii, Tahiti, and the Marquesas are picture-book “South Sea Islands,” with tall volcanic mountains, tumbling waterfalls, broad white beaches, and swaying palms. When Melville (1846) jumped ship in the Marquesas and subsequently described his experiences in *Typee* he was responsible for many misinterpretations of life on a tropical island. Not all island groups boasted plentiful paw-paws and willing wahines. Many of these tiny specks in the Pacific were mercilessly unforgiving coral atolls; low rings of sand. All along the Equator in the Pacific—the grounds known as “On the Line”—sperm whales occurred in some profusion. Although the vicinity of the Gilbert Islands (then known as the Kingsmill Group) was a good

place to kill sperm whales, it was almost as dangerous for the whalers as it was for the whales. The Gilbertese natives were a particularly aggressive and warlike people, but there were also many beachcombers who had been stranded on these islands, men who were eager to lead the natives in attacks on visiting whalers.

Although an occasional whaler was killed by unfriendly or unresponsive islanders, the effect of the ships’ landings on the natives was considerably more severe. Unscrupulous captains would often offer to trade for provisions, and then sail away without giving anything in return, and it is likely that trigger-happy sailors took the lives of many natives without having to worry about punishment so far from any law but the captain’s. In *Nimrod of the Sea* (1874), Davis recounts the story of three “kanakas” (probably Maoris from New Zealand) who deserted on a tropical island. After demanding their return from the local natives, “the captain double shorted his 9-pound guns, sent a round into the crowded grass huts of the village, and carried off three natives.” From their home ports and pestilent fo’c’s’les, the whalers brought every conceivable communicable disease to the natives, including yaws, influenza, tuberculosis, cholera, syphilis, and the greatest scourge of the unresistant, measles. Before exploration, the population of Tahiti was estimated at some 40,000; by 1830, there were only 9000 Tahitians left. A single measles epidemic in 1875 killed nearly 30,000 Fijians.

There was only so much eating, drinking, holystoning of decks, repairing of sails, and rigging and yarn spinning to occupy the sailors on these seemingly endless voyages. To pass the time, some of them created what Ashley called “the only important indigenous folk art, except for that of the Indians, we have ever had in America; the Art of Scrimshaw.” Although there are very few contemporaneous records of scrimshanders at work—probably because the craft was too insignificant to mention—we assume that the whale teeth were carved during periods of sailing or while waiting in port for provisions or repairs. The baleen of the right and bowhead whales was packed into bundles for commerce at home, but occasionally a piece would be shaped into a busk and decorated with contemporary designs. Baleen was colloquially known to the whalers and merchants of the time as *whalebone*, but it is not bone at all; it is made of keratin, the substance of human hair and fingernails. Whales have bones like any other mammals, but with the exception of the lower jaw—known as the “pan bone”—and the teeth, whale bones are too porous for carving. (Other cultures recognized the attractive nature of whale ivory. Certain Polynesian natives made necklaces of dolphin teeth, and the pre-missionary Hawaiians crafted the beautiful *le niho palaoa*, a gracefully carved sperm whale tooth that was worn by royalty on a necklace of braided human hair.)

Despite their discomfort, low wages, and even occasional floggings, the crews of whaleships were remarkably docile. The master’s word was law, and when the crew became obstreperous, a “taste of the cat” was not unheard of. Only infrequently did they become so desperate that they rebelled. Since harsh treatment, long hours, uncomfortable quarters, and bad food were expected, the whalers generally endured these indignities in stoic silence. Also, as with any uprising, a leader is required to galvanize men into action, and on the whaleships, these troublemakers were rare. The story of the *Bounty’s* mutiny, which had occurred in 1789—and had nothing whatever to do with whales or whaling—was probably known to every seaman and landlubber on either side of the Atlantic. The fate of Fletcher Christian and the mutineers was not known until 1808, when Captain Mayhew Folger of the Nantucket sealer *Topaz* landed at Pitcairn Island and found the survivors.

On Nantucket Island there lived a young man named Samuel Comstock, who may or may not have heard the tale told by Captain Folger. At the age of 19, after three previous cruises, he shipped out aboard the Nantucket whaler *Globe*, departing from Edgartown on the neighboring island of Martha's Vineyard on December 15, 1822. The ship rounded the Horn on March 5, and stopped briefly at Hawaii before heading for the newly discovered Japan Grounds. Despite the reports of plentiful whales off Japan, Captain Worth was unable to locate them, and as they sailed in fruitless circles, the crew became increasingly discontented. Rotten meat was an issue, and conditions were so bad that the captain turned back and headed for Hawaii to re-provision. There several members of the crew deserted, and the *Globe's* depleted crew was replenished with beach combers and drunkards. Repeated conflicts between officers and crew increased the tension, and when the captain had one of the men flogged, Comstock decided to initiate a mutiny.

On January 26, 1824, Samuel Comstock led his followers in one of the bloodiest mutinies in American naval history. They murdered Captain Worth with an axe, slaughtered First Mate Beetle with a boarding knife, shot Second Mate Lumbard in the mouth and then bayoneted him, and shot Third Mate Fisher in the back of the head. They heaved the bodies overboard, and with Comstock at the helm, looked for a place where they could land. En route, Comstock decided that one of his crew members was plotting against him, held a "trial" and sentenced him to hang. For 2 weeks they wandered around, uncertain of their location or destination, until they decided to land at tiny Mili Atoll, in what was then known as the Mulgrave Islands and is now known as the Ratak chain of the Marshall Islands. It appears that Comstock's original plan was to arrange things so that he was the only survivor, but the natives and his fellow mutineers conspired against his plan for the perfect mutiny. As Comstock began to give the ship's stores to the natives (to ensure their support), the crew members who had signed on in Hawaii realized that they were in for trouble either from their leader or from the natives, and they shot Comstock dead (Hoyt, 1975).

Those members of the crew of the *Globe* who had not participated in the mutiny managed to gain control of the ship and sailed away, leaving the mutineers stranded on the island. They would not last long. A bloody conflict between the natives and the whalers resulted in the death of all the latter but two: William Lay, of Saybrook, Connecticut, and Cyrus Hussey, of Nantucket. The *Globe* was sailed to Valparaiso, where the news of the mutiny was made known, and then returned to Nantucket. Her crew was cleared of complicity in the mutiny, and the *Dolphin*, under the command of Lieutenant John ("Mad Jack") Percival, was dispatched to the Pacific to find and bring back the mutineers. Hussey and Lay (1828) had been with the natives for almost a year and a half by the time the *Dolphin* arrived, and they looked more like natives than American whalers. After considerable tension—the Marshallese chiefs were prepared to kill the newly arrived Americans and take their ship—and confusion about who they were, the last of the *Globe's* crew were transported home. Thus ended the story that Starbuck called "the most horrible mutiny that is recounted in the annals of the whaling industry from any port or nation."

White-Beaked Dolphin

Lagenorhynchus albirostris

CARL CHRISTIAN KINZE

I. Characteristics and Taxonomy

A. Taxonomy

Traditionally, the genus *Lagenorhynchus* comprises six species: *L. albirostris*, *L. acutus*, *L. obliquidens*, *L. obscurus*, *L. cruciger*, and *L. australis*. However, recent research (LeDuc *et al.*, 1999) has found this entity to be paraphyletic and suggests a split into three or even four entities instead: the monotypic genus *Lagenorhynchus* containing solely the white-beaked dolphin, another monotypic genus *Leucopleurus* containing *L. acutus*, and a third genus *Sagmatias* for the four Pacific members of the old genus *Lagenorhynchus*. So far, the closest allies of the *L. albirostris* lineage within the delphinids remain obscure. It is not closely related with its present congeners. *L. acutus* shows some affiliation to the generic complex containing *Delphinus*, *Stenella*, and *Tursiops*, whereas the four Pacific species *L. obscurus*, *L. cruciger*, and *L. australis* are related with *Lissodelphis* and in particular *Cephalorhynchus*. *L. cruciger* and *L. australis* may be found to be more closely related to the genus *Cephalorhynchus* than their present congeners.

Recognized only as separate species in 1846, the white-beaked dolphin was among the last of the commonly occurring North Atlantic dolphin species to enter the cetological theater. Earlier finds remain obscure because they have been confused with either bottlenose (*Tursiops truncatus*) or common dolphins (*Delphinus* spp.) and even after its formal description, for many years it was considered a rare species or worse merely a white-beaked type of bottlenose dolphin. It was described twice during 1846: first, in March by the English cetologist John Edward Gray based on an animal that was caught off Great Yarmouth, England in October 1845, and subsequently in November

by the Danish cetologist Daniel Frederik Eschricht, who (probably also in 1845) had received another specimen from the northwest coast of Jutland (believed to be Agger Tange) which he named *Delphinus ibsenii* honoring I. P. Ibsen, the donor of the specimen.

As noted, recent DNA studies suggest that the white-beaked dolphin represents its own lineage within the delphinids. However, there is no fossil record to confirm this. Sub-fossil finds of the species exist from the greater North and Baltic Sea area, in particular from Danish and Swedish sites, and document the presence in European waters since the last glacial epoch.

The generic name *Lagenorhynchus* means bottlenose (*lago* = flask or bottle, *rhynchus* = nose, beak) while *albirostris* refers to the white beak (*albus* = white, *rostrum* = beak).

Vernacular names include Hvidnaese (Danish), Witsnuitdolfijn (Dutch), Kjarthvitur springari (Faroese), dauphin avec bec blanc (French), Weisschnauzendelfin (German), Blettahnydir (Islandic), Kvitnos or Hvitnos (Norwegian), delfin bialosy (Polish), belomordyi del'fin (Russian), delfin de hocicio blanco (Spanish), and ardluasuk (Greenlandic). The names in most languages note the white beak of the species. The Greenlandic name means "killer whale look-alike" obviously due to the marked black and white coloration of the white-beaked dolphin.

B. Description

The white-beaked dolphin has a robust appearance. The beak is short, only 5–8 cm long. There is an erect falcate dorsal fin on the middle of the back. Adults grow to between 2.4 and 3.1 m long and may weigh between 180 and 360 kg. Males usually grow larger than females. Newborn animals are about 1.2 m long and weigh approximately 40 kg.

The coloration is typically black on the back with a white saddle behind the dorsal fin and whitish bands on the flanks that vary in intensity from shining white to light gray. The belly and the beak normally are white (Figs 1 and 2). The beak sometimes is ashy gray or even darker, but never all black. The belly may also exhibit a grayish

Figure 1 Close-up of the white beak of the species. Photograph courtesy Martin Abramhamsson, Midtstrønderjyllands Museum, Gram, Denmark.

Figure 2 School of white-beaked dolphins encountered off the Belgian coast in the southern North Sea. Photograph courtesy Christophe Van Driesche.

coloration leaving only a median narrow band of pure white. Younger animals may exhibit generally a lighter coloration. The whitish bands on the flank will fade shortly after the death of the animal.

There are between 25 and 28 conical teeth in each half of the upper and lower jaws. In very old animals the teeth show considerable wear.

The rostrum of the skull has a broad base and is relatively short. The vertebral column consists of 90–94 vertebrae (C7 Th15–16 L23–24 Ca 45–47). There are either 6 or 7 double-headed ribs anteriorly to 9 or 10 single-headed ribs, the total number of rib pairs usually being 16. The posterior-most pair of ribs may only be present as “floating ribs” without connection to the vertebral column. The phalanges formula is $I_2, II_6, III_4, IV_1, V_0$. The pelvic bones in adult specimens are sexually dimorphic and allow both determination of sex and sexual maturity, with male pelvic bones growing longer and heavier.

The blubber thickness varies between 20 and 35 mm. The total blubber weight amounts to between 20% and 30% of the total weight, with the highest figures found in pregnant females. The lungs on their outer edges carry fringes of adipose tissue (missing when animals are in severely deteriorated body condition).

The alimentary tract exhibits the typical delphinid scheme with a stomach consisting of three compartments. The uppermost part of the small intestine may possess a diverticulum sometimes referred to as a “fourth stomach.”

Normally, there are two equally well-developed ovaries. Sometimes, however, the right ovary remains sub-mature throughout life, indicating a tendency toward ovarian asymmetry. The mature testes undergo seasonal changes and increase fourfold in weight during the breeding season.

Detailed information on organs and internal anatomy can be found in Reeves *et al.* (1998) and the other references given later.

Based on certain skull measurements significant differences have been found between specimens from either side of the North Atlantic. The use of molecular methods and photo-ID studies may when carried out provide further evidence on the stock identity and possible management stocks.

II. Distribution and Abundance

The species is endemic to the temperate and subarctic North Atlantic (Fig. 3). On the western seaboard it has been documented as far north as the southern tip of Greenland and as far south as Cape Cod on the American east coast. The northernmost record on the eastern side of the North Atlantic originates from the White Sea, the southern most from the Strait of Gibraltar. The species has been reported to stray into the Mediterranean Sea, but these records need confirmation. Being a native species of the northern North Sea and the adjacent Skagerrak, there are frequent intrusions into the Kattegat and western part of the Baltic Sea.

Reflecting the on a gross scale the distribution of shelf waters of the Northern North Atlantic, four principal centers of high density can be identified: (1) the Labrador Shelf including south western Greenland, (2) Icelandic waters, (3) the waters around Scotland including the northern Irish Sea and the North Sea, and (4) the small shelf stretch along the Norwegian coast extending north into the White Sea. The population structure is not known in any detail. So far, comparisons have been carried out only between areas 1 and 3; they revealed significant differences in skull morphology. The size of these designated populations is not known, but abundance estimates are available from the Labrador coast (“at least several thousands” according to Alling and Whitehead, 1987) and the greater North Sea (Hammond *et al.*, 2002): 7856 (95% CI = 4,032–13,301).

III. Ecology

The diet of the species seems to reflect the local abundance and availability of certain prey species and therefore geographical differences exist. In Danish waters, cod and other gadid fish were found to be the main prey items. White-beaked dolphins prey on larger cods (about 20 cm longer in total length) than do sympatric harbor porpoises. Similar diet analysis from the Netherlands also found codfish as the most common prey, with whiting as the next most common. A German study calculated that by numbers 79% and by mass contribution 94% of the consumed fish were cod (Kinze *et al.*, 1997). Analyses from Scottish waters showed that white-beaked dolphins in addition also consume cephalopods (Santos *et al.*, 1994).

There are no reports of direct attacks on white-beaked dolphins by killer whales (*Orcinus orca*), but schools of white-beaked dolphins have been observed to flee from pods of killer whales. White sharks potentially also could prey on weakened or younger white-beaked dolphins.

The most commonly encountered infestation found in this species is by the nematode *Anisakis simplex* in the first and second stomachs. Severe infestations may cause the development of stomach ulcers. The tape worm, *Plicobotrium globicephalae*, is found in the intestines and another nematode, *Halocercus lagenorhynchi*, in the lungs (Raga, 1994).

Spondylitis deformans, a degenerative disease of the vertebral column, is rather common in physically mature individuals. In general, females seem to be more susceptible, exhibiting a higher number of affected vertebrae and more severe cases of the disease (Galatius *et al.*, 2009).

The species mainly dwells in shelf waters ranging from 150 to 1000 m in depth but also is a facultative coastal species. It is present where prey items concentrate, i.e., where fronts between water masses of different salinity form or where there is up-welling. It prefers water temperatures from 5°C to 15°C.

The white-beaked dolphin is known to occur in mixed groups with white-sided dolphins, e.g., in the North Sea. In the western

Figure 3 Distribution of the white-beaked dolphin.

Baltic, a single white-beaked dolphin paired with a common dolphin for a period of several weeks. In Scottish waters, common bottlenose dolphins (*Tursiops truncatus*) and white-beaked dolphins have been sighted in close vicinity to each other. Hybridization between these two species, however, has not been documented. Other delphinids known to mingle with white beaks are short-beaked common dolphins (*Delphinus delphis*) and Risso's dolphins (*Grampus griseus*). Interactions with larger baleen whales such as fin (*Balaenoptera physalus*), sei (*B. borealis*), and humpback (*Megaptera novaeangliae*) whales have also been documented.

IV. Behavior and Physiology

White-beaked dolphins readily approach vessels and bow-ride. They frequently leap out of the water, earning them their vernacular name "jumper." They usually travel at speeds of 6–12 km/h, but speeds up to 30 km/h have been recorded (Evans and Smeenk, 2008).

Details on diving behavior only recently have been revealed from a study in Icelandic waters. A 209-cm male tagged in Faxaflói Bay in southwest Iceland performed dives down to 45 m lasting up to 78 sec, with averages of 24 m and 28 sec, respectively (Rasmussen *et al.*, 2007).

Foraging is conducted both in smaller or in larger groups depending on prey availability. The dolphins hunt in a broad front to encircle their prey.

The mean school size is 9 in Icelandic waters and between 4 and 6 in Danish North Sea waters, whereas in offshore waters

much larger aggregations have been reported. School composition is known from ice entrapments, strandings, and sightings. All-male groups have been reported. Calves were found in larger groups containing adult animals of both sexes and in cow-calf aggregations.

Migrations over longer distances are not known. Pilot studies conducted in the Skagerrak and northern North Sea applying photo-ID techniques established matches between these areas and the Scottish coast.

Source levels of clicks have been recorded from free-ranging white-beaked dolphins in Icelandic waters. In a single click train they were found to vary from 194 to 211 dB peak-to-peak (p-p) re: 1 μ Pa. The source levels varied linearly with the log of range. The maximum source levels recorded were 219 dB (p-p) re: 1 μ Pa. The 3 and 10 dB beam widths were calculated to be 8° and 10°, respectively, indicating a narrower transmission beam for white-beaked dolphins than that reported for common bottlenose dolphins (*Tursiops truncatus*). The beam width was more similar to that found for belugas (*Delphinapterus leucas*). The directivity index was 29 dB. This was the first attempt to estimate the directionality index of dolphins in the field (Rasmussen *et al.*, 2002, 2004).

V. Life History

The pattern of growth and the age at sexual maturity in the white-beaked dolphin are rather similar to what is known for the bottlenose dolphin. Data on age determination are still in need of further improvement. However, Galatius and Kinze (2007) have aged a sample of 86

specimens originating from Danish North Sea and Kattegat waters. Females become physically mature on average at lengths of 251 cm, males at lengths of 271 cm, corresponding to mean age of 15.6 years (95% CI = 9.8–23.1) and 11.4 years (95% CI = 7.7–18.1), respectively.

Females attain sexual maturity at a mean age of 8.7 years (95% CI = 5.1–14.6), males at 11.6 years (95% CI = 8.2–16.1). The mean lengths at sexual maturity were found to be 240 cm and 270 cm in females and males, respectively. There is a marked seasonality in the testes' size in mature males. During the mating season (July and August) the combined testes mass will have increased 6 times from 500 g to nearly 3000 g. The gestation period lasts about 11 months. Preliminary studies indicate a rather high annual ovulation rate of 0.7. Maximum recorded age for females is 34 years. Pregnant females are rarely encountered among stranded individuals, possibly indicating long periods of resting.

There are several known cases of ice entrapment of white-beaked dolphins from the northern part of the range. Sub-adult animals may get entangled in gill nets, whereas adults accidentally get drowned when pursuing fish into trawls. There are several reports of live strandings in tidal waters.

VI. Interactions with Humans

Directed catches or kills are not common today but have occurred off Norway, Iceland, and Newfoundland. There is still opportunistic take in southwestern Greenland. Incidental catches in gillnets mainly affect younger animals.

The first life catch for public display (five animals for the Mystic Aquarium in Connecticut) was conducted in 1983. In Europe live-stranded animals have been brought into rehabilitation facilities.

White-beaked dolphins carry loads of organochlorines in the blubber and heavy metals in the liver and kidneys. Off Newfoundland, the loads were high even in younger animals.

The white-beaked dolphin is probably still one of the most common dolphins of the temperate North Atlantic, but there is a need for further data to ensure proper management.

MARINE MAMMAL SPECIES¹

ORDER CARNIVORA

Family Otariidae

- Arctocephalus pusillus* (Schreber, 1775), Tasmanian and Cape fur seals
- Arctocephalus gazella* (Peters, 1875), Antarctic fur seal
- Arctocephalus tropicalis* (Gray, 1872), Subantarctic fur seal
- Arctocephalus townsendi* Merriam, 1897, Guadalupe fur seal
- Arctocephalus philippii* (Peters, 1866), Juan Fernández fur seal
- Arctocephalus forsteri* (Lesson, 1828), South Australian and New Zealand fur seals
- Arctocephalus australis* (Zimmerman, 1783), South American fur seal
- Arctocephalus galapagoensis* Heller, 1904, Galapagos fur seal
- Callorhinus ursinus* (Linnaeus, 1758), Northern fur seal
- Zalophus japonicus* (Peters, 1866), Japanese sea lion
- Zalophus californianus* (Lesson, 1828), California sea lion
- Zalophus wollebaeki* Sivertsen, 1953, Galapagos sea lion
- Eumetopias jubatus* (Schreber, 1776), Steller sea lion, northern sea lion
- Neophoca cinerea* (Péron, 1816), Australian sea lion
- Phocarcos hookeri* (Gray, 1844), New Zealand sea lion, Hooker's sea lion
- Otaria flavescens* (Shaw, 1800), South American sea lion

Family Odobenidae

- Odobenus rosmarus* (Linnaeus, 1758), Walrus

Family Phocidae

- Erignathus barbatus* (Erxleben, 1777), Bearded seal
- Phoca vitulina* (Linnaeus, 1758), Harbor seal, common seal
- Phoca largha* (Pallas, 1811), Spotted seal, larga seal
- Pusa hispida* (Schreber, 1775), Ringed seal
- Pusa caspica* (Gmelin, 1788), Caspian seal
- Pusa sibirica* (Gmelin, 1788), Baikal seal
- Halichoerus grypus* (Fabricius, 1791), Gray seal
- Histiophoca fasciata* (Zimmerman, 1783), Ribbon seal
- Pagophilus groenlandicus* (Erxleben, 1777), Harp seal
- Cystophora cristata* (Erxleben, 1777), Hooded seal
- Monachus tropicalis* (Gray, 1850), Caribbean monk seal, West Indian monk seal
- Monachus monachus* (Hermann, 1779), Mediterranean monk seal
- Monachus schauinslandi* Matschie, 1905, Hawaiian monk seal
- Mirounga leonina* (Linnaeus, 1758), Southern elephant seal
- Mirounga angustirostris* (Gill, 1866), Northern elephant seal
- Leptonychotes weddellii* (Lesson, 1826), Weddell seal
- Ommatophoca rossii* Gray, 1844, Ross seal
- Lobodon carcinophaga* (Hombron and Jacquinot, 1842), Crabeater seal
- Hydrurga leptonyx* (Blainville, 1820), Leopard seal

Family Ursidae

- Ursus maritimus* Phipps, 1774, Polar bear

¹Living and recently extinct. Author(s) and year of description of the species follow the Latin species name; when these are enclosed in parentheses, species was originally described in a different genus. Classification and scientific names follow Rice (1998), with adjustments reflecting more recent literature. The cetaceans genetically and morphologically fall firmly within the artiodactyl clade (Geisler and Uhen, 2005) and therefore we provisionally include them as a suborder in the order Cetartiodactyla, with infraorders Mysticeti and Odontoceti (recognizing that the suborder-level classification of the rest of the cetartiodactyls remains unresolved). The use of *Lontra* rather than *Lutra* for the marine otter follows Larivière (1998) in recognizing the otters of North and South America as a monophyletic taxon distinct from the otters of Eurasia. Recent genetic evidence strongly supports the recognition of three separate phylogenetic species of right whales (Rosenbaum *et al.*, 2000). In addition, the genus *Eubalaena* (rather than *Balaena* as in Rice, 1998) is retained for the right whales as recommended by the Scientific Committee of the International Whaling Commission (IWC, 2002). All Bryde's whales are provisionally considered to comprise a single species, *Balaenoptera edeni*, following the usage of the IWC (IWC, 2001, 2008). We also follow the IWC in listing only two species of *Sousa*; the taxonomy of this group is in flux (see chapter Humpback Dolphins). The Irrawaddy dolphin was recently split into *O. brevirostris* and *O. heinsohni*, the Australian snubfin dolphin (Beasley *et al.*, 2005). The tucuxi has been split into *Sotalia fluviatilis* (tucuxi) and the Guiana dolphin *S. guianensis* (Caballero *et al.*, 2007). *Delphinus tropicalis* is now considered a subspecies of *D. capensis* (Jefferson and Van Waerebeek, 2002). *Mesoplodon traversii* (spade-toothed whale) has been recognized as the senior synonym for *M. bahamondi* (Bahamonde's beaked whale) (van Helden *et al.*, 2002). *Balaenoptera omurai* and *Mesoplodon perrini* are newly described species (Wada *et al.*, 2003 and Dalebout *et al.*, 2002, respectively). The former, previously confounded with Bryde's whales, has been confirmed as having a separate and ancient lineage (Sasaki *et al.*, 2006). For the rest, we do not necessarily endorse Rice's (1998) classification and usage in all their details but have used them as a standard to avoid editorial confusion in the volume.

Family Mustelidae

- Enhydra lutris* (Linnaeus, 1758), Sea otter
Lontra felina (Molina, 1782), Marine otter, chungungo

ORDER CETARTIODACTYLA**Suborder Cetacea****Infraorder Mysticeti****Family Balaenidae**

- Eubalaena glacialis* (Muller, 1776), North Atlantic right whale
Eubalaena japonica (Lacépède, 1818), North Pacific right whale
Eubalaena australis (Desmoulins, 1822), Southern right whale
Balaena mysticetus Linnaeus, 1758, Bowhead whale, Greenland whale

Family Neobalaenidae

- Caperea marginata* (Gray, 1846), Pygmy right whale

Family Eschrichtiidae

- Eschrichtius robustus* (Liljeborg, 1861), Gray whale

Family Balaenopteridae

- Megaptera novaeangliae* (Borowski, 1781), Humpback whale
Balaenoptera acutorostrata Lacépède, 1804, Common minke whale
Balaenoptera bonaerensis Burmeister, 1867, Antarctic minke whale
Balaenoptera edeni Anderson, 1879, Bryde's whale
Balaenoptera omurai Wada, Oishi and Yamada, 2003, Omura's whale
Balaenoptera borealis Lesson, 1828, Sei whale
Balaenoptera physalus (Linnaeus, 1758), Fin whale
Balaenoptera musculus (Linnaeus, 1758), Blue whale

Infraorder Odontoceti**Family Physeteridae**

- Physeter macrocephalus* Linnaeus, 1758, Sperm whale

Family Kogiidae

- Kogia breviceps* (Blainville, 1838), Pygmy sperm whale
Kogia sima (Owen, 1866), Dwarf sperm whale

Family Ziphiidae

- Ziphius cavirostris* G. Cuvier, 1823, Cuvier's beaked whale, goose-beaked whale
Berardius arnuxii Duvernoy, 1851, Arnoux' beaked whale
Berardius bairdii Stejneger, 1883, Baird's beaked whale
Tasmacetus shepherdii Oliver, 1937, Shepherd's beaked whale, Tasman beaked whale
Indopacetus pacificus (Longman, 1926), Indo-Pacific or Longman's beaked whale
Hyperoodon ampullatus (Forster, 1770), North Atlantic bottlenose whale

- Hyperoodon planifrons* Flower, 1882, Southern bottlenose whale
Mesoplodon hectori (Gray, 1871), Hector's beaked whale
Mesoplodon mirus True, 1913, True's beaked whale
Mesoplodon europaeus (Gervais, 1855), Gervais' beaked whale
Mesoplodon bidens (Sowerby, 1804), Sowerby's beaked whale
Mesoplodon grayi von Haast, 1876, Gray's beaked whale, scamperdown whale
Mesoplodon perrini Dalebout, Mead, Baker, Baker, and van Helden, 2002, Perrin's beaked whale
Mesoplodon peruvianus Reyes, Mead, and Van Waerebeek, 1991, Pygmy beaked whale, Peruvian beaked whale
Mesoplodon bowdoini Andrews, 1908, Andrew's beaked whale
Mesoplodon traversii (Gray, 1874), Spade-toothed whale
Mesoplodon carlhubbsi Moore, 1963, Hubbs' beaked whale
Mesoplodon ginkgodens Nishiwaki and Kamiya, 1958, Ginkgo-toothed beaked whale
Mesoplodon stejnegeri True, 1885, Stejneger's beaked whale
Mesoplodon layardii (Gray, 1865), Layard's or strap-toothed beaked whale
Mesoplodon densirostris (Blainville, 1817), Blainville's or dense-beaked whale

Family Platanistidae

- Platanista gangetica* (Roxburgh, 1801), Susu, bhulan, South Asian river dolphin, Indian river dolphin

Family Iniidae

- Inia geoffrensis* (Blainville, 1817), Boto, Amazon river dolphin

Family Lipotidae

- Lipotes vexillifer* (Miller, 1918), Baiji, Yangtze river dolphin

Family Pontoporiidae

- Pontoporia blainvillei* (Gervais and d'Orbigny, 1821), Franciscana, La Plata river dolphin

Family Monodontidae

- Monodon monoceros* Linnaeus, 1758, Narwhal
Delphinapterus leucas (Pallas, 1776), Beluga, belukha, white whale

Family Delphinidae

- Cephalorhynchus commersonii* (Lacépède, 1804), Commerson's dolphin
Cephalorhynchus eutropia (Gray, 1846), Chilean dolphin
Cephalorhynchus heavisidii (Gray, 1828), Heaviside's dolphin
Cephalorhynchus hectori (van Bénédén, 1881), Hector's dolphin
Steno bredanensis (G. Cuvier in Lesson, 1828), Rough-toothed dolphin
Sousa teuszii (Kükenthal, 1892), Atlantic humpbacked dolphin
Sousa chinensis (Osbeck, 1765), Pacific humpbacked or Chinese white dolphin
Sotalia fluviatilis (Gervais and Deville, 1853), Tucuxi
Sotalia guianensis (Van Bénédén, 1864), Guiana dolphin
Tursiops truncatus (Montagu, 1821), Common bottlenose dolphin
Tursiops aduncus (Ehrenberg, 1833), Indian Ocean or Indo-Pacific bottlenose dolphin

Stenella attenuata (Gray, 1846), Pantropical spotted dolphin
Stenella frontalis (G. Cuvier, 1829), Atlantic spotted dolphin
Stenella longirostris (Gray, 1828), Spinner dolphin
Stenella clymene (Gray, 1850), Clymene dolphin
Stenella coeruleoalba (Meyen, 1853), Striped dolphin
Delphinus delphis Linnaeus, 1758, Short-beaked common dolphin
Delphinus capensis Gray, 1828, Long-beaked common dolphin
Lagenodelphis hosei Fraser, 1956, Fraser's dolphin
Lagenorhynchus albirostris (Gray, 1846), White-beaked dolphin
Lagenorhynchus acutus (Gray, 1828), Atlantic white-sided dolphin
Lagenorhynchus obliquidens Gill, 1865, Pacific white-sided dolphin
Lagenorhynchus obscurus (Gray, 1828), Dusky dolphin
Lagenorhynchus australis (Peale, 1848), Peale's dolphin
Lagenorhynchus cruciger (Quoy and Gaimard, 1824), Hourglass dolphin
Lissodelphis borealis Peale, 1848, Northern right whale dolphin
Lissodelphis peronii (Lacépède, 1804), Southern right whale dolphin
Grampus griseus (G. Cuvier, 1812), Risso's dolphin, gray grampus
Peponocephala electra (Gray, 1846), Melon-headed whale, electra dolphin
Feresa attenuata Gray, 1874, Pygmy killer whale
Pseudorca crassidens (Owen, 1846), False killer whale
Orcinus orca (Linnaeus, 1758), Killer whale, orca
Globicephala melas (Traill, 1809), Long-finned pilot whale
Globicephala macrorhynchus Gray, 1846, Short-finned pilot whale
Orcaella brevirostris (Owen in Gray, 1866), Irrawaddy dolphin, pesut
Orcaella heinsohni Beasley, Robertson, and Arnold, 2005, Australian snubfin dolphin

Family Phocoenidae

Neophocaena phocaenoides (G. Cuvier, 1829), Finless porpoise
Phocoena phocoena (Linnaeus, 1758), Harbor porpoise, common porpoise
Phocoena sinus Norris and McFarland, 1958, Vaquita, Gulf of California harbor porpoise
Phocoena spinipinnis Burmeister, 1865, Burmeister's porpoise
Phocoena dioptrica Lahille, 1912, Spectacled porpoise
Phocoenoides dalli (True, 1885), Dall's porpoise, Dall porpoise

ORDER SIRENIA

Family Trichechidae

Trichechus manatus Linnaeus, 1758, Caribbean manatee, West Indian manatee
Trichechus senegalensis Link, 1795, African manatee, West African manatee
Trichechus inunguis (Natterer, 1883), Amazon manatee

Family Dugongidae

Dugong dugon (Müller, 1776), Dugong, sea cow
Hydrodamalis gigas (Zimmerman, 1780), Steller's sea cow, giant sea cow

BIOGRAPHIES

Science is done by individuals, and the student or practicing scientist often wants to know something about those who came before, who developed the field. The brief biographies listed here are meant to meet that need, however sketchily. The list includes those who, in the opinion of the editors, made an important and lasting contribution to the study of marine mammals. Some of their most important works are also listed, and the student is urged to peruse some of these classics. Living persons are not included, as lifetime contributions cannot be fairly weighed until they are completed.

- Abel, Othenio** (1875–1946) Austrian paleontologist, the main European researcher on fossil whales in the early twentieth century, working on the Belgian Miocene and on *Basilosaurus*. He expanded the perspective of marine mammal paleontologists to include higher level phylogeny.
- Abel, O. (1905). Les Odontocètes du Bolderien (Miocene supérieure) d'Anvers. *Mem. Mus. Roy. Hist. Nat. Belg.* **3**, 1–155.
- Abel, O. (1907). The genealogical history of the marine mammals. *Ann. Rep. Smithsonian Inst.* **1907**, 473–496.
- Allen, Glover M.** (1879–1942) One of the great naturalists of his day; among his enduring works relating to marine mammals are his monograph on the baleen whales of New England and his 1942 book on extinct and endangered mammals, which included the first review of the status of marine mammal species and the conservation problems affecting them.
- Allen, G. M. (1916). The whalebone whales of New England. *Mem. Boston Soc. Nat. Hist.* **8**, 109–322.
- Allen, G. M. (1942). “Extinct and Vanishing Mammals of the Western Hemisphere with the Marine Species of All the Oceans.” American Committee for International Wildlife Protection, Cambridge, Massachusetts. (1972 reprint by Cooper Square, New York).
- Allen, Joel A.** (1838–1921) Completed the first comprehensive bibliography of cetology and sirenology (1495–1840), which is still highly useful today. He also produced a series of important monographs and papers on the marine mammals of North America.

- Arnold, Peter W.** (1949–2006) Highly respected Australian systematist who applied rigorous cladistic analysis to cranial morphology of delphinoid cetaceans and documented the occurrence of two species of minke whales in Australian waters. Born in Nova Scotia, he spent most of his scientific career in Queensland. He also worked with harbor porpoise parasites, took part in description of the new dolphin species *Orcaella heinsohni*, and pioneered behavioral studies of minke whales subject to whale-watching.

- Berzin, Alfred A.** (1930–1996) Latvian whale biologist, born in Rostov-on-Don, Russia; known for his comprehensive research and monograph on the sperm whale. He spent his career at the Pacific Ocean Research Institute for Fisheries and Oceanography (TINRO) in Vladivostok. Most recently, he took part in the recovery and reporting of the true Soviet whaling catch data, which exposed massive unreported kills of protected whales in the 1960s and 1970s that may explain the apparent failure of some stocks to recover.

- Bigg, Michael A.** (1939–1990) Born in London and emigrating to British Columbia as a child, he was the first to use individual identification of killer whales to study long-term social structure, life history, and movements. He discovered the existence of sympatric but nonmixing fish-eating and mammal-eating forms/groups ("residents" and "transients") and established the fact that killer whale pods are matrilineal groups, with all offspring remaining with the maternal pod.

- Chapman, Douglas G.** (1920–1996) Noted mathematician, wildlife scientist, and teacher, born in Canada and spending his career at the University of Washington in Seattle. He was a member of the famous Committee of Three Scientists established by International Whaling Commission in 1961 as an independent body to advise on status and trends of whale stocks, leading to accurate predictions of collapse of stocks under commercial exploitation. A pioneer in the development and use of quantitative models for marine mammal assessment and management, he worked on pinnipeds as well as cetaceans.

- Cuvier, Frederic** (1773–1838) Comparative anatomist and physiologist, brother of Georges Cuvier; Frederic Cuvier synthesized the available information on cetaceans in his landmark volumes, correcting many errors about cetacean natural history accumulated through the centuries.
- Cuvier, F. (1829). Cétacés. In "Histoire Naturelle des Mamifères" (E. Geoffroy Saint-Hilaire and F. Cuvier, eds). Belin, Paris.
- Cuvier, F. (1836). "De l'Histoire Naturelle des Cétacés." Roret, Paris.
- Cuvier, Georges** (1769–1832) Famed paleontologist, zoologist, and evolutionary thinker, widely respected in his time as one of the originators of the idea of evolution and the founder of modern biology and comparative anatomy. He spent his career at the Museum national d'Histoire naturelle, Paris. His enormous treatise on fossils included a volume on cetaceans, and he carried out many basic studies of cetacean anatomy, including the first

- description of the inner ear, and compiled one of the first stranding reports (1812).

- Dawbin, William H.** (1921–1998) New Zealand-born biologist, historian, and teacher who pioneered much of the early research on distribution and movements of humpback whales and right whales in the Southern Hemisphere. He was launched into marine mammalogy by early years spent in the whaling grounds of the Southern Ocean. His later work focused on catch history of whales in the Southern Hemisphere. He was also a noted herpetologist.

- Eschricht, Daniel Frederick** (1798–1863) A pioneer in many aspects of modern cetology: the first to consider cetaceans, including harbor porpoises, narwhals, and belugas, as migrating animals; the first to describe the embryo of a whale based on dissections; the first to distinguish between the bowhead and right whales; the first (with Owen) to see concentric layers of growth in the teeth of cetaceans; and the first to identify different populations of killer whales in the Arctic. Most of his work was in Danish and largely inaccessible to other marine mammal scientists until published in English by Flower (1866). The gray whale, *Eschrichtius robustus*, bears his name.
- Eschricht, D. F. (1840–1842). Om undersøgelsen af de nordiske Hvaler. *Skand. Naturf. Förhandl.* **2**, 83–108, 203–227.

- Fabricius, Otto** (1744–1822). Danish missionary, cleric, philologist, naturalist, and ethnographer. He published the first account of the fauna of Greenland, including descriptions of 143 new species. This work included precise descriptions of all five pinnipeds inhabiting Greenland. Later works included a monograph on the seals of Greenland and a work on seal hunting implements.

- Kapel, F. O. (2005). “Otto Fabricius and the Seals of Greenland.” Danish Polar Center, Copenhagen.
- Fay, Francis H.** (1927–1994) Born in Massachusetts and spending most of his career at the University of Alaska, “Bud” Fay was the world’s leading expert on the walrus. He translated and made accessible to western scientists much of the massive Russian literature on marine mammals of the North Pacific and Arctic.
- Fay, F. H. (1982). Ecology and biology of the Pacific walrus, *Odobenus rosmarus divergens Illiger*. *N. Am. Fauna* **74**, 1–279.
- Fay, F. H. (1997). Status of the Pacific walrus population, 1950–1989. *Mar. Mamm. Sci.* **13**, 537–565.
- Flower, William Henry** (1831–1899) Gray’s student and his successor as curator of the huge collection of marine mammal specimens at the British Museum in the last quarter of the nineteenth century, Flower was an extremely able zoologist who contributed major works on the beaked whales and the delphinid cetaceans, as well as publications on manatees and pinnipeds.
- Flower, W. H. (1871). On the recent ziphioid whales, with a description of the skeleton of *Berardius arnuxi*. *Trans. Zool. Soc. London* **8**, 203–234, pl. 27–29.

- Fraser, Francis C.** CBE, FRS (1903–1978) The main practitioner of British cetology in the mid-twentieth century, which was far ahead of its state in North America. A Scot by birth, he was Keeper of Zoology in charge of the whales, dolphins, and porpoises at the British Museum for several decades. A UK-wide stranding program had started early in the century (stranded animals are “royal fish” and property of the sovereign), and Fraser kept it going and authored elaborate periodic reports up into the 1970s. His classic work with Peter E. Purves on the comparative functional morphology of the cetacean ear resulted in a classification that has endured and proved to be largely consonant with phylogenies generated by the most modern methods. He described Fraser’s dolphin, *Lagenodelphis hosei*, from a skeleton that had languished in the BM collection for over 50 years as an “abnormal” or hybrid specimen. Much of today’s cetology is built on his work.
- Fraser, F. C. (1956). A new Sarawak dolphin. *Sarawak Mus. J.* **7**, 478–503, pl. 22–26.

- Gilmore, Raymond W.** (1907–1984) The “father” of whale-watching, first naturalist to accompany a whale-watching cruise, on gray whales out of San Diego, California in 1959. Active in early population assessments of gray whales and in observations of gray whales in their breeding lagoons in Baja California. Began his professional career as an entomologist, working on mosquitoes in Central America; a demonstration of how many scientists early on “backed into” marine mammalogy.
- Gilmore, R. W. (1960). A census of the California gray whale. *U.S. Fish Wildl. Serv. Spec. Sci. Rep.-Fish.* **342**, 1–30.
- Gilmore, R. W. (1976). The friendly whales of Laguna San Ignacio. *Terra* **15**, 24–28.
- Gray, John Edward** (1800–1875) had a plan as a young man to “form the largest and most complete Zoological Collection known” and he succeeded, being personally responsible for the building of the huge collections of the British Museum amassed during the Victorian period of wide zoological exploration. He worked and published prolifically on nearly every animal group. To keep track of the current literature, he started the Zoological Record. Among his 1096 publications (1820–1875) were scores on whales, dolphins, porpoises, seals, otters, and other aquatic mammals. We still recognize 16 of the marine mammal species he described (3 pinnipeds, 1 baleen whale, 2 toothed whales, and 10 dolphins and small toothed whales), as well as many of his higher taxa. *Mesoplodon grayi* is named after him.

- Gulland, John** FRS (1926–1990) Eminent English fisheries mathematician and teacher who was a member of the independent committee of scientists commissioned in the 1960s to assess the status of Antarctic whale stocks; the committee predicted collapse of the stocks due to commercial overexploitation, and that came to pass. He was the mainstay of the fisheries department of the Food and Agriculture Organization (FAO) of the UN in Rome for nearly 20 years, running highly effective training courses in developing countries around the world, and authored several important texts on fishery assessment and management.

- Gulland, J. (1983). “Fish Stock Assessment: A Manual of Basic Methods.” J. Wiley and Sons, New York.
- Harrison, Sir Richard J.** FRS (1920–1999) English anatomist and functional morphologist who first made his mark in human anatomy and medicine. He became deeply interested and intrigued by marine mammals through discussions with Francis Fraser of the British Museum and went on to produce landmark works on the reproduction and general biology of whales, dolphins, and seals. He received a knighthood for his contributions to marine biology, education, and public service.

- Hershkovitz, Phillip** (1909–1997) Known mainly for his voluminous works on the systematics and ecology of neotropical terrestrial mammals, Hershkovitz turned to cetaceans at one point and produced his classic *Catalog of Living Whales*, a definitive reference indispensable to any cetacean systematist. While many of his taxonomic “calls” subsequently have been second-guessed, he led the way for cetological systematists in the last half of the twentieth century.
- Hershkovitz, P. (1966). Catalog of living whales. *U.S. Nat. Mus. Bull.* **246**, 1–257.
- Heyning, John E.** (1957–2007) Born and reared in southern California, Heyning became Curator and later Deputy Director of the Los Angeles County Museum and built the marine mammal collection there to the second largest in the United States. A dynamic educator and specialist in systematics and functional morphology, he took active roles in the American Cetacean Society and the Natural Science Collections Alliance.

- Hubbs, Carl L.** (1894–1979) A polymath naturalist born in Arizona whose career and publications spanned over 65 years and included the study of fishes, birds, marine mammals, archeology, geochronology, geology, climatology, evolution, hybridism, and the practice of systematics. He carried out the first aerial surveys of gray whales, rediscovered the supposedly extinct Guadalupe and Juan Fernandez fur seals, and was a major force for the conservation of marine animals and their habitats. He persuaded the Mexican Government to establish the first gray whale sanctuary, in Scammon's Lagoon. Hubb's beaked whale, *Mesoplodon carlhubbsi*, was named in his honor; he and other faculty members at the Scripps Institution of Oceanography ate the type specimen during World War II meat rationing (the osteological portions fortunately were saved).

- Kellogg, Remington** (1892–1969) Paleontologist, mammalogist, and popularizer of cetaceans at the Smithsonian Institution. He produced dozens of works on fossil whales, dolphins, porpoises, and seals, including the classic and massive “Review of the Archeoceti.” His doctoral thesis “History of Whales – Their Adaptations to Life in the Water” has served as a primer for cetologists for generations. He took part in the early stages of the organization of international agreements on whaling beginning in the 1930s. The first U.S. Commissioner to the IWC, he battled vigorously but unsuccessfully in the 1960s for limitation of commercial exploitation of whales to sustainable levels. Although he did not win the day, the heat of the controversy led to later independent review of the whale stocks and eventual effective regulation of whaling.

- Kellogg, R. (1940). Whales, giants of the seas. *Nat. Geogr.* **77**(1), 35–90.
- Kellogg, Winthrop N.** (1898–1972) A physiologist at Florida State University, discovered ultrasonic hearing in dolphins and was the first to demonstrate cetacean echolocation. The research was accomplished with captive dolphins from Florida Marine Studios. Also worked with dolphin visual learning and sonic size discrimination.

- Kirkwood, Geoffrey P.** (1947–2006) Australian quantitative modeler who pioneered the application of simulation studies to test the performance of fishery management models. He was pivotal in development of the IWC's Revised Management Procedure for the large whales, serving also as chairman of the IWC Scientific Committee. His last professional berth was at Imperial College, London.
- Kirkwood, G. P. (1997). The Revised Management Procedure of the International Whaling Commission. In "Global Trends: Fisheries Management". (E. K. Pikitch, D. D. Huppert, and M. P. Sissenwine, eds.) American Fisheries Society Symposium 20. Bethesda, Maryland.
- Kleinenberg, Sergei Evgenyevich** (1909–1968) Russian biologist who studied mammals in the field and laboratory; published extensively on the dolphins and porpoises of the Black Sea and, with three colleagues, produced a monograph on the beluga that has been the basis of all subsequent studies of the species. With his student G. A. Klevezal', he contributed greatly to development of the methodology of determining age in mammals through the examinations of layers in hard tissues.

- Lacépède** (Bernard Germain Etienne de Laville-sur-Ilon, Comte de Lacépède) (1756–1826) French zoologist who was one of the first modern zoologists to critically review the cetaceans. Colored plates from his book were extensively copied in other authors' works of the nineteenth century. He listed 34 species in the first edition (more in later editions), many more than any previous worker. Working with the collections in the Museum National d'Histoire Naturelle, Paris, beginning in 1784, he was highly honored in his time and worked successfully under the monarchy, the republic, the empire, and the new monarchy.

- Linnaeus, Carolus** (1707–1778) Swedish physician and avid naturalist considered the father of modern taxonomy; he worked extensively in the field with birds and plants. Linnaeus named and classified all the then known species of plants and animals in the first edition of his *Systema Naturae* in 1735, using his binomial system of a species name consisting of genus and trivial name. The official starting point of zoological nomenclature is 1758 (International Commission on Zoological Nomenclature – 1985), the year of publication of the 10th edition of his work. In that edition, he gave us 13 species of marine mammals that are still recognized.

- Linnaeus, C. (1758). "Systema Naturae." Laurentii Salvii, Stockholm.
- Mackintosh, Neil A.** (1900–1974) British biological oceanographer and authority on Antarctic whales; his contributions were massive. He was one of the prime organizers of the Discovery investigations that have contributed much to the knowledge of marine mammals and ecology of the Southern Ocean. He authored landmark monographs on whales, plankton, and ice, edited and shepherded the Discovery Reports, launched the international whale-marking scheme, was instrumental in the founding of the British Antarctic Survey, and was a leading player in (and first chairman of the Scientific Committee of) the IWC.
- Mackintosh, N. A., and Wheeler, J. F. G. (1929). Southern blue and fin whales. *Discovery Rep.* **1**, 257–540, pl. 25–44.

- Nishiwaki, Masaharu** (1915–1984) A "force of nature" for the study and conservation of marine mammals in Asia. After serving as a

- fighter pilot in World War II, he spent several seasons with the Japanese whaling factory-ship fleet in the Antarctic; this set the direction of his career. He made basic contributions to knowledge of systematics, life history, and reproduction of whales, dolphins, and seals and effectively promoted conservation of cetaceans and sirenians in Japan, China, Bangladesh, India, Pakistan, Nepal, Indonesia, Russia, and several nations in West Africa. He campaigned against overexploitation of whales and dolphins in Japan; his was a lone voice at the time.

- Norris, Kenneth S.** (1924–1998) The virtual founder of modern cetology in the United States; born in Los Angeles. He organized and chaired the first international conference on cetaceans in 1963 in Washington, D.C. Scientist, teacher, and natural historian, he cofounded the Society for Marine Mammalogy and served as its first president. With William McFarland, he described the vaquita, *Phocoena sinus*, from the Gulf of California in 1958. He demonstrated echolocation in dolphins, developed theories of hearing and sound production in dolphins and the sperm whale, and carried out extensive innovative research on dolphin behavior and ecology. Also an active "biopolitician," he was influential in development of the landmark US Marine Mammal Protection Act of 1972.
- Norris, K. S., Prescott, J. H., Asa-Dorian, P. V., and Perkins, P. (1961). An experimental demonstration of echolocation behavior in the porpoise, *Tursiops truncatus* (Montagu). *Biol. Bull.* **120**, 163–176.

- Omura, Hideo** (1906–1993) Considered the dean of Japanese cetology; published detailed monographs on the osteology, systematics, and distribution of baleen whales in Japanese waters and from around the world. He served for decades as Director of the industry-sponsored Whales Research Institute in Tokyo, which fostered and published the bulk of the Japanese research on cetaceans from after World War II until the late 1980s.

- Omura, H. (1984). History of the gray whale in Japan. In "The Gray Whale." (M. L. Jones and S. L. Swartz, eds.), pp. 59–77. Academic Press, San Diego.
- Poulter, Thomas C.** (1897–1978) US bioacoustician who worked extensively in the Arctic and Antarctic. He long advocated the idea that pinnipeds, like odontocete cetaceans, use echolocation; this was eventually discounted (see Schusterman, 1967). He is most remembered for organizing a series of conferences on biological sonar and diving mammals in the 1960s and 1970s at Stanford Research Institute; these were the forerunners of the current Biennial Conferences on the Biology of Marine Mammals.

- St. Aubin, David J.** (1952–2002) Canadian pathologist and endocrinologist who explored the role of health in the ecology of cetaceans and seals, what goes wrong and causes epidemics, strandings, and population decline. In his too-short career, he worked in the field from the Arctic to the tropics, probing the effects of contaminants, microbes, and stress.
- St. Aubin, D. J. (1979). Strandings: A rare look into the biology of the Atlantic white-sided dolphin, *Lagenorhynchus acutus*. In "The biology of marine mammals: Insights through strandings." (J. R. Geraci and D. J. St. Aubin, eds.), pp. 190–206. *Marine Mammal Commission contract report MMC-77/13*, 343pp.

- Scammon, Charles M.** (1825–1911) American whaling captain and naturalist who published only one book and one technical paper but greatly influenced cetology and the history of whaling. He discovered the breeding grounds of the gray whale in Laguna Ojo de Liebre (also called Scammon's Lagoon) in Baja California in 1855, which led to the near-extinction of the species in the eastern Pacific. His book (rare and valuable in the original edition) is a detailed chronicle of American whaling and description of the marine mammals of the west coast of North America.
- Scammon, C. M. (1869). On the cetaceans of the western coast of North America. *Proc. Acad. Nat. Sci. Philadelphia* **1869**, 13–63.

- Schevill, William E.** (1906–1994) Pioneering bioacoustician who was born in Brooklyn and spent most of his career at Harvard. He made the first recordings of underwater cetacean sounds in the wild and recorded and described sounds of many species. He published the first phonograph record of cetacean sounds. With wife and research partner Barbara Lawrence he described the anatomy of the delphinid nasal passages functional in sound production.

- Scholander, Per F. ("Pete")** (1905–1980) Norwegian-born physiologist who made many basic discoveries and advances in the respiratory physiology and ecology of diving mammals, including observation of the slowing of heart rate (the "diving response") in submerged seals and description of countercurrent heat-exchange structures in the dorsal fin and flukes of cetaceans. He pioneered direct physiological monitoring and experimentation with captive live marine mammals to explore their respiratory and cardiovascular adaptations.

- Scoresby, William** (1789–1857) Born in Yorkshire, England; accompanied his father on a whaling expedition when he was 10 years old, an event that shaped his life; he published his first paper on whales at the age of 19. His most important work "An Account of the Arctic Regions and Description of the Northern Whale Fishery" is the best contemporary account of the Arctic and whaling as it existed in the early nineteenth century. Several equally important books followed.
- Scoresby, W. (1808). Account of the *Balaena mysticetus* or great northern or Greenland whale. *Edinb. Mem. Wern. Soc.* **1**, 578–586.

- Sergeant, David E.** (1927–2008) Born in Hangzhou, China of medical missionary parents and obtained his Ph.D. at Cambridge in 1951. Dedicated natural historian of pinnipeds and cetaceans who produced classical studies of harp seals, belugas, pilot whales and other marine mammals during a long career with the Newfoundland and Canadian Governments. A pioneer in age determination of toothed whales and a creative thinker about population regulation. Unsung hero for efforts to collect, interpret and report data on harp seals every year in the face of abuse from all quarters, including the Canadian Government.

- Slijper, Everhard Johannes** (1907–1968) Like many cetologists of the first half of the twentieth century, E. J. Slijper, the Dutch functional anatomist and student of whales and whaling had his first experience with whale biology on a whaling expedition to the Antarctic. He authored "Walwissen" (1958), which became the famous book "Whales" in English. He analyzed reproduction, locomotion, and other functions in cetaceans and other mammals with a comparative anatomical approach that became standard in such studies.

- Steller, Georg W.** (1709–1746) German-born botanist who in his relatively short life spent years in the wilds of the Russian Far East with the Great Siberian Expedition and collected specimens and detailed accounts of many new animals, including the Steller's sea lion and the extinct Steller's sea cow of Bering Island.
- Steller, G. W. (1751). "De Bestiis Marinis." St. Petersburg Acad. Sci. (posthumous; published in translation as *Von Sonderbaren Meerthieren*, Kummel, Halle, Germany, 1753).
- Tomilin, Avenir Grigoryevich** (1912–2000) Grand old man of Russian cetology who began his 66-year career with a season with the whaling expedition "Aleut" in the Kamchatka, Bering, and Chukchi Seas in 1934. The most famous of his hundreds of technical and semipopular contributions is the massive volume on Cetacea in the series "Mammals of the U.S.S.R. and Adjacent Countries" (1957), which has been translated into English. Tomilin followed a lifelong commitment to popular scientific education, and his books were read by millions.

- True, Frederick W.** (1858–1914) The dominant figure in American cetology at the turn of the century; built the marine mammal collection of the US National Museum into the second largest in the world, after that of the British Museum. Highly prolific, he documented the American dolphin fisheries in New Jersey and North Carolina and produced scores of reports on the systematics of cetaceans, pinnipeds, and other mammals, describing many new species and including the important monographic "Review of the family Delphinidae," which largely delineated the array of dolphin species recognized today, and "Whalebone whales of the North Atlantic."
- True, F. W. (1889). Contributions to the natural history of the cetaceans, a review of the family Delphinidae. *Bull. U.S. Nat. Mus.* **36**, 1–191, pl. 1–47.

- van Utrecht, Willem Lodewijk** (1926–1994) Dutch zoologist who was an important early worker in the study of age and growth structures in both toothed cetaceans and baleen whales, working with teeth in the former and both ear plugs and baleen plates in the latter. He turned to the study of aging of fishes in his later years. Much of his research was in collaboration with his wife Clara N. van Utrecht-Cock.

- Watkins, William A.** (1926–2004) Influential and productive researcher at Woods Hole Oceanographic Institution who worked with William Schevill to produce some of the first underwater recordings of marine mammals. A deep background in physics, electronics, and acoustics made him a rigorous mentor to marine mammal bioacousticians and behaviorists. In later years he pioneered telemetry and satellite tracking of large whales.

- Yamada, Munesato** (1921–1994) Noted Japanese anatomist and naturalist, described the cetacean ear in detail. He also produced one of the first analyses of cetacean osteology that took into account individual variation, based on specimens from a mass stranding of false killer whales in Scotland. He rediscovered and described the external appearance of the pygmy killer whale, previously known only from two skulls described by Gray in 1871, and founded the Sea of Japan Cetology Research Group.

GLOSSARY

The following section provides definitions for a list of terms that appear in the text of this Encyclopedia. For the most part these are specialized technical terms used in the field of marine mammalogy that are likely to be unfamiliar to a lay reader. Also included are terms that, though likely to be known in their common sense, have a distinctive or highly specific use in marine mammalogy.

A

- α -male** The dominant male which appears to monopolize matings with the females.
- abduction** The movement of a part of the body (limb) away from the midline of the body (opposite is adduction).
- abuse** In the context of human interaction with marine mammals, a term for mistreatment involving violence that may result in injuries or death.
- accessory denticles** Cusps on archaeocete teeth that are not clearly homologous with primitive mammalian tooth cusps.
- accidental reinforcement** Another term for ADVENTITIOUS REINFORCEMENT.
- acetabulum** A depression in the pelvis in which the head of the femur is secured.
- acoustic harassment device (AHD)** A sound-generating device that, because of some combination of intensity, frequency, or other sound characteristic(s), is aversive to marine mammals and keeps or drives them away from an area or structure.
- adduction** The movement of a part of the body (limb) toward the midline of the body (opposite is abduction).
- adenohypophysis** A glandular structure, also known as the anterior pituitary, located at the base of the hypothalamus in the brain and producing a variety of hormones primarily responsible for stimulating the function of other endocrine glands.
- adenosine triphosphate (ATP)** A high-energy compound that, when split by enzymic activity, releases energy in the reaction.
- adipocytes** The cells of adipose tissue which store fat.
- advanced** See DERIVED.
- adventitious reinforcement** Reinforcement that happens to coincide with a particular response even though that particular response was not responsible for delivery of the reinforcement. In effect, the “wrong” behavior is modified. Also, ACCIDENTAL REINFORCEMENT.
- aerial behavior** Any behavior that takes the animal partly or completely out of the water, for example lobtails, breaches, spy-hops, head, side or back slaps, leaps, flips, and spins.
- aerobic** Pertaining to activity or metabolism in which oxygen is the final electron acceptor in the breakdown of glucose. This process produces 39 ATPs from 1 mole of glucose.
- aerobic dive limit** The maximum length of a dive accomplished using mainly aerobic metabolic pathways, and with no net production of anaerobic metabolites.
- AFLPs** Amplified Fragment Length Polymorphisms. DNA sequences amplified by PCR using generic PCR primers. Mutations in the priming site lead to loss of priming and no PCR amplification, resulting in a bi-allelic dominant genotype (amplification or no amplification).
- aggregation** A term for a group of individuals that come together because of a common resource, such as a predator-free habitat, rather than by social attraction.
- aggressive behavior or aggression** A set of social interactions ranging from threats to open fights, reflecting in a conflict of interest over limited resources and having the potential to cause injuries and sometimes death to participants. Generally refers to conflict involving members of the same species but may refer to any interaction of this kind.
- agonistic behavior** See AGGRESSION.
- agviq** Northern Alaskan Inuit term for a bowhead whale.
- air gun** In this context, a device that releases a burst of high-pressure air into the water. Groups (“arrays”) of air guns are used by the marine seismic industry to create low-frequency, high-level sound pulses that can characterize rock formations below the seafloor.
- aiviq** Northern Alaskan Inuit term for a walrus.
- aldosterone** Steroid hormone released by the adrenal gland that increases Na⁺ retention in the distal convoluted tubule and the collecting duct of the kidney.
- algae** A general term for various small aquatic organisms, usually single celled, which can synthesize organic matter from carbon dioxide using the energy of sunlight and whose reproductive organs are contained in a single cell. Two groups of algae, diatoms and dinoflagellates, form the basis for all other life in the sea.
- allantois** Fetal membrane developing from the hindgut or yolk sac that often contributes to the formation of the umbilical cord and placenta in mammals.
- Allee effect** A form of density dependence in which the population growth rate slows at smaller population sizes, due to factors such as the difficulty of finding suitable mates. (First described by W. C. Allee, 1931).
- allele** A unique and discernable (haploid) variant of a locus.
- allelic drop-out** The “loss” of an allele during a PCR amplification resulting in a false homozygote genotype.
- allomaternal care** Care provided to offspring by individuals other than the mother.
- alloparenting** Parental behavior by an animal (male or female) shown toward an offspring that is not its own.
- allopatric** Describing taxa, species, or populations whose ranges are physically separated.
- allopatric speciation** Speciation when reproductive isolation is caused by geographical isolation.
- allopatry** The fact of having separate, nonadjacent geographic ranges.

- allozygous** Describing alleles that are identical by state but not descent.
- allozymes** Variant forms of an enzyme, differing in amino acid sequence.
- alternate stable states** The same species assemblage forming different biological communities in a common physical setting.
- alternating carpus and tarsus** An arrangement of the carpal and tarsal bones in an alternate way, in the manner of bricks in a wall. This is the primitive condition for mammals as seen from various Mesozoic mammalian groups. *Cf.* SERIAL CARPUS AND TARSUS.
- altricial** Being born in a helpless state and depending heavily on adult care. In contrast, precocial young are born in an advanced state of maturation and require relatively little adult care.
- ambergris** A grayish waxy substance formed in the intestines of sperm whales; once widely used in perfumes.
- amniote** An air-breathing vertebrate with cleidoic eggs having amniotic membranes, which can be laid outside water; that is, the nonamphibian tetrapods comprising reptiles, birds, and mammals.
- amphibious** Able to move, feed, and so on, both on land and in water.
- amphipod** A crustacean of the order Amphipoda, including those on the ocean bottom, fed on by gray whales.
- anadromous** A fish that swims up a river from the sea to spawn.
- anaerobic** Relating to activity or metabolism in which the breakdown of glucose occurs in the absence of oxygen.
- anaerobic dive** A dive during which enough of the required metabolic energy comes from anaerobic pathways to result in net production of anaerobic end products.
- anaerobic metabolism** Chemical processes that temporarily sustain life in the absence of oxygen.
- anal canal** The terminal specialized portion of the gastrointestinal system.
- ancestral species** The species from which a present species has evolved.
- anestrus** The period of quiescence between two periods of sexual receptivity in cyclically breeding mammals.
- anlage** (*plural, anlagen*) Undifferentiated embryonic cells or tissue from which an organ or part develops; primordium.
- annual pregnancy rate** The proportion of sexually mature females that are pregnant during any given year, adjusted for the length of the gestation period.
- antecedent** In operant conditioning, a stimulus (signal or cue) that precedes a behavior emitted by the animal.
- anterior** Toward the front or head of the body.
- anterior pituitary** Another term for ADENOHYPOPHYSIS.
- anthropogenic** Created, directly or indirectly, by human activity.
- antidiuretic hormone** Another term for VASOPRESSIN.
- antipolytic** Inhibiting the breakdown of lipids.
- antitropical** Found in both hemispheres but not in equatorial regions.
- apnea** A respiratory pause; elapsed time between inspiration and expiration.
- apneustic breathing** A method of breathing in which the animal rapidly exhales and inhales and then holds its breath for an interval before repeating. This pattern facilitates rapid air exchange while swimming rapidly.
- aponeurosis** A broad tendon, connecting muscle to muscle or muscle to bone.
- appendicular skeleton** Bony elements of the limbs.
- Appendix I** As defined under CITES, this listing includes species that are threatened with extinction.
- Appendix II** Species listed by CITES as not necessarily threatened with extinction at present, but that may be if trade is not strictly controlled.
- aquatic** Having to do with water; living in or situated in water, which can be either fresh water or the sea.
- archaeocete** A cetacean that lacks the synapomorphies of either odontocetes or mysticetes. Archeocetes are restricted to the Eocene.
- Archaeoceti (archaeocetes)** The suborder of whales that includes the first Cetacea to enter the sea and all their descendants that do not have cranial telescoping.
- Arctoidea** A phylogenetic grouping that includes the Ursidae (the bear family), Pinnipedia (seals, sea lions, and walruses), Procyonidae (the raccoon family), and Mustelidae (weasels, badgers, otters, and skunks) and that is the sister group to the Cynoidea (the dog family).
- ARGOS** A joint US–French agency that operates a polar-orbiting satellite system that is used to collect data from and determine locations of transmitters attached to free-ranging wildlife.
- arterio-venous anastomoses (AVAs)** Vascular shunts between the arterioles and venules in blubber near the body surface.
- artificial insemination** The introduction of semen into the vagina, cervix, or uterus by artificial means in an attempt to cause conception.
- Artiodactyla** Even-toed hoofed mammals; the mammalian order that includes hippopotamuses, pigs, peccaries, camels, chevrotains, cattle, antelopes, deer, and giraffes. Among living mammals, the closest relatives of whales.
- asphyxia** A combination of decreased oxygen (hypoxia), increased carbon dioxide (hypercapnia), and the accumulation of acidic metabolic by-products (acidosis).
- assemblage** A predictable and particular collection of species within a biogeographic unit.
- assortative mating** Nonrandom mating in which members of a population pair up with individuals who are either more (positive) or less (negative) like themselves than the average for one or more traits.
- atavistic** Referring to the reappearance of a characteristic or feature in an individual belonging to a lineage whose members have secondarily lost that characteristic.
- audiogram** A hearing sensitivity curve drawn as a function of frequency.
- auditory bulla** The ear bone in odontocetes that houses the middle ear structure.
- auditory meatus** An opening to the ear.
- autosomal chromosomes** All chromosomes in the nucleus except the sex chromosomes.
- autozygous** Alleles identical by state and descent.
- axial skeleton** The bony elements of the body, excluding the limbs.

B

- bachelor school** A term for an apparently loose aggregation of mature or maturing male sperm whales, usually consisting of animals of similar ages.
- backdown procedure** A procedure used to release dolphins from the purse seine by pulling on the net after it has been pursed.
- baleen** Plates of dense, hair-like material (keratin) that hang side by side in rows from the roof of the mouth of whales in the order Mysticeti (the baleen whales); forming the “baleen apparatus” for

- filter feeding on surface plankton. Formerly known as “whale-bone” but bearing no actual resemblance to true bone.
- barnacles** A collective name for various marine crustaceans of the subclass Cirripedia; the adults form a hard outer shell and attach to underwater surfaces such as rocks and ships, as well as to certain whales.
- barrage** In this context, a low gated dam used to divert water for irrigation, flood control, and/or navigation purposes. Normally the gates remain closed during the low-water season and are opened during the high-water season with differing levels of regulation in between.
- basal insectivores** Plesiomorphic representatives of Insectivora (hedgehogs, shrews, moles, etc.). They can be used as a theoretical basis for the calculation of encephalization and size indices and for the derivation of more progressive insectivores and other eutherian mammals.
- basal metabolic rate** Metabolic rate for a adult animal resting within its thermoneutral zone without food in its gut.
- basicranial anatomy** The base of the skull, particularly the size and shape of bones contributing to the auditory bulla; this has proven to be very important for interpreting phylogenetic relationships within Carnivora.
- Bayesian** Referring to a method of drawing inference about unknown parameters in which parameters are assigned a prior distribution independent of new data and a posterior distribution given the new data is calculated. (From Thomas Bayes, 1702–1761, English mathematician.)
- beak** In cetaceans, a term for the elongated anterior portion of the skull that includes both the upper jaw and the lower jaw.
- beaked whales** Members of the family Ziphiidae that includes five current genera: *Berardius*, *Hyperoodon*, *Mesoplodon*, *Tasmacetus*, and *Ziphius*.
- behavior** An observable and measurable event performed by an organism. Can also include nonobservable phenomena (such as emotion, cognition, recall) that can be measurable through other assessment strategies.
- behavioral adaptation** An animal’s ability to learn to discern dangerous from nondangerous stimuli, and to react accordingly upon subsequent encounters.
- behavioral ecology** The influence of the environment on behavior.
- behavior medicine** Training programs and behavioral procedures intended to specifically condition behaviors that treat or prevent health disorders.
- bellyflop** A term for a breach in which the animal lands ventrally, on its stomach.
- benthic** Living in or on the ocean floor.
- bicipital groove** A groove on the humerus through which a tendon of the biceps muscle runs.
- binocular vision** The act of seeing an object with two eyes simultaneously, as in humans. Necessary (but not sufficient) for stereoscopic vision.
- binomial name** The scientific Latin name of a species, consisting of two parts: the generic name and the trivial name. Note that the trivial name is not the “species names”; two species can have the same trivial name (e.g., the cetaceans *Stenella attenuata* and *Feresa attenuata*), but each has a unique, two-part species name.
- biodiversity** The diversity of species; a term variously defined but generally construed to mean the relative abundance of different species (and their population size) within a given area, or on earth as a whole.
- bioindicator** A species linked to a particular habitat or biological community.
- bioluminescence** Light emitted by certain marine organisms as the result of a chemical reaction; this may be used to avoid or confuse predators, to attract prey, or to attract mates.
- biomarker** A biological response to a chemical that gives a measure of exposure and sometimes a toxic effect.
- biomass** A measure of the amount of plant or animal matter in a given context or system, expressed in terms of its aggregate weight.
- bipolar** Living or found in both polar regions.
- blow** A term for a cloud of vapor and sea water mixed with air that is exhaled by cetaceans.
- blowhole** The external opening of a whale’s ventilatory system. Two blowholes occur in baleen whales and one in toothed whales.
- blue whale unit (BWU)** A measure of baleen whale harvest that reflects oil production. One BWU is equivalent to a blue whale, 2 fin whales, 2.5 humpback whales, or 6 sei whales.
- blubber** A specialized layer of fat that functions as an insulator, found between the skin and underlying muscle of most marine mammals.
- bow-riding** The action or behavior pattern of riding on the pressure wave in front of the bow of a ship.
- bradycardia** A condition of decreased heart rate.
- brainstem-evoked potential** Electrical nervous discharges generated by an external stimulus in a sensory system.
- branchial arches** Embryonic precursors of mammalian jaw, ear, face, and throat structures that are derived from elements homologous to the gill arches of fish.
- breaching** A behavior in which a whale leaps out of the water.
- breeding sites** Traditional land areas (mostly beaches) where adult females give birth and adult males defend territory. In old sealer’s jargon, breeding sites were called “rookeries” after breeding aggregations of rooks.
- bridging stimulus** A conditioned stimulus that signals the imminent delivery of reinforcement.
- brine channels** Small pockets of brine in seawater ice that have a lower freezing point than the rest of the ice and often remain liquid.
- bristles** The fine fringe on the inner side of baleen plates that mats to form a sieve for food.
- bristle worm** A marine worm with short legs.
- bunolophodont** Referring to a molar having rounded (bunodont) cusps that are joined to form crests (lophs).
- buoyancy** Upward force exerted on a swimmers body when it is immersed or floating in water.
- burden of proof** The duty of proving a disputed assertion. In ecology, traditionally the burden of proof has been placed on scientists to show that harm to resources will result from some human action. The precautionary principle reverses this standard to require proof that a human action will not harm the resource.
- bycatch** Animals that are caught accidentally in fishing operations; the capture and mortality of all organisms that are not the target species of a fishery.

C

- calcareous** Composed of calcium carbonate, a chemical compound similar to chalk.
- calf** A young animal dependent on its mother.
- callosity** A patch of thickened, keratinized tissue on the head of a right whale, inhabited by large numbers of whale lice.

- calving interval** Mean period of time between two successive parturitions for the females of a given population.
- calyptosis larvae** Developmental series of euphausiid larval stages following the nauplius larvae during which stalked eyes and the abdomen develop.
- cannibalism** The consumption by an animal of members of its own species.
- carcinoma** A cancer arising in an epithelial tissue.
- cardiac** Relating to or describing the portion of the stomach that lies next to the esophageal opening and contains the cardiac glands.
- Carnivora** An order of living and extinct mammals that includes such species as dogs, cats, bears, and seals.
- carnivoran** A term applied to all members of the order Carnivora, distinguishing them from other mammals that may be ecological carnivores.
- carnivore** An organism that feeds on five prey, in the case of marine mammals including fish and cephalopods as well as mammals, birds, and reptiles.
- carnivorous** Meat-eating; describes the diet of members of the order Carnivora but many other mammals as well.
- carrying capacity** The maximum population that can be sustained in a given ecosystem without altering the ecosystem in ways that will ultimately reduce the sustainable population.
- catecholamines** A class of biologically active compounds, including epinephrine (adrenalin) and norepinephrine (nor-adrenalin), produced by cells of the adrenal medulla and other neurological structures.
- caudal** Having to do with or near the tail or fluke; behind.
- caudal fin** The fin located on the extremity of the tail of fishes, dolphins, and so on.
- caudal vertebrae** Vertebrae caudal to the sacral vertebrae in most marine mammals; in cetaceans and sirenians, the vertebrae associated with chevron bones.
- caecum or caecum** A large blind pouch forming the beginning of the large intestine.
- celomic cavity** The main body cavity.
- cementum** A calcified tissue that fastens the roots of teeth to the teeth sockets.
- centrum** The center part of the vertebra.
- cephalopod** A member of the group of mollusks including squids, cuttlefish, and octopuses.
- cervical** Relating to or near the neck region.
- cervical vertebrae** The vertebrae of the neck.
- cestode** Any flatworm of the class Cestoda, including tapeworms.
- Cetacea** An order of living and extinct mammals that includes such species as whales, dolphins, and porpoises.
- cetacean 1.** Any member of the order Cetacea of aquatic, mostly marine mammals that includes whales, dolphins, porpoises, and related forms; among other attributes they have a long tail that ends in two transverse flukes. **2.** Belonging to or describing this order.
- chevron bone** Any of a number of small bones positioned on the ventral aspect of the caudal intervertebral discs. These bones are common in mammalian tails, but they are particularly large in cetaceans and sirenians. In cetaceans, chevron bones are V-shaped and embrace the arteries that supply the tail.
- chin slap** A cetacean behavior pattern in which the animal raises its head out of the water and slaps it back down to make a splash.
- chitin** A tough insoluble polysaccharide, the main constituent of the arthropod exoskeleton.
- Chordata** One of the phyla (large groupings) of animals. They are characterized by the presence of a chorda (= notochord), a bar that supports the dorsal side of the animal.
- choroid** The thin, pigmented, vascular layer between the sclera and the retina of the eye. It consists mainly of blood vessels, which provide nourishment to the retina. The choroid also reduces internal reflection of light.
- chromatophore** Pigment cell or group of cells, which can be altered in shape or color in response to stimuli from the nervous system or hormones.
- cingulum** A rounded projection at the lower half of the tooth crown.
- circadian** Describing a biological rhythm with a period of approximately 24 hours.
- circumpolar** Distributed around the North or South Pole; in this context, referring to the distribution of species living in the cold water masses of the Southern Ocean.
- clade** An evolutionary line; a monophyletic group containing all the descendants of the most recent common ancestor of that group.
- cladistic** Based on a pattern of descent, with the most closely related (sister) taxa having a common immediate ancestor.
- cladistics** A method of classifying organisms in which species are delimited in time by branching points on an evolutionary tree (speciation events), with taxa being defined solely on the basis of common ancestry.
- clan** In this context, killer whale pods that share parts of their vocal repertoire (related dialects), reflecting a probable common matrilineal ancestry.
- classical conditioning** A type of learning in which a conditioned (learned) stimulus is presented in conjunction with an unconditioned stimulus, creating a conditioned (learned) response. During classical conditioning, learning occurs independent of the ongoing activities of the organism.
- clean-entry leap** A term for a breach in which the animal returns to the water smoothly, head first.
- click** In odontocete cetaceans, a sound of small duration (microseconds) and of narrow band produced at center frequencies between 110 and 150 kHz.
- cline** Gradual change over a geographic range.
- clupeoid fish** A member of an order of schooling marine fishes including sardines, anchovies, and herrings that are often observed in the diets of marine mammals.
- coalescence** Convergence of genetic lineages at some point in the past.
- coda** A patterned series of 3–20 clicks lasting about 0.5–2.5 seconds, used by sperm whales for communication.
- codon** The sequence of three nucleotides in DNA or messenger RNA that encodes for a particular amino acid.
- coefficient of variation** A description of the error associated with a statistical estimation (CV).
- coelom** The body cavity holding the organs.
- collagen matrix** A protein web that forms the structure of blubber found in marine mammals.
- collecting duct** The terminal segment of the mammalian nephron.
- colonization** Occupation or use of an area for breeding by a group of animals.
- commensalism** A relationship or association of organisms in which one individual benefits at no expense or damage to the other organism (the host).

- community** An association of interacting groups within a larger population, usually defined by the nature of their interactions or by the place in which they live.
- compensation** A form of density dependence in which the population growth rate slows at larger population sizes.
- competition** Interaction between individuals of the same species (intraspecific competition) or between different species (interspecific competition) such that the simultaneous presence of the two competitors is mutually disadvantageous. In terms of competition between humans and marine mammals, the competitive mechanism may be direct, as when a marine mammal eats a fish that could otherwise have been caught by a fisherman, or indirect, as when a marine mammal consumes a fish that is an important prey species of a commercially desirable fish species.
- competitive group** In this context, a group of three or more humpback whales characterized by a nuclear animal (usually female), a principal escort (male), and one or more other males, who may challenge the principal escort for his position. Competitive groups are assumed to be related to mate choice or mate defense; they are often large and sometimes involve considerable intrasexual aggression.
- competitive release** A phenomenon of competitive interaction that occurs when predation (natural or from increased fishing) causes a reduction in one of two groups that are in competition. The second group then increases in size as a result of this “competitive release.”
- computed tomography (CT)** A method of using X-rays to produce visual “slices” through an object.
- conditioned stimulus** A stimulus that attains the ability to “cue” behaviors as a result of learning.
- confidence interval** In statistics, a range of values, expressed as a minimum and a maximum, in which the real value of an estimate can be placed with a desired confidence.
- connecting chamber** A stomach compartment in cetaceans that lies between the main and pyloric chambers; lined with pyloric epithelium.
- conspecific** **1.** Of an organism, belonging to the same species as another or others. **2.** An individual of the same species as another or others.
- contest competition** A mechanism of sexual selection in which males compete by fighting with each other to achieve exclusive access to one or more mating females and in which females typically mate with the winners of such battles.
- context-specific learning** Learning that occurs in an environment in which background stimuli and discrete environmental cues are required for the animal to respond correctly.
- continental shelf** The part of a continent that is submerged in relatively shallow waters.
- continental slope** The slope of the sea floor between the continental shelf and the ocean floor, which is steep and 150–4000 m deep.
- convergence zone** An equatorial region where two north–south currents meet, forming an east–west current.
- convergent evolution** The evolution by unrelated organisms of structures that are similar in appearance or function.
- copepod** An organism of the order Copepoda; a small crustacean.
- Copepoda** An order of very small planktonic crustaceans present in a wide variety and great abundance in marine habitats, forming an important basis of ecosystems.
- corpus** Scar on the ovary resulting from ovulation.
- cortex** The outermost layer of tissue of an organ.
- cortisol** A steroid hormone of the adrenal cortex that is involved in the regulation of protein and carbohydrate metabolism.
- cosmopolitan** Found in most parts of the world and under varied ecological conditions.
- costal** Wing-like or lateral.
- cotyledon** A unit of the placenta grossly visible as a lobe circumscribed by a deep cleft.
- cranial** Having to do with the head or nose.
- cranial muscle** A muscle innervated by one of the cranial nerves.
- cranial nerve** A nerve that leaves the central nervous system near its anterior end and enters the periphery of the body by traversing one of the foramina of the skull. There are 12 named pairs of cranial nerves in all mammals.
- cranial vertex** The highest point of the skull immediately caudal to the bony external nares. The nasal, maxillary, pre-maxillary, and frontal bones contribute to this region.
- crepuscular** Having to do with or active at the margins of the day, that is, at dawn and/or dusk.
- Cretaceous** A period of geological time, from about 144 to 65 million years before the present, ending with a mass extinction.
- critically endangered** As defined by the IUCN, a taxon that faces an extremely high risk of extinction in the wild.
- critical period** A period of rapid acquisition that is usually associated with early stage development.
- crossbow whaling** A whaling method using a harpoon that is shot from a rubber-powered crossbow instead of a cannon, originating in Okinawa in 1975 to take advantage of a loophole in whaling regulations.
- cross-sectional studies** Research that captures a snapshot in time.
- crown group** A clade that includes the most recent common ancestor of all living species, plus all its descendants. Examples in Cetacea: Odontoceti and Mysticeti.
- crus** The middle region of the hind limb, consisting of the tibia and fibula and surrounding structures.
- cryopreservation** A process of maintaining the viability of cells, tissues, or organs by storing them at very low subzero temperatures.
- cull** **1.** To remove certain individuals from a population to control the overall population. **2.** An individual removed in this manner.
- culling** The process of reducing the population level of a given species. Distinguished from HARVEST, which refers to taking animals for commercial purposes.
- cursorial** Adapted for moving quickly over land; fast-running.
- cusp** A point on the grinding surface of a tooth.
- cutaneous** Referring to the skin surface of an animal.
- cyamid** A term referring to whale lice, all of which belong to the family Cyamidae.
- cyclonic** Describing rotation in the same direction as the earth (clockwise in the Northern Hemisphere and counterclockwise in the Southern Hemisphere).
- cytochrome *b*** A protein involved in respiration, coded for by an 1100-bp region of the mitochondrial genome.

D

- dactyli** The fingers or claws on appendages of invertebrates.
- deciduous dentition** The first generation of teeth of a mammal that erupt early in life and are later replaced by a second generation of permanent teeth. Unlike other mammals, modern cetaceans only have one tooth generation.

- deciduous tooth** A tooth that will be replaced, a replacement tooth, as opposed to a permanent tooth.
- deep scattering layer (DSL)** Organisms associated with the edge of the light, or photic, zone in deep water. The DSL tends to migrate vertically on a daily-nightly (diel) basis, being many hundreds of meters below the surface in daytime and closer to the surface at night.
- definitive host** The host in which a parasite achieves sexual maturity.
- delayed implantation 1.** A period of suspended development or growth. **2.** Specifically, in pinnipeds, the suspended development of an embryo between shortly after conception and subsequent attachment (implantation) to the uterine wall.
- delphinid** A dolphin or small whale species belonging to the family Delphinidae.
- demersal** A fishing term referring to marine resources captured near the bottom.
- demographic connectivity** Primarily a function of the level of female dispersal between natural groupings.
- demographics** Population characteristics such as growth rate and age structure.
- demography** The birth and death rates that determine a population's dynamics.
- density dependence** The dependence of population growth rate on population density or size.
- density-mediated indirect effects** Ecological effects that result from the rate of consumption of one species by another.
- dental formula** A numerical summary of the numbers of teeth of each class (incisor, canine, premolar, molar) in the dentition of a mammal. For example, a dog has three incisors, one canine, four premolars and two molars in the upper jaw, and three incisors, one canine, four premolars, and three molars in its lower jaw; thus its dental formula is 3.1.4.2/3.1.4.3.
- dentinal growth layer group** A layer of dentine, consisting of one translucent and one opaque zone when examined in the longitudinal, thin section of a tooth (GLG). The number of these growth layer groups is used to indicate the age of toothed whales.
- depleted** A term used in the US MMPA to indicate that a species or population is below its Optimum Sustainable Population level or that a species or population is listed as endangered or threatened under the US ESA.
- depredation** An act of facilitated predation, in which an animal raids or plunders something already caught or otherwise claimed by a fishery.
- derived** Referring to a character or structure of an organism that has been modified relative to its ancestor; an evolutionary "new" feature.
- Desmostylia** Extinct "seahorses," a group of herbivorous marine mammals characterized by cheek teeth consisting of clusters of enamel/dentine columns.
- diaphragm** A musculotendinous sheet between the pleural and peritoneal cavities of mammals; generally considered the most powerful muscle associated with breathing.
- diastole** The period of ventricular relaxation during the contraction-relaxation cycle of the heart.
- diatoms** Single-celled algae abundant in marine and freshwater environments.
- diel** Occurring on a 24-hour cycle.
- die-off** Mortality on a large scale. This may involve more than one species and can occur over days, weeks, or months.
- differential reinforcement** A procedure in which reinforcement occurs for any behavior other than the target behavior. The effect is to decrease the target behavior while increasing other (more appropriate) behaviors.
- dimethyl sulfoxide (DMSO)** A chemical compound that increases cell wall permeability.
- dimorphism 1.** A difference in form (body size, shape, or color) between two individuals or two groups of individuals. **2.** see SEXUAL DIMORPHISM.
- dinoflagellates** Single-celled algae, which, unlike diatoms, are capable of active movement.
- diphyodont** Developing two successive sets of teeth.
- diphodonty** Erupting two sets of teeth, deciduous (milkteeth) and adult.
- diploid** Two complements of chromosomes (in mammals one paternal and one maternal).
- direct fitness** The gene contribution of an individual to the ensuing population through its own offspring.
- dispersal** Outward spreading of organisms from their point of origin.
- display behavior** Behavior that is evolutionarily specialized for some form of communication, such as bird song. Special structures, colors, or coat patterns commonly evolve as parts of displays.
- distinct population segments or DPS** A term applied in the US ESA to describe a population of organisms that is discrete from the other populations of its taxon and represents a significant (in terms of numbers or range) or ecologically unique portion of a vertebrate species or subspecies. Also called a "distinct vertebrate population" in the Act.
- diurnal** Active during the daylight hours, while inactive or sleeping at night.
- diversity 1.** See GENETIC DIVERSITY. **2.** See BIODIVERSITY.
- diving response** A suite of physiological and biochemical reactions that are activated when a marine mammal dives, in order to conserve oxygen and extend dive time.
- dolphin** Any of the small cetaceans in the families Delphinidae (under about 3–4 m in length), Iniidae, Pontoporiidae, Lipotidae, and Platanistidae.
- dolphin-assisted therapy** The use of dolphins to assist in the treatment of such human disorders as depression, autism, cerebral palsy, or mental retardation.
- dominant allele** At a dominant locus only the dominant allele is detectable, making it impossible to discern between homo- and heterozygote genotypes.
- Doppler shift** A change in frequency due to the relative motion of a transmitter and observer.
- dorsal** Toward or relatively near the back and corresponding surface of the head, neck, and tail.
- dorsal cape** A region of solid color extending along the forward dorsal surface of a dolphin and sweeping up behind the dorsal fin.
- dorsal fin** The fin on the top midline of the body, as in dolphins.
- dorsoventral** From top to bottom.
- drag** The physical force resisting the movement of a body or limb through water or another fluid medium.
- drive fishery** A style of fishing for dolphins in which speedboats are used to corral a school of dolphins into a bay or shallow water. A net is drawn across the mouth of the bay or around the school, which prevents their escape. The fishermen then wade among the dolphins to kill them. Usually, the entire school is killed.
- Drosophila** A genus of fruit flies often used as experimental subjects in laboratory studies of chromosome structure and evolution, including *D. mehnogaster*, the familiar fly-in-a-bottle of high school and college genetics laboratories.

ductus arteriosus Artery connecting pulmonary arteries and aorta prenatally, shunting oxygen poor blood into the distal part of the arch of the aorta. After birth it becomes a ligament, the ligamentum arteriosum.

dugong A strictly marine, herbivorous mammal foraging at the bottom, primarily on seagrasses, and propelling itself with a forked caudal fluke.

duodenum The proximal part of the small intestine that is fixed to the dorsal abdominal wall and does not have mesenteries.

dura mater The outermost protective layer covering the brain and spinal cord in vertebrate animals.

E

easterly Blowing from the east.

eared seals Seals of the suborder Otariidae. They propel themselves with their fore flippers underwater and “waddle” with all four limbs on land. So termed because they have external pinnae, or ear flaps, visible to the casual observer.

earless seals Seals of the suborder Phocidae. These “true seals” all use blubber to thermoregulate, do not have external ear pinnae, use their hindlimbs to propel themselves in water, and have a hunching, caterpillar-like mode of locomotion on land.

echolocation The production of high-frequency sound waves and reception of echoes to locate objects and investigate the surrounding environment.

ecology of fear Ecological effects resulting from the behavioral avoidance of the risk of predation.

ecophenotypic Resulting from effects of the environment rather than the genome.

ecosystem A biological community and its environment, functioning as a unit in nature.

ecosystem model A mathematical representation of an ecological system that attempts to include all the major components of the system.

ecotype Ecological form or variation of a species.

ectoparasite A type of parasite that resides on the external surface of its host.

ectotympanic One of the bones that make up the skull in mammals. In primitive mammals, it is in the form of a horseshoe, and the tympanic membrane (eardrum) is suspended by it; this shape is retained by sirenians. In most mammals, the ectotympanic consists of additional flanges of bone that may form the wall of the middle ear (as in cetaceans and pinnipeds) and that may fuse with other skull bones.

effective population size The number of individuals in an ideal population with a level of genetic variation equal similar to that observed, that is, the number of individuals participating in breeding.

electrolytes Charged ions such as sodium, chloride, potassium, calcium, and magnesium that are important components of the internal fluid of an organism.

embryonic diapause Delayed implantation of the blastocyst (embryo) in the uterine wall and a pause in the process of development. Implantation reactivates the blastocyst and allows placental gestation to proceed.

emmetropia The proper eye refraction, as opposed to myopia (near-sight) and hyperopia (far-sight).

empirical Describing phenomena that are directly observable or measurable or that require a minimum of models and assumptions to be characterized.

encephalization An evolutionary increase in brain size relative to body size.

encephalization quotient The numeric comparison of brain size to body size.

endangered As defined under the US ESA, “any species which is in danger of extinction throughout all or a significant portion of its range”. The IUCN Red List defines the term to mean a taxon that is not critically endangered, but which nonetheless faces a high risk of extinction in the wild in the near future.

endemic A species or race which is restricted or peculiar to a locality or region.

endocranium The internal space within a cranium that houses the brain and surrounding tissues.

endocrine Referring to a ductless gland that secretes hormones.

endocrine gland Ductless gland that secretes hormones.

endotherm An animal that generates its own body heat for thermoregulation. Mammals and birds are endotherms. Also known as “warm-blooded” in common literature.

endothermic Producing its own body heat for temperature regulation; in popular use, warm-blooded.

endothermy The physiological condition wherein the body temperature of an animal is controlled by the generating of heat produced in its own body.

energy reserve The amount of energy usually stored as fat in the body of the animal that is excess to current requirements.

entoconid The cusp (elevated part of a tooth) on the posterolingual side of the posterior heel of a lower cheek tooth.

environmental carrying capacity See CARRYING CAPACITY.

Eocene 1. The geologic epoch spanning 55–34 million years ago during which most, if not all, of the lineages leading to modern carnivorans evolved. **2.** The sediments deposited in this time period.

epaxial muscles Muscles that form, in the embryo on the dorsal side of the vertebrae. In adult mammals these muscles form the back of the neck, the back, and the dorsal surface of the tail.

epimeletic behavior Behavior that supports caregiving, nurturing, and survival in young. This also includes the soliciting of caregiving behavior by other animals.

epipelagic Occurring at or near the surface in pelagic waters.

epithelial cells Cells that form firmly coherent layers of tissue on exposed surfaces.

epizoic Referring to nonparasitic animals that attach themselves to the outer surface of another, normally larger, animal.

epizootic 1. Referring to a temporarily prevalent and widespread disease in an animal population. **2.** A disease outbreak of this type.

escort A term for an adult male humpback whale that accompanies a female with calf on the breeding ground.

estrous Relating to the stage of the mammalian sexual cycle when females are receptive to copulation.

estrus A phase of the female reproductive cycle when she is receptive to breeding, commonly called “heat” in dogs and other domestic mammals.

estrus lordosis See LORDOSIS.

etiology 1. Generally, the assignment of a cause or reason for some condition or event. **2.** The field of science that studies the causes of diseases.

eumustelids Fossil and extant mustelids that belong to one of the five currently recognized subfamilies; the Mustelinae (weasels), Melinae (badgers), Melivorinae (honey badger), Lutrinae (otters), and Mephitinae (skunks).

euphausiid Any of an order (Euphausiacea) of small, usually luminescent shrimp-like crustaceans, forming an important part of the marine zooplankton; commonly known as krill.

Euphausiacea (euphausiids, krill) Order of small, usually luminescent shrimp-like crustaceans forming an important part of the marine zooplankton.

eustachian tube A slender tube that connects the tympanic cavity with the pharynx and serves to equalize air pressure on either side of the eardrum; the remnant of the embryonic first gill (or pharyngeal) pouch.

Eutheria An infraclass of therian mammals including all living forms except the monotremes and marsupials.

evoked potential An electric response of the brain to sensory stimulation; reflects an integrated simultaneous activity of many neurons evoked by the stimulus.

evolution Descent with modification, with ancestral species giving rise to one or more descendant species.

evolutionary stable strategy Patterns of reproduction or behavior that have equal fitness value.

exon Part of the DNA sequence at a coding locus that is translated into amino acids.

exoskeleton Hard supporting structure made of chitin, secreted by a crustacean and external to the epidermis.

exponential growth Population growth for which a constant percentage is added each year, which means that a greater number of animals are added to the population each year.

ex situ conservation The process of maintaining and breeding animals or plants outside their natural environment.

extant Still existing, not extinct.

extinct A taxon for which there is no reasonable doubt that the last individual has died. A taxon is considered to be *extinct in the wild* when the only surviving individuals exist in cultivation, in captivity, or in a naturalized population(s) well outside the past range.

extinction The irreversible disappearance of a population, species, or higher taxonomic group.

extirpation The extinction of an organism in part of its range; loss or removal of part of a population.

extradural Referring to a location superficial to the dura mater, usually within the vertebral canal.

F

facultative “As need dictates;” referring to those animals that can or do live in one particular environment, but are also reasonably well adapted to another environment. For example, facultative river dolphins live in both ocean and river systems. *Cf.* OBLIGATE.

falcate Recurved and usually pointed; sickle shaped.

fast ice Stable ice that is attached to land.

fasting A limited period of not eating or abstaining from food. Differs from starvation in that it is usually a periodic event for which the animal prepares by laying down extra body fat.

fathometer A sonar that is directed downward to measure water depth.

fatty acid The main constituent of animal storage lipid, composed usually of even-numbered straight chains of 14–24 carbon atoms that are either saturated (i.e., contain no double bonds) or unsaturated (containing from one to six double bonds).

fecundity 1. The potential level of female reproductive performance in a population; that is, the average maximum number of

offspring that females may bear during their fertile years. **2.** The actual average number of live births (more specifically, of female offspring) per year per female.

feedback loops A process through which substances or conditions occurring in the blood stimulate (positive) or inhibit (negative) the release of hormones responsible for affecting changes that modify the physiological state.

female choice A mechanism of sexual selection in which females prefer to mate with males exhibiting particular qualities, such as bright colors or vigorous displays, and reject other males.

female sexual maturity The stage of female sexual development in which ovulation occurs. Most cetaceans conceive at first ovulation, and past ovulations are identifiable on ovaries.

fertilization Union of the sperm and egg.

fetal folds Grooves in the skin that appear as stripes on only one lateral surface of the abdominal region and tail of a cetacean fetus, resulting from the curled fetal position.

fibrosis A thickening and scarring of connective tissue, as may result from disease or injury.

filter feeding Method used by some marine mammals to strain small particles of food from the water, using baleen or serrated teeth.

fineness ratio Ratio of body length to maximum diameter.

fisheries The enterprise(s) of catching or harvesting fish for human consumption.

fish ladder A human-made structure that allows fish to pass upstream with no more effort than they would use to swim against natural river rapids.

fissipeds The group of four-legged, mainly carnivorous mammals with toes separate from each other; includes bears, otters, dogs, cats, raccoons, and hyenas.

fitness The ability of an organism to survive and to transmit genetic information to future generations.

flaw zone An area of labile, fractured or broken ice; caused by various factors that result in impingement or interaction among different types of sea ice, for example, between drifting pack and shore-fast ice.

flensing The process of removing the blubber from a marine mammal carcass.

flipper The flattened forelimb of a marine mammal.

flipping The act of slamming the pectoral fin, or flipper, on the surface of the water.

flotsam The traditional term for bits of debris floating at the surface or in the water column, usually but not necessarily of human origin. Contrasted with **jetsam**, which is human debris that has been purposefully discarded.

flukes The horizontally spread tail of a whale (in contrast to the vertical tails of fish).

fluking The act of raising the tail, or flukes, above the surface of the water during the beginning of a dive.

food web The interconnection of species through their diets.

food web competition A mutually disadvantageous interaction that occurs due to indirect competition for a shared resource, such as when there is overlap of the trophic flows supporting marine mammals and fisheries.

foraging Searching for prey; the process of finding, catching, and eating food.

foramen ovale Foramen connecting left and right atrium of the heart prenatally, shunting oxygen-rich blood to the left side of the heart. It usually becoming closed over shortly after birth (then called fossa ovalis).

foregut The anterior portion of the digestive tract, which includes the stomach.

forestomach Cetacean stomach chamber lined with stratified squamous epithelium; lies between the esophagus and the main or fundic stomach.

fossil The prehistoric remains of once-living organisms, either extinct or living species.

free hormone Any hormone in the blood not bound to proteins and therefore more readily available to influence cellular functions.

freeze brand A cryothermic procedure for marking animals with numbers or symbols. Metal brands are cooled in liquid nitrogen or a slurry of dry ice and alcohol, and touched to the skin of an animal, resulting in depigmentation of the area.

fundic The portion of the stomach distal to the cardiac portion, containing the fundic glands.

G

gadids Fish species of the cod family (Gadidae).

gape The mouth in cetaceans, usually referring to the junction of upper and lower lips.

gastric Relating to or situated in the stomach.

gene The coded information inside cells, which tells the body how to make enzymes, proteins, and other molecules necessary for life.

gene/allele frequency The proportion of gene copies in a population of a particular type; for example, if 40% of the alleles in a population are type W (as opposed to w), the frequency of W in that population is 0.4.

gene flow The exchange of genetic material within and between populations.

genetic bottleneck A severe reduction in genetic diversity.

genetic diversity Variation in the chromosomes of a community of organisms, due to a large number of slightly dissimilar ancestors.

genetic drift Random changes in the gene frequencies of finite populations.

genetic fingerprinting A method of uniquely identifying an individual animal from a sample of tissue.

genital tubercle Swelling and protrusion of tissue in the genital region that appears before differentiation into male or female genitalia.

genotype For a diploid locus, the combined state of both alleles. For a haploid locus the state of the one allele.

geochronology The study of time in relationship to the history of the earth.

geologic range The geologic time span between the first and last appearance of fossil taxa.

gestation The period of time during which the embryo and later the fetus is carried by the mother in the pregnant state.

gilling The process of catching a fish by its gill covers, usually in a mesh of netting, so that the twine, under the gill covers, prevents the fish from moving backwards, while forward movement is prevented by the mesh of the net encircling the fish's head.

gill net A fishing net that is suspended in the water more or less vertically and ensnares fish by the gill covers as they try to swim through its meshes.

glucagon Protein hormone formed in the pancreas that when released to the blood increases the glucose content of the blood by increasing the breakdown of glycogen in the liver.

glucocorticoid Steroids such as cortisol and corticosterone produced by the adrenal cortex and affecting a broad range of metabolic and immunologic processes.

gluconeogenesis The synthesis of glucose from other carbon sources, occurring primarily in the liver.

glycogen The polysaccharide in which carbohydrate is most commonly stored in muscles and liver.

glycolysis The series of reactions that convert glucose to pyruvic acid.

grade A cluster of species that have a common pattern of organization but are not necessarily a clade.

granuloma The product of a type of inflammation, resulting in the formation of distinct nodules of inflammatory tissue.

gravid Pregnant with young (whether live young or eggs).

gross annual recruitment rate The product of the proportion of females in a population, the proportion of sexually mature females, and the annual pregnancy rate.

ground A term for an area of ocean where whalers find abundant sperm whales.

group selection Differences in the attributes of groups are related to differences in group survival, particularly when groups are competing.

growth layer group (GLG) A repeating or semirepeating pattern of adjacent groups of incremental growth layers within the dentine, cement, bone, or other persistent tissue, which is defined as a countable unit. Such a unit must involve at least one change in appearance.

growth layers Incremental layers deposited in structures that persist and reflect growth or physiological processes at the time of deposition.

groynes A transverse structure that deflects water flow to prevent erosion of an embankment.

gubernaculum A fibrous cord connecting the testis to the scrotum that usually plays a significant role to testicular descent.

gyrification The degree of folding of the cerebral cortex of the brain.

H

habituation A gradual waning of behavioral (or physiological) responsiveness over time, as an animal learns that a repeated or ongoing stimulus is lacking in significant consequences, *Cf.* SENSITIZATION.

hair cell A special kind of cell that has tiny hairs projecting from its surface into the intercellular space. Movement of the hairs is registered by neurons that contact the hair cell. Hair cells are found in the ear of mammals.

halogenated organic compounds Organic compounds, usually andriropogenic or produced by the breakdown of anthropogenic compounds, that contain chlorine or fluorine atoms. Many, including organochlorines such as DDT and the PCBs, break down slowly when released into the environment and are potentially pathogenic.

hand-harpoon whaling A historic Japanese whaling technique that used hand harpoons and lances.

haploid One complement of chromosomes.

haplotype Unique sequence of DNA.

harem A group of females whose breeding is controlled by a single male who seeks to prevent other males from breeding with them.

- harpoon** A fishing spear composed of a barbed head, a shaft, and a line that connects the shaft to a speared animal.
- harvest** The deliberate taking of wild animals, usually by hunting, netting, or trapping (not including live capture or removals for scientific purposes).
- haulout** The act of a seal leaving the ocean and crawling onto land or ice.
- heat increment of feeding** Increase in metabolism associated with the processing and digestion of food.
- hemoglobin** The iron-containing protein that binds to oxygen and is found in red blood cells.
- hemopoietic tissue** Tissue in which blood cells are formed (e.g., red blood cells are formed in the spleen of developing mammals and in the bone marrow of adults).
- hepatopancreas** Gland in many invertebrates that secretes digestive enzymes.
- hepatic** Relating to or occurring in the liver.
- herbivore** A feeder on plants.
- herbivorous** Plant-eating.
- hertz** A measure of frequency corresponding to one cycle per second.
- heterodont** Having teeth of different types.
- heterodont dentition** A type of dentition in which there are different tooth shapes in different parts of the mouth: incisors and canines in front and premolars and molars in back. *Cf.* HOMODONT DENTITION.
- heterodonty** Having teeth that differ in shape.
- heterospecific** Individual coming from a different species.
- heteroxenous** Describing a parasite life cycle involving more than one host.
- heterozygosity** The probability of selecting two different alleles at random from one or more target loci denotes the expected heterozygosity. In contrast the observed heterozygosity describes the proportion of heterozygous individuals.
- heterozygous** Having one or more pairs of dissimilar alleles (alternative forms of a gene).
- hilus** The point where the renal artery enters the kidney and the renal vein and ureter exit.
- Hippopotamidae** The mammalian family that includes extant hippopotamuses and their close extinct relatives.
- histogram** A graph showing statistical distribution of the probability of events, for example, how frequently cells of one or another size appear in the overall cell population.
- holotype** A single specimen laying at the base of the scientific name of a species or subspecies.
- home range** The total area covered or traversed by an individual animal during the course of normal activities.
- home range** The area covered by individuals during the course of their normal activities.
- homodont** Species having teeth of similar type.
- homodont dentition** A type of dentition in which all of the teeth have similar size and shape. *Cf.* HETERODONT DENTITION.
- homodonty** See HOMODONT.
- homologous** Pertaining to a relationship between corresponding parts in different organisms due to evolutionary development from the same structure, such as the wing of a bird and the flipper of a dolphin.
- homoiotherm** Having a constant body temperature, typically inferred as warm-blooded.
- homoplastic** Describing a character whose presence in various species is not due to a common origin.
- homoplasy** Similarity in character state due to other phenomena than inheritance.
- homozygosity** The probability that two alleles selected at random are identical at the target locus. In contrast the observed homozygosity describes the proportion of homozygous individuals.
- homozygous** Having one or more pairs of identical alleles (alternative forms of a gene).
- hormone** An organic compound produced by an endocrine gland that affects other tissues and organs within the body; for example, the hormone progesterone is secreted by the corpus luteum and stimulates the uterus for implantation.
- hormone-sensitive lipase** An enzyme inside adipose cells that mobilizes free fatty acids stored in triglycerides and makes them available to other cells.
- hydrofoil 1.** An asymmetrical blade whose shape produces lift forces due to differential fluid flow around its upper and lower surfaces. **2.** A wing-like limb flapped underwater to produce lift; for example, penguin "wings."
- hydrophone** An underwater microphone.
- hyoid apparatus** A set of bones and/or cartilages attached to the base of the skull that help move the tongue and larynx during feeding and swallowing.
- hyperglycemic** Describing a condition in which blood glucose concentration is greater than normal.
- hyperoxic** Describing a gas mixture having a higher concentration of oxygen than in normal air.
- hyperphagia** Intense feeding.
- hyperventilation** Increased total ventilation produced by tidal volume and ventilation rate above the resting rate.
- hypoconal crest** The crest extending to the cheek side from the hypocone on an upper cheek tooth or to the tongue side from the hypoconid on a lower cheek tooth.
- hypocone** The cusp on the postero-lingual side of an upper cheek tooth of a derived placental mammal having quadritubercular (four-cusped) teeth.
- hypoconid** The cusp on the postero-labial side of the posterior heel of a lower cheek tooth.
- hypoinsulemic** Describing a condition in which the level of insulin in the blood is lower than normal.
- hypometabolism** A metabolic rate that is less than resting or basal metabolism.
- hyponatremia** An abnormally low blood concentration of sodium.
- hypoxia** Reduced availability of oxygen.
- hypaxial muscles** Muscles that form, in the embryo, on the ventral side of the vertebrae. In adult mammals, these muscles are located in front of the neck, the front of the chest and abdomen, the limbs, and the ventral side of the tail.
- Hz** Short for HERTZ.

I

- ichthyophagous** Feeding on fish.
- igneous rock** Rocks derived from the cooling and solidification of a magma or lava.
- ileum** The distal part of the small intestine.
- immunodepressive** Negatively affecting any aspect of the immune response system.
- inbreeding** Reproduction with a mate more closely related to the individual than the average pair in the population are related to each other.

inbreeding depression Diminution of growth, fertility, or survival as a consequence of inbreeding.

indirect effects Ecological effects of one species on another involving one or more intermediate species.

indirect fitness The gene contribution of an individual to the population through the relatives that it successfully aided in rearing and that would not have existed without its help.

infanticide The killing of young by parents or other members of the same species.

infrasonic Describing sound that is lower in frequency than the minimum audible to humans. Some baleen whales produce infrasonic calls.

infrasound Sound below the human hearing threshold, or 20 Hz (cycles per second). These sounds approximate a very low frequency roar or vibration.

insectivorous Feeding mainly on insects, and often also on other small invertebrates such as scorpions, spiders, worms, and snails. Insectivores are members of the Insectivora, a group of small mammals such as shrews and hedgehogs.

in situ conservation The process of conserving animals or plants within their natural environment, in habitats within which evolutionary processes are maintained.

instar A juvenile stage of invertebrate development, which may be a configuration quite distinct from the adult.

insulin A protein hormone released by the pancreas that stimulates the uptake of glucose by peripheral tissues.

integument The organ system composed of skin, blubber, and pelage. Functions include protection, thermoregulation, buoyancy, and drag reduction or streamlining.

intermediate host A host in which a parasite, develops to some extent but not to sexual maturity. Where more than one intermediate host is involved in a life cycle, they are ordered in chronological sequence as first, second, and so on.

intermodal transfer The transfer of sensory information from one sensory modality to another, for example, from vision to somatic sense and back and from vision to echolocation and back.

interspecific Involving individuals of different species.

interspecific mating Mating occurring between two individuals of different species.

intraspecific Pertaining to a level below or within a species (e.g., subspecies, population, and deme).

intrinsic rate of increase The maximum rate of increase a species is capable of; thought to occur at a relatively small population size where a species has its greatest rates of reproduction and survival.

introgression The incorporation of genes of one species into the genetic constitution of another species, as by means of interspecific hybridization.

intron The part of the nucleotide sequence at a protein-coding locus that is transcribed into messenger RNA but not amino acids.

Inuit The native people of Arctic Chukotka, Alaska, Canada, and Greenland, popularly known as Eskimos.

Inupiaq (*plural, Inupiat*) An Inuit person.

invasive sampling Collection of tissue samples that require penetration of the epidermis.

involucrum The internal medial part of the tympanic bulla of cetaceans, which is made of extremely dense and heavy (pachyostotic) bone.

ischemia A blockage or reduction of blood flow that interrupts oxygen supply.

ischium The dorsal posterior part of the hip bone.

iteroparous Describing or referring to animals that reproduce more than once.

J

jejunum The middle portion of the small intestine. (From a Latin word for dry; this part of the intestine was often empty in cadavers because of postmortem peristalsis.)

jetsam See FLOTSAM.

junk A complex arrangement of whitish tissue beneath the spermaceti organ, saturated with spermaceti oil.

K

karyotype A display of the chromosomes.

kelp Algae belonging to the division Phaeophyta, which includes the large “macroalgae” commonly known as seaweeds.

ketone bodies Any of three compounds—acetoacetate, acetone, and β -hydroxybutyrate—that can be produced by the liver as a result of lipid oxidization.

ketosis Accumulation of ketone bodies in the blood, usually associated with prolonged fasting or excessive lipid oxidization.

keystone species A species whose presence in (or absence from) a given ecosystem has a significant influence on the structure and function of the system, disproportionate to its numerical abundance.

killer whale The largest species (*Orcinus orca*) of the family Delphinidae, an aggressive cetacean that preys upon other marine mammals.

kinematics The study of motion. Often used in reference to the movement of limbs relative to the body of active animals.

kin selection Individuals engage in activities that benefit their relatives and thus indirectly contribute genes to the population.

kleptogyny Female stealing by males from the territories of other males for the purpose of mating.

krill A general term describing shrimp-like crustaceans in the family Euphausiidae. Krill form an important food resource for filter-feeding marine mammals.

k-selection The reproductive strategy of a species that tends to grow slowly and have relatively few offspring but that has a longer life span and parental involvement in the rearing of young. Certain large mammals are cited as an example of k-selection. Contrasted with an r-selected species, which has more rapid growth and a large number of offspring, but a shorter life span and negligible parental involvement.

k-selected A species is said to be k-selected when it tends to grow and reproduce slowly but has high survival rates, compared to an r-selected species which has higher life history rates and lower survival.

L

lactation The production of milk by a female mammal for the feeding of young.

lactose A sugar found in some milks.

Lagrangian study The study of individual movement.

- laminar flow** A smooth and steady flow in which particles travel along a well-defined path.
- lance** A spear with a blade on both sides, thrust into a harpooned animal for killing.
- land fast ice** Polar ice that forms large sheets continuous with the shore. It is generally more persistent and stable than pack ice, which floats free of the land.
- landing sites** Traditional areas used by nonbreeding males for resting, playing, and other activities. In old sealer's jargon, landing sites were called "hauling-out grounds."
- lanugo** Woolly hair coat of some fetal or neonatal phocids. In some species (e.g., harbor seals) the coat is shed before birth. In other species (e.g., gray seals) the coat is retained for days or weeks after birth and is thought to provide anti-predator and thermoregulatory functions.
- laparoscopy** The examination of abdominal organs, including the reproductive tract, by means of an illuminated visual instrument (laparoscope).
- large-type whaling** A historic form of Japanese coastal whaling that took sperm and baleen whales other than minke whales using a vessel and harpoon cannon of large size.
- larynx** The group of cartilages and muscles in the neck that house the vocal cords and are used for sound production in most mammals. In odontocetes, the larynx is not the main sound-producing organ, and it projects far rostrally, reaching the posterior side of the palate.
- lateral** Away from, or relatively farther from, the middle of the body.
- lead** A long linear area of open water or thin, newly formed ice; this occurs along shorelines, at the seaward margin of shore-fast ice, or in the drifting pack; often persistent or recurring.
- lead line** A weighted line onto which netting material has been fixed in order to keep part of the netting relatively low in the water column, typically on or near the seabed.
- least concern** A category used by the IUCN to describe a taxon which has been evaluated, but which does not satisfy appropriate criteria to be classified as Vulnerable, Endangered, or Critically Endangered (World Conservation Monitoring Centre, 2000).
- lek** A traditional display site where males gather to defend small individual territories (that lack essential resources) and advertise for mates. (From a Swahili word for a mating ground.)
- lekking** The social system in which males gather on a communal display ground, and females choose mates by some criteria of "maleness."
- length-specific speed** Speed measured using the body length of the animal as a scale and calculated as the velocity of the animal divided by the body length.
- Leydig cells** Testosterone-producing cells between the seminiferous tubules of the testis.
- life history** The significant features of the life cycle of an organism, particularly the strategies influencing reproduction and survival.
- life span** Average probability of survival at birth for the individuals of a given population.
- lighting regime** The ratio of number of hours of light versus number of hours of dark in a 24-hour period (light:dark).
- limiting resource** A resource whose relative abundance is a determining factor in the size of a given population.
- lineage** Ancestor-descendant populations of organisms through time.
- lipoprotein lipase** A tissue-bound enzyme that hydrolyzes circulating triglycerides in the blood, enabling transport of free fatty acids into cells.
- lithification** The conversion of a newly deposited sediment into solid rock, involving processes of compaction, cementation, and crystallization.
- lithology** A description of a rock unit based on characteristics such as color, mineralogy, and grain size.
- lithostratigraphy** The study of rock strata with emphasis on the lithology, succession, and correlation of strata.
- lobster krill** Larval crustaceans forming dense, often red, shoals in temperate waters.
- lobtailing** A behavior in which a whale slams its flukes down on the water, usually repeatedly.
- locus** A specific location in the genome, for example, a gene or DNA sequence.
- longevity** The average life span of an individual.
- longitudinal studies** Long-term research that captures temporal variability.
- long line** A buoyed line onto which are attached numerous branch lines each terminating in a baited hook. Long lines may extend for tens of kilometers and are usually left to drift in the surface waters of the ocean to catch large pelagic fish.
- lordosis** A reproductive behavior of females in which they arch their back in a manner that raises their rear end upward to make mounting by the male easier.
- low-frequency active sonar (LFA)** A naval sonar system designed to detect and locate quiet submarines at long range. Operates at frequencies below 1 kHz (typically 100–500 Hz) and at nominal source levels up to at least 230 dB re 1 mPa.
- luciferase** An enzyme involved in the chemical reaction to create bioluminescence.
- luciferin** A substrate involved in the chemical reaction to create bioluminescence.
- lumbar** Describing or located in the region near to the portion of the vertebral column between the thorax and the sacrum.
- lunge** A term for a thrusting of the forward part of an animal through the water surface, showing less than about 40% of the body (often the result of feeding at the surface).
- lutrine** Referring to a member of the otter subfamily (the Lutrinae).

M

- magnetic declination** The angle between the earth's surface and magnetic lines of force for the earth.
- magnetite** A magnetic mineral that is composed of iron oxide.
- main stomach** The glandular portion of the cetacean stomach, lying between the esophagus or forestomach and the connecting chambers.
- maintenance metabolism** The energetic cost associated with the maintenance of all physiological processes necessary to sustain an animal.
- maktak** Northern Alaskan Inuit term for the skin and blubber of whales.
- male sexual maturity** The stage of male sexual development in which all seminiferous tubules at the testicular center produce spermatozoa. Sperm production starts before this and testicular growth continues after.
- management unit** A group of animals that is the target of a particular management measure.
- manaq or manaqtuun** Northern Alaskan Inuit term for a retrieval hook used during ice edge seal hunting.

- manatee** A wholly aquatic herbivorous mammal generalize foraging throughout the water column in fresh or salt water, and propelling itself with a broad caudal paddle.
- maritory** Underwater territories held by males.
- mark-recapture** A set of methods for estimating one or more of abundance, survival, and recruitment by recording repeated sightings or captures of animals, some of which are identifiable from marks previously placed on them. Increasingly, natural marks are used, identified from photographs or DNA fingerprinting.
- marsupial** Members of the Marsupialia, mammals found mainly in Australasia and South America, which give birth to very small young that then develop while attached to the mother's teats, often in a pouch, for example, the kangaroo, opossum, wombat.
- mass die-off** Mortality on a large scale that may result in many strandings.
- mass stranding** The simultaneous stranding of two or more animals other than a female and her offspring.
- mastoid process** A component of the petriotic bone (which makes the inner ear) that can be seen on the lateral face of the cranium.
- mate choice competition** A mechanism of sexual selection in which males compete among themselves by attempting to entice and attract females with visual, acoustic, or pheromonal displays; females typically mate with the male having the most exaggerated display.
- maternal** Inherited from the mother.
- maternal care** Any form of maternal behavior that appears likely to increase the fitness of her offspring.
- maternally inherited** Inheritance through maternal cell line such as the mitochondrial gene.
- mathematical model** A representation of a system or a synthesis of observations and ideas that is translated into the language of mathematics to facilitate understanding and analysis of the system or process.
- matriline** A descent system in which daughters reproduce in their mothers' social unit, leading to a group of maternally related females.
- matrilineal** Group members are descendants of a single female.
- matrilineal habitat fidelity** The continued return to habitats first learned from the mother during the months before weaning, which may persist for generations.
- maxilla or maxillary bone** One of the two major bones found in the upper jaw of mammals, the other being the premaxilla.
- maxillary crest** The anterior portion of the maxilla, which is enlarged in cetaceans due to telescoping of the cranial bones.
- maximum net productivity level** The population size that will result in the maximum growth rate (in number of individuals added to the population per year).
- maximum sustainable yield** The maximum human harvest from a population that can be sustained continuously and, for a non-selective harvest, that is equivalent to the maximum net productivity level.
- medial** Toward, or relatively closer to, the middle of the body.
- mediastinum** In mammals, the region between the lungs.
- melanin** The pigment responsible for dark coloration in the skin and eyes of many animals.
- melon** A lump of fatty tissue that forms the "forehead" of toothed whales and that is thought to function as a means of focusing sound for echolocation.
- Mendelian inheritance** Loci that are inherited from both parents.
- mendelian transmitted nuclear genes** When the parents pass on to their offsprings discrete genes that retain their identity through the generations.
- menopause** The termination of reproductive function in a female, as a result of aging.
- mesentery** The double layer of peritoneum that suspends the abdominal organs from the dorsal wall; it contains blood vessels and nerves that supply the organs.
- mesonephros** Embryonic kidney that functions only until the metanephros is formed and then regresses. Its duct (Wolffian) is retained in the male as the epididymis and ductus deferens.
- mesopelagic** Referring to the middle portion of the water column, generally from 200 to 1000 m.
- mesosalpinx** A special paired mesentery structure, forming part of the broad ligament, and supporting the oviducts.
- Mesozoic** An era of geological time, from about 285 to 65 million years before the present, comprising the Triassic, Jurassic, and Cretaceous periods.
- metabolic overhead** The amount of energy expended by a lactating female for her own maintenance, relative to the total energy expended during lactation.
- metabolic water** Water that is produced as a result of the oxidation of food or stored body tissue.
- metanephros** Precursor of the kidney that will function postnatally.
- metapopulation** An overall population consisting of two or more subpopulations more or less isolated from each other, treated as a single evolutionary or management entity.
- metatarsal** A bone in the middle portion of the hind foot.
- microallopatric** Sharing a geographic range but occurring in different habitats or portions of a habitat, so that there is no mixing on a small spatial scale.
- microsatellite** A subset of genomic locations (loci) that contain variable numbers of very short tandemly repeated DNAs, often highly variable.
- microsatellite loci** Loci that consists of tandem-repeated nucleotide sequences, each of less than six nucleotides.
- minisatellite** Tandem repeated nucleotide sequences with repeats larger than 20+ nucleotides.
- migration** The process of seasonal movement of individuals between different geographic locations.
- migration count** A sample count of migrating whales carried out from a coastal watch point from which population size is estimated.
- mimicry** Behavior resembling the behavior of others occurring in the same locale or within some relationship of time and space; an important component of early social development. Various forms of mimicry are exhibited by many animals for separate survival strategies.
- mineralocorticoids** Steroids such as aldosterone produced primarily in the zona glomerulosa of the adrenal cortex and regulating the metabolism of ions such as sodium and potassium.
- Minoan** Referring to the Bronze Age civilization centered on the Mediterranean island of Crete (c. 3000–1000 B.C.) prior to the Greek empire. (*Mino* was Crete's legendary king.)
- mitochondria** Small cytoplasmic organelles found in almost all living cells.
- mitochondrial DNA** A circular DNA molecule that is found within mitochondria in large numbers of copies. In mammals, mitochondrial DNA is inherited maternally, the gene sequence

and contents are much conserved, and the DNA is composed of about 14,000–17,000 nucleotide base pairs.

molar One of the rearmost teeth used mainly for crushing and chewing.

molt or **molting** The relatively abrupt shedding of an old outer covering (in mammals, the skin) to be replaced by a new layer recently formed underneath.

monstrous Having a single estrous cycle once each year.

monogamy A mating system in which one male and one female are together for at least one seasonal breeding cycle.

monomorphic All of the same type, that is identical (e.g., all samples have the one and same allele).

monophyletic Taxa derived from a single common ancestor.

monophyly Phylogenetic term that indicates that a group of related species includes an ancestral species and all its descendant.

monophyodont Developing only a single set of teeth, rather than deciduous and adult sets.

monophyodonty Erupting a single set of teeth, lacking deciduous (milk) teeth.

monotypic Being the sole type in its group (genus).

monoxenous Describing a parasite life cycle in which only a single host is used.

monsoon A constant, seasonal wind within the tropics.

morphological Having to do with the appearance or form of an individual or species.

morphology 1. The physical appearance or form of an individual or species. **2.** The study of such properties.

motorboating A behavior pattern of very rapid tail slapping (two to three slaps a second) in trains up to 15 seconds in length.

motor pattern A pattern of coordinated movements, positions, and postures of the body that is recognizable, repeated, and characteristic of particular classes of movements or functions.

mtDNA DNA of the closed, circular genome found in mitochondria.

multiparous Describing a female that has had more than one pregnancy, as contrasted with nulliparous (no pregnancy) and primiparous (first pregnancy).

multireniculate Describing a type of kidney that contains many reniculi.

multispecies model A mathematical representation that includes a minimum of two interacting species in the system.

multivariate analysis Statistical methods that can be used to simultaneously examine multiple variables and their interactions.

muscular hydrostat A three-dimensional array of muscles having constant volume, capable of highly controlled, precise, and varied movements, and not dependent on bony attachments for the support of antagonistic actions of the muscles. Examples include the tentacles of squid, trunks of elephants, and tongues and lips of mammals.

museau de singe In sperm whales, a valve-like clapper system at the end of the right nasal passage, thought to be the producer of the whale's clicks.

mustelids or mustelidae Members of the family Mustelidae of carnivorous mammals, which includes the otters, stoats, minks, and fishers.

musteloids All members of the family Mustelidae and its generally accepted sister taxon Procyonidae, as well as those stem taxa that are thought to have given rise to this clade.

mutation An alteration in a gene that causes it to produce a faulty product, or no product at all.

mutualism Mutually beneficial interactions between species.

myoglobin A protein in mammalian muscle that carries oxygen. Hemoglobin has a similar function in the blood.

mysid A shrimp-like crustacean of the order Myscidea.

Mysticeti (mysticetes) The toothless or baleen (whalebone) whales, including the rorquals, gray whale, and right whales; the suborder of whales that includes those that bulk feed and cannot echolocate. Their skulls have an antorbital process of the maxilla, a loose mandibular symphysis, a relatively small pterygoid sinus, and the maxillary bone telescoped beneath the supraorbital process of the frontal.

N

nanuq Northern Alaskan Inuit term for a polar bear.

nares Openings of the nasal cavity.

nasal turbinate Specialized structures in the nasal passage of mammals that allow for the recovery of water.

nasolaryngeal air sacs Air sacs of the larynx that are continuous with the nasal passages.

natal site The group of islands or rookery where animals were born.

natchiq Northern Alaskan Inuit term for a ringed seal.

natriuresis Excretion of sodium ions in the urine.

natural mark(ing) Any distinctive feature of an animal that is useful to researchers for individual identification, without any involvement by the researcher in producing the mark.

natural selection One of several evolutionary mechanisms; it accounts for an attribute becoming more common (selected) because of some benefit that leads to more offspring being produced.

Nauplius larvae Developmental series of free-swimming, non-feeding planktonic euphausiid larval stages. It is the earliest and the most basic type of euphausiid larva in which only three pairs of appendages are present. At this stage in development the trunk segment has not developed, however an eye, or naupliar, is present on the front of the head.

necrosis The death of cells or tissue caused by disease or injury.

nematodes Cylindrical worm-shaped invertebrates generally known as roundworms; widespread in diverse habitats. Many are parasitic on vertebrates, including marine mammals.

neocortical Referring to the dorsal region of the cerebral cortex, which is the most recently evolved part of the mammalian brain.

neomorph A new structure produced by evolution, in a species or lineage in which no comparable structure existed previously.

neonatal Referring to or occurring in the period immediately after birth.

neonate A newborn.

neoplasia The process of formation of a new and abnormal growth of tissue.

nephron The functional unit of the kidney. The nephron is a tubule with regions specialized for the reabsorption and secretion of various solutes, processes which ultimately produce urine from fluid filtered from the blood. Each kidney (or reniculus) can contain millions of nephrons.

neritic Referring to or occurring in waters above the continental shelf.

net sounder An acoustic transmitting device used to try to ensure that fish schools enter a trawl. The device is usually fixed to the trawl head line and provides the ship captain with an indication of the position of the device in relation to the surface and the seabed, and also the position of fish schools underneath the device.

net whaling A historic whaling method in which whales were first driven into nets and then harpooned.

neurohypophysis Downgrowth of the base of the hypothalamus in the brain, containing the secretory extremities of neurons extending from the brain and producing the hormones oxytocin and vasopressin.

neutering Surgical removal of the testicles; often used for permanent contraception.

neutral buoyancy A state in which the upward force of buoyancy is equal to the downward force of gravity.

niche The ecological space occupied by a species.

nitrogen narcosis A marked decrease in motor coordination and mental capacities, caused by increased concentrations of nitrogen gas in the brain and other nervous tissue.

nocturnal Active at night, while sleeping or at rest during daylight hours.

nominal species A term for any properly named and described (authored) species, whether or not it is recognized today as a valid species.

nonbasilosaurid archaeocete An archaeocete in the families Pakicetidae, Ambulocetidae, Remingtonocetidae, or Protocetidae. Members of this group were formerly included in Protocetidae.

nonessential amino acids Amino acids that can be synthesized.

nonesterified fatty acids A fatty acid that is not attached to a glycerol molecule.

noninvasive sampling The collection of tissue samples in a manner that does not require penetration of the epidermis.

nonsynonymous mutations Single nucleotide substitutions that result in amino acid replacements.

nontarget species A species that is taken in by a fishery even though it is not one that the fishery is primarily concerned with catching.

Norwegian-type whaling A technique of modern whaling, using a harpoon shot from a cannon mounted on a motor-driven vessel.

nulliparous Describing a female that has had no pregnancy, as contrasted with multiparous (more than one pregnancy) and primiparous (first pregnancy).

O

obligate Those animals consigned to a particular ecological regime by their evolutionary history. Obligate river dolphins can only live in fresh water, *Cf.* FACULTATIVE.

observational learning A process in which animals can acquire changes in their own behavior by observing as another or others engage in some behavior and experience positive or negative consequences.

oceanic Relating to or occurring in deep water off the continental shelves.

oceanic front The point at which two masses of seawater meet that differ in temperature, salinity, or both.

Odontoceti (odontocetes) The toothed whales, including sperm and killer whales, belugas, narwhals, dolphins, and porpoises; the suborder of whales including those able to echolocate. Their skulls have premaxillary foramina, a relatively large pterygoid sinus that extends anteriorly around the nostril passage, and the maxillary bone telescoped over the supraorbital process of the frontal.

offshore killer whales A provisional name for a genetically distinct population of killer whales recently identified from British

Columbia, California, and southeastern Alaska, which appears to range mostly over continental shelf waters rather than nearshore waters. They are not observed to associate with either resident or transient killer whales, and their feeding habits are unknown.

ommatidium A single functional unit of a compound eye in an arthropod.

oocyte A developing egg cell in one of two stages. The primary oocyte begins differentiation near the time of birth; maturation is arrested until after puberty, when recruitment of the egg causes further differentiation toward potential ovulation.

operant conditioning The process of teaching a specific behavior by rewarding or reinforcing the occurrences of that behavior.

optimum sustainable population Term used in the US MMPA for a population the size of which lies between the presumed carrying capacity of the local environment (K) and the population's maximum net productivity level (MNPL).

organochlorines Synthetic compounds containing chlorine atoms such as PCBs and pesticides.

organogenesis The formation of organs and organ systems.

osmolality A measure of the osmotic pressure of a solution.

osmolarity Changes in the properties of a solution that result from the number of particles that are dissolved in it. The greater the number of dissolved particles, the greater the osmolarity of the solution.

osmoregulation The process by which an organism maintains its internal salt and water composition constant.

osmotic Referring to properties of solutions that depend on concentrations of dissolved salts and other substances.

osteological Relating to the bony structures.

osteology The study of bones and their structures.

osteoporosis Extreme thinning of cortical compact bone, reduction in number of trabeculae, and overall bone loss.

osteosclerosis Increased density of bone due to replacement of spongy or cancellous bone tissue by compact bone tissue. In several groups of marine mammals, this condition is normal and characteristic rather than pathological as it would be in humans.

Otariidae (otariids) The eared seals (sea lions and fur seals), which use their foreflippers for propulsion.

otolith One of three calcareous bodies in the ear of a bony (i.e., teleost) fish, used in orientation.

overexploitation The reduction, as a result of overfishing, of the size of a population to below the level that provides the maximum sustainable yield. Sometimes referred to as "biological overexploitation," because there can be circumstances where it is economically optimal to reduce populations below their maximum sustainable yield levels.

oxidation The "burning" of food items for energy by the body. This biochemical process produces energy by breaking down fats, sugars, and proteins.

oxygen store The total amount of oxygen available for aerobic metabolism. This oxygen can be a gas in the lungs, bound to hemoglobin in the blood, or bound to myoglobin in muscles.

P

pachyosteosclerosis Combined condition of osteosclerosis and pachyostosis, typified in the thoracic skeleton of sirenians.

pachyostosis Increased density of bone resulting from expansion of bony cross-sectional area through increased deposition of periosteal compact bone.

- pack ice** Pieces of unstable seawater ice, often called pans, which vary from a few meters to several hundred meters in diameter. These pieces are not attached to land; instead they drift according to local current and wind conditions.
- paedomorphosis** The retention of juvenile characters in the adult form.
- pagophilic** Associated with ice.
- PAHs** Polycyclic aromatic hydrocarbons; large groups of naturally occurring aromatic compounds containing two or more benzene rings fused together. Also, oil compounds derived directly (petrogenic) or indirectly via combustion (pyrogenic). Some of these compounds, such as benzopyrene, are known carcinogens.
- palatine** One of the two bones that make up the palate.
- pan bone** Area in the posterior part of the lower jaw, where the bone is very thin.
- panmictic** Describing the mingling of genetic material throughout a breeding population.
- panmixia** Random mating, that is, when mate choice is independent of the genotype at the target locus.
- paramesonephric (Mullerian) duct** Precursor of the uterus and oviduct.
- panropical** Occurring or distributed throughout the tropical regions of the world.
- parapatric** Referring to populations, species, or taxa whose ranges border each other but do not overlap.
- parapatry** The fact of occurring in adjacent or slightly overlapping geographical areas.
- paraphyletic** Taxa that are not derived from a single common ancestor.
- paraphyly** Phylogenetic term that indicates that a group of related species includes an ancestor with some, but not all of its descendants.
- paratonic host** See TRANSPORT HOST.
- paraxonic** Describing the hand or foot of a four-footed animal in which the axis of symmetry passes between digits three and four.
- parental investment** Behavioral and energetic effort expended by a parent on offspring that benefits the offspring at a fitness cost to the parent. Such fitness costs are often measured as a reduction in fertility or as an increase in mortality due to the effort expended on offspring.
- parity** Number of pregnancies and/or number of times a female has given birth; from the Latin *parere* "to bear." Nulliparous females have never been pregnant. A primiparous female is pregnant with her first offspring or has had only one offspring. Multiparous females have had more than one pregnancy or offspring.
- partial pressure** The portion of the total pressure of a gas mixture attributable to one gas component.
- parturition** Giving birth.
- paternal** Inherited from the father.
- pathogens** Organisms or chemicals which can cause disease as a result of infection or ingestion.
- pathogenic** Causing disease; harmful to an organism.
- PGBs** polychlorinated biphenyls; a family of toxic compounds formerly used in industry and manufacturing and frequently discharged into rivers in chemical wastes.
- peduncle** In cetaceans, the posterior portion of the body bearing the tail, or flukes.
- pelage** Hair or fur. A hair canal may contain a single, usually coarse, primary or guard hair (cetaceans, sirenians, elephant seals, monk seals). In some species, however, the hair canal may contain up to 100 (sea otter) smaller, softer underhairs or fur hairs in addition to a guard hair.
- pelagic** Living or occurring in the open sea.
- pelagic trawls** Bag-like nets that are towed through the upper parts of the water column rather than near the seabed.
- pelagic whaling** A whaling operation that does not depend on the use of a land station for processing whales, but uses a floating factory ship (mother ship) or catcher boat with factory facilities.
- pelvis** A bone complex normally formed from the fusion of three bones (ilium, ischium, and pelvic) that forms the pelvic girdle and attaches to the sacral vertebrae.
- perilymphatic duct** A duct that carries the lymphatic fluids between the inner ear and the otic space of the cranium.
- perinatal** Relating to or occurring in the period immediately after giving birth.
- permanent ice** The core area of ice around both poles that does not melt completely in summer.
- periotic** The bone housing the inner ear of cetaceans. This complex bone is very dense and is loosely attached to the skull in most odontocetes. It is frequently found as an isolated fossil and may be diagnostic as to the level of genus or species.
- Perissodactyla (perissodactyls)** An order of living and extinct mammals with hooves distinctive for being "odd-toed," a condition in which the weight of the limb is transmitted along digit 3. Examples include horses, tapirs, and rhinos.
- peritoneal** Refers to the peritoneum, the lining of the abdominal cavity.
- perturbation experiments** Studies of species interactions based on response to changes in the distribution or abundance of one of the interactors.
- pes** The foot, consisting of tarsal (ankle) bones, metatarsals, phalanges, and adjacent tissues.
- petasma** A complex membranous plate on the inner side of a single pair of limbs in the male of several crustaceans. The petasma enlarges during sexual maturation and is used during copulation to aid in the transfer of spermatophores.
- P450 enzyme system** A group of enzymes induced by and metabolizing a wide range of natural products (e.g., hormones) as well as unnatural chemicals (e.g., dioxins, some PCBs, dibenzofuranes).
- phalanges** The bones of the toes.
- pharynx** The anatomical area posterior to the nasal cavity and mouth, where the passage for air crosses that for food. Air passes from the nasal cavity to the nasopharyngeal duct to the pharynx to the larynx to the trachea. Food passes from the oral cavity to the pharynx to the esophagus.
- phenotype 1.** The visible or observable traits of an organism. **2.** More generally, all the collective morphological, physiological, or behavioral aspects of the individual; an expression of the genotype as influenced by environmental factors.
- phenotypic** Relating to the visible body form that is exhibited by an organism.
- pheromone** A body secretion that affects or influences the behavior of other individuals, such as a sex attractant.
- philopatric** Describing individuals that tend to return to breed near the site of their birth.
- philopatry** Mating as an adult at the site of one's own former birth. See site fidelity.
- Phocidae (phocids)** A family group within the pinnipeds that includes all of the "true" seals (i.e., the "earless" species). Generally used to refer to all recent pinnipeds that are more closely related to *Phoca* than to otariids or the walrus.

- Phocoenidae** The family of true porpoises.
- Phoresy** The transportation of one species by another so as to benefit the transported species.
- photic zone** The depth in the ocean into which natural light penetrates.
- photoidentification** The use of photographs to identify animals individually.
- photoperiodism** The fact of an animal's being affected by phase changes in a day–night or light–dark cycle.
- photophore** Light-emitting organ composed of a cluster of light-producing cells, a reflector, and a lens. The luminescence produced by photophores in euphausiids is presumed to be an adaptation for swarming and reproduction.
- photopic vision** Vision in conditions of high luminance.
- phycotoxins** Pathogens produced by algae.
- phylogenetic** Relating to the evolutionary ancestry or lineage of an organism or group of organisms.
- phylogenetic analysis** A method of codifying and comparing heritable biological data for a group of organisms, including molecules, soft tissues, bones, and behavioral data, to formulate a hypothesis of how the organisms are related to each other (a **phylogenetic tree**).
- phylogeny** The evolutionary relationships among different taxa, usually at the species level.
- phylopatry** See PHILOPATRY.
- phytoplankton** Collectively, planktonic plant life.
- pigment** A dark compound that imparts color to hair, eyes, and skin.
- pinna** A nap of skin supported by cartilage, and sometimes moved by small muscles, that projects from the side of the head in vertebrates and functions as a sound funnel. In popular use, it is called the ear, but scientists reserve the term “ear” for the much larger organ of hearing, which includes many parts not visible externally.
- pinniped** Seals and sea lions.
- piscivorous** Feeding primarily on fish.
- pisiform** A small bone at the junction of the ulna and the carpus (wrist).
- placenta** The organ of metabolic interchange between fetus and mother.
- placental** Describing the members of a major group of mammals whose young develop in the womb supplied with nutriment and oxygen from the mother through a placenta; in contrast to the marsupials, in which significant development takes place outside the womb after birth.
- plankton** Collectively, the passively floating or weakly swimming plant and animal life of a body of water; usually minute.
- plantigrade 1.** Walking on the sole with the heel touching the ground. **2.** An animal that moves in this manner.
- plantigrady** A foot posture in which the entire palm and sole of the forefoot and hindfoot are in contact with the ground in the standing position.
- platform transmitter terminal (PTT)** A radio transmitter that operates on specific radio frequencies to communicate with earth-orbiting satellites to allow collection of diving and environmental data and determination of the geographic location of the transmitter.
- play** An imprecisely defined category of behavior, especially in juvenile animals; generally including activities that, while having no immediate identifiable value, may benefit the animal in some other situation or at some later stage in life.
- Pleistocene** The first of two epochs in the Quaternary, extending from 2 million years ago until approximately 10,000 years ago.
- pleomorphic** Having more than one distinct form within a single species, group, or life cycle.
- pleopod** Anterior abdominal appendage modified for swimming.
- plesiomorphic** Describing shared primitive characters inherited from a distant ancestor.
- plesiomorphy** The existence of shared primitive characters (**plesiomorphies**) inherited from a distant ancestor.
- plicae circulares (circular folds)** Folds in the epithelium of the small intestine that serve to increase the surface area.
- plicae semilunares (semilunar folds)** Folds of the epithelium of the large intestine produced by the longitudinal muscles.
- pneumotachograph** A mechanical device to measure the volume and rate of flow of air moved in and out of a mammal's lungs.
- pod** In resident killer whales, a group of closely related matrilineal lines that regularly associate with each other in preference to other matrilineal lines within the community.
- poikilotherm** Animals whose body temperature varies with the surroundings.
- polar front** The border between the cold waters of the Southern Ocean and the temperate water masses of the south Atlantic, south Pacific, and Indian Oceans (formerly known as the Antarctic convergence).
- polychlorinated biphenyls** See PCBS.
- polycyclic aromatic hydrocarbons** See PAHS.
- polydonty** Having more than the primitive number of teeth (11 per half jaw in placental mammals; 44 total).
- polyestrous** Having more than one estrous cycle in a single year.
- polygynous** Describing a mating system in which one male mates with multiple females during a breeding season.
- polygyny** Mating system in which one male mates with several females within one breeding season. The term usually refers to a mating system in which relatively few successful males breed with most of the females, while others do not mate. The reverse, one female mating with several males, is rare among mammals.
- polynya** Areas of open water surrounded by heavy pack ice.
- polyphyletic** Taxonomic group that includes members (as genera or species) from different ancestral lineages.
- polyphyly** Phylogenetic terms that indicate that a group of related species does not include the last common ancestor of all species.
- polyunsaturated fatty acids (PUFA)** Fatty acids which contain two to six double bonds. A fatty acid that has 20 carbon atoms with 5 double bonds, where the first double bond is at the third methyl carbon atom, is named 20:5n–3.
- population** A group of conspecific organisms occupying a specific geographic region at the same time. “Population” tends to be used informally to connote a distinct biological entity, whereas people may tend to use the term “population” as more of a management unit. US MMPA defines this as a group of animals “of the same species or smaller taxa in a common spatial arrangement, that interbreed when mature”. This term is used in the MMPA interchangeably with the term “stock.”
- population bottleneck** A rapid reduction in the size of a population.
- population stock** See stock.
- porpoise** Any of several small cetaceans in the family Phocoenidae. The dorsal fin may be absent; teeth are spatulate or vestigial.
- porpoising** The behavior of penguins, dolphins, or whales leaping at least partially clear of the water surface during rapid swimming.

- posterania** A collective term for bones that are not part of the skull, for example, the vertebrae, limbs, hands, or feet.
- postpartum** After birth; especially, shortly after birth.
- postreproductive** Describing a female of certain toothed whales that ceases ovulating at an advanced age but well before her expected longevity.
- power stroke** The part of the movement of a locomotor organ (tail, limb) that contributes most to propulsive motion. The opposite is the recovery stroke.
- practical salinity units (psu)** The measure of salinity of seawater, approximately equal to parts per thousand.
- precautionary principle** An ecological management philosophy that seeks to maintain natural resources by managing more conservatively when there is greater ignorance about the status of the resource.
- precocial** A high degree of maturation and independence exhibited by newborns that require relatively little adult care. By contrast, *altricial* young are born in a helpless state and depend heavily on adult care.
- predation** A situation in which an animal exerts time and energy to locate living prey and expends additional effort to kill and consume it.
- predator** An animal that obtains its food primarily or exclusively by hunting and killing other animals.
- predatory** Describing an animal that obtains its food by preying on other animals.
- preening** In birds, the act of smoothing or cleaning feathers with the beak of the bill.
- preformed water** Water that exists as water when it is consumed in the food or drunk.
- premaxilla** One of the two major bones found in the upper jaw of mammals. The other is the maxilla.
- premaxillary sacs** Premaxillary elements of the air sac system, which is a net of diverticula of the nasal passages between the external nares (blowhole) and the bony nares of the skull.
- premolar** A tooth behind the large canine, used to slice or chew.
- prepartum** Describing or occurring in the time before birth, especially shortly before birth.
- prey** Animal that is hunted and killed by another.
- primary production (productivity)** Organic matter and/or energy produced or captured by organisms (plants) from inorganic compounds and incident solar radiation.
- primiparous** Describing a female that gives birth for the first time, as contrasted with multiparous (more than one pregnancy) and nulliparous (no pregnancy).
- primordium** See ANLAGE.
- probability of identity** The probability that two different individuals have identical genotypes.
- procombent** Describing a tooth (generally apical) that tends to acquire a subhorizontal to horizontal orientation.
- protocetid** A member of the family Protocetidae, a paraphyletic family that is thought to have given rise to the basilosaurids.
- proximate explanation** An explanation that describes the immediate or short-term causes of a biological incident or occurrence, in contrast to ultimate explanations, which are historical (specifically, evolutionary) in nature. For example, a threat between neighboring territorial male sea otters can be said to have occurred because the two males encountered one another near their common boundary or had high levels of testosterone (proximate explanation). Or, it can be stated that the threats evolved as a low-risk alternative to fighting (ultimate explanation).
- pseudocervix** Folds of tissue, usually vaginal in origin, that are distal to the true cervix, but play a similar role or barrier as the true cervix.
- psychophysical test** A test in which an animal is trained to show the experimenter when it detects a physical stimulus, such as light, sound, or a chemical.
- psychosphere** Global, nutrient-rich, relatively biologically unexploited deep water.
- pteropod** Small molluscs with two “wings,” with which they swim through the water.
- pterygoid** An anatomical process descending from the sphenoid bone.
- pterygoid sinus** An airspace adjacent to the flat pterygoid bones of the skull.
- purse seine** A type of fishing gear that surrounds fish schools with a vertical curtain of netting that is then pursed, or closed off, at the bottom by means of ropes and heavy winches, in order to prevent fish from swimming out of the bottom of the net.
- pyloric stomach** The most distal portion of the cetacean stomach, adjacent to the pyloric sphincter; contains pyloric glands.

Q

qargi Northern Alaskan Inuit term for whalers' ceremonial house.

R

- race** An interbreeding subgroup of a species that is genetically distinct and usually geographically isolated from other such groups of the same species.
- radius** A bone extending from the elbow to the wrist on the outside of the forelimb, opposite the ulna.
- range** The maximum extent of geographic area used by a species.
- rank** A designated level in a classification scheme.
- raptoria** Describing a process of feeding by seizing individual food organisms.
- rare** Not common, widespread, or generalized; not generally found.
- reciprocity** Individuals engage in helpful actions that will be repaid by the recipient.
- refractive index** A parameter of a light-transparent medium determining the degree of light refraction at a boundary between media with different indices. The more index difference, the stronger the refraction. The refractive index of a vacuum is 1, that of air is almost the same, and that of water and some eye media (anterior chamber liquid, vitreous body) is 1.33.
- regime shift** A radical and persistent change in the state of an ocean-atmosphere system or ecosystem.
- regression** The mathematical relationship between two variables, for example, body mass and brain mass.
- reinforcement** An event (reward or punishment) that follows a response and that increases or decreases the likelihood that the response will recur.
- reintroduction** The reestablishment of a species within its natural range.
- release** The act or technique of moving an animal that has been born in captivity, or that has been in captivity for long enough that it requires retraining in the skills required to survive, back into the wild so that the animal can become free-ranging and no longer under human supervision.

- relict species** Persistent remnants of formerly widespread biotas, typically existing in specific isolated areas or habitats.
- remora** A type of fish that has a modified dorsal fin to suck onto other fish, marine mammals, or turtles; also called “suckerfish.”
- renal** Relating to or occurring in the kidney.
- renal pelvis** A funnel-like structure into which urine drains from the nephrons.
- reniculus** In discrete multireniculate kidneys, the anatomically independent functional units into which the kidney is divided. The reniculus resembles a miniature kidney with a cortex, medulla, vascular supply (renicular artery and vein), and ureteral tubule.
- replacement yield** The number of animals, which if removed from a population stock, results in the same number of animals at the end of the year as in the beginning.
- reproductive ecotype** An array of species of plants or animals adapted to the conditions of some breeding site and having inheritable features.
- reproductive success** Number of offspring successfully reared to independence by an individual adopting a particular strategy.
- reproductive value** The number of offspring fit an individual of a given age can be expected to produce over the rest of its life discounted by the population growth rate.
- resident killer whales** A genetically distinct population of killer whales found in coastal waters of the northeastern Pacific Ocean, which feeds preferentially on fish and squid. *Cf.* OFFSHORE KILLER WHALES, transient killer whales.
- resilience** The recuperative power of a population to recover from or absorb sudden environmental stress and deprivation.
- resource** Any item, factor, or condition that contributes to the ability of an organism to survive and reproduce; for example, food, space, and mates.
- respiratory acidosis** A decrease in blood pH level, caused by an increase in the partial pressure of carbon dioxide that shifts the normal equilibrium of the bicarbonate-carbonic acid buffer system.
- restriction endonuclease** An enzyme that recognizes a specific (typically 4–8 nucleotides) DNA sequence at which point the DNA strands are digested (cut). A mutation resulting in the change of the DNA sequence will then result in failure of digestion by the restriction endonuclease, yielding another detectable allele.
- rete mirabile** (*plural, retia mirabilia*) Complex networks of anastomosis, coiled blood vessels.
- retia mirabilia** See RETE MIRABILE
- reticulation** The fact of crossing over or connection between lines of descent.
- retroperitoneal** Outside of but projecting into the body cavity; completely or partially covered by peritoneum.
- rhizome** An elongate, horizontal subterranean stem of a seagrass or other plant, producing shoots above and roots below and serving for the storage of reserve food material.
- ritualization** An evolutionary process through which behavior becomes partly or completely “emancipated” from its original function(s) and acquires new functions for communication. For example, vocalizations presumably represent ritualized breathing.
- riverine** Living in rivers; found in or relating to a river.
- rookery** A terrestrial breeding area used by a colony of pinnipeds on a seasonal or permanent basis. (From an earlier use of the term to describe the breeding or nesting area of a large number of rooks, a crow-like bird of Europe.)
- rooster tail** A spray of water formed when certain small cetaceans surface at high speed; caused by a cone of water coming off the animals head. (So named because the form of the spray resembles a roosters feathers.)
- rorqual** Any of seven species of baleen whales (the minke, blue, humpback, fin, Bryde’s, Omura’s or sei whale) belonging to the family Balaenopteridae, characterized by a variable number of pleats that run longitudinally from the chin to near the umbilicus. The pleats expand during feeding to increase the capacity of the mouth.
- rostral** Having to do with the nose or head; toward the front.
- rostral hairs** Small hairs on the outside edge of the rostrum of a cetacean.
- rostrum** The beak-like projection found at the front of the skull or head of a cetacean; the term also refers to the skeletal support of the upper jaw, comprising the anterior parts of the maxillary, premaxillary, and vomerine bones of the skull.
- r-selection** The reproductive strategy of a species that tends to grow quickly and have a large number of offspring, but that has a relatively short life span and negligible parental involvement in the rearing of young. Certain insects are cited as an example of r-selection. Contrasted with a k-selected species, which has slower growth and a smaller number of offspring, but a longer life span and significant parental involvement.
- ruminant** A hoofed mammal that feeds by grazing or browsing; it has a complex four-chambered stomach (**rumen**) and thus is able to regurgitate and then rechew its food (i.e., it “chews its cud”). Ruminants include domestic cattle, sheep, goats, deer, antelopes, and giraffes.

S

- sacral vertebrae** Vertebrae associated with the pelvis; a feature that is not present in cetaceans and manatees.
- school** An aggregation of fish or other animals that regularly swim together as a unit.
- scotoma** An area of diminished vision within the visual field.
- scotopic vision** Vision in conditions of dim luminance.
- scramble competition** A mechanism of sexual selection in which males compete for access to females by searching and locating females more efficiently than their rivals. Females may mate with one or several males.
- sea cow** A strictly marine herbivorous mammal foraging near the surface, primarily on large marine algae, and propelling itself with a forked caudal fluke. The term is also used loosely for any member of the order Sirenia.
- seagrass(es)** Any of various marine flowering plants belonging to the families Potamogetonaceae and Hydrocharitaceae, consisting of 12 genera and some 50 species.
- sea ice** Frozen seawater, which forms ice floes (i.e., pack ice).
- seal bomb** An explosive noise-making device designed to chase marine mammals away from areas where they are regarded as harmful to fisheries, nets, and so on.
- seasonality** The fact of being affected by or dependent on a change of seasons; for example, changes in population distribution that are related to changes in seasons.
- sebaceous glands** Glands located at the base of mammalian hairs that release an oily secretion, sebum.
- secondary sexual characteristic** A feature of a male or female animal that is produced as sexual maturity occurs.
- sedimentology** The scientific study of sediments, solid fragmentary material transported and deposited by wind, water, or ice, or precipitated from solution, or secreted by various organisms.

- selection** The evolutionary process favoring individuals with genotypes that enable them to raise the greatest number of young which survive to breed.
- selection coefficient** A mathematical term indicating the decrease in disfavored gene types contributed to the next generation; for example, a selection coefficient of 0.5 for a given genotype indicates a decrease of 50% of that genotype entering the next generation.
- semiaquatic** Only partly aquatic, for example, an animal that forages for food in water but otherwise lives and breeds on land.
- semiferous tubules** Convolved loops within the testis where spermatozoa are formed.
- sensillum** A sensory receptor or a receptor complex in the cuticle of an invertebrate.
- sensitization** An increased behavioral (or physiological) responsiveness occurring over time, as an animal learns that a repeated or ongoing stimulus has significant consequences. *Cf.* HABITUATION.
- sensor** A device that reacts to a certain physical stimulus in a quantifiable manner.
- sensory adaptation** The lessening of a response to a stimulus due to physiological fatigue.
- sentience** The ability to sense; in particular, the capacity to experience pleasure and pain.
- serial carpus and tarsus** An arrangement of the carpal and tarsal bones in a serial way; that is, the pattern of relations between carpal and tarsal bones is “pillar-like.” Each bone of the first row articulates mostly with only one bone just under. This is a derived condition compared to the generalized mammalian condition. *Cf.* ALTERNATING CARPUS AND TARSUS.
- sessile** Stationary or fixed, for example, plants growing on the sea floor or mussels attached to rocks.
- sex chromosomes** Nuclear chromosomes that are involved in sex determination, for example, the X and Y chromosomes in mammals.
- sexual bimaturation** The sexual maturing of one sex significantly earlier than the other.
- sexual dimorphism** Phenotypic differences between males and females of the same species.
- sexual selection** Selection due to the advantage some individuals have over others of the same sex in exclusive relation to reproduction. This may lead to the evolution of costly secondary sexual characters found only in one sex (such as a male peacocks tail or a stag’s antlers), which may decrease the probability of survival and which therefore is opposed by natural selection.
- SINES** Short interspersed nuclear elements, that is, an interspersed repetitive element less than 500 nucleotides long of viral origin.
- shelf** A sea zone located close to land and having the same geological structure. A shelf zone is 100–200 m deep.
- sibling species** A species that is morphologically very similar to another, sometimes to the point of seeming identity, but demonstrated to be a separate species on the grounds of genetic, behavioral, or cryptic morphological evidence.
- sister group** The closest relative with which a taxon has a common ancestor.
- site fidelity** The tendency to return to mate at the same site repeatedly in different breeding seasons. This term is used instead of PHILOPATRY if the animal’s original birth site is not known.
- size index** An analog of the ENCEPHALIZATION INDEX, related to single brain components rather than the total brain.
- small-type whaling** Japanese coastal whaling that uses a vessel and cannon of small size. Operated since the beginning of the twentieth century for minke and toothed whales (other than sperm whale); came under the control of the Japanese government in 1947.
- SNPs** Single nucleotide polymorphisms, the substitution of a single nucleotide with another at a specific location in the genome.
- soak time** A term for the length of time that a piece of fishing gear such as a gill net is left in the water to fish.
- social learning** The social transfer of information and skill among individuals by processes that include imitation, teaching, exposure, social support, matched dependent learning, stimulus enhancement, observational conditioning, and goal emulation.
- somersault** A behavior involving an acrobatic stunt in which the body rolls in a complete circle, head over heels, or, in the case of dolphins, head over tail.
- sonar 1.** An acoustic system or device that emits sound into water or another medium, detects echoes received from objects, and processes those signals to characterize and/or visualize the objects. **2.** In marine mammals, a means of detecting, identifying, and tracking prey by the emission of sound pulses and the analysis of the resulting echo patterns.
- song** A series of sounds repeated in a specific pattern.
- sonic lens** An anatomical structure that focuses sound as optical lenses focus light, that is, the melon of odontocete whales.
- sound** A form of energy manifested by small pressure variations in a medium (such as water or air). Depending on the strength and frequency of the sound, it may be detectable by an organ of hearing.
- source level** The acoustic pressure that would be measured at a standard distance (usually 1 m) from a point source radiating the same amount of sound as the actual source.
- species interactions** The effects of one species on another.
- spectral sensitivity** Selective sensitivity of visual receptors to a certain region of the light wavelength spectrum that corresponds to different light colors.
- spectrogram** A graphic representation of sound waves per unit of time.
- spermaceti** A white, translucent substance, obtained from the distinctive form of oil made of wax esters and triglycerides that is found in the spermaceti organ of sperm whales.
- spermaceti organ** An elongated, barrel-shaped structure making up much of the sperm whale’s head, made of soft spongy tissue filled with spermaceti oil.
- spermatogenesis** The process by which sperm develop and mature from primitive sperm cells (spermatogonia and subsequently spermatids).
- spermatophore** Collection of spermatozoa enclosed in a sheath of gelatinous material.
- sperm competition** A mechanism of sexual selection in which a female mates with more than one male, and males compete to fertilize her eggs by producing more sperm per ejaculation, or by mating with her more frequently than their rivals.
- sphincter** A muscle that forms a ring and contracts upon itself, closing the structure it surrounds (e.g., the external anal sphincter muscles closes the anal canal).
- splanchnic** Pertaining to the viscera, such as the liver, stomach, and pancreas.
- sporta peiimedullaris** A sheet-like structure of connective tissue and muscle that lies between the renal cortex and the medulla.
- spout** A term for a cloud of vapor and sea water mixed with air that is exhaled by cetaceans.
- sprint** A high-speed, maximum effort or movement of short duration.

- spyhopping** A behavior that involves raising the head vertically out of the water, then sinking below the surface without much splash.
- stable isotope** An alternate form of an element that is more persistent than the common form.
- statistical power** The ability of an analysis to correctly reject the null hypothesis, that is, not to miss a real effect.
- stem group** One extinct species, or several extinct species, that form an extinct sister group, or sequence of sister groups, to the crown group.
- stereoscopic vision** A capability of vision to discriminate the distance to an object based on a small difference of images (disparity) projected on the retinae of two eyes. This ability requires binocular vision.
- stereotyped behavior** A pattern of repetitive movements, such as pacing back and forth or swaying to and fro, that often are performed by captive animals held in impoverished environments, and that are not associated with any behaviors normally performed by these animals in the wild.
- stochasticity** A random occurrence of events in space and/or time; random variability.
- stock** A group of animals of the same species or smaller taxa, existing in the same locale and interbreeding when mature.
- stored reserves** Body components that are supplementary to immediate requirements, most often of fat and blubber.
- stranding** The directed action of beaching.
- strandling** A term for any marine animal that cannot cope with its immediate situation, either ashore or at sea (e.g., a beached whale, an Arctic seal in Florida waters, or a sea otter drenched with oil).
- strategy** Genetically distinctive rules for individual behavior. Selection favors the strategy that yields the highest reproductive success in relation to competing strategies.
- stratification** A vertical density gradient caused by changes in temperature and salinity with depth.
- streamlining** Body shape that causes little distortion to the fluid flow around it and minimizes drag.
- striated muscle** The skeletal or locomotor muscles of the body.
- strip transect sampling** A sample count method in which counts are conducted within long, narrow strips.
- subarachnoid space** A space under the arachnoid membrane, one of the coverings of the brain.
- subarctic** Living in an intermediate zone between arctic and temperate waters.
- subspecies** A formally described and named geographic entity within a species.
- supraoccipital** A bone at the top of the rear of the skull.
- surface-active group** A group of right whales, typically consisting of one female and one to many males, engaged in vigorous physical interactions at the surface, which appear to be courtship or other social behavior.
- surfing** The behavior of riding on a wave or waves. There are two basic patterns: floating on top of the water and falling down the advancing edge of a wave or riding within a wave being created by water being pushed upward by the movement of a denser medium (such as a whale or vessel). Dolphins engage in both types of surfing or “wave riding.”
- survival rate** The probability of an animal remaining alive over a given time period; typically expressed as the proportion of individuals in a population surviving from one period (usually defined as a year) to the next.
- sustainability 1.** The combined capacity of a system and its parts to retain their interactions and other natural qualities. **2.** Specifically, the level of human activity in a given ecosystem that can continue without degrading the ecosystem or seriously depleting resources.
- sustained swimming** Long-duration activity generally performed at low speeds.
- sympatric** Occurring together geographically; coexisting in the same place.
- sympatric speciation** Denotes reproductive isolation in the absence of geographical separation.
- sympatry 1.** The fact of occurring or living in the same geographical area. **2.** Specifically, the existence of two or more populations of closely related species in identical or broadly overlapping geographical areas.
- symphysis** A joint between two bones that consists of connective tissue only and lacks a synovial cavity.
- synapomorphic** Sharing a derived character state.
- synapomorphy** Derived character state shared by several taxa, not the ancestral stage.
- synonymous mutations** Single nucleotide substitutions that do not result in amino acid replacements.
- systematics** A method of taxonomy which attempts to ensure that the categories represent evolutionary history and relationships.
- systemic** Broad or universal in application while accounting for everything of importance in proportion to its importance; applying to, and accounting for, complexity.
- ystole** The period of ventricular contraction during the contraction–relaxation cycle of the heart.

T

- tachycardia** A heart rate above the resting rate.
- tag** Any artificial mark attached to animals.
- tail-slapping** Another term for lobtailing, sometimes used when referring to dolphins.
- take** Term used in the MMPA and US ESA. In the MMPA, “take” means “to harass, hunt, capture, or kill, or attempt to harass, hunt, capture, or kill any marine mammal.” In the ESA it means approximately the same thing.
- taxon (plural, taxa)** A natural grouping of related organisms, usually named, and of a given rank (e.g., order, family, genus, species, subspecies).
- taxonomic(al)** Based on or describing the classification of organisms according to species or higher levels.
- taxonomy** The science of classifying organisms into species, genera, and higher categories.
- telemetry** The remote sensing of environmental, behavioral, and physiological data, particularly from animals and via radio frequency signals.
- telescoping** One of two patterns of cranial sutures found in mysticetes and odontocetes. In mysticetes, the occiput is thrust forward and maxilla floors the orbit. In odontocetes the rostral elements are thrust caudally over the cranial elements.
- telson** An impaired terminal abdominal segment of crustaceans.
- temporal fossa** A cavity or depression in the pair of compound bones that form the sides and base of the skull.
- temporary threshold shift** A temporary impairment in hearing capability caused by exposure to strong sounds.
- tension** The partial pressure of a particular gas in solution.

- terrestrial** On land; occurring or living on land rather than in water or in the air.
- territorialism** The fact of establishing and defending a territory (see below).
- territory** Space on the breeding grounds that adult males maintain by calling, threatening, and fighting other males, and in which they mate without harassment from other males.
- Tertiary** A period of geological time from about 65 to 2 million years before the present day.
- testosterone** The primary male hormone, produced in the testis.
- teutophagous** Feeding on squid.
- thelycum** A female organ to which spermatophores are attached with a sticky fluid.
- thermal insulator** A material, such as fur or blubber, that serves to retain heat in an animal. The inverse of *insulation* is *conductance* which describes how easily heat flows through a material.
- thermocline** Steep vertical temperature gradient below a well-mixed surface layer.
- thermohaline** Concerning the temperature and salinity of seawater.
- thermoneutral** Falling within the range of temperatures at which thermoregulation can be maintained.
- thermoneutral zone** Range of environmental temperatures at which an animal does not require an increase in metabolism to maintain its body temperature.
- thermoregulation** The active process of controlling body temperature in an animal. Sweating to cool down and shivering to warm up are examples of thermoregulation.
- thoracic** Describing the region within the thorax, or the portion of the vertebral column within the thorax.
- thoracic vertebrae** Rib-bearing vertebrae.
- thorax** The part of the vertebrate body that contains the heart and the lungs, in mammals divided from the abdomen by the diaphragm.
- threatened** As defined under the US ESA, this term describes species likely to become endangered "within the foreseeable future throughout all or a significant portion of its range" (US Fish and Wildlife Service, 1996, p. 4).
- time-activity budget** A quantitative description of the amount of time spent by animals in different behavioral activities. Energetic costs of different behavioral activities are used to construct such budgets.
- time-depth or time-data recorder (TDR)** Mechanical or electronic instruments that measure and store information on diving and swimming behavior and environmental variables of aquatic mammals, birds, fish, and turtles.
- toothed whale** See ODONTOCETI.
- tooth replacement** The shedding of deciduous (or milk) teeth followed by the eruption of permanent teeth.
- top-down control** Consumer-mediated regulation of community structure and function.
- trade winds** Winds blowing almost continually westward and toward the equator from the subtropical high-pressure belts at latitudes near 30° N and 30° S. Trade winds are from the northeast in the Northern Hemisphere and from the southeast in the Southern Hemisphere.
- trait-mediated indirect effects** Ecological effects that result from the behavior response of one species to another.
- transition** The substitution of a nucleotide from one purine to another purine (e.g., guanine to adenine) or from a pyrimidine to another pyrimidine (e.g., cytosine to thymidine).
- transient killer whales** A population of killer whales found in coastal waters of the northeastern Pacific that is sympatric with residents and offshores, but socially and reproductively isolated from them, and genetically distinct. Transients feed preferentially on marine mammals and seabirds.
- transport host** A host infected by a larval parasite stage in which the parasite survives, and can be transmitted to another host, but does not develop. Transport hosts are not required to complete the life cycle but enhance the chances of transmission to the definitive host.
- transverse septum** A membrane that functions as a separator between the heart and the liver.
- transversion** The substitution of a nucleotide from a purine to a pyrimidine (e.g., guanine with cytosine).
- trawl** A bag-like net that is dragged through the water in order to catch fish.
- trematode** Any parasitic flatworm of the class Trematoda, especially a fluke, equipped with hooks or suckers.
- triglyceride** An ester of glycerol that is combined with three fatty acids. It is the primary chemical form in which lipids are stored in the tissue.
- trophic** Relating to the process of feeding or feeding patterns.
- trophic cascade** Interactions among trophic levels through top-down control.
- Trophic flows** The transfer of food or energy between the different groups of species comprising a food web.
- true seals** See EARLESS SEALS.
- trying down** The traditional practice of cooking blubber to extract the valuable oil; rendering.
- tubercle 1.** One of a series of small, raised epidermal protuberances found on the dorsal fin of most porpoise species. Their distinctness, density, and covering area vary among species.
- 2.** A knob-like structure of unknown (but probably sensory) function, found on the head and jaws of humpback whales. Each tubercle contains a single hair (vibrissa).
- tumor** A swelling, especially from an abnormal growth of tissue.
- tuna purse seine** See PURSE SEINE.
- tunica albuginea** A white fibrous layer covering an anatomical structure.
- tunicate** Subphylum of chordates containing the classes Ascidiacea (the sessile sea squirt), the free-swimming tadpole-like Larvacea, and the Thaliacea (free-swimming salps). Chordate features (i.e., notochord and nerve chord) are found only in the larva and are generally lost in the adult. The adult secretes a tough cellulose sac (tunic) in which the animal is embedded.
- turbid** Exhibiting reduced water clarity because of the presence of suspended matter.
- turbulent flow** An unsteady and eddying flow of water. Turbulent boundary layers are thicker than laminar boundary layers and likely to separate prematurely.
- tympanic cavity** A large, irregularly shaped cavity of the middle ear.
- tympanoperiotic earbones** Very dense bones at the base of the skull consisting of the ventral ectotympanic bone or bulla, which encloses the middle ear cavity, and the more dorsal periotic or petrosal bone, which contains the cochlear apparatus of the inner ear and the balance organ (vestibulum plus semicircular canals). The structure of tympanoperiotic bones is used widely to indicate taxonomic relationships of both extant and fossil cetaceans.

U

unequal crossover When the breaks in the DNA strands that later recombine during meiosis is not in the exactly homologous position in the pairs of sister chromatids involved. In mini-satellites unequal crossover will result in a mutation, a change in the number of tandem nucleotide repeats.

ugruk Northern Alaskan Inuit term for a bearded seal.

ultimate explanation See PROXIMATE EXPLANATION.

ultrasonic Describing acoustic signals that are above the normal human range of hearing.

ultrasonography The visualization of deep structures of the body by recording and displaying the echoes of pulse of ultrasonic waves directed into the tissues.

ultrasound 1. A sound that is higher in frequency than the maximum audible to humans, usually said to be 20kHz. Many marine mammals can hear ultrasound. **2.** see ULTRASONOGRAPHY.

umialik Northern Alaskan Inuit term for a whaling captain.

umiaq (*plural, umiat*) Northern Alaskan Inuit term for a skin boat used to hunt whales, seals, and walrus.

underhair A layer of shorter, finer hair that provides better insulation than the longer, thicker hair (called guard hairs) covering it.

ungulate Any of a taxonomic group (Ungulata) comprising the hoofed mammals and their derivatives, including the living Artiodactyla, Cetacea, Perissodactyla, Hyracoidea, Sirenia, and Proboscidea, together with the extinct Desmostylia and numerous other fossil groups.

unguligrade Referring to limbs that are elongated and slim with an efficient fore-and-aft drive and nearly no capability of rotating. Unguligrade limbs are typical of ungulate mammals.

upwelling A process by which ocean water rises from a deeper to a shallower level, usually by divergence and offshore currents. This process often occurs along the edges of continental shelves and brings nutrient-rich water to the surface.

ureter The duct that carries urine from the kidney to the urinary bladder.

urethra In anatomy, duct that carries urine from the bladder out of the body.

uropod Fan-shaped paired appendages on the penultimate segment of euphausiids, used for swimming.

Ursidae A family of arctoid carnivorans that includes the subfamilies Ursinae, Hemicyoninae, and Amphicyonodontinae, the latter two being represented only by fossil taxa.

V

vacuole A fluid-filled space in a cell, usually small in animal cells; several vacuoles coalesce in the developing follicle to produce the antrum.

vaginal process Outpocketing of the peritoneal membrane of the abdomen into the scrotum that is associated with testicular descent.

vascular The system of vessels in the body that carry blood. For example, the arteries, veins, capillaries are part of the vascular system.

vasculitis The inflammation of a blood vessel.

vasopressin A peptide hormone (antidiuretic hormone) that is released from the posterior pituitary gland. It increases the permeability of the collecting duct, thereby suppressing urine formation and output.

venae cavae Major veins returning blood from the periphery to the heart.

ventral In anatomy, toward, or relatively near to the belly and the corresponding surface of the head, neck, thorax, and tail.

ventral grooves A series of parallel grooves or pleats running longitudinally on the undersurface of the throat and chest region in balaenopterid whales, allowing great expansion of the mouth during feeding.

vertebra (*plural, vertebrae*) A bone of the spine.

vertebral canal The space within the vertebral column that houses the spinal cord.

vertebral column The row of bones forming the longitudinal axis of the body; the backbone.

vertebrate One of the Vertebrata, the subphylum including those animals having a backbone; that is, fish, amphibians, reptiles, birds, and mammals.

vertex An elevated conjunction of the nasal, frontal, and supraoccipital bones at the top of the skull.

vestigial tooth A tooth that has no function in food processing. Usually these teeth do not erupt out of the jawbone or do not break through the dental gums.

vibrissae Large, tactile, sensory hairs present on the upper lip of mammals.

vicariance event The development of a natural biogeographical barrier causing groups that previously occupied the same area or adjacent areas to become physically separated.

vicariant Describing a major geological or oceanic split in habitat, such as the geological closure of a strait, thus splitting distributions of many organisms.

vicariant speciation Evolution of species triggered by fragmentation of the ancestral species' distribution area.

villus (*plural, villi*) Finger-like projection that greatly increases the surface area and facilitates exchange between two media (e.g. the surface of the small intestine and its contents) or tissues (e.g. the maternal and fetal parts of the placenta).

visual acuity Sharpness of vision; the capability to discriminate visual pattern details.

vital rates Key indicators describing the dynamics of animal populations, including birth rates, recruitment rates, mortality rates, immigration, emigration.

vomer nasal organ An organ for chemical reception situated in the anterior part of the roof of the mouth; anatomically and functionally distinct from the senses of smell and taste; well developed in many species of mammals, in which it is especially important: in reproduction.

vortex The rotating motion of a fluid around a central core.

vulnerable This term, used by the IUCN Red List refers to taxa that are neither endangered nor critically endangered, but which face a high risk of extinction in the medium-term future (World Conservation Monitoring Centre, 2000).

W

weaning The end of the lactation period; the process of changing from milk to a solid diet in juvenile mammals.

Westerly Blowing from the west.

whale A term commonly used for a subset of the mammalian order Cetacea. In general, it includes the larger members of the order, but the term is inconsistently used for animals of vastly different

sizes that are not closely related. In some cases, it refers to the Great Whales, that is, the baleen whales and the (unrelated) sperm whale. Others use whale to include larger members of the dolphin family (such as the killer whale). In that usage, some larger dolphins (such as the bottlenose dolphin) are well above the smallest whales (such as pygmy sperm whales) in size. Paleontologists use the word whale to describe all Eocene forms (some of which were no larger than a dog) and many modern cetaceans. Thus the term whale is scientifically imprecise, and subjects relating to it can be found in tills work under more specific headings.

whalebone See BALEEN.

whale louse (*plural, whale lice*) An amphipod crustacean of the family Cyamidae; adapted for living in crevices and other secure places on the skin of cetaceans, on which whale lice largely feed.

whelping The process of giving birth; used to refer to seals.

windkessel A capacitance blood vessel, which due to elastic properties in its wall, first expands and accepts blood volume on blood entry and then passes blood onward due to recoil within its wall.

X

xenobiotic **1.** A chemical compound (that is foreign to biological systems, especially one that is toxic). **2.** Relating to or describing a compound of this type.

Z

ziphiid Any of at least 19 extant species of beaked whale, of the family Ziphiidae.

zona glomerulosa The outermost layer of the adrenal cortex principally responsible for the production of the mineralocorticoid aldosterone.

zoonosis (*plural, zoonoses*) **1.** A disease of animals that is transmittable to humans. **2.** The process of disease transfer from animals to humans.

zooplankton Collectively, planktonic animal life.
