# Contents

*Foreword by Frederick W. Oehme* ix
*Preface* xiii
*List of Contributors* xv

**Part 1 General**

1 Concepts in veterinary toxicology 3
*Roger O. McClellan*
2 Pharmacokinetics and toxicokinetics: fundamentals and applications in toxicology 25
*Rakesh Dixit*
3 Physiologically based pharmacokinetic modeling 42
*Deon van der Merwe, Jennifer L. Buur, and Jim E. Riviere*
4 Toxicological testing: *in vivo* and *in vitro* models 51
*Magda Sachana and Alan J. Hargreaves*
5 Epidemiology of animal poisonings 67
*Sharon M. Gwaltney-Brant*
6 Chemicals of terrorism 74
*Tina Wismer*
7 Regulatory considerations in veterinary toxicology 92
*Lynn O. Post*
8 Toxicology and the law 110
*Michael J. Murphy*

**Part 2 Organ Toxicity**

9 Neurotoxicity 129
*Donna Mensching and Petra A. Volmer*
10 Liver toxicity 145
*Karyn Bischoff and Shashi K. Ramaiah*
11 Renal toxicity 161
*Manu M. Sebastian, Steven I. Baskin, and Steven E. Czerwinski*
12 Respiratory toxicity 177
*John A. Pickrell*
13 Cardiovascular toxicity 193
*Steven I. Baskin, Steven E. Czerwinski, Jaime B. Anderson, and Manu M. Sebastian*
14 Reproductive toxicity and endocrine disruption 206
*Tim J. Evans*
15 Placental toxicity 245
*Ramesh C. Gupta*
16 Dermal toxicity 263
*Faqir Muhammad and Jim E. Riviere*
17 Blood and bone marrow toxicity 277
*Shashi K. Ramaiah and Mary B. Nabity*
18 Immunotoxicity 289
*Raghubir P. Sharma*

**Part 3 Nanoparticles, Radiation, and Carcinogenesis**

19 Biomedical responses and toxicity of nanoparticles 305
*John A. Pickrell*
20 Oxidative stress and neurodegeneration 313
*Manashi Bagchi, Shirley Zafra-Stone, Debasis Bagchi, and Sangeeta Patel*
21 Radiation and radioactive materials 335
*John A. Pickrell*
22 Carcinogenesis: mechanisms and models 343
*Supratim Choudhuri, Kirk Arvidson, and Ronald Chanderbhan*

## Part 4 Drugs of Use and Abuse

23 Toxicity of over-the-counter drugs 363
*Karyn Bischoff*
24 Toxicity of drugs of abuse 391
*Karyn Bischoff*

## Part 5 Metals and Micronutrients

25 Aluminum 413
*Ramesh C. Gupta*
26 Arsenic 418
*Tam Garland*
27 Cadmium 422
*Stephen B. Hooser*
28 Copper 427
*Larry J. Thompson*
29 Fluoride 430
*Larry J. Thompson*
30 Iron 433
*Stephen B. Hooser*
31 Lead 438
*Larry J. Thompson*
32 Mercury 442
*Ramesh C. Gupta*
33 Molybdenum 449
*Jeffery O. Hall*
34 Selenium 453
*Jeffery O. Hall*
35 Sodium chloride (salt) 461
*Larry J. Thompson*
36 Sulfur 465
*Jeffery O. Hall*
37 Zinc 470
*Tam Garland*
38 Chromium, iodine and phosphorus 473
*Larry J. Thompson*

## Part 6 Insecticides and Molluscicides

39 Organophosphates and carbamates 477
*Ramesh C. Gupta*
40 Organochlorines 489
*Steve Ensley*
41 Pyrethrins and pyrethroids 494
*Steve Ensley*
42 Rotenone 499
*Ramesh C. Gupta*
43 Fipronil 502
*Ramesh C. Gupta*
44 Imidacloprid 505
*Steve Ensley*
45 Ivermectin and selamectin 508
*Ramesh C. Gupta*
46 Amitraz 514
*Ramesh C. Gupta*
47 Metaldehyde 518
*Ramesh C. Gupta*

## Part 7 Rodenticides and Avicides

48 Anticoagulant rodenticides 525
*Michael J. Murphy*
49 Non-anticoagulant rodenticides 548
*Ramesh C. Gupta*
50 Avitrol 561
*Ramesh C. Gupta*

## Part 8 Herbicides and Fungicides

51 Toxicity of herbicides 567
*P.K. Gupta*
52 Toxicity of fungicides 587
*P.K. Gupta and Manoj Aggarwal*

## Part 9 Industrial Toxicants

53 Alcohols and glycols 605
*Mary Anna Thrall and Dwayne W. Hamar*
54 Petroleum 615
*Robert W. Coppock and Ralph G. Christian*
55 Polychlorinated biphenyls, polybrominated biphenyls, polychlorinated dibenzo-*p*-dioxins and polychlorinated dibenzofurans 640
*Steven Bursian*

## Part 10 Environmental Toxicology

56 Avian toxicology 663
*Robert H. Poppenga*
57 Principles of ecotoxicology 689
*Jeffrey M. Levengood and Val R. Beasley*
58 Aquatic toxicology 709
*Robert W. Coppock and P.N. Nation*
59 Cyanobacterial (blue-green algae) toxins 714
*Birgit Puschner and Jean-François Humbert*
60 Toxicology of marine toxins 725
*Aurelia Tubaro and James Hungerford*

## Part 11 Bacterial Toxins

61 Botulinum neurotoxin 755
*Julie A. Coffield and Dorothy D. Whelchel*
62 Enterotoxins 771
*Larry J. Thompson*

## Part 12 Poisonous and Venomous Organisms

63 Caterpillars and mare reproductive loss syndrome 777
*Manu M. Sebastian, William Bernard, and Lenn R. Harrison*
64 Terrestrial zootoxins 785
*Sharon M. Gwaltney-Brant, Eric K. Dunayer, and Hany Y. Youssef*

## Part 13 Estrogenic Toxicants

65 Chemical-induced estrogenicity 811
*Stephen H. Safe, Shaheen Khan, Fei Wu, and Xiangrong Li*

## Part 14 Poisonous Plants

66 Important poisonous plants of the United States 825
*Kip E. Panter, D.R. Gardner, S.T. Lee, J.A. Pfister, M.H. Ralphs, B.L. Stegelmeier, and L.F. James*
67 Cyanogenic plants 873
*Steven S. Nicholson*
68 Nitrate and nitrite accumulating plants 876
*Steven S. Nicholson*
69 Oxalates-containing plants 880
*Theuns W. Naudé and V. Naidoo*
70 *Datura* spp. and other related plants 892
*Theuns W. Naudé*
71 Fescue toxicosis 907
*Dennis J. Blodgett*
72 Mushroom toxins 915
*Birgit Puschner*
73 Cottonseed toxicity 926
*Steven S. Nicholson*
74 Toxicity of yew (*Taxus* spp.) alkaloids 929
*Christina R. Wilson and Stephen B. Hooser*

## Part 15 Mycotoxins

75 Aflatoxins 939
*Robert W. Coppock and Ralph G. Christian*
76 Trichothecenes 951
*Michelle S. Mostrom and Merl F. Raisbeck*
77 Zearalenone 977
*Michelle S. Mostrom*
78 Fumonisins 983
*Geoffrey W. Smith*
79 Ochratoxins and citrinin 997
*Ramesh C. Gupta*
80 Tremorgenic mycotoxins 1004
*Tim J. Evans and Ramesh C. Gupta*
81 Slaframine 1011
*Geoffrey W. Smith*
82 Ergot 1015
*Steven S. Nicholson*

## Part 16 Feed and Water Contaminants

83 Ionophores 1021
*Meliton N. Novilla*
84 Nonprotein nitrogen (urea) and hyperammonemia 1042
*Patricia A. Talcott*
85 Water quality and contaminants 1045
*Michael P. Carlson and Steve Ensley*

## Part 17 Diagnostic Toxicology

86 Basic concepts of analytical toxicology 1063
*Anant V. Jain and Beverly Arnold*
87 Sample submission for toxicological analysis 1077
*Anant V. Jain*
88 Toxicoproteomics in diagnostic toxicology 1083
*Christina R. Wilson and Stephen B. Hooser*
89 Microscopic analysis of toxic substances in feeds and ingesta 1091
*Lynn S. Bates*
90 Role of pathology in diagnosis 1100
*Manu M. Sebastian*

## Part 18 Therapeutic Measures

91 Prevention and treatment of poisoning 1139
*Camille DeClementi*

*Index* 1159

*There are in fact two things, science and opinion; the former begets knowledge, the latter ignorance*

Hippocrates (460BC–377BC)

# Foreword

## WHAT'S THIS ABOUT "VETERINARY TOXICOLOGY"?

"Exciting!" "Challenging!" "Progressive!" "Rewarding!" Certainly not "Dull!" "Routine!" "Old stuff!" "Repetitious!" Just look at the titles of the chapters in this encyclopedic reference, and you'll get turned on to the relevant and cutting-edge science, diagnostics and real-world problem-solving going on in the discipline of "Veterinary Toxicology".

Where did it come from? How did it evolve to get that way? What is its current focus and where is it going? These are all stories worth telling. Let us start at the beginning . . .

In the beginning was folk medicine to deal with sufferings. That evolved into ritualistic "medicine", the use of herbs, plants, and incantations. Studies of how things work and categorizing illnesses organized into formal medicine, and then disciplined further to physiology. With the use and application of natural and synthetic chemicals to challenge body functions, pharmacology grew into its own specialty dealing with using these same compounds for therapeutic purposes. With even more sophistication, recognition of numerous dangerous effects from these products called for a clearer definition and understanding of what separated a "safe" medicinal from one that caused more pain and danger than the illness being treated. The thesis of "dose is everything" was born . . . and with it and its confounding parameters, toxicology was born!

And what a prodigious science that birth produced! Spurred on by the industrial revolution, urbanization, and "Better living through chemistry", the unfortunate ill effects of "too much" became obvious. Instances of chemical misuse, finding chemicals in unexpected locales, and the lack of the knowledge needed to deal with environmental, human, and animal toxic misadventures spurred public outcries. Government actions followed, but were also led by concerned and inquiring scientists. Their recognition that there is strength and opportunities in bonding together to encourage and share the development of this necessary and energetic science flowed into the growth of international organizations fostering and sponsoring the growth of toxicology in all its important ramifications.

As a specialty, veterinary toxicology was an early player in the toxicology arena. At first it was closely related to veterinary clinical medicine and pathology, particularly concerned with animal losses associated with the large scale use of open ranges for livestock grazing and then later the application of various insecticides to control insect-borne diseases in animals. But expanding agricultural needs triggered by the growing US population and scientific advances in chemistry, biochemistry and diagnostic techniques "pushed the envelope" to understand and resolve these losses and improve animal health. If animals were being challenged by these risks, could humans be far behind?

Increased sophistication of human pathology and forensic medicine stimulated similar developments in veterinary medicine. With the ever-increasing expansion of livestock populations on western ranges, concern developed for the death losses from consumption of poisonous plants. Poor grazing conditions and access to often unrecognized toxic range plants stimulated a wide range of investigations by federally employed as well as private veterinarians and resulted in large numbers of publications in the 1920s and the 1930s to inform livestock owners and to reduce losses. With this came the need for clearly identifying what toxic components were present and how they might be effectively treated. Such studies recognized the value of the veterinarian's training and utilized his multifaceted skills in toxicologic studies for clinical evaluations. This was rapidly recognized by industrial institutions and the veterinarian's talents were

sought for application to commercial drug trials in laboratory animals. These veterinary scientists wearing the hat of toxicology began expanding their responsibilities to biochemical separations, electron microscopy and studies of the cellular and molecular mechanisms of these chemical actions.

World War II and the extensive use of insecticides for pest control and speculative gas warfare resulted in veterinarians being employed by the armed forces in other experimental animal studies. After the war, these and newer chemicals were widely applied to problems in agriculture. Their use required skilled veterinary supervision and all too quickly veterinary treatment when the misuse of these potent chemicals occurred. Facilities at universities, such as Texas A&M, and at governmental research institutions, such as the Poisonous Plant Laboratory at Logan, Utah, focused efforts on the growing hazards and clinical problems resulting in domestic animals. The growth of the pesticide field, coupled with the intensive land use encroaching on plant and animal habitat, required increasing chemical and biological knowledge to understand and identify the disease processes involved.

Veterinary pathologists, such as C.C. Morrill, W.L. Sippel, K. McEntee, and P. Olafson, became increasingly interested in the toxic problems now being seen in expanding numbers. J.L. Shupe concerned himself with detail studies of fluorine intoxication associated with industrial pollution problems. Veterinary pharmacologists began to investigate specific toxicants and their effects on domestic animals; W.G. Huber studied toxic effects of chemotherapeutic agents and antiseptics; R.P. Link identified dicumarol as the anti-clotting factor in sweet clover poisoning and spoke out warning against insecticide poisonings; P.B. Hammond investigated heavy metal toxicities with particular interests in utilizing chelating agents to treat lead poisoning; O.H. Muth studied trace minerals and their interactions in animal intoxications; R.D. Radeleff worked extensively with insecticides and their harmful effects in domestic animals; J.S. Palmer worked closely with Radeleff performing similar investigations on herbicide and pesticide toxins; W. Binns and J.W. Dollahite studied the pathology and biochemistry of numerous poisonous plant intoxications in livestock. Information describing the specific pathology and biochemistry produced by the increasingly recognized number of xenobiotics and naturally occurring materials were coupled with the veterinary experiences discovered in diagnosing clinical cases and effectively providing treatment.

By the mid-1950s, toxicology was a highly active area of veterinary medicine. Biochemical and molecular interactions were discussed and the tools of other disciplines were brought to focus upon the problems of domestic animal poisonings. With it, a new breed of veterinarian emerged. The developing veterinary toxicologist had to understand physiology and pathology, but equally important he had to be a chemist with wide knowledge of separative and quantitative instrumental techniques. Professional judgment of clinical episodes and a working knowledge of metabolic and excretory processes were needed. He had to become intimately familiar with pharmacology and the molecular action of a wide variety of chemicals. Understanding treatments to be administered for specific intoxications was necessary, and finally he had to logically and scientifically put into perspective the often confusing and confounding assortment of signs, lesions and analytical results to reach rational interpretations and conclusions for the numerous problems being solved. Since increasing knowledge was being sought, this well-grounded veterinarian had also to be able to conduct significant independent research in well-equipped facilities. More and more veterinarians now were conducting toxicological research investigations as their primary mission.

In the presence of this increasing need and professional situation, a small group of veterinarians specializing in toxicology united to focus attention on the needs of veterinary toxicology and to assist the progress and growth of this discipline. The formation of the American College of Veterinary Toxicologists (ACVT) in 1958 was the beginning of formal development and recognition of veterinary toxicology. At a meeting in Salt Lake City, Utah, on January 15, 1958, the ACVT was formed by 11 veterinarians stimulated by, and engaged in, toxicology. The organizing committee consisted of Doctors Chapman, Christofferson, Furgeson, Harris, Hayden, Holmes, Jones, Phelps, Shupe, Spencer, and Vinsel. The group's objectives were: "To further the educational and scientific progress in veterinary toxicology and to encourage education, training and research in veterinary toxicology; To establish standards of training and experience for . . . specialists in veterinary toxicology; To further recognition of such qualified specialists . . .; To arrange meetings to promote discussion and interchange of ideas in the following fields of veterinary toxicology: teaching, research and development, diagnosis, nomenclature, public health . . .; To provide all possible aid and assistance to its members by the interchange of ideas and scientific information; To review manuscripts . . .; To review published material and keep a file on such reviews . . .; To accumulate and disseminate information in the field of veterinary toxicology . . .; To encourage adoption . . . of uniform clinical and laboratory reporting methods . . .; To suggest or direct basic research in those areas of deficient knowledge . . . " (Constitution, *American College of Veterinary Toxicologists*, Adopted 1958, Salt Lake City, Utah.)

By 1968 the ACVT grew to over 100 Fellows and Associate Fellows. It has worked efficiently and had stimulated national and international recognition of veterinary toxicology as a progressive and dynamic specialty.

This vitality was further stimulated in 1964 by the New York Academy of Sciences publishing a volume devoted to veterinary toxicology based on the proceedings of an international meeting held in New York City (Gabriel, K.L., editor. 1964. Veterinary toxicology. *Annals of the New*

*York Academy of Science* III, Art. **2**: 559–812). This symposium provided basic information on the energetic activities in veterinary toxicology at that time and had the effect of stimulating further growth and multidisciplinary efforts in the field. The increasing demand for specialized training in veterinary toxicology also encouraged academic training programs. Early efforts were established in universities at Cornell, Utah State, Iowa State, Florida, Kansas State and others. This proliferation has continued with training centers established in other universities and institutions, in veterinary diagnostic laboratories and including research training in molecular and genomic toxicology investigations throughout the United States and around the globe. These early centers and their offsprings have fostered the talents to understand and deal with numerous environmental and clinical problems in veterinary medicine.

Formal recognition of veterinary toxicology was initiated with the American Board of Veterinary Toxicology (ABVT) being formally recognized by the American Veterinary Medical Association (AVMA) in the mid-1960. Largely through the efforts of R.D. Radeleff during his term as president of the ACVT, an application for approval of the specialty was accepted by the AVMA Council on Specialty Organizations. A Certifying Board of W. Binns, J.W. Dollahite and R.D. Radeleff was designated to conduct the first examination leading to Diplomate status in the ABVT. Specific training and experience requirements were established for applicants and approval of each applicant's credentials was necessary before the candidate was admitted to the examination. Satisfactory completion of a comprehensive written examination was the final requirement for certification and the privilege of adding "DABVT" behind the successful candidate's name. The first ABVT certifying examination was held in July 1967 in Dallas, Texas. The five successful candidates joined the three original members of the Certifying Board to form the initial group of certified, i.e. "Boarded" Veterinary Toxicologists (Oehme, F.W. 1970. The development of toxicology as a veterinary discipline in the United States. *Clinical Toxicology* **3**: 211–20).

Since that time, annual certifying examinations of the ABVT have been given associated with the Annual Meeting of the AVMA. This certifying body has continued to set and maintain standards of qualification for veterinary toxicologists, and has complimented the continuing growth of veterinary toxicology experience and knowledge. By 2007 a total of 115 veterinarians have successfully completed the examination challenge and become Diplomates. Their special talents and skills continue to be professionally applied in academia, in industrial roles, as regulatory officials, at poison control centers and within diagnostic laboratories, and in consulting responsibilities throughout the world.

In the years since the discipline's early embryonic period, veterinary toxicology has evolved into a multidisciplinary focus that embraces all of basic and clinical sciences. Its unique focus is not only the diversity of its embracing activities, but also the many talents and energies of its participants. It harbors a true global theme and is proud of its recognition and membership in "the only medical profession licenced for treating more than one animal species".

*Veterinary Toxicology: Basic and Clinical Principles* is an encyclopedic documentation of the developments in veterinary toxicology the past four decades and glimpses into the promises of exciting future growth. In a logical and well organized fashion, the contributors cover the vast and dynamic field of veterinary toxicology. Of special interest is the initial chapter on "General Principles of Veterinary Toxicology" by R.O. McClellan, one of the initial ABVT certified veterinarians from the 1967 examination in Dallas. The appropriateness of the first contributor to this volume being a 40-year boarded veterinary toxicologist should not be lost to the readers or the general toxicological community.

The initial part highlights the intensity and diversity of the veterinary contributions to toxicology. Pharmacokinetics, testing models, epidemiology and regulatory concerns, backed up by the timely heightened awareness of terrorism and the increasing necessity for legal compliance and actions are well documented.

Any toxicology text would be remiss if it did not focus on individual organ systems and their respective toxicological effects and clinical manifestations. Part 2 moves through each biological system and ends with immunotoxicology and the disastrous effect that various chemicals can have by upsetting this balance of nature.

Of more recent origin are the veterinary efforts of exploring nanoparticles, radiation, and the mechanisms and models of investigative carcinogenesis utilizing various animal species. The veterinary toxicologist is foremost in working with such models and evaluating study results. Of additional current importance are the chapters on over-the-counter drug toxicity and the prevalent potential of various drugs of abuse to affect animal health.

The traditional group of toxic elements are intelligently and dramatically discussed in Part 5, where metals and micronutrients ranging from aluminum through zinc are laid out in all their toxicity. No group of toxic elements is more historically relevant to toxicology than compounds such as arsenic, copper, fluoride, lead, mercury, selenium, and zinc, and when interspersed with some of the minor minerals a complete array of metal and mineral animal intoxications is provided in this part.

The original emphasis for development of veterinary toxicology comes to the forefront in the middle of this volume. The organochlorines and the organophosphates/carbamates are extensively reviewed. Rotenone sneaks in, but the more recent toxic developments with pyrethroids, fipronil, imidacloprid, amitraz, and ivermectin and selamectin are prominently presented. The part on

rodenticides and avicides, as well as the brief part on herbicides and fungicides, highlight the array of agricultural chemicals that have spurred not only the long-term developments in toxicology but also the environmental impact of widespread use of these groups of compounds.

The environmental areas of veterinary toxicology are discussed by reviewing industrial toxicants and the residual impacts of the biphenyls, dioxins and dibenzofurans. The environmental impact of these and other chemicals found in the environment are highlighted by extensive chapters dealing with their toxicity in birds, an introduction to ecotoxicology, and the distribution of chemicals in the global marine environment through aquatic toxicology, and the adverse effects of cyanobacterial toxins and others affecting marine animals.

Although reviewed in only two chapters, the extensive information on botulinum neurotoxin and the enterotoxins are not overlooked. Neither are the poisonous and venomous compounds generated by animals in the terrestrial environment. The chapter on "Caterpillars and mare reproductive loss syndrome" presents up-to-date information on this event's disastrous effect on equine breeding stables and the puzzling origin of these problems. An in-depth discussion on chemically induced estrogenicity brings readers current with this unique toxic hazard in all animal species including humans.

Part 14 is another expansive discussion of the still important poisonous plant concerns that contributed to and continue to stimulate the interests and skills of veterinary toxicologists. The groups of important United States' poisonous plants are reviewed, and then specific categories of plant toxins are presented: cyanide; nitrate/nitrite; oxalates; *Datura* and related plants; fescue; mushrooms; cottonseed toxicity; and the *Taxus* alkaloids. All these are common and highly concerning dietary risks for livestock and other animal species existing in the natural environment.

Fungal toxins are grouped under the "Mycotoxins" part where aflatoxins, trichothecenes, zearalenone, fumonisins, ochratoxins/citrinin, slaframine, ergot, and the interestingly and dynamic tremorgenic mycotoxins are nicely presented. These compounds present not only animal hazards, but are also important public health concerns for the dietary contamination of grains and other human food sources. Other dietary contaminants are reviewed in the part dealing with "Feed and water contaminants". Ionophores and nonprotein nitrogen dietary supplements are highlighted. Not to be overlooked, water quality and contaminants of water sources alert diagnosticians to the hazards and often animal-threatening risks involved with these aqueous contaminants.

The concluding parts in this book of facts and knowledge address how current methodology allows confirmation of specific poisonings and the appropriate means by which poisoned animals may be treated and managed. After reviewing the basic concepts of analyses, appropriate sample submission requirements for such procedures, the use of proteomics for diagnostic application, the application of microscopic analyses of feeds and animal ingesta for toxic components, and the complementing role of pathology in the diagnostic process are presented. To wrap it all up, a concluding part on therapeutic measures offers recommendations on how to prevent poisonings and, if necessary, what treatments may be applied to treat individual intoxications.

In a full circle, the basic principles of veterinary toxicology have been utilized to understand the mechanisms of toxicology, to relate to the numerous and challenging individual chemical constituents that offer risk and produce injury to animals and indirectly to humans, and to offer current information and recommendations for identifying such problems and specifically managing their animal and public health effects.

It should be apparent that Veterinary Toxicology is about everything – from initial concerns of animal illness to specific molecular and genomic impacts in all of society. The veterinary toxicologist is well equipped and active in identifying the opportunities and challenges presented. The discipline stands increasingly ready to contribute to medical science by utilizing its broad talents to have significant impacts for the health of all animals on this globe.

What's Veterinary Toxicology all about? Those answers are what this encyclopedic volume offers! Enjoy them and use the information to the benefit of society and science!

*Frederick W. Oehme*

# Preface

Veterinary toxicology is a very complex, yet fascinating, subject as it deals with a wide variety of poisons of chemical, mineral, plant, fungal, and animal origins. Presently, synthetic compounds constitute the largest class of chemicals that are most frequently encountered in animal poisonings. Veterinary toxicology is greatly complicated by the wide variations in responses of domestic, aquatic, wild, and exotic animal species to toxicants. In the last few decades, veterinary toxicologists have faced the enormous task of dealing with a flood of new farm chemicals and household products. Understanding the complete profile, especially the mechanism of toxicity, of each toxicant is the biggest challenge for today's veterinary toxicologists. At the present time, toxicologists are facing many new problems. For example, during the incident of September 11, 2001, a large number of pets died in the collapse of the World Trade Center in New York City, while the survivors continue to suffer from respiratory illnesses (Ground Zero Illnesses) caused by dust, debris, and toxic chemicals. In 2005, Hurricanes Katrina and Rita, devastated the lives of many animals in the Gulf coast states (Louisiana and Mississippi). Thousands of animals died, while a large number of others suffered from intoxication with high levels of metals, pesticides, mold, and other toxic substances. Recently, a fatal food from Diamond Pet Foods Company has sparked concern as more than 125 dogs died in more than 25 states in the United States. Aflatoxin was proven to be the culprit. From time to time, unusual toxicological problems are encountered on a large scale, and this trend is likely to continue in the future. Around the world, animals and humans are living in a more polluted environment today than ever before. Many of the toxicological problems are global, while others are regional. Unfortunately, antidotes for common poisons are not readily available, resulting in either delayed or no treatment. Thus, veterinary toxicologists have the tremendous task ahead of facing new challenges of the 21st century.

The primary objective of this book, *Veterinary Toxicology: Basic and Clinical Principles*, is to offer a comprehensive text/reference source to research veterinary toxicologists, students, teachers, clinicians, and environmentalists. The volume is organized into 18 parts, with a total of 91 chapters, in order to offer a stand alone chapter on as many topics as possible. Although the book is heavily focused on target organ toxicity (Part 2), it has many novel chapters on timely topics, such as veterinary toxicology and the law, physiologically based pharmacokinetic modeling, *in vivo/in vitro* toxicity testing models, neurotoxic oxidative stress, nanoparticles, radiation, immunotoxicity, reproductive/endocrine/placental toxicity, chemical terrorism, and carcinogenesis. Poisonous plants, mycotoxins, feed, and water contaminants are covered extensively. Several chapters provide the latest information on problems related to industrial, environmental, aquatic, marine, avian, and zoo toxins. A significant part of the book (Part 16) is devoted to diagnostic toxicology, which includes basic principles, method validation and QA/QC, sample submission, current diagnostic criteria, toxicoproteomics, pathology, and microscopic analysis of feed. Finally, the last part of the book emphasizes prevention and therapeutic measures of common poisonings.

In the past few years, veterinary toxicologists from many parts of the world have realized the need for a standard book that can provide a detailed coverage of the basic and clinical principles of veterinary toxicology. This book addresses global as well as regional toxicological problems, and offers practical solutions. A stand alone chapter is provided on every major topic, with major references for further reading. This book represents the collective wisdom of more than 75 authors, and offers a unique text/reference source for those involved in

veterinary medicine in general and toxicology in particular. Contributing authors for chapters of this book are the most qualified and well-experienced authorities in their respective areas of veterinary toxicology.

The editor is deeply indebted to all the authors for their sincere and dedicated contributions. Technical assistance of Joan Jenkins, Debra Britton and Robin Doss is immensely appreciated. The editor and the authors would like to thank Renske Van Dijk, Keri Witman, Mara Conner, and Tari Broderick, the editors at Academic Press/Elsevier, for their vital input in preparation of this book.

# Concepts in veterinary toxicology

*Roger O. McClellan*

## INTRODUCTION

Toxicology, from the Greek words toxicon for poison and logos for scientific study, is the study of poisons. Veterinary medicine is that branch of medical science concerned with the diagnosis, treatment and prevention of diseases of animals. The adjective veterinary is derived from Latin – veterinae, beasts of burden. Obviously, the modern field of veterinary medicine extends beyond the "beasts of burden" to include all the domesticated animal species, both livestock and companion animals, as well as non-domesticated species. Indeed, it has expanded to include non-mammalian species. While the focus of toxicology remains on chemicals, it is generally acknowledged that the study of effects of ionizing radiation is a part of the field or at least a closely related specialty. Pharmacology, from the Greek words pharma for drugs and logos for scientific study, is a closely related field concerned with the science of drugs: their preparation, properties, effects and uses in the diagnosis, treatment and prevention of disease.

The field of toxicology is very broad including the identification and characterization of poisons, their physical and chemical properties, their fate in the body and their biological effects. In addition, toxicology is concerned with the treatment of disease conditions caused by poisons. The terms toxicant and poison are used interchangeably. A toxicant is a material that when it contacts or enters the body via ingestion, inhalation, dermal contact or injection, interferes with the normal biological processes and causes adverse health effects. The term toxin is used to describe poisons originating from biological processes. The term toxic is used to describe the effects of a poison on biological systems. Toxicosis is the term used to describe the syndrome of adverse health effects that result from exposure to a toxicant. During the last several decades, increased concern has developed for the effects of long-term low-level exposures to toxicants. With these exposures, adverse health effects, if they occur, may be manifest in a non-specific manner as an increase in the incidence of common diseases in a population.

A wide range of materials produces toxic effects when exposure occurs at sufficiently high levels. Indeed, with extreme levels of exposure most agents can produce adverse effects. For example, while both water and oxygen are required to sustain life, they are toxic when the level of intake is excessive. The nature of the toxic responses depends not only on the toxicant, but also the route of exposure, the duration and intensity of the exposure and the characteristics of the exposed individual, i.e. species, gender, age, pre-existing disease states, nutritional status and prior exposure to the agent or related compounds. The exposure may be brief or prolonged. The response may occur acute or chronic and occur soon after exposure or much later and only after prolonged exposure. The response may be relatively unique to the toxicant, i.e. a specific toxicosis, or distinguishable from common diseases caused by natural processes or exposure to other agents. In many cases, sophisticated statistical methods are required to associate some excess health risk, over and above that caused by other factors, with a particular toxicant exposure. This is especially true today after much progress has been made in controlling exposure to toxic materials.

In this chapter, I first provide a brief historical perspective on the development of veterinary toxicology as a subspecialty of the veterinary medical profession and as a specialized area within the general field of toxicology. This

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

is followed by a section on the evolution of veterinary toxicology from an observation-based profession and science to one that places increasing reliance on science developed through experimentation. This includes a discussion of the risk paradigm which has become an integral part of toxicology in recent decades. In the next section, I offer several related paradigms for acquiring, organizing and using knowledge in veterinary toxicology so as to maximize its potential impact. Next, there is a section on the sources of knowledge that may be obtained either through observation or experimentation. These sources may include studies on the species of interest, i.e. people or some other specific animal species, controlled exposure studies in the species of interest, studies in other species, investigations using tissues and cells and structure–activity analyses. This is followed by a section discussing the design of experimental studies to optimize the interpretation and use of the results. This chapter concludes with a discussion of key toxicological descriptors and a brief conclusion section.

## HISTORICAL PERSPECTIVE

### Historical events

The father of modern toxicology is generally acknowledged to be Auroleus Phillipus Theostratus Bombastus Von Hohenheim (1493–1541), who referred to himself as a Paracelsus, from his belief that his work was beyond the work of Celsus, a first century Roman physician (Pagel, 1958). Paracelsus is credited with the well-known statement: "All substances are poisons; there is none which is not a poison. The right dose differentiates a poison from a remedy." Paracelsus advanced many views that were revolutionary for his time that are now accepted as fundamental concepts for the field of toxicology. In contrast to earlier emphasis on mixtures, he focused on the toxicon as a specific primary chemical entity that was toxic. Paracelsus advanced four fundamental concepts:

1 Experimentation is required for examining responses to chemicals.
2 A distinction should be made between the therapeutic and toxic properties of chemicals.
3 The therapeutic and toxic properties are something closely related and distinguishable by dose.
4 It is possible to ascertain a degree of specificity for chemicals and their therapeutic or toxic effects.

It is obvious from the foregoing that toxicology and pharmacology are closely related fields of scientific endeavor. Pharmacology is focused on drugs, including both their effectiveness and safety. Toxicology is concerned with all kinds of chemicals and other agents that may, at some level of exposure, cause adverse health effects. As will be noted at several places in this chapter, toxicology is increasingly concerned with low-level exposures for which the effects, if any are observed, may not be specific to a particular chemical.

Toxicology, in a sense, dates back to the earliest activities of humans. By observation, people came to learn that which could be ingested without harm and, by contrast, the foodstuffs to be avoided because of their harmful properties. They also came to know which animal venoms, plant extracts and other materials could be used for hunting, warfare and assassination. No doubt as animals were domesticated, it became apparent that the human observations and practices could be extended to domestic animals. Unfortunately, domestic animals are not always as astute as people in learning to avoid poisonous plants and other harmful situations. Thus, veterinary practitioners still encounter toxicoses involving animals ingesting poisonous plants.

The history of toxicology has been well documented by several contemporary authors (Milles, 1999; Borzelleca, 2001; Gallo, 2001). The history of veterinary toxicology has not been as well documented, although it is apparent that veterinary toxicology has been an integral part of veterinary medicine since the origins. Veterinary medicine is a specialized branch of medical science with formal programs of study leading to a professional degree. The history of veterinary medicine has been reviewed by several authors (Smithcors, 1957; Stahlheim, 1994; Swabe, 1999; Wilkinson, 2005). The role of veterinary toxicology in the veterinary curriculum is well documented for one of the earliest veterinary medical colleges, that at the Free University of Berlin. Wilsdorf and Graf (1998) provide an account of the development of veterinary toxicology at that University from 1790 to 1945. Oehme (1970) has briefly reviewed the development of veterinary toxicology as a discipline in the United States.

### Textbooks

In the English language, the earliest veterinary toxicology publication I could find was a synopsis of *Veterinary Materia Medica, Therapeutics and Toxicology* (Quitman, 1905) apparently used at Washington State University College of Veterinary Medicine in the early part of the 20th century. I am uncertain of the extent to which this synopsis is based on a French text by Kaufmann (1901). The earliest English language veterinary toxicology textbook I was able to locate was that authored by an Englishman, Lander (1912). This book was also prepared in a second edition (1926) and a third edition was prepared by an Irishman, Nicholson (1945). I am uncertain how widely it was used in the United States. The text included four sections: a brief introduction to toxicology followed by sections on

classes of toxicants; mineral or inorganic poisons; organic poisons and drugs; and poisonous plants. This last section represented half of the book.

Many early students in veterinary medicine in the United States used textbooks prepared for physicians such as Kobert (1897), *Practical Toxicology for Physicians and Students*. It was also common to use either textbooks in pharmacology or veterinary pharmacology that contained a brief coverage of toxicology. Indeed, few veterinary medical colleges prior to the 1950s had full-time veterinary toxicologists on their faculty. Lectures on toxicology were usually included in courses in pharmacology, pathology and clinical medicine.

The first veterinary toxicology text I personally used was authored by Garner (1957) who was then a Senior Lecturer in Chemical Pathology (Veterinary) at the University of Bristol in the United Kingdom and later Head of the Radiobiology Department at the Agricultural Research Council Field Station, Compton, Berks, UK. The text by Garner (1957) was intended as a successor to the third edition of Lander's *Veterinary Toxicology*. A second edition was prepared by Garner (1961) after he became Head of the Public Health Section, Radiological Protection Division, UK Atomic Energy Authority, Harwell, Berks, UK. Later, Garner came to the United States where he was initially associated with Colorado State University directing studies of the long-term effects of radiation on beagle dogs. I recall asking Garner in the early 1970s about the possibility of preparation of a third edition of his *Veterinary Toxicology* text. He indicated that the field of veterinary toxicology had become so broad that it was not readily feasible for a single individual to author a text in veterinary toxicology and he was not interested in "shepherding" a herd of individual chapter authors with specialized knowledge of various aspects of veterinary toxicology.

Radeleff (1964) authored one of the first veterinary toxicology texts published in the United States. A second edition appeared in 1970. This was followed by a text prepared by Osweiler *et al.* (1985). Several books published in the 1960s became classics on the effects of poisonous plants (Kingsbury, 1954, 1964; Hulbert and Oehme, 1968). Recent books on poisonous plants have been authored by Garland and Barr (1998), Burrows and Tyrl (2001, 2006) and Knight and Walter (2001). Murphy (1996) has authored a field guide to common animal poison. It is organized by the organ system affected and then by toxicant.

Osweiler (1996) has authored a text focused on toxicology as part of the National Veterinary Medical Series for Independent Study. It has been widely used by individuals preparing for the National Board Examinations for Veterinary Medical Licensing. Roder (2001) has prepared a text, *Veterinary Toxicology*, as part of a series *The Practical Veterinarian*. Plumlee (2004) has edited *Clinical Veterinary Toxicology* and Peterson and Talcott (2001, 2006) have edited two editions of *Small Animal Toxicology*. The present multi-authored text promises to be the most comprehensive text on veterinary toxicology published to date. A *Veterinary Toxicology* text edited by Chapman (2007) is in preparation.

There are a number of comprehensive general toxicology texts available today. I will note four that the serious student of toxicology will find useful to have in their reference library. *Casarett and Doull's Toxicology: The Basic Science of Poisons* edited most recently by Klaassen (2001) was first published in 1975 and is now in its sixth edition. Hayes (2001), *Principles and Methods in Toxicology*, is now in its fourth edition. *Toxicology*, edited by Marquadt *et al.* (1999), built on an earlier German text by Marquadt and Schafer. *Biological Concepts and Techniques in Toxicology: An Integrated Approach* edited by Riviere (2006) was just released. Serious students will also want to be aware of a 13 volume comprehensive set of toxicology text edited by Sipes *et al.* (1997). Moreover, there are numerous text and reference books available now covering various sub-specialty areas such as *Inhalation Toxicology*, *Reproductive and Developmental Toxicology* and *Dermal Toxicology*.

In addition to text and reference books, there are numerous journals published in the field of toxicology that regularly contain articles that relate recent findings in veterinary toxicology. Many clinically oriented veterinary medical journals contain articles on veterinary toxicology. The on-line search capabilities serving the medical sciences including toxicology and veterinary toxicology are expanding at an exponential rate. Of special note are those maintained under the auspices of the National Library of Medicine, MEDLINE and TOXLINE.

## Organizations

A number of professional scientific organizations have been created as the field of toxicology, including veterinary toxicology, has matured. The most noteworthy include the American College of Veterinary Toxicology (ACVT), American Board of Veterinary Toxicology (ABVT), Society of Toxicology (SOT), American Board of Toxicology (ABT) and Academy of Toxicological Sciences (ATS). The ACVT was one of the earliest scientific societies in the field being founded in 1958. It now exists as the American Academy of Veterinary and Comparative Toxicology (AAVCT). The ACVT was instrumental in fostering the creation of the ABVT and its recognition by the American Veterinary Medical Association (AVMA) as the approved certifying specialty organization for veterinary toxicology. Three well-known veterinary toxicologists, W. Binns, J.W. Dollahite and R. Radeleff, were accepted by the AVMA as Charter Members of the ABVT. They prepared the first certifying ABVT examination which was given in 1967 (see www.abvt. org). I was pleased to be one of seven

individuals in the first class certified, based on examination, as Diplomates of the ABVT.

The SOT, with the world's largest membership of toxicologists, was organized in 1961 (see www.sot.org). Many of the organizers of the SOT were members of the American Society for Pharmacology and Experimental Therapeutics (ASPET) who felt toxicologists needed a "home" of their own. I recall attending an organizational meeting of the SOT held in conjunction with an ASPET meeting at the University of Rochester and the excitement and enthusiasm of the attendees for creating the SOT. As an aside, it would be a few years before I felt my credentials were sufficient that I could apply for membership in the SOT. The SOT fostered the creation of the ABT which held its first certifying examination in 1980 (see www.abtox.org). I was pleased to be one of the first class of individuals certified, based on examination, as Diplomates of the ABT. The SOT includes a number of specialty sections including the Comparative and Veterinary Specialty Section.

A third certifying entity, the ATS, which accepts individuals as Fellows based on a review of credentials, was created in 1981 (see www.acadtoxsci.org). Many veterinary toxicologists belong to all of the organizations noted above and some have been certified by one or more of the certifying organizations: the ABVT, ABT and ATS. Veterinary toxicology has evolved greatly over the past several decades.

# EVOLUTION OF VETERINARY TOXICOLOGY

## Roots in veterinary medicine and toxicology

The evolution of veterinary toxicology occurred concurrently with evolution of its two roots: the profession of veterinary medicine and the science of toxicology. The veterinary medicine profession was initially focused on domestic animals, particularly those used for food, fiber, transportation and to provide power for agricultural endeavors and transportation. With the growth of more specialized agriculture and production practices, the profession with its linkage to domestic livestock stimulated growth of the profession. Veterinary toxicology focused on poisonous plants and then on antidotes for various toxins. The early part of the 20th century presented a special challenge for veterinary medicine as the use of horses and mules in agriculture decreased in favor of the use of equipment powered by internal combustion engines. During this period of time, there must have been considerable uncertainty as to the future of the profession.

By the mid-20th century three movements transformed veterinary medicine. The first related to the traditional roots of the profession in animal agriculture and related to the increasing emphasis given to large-scale highly specialized livestock endeavors. The second related to the increased attention given to providing veterinary medical services to a growing population of companion animals. In both areas the science of veterinary medicine was strengthened as observation-based medical practice was complemented and, ultimately, supplemented by science-based medicine. During this period, veterinary toxicologists began to play an important role in veterinary medical diagnostic laboratories, both in veterinary medical colleges and in state and federal agencies. With the strengthening of the science base of veterinary medicine, including the quality of the science in the veterinary medical curriculum, the third movement, the emergency of the comparative medicine character of veterinary medicine, became more apparent and was enhanced (Wilkinson, 2005). These changes in the profession were accompanied by increased involvement of veterinarians in research on the species of traditional concern to the profession, domestic and companion animals (Stahlheim, 1994), and to participation in a broader range of biomedical research activities, involving use of the traditional laboratory animal species, driven largely by concern for human health (Wilkinson, 2005).

## Emergence of science-based toxicology

Toxicology, like veterinary medicine, was also rapidly changing and evolving in the mid-20th century. The previous strong emphasis on field observations was first complemented and then supplemented by experimentation. This led to the current strong mechanistic orientation of toxicology. With this shift in toxicology came an increased awareness of the utility of a comparative medicine orientation in research directed primarily toward improving human health (Wilkinson, 2005). With this comparative medicine orientation came increased opportunities for individuals educated in veterinary medicine, including veterinary toxicology, to contribute to general toxicology and biomedical science.

These changes in the veterinary medical profession and the emergence of toxicology as a science came during a period when the public was giving increased attention to the health risks, and its counterpoint safety, of new technologies and products. A landmark of the era was publication of Rachel Carson's book, *Silent Spring* (Carson, 1962). She focused on both human health impacts and impacts on the total ecosystem of which people were just a part. Her book was certainly one of the key stimuli to a tidal wave of legislative actions in the United States that focused broadly on the environment with concern for clean air and water; safe food, pharmaceuticals, pesticides, fungicides, rodenticides and consumer products; and a safe working environment.

The legislative actions and related administrative actions in the 1970s created the US Environmental Protection

Agency (USEPA), the Consumer Product Safety Commission, the National Institute of Occupational Safety and Health (NIOSH), the National Center for Toxicological Research, the National Institute of Environmental Health Sciences and the Cancer Bioassay Program within the National Cancer Institute, which evolved into the National Toxicology Program (NTP) now administered by the National Institute for Environmental Health Sciences. This was also a period of rapid expansion of research activities in the pharmaceutical food, chemical and petroleum industries. The chemical industry in 1976 started the not-for-profit Chemical Industry Institute of Toxicology, which now exists as the CIIT Center for Health Sciences, to test commodity chemicals, investigate the mechanisms of chemical toxicity and train additional toxicologists. The Food and Drug Administration (FDA) continued its traditional dual emphasis of ensuring both the efficacy and the safety of drugs and medical devices continued. Increased emphasis was given by the FDA to veterinary drugs and to the potential for veterinary drugs to contaminate meat and milk.

Increasing public concern for safety/risk and the resulting legislation led to the development of increasingly formalized approaches to both safety and risk analysis. This included more clearly defined roles for using the results of toxicological studies, including studies with laboratory animals, to assess the safety, or conversely risk, to humans of the use of pharmaceuticals, other products in commerce, and technologies.

## Toxicology joined to the risk paradigm

As noted earlier, federal legislation passed in the 1970s focused on the health impacts of environmental and occupational exposures and led to more formalized approaches to evaluating the risks and safety of various exposures. The risk paradigm built on the long-standing paradigm linking sources to exposure to dose to adverse health outcomes that had guided toxicology from its earliest days (Figure 1.1). I have reviewed elsewhere the development of the risk analysis paradigm (McClellan, 1999). The risk analysis paradigm originally proposed by the National Research Council (NRC, 1983) and used by the USEPA is shown in Figure 1.2. A later report *Science and Judgment in Risk Assessment* (McClellan, 1994; NRC, 1994) and reports from the Risk Commission (1997) re-affirmed use of the risk paradigm which continues to be a cornerstone of activities not just at EPA but in other national and international agencies and in the private sector.

The original key elements of the risk paradigm were (1) hazard identification, (2) exposure–response assessment, (3) exposure assessment and (4) risk assessment. The NRC (1994) report emphasized the importance of a fifth element – using the results of the risk analysis to guide future research and, thus, reduce uncertainty in future risk estimates. In addition, I have added a sixth over-arching element - risk communication. The hazard identification element has been a source of contention and confusion both with the public and in the scientific community, especially with regard to cancer as I will discuss later.

Hazard is defined as the potential for an agent under some conditions of exposure to cause an adverse effect (NRC, 1983, 1994; McClellan, 1999). With this definition the level of exposure or dose required to produce an adverse health effect is not considered. An agent may be classified as a hazard irrespective of whether or not the exposure conditions required to elicit adverse effects are relevant to human situations. The exposure–response assessment involves characterization of this relationship as it may pertain to likely levels of human exposure. The exposure assessment quantifies, either retrospectively or prospectively, the likely duration and intensity of human

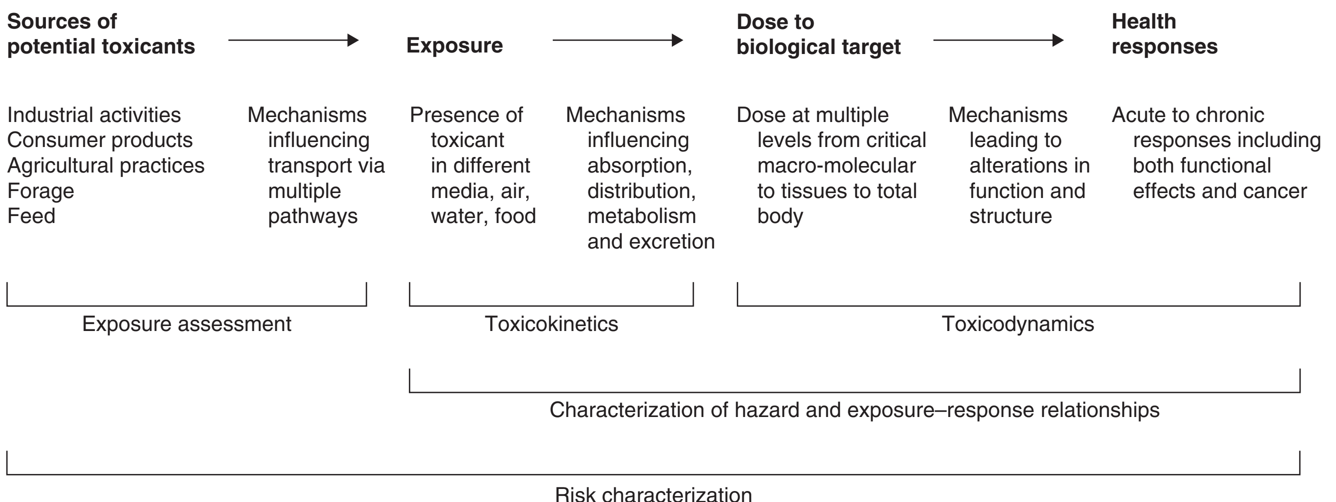

**FIGURE 1.1** Critical linkages for integrating information from sources of toxicants to the development of adverse health effects.

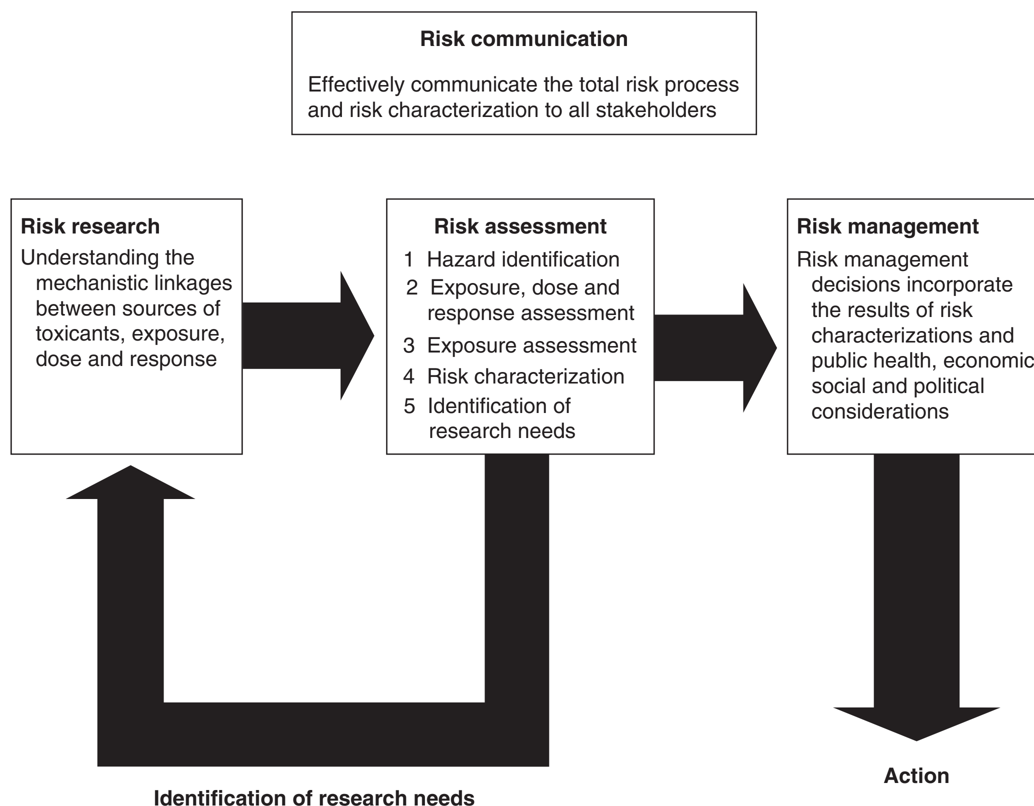

**FIGURE 1.2** Risk paradigm for evaluating potential health impacts of a toxicant.

exposure to the hazardous agent. The risk assessment element brings together information from the other three elements to characterize risk as illustrated in Figure 1.1. Risk is defined as the probability of occurrence of an adverse health effect from exposure to a hazardous agent at a specified duration and intensity of exposure. As an aside, especially in Europe, the word hazard is used as risk has been defined in the United States. Safety is defined as being a condition with a high probability of freedom from any increase in adverse health outcome when the agent is used in a specified manner. Obviously, both safety and risk are relative recognizing that it is not possible to ensure absolute freedom from some small level of risk.

The more formalized risk analysis approaches developed starting in the 1970s built on approaches developed earlier for providing guidance for controlling occupational exposures, the intake of contaminants in food and the safety of pharmaceutical agents. Pre-World War II, the primary focus was on adverse health outcomes that caused functional impairment such as decreased respiratory function. As will be discussed later, the issue of carcinogenic responses received limited attention before World War II. The approach to developing guidance for the control of toxicants was based on the assumption that a threshold exists in the exposure (dose)–response relationship – just as discussed by Paracelsus. The threshold exposure–response

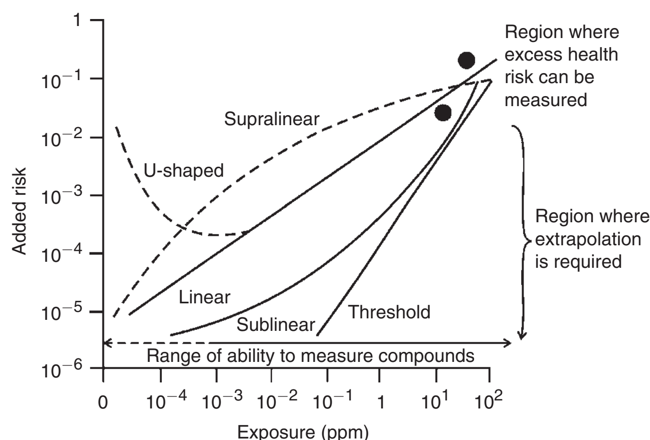

**FIGURE 1.3** Schematic rendering of exposure–response relationships for various toxicants.

relationship is shown in Figure 1.3 along with four other relationships: sub-linear, linear, supralinear and a U-shaped or hormetic function. Note that both scales in this schematic rendering are logarithmic.

Technically, in hormesis there is a beneficial effect at some low level of exposure which decreases with increasing exposure/dose and at yet higher levels adverse effects become apparent. During the last decade, there has been

increased discussion of the concept of hormesis in which very low-level exposures have positive effects with negative effects observed only at higher exposure levels (Calabrese and Baldwin, 2003; Calabrese and Blain, 2005). The concept of hormesis is well known to veterinarians who are aware that certain agents, such as vitamins and minerals, are essential for life at low concentrations and can produce toxicity with excess intake.

As an aside, there has been on-going debate for decades as to whether linear exposure–response relationships, especially for cancer, are realistic, i.e. an added level of exposure, regardless of how small, results in a calculable monotonic increase in cancer risk. It has been argued by some that the linear exposure–response model is appropriate for regulatory purposes for assessing cancer risks because every dose of a new agent is added to a background of genetic damage in somatic cells arising from multiple agents and endogenous factors.

The early development of threshold limit values (TLVs) for control of occupational exposures by the American Conference of Governmental Industrial Hygienists (ACGIH), organized in 1938, assumed the existence of thresholds in exposure–response relationships. The initial data were provided primarily by opportunistic studies of exposed human populations. In the absence of human data, data from controlled exposure studies in laboratory animals were used. This necessitated the use of safety factors to account for inter-individual variability, inter-species extrapolation and duration of the study as will be discussed later. The original safety factors were formally proposed by Lehman and Fitzhugh (1954) of the FDA. Later, the USEPA was organized and began using the same factors. However, the EPA identifies them as uncertainty factors apparently out of a desire to avoid use of the potentially contentious word – safety.

Post-World War II increased public concern developed for the occurrence of cancer. This was stimulated by multiple factors. Extensive research conducted during and after the war on the effects of both external ionizing radiation and internally deposited radionuclides emphasized the importance of cancer as a radiation-induced disease. Concern for radiation-induced cancer was further heightened when the intensive follow-up of Japanese A-bomb survivors revealed an increase, first in hematopoietic neoplasms, and, later in solid cancers. These findings soon led to abandoning a threshold approach to evaluating radiation risks in favor of using a probabilistic approach to assess the health risks of using radiation devices in space and nuclear power. The probabilistic approach using the linear exposure–response model discussed earlier was convenient to use because it could be readily applied to assessing the risks to individuals or populations. My first experience with probabilistic risk assessment came in the mid-1960s when I was on a temporary assignment with what was then the US Atomic Energy Commission (AEC). I worked with a joint AEC–National Aeronautical and Space Administration assessing potential human cancer risks of accidents involved with the launch of spacecraft containing plutonium-238 fueled thermal electric power systems.

Another factor influencing public concern was the increasing incidence of total cancers being observed in all of the economically developed countries including the US driven largely by lung cancer. It is now well known that the increase in lung cancer, first observed in men and then in women, was largely related to cigarette smoking. Rachel Carson's book also helped to create concern for exposure to man-made chemicals contributing to the increasing incidence of cancer. It is now known that this is not the case (Gold *et al.*, 2003).

The experience with radiation soon resulted in its use as a proto-typical carcinogen in developing approaches to risk analysis and risk regulation. Albert (1994) documented the development of the USEPA's approach to assessing cancer risks. Key assumptions in the approach were (a) cancer-causing chemical agents acted like radiation in causing cancer; (b) there was a linear relationship between exposure (dose) and increased risk of cancer extending to the lowest levels of exposure; (c) agents causing cancer in laboratory animals could be viewed as also causing cancer in people and (d) exposure–response relationships could be extrapolated between species by considering differences, body weight and surface area, i.e. metabolic activity. These assumptions were viewed as default options to be used in the absence of specific scientific data to the contrary (McClellan, 1994, 1999, 2003; NRC, 1994).

In response to public concern for chemicals causing cancer, the International Agency for Research on Cancer (IARC) became the first organization to propose a scheme for classifying agents as to their carcinogenic potential (IARC, 1972). The view was that if cancer-causing chemicals or other agents, such as radiation, or workplace conditions involving exposure to chemicals or other agents could be identified, then these could be controlled and the occurrence of cancer in people reduced. The IARC carcinogen classification scheme considers human, laboratory animal and supporting data to classify agents or workplace conditions as (1) carcinogenic to humans, (2) probably carcinogenic to humans, (3) possibly carcinogenic to humans, (4) not likely to be carcinogenic to humans or (5) not classified as to carcinogenicity. The IARC classification is strictly hazard oriented, it does not formally evaluate the potency of these agents for causing cancer at a specific level of exposure. The USEPA, the NTP and other organizations have developed similar carcinogen classification schemes (EPA, 1986, 2005a, b; NTP, 2005). In recent years, IARC (1991) has made provision for increased use of mechanistic data in classifying chemicals as human carcinogens. Both the EPA and NTP now also give increased emphasis to the use of mechanistic data in classifying chemicals as carcinogens

(EPA, 2005a, b) unlike IARC and the NTP, the EPA does develop estimates of cancer-causing potency for some agents classified as having cancer-causing potential. This in turn, using measurements or estimates of exposure, provides the basis for calculating lifetime cancer risks for individuals or populations.

It should be apparent that the cancer classification of a given agent is insufficient for characterizing cancer risk since the hazard-based classification does not include an estimate of the agent's potency. The USEPA has estimated the carcinogenic potency for a number of chemicals. The results are usually related as the concentration of a chemical in water or air that will result in a calculated one in a million probability of cancer occurring above the background incidence (EPA/IRIS, 2006). To estimate the cancer risk for any agent and exposure situation, it is also necessary to estimate the exposure to the agent, both as to intensity and duration. In short, risk is a product of exposure and the potency of the agent for causing the effect.

There has been a tendency for regulatory agencies, such as the USEPA, to use their experience with classifying chemicals as to their carcinogenic potential as a template for also classifying chemicals as to their potential for producing other non-cancer hazards. Thus, there has been a trend toward classifying chemicals as to their potential hazard for causing different health outcomes and labeling them as such, i.e. neurotoxins, reproductive toxins, hepatic toxins, etc. Indeed, some even broader classifications have emerged, i.e. endocrine disrupting chemicals. In my view, this short-hand approach to identifying and classifying hazardous agents as to their potential to cause cancer or other effects is confusing to the public. In my view, the labeling approach has contributed to both radiation reactions and chemical phobia and sometimes irrational actions. It certainly flies in the face of the fact that for many chemicals the admonishment of Paracelsus that "the dose makes the poison" remains true for many chemicals. For many chemicals, even when toxic effects are apparent at high doses, these same adverse effects are no longer manifest at sufficiently low doses. Gold *et al.* (2003) have discussed the challenge of using high exposure (dose) animal studies to identify either man-made or natural chemicals as human carcinogens.

## A FRAMEWORK FOR ACQUIRING INFORMATION

### Linkages from sources to health impacts

The purpose of this section is to provide a conceptual framework for using information to evaluate specific cases of actual or alleged toxicosis and to facilitate the acquisition of new knowledge that will have impact in understanding potential toxic effects. Earlier, in Figure 1.1, a conceptual framework was provided for evaluating the linkages extending from a source of a toxic material to manifestation of an adverse health outcome in an individual or a population. The conceptual framework is equally applicable to humans or other animal species.

The source to exposure linkage has been expanded in Figure 1.4 (Paustenbach, 2001). In this example, an industrial plant is illustrated as the source. The figure serves to illustrate the complex nature of the exposure pathways that may be encountered including the role of livestock. The focus in the figure is on the multiple pathways by which a potential toxicant may reach a human population: inhalation, drinking water, dermal absorption, ingestion of soil, and ingestion of a variety of foodstuffs including milk and meat from domestic animals. All of these pathways might also serve to expose the cow in the figure to the toxicant. The quantities of the toxicant taken in by the cow could cause toxicity in a herd of cows. Equally as important is the role of the cow as a pathway for the toxicant to reach people. For example, the figure illustrates that a toxicant could be present in cow's milk and the milk could be consumed by people. The cow could also be slaughtered and the meat

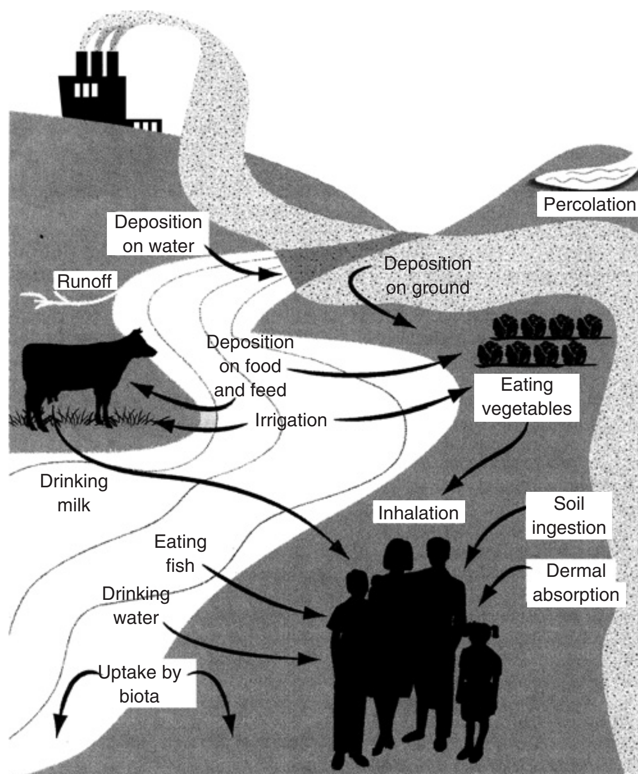

**FIGURE 1.4** Schematic rendering illustrating exposure pathways extending from a source of toxicants to exposure of livestock and people (from Paustenbach, 2001).

ultimately consumed by people. Thus, it is important to recognize that the cow, or any other food animal species, can both manifest toxic effects and serve as a pathway for toxicants to reach people via the food supply.

It is readily apparent that the schematic rendering shown in Figure 1.4 can be expanded or contracted. In natural ecosystems, multiple species might be involved as a toxicant moves from a source or multiple sources via various pathways. In some cases, various species in the ecosystem may be impacted as individuals. Moreover, natural populations may be impacted. In addition, these pathways may ultimately result in the toxicant reaching people. An example is mercury in fish. In practice, veterinarians may encounter situations where poisonous plants in the pasture or in harvested forage may be the source of the toxicant. Feed may be contaminated at a mill and serve as the pathway by which a toxicant reaches the livestock. In other cases, the potential human toxicant may be a pharmaceutical purposefully given to the cow.

## Toxicokinetics

The simple schematic rendering shown in Figure 1.1 can be used to illustrate several important concepts. First, it is important to recognize that contrary to common usage, exposure and dose are not the same. The exposure environment is characterized by the concentration of the toxicant in the media, be it water, air or feed, the quantities taken in and the time course of the intake. Dose is the concentration, over time, of the toxicant in the various tissues of the subject, whether it be a cow, a human or a laboratory rat. The characterization of the kinetics linking exposure with dose is referred to as toxicokinetics (for a toxic agent) or pharmacokinetics (for a pharmaceutical). In actual practice, the term pharmacokinetics is frequently used when it would be more appropriate to use the term – toxicokinetics. Several chapters in this book deal specifically with kinetics of toxicants and pharmaceuticals.

Toxicokinetics (see Figure 1.1) are used to describe the movement and disposition of the toxicant in the organism. This includes consideration of the route of entry: ingestion, inhalation, dermal or purposeful administration by injection. A complete description of the toxicokinetics of a toxicant will take into account (a) the intensity and duration of the exposure, (b) the rate and amount of absorption of the toxicant from the site of entry, (c) the distribution of the toxicant within the body, (d) potential biotransformation to less, equal or more toxic form and (e) the rate of excretion by route (urine, feces or exhalation). All of these aspects of toxicokinetics may be influenced by species differences in physiological and biochemical characteristics. Modern approaches to modeling toxicokinetics attempt to take account of both species differences and similarities in influencing the fate in the body of toxicants. It is also important to recognize that the exposure or dose level may influence the kinetics of a toxicant and its metabolite(s). This is an especially important consideration in extrapolating from laboratory studies that may be conducted at high doses to lower more environmentally relevant exposures/doses.

## Toxicodynamics

The linkage between dose and adverse health outcome shown in Figure 1.1 involves multiple mechanisms as various toxicants may potentially impact all the cells and organ systems of the body. Increasingly, scientists have attempted to model these relationships which, in parallel to the nomenclature for the kinetic phase, are called toxicodynamic or pharmacodynamic models. It is obvious that multiple pathways may be involved in a toxicant producing disease and that knowledge of the individual steps will increase as knowledge of basic biological mechanisms increases. For example, the explosion of knowledge of basic biology at the level of the genome (genomics), proteins (proteomics) and metabolism (metabolomics) has provided a basis for exploring the mechanistic basis of toxicant-induced disease with a degree of refinement that could not even be envisioned even a short time ago.

A later chapter reviews the basic mechanisms of toxicity. In addition, many of the chapters on organ toxicity and specific toxicants contain detailed information on mechanisms of toxicity. As the reader reviews this material, and especially the detailed discussion of biochemical mechanisms of action, it will be important to place those in the context of processes at the cellular and tissue level; i.e. inflammation, cell death, cell proliferation, hypertrophy, hyperplasia, metaplasia and neoplasia. A strength of the veterinary medical curriculum, as with the human medical curriculum, is the emphasis given to understanding both normal and disease processes extending from the molecular level to cells to tissues to organs and, ultimately, to the integrated mammalian organism. A special opportunity exists for medically trained personnel, both veterinarians and physicians, to put the expanding knowledge of molecular and cell processes into the context of overt disease. After years of emphasis on a reductionist approach to basic biomedical science, it has become recognized that this approach needs to be complemented by an integrative approach. This has recently been termed systems biology. In my view, this is not really a new concept. It is more a rediscovery and refinement of the concepts of integrated biology and pathobiology used in veterinary medicine for decades.

There has been great enthusiasm for the use of mechanistic information in safety/risk evaluations as will be discussed later. Recognition of the difficulty of characterizing of all the individual mechanistic steps has given rise to a new term – mode of action. The mode of action has

been defined as the dominant step(s) involved in producing a given toxic endpoint. An example is the role of cell killing as the mode of action for large intakes of chloroform (Butterworth *et al.*, 1995) or formaldehyde (Conolly *et al.*, 2004), over extended periods of time causing tumors in rodents. The exposure–response relationship for cell killing may likely have a threshold which must be considered in extrapolating the findings from high exposure level studies in rodents to humans exposed to low concentrations of these chemicals.

It is my contention that understanding the basic concepts conveyed in Figures 1.1, 1.2 and 1.4 can be very useful in investigating a range of situations where the objective is to establish or refute a causal association between a given source and toxic agent and an increased incidence of an adverse health outcome. I use the term, increased incidence, advisably recognizing in most situations involving domestic animals, either as commercial herds or as companion animals, the situation is one of presence or absence of a given disease and the "ruling out" of other differential diagnoses. However, in situations involving human populations the issue frequently encountered is whether a given toxicant exposure has caused an increase in a disease recognizing that most diseases may have multiple etiologies, e.g. hypertension and diabetes. This is especially the case in evaluating diseases that typically occur late in life, such as cancer and chronic diseases, and with exposure to toxicants that may occur at low levels over long periods of time. In some cases, such as lung cancer and cardiorespiratory disease in humans, a risk factor such as cigarette smoking is so substantial, it is a challenge to determine if low-level exposure to other toxicants such as air pollutants has chronic effects at low exposure concentrations.

## Veterinary toxicology is multi-faceted

It will be apparent to the reader of this book that veterinary toxicology is multi-faceted. Thus, there are many ways to organize and synthesize the knowledge base that we call veterinary toxicology. One dimension is the various classes of toxicants. Another dimension of the field relates to the media that contains the toxicant: air, water, soil and feed. Another dimension considers the various routes of exposure of toxicants: inhalation, ingestion, dermal or purposeful injection. It is also convenient to consider the various organ systems and processes that may be affected by toxicants. This is the basis for organization of a major section in this book. It is also important to consider the individual toxicants or classes of toxicants. This approach is used in organizing another major section of this book. Finally, veterinary toxicologists recognize the necessity of considering the various species of concern. Increasingly veterinary medical practitioners have become more specialized with many focusing their clinical skills on a single species. This book does not include a section addressing the toxicology of individual species. To have done so would have substantially increased the size of this text. However, chapter authors have endeavored to discuss species variations in responses to toxic agents. It is noteworthy that at least one textbook, that of Peterson and Talcott (2006), focuses on small animals. Some of the major comprehensive veterinary medicine texts that focus on other species include chapters on toxicology related to that species such as the *Current Veterinary Therapy* series.

# SOURCES OF INFORMATION

## Case observations in the species of interest

There are multiple sources of scientific information for characterizing the relationship between exposure to a toxicant and toxicant-induced response. Figure 1.5 is a schematic rendering of the multiple sources of information that may be used to understand the toxicity of a given agent.

As discussed earlier, the origins of veterinary toxicology and toxicology, in general, are both rooted in observations. An adverse health effect, either a pattern of morbidity or death in an individual or population, is observed and the disease linked to exposure to a toxicant. Typically, the time interval between exposure and the adverse health outcome was brief which aided in deducing an association. Because the causal association was identified in the species of interest, whether it be a person, a horse or a cow, it was

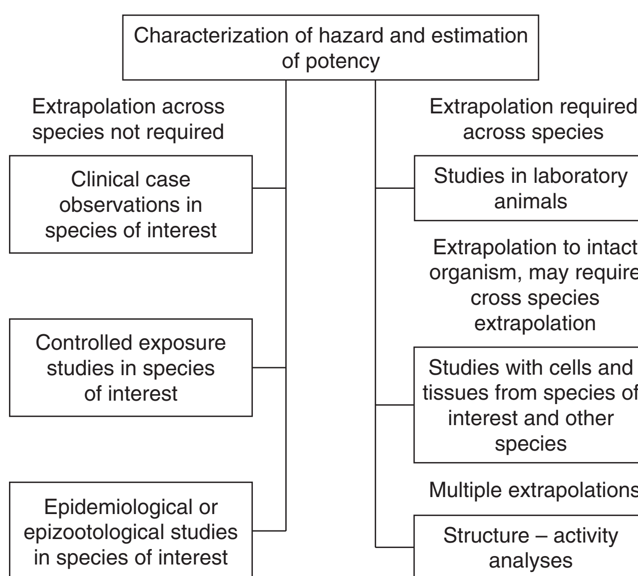

**FIGURE 1.5** Sources of information for evaluating potential toxicants.

not necessary to extrapolate between species. Nor was it necessary to explore in depth the mechanistic basis for the causal association to either diagnose a particular case or prevent future cases. Action to prevent exposures and, thus, prevent disease, could be based on empirical observations.

As you read many of the chapters in this book, you will note that details of the mechanism by which a particular toxicant causes disease have been elucidated to a variable extent. When the toxicant is exclusively of concern in veterinary medicine and has no implications for human health, there has been limited impetus for developing a mechanistic understanding of how a toxicant causes disease. Concern for human health has been a major driver of the biomedical research agenda. An obvious exception is when the toxicoses observed in veterinary medicine have large economic impact or toxicants can reach people via animal products.

There are many circumstances where observational knowledge is not adequate and it is necessary to conduct experiments to characterize the toxicology of an agent. It is obvious that if concern for the potential toxic response is in a non-human species, controlled experiments can be conducted using the species of interest. This is obviously the case for domestic livestock as well as companion animals.

A much more common situation is when concern focuses on potential toxicity of a newly developed agent for use in people or animals. For example, it is necessary to establish the safety of a potential new pharmaceutical or consumer product before it is introduced into commerce. In these instances experimental animals are used as a "first approximation" of the safety of the new compounds to humans. In the case of products intended for use in animals, studies on both efficacy and safety can be conducted in the species of interest. This remains an imperative step in the safety evaluation of new products. There are also circumstances in which it is desirable to extend limited observations from opportunistic studies on people or animals that have been exposed. When a new product is developed and marketed, either a pharmaceutical or a consumer product, various post-marketing surveillance systems should be put in place to attempt to detect any unexpected adverse outcomes.

## Epidemiological/epizootological studies

If a particular chemical has been used for an extended period of time and human exposure has occurred either in the workplace or from the environment, it may be feasible to conduct epidemiological studies. Epidemiology is the study of how disease is distributed in the population and the factors that influence or determine this distribution. The design of a particular epidemiological study will be guided by the hypothesis being tested and the nature of the population(s) available for study. As an aside, the term epidemiology (epi for across, dem for people and ology for scientific study) is applicable to people while the more appropriate related term for studies on animals would be epizootology (epa for across, zoo for animal and ology for scientific study). The details of conducting epidemiological or epizootological studies are beyond the scope of this chapter. A relevant reference for basic concepts in epidemiology is the text by Gordis (2005).

Retrospective epidemiological studies may be feasible for previously introduced agents for which prior exposure has occurred or prospectively for a newly introduced agent. If the agent is new it is obvious that it is not feasible to conduct epidemiological studies to retrospectively evaluate the potential safety/hazard of the agent. If the ultimate interest is in the effects on people, it may be feasible to conduct controlled exposure studies with human volunteers. It is advisable for the planning of such studies to be based on a solid database on the potential toxicity of the agent acquired from studies in laboratory animals. The design and conduct of such human studies must be guided first and foremost by ethical considerations (NRC, 2004). If a non-human species is the target species of concern, then it is obvious that the most relevant information is that acquired from studies conducted in that species.

## Experimentation

An additional option for acquiring information is to conduct toxicological studies in the typical laboratory animal species. Such studies are the cornerstone of research conducted to evaluate the safety/risk of newly synthesized agents whether they be a potential new pharmaceutical, pesticide or herbicide, a significant consumer product or a new chemical or intermediate to be used in commerce. It is well recognized, certainly by veterinarians, that no single laboratory animal species is a miniature version of the human species, i.e. 15 cm in height, weighing 180 g and sharing all of the common biological traits of humans. Fortunately, humans and laboratory animals do share many common biological traits. Knowledge of the extent to which there are similarities and differences between humans and a given laboratory animal species can be used to guide the selection of a species to serve as a surrogate for humans in developing data for safety/risk evaluations for humans. It is encouraging that some veterinary medical schools are recognizing the importance of extending the range of species studied in the core curriculum from the usual companion animal and domestic livestock species to include the common laboratory animal species.

At this juncture, it is appropriate to note the importance of animal welfare issues. The Animal Welfare Act (AWA), initially enacted in 1966 and amended in 1970, 1976, 1985, 1990 and 2002, is the principal federal statute in the United

States governing the sale, handling, transport and use of animals. The AWA applies to all species of warm-blooded vertebrate animals used for research, testing or teaching excluding animals used for agricultural research. The US Department of Agriculture, Animal and Plant Health Inspection Service has responsibility for implementing the AWA. The 1985 Amendments to the AWA clarified the importance of humane care, minimization of pain and distress, consideration of alternatives, the role of institutional animal care and use committees, the psychological well-being of primates and exercise for dogs. The primary reference on animal care and use is the *Guide for the Care and Use of Laboratory Animals* prepared under the auspices of the Institute of Laboratory Animal Resources of the National Academy of Sciences/National Research Council (ILAR, 1996). All toxicologists involved with laboratory investigations should be familiar with the contents of the guide irrespective of the species they use for their research.

An additional matter the experimentalist should be aware of is the need for use of good laboratory practices (GLPs) in the conduct of research intended to be used for regulatory decisions. Both the FDA (FDA, 2001) and the EPA (TSCA, 1985; FIFRA, 1991) have requirements for the use of GLPs. The FDA GLP requirements do not extend to exploratory, mechanism of action or efficacy studies. The basic elements of GLPs are (1) the appointment by the institution of a study director, (2) the use of an independent quality assurance unit, (3) the use of documented standard operating procedures, (4) a written protocol for each study and (5) preparation of a final report containing a GLP compliance statement for each study. The use of GLPs is not required by FDA for studies with domestic livestock. However, investigators conducting studies using domestic livestock would be well advised to attempt to adhere to the basic principles that under-gird GLPs to help ensure the quality and reproducibility of the data being generated.

Another option for acquiring useful toxicity data is to conduct investigations in *in vitro* using tissues or cells from mammalian species, both humans and laboratory animals, and using bacteria and yeasts. An additional option is to conduct structure–activity analyses on the new agent using the large data bank of structure–activity information already available on other related chemicals.

All of the options outlined, to some extent, create extrapolation issues. Even if studies are conducted in the species of interest, it is typically necessary to extrapolate from the high levels of exposure or administered doses studied experimentally to lower exposures or doses anticipated to be representative of intended use. It may also be necessary to extrapolate from a relatively short period of study, say days or a few weeks, to the intended period of use, over months or years. If the studies are not conducted in the species of ultimate interest, there is need to extrapolate between species. It may also be necessary to extrapolate observations made in a population of healthy individuals to a population that includes individuals with pre-existing disease. Some aspects of the extrapolation between species and across exposure/dose levels may be facilitated by physiologically based toxicokinetic and toxicodynamic modeling. However, toxicodynamic modeling is still in its relative infancy.

It is important to recognize that even with today's level of knowledge of these extrapolation issues, it is not possible to estimate, with absolute certainty, the precise numerical level of human exposure to a given agent that may be without any risk of potential harm or will produce a specific level of harm. This is generally recognized in contemporary safety/risk evaluation methodology such that conservative approaches are used in estimating safe levels of human intake of chemicals. By taking a conservative approach to setting standards or providing guidance to limit exposures, there can be a high degree of confidence that an agent can be used safely if used as intended. Ultimately, all processes that develop guidance or standards to limit exposures and thus limit disease require judgments to be exercised. In short, science can inform the standard or guidance development process; however, it cannot prescribe specific standards.

# SCHEMATIC EXPERIMENTAL DESIGNS

The experimental design for testing of any specific hypothesis must be matched to the hypothesis, the desired statistical power and the resources available. Inevitably, decisions on an experimental design involve making difficult choices among options because of resource constraints. In this section, two schematic experimental designs will be discussed to illustrate some of the key issues that must be addressed in planning toxicological studies. The discussion in both cases will assume that the species to be used in the study has already been selected.

## Acquiring toxicokinetic data

The first design, Figure 1.6, illustrates an approach to acquiring data for understanding the link between exposure and internal dose, the kind of data that can be used for toxicokinetic modeling. Recall the toxicokinetic linkage in Figure 1.1. The design shown is based on a single brief intake of the test agent. However, the design can be modified for studying chronic intake of an agent. A critical decision is the choice of the route of administration or intake of the test material. Obviously, such studies are most readily carried out with parenteral administration of the agent. This may be the most appropriate route for a pharmaceutical

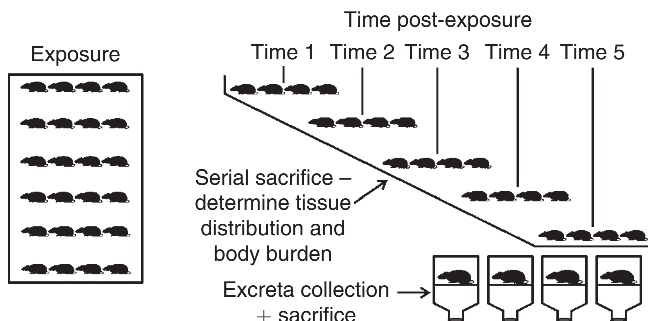

**FIGURE 1.6** Schematic rendering of an experimental design for evaluating the kinetics of an administered toxicant.

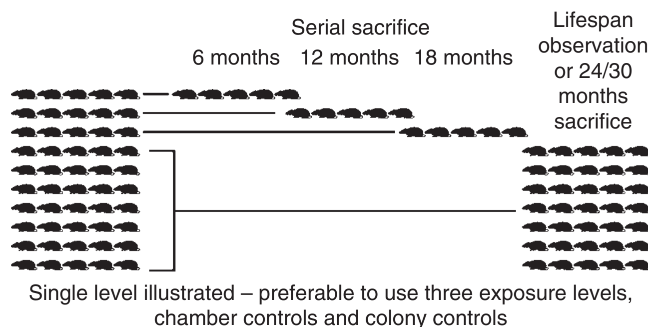

**FIGURE 1.7** Schematic rendering of an experimental design for evaluating exposure (dose)–response relationships for a toxicant.

agent that is to be parenterally administered. However, the resulting data may be of limited relevance to other routes of intake. For example, it may not appropriately mimic oral intake since only a small fraction of some toxicants may be absorbed from the gastrointestinal tract. In short, the route of administration should be matched to the route of concern for real-world exposure to the agent.

With inhalation, the particle size distribution of the airborne toxicant will influence what portion of the inhaled material will be deposited and where it is deposited in the various regions of the respiratory tract. The pattern of retention and subsequent translocation of the deposited material will depend on the size, chemical composition and dissolution properties of the deposited material.

Another key decision is whether conduct of the toxicokinetic studies may be facilitated by using a test agent labeled with radioactive or stable element tracers. Analytical considerations for the initial toxicant as well as any metabolite are of major importance in the conduct of toxicokinetic studies.

The schematic design (Figure 1.6) shows a group of animals maintained for collection of excreta and, perhaps, even sampling of expired air. Data from these analyses can be used along with tissue analyses to obtain a mass balance between the quantity administered and the quantity recovered. The schematic design shows multiple times at which animals will be euthanized and tissues collected for analysis. This allows the development of a dynamic profile of how the body handles the administered material. For organic compounds, provision needs to be made for analyzing for both the parent compound and potential metabolites.

The selection of the sacrifice times will be guided by the anticipated kinetic profile of the agent and its metabolites. It may be useful to obtain preliminary information on retention kinetics from pilot studies. Some organic compounds may be rapidly metabolized leading to the need to schedule all of the sacrifices over a few hours. On the other hand, certain inhaled relatively inherent materials may have long-term retention in the lungs extending over hundreds of days. It is important to recognize that the quantity of material administered may influence the kinetics of the material. Hence, it is desirable to use multiple administered exposure/dose levels as an experimental variable. Without question, the design of any particular toxicokinetic study requires the exercise of considerable professional judgment. Toxicological research is not a “cookie cutter” or “check the box” science.

## Acquiring exposure (dose)–response data

A schematic experimental design for a study to evaluate exposure (dose)–response relationships for toxicants is shown in Figure 1.7. Recall the exposure–response linkage shown in Figure 1.1. The design shown is typical of that which might be used in the conduct of a 2-year bioassay, typically to evaluate carcinogenicity, in rats and mice. The same design, and indeed the same experiment, can be used to evaluate other endpoints and to conduct shorter-term studies. The study should involve administration of the material by a route matched to likely exposure conditions to be encountered with the agent. Administration of an agent by gavage may be acceptable as a surrogate for ingestion, especially when it is desirable to administer specific quantities of material. However, I am not enthusiastic about the repeated use of gavage as a substitute for ingestion of an agent in feed. The use of intratracheal instillation as a surrogate for conducting inhalation exposures to an agent remains controversial. It is my professional opinion that intratracheal administration is a non-physiological mode for delivery of materials to the respiratory tract. It may result in exaggerated quantities of material being deposited in some regions of the respiratory tract while other regions are spared any exposure. This unusual pattern of distribution of the agent is very likely to influence the toxic response of the airways and alveoli. Thus, I am hesitant to even recommend intratracheal instillation for mechanistic studies; the mechanistic information acquired may be irrelevant to the inhalation exposure situations that are of concern for people.

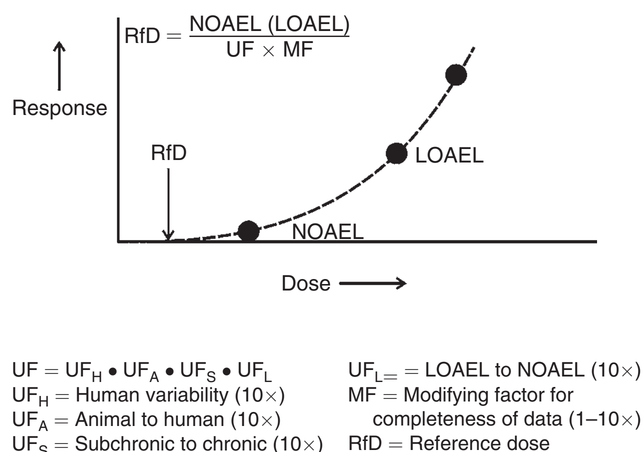

**FIGURE 1.8** Schematic rendering of a threshold exposure–response relationship.

It is critical that exposure–response studies utilize multiple exposure levels, perhaps three or four exposure levels. The choice of the specific exposure levels is one of the most important decisions to be made in planning such studies. One consideration relates to the potential level(s) of exposure to be encountered with intended use. Higher additional levels can be selected above this base level. Selection of exposure/dose levels can also be informed by the results of the kinetic studies. For example, it would not be desirable to use only exposure levels above a level at which metabolic processes are saturated. Another consideration emphasized by the EPA and NTP, especially when cancer is an endpoint, is to select a maximum tolerated dose (MTD) level as the highest exposure/dose level and establish lower levels by some fraction of the MTD level, perhaps 1/2 and 1/4 or 1/3 and 1/9. The use of an MTD has been justified on the grounds that it is necessary to maximize exposure to potentially observe carcinogenic responses recognizing the blunt experimental approach (NRC, 1993).

The extent to which animal bioassays are a blunt approach to detecting the carcinogenic potential of agents is illustrated in Figure 1.8. It can be noted that for a species and train of animals with a background incidence of 1%, a study of 50 animals will require a 20% response to detect a statistically significant effect. As an aside, a population of non-smoking people will experience about a 1% lifetime incidence of lung cancer. A population of two pack a day cigarette smokers will experience about a 20% lifetime incidence of lung cancer compared to the 1% expected in non-smokers. Consideration of statistical information such as these emphasizes the importance of using care in interpreting the results of cancer bioassays using the typical 100 animals per exposure level. The interpretation of the relevance of the results of animal studies for estimating human hazards will be greatly enhanced by knowledge of the mechanisms involved in the toxicant causing disease in the animals.

A key feature of the exposure–response experimental design illustrated in Figure 1.7 is the use of multiple sacrifice times for all exposure levels. In some cases it may be possible to evaluate the functional status of organs at these times, i.e. pulmonary function. In animals with inhalation exposure, when a respiratory tract response is of concern, it may be feasible to collect bronchoalveolar lavage fluid samples for analysis of biochemical and cellular parameters. Most importantly, tissue samples can be collected for histopathological evaluation. The information obtained from the serially sacrificed animals, combined with that obtained from the terminal sacrifice animals, can provide valuable insight into the progression of disease processes over the course of the study. Without question, insight into the pathogenesis of toxicant-induced disease processes will be much more complete when serial sacrifices are conducted than that obtained only from an evaluation of the terminal sacrifice animals. Another option in the design of exposure–response studies is to include a group of animals at each level that are removed from further exposure at one or more times post-inhalation of exposure for maintenance without further exposure. These animals may be euthanized at later times and evaluated for evidence of recovery or reversibility of earlier toxicant-induced changes.

The basic guidance for using multiple exposure (dose) levels and making experimental observations at multiple times is as applicable to the conduct of studies examining hypotheses on the mechanisms of action of toxicants as it is to studies developing information for regulatory decisions. I remain disappointed at the number of published articles on mechanisms of action of specific toxicants that fail to use multiple exposure (dose) levels and multiple observation times. It is only when exposure (dose) level and duration of exposure are included as experimental variables that a true understanding of the mechanisms of toxicity for an agent can be elucidated. Mechanisms are frequently exposure (dose) level and exposure duration dependent.

As the science of toxicology has advanced, increasing attention has been given to developing specialized approaches for evaluating toxicity induced in different organ systems. The various guidelines developed by the USEPA, FDA and NTP are useful references for these specialized approaches. For example, the EPA has published guidelines for evaluating carcinogenicity (EPA, 1996a), gene mutation (EPA, 1996b), reproductive toxicity (EPA, 1996c), developmental toxicity (EPA, 1991) and neurotoxicity (EPA, 1995). The EPA is continually reviewing and updating its guidelines for toxicity testing. Forty-nine harmonized health effects test guidelines used in the testing of pesticides and toxic substances have been developed and can be found on the EPA Office of Prevention, Pesticides and Toxic Substances website (EPA/OPPTS, 2006).

The FDA has provided specific guidance for evaluating the safety of compounds used in food-producing animals (FDA, 1994) and principles for evaluating the safety of

food ingredients (FDA, 2000). The EPA has provided guidelines for evaluating the safety of products intended for use with cats and dogs (EPA, 1998) and domestic livestock (EPA, 1996d).

The various guidelines are useful for planning safety evaluation studies. However, the guidelines should not be used as a substitute for the use of professional judgment in planning, conducting and interpreting toxicological investigations. As noted earlier, toxicology is not a "cookie cutter" or "check the box" science.

# TOXICOLOGICAL DESCRIPTORS

## Toxicology rooted in observations

The results of toxicological investigations, either from clinical case observations or planned experimentation, involve describing the exposure, the dose, the response and interrelationships between these parameters. Exquisite knowledge of exposure or dose or response is not sufficient. Ultimately, it is necessary to understand their interrelationships. With clinical case observations, the initial emphasis is on the clinical findings – what is the response and the need, on the basis of a differential diagnosis, to establish that a toxicant is or is not involved. The evidence for a specific toxicant may be based initially on clinical findings complemented by gross necropsy findings potentially buttressed by histopathological findings. The differential diagnosis of a toxicosis may be strengthened by evidence of a marker of dose, i.e. urine, blood or tissue levels of suspected toxicant. The diagnosis may be further strengthened with evidence of exposure, i.e. the presence of the toxicant in the feed or identification of a poisonous plant. At each step, the qualitative evidence of a toxicosis and a specific toxicant is enhanced as qualitative findings are supplemented by quantitative findings. The analysis is not completed there, though. Other reasonable differential causes of the same or similar clinical signs must also be "ruled out" if the animals or humans are in a real world or field setting.

## Quantifying exposure

Quantitation is paramount in evaluating exposure. In the experimental setting, quantitation is considered beginning with the design of the study and continued through all aspects of the experimentation. To the extent feasible, exposure to the toxicant should be rigorously characterized. This starts with physical and chemical characterization of the test material, be it an alleged pure compound or a mixture, including identification of any contaminants. The exposure circumstances need to be rigorously characterized. This, of course, is easiest to do when the test material is administered by injection. Even with injection, care must be taken to ascertain that the desired quantity of toxicant was actually injected. The quantity administered is typically related to the body weight of the subjects.

With administration by routes other than injection, the situation becomes more complicated. This may involve providing the experimental subjects' feed to which the toxicant has been added. If this approach is used, samples of the contaminated feed should be collected periodically for analysis of the test agent. In some cases, the concentration of the test agent in the feed will be used as a measure of the exposure. To accurately quantify exposure, it will be necessary to know the concentration of the test agent in the feed and also determine the quantity of the contaminated feed containing the test agent that has been ingested. For dermal administration, it is necessary to know the concentration of the test agent in the liquid media applied to the skin and the quantity of the media applied to the skin.

The situation is much more complex for a test agent in the air, whether it is a diluted gas or suspended particulate material. In both cases, it will be necessary to sample and measure the concentration of the test agent in the air at a location as close to the breathing zone of the experimental subjects as possible. For both particulate material and reactive gases, there may be substantial loss of the test agent in the delivery system between the generator used to create the test atmosphere and the breathing zone of the subject(s). Care needs to be taken to minimize such losses. For a toxic agent in a particulate matter form, it is essential to know not only the concentration of the test agent, but also the size distribution of the particulate matter since the aerodynamic particle size distribution will influence the fraction of the inhaled material that will be deposited and where it deposits in the respiratory tract. In some experiments, it may be possible to use a plethysmograph to measure respiration of individual subjects during inhalation exposure. This is most readily accomplished when the exposure period is relatively brief as in a study of the toxicokinetics of the agent. The total quantity of test agent inhaled can be estimated from knowledge of the air volume inspired and the concentration of the test agent in the air. In many studies the air concentration of the test agent may be used as a surrogate measure of exposure. As indicated earlier, exposure and dose are not synonymous. However, in many studies it may be necessary to use the concentration of the test agent in the feed, water or air as a surrogate measure of dose.

## Describing absorption, distribution, metabolism and excretion

A number of different parameters may be evaluated in assessing the kinetics of a test agent (recall Figure 1.6). Some

of the common parameters and terms used are shown in Table 1.1 adapted from Spoo (2004). The four key events involved are absorption, distribution, metabolism and excretion. It is important to recognize that species differences may exist for each of these events. Absorption is the amount of the material that enters the body. As already discussed, the concept is simple. However, in reality it becomes complex as one moves from parenteral administration to oral intake, to dermal uptake or inhalation exposure. Distribution of the material will be influenced by the route of entry and the physicochemical properties of the test agent. Metabolism for compounds varies dependent on the physicochemical properties of the material. In some cases, the material may be very inert and simply be transferred mechanically within the body with some portion excreted over time. In other cases, especially with organic compounds, the metabolism may be quite complex and result in metabolites that are either more toxic, less toxic or have toxicity similar to the parent compound.

Excretion or elimination of the material and its metabolites, if metabolized, may occur via the kidney (urine), gastrointestinal tract (feces) or the lungs (exhalation of volatile compounds). In addition, the agent or metabolites may appear in tears, sweat or exfoliated skin. Some species, such as the rat, may engage in coprophagy, ingestion of feces, such that the test material in the feces is ingested and some portion passes through the body multiple times. Animals may be euthanized at various times during the course of the study and samples of various tissues collected and analyzed for the test agent or metabolites. With small experimental subjects, it may be possible to analyze all the tissues and obtain an estimate of the total body burden of the test agent and metabolites.

In some short-term studies it may be possible to collect and analyze excreta and expired air, if the compound is metabolized to a form that will be present in expired air. This information, along with the results of tissue analyses, can provide an estimate of the total quantity in the body, excreta and expired air for comparison with an estimate of the quantity administered. This kind of mass balance approach is obviously most feasible when radioactive or stable isotope tracers are used. One should not be surprised to find the estimated quantity recovered varying from 75% to 125%; there will be a high degree of experimental variability when multiple samples are being collected and analyzed. Obviously, one should view with suspicion data tables showing recovery of exactly 100% of the administered dose. Such values are typically the result of an over zealous investigator normalizing the data to 100% recovery. For chronic exposure studies, it may be possible to use kinetic modeling to estimate the quantity of the test agent or metabolites present in the experimental

**TABLE 1.1 Common terms used to describe the ADME characteristics of chemicals (Adapted from Spoo, 2004)**

| Term | Abbreviation | Definition |
|---|---|---|
| Concentration | $C_p$ | Concentration of a chemical in plasma (p) at a specific time ($t$) |
| Time | $t$ | Chronological measurement of a biological function |
| Half-life | $t_{1/2}$ | Time required for exactly 50% of a drug to undergo some defined function (i.e. absorbed, distributed, metabolized or excreted) |
| Volume of distribution | $V_d$ | Unitless proportionality constant that relates plasma concentration of a chemical to the total amount of that chemical in the body at any time after some pseudoequilibrium has been attained |
| Volume of distribution (steady state) | $V_{d(ss)}$ | Same as $V$?, except measured when the chemical has reached a steady state in the body |
| Area under the curve | AUC | Total area under the plasma chemical concentration curve from $t = 0$ to $t = \infty$ after the animal receives one dose of the chemical |
| Body clearance of a chemical | $Cl_B$ | The sum of all types of clearance from the body |
| Renal clearance of a chemical | $Cl_R$ | Volume of chemical that is completely cleared by the kidneys per unit of time (ml/min/kg) |
| Non-renal clearance of a chemical | $Cl_{NR}$ | Volume of chemical that is completely cleared by organs other than the kidneys per unit of time (ml/min/kg) |
| Dose | D | The amount of chemical that is administered to an animal; can be further defined as the total dose, that total dose the animal was exposed to, or the absorbed (effective) dose, that being the fraction of the total dose that was actually absorbed by the animal |
| Bioavailability | F | Also known as systemic availability of a chemical. The quantity of percentage portion of the total chemical that was absorbed and available to be processed (CME) by the animal, in the case of intravenous administration, $F = 100\%$ |

ADME: absorption, distribution, metabolism and excretion; CME: chemical metabolism and excretion.

subjects at each exposure concentrations at various times after initiation of exposure.

## Toxicant–induced responses

The types of studies typically used by toxicologists to investigate exposure–response relationships can be placed in four categories related to the duration of the studies: acute, sub-acute, sub-chronic and chronic (recall Figure 1.7). Acute studies are usually of a day or less and may involve intraperitoneal, intravenous or subcutaneous injection, gavage, dermal application or inhalation. Injections may be given once or several times in the 24-h period. Acute inhalation exposures are typically 4-6 h in duration. In all cases, the observations are made over a 24-h period. Sub-acute studies typically involve repeated exposures made on a daily, or 5 days/week, basis for 2-4 weeks with observations over the same period of time. Sub-chronic studies are usually conducted over a period of 1-3 months. In the case of inhalation exposures, these are typically conducted for 4-6 h/day, 5 days/week. Chronic studies are usually conducted for more than 3 months and, most typically, for 2 years. I personally view the use of the terms acute, sub-acute, sub-chronic and chronic as jargon and prefer to communicate the duration of studies in a specific manner, i.e. number of days or months, or as short or long term. I prefer to use the terms acute, sub-acute or chronic as descriptors of a medical condition.

The kinds of toxicant-induced responses that may be encountered are broad, essentially mirroring the range of disease processes that may occur in humans and other animal species. In any well-conducted toxicity study, the investigator should use as broad an array of observational techniques as are reasonably available to characterize the pattern of morbidity and mortality that may develop. Inevitably, cost constraints will influence the choice of endpoints evaluated. It will be useful to prioritize the potential endpoints as to their likely value in terms of the information gained. It is crucial that detailed necropsies be conducted on subjects euthanized at prescribed times and at termination of the study. Tissues should be collected from any gross lesions and tissues identified in the protocol as likely target tissues and processed for histopathological evaluation. It is now routine to establish a defined set of criteria for evaluating the various tissues and characterizing lesions. This approach allows the quantitative evaluation of any pathological findings on a group basis rather than restricting the evaluation to qualitative descriptions of responses in individual subjects.

Toxicity studies to evaluate exposure (dose)–response relationships may extend from minutes to hours when biochemical and physiological responses are being evaluated, to hours to days when acute morbidity and mortality are being assessed, to weeks to months and finally to a significant portion of the lifespan of the species, e.g. 2 years for mice and rats when chronic effects, including cancer induction, are being evaluated. With increased attention given to animal welfare considerations, emphasis is being given to using as few animals as possible to define the acute morbidity and mortality of test materials. Rather than use a traditional approach to attempt to precisely define a lethal dose 50% ($LD_{50}$), it has become customary to use approaches with many fewer animals to define an approximate $LD_{50}$. In some cases, it may be desirable to determine the concentration of a test agent in water or air that produces 50% lethality over a defined period of time, a lethal concentration, $LC_{50}$. This approach remains in common use when studying aquatic organisms.

In modern toxicology, increasing attention is given to conducting studies with exposures that are defined by the anticipated conditions of use of the test material. This may involve initially conducting a study of 2-week duration, perhaps with up to five exposure levels anchored by a level related to anticipated use. The results of this study are then used to select exposure levels, perhaps three or four, and to sharpen the focus of a 90-day study. The results of the 90-day study, in turn, are used to select the exposure levels and sharpen the focus of a study of 2-year duration. Although it has become customary to conduct chronic exposure or 2-year studies with three exposure levels, it should be recognized that use of a control group and three exposure levels spanning a range of concentrations differing by a factor of 2, i.e. 1, 1/2 and 1/4, or a factor of 3, i.e. 1, 1/3, and 1/9, does not provide a robust data set for characterizing the shape of the exposure (dose)–response relationship. On the other hand, the use of exposure levels differing by a factor of 10, i.e. 1, 1/10 and 1/100, may provide an excessively broad range of exposure levels for identifying a lowest observed adverse effect level (LOAEL) or no observed adverse effect level (NOAEL) as will be discussed later.

In chronic studies, major attention is directed to evaluating any toxicant-induced changes in animals at the several exposure levels compared to controls over a 2-year period or until a defined mortality level is reached, such as 20% surviving. Any changes in various indices of morbidity or pathological alterations will be evaluated compared to controls as well as tested for trends across the exposure levels. In many cases, the primary endpoint of concern will be cancer which should include evaluation of all stages of tumor development up to sarcomas and carcinomas. It has become customary to use life table statistical methods such as that of Kaplan–Meier (1958) to evaluate the incidence of key changes. This approach allows for the use of data not only from the survivors at the end of the study, but also animals that have died or been euthanized at interim times. This situation is analogous to that encountered in human epidemiological studies when subjects may be lost to follow up.

It has become customary when the results of chronic studies will be used for regulatory purposes to convene a pathology peer review panel of expert veterinary pathologists, typically Diplomates of the American College of Veterinary Pathology (ACVP), to evaluate histological specimens from representative cases and the diagnoses of the original pathologist to verify that the diagnoses are appropriate and consistent with the scientific norm. As an aside, I encourage veterinary toxicologists to personally review the pathology findings in studies with the study pathologist so as to be familiar with the nature of the pathology findings. However, I discourage veterinary toxicologists from taking on a dual role of toxicologist and pathologist for a study. Indeed, this approach would be unacceptable for a study to be submitted for regulatory purposes unless the toxicologist was also an ACVP Diplomate.

## Describing exposure–response relationships for non-cancer endpoints

It is appropriate to now consider how the data generated from toxicological investigations can be used. Let us first examine a threshold exposure-response relationship as shown in Figure 1.3 and shown now in an expanded form in Figure 1.9. The first step is to examine the data set from critical exposure–response studies to identify key parameters to be used to describe the results. Key determinations are the no observed effect level (NOEL), the highest exposure level for which no effects are observed and the NOAEL, the highest exposure level that produces no adverse effects. Obviously, characterization of an effect as adverse or not adverse is a matter of professional judgment. For example, in a cholinesterase inhibitor study, is a reduction in blood cholinesterase in the absence of salivation or other clinical signs an adverse effect or merely an effect?

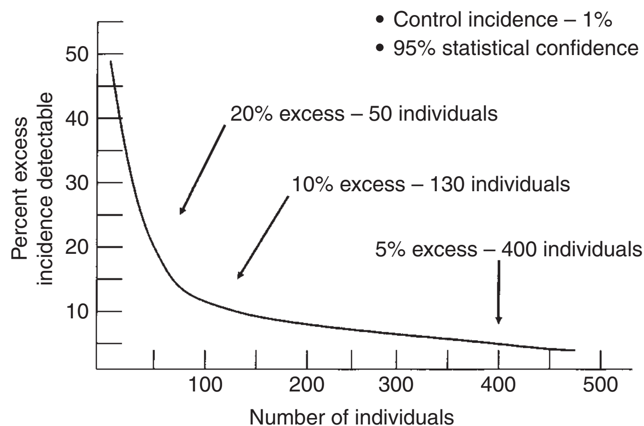

**FIGURE 1.9** Relationships between number of subjects required to detect excess risk and the level of detectable excess risk.

In the absence of the identification of an NOAEL, there is a need to identify the LOAEL, the highest exposure level at which an adverse effect is observed. The specific NOAEL and LOAEL that can be identified are a function of the exposure levels originally selected for studies. To state the obvious, observations can only be made at the exposure levels studied. For example, if the exposure levels studied did not extend to a sufficiently low level, the lowest level might produce an effect thereby precluding observation of an NOAEL. Alternatively, the study might be designed with three exposure levels separated by a factor of 10 with the lowest exposure level identified as an NOAEL and the next higher exposure level identified as producing some modest adverse effects and, thus, identified as the LOAEL. In retrospect, in such a study it is not known whether the "true" LOAEL might have been a factor of 3 or 5 above the NOAEL since these levels were not investigated.

Another consideration is the nature of the effects identified at the NOAEL, was there evidence of enzyme induction or hyperplasia, hypertrophy or atrophy with no evidence of a change in organ weight? Likewise, at the LOAEL was hyperplasia, hypertrophy or atrophy present resulting in modest or substantial changes in organ and body weight? Were histological changes observed that were reversible? Were the changes sufficiently profound that the level would be identified as a functional effect level (FEL)? These questions serve to emphasize the extent to which professional judgment is involved in interpreting the results of all toxicological investigations.

For non-cancer effects a reference dose (RfD) for oral intake or a inhalation reference concentration (RfC) for airborne materials is calculated using the NOAEL or LOAEL as a starting point (Jarabek *et al.*, 1990; Jarabek, 1994). An RfD or RfC may be defined as an estimate (with uncertainty spanning perhaps an order two magnitude) of a continuous oral or inhalation exposure to the human population (including sensitive subgroups) that is likely to be without appreciable risk of deleterious non-cancer effects during a lifetime. The RfD and RfC values are developed from the experimentally determined NOAEL or LOAEL values as shown in Figure 1.9 (Jarabek, 1994) and normalized to continuous exposure. For a more complete description of the process, the reader is referred to a recent book chapter by McClellan *et al.* (2006). The EPA maintains an Integrated Risk Information System that includes comprehensive summaries of the toxicological information available on specific chemicals including RfD and RfC values and estimates of cancer-causing potency. These profiles are available on line (EPA/IRIS, 2006).

A somewhat similar approach for non-cancer effects has been used by the ACGIH to develop TLVs (ACGIH, 2006). A TLV is defined as airborne concentrations of substances that represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects. Since the ACGIH TLVs

apply to healthy workers they may not always incorporate an SF or UF of 10 for human variability. The exposure duration for TLVs is based on a 40-h/work week and, thus, the results of animal studies will be normalized to 40 h/week.

The Agency for Toxic Substances and Disease Registry (ATSDR) develops minimal risk levels (MRLs) using a similar methodology. An MRL is an estimate of the daily human exposure to hazardous substance that is likely to be without appreciable risk of adverse non-cancer effects over a specified duration of exposure. For example, MRLs are derived for acute (1–14 days), intermediate (14–365 days) and chronic (365 days and longer) exposure durations. The MRLs are intended to serve as a screening tool to help public health professionals decide to look more closely at particular exposure situations. The ATSDR has prepared toxicological profiles on many chemicals including their MRLs. More than 200 profiles are available on line (ATSDR, 2006).

The NIOSH develops recommended exposure levels (RELs). RELs are set at levels such that virtually all persons in the working population (with the possible exception of hypersensitive individuals) would experience no adverse effects. The Occupational Safety and Health Administration (OSHA) sets permissible exposure levels (PELs) based on consideration of the NIOSH RELs. However, the OSHA values are legally enforceable limits unlike the NIOSH RELs which are guidance.

The International Program on Chemical Safety (IPCS) prepares authoritative reviews on the environmental health impact of various chemicals. The reports are available on line (IPCS, 2006). The exposure limiting values developed by the IPCS are guidance values and not legally enforceable limits. The United States makes extensive use of legal enforceable exposure limits. Many other countries emphasize the use of guidance values. This distinction is important when comparing standards versus guidance originating from different countries.

In considering all of the foregoing guidance or regulatory levels, it is important to recognize that they are set to control exposures for workers or the general public. In each case, they are set to be health protective and, thus, are set at levels below where human effects have been observed or are expected to occur. These values should not be interpreted as being equivalent to levels producing adverse effects in humans.

## Cancer as an endpoint

For cancer as an endpoint, animal exposure–response studies may provide two kinds of input. First, the results may be used in carcinogen classification processes such as those of the IARC, the EPA or NTP. As discussed earlier, these are hazard-based classification schemes – Is a given agent capable of causing human cancer without consideration of the potency of the agent? These schemes have been described elsewhere (McClellan, 1999; McClellan *et al.*, 2006).

If a positive cancer outcome is observed in animal studies, the quantitative exposure–cancer response data may be used in a second way – to develop a risk coefficient, lifetime cancer risk per unit of exposure, for the potency of the agent for causing human cancer. Such extrapolations typically involve linear statistical extrapolations from high levels of exposure used in the animal studies to potential human exposure levels several orders of magnitude lower (recall Figure 1.3). In addition, they may purposefully be calculated based on upper 95% confidence limit on some level of risk, for example, with a probability of a one in one million occurrence. In my opinion, these extrapolated values are highly uncertain. It is quite possible that for some agents classified as possibly or probably carcinogenic to humans based on high exposure level animal study results there is no added cancer risk at very low levels of exposure (Gold *et al.*, 2003). The EPA (2005a) has recently issued guidance for alternative approaches to estimate cancer risks when information is available on the mode of action of the agent, for example, if the cancer arises as a result of the toxicity and secondary cell proliferation rather than a direct effect of the chemical or metabolite on DNA. For example, chloroform has been shown to cause cancer by this mode of action (Butterworth *et al.*, 1995). The EPA (2005b) has also provided guidance for considering the impact of susceptibility of early life exposures for causing cancer.

Information on the cancer-causing potential of various chemicals is included in the material summarized in the USEPA's Integrated Risk Information System (EPA/IRIS, 2006). The IARC monographs on the evaluation of carcinogenic risks to humans are all available on line (IARC, 2006). The monographs cover the carcinogen classification reviews of over 800 compounds. The NTP publishes, on a biannual basis, a *Report on Carcinogens*. The 11th report contained 246 entries, 58 of which were listed as "human carcinogens" with the remaining 188 being listed as "reasonably anticipated to be human carcinogens" (NTP, 2005). The potency of the various agents for causing cancer is quite varied. When examining this literature, many in the public, including some scientists, are surprised to learn how few agents have been conclusively identified as "human carcinogens." The facts stand in sharp contrast to the view conveyed in the popular media and some scientific publications that people live in a "world of carcinogens."

## New potential endpoints

In recent years, the expansion of knowledge at the molecular and cellular level has provided the opportunity for considering the addition of a myriad of new endpoints to toxicological evaluations. This includes an array of new molecular biomarkers which have received substantial

attention. Although biomarkers are frequently discussed as new approaches, it is well known to the veterinary clinician and toxicologist and to physicians that biomarkers have been used in both human and veterinary medicine for centuries.

In some cases, measurement of the biomarkers present in body fluids, urine or exhaled breath serves as an indicator of exposure or, even, dose of a toxicant. Recall the report of the individual arrested for "driving while intoxicated" based on a breathalyzer test for exhaled alcohol which has been converted to a blood alcohol level. In other cases, the biomarker is an indicator of a disease process. Recall individuals being evaluated for prostate cancer based on an elevated level of prostate specific antigen in serum samples.

New biomarkers of exposure will continue to be proposed. For each potential biomarker of exposure, it will be necessary to conduct experiments to validate the utility of the biomarker. A special challenge relates to recognizing the dynamics of the toxicokinetics of various toxicants and establishment of quantitative relationships between exposure and dose at any particular time over the course of the intoxication.

The potential list of biomarkers for toxic responses is seemingly endless. In all fields of medicine, from different kinds of cancer to various functional diseases of every organ system, new molecular markers are being identified on a regular basis. The challenge for toxicologists is to consider from among this array of opportunities which biomarkers are sufficiently well validated with regard to their linkage to diseases and sufficiently reasonable in cost to warrant their use in exposure–response studies. This includes consideration of the new and highly sophisticated genomic tools. There is a special challenge in designing validation studies to make certain that the experimental design is directed toward identifying specific disease-related endpoints or toxicant-related effects rather than merely being another, albeit more sophisticated, marker of non-specific toxic effects. A serious issue in many previous validation studies has been the use of a single high exposure level and a few short-term observation times. Such studies are unable to evaluate exposure-related changes in biomarkers and may not be able to identify toxicant specific changes.

## CONCLUSIONS AND SUMMARY

Veterinary toxicology is a multi-faceted hybrid that draws on and contributes to the veterinary medical profession, the scientific field of toxicology and, broadly, to medical science. Some have characterized toxicology as a distinct scientific discipline. I view toxicology as an applied area of science addressing important societal issues by drawing on multiple scientific disciplines and professions. Veterinary toxicology, as a sub-specialty in veterinary medicine, had a very applied origin – the diagnosis and treatment of toxicoses in domestic animals and companion animals. That important role continues today. However, the field has broadened to include concern for contaminants in human food products originating from animals and for contributing to the conduct and interpretation of safety/risk evaluations for pharmaceuticals, food additives, consumer products and specific chemicals. Veterinary toxicologists who understand both normal and disease processes extending from the molecular level to the integrated mammalian organism and, indeed, populations, have an array of opportunities for making significant contributions to society. The prospects for the future of veterinary toxicology and the opportunities for veterinary toxicologists have never been brighter.

## ACKNOWLEDGMENTS

Many of the concepts presented in this chapter are based on my experience working with talented scientists at three institutions: the Hanford Biology Laboratory at Richland, WA, the Lovelace Inhalation Research Institute (now a part of the Lovelace Respiratory Research Institute) in Albuquerque, NM, and the Chemical Industry Institute of Toxicology (now the CIIT Centers for Health Sciences) in Research Triangle Park, NC. Moreover, my insights into the basic concepts of toxicology have been sharpened by my experience serving as an advisor on toxicology and health risk issues to public agencies and private clients and the opportunities I have had for working with many outstanding toxicologists and other scientists.

The excellent assistance of Mildred Morgan in preparing this chapter and the useful review comments of Drs. Ramesh C. Gupta, Fred W. Oehme and Mike Murphy on an early draft are gratefully acknowledged.

# Pharmacokinetics and toxicokinetics: fundamentals and applications in toxicology

*Rakesh Dixit*

## INTRODUCTION

The combined and well coordinated processes of the absorption (A) of a drug or a xenobiotic into the systemic circulation, its distribution (D) to organs and tissues, metabolism (M) to other active or inactive chemical species, and its elimination (E) from the body is collectively known as ADME (Gibaldi and Perrier, 1982; Voisin *et al.*, 1990; Shargel and Yu, 1993; Rowland and Tozer, 1995; Medinsky and Valentine, 2001). The pharmacokinetics refers to the kinetics of ADME processes employed at relevant low pharmacological doses where pharmacokinetics generally follow first-order kinetics and kinetic processes are expected to be linear (Gibaldi and Perrier, 1982; Shargel and Yu, 1993; Rowland and Tozer, 1995). Toxicokinetics unlike pharmacokinetics represent the study of kinetic processes of ADME under the conditions of preclinical toxicity/safety testing where depending on the doses employed both first- and zero-order kinetics are expected and kinetic process can substantially change between low and high doses (Medinsky and Valentine, 2001; Dixit *et al.*, 2003). During the last 20 years, the application of toxicokinetics has evolved in the pharmaceutical and chemical industry and toxicokinetics often refer to exposure assessment in drug or chemical safety assessment studies. In contrast to pharmacokinetics, the pharmacodynamics refer to effects elicited by the drug and active metabolites at relevant pharmacological doses while toxicodynamics refer to toxic effects related to doses (systemic exposures) used under the conditions of toxicity testing (Gibaldi and Perrier, 1982; Shargel and Yu, 1993; Rowland and Tozer, 1995).

With a full understanding of dose response, including dose administered and circulating drug levels (systemic exposure) and their relationship to toxicity, the toxicity and safety of xenobiotics, including drugs can be better assessed. In contrast to pharmacokinetics studies where ADME processes are generally first order and linear, toxicokinetics especially at higher doses encompass zero-order and non-linear processes. Non-linearity in toxicokinetics typically result from saturable metabolic clearance processes, saturable transporters, drug-specific biopharmaceutical factors, and toxicodynamics. Biopharmaceutical factors may include alterations in drug absorption at different doses (e.g. from low solubility of drug), differences in blood or tissue distribution (e.g. due to saturable protein binding, changes in tissue pathology), differences in metabolism (e.g. saturable metabolic enzymes kinetics), and in drug elimination (e.g. urinary and fecal excretion) (Medinsky and Valentine, 2001; Dixit *et al.*, 2003). In practice, the most practical surrogate or measure of dosimetry is the determination of the time course of drug and its major metabolite(s) in easily accessible body fluids, including blood or plasma or urine. With a good quantitative understanding of the time course of plasma drug concentration, one can gain information on the kinetics of absorption, distribution, metabolism, and elimination of a given drug. Because of the difficulty in quantifying drug and metabolites concentrations in target organs of toxicity, it is expected at the steady state the concentrations of a drug in blood or plasma are likely to be in equilibrium with concentrations in tissues. At the steady state, the plasma/blood can be considered a reasonable practical

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

surrogate for tissue(s) exposure to drug and changes in plasma drug concentrations may reflect changes in tissue drug concentrations over time, and relatively simple pharmacokinetic calculations or models can be extremely useful to describe the behavior of that drug in the body. In order to integrate preclinical animal toxicology data into human risk assessment, it is imperative to have some comparative human pharmacokinetics data at relevant exposures. In veterinary risk assessment, toxicokinetics/pharmacokinetics data from multiple species need to be incorporated into risk assessment.

The fundamental objective of the toxicokinetics is to obtain information on the relationship between the dosage administered and circulating levels of xenobiotics (systemic exposure) under the conditions of toxicity testing. Toxicokinetics data when appropriately obtained may provide the following additional useful information:

1 Relationship between increasing doses and exposures attained (linear, non-linear, or plateau).
2 Sex differences in exposures and their relationship to any potential sex-related differences in toxicity.
3 Effect of repeated administration on exposures and if increase or decrease in toxicity is related to changes in ADME toxicokinetics.
4. Safety of the proposed initial doses in clinical trials or proposed acceptable daily intake (ADI), tolerable daily intake (TDI), or reference dose (RfD).
5 Support dose escalation in subsequent clinical trials.

In pharmaceutical risk assessment, the most important use of the toxicokinetics data has been in assessing safety margins based on interspecies comparison of plasma $AUC$ or $C_{max}$ at no-observed adverse-effect level (NOAEL) and observed adverse-effect level from animal toxicology studies and expected/observed exposures at relevant clinical doses. Unlike the pharmaceutical industry, the human risk assessment of exposures to chemicals present in food, water, or air has traditionally relied on safety or uncertainty factor approach. The ADI or TDI or RfD on mg/kg basis is determined by dividing the NOAEL in mg/kg/day from most sensitive animal species by a factor of 100 which includes a factor of 10 each for extrapolation of safe doses: interspecies (animals to humans) and intraspecies (within humans). The use of this approach has often given low ADI or TDI and RfD for chemicals which are not easily achievable or enforceable. In recent years, there has been an increased emphasis on the use of toxicokinetics to reduce uncertainty in extrapolation of doses across species.

This chapter provides a general introduction to toxicokinetics, description of toxicokinetics parameters, and their assessment using simple equations. The chapter also discusses the applications of toxicokinetics in veterinary risk assessment and drug development.

# FUNDAMENTALS OF XENOBIOTIC DISPOSITION

Animals and humans may be exposed to xenobiotic chemicals present in our air, water, and food through multiple routes, including oral, dermal, and pulmonary. Intentional therapeutic drug exposure may occur through multiple routes, including oral, intravenous, intraperitoneal, subcutaneous, intramuscular, buccal, pulmonary, ocular, and direct regional administration. Therefore, a good understanding of the fundamental processes of ADME processes is critical to understanding toxicokinetics.

# ABSORPTION

Absorption is collectively defined as all processes that comprise the transfer of an unchanged xenobiotic introduced into the body into systemic circulation or site of measurement may be exposed to xenobiotic chemicals present in our air, water, and food through multiple routes, including oral, dermal, and pulmonary. Intentional therapeutic drug exposure may occur through multiple routes, including oral, intravenous, intraperitoneal, subcutaneous, intramuscular, buccal, pulmonary, ocular, and direct regional administration. Therefore, a good understanding of the fundamental processes of ADME processes is critical to understanding toxicokinetics. Some basic concepts in absorption following extravascular routes of administration are demonstrated in Figure 2.1.

## Gastrointestinal absorption

Oral route is the predominant route of exposure to drugs and chemicals. A prerequisite for the absorption through membrane is that the chemical must be dissolved in gastrointestinal (GI) fluids, have enough lipophilicity, and lack charge to pass through the lipid layers. Chemicals that are water soluble, metabolically resistant, and have sufficient lipid solubility are generally rapidly absorbed with a rapid peak concentration. If a chemical is not appropriately soluble in GI fluids, it will have difficulty in making it available to membranes and may face slow and/or sustained dissolution-limited absorption. This may occur when sparingly soluble chemicals/drugs are administered as suspensions. From biopharmaceutical perspectives, drug absorption across biological membranes is governed largely by the p*K*a, pH at the site of absorption, molecular size, molecular weight, and dissociation constant, degree of ionization, aqueous and lipid solubility, partition coefficient, chemical reactivity. Other factors that may impact the biological absorption process include

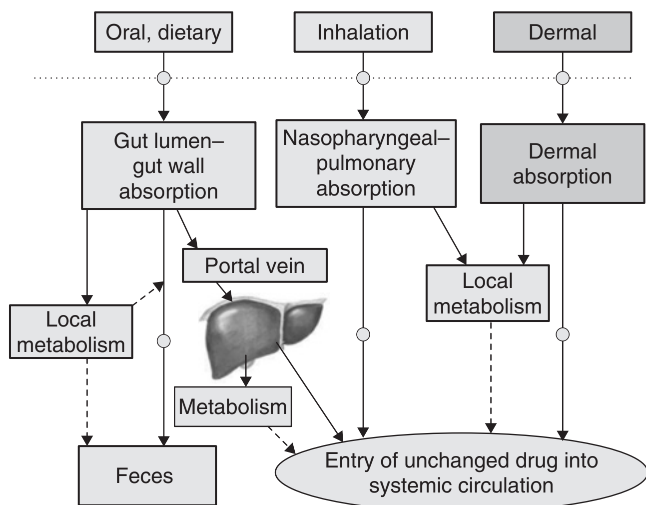

**FIGURE 2.1** *Concepts in extravascular absorption.* When a xenobiotic such as a drug is administered via non-intravenous route, the absorption at the local site is the key process in the systemic delivery of the active substance. Some of the most important extravascular routes include oral/dietary, inhalation (nasopharyngeal–pulmonary), and dermal. With extravascular routes of administration, significant portion of drug can be lost as a result of local site metabolism. In addition, when a drug is administered through oral route, hepatic first-pass metabolism plays a pivotal role in controlling the systemic availability of drug (see text for additional discussion).

gastric emptying time, intestinal transit time, presence or absence of food, gut microflora, and specific drug transporters (Dethloff, 1993).

Route-specific/site of delivery-specific factors includes cell types, surface area at the absorption site, blood flow to and from site of absorption, pH at site of absorption, and site-specific metabolic/transporter effects (Dethloff, 1993). Chemicals, including drugs, are absorbed across lipid-rich membranes principally by (a) diffusion, (b) membrane pores (aqueous channels) and (c) energy-dependent active carrier mediated saturable processes. The majority of xenobiotics pass through membranes through a diffusion process, a process largely controlled by Fick's law. Very small molecules (chemicals up to $4 \times 10^{-4}$ μm in diameter with a molecular mass of less than approximately 200 Da) can filter through the membrane pores without much difficulty.

According to Fick's law (Dethloff, 1993), the rate of diffusion is proportional to concentration gradient (C1−C2) across the membrane, the surface area available for diffusion ($a$), and a diffusion constant ($k$). Overall the diffusion rate is inversely proportional to the thickness of the membrane ($d$):

$$\text{Diffusion rate} = k \times \frac{a(\text{C1} - \text{C2})}{d}$$

Most chemicals or drugs are weak acids or weak bases and therefore exist as ionized or non-ionized species. Because non-ionizable form is lipid soluble, it facilitates diffusion through lipid membranes. In contrast, the ionizable form is poorly lipid soluble and is generally unable to pass through the lipid membranes.

The pH and p*K*a on both sides of microenvironment largely determine the extent of ionization. The Henderson–Hasselbach equation to determine the extent of ionization can be as follows:

$$\text{pH} = \text{p}K\text{a} + \log \frac{[\text{conjugated base}]}{[\text{conjugated acid}]}$$

The pH at the absorption sites in relation to p*K*a has been exploited for improving the absorption and/or increasing urinary elimination of many drugs by reducing renal reabsorption of drugs. For example, when poisoned with salicylate, urinary excretion of salicylate can be substantially increased due to increased alkalinization of urine (from pH 6.5 to 8.0) by giving sodium bicarbonate. Because the p*K*a of salicylate is 3.5, the alkalinization of urine (pH 3.8) decreases the non-ionization form substantially (approximately 25-fold decrease) which reduces the renal reabsorption of salicylate and increases (approximately 5-fold) its urinary excretion. *It can be generally concluded that weak acids are likely to be better absorbed in the low pH of stomach whereas weak bases are likely to be better absorbed in the intestine.* It is not surprising to note that strong organic acids and bases are generally incompletely absorbed in the GI tract due to very strong ionization at all absorption sites. The absorption of most xenobiotics occurs in small intestine because this is well suited for absorption owing to its large surface area afforded by millions of villi and their specialized absorptive epithelium. The absorption through villus is also greatly supported by hepatic portal circulation and central lacteal (absorption into lymphatic system).

### *Factors impacting GI absorption*

There are a large number of factors that limit the availability of xenobiotics. Extreme pH and hydrolytic enzymes (e.g. proteases and lipases) in the GI tract substantially impact the stability of the xenobiotics. The GI tract microflora is known to metabolize a large number of xenobiotics and this process can reduce the availability of xenobiotics absorption, and in some cases, may activate fairly benign xenobiotics into toxic metabolites. Despite very good absorption through the small intestine, many drugs fail to reach systemic circulation in sufficient amounts. Small intestine is very rich in both phase I and II metabolizing enzymes which can actively biotransform a

well absorbed drug. Overall, metabolism by the small intestine can prevent a well absorbed drug getting into portal circulation. In addition to the first-pass effects by intestine, the liver is the chief site of metabolism and contributes greatly to the first-pass metabolism leading to poor circulation of well absorbed drugs. Efflux and influx transporters present on the intestinal wall and liver can also modulate the systemic availability of drugs. Food present in the gut lumen can also substantially impact the absorption of drugs.

## NON-ORAL ROUTES AND XENOBIOTIC ABSORPTION

### Intravenous

For drugs that are poorly absorbed through oral route, intravenous route is often used to bypass absorption and deliver drug directly into systemic circulation. Intravenous route can also deliver very high peak concentrations very rapidly. Continuous intravenous infusion is often used to deliver the desired concentration in a well controlled manner.

### Intramuscular, subcutaneous, and intradermal

These alternate routes are used to deliver drugs rapidly into systemic circulation because drugs delivered through these routes are not susceptible to first-pass metabolism. However, these different routes will deliver drugs with varying rates due to local site-specific absorption influenced largely by blood flow at local sites.

### Buccal and sublingual

Oral mucosa has significant ability to absorb certain drugs. Because these routes are convenient ways to attain desired plasma concentrations, efforts have been made to actively exploit these routes for rapid delivery of drugs into systemic circulation. These routes offer a distinct advantage in delivering drugs into systemic circulation because they can bypass first-pass hepatic metabolism. Major limitations for these routes are local irritation and limitations of the doses.

### Intraperitoneal

The advantage of the intraperitoneal route is that poorly absorbed drugs can be directly delivered to liver by bypassing intestinal absorption and without being subjected to intestinal first-pass metabolism. Drugs when given by the intraperitoneal route can attain a very rapid absorption when compared to the oral route.

### Dermal

For environmental and industrial chemicals, the dermal route is a significant route of exposure. When compared to the oral route, the skin serves as an important barrier for absorption because of the substantially lower surface area, membrane thickness, and poor blood flow. Despite these limitations, many chemicals when presented at large doses can be substantially absorbed. Outer layers of skin (epidermis or stratum corneum) provide a significant barrier to absorption; however, hydration, epidermal erosion, or abrasion can greatly enhance absorption. Unlike the outer layers of skin, the inner layers such as dermis are well perfused. One additional advantage of the dermal route is that drugs given by the dermal route are not subject to significant metabolism, though epidermis has been shown to metabolism certain xenobiotics.

## INHALATION

The inhalation route is one of the major routes of xenobiotic exposure. In recent years, the pulmonary delivery of drugs has become an important route of drug delivery. Lungs receive 100% of the cardiac output and the repetitive branching of the airways from trachea to terminal alveoli provides an enormous surface area for absorption. Absorption from lungs is quite rapid because there is little barrier (alveolar region thickness is only 0.2 μm) and up to 90% of the alveolar surface is exposed to capillary bed. Inhaled drugs are deposited on lungs epithelial surface and deposition of aerosols is influenced by lung-specific anatomical regions. Particles less than 1 μm are typically excluded from alveolar absorption. In certain regions such as nasopharyngeal, tracheal, bronchial and upper bronchiolar, xenobiotics are likely deposited by impactation while in deeper regions of lungs, xenobiotics are deposited by diffusional and sedimentation processes. Passive diffusion plays an important role in xenobiotic absorption and the alveolar region because its enormous surface area coupled with high blood flow is the major site for pulmonary absorption. Although the lung has capacity to metabolize chemicals which will likely decrease the systemic availability, chemicals delivered through lung absorption process bypass hepatic first-pass metabolism and directly enter systemic circulation through heart.

## SPECIES DIFFERENCES IN ABSORPTION

This topic has been discussed in great depth by Beasley (1999). Of over 4000 species of mammals, there are large numbers of species differences in absorption. The food habits of carnivores, herbivores, and omnivores differ greatly and this can be responsible for differences in bioaccumulation of potentially toxic chemicals. It is not too surprising that the accumulation of fat-soluble xenobiotics is higher in carnivores than in herbivores and the extent of accumulation of food chain derived xenobiotics or bioaccumulation factor (concentration in animal tissues divided by concentration in environment/food chain) may vary a log order of magnitude. Ruminants show age-dependent absorption of xenobiotics. Young calf and lamb behave like monogastric animals until maturity when they adapt to high roughage diet. These species also dilute xenobiotics exposure with a longer GI transit time. Additionally consumption of foods rich in fiber tends to lower the bioavailability of toxic compounds. Anaerobic environment in the rumen tends to reduce xenobiotics much more efficiently than in non-ruminants.

Monogastric animals, including carnivores and omnivores, have a lower stomach pH. For example, the gastric pH in dogs and pigs is between 1 and 2. Unlike other species, horses have a higher gastric pH of about 5.5 and their stomach size is smaller in relation to their overall body size. This means they need to eat more often.

## DISTRIBUTION

Organ distribution of xenobiotics is mainly controlled by three different factors: (1) diffusion rate, (2) perfusion rate, and (3) relative affinity to various components (e.g. enzymes, receptors, transporters) in a given organ. When the diffusion rate across membrane is poor, the physicochemical properties of xenobiotics control the rate of tissue penetration. The perfusion rate (rate of delivery to an organ) becomes rate limiting when diffusion is rapid. The well perfused organs include lungs, liver, kidneys, heart, intestines, and brain. Poorly perfused organs include skin, skeletal muscle, connective tissue, and fat. Compounds that are highly plasma protein bound may show a lower tissue distribution and vice versa; however, it is to be stressed that it is the balance between the relative affinity of a chemical to tissue components and protein binding association and dissociation rates that control overall tissue distribution. Protein binding alone does not necessarily control the entire tissue distribution. For example, beta blocker propranol shows a high protein binding and yet has a high tissue distribution because it has a higher affinity for many tissues. Extensive plasma protein binding may decrease the unbound fraction available for tissue distribution; however, in rapidly perfused organs this can increase the diffusion rate from blood to organs. This may happen due to an increase in the concentration gradient due to build up of the protein bound drug in blood which in turn can increase the off rate of protein bound drugs/chemicals to release more drug for tissue distribution. This illustrates that protein binding is a dynamic process and highly protein bound may indeed show high tissue distribution if relative affinities to tissue components are high.

## METABOLISM AND ELIMINATION

Metabolism of xenobiotics is very complex and diverse. It shows differences in occurrence, function, and rates. Species differences in quantitative metabolism are fairly common and it is important to appreciate this when interpreting toxicology data from one species to another species. For a detailed review of metabolism, refer to DeBethizy and Hayes (2001). Primitive species like microbes also have significant metabolism capacity, though microbes generally have very different pathways than mammals and may modify drug toxicity in an unexpected manner. Metabolism generally occurs through both phase I and II pathways. Phase I reactions result in functionalization, which result in the addition or uncovering of functional groups that are needed for subsequent metabolism by phase II pathways. Phase I reactions include oxidation (e.g. cytochrome P-450 (CYP) isoenzymes, xanthine oxidase, peroxidases, amine oxidase, monoamine oxidase, dioxygenases), reduction (e.g. CYP isoenzymes, ketoreductase, glutathione peroxidases), hydration (epoxide hydrolase), and dehydrogenases (alcohol dehydrogenase, aldehyde dehydrogenase). Phase II reactions are biosynthetic in nature and a common goal of all phase II reactions is to make xenobiotics more water soluble, more polar, and more easily excretable. Phase II enzymes include glutathione-*S*-transferases, UDP-glucuronyltransferase, thioltransferase, sulfotransferase, amide synthesis transacylase, *O*-, *N*-, *S*-methyltransferase, acetyltransferases, and thiosulfate sulfotransferase (rhodanese).

Excretion of xenobiotics and their metabolites usually occurs via urine, feces, and expired air for volatile substances. Three major processes within kidney control urinary excretion. These processes are glomerular filtration, reabsorption, and tubular excretion. Glomerular filtration because of the limits of pore size of 70–80 Å filters anything smaller than molecular weight of 20,000 Da.

All high molecular proteins and protein bound chemicals or their bound metabolites are not filtered and remain in blood and will likely be excreted through fecal excretion. Reabsorption of filtered components from urine to

blood occurs through specific active transport process occur in tubules. With the reabsorption of water urine may become concentrated and when this occurs, the reabsorbed components may diffuse back from tubules to blood. Many foreign compounds may also be secreted back into renal tubules against concentration gradient through both cation and anion carrier processes. Because these carrier processes are energy-dependent active process, they are saturable and with increasing doses renal secretion may get decreased causing accumulation of xenobiotic metabolites. Fecal excretion of xenobiotics and their metabolites is an important route of excretion. There are two sources for the excretion of compounds into feces. Unabsorbed drug and drug excreted through bile constitute the fecal excretion. For large molecular weight compounds and their metabolites biliary transport occurs through cationic transporters from hepatocytes into bile. Generally, large molecular weight drugs and their conjugative metabolites are excreted through bile. Based on the evaluation of molecular weight versus biliary excretion of a large number of molecules and their metabolites, it has been estimated that the molecular weight (Da) cutoff for the biliary excretion of chemical moieties in rats, guinea pigs, rabbits, and humans is 325 (±50), 440 (±50), 475 (±50), and 550, respectively (Hirom and Birch, 1976). Chemical moieties of molecular weights ranging from 350 to 450 Da are generally excreted via both urine and feces (Hirom *et al.*, 1972). The estimate of fecal excretion is often complicated by the fecal excretion of the unabsorbed drug when given by the oral route. Bile duct ligation studies can be helpful in evaluating the contribution of bile versus unabsorbed drug in fecal excretion of drug-related moieties.

## CLASSICAL TOXICOKINETIC MODELS

The classical toxicokinetic models represent the most simple form of the pharmacokinetic models (Medinsky and Valentine, 2001; Dixit *et al.*, 2003). The principal component of a classical toxicokinetic model is a central compartment consisting of plasma (systemic) and tissues into which drug and its metabolites equilibrate. The basic principle of a simplistic one central compartment model is that it is assumed that all tissues, including both rapidly and slowly equilibrating tissues, and plasma will attain a rapid equilibrium and the kinetic profile of tissues can be described by measuring drug and its major metabolite(s) in plasma. Similarly, in the multiple compartmental models, drug is present into the central compartment and distributes rapidly between the central and peripheral compartments and the distribution between central and peripheral compartments follows a first-order process. In this model, drug elimination occurs from the central compartment, which is assumed to contain all major rapidly perfused drug eliminating tissues (e.g. kidneys and liver). The major advantages of the classical compartmental toxicokinetic models are that the models do not require information on disposition characteristics of drug-based tissue physiology or anatomical structure (Dethloff, 1993; Dixit *et al.*, 2003). These models, because of their simplicity, provide valuable information in describing and predicting the time course of drug concentrations in the systemic circulation at different doses, the extent of drug accumulation with multiple doses, and aid in selecting effective doses and dose regimens in efficacy and toxicity studies to achieve specific exposures.

One major disadvantage of classical models is their simplistic description of the kinetics of ADME processes in the body since these models are simple mathematic solutions for goodness of fit (Clewell and Andersen, 1985; Dixit *et al.*, 2003). Therefore, the classical models are not able to assess or reflect (1) the biology of specific tissues; (2) individual rates of transfer between compartments; (3) individual contributions and rates in routes of elimination; (4) the time course and exposure information in a specific tissue; and (5) specific drug disposition and elimination which involves dose-dependent non-linear and zero-order processes (Beasley, 1999; DeBethizy and Hayes, 2001).

## FUNDAMENTAL NON-COMPARTMENTAL TOXICOKINETIC PARAMETERS

The non-compartment methods are simplistic and represent the most practical way to describe the kinetic behaviour of the drug. The most relevant pharmacokinetic parameters in the non-compartmental models typically include plasma or tissue area under the concentration versus time curve ($AUC$), maximum concentration achieved ($C_{max}$), time to maximum concentration ($T_{max}$), apparent volume of distribution ($V_d$), systemic clearance ($CL_s$), and terminal half-life ($T_{1/2}$). Figure 2.2 shows the visual concepts in toxicokinetics.

### Area under the plasma/tissue concentration versus time curve

The AUC is considered the most important kinetic parameters in pharmacokinetics and is the quantitative measure of the exposure to drug over the sampling period. The linear trapezoidal rule is the most frequently used method to calculate AUC. Typically plasma concentration versus time curve is constructed. The overall curve is then divided into a series of trapezoids, typically indicated by observed time points and achieved concentrations. Overall AUC is calculated by the summation of the area within each individual trapezoid.

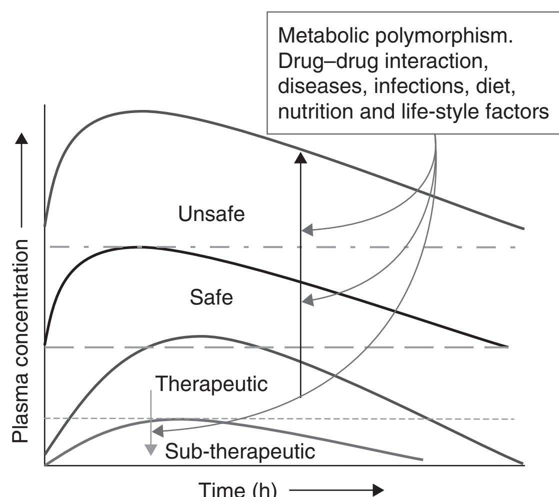

**FIGURE 2.2** *Pharmacokinetics–pharmacodynamics and impact of intrinsic and extrinsic factors.* The use of pharmacokinetics data in clinical settings to maintain therapeutically efficacious concentrations. This is based on a thorough analysis of pharmacokinetics versus pharmacodynamics (effects associated with drug) during clinical trials. It is to realize that there are a large number of intrinsic (patient derived) and extrinsic factors that may increase drug levels which may be unsafe or decrease drug levels that may be sub-therapeutic and may decrease drug's efficacy (see text for additional discussion).

The area under each trapezoid can be calculated as follows:

$$\text{Area}_{\text{Trap}} = 0.5 \times (C_n + C_{n+1}) \times (t_{n+1} - t_n)$$

where $C_n$ is the concentration at the earlier time; $C_{n+1}$ is the concentration at the next later time; $t_{n+1}$ is the later time; and $t_n$ is the earlier time. The overall $AUC_{0-t_{\text{last}}}$ is then calculated as follows:

$$AUC_{0-t_{\text{last}}} = \sum 0.5 \times (C_n + C_{n+1}) \times (t_{n+1} - t_n)$$

The area calculated above is $AUC_{0-t_{\text{last}}}$ when the concentration at time zero is the first concentration (typically immediately prior to dosing); $t_{\text{last}}$ is the time when the last sample was collected and concentration measured. In toxicokinetic studies supporting drug safety evaluation, $AUC_{0-t_{\text{last}}}$ is often measured from time 0 to 24 h. This is a measure of the daily systemic exposure during a repeated dosing. When steady-state toxicokinetics are expected (typically after attaining 5 half-lives), zero-hour concentrations are assumed to be equal to the 24-hour plasma concentrations. The measurement of $AUC$ from time 0 to time $\propto$ represents the most accurate assessment of total systemic exposure following a single dose. When calculating, the remaining $AUC$ from $t_{\text{last}}$ to time $\propto$ is calculated with the terminal elimination rate constant, and is added to $AUC_{0-t_{\text{last}}}$. $AUC_{0-\infty}$ is then estimated as follows:

$$AUC_{0-\infty} = AUC_{0-t_{\text{last}}} + \frac{C_{\text{last}}}{k_{\text{el}}}$$

- $C_{\text{last}}$: Concentration measured at the last time point; $k_{\text{el}}$ is the terminal elimination rate constant and is a measure of the fraction of drug removed from the site of collection per unit of time. The $k_{\text{el}}$ has units of reciprocal time (e.g. $\text{min}^{-1}$ and $\text{h}^{-1}$) and can be determined from the slope of the straight-line portion of the terminal phase of the concentration versus time curve when the concentration data are log-transformed as follows:

$$k_{\text{el}} = -2.303 \times slope$$

The multiplier 2.303 is a conversion factor from log units to natural log (ln). The first-order elimination rate constant $k_{\text{el}}$ is independent of dose.

- $C_{\max}$: This refers to the maximum drug concentration ($C_{\max}$) attained during the time course of the measurement of drug levels. In the non-compartment methods, the information on $C_{\max}$ is often used to determine the extent of drug absorption.
- $T_{\max}$: This refers to the time to attain maximum concentration. This parameter is often useful to assess the rate of drug absorption.
- *Trough levels* ($C_{\min}$): This refers to the minimum drug concentration ($C_{\min}$) attained during the elimination phase in time course of the plasma drug versus time curve. In the non-compartment methods, the ratio of trough level to maximum concentration can often provide valuable information on the rate of drug elimination.
- *Half-life* ($T_{1/2}$): It is the time required for the blood or plasma drug concentration to decrease by one-half, and can be determined from the terminal elimination rate constant by the following calculation:

$$T_{1/2} = \frac{0.693}{k_{\text{el}}}$$

The numerator 0.693 is the natural log of 2. It is to be emphasized that the accuracy of $k_{\text{el}}$ and $T_{1/2}$ estimates is dependent on selection of time points. As a general rule, time points covering up to 5 half-lives should be taken. Both $k_{\text{el}}$ and $T_{1/2}$ are dependent on both volume of distribution and clearance by the following relationship:

$$T_{1/2} = \frac{0.693 \times V_{\text{a}}}{CL_{\text{s}}}$$

## Clearance

Drugs and their metabolites are removed from body via a variety of routes that may include fecal and urinary excretion, excretion in tears or sweat, metabolism in liver, kidneys, lungs, intestinal or other tissues, or by exhalation. Clearance is defined as the volume of drug removed from the body per unit of time with units as ml/min. For example, a $CL_{\text{s}}$ value of 30 ml/min means that 30 ml of blood or

plasma containing drug is removed each minute. This parameter is often normalized to body weight, and thus clearance values are often reported in units of ml/min/kg. The $CL_s$ means clearance as measured from the systemic circulation. $CL_s$ is best calculated from concentration versus time data after an intravenous bolus or infusion dose because there is no absorption and nearly 100% of the drug is bioavailable following intravenous administration. Following extravascular administration (e.g. oral), estimates of clearance should be normalized to bioavailability and can be calculated as follows:

$$CL_s = \frac{F \times dose}{AUC_{0-\infty}}$$

where $F$ is the fraction of the drug dose that entered the systemic circulation following extravascular administration. When constant intravenous infusion to steady state is used, $CL_s$ may be calculated as a function of the infusion rate and the achieved steady-state concentration:

$$CL_s = \frac{k_0}{C_{ss}}$$

where $k_0$ is the rate of intravenous infusion and $C_{ss}$ is the steady-state concentration.

*Total body clearance* can be estimated as the sum of clearances by individual eliminating organs such that:

$$CL_s = CL_r + CL_h + CL_i + \cdots$$

where $CL_r$ is the renal clearance, $CL_h$ the hepatic clearance, and $CL_i$ the intestinal clearance. It is worthy to note that clearance of compounds from a particular organ cannot be higher than blood flow to that organ.

## Volume of distribution

The apparent volume of distribution ($V_d$) relates the total amount of drug in the body to the plasma concentrations in the body. $V_d$ is essentially the volume into which the drug distributes in the body. $V_d$ is considered an indicator of extravascular distribution and has units of liters or liters/ kg of body weight.

$V_d$ can be calculated as follows:

$$V_d = \frac{F \times dose}{k_{el} \times AUC_{0-\infty}}$$

where $F$ is the fraction of dose that enters the systemic circulation. Following intravenous administration, $F$ will have a value of 1 because the bioavailability is 100%.

$V_d$ is considered the *"apparent" volume of distribution* and it has very little or no physiological significance because it usually does not relate to a real biological volume. $V_d$ term is typically drug specific and represents the distribution of drug out of the central plasma compartment. In this context, a drug with a larger $V_d$ will have high extrasystemic tissue distribution and if the drug binds to tissue extensively, $V_d$ may exceed the tissue volume. Once the $V_d$ for a compound is known, it can be used to estimate the amount of drug in the body as follows:

$$X_{drug} = V_d \times C_p$$

where $X_{drug}$ is the amount of drug in the body and $C_p$ is the plasma drug concentration.

# BIOAVAILABILITY

The oral route is the predominant route of administration of pharmaceuticals and the fraction of dose that is available after absorption and first-pass clearance in the systemic circulation is termed *bioavailability* ($F$). Bioavailability can be essentially described as the amount of a drug that enters the systemic circulation and is considered a measure of drug absorption. The route of drug administration, intestinal first-pass effect, hepatic first-pass effect, transporters, formulations, and dissolution rate characteristics can greatly impact the bioavailability. In simplest terms, to determine bioavailability one needs to know the blood/plasma systemic exposure ($AUC_{0-\infty}$) values following intravenous and extravascular (e.g. oral, intramuscular, subcutaneous, intraperitoneal) dosing at the same doses; however, bioavailability can also be determined at varying doses provided the drug pharmacokinetics is linear and follows first-order pharmacokinetics. The bioavailability following an oral exposure is determined as:

$$F\% = \frac{dose_{iv} \times AUC_{0-\infty,ev}}{dose_{ev} \times AUC_{0-\infty,iv}} \times 100$$

$dose_{iv}$ is the intravenous dose; $dose_{ev}$ the extravascular dose administration; $AUC_{0-\infty,iv}$ the area under the curve after the intravenous dose; and $AUC_{0-\infty,ev}$ the area under the concentration versus time curves for the extravascular dose.

Relative bioavailability is often necessary to evaluate the impact of different dose forms (e.g. particle size, solubility, dissolution, vehicle delivery, etc.) on the systemic bioavailability of a drug. To assess bioavailability, intravenous data is not essential, as one extravascular dose form can be compared against another extravascular dose form, where one of the dose forms may be used as the reference material.

# CLASSICAL PLASMA/TISSUE TOXICOKINETICS: APPLICATIONS IN DRUG DISCOVERY AND DRUG DEVELOPMENT

Prior to the testing of promising new therapeutics in healthy humans and/or sick human patients, non-clinical safety studies in laboratory animal species and/or appropriate *in vitro* models are conducted. Figure 2.2 shows a pharmacokinetics guided dosing strategy to improve therapeutic efficacy. Maintenance of plasma drug within a defined window is critical to the success of attaining the therapeutic efficacy. However, a large number of intrinsic and extrinsic factors, including metabolic polymorphism, drug–drug interaction, diseases, infections, diet, nutrition, and life-style factors could influence the therapeutically effective concentrations. Although it is not possible to evaluate many intrinsic and extrinsic factors in animal toxicology studies, it is believed that the use of safety factors/uncertainty factors (10 or greater) will allow the safe conduct of clinical studies.

Non-clinical toxicology studies when conducted properly in two species, typically in one rodent and one non-rodent, provide critical information on dose response in toxicity and its reversibility under a variety of exposure scenarios. The major objective of each toxicity study is to determine an NOAEL and adverse-effect level. Additionally, it is critical to know if toxicity is reversible or irreversible in nature and how long it will take to recover completely from toxicity. With the knowledge of quantitative species differences in ADME and susceptibility to toxicity, the risk assessment of preclinical safety data for human safety has been challenging. There has been a steady progress in integrating toxicity mechanisms, toxicology–pathology data, toxicokinetics, and ADME data into risk assessment. This has greatly helped to reduce the uncertainty regarding the extrapolation of animal toxicology data to estimate the probably of harm at relevant clinical exposures.

# APPLICATIONS OF ADME AND TOXICOKINETICS IN DRUG DISCOVERY AND DEVELOPMENT

## Early optimization of promising discovery candidates

Drug discovery process starts with a hypothesis, including the identification of biological target related to a given disease or illness, and strategies to block the specific target without ensuing toxic effects. A specific disease target may involve an up-regulated target enzyme or receptor, and its blockage may lead to effective treatments. Once a suitable target is characterized, molecules are screened to identify hits with desired biological activity. Prior to undertaking *in vivo* investigations, adequate *in vitro* and *in vivo* pharmacokinetics and metabolism characteristics are usually obtained.

## Toxicokinetics information and its utility in toxicity studies

Because of the limitations associated with the frequency of sampling and total blood withdrawn in a given time, toxicokinetic information from an integrated toxicity-toxicokinetic protocol is limited to an assessment of *AUC*, $C_{max}$, $T_{max}$, $C_{min}$, and the ratio of $C_{min}/C_{max}$. Figure 2.3 shows the potential utility of toxicokinetics in toxicity studies. Below is a scientific discussion on the basics of toxicokinetic information (Figure 2.4).

### *Extent of drug absorption: rate and extent of drug exposure*

The rate and extent of drug entering the blood stream following drug administration is extremely important. A drug may be very rapidly absorbed (rapid attainment of $C_{max}$ with $T_{max}$ of generally less than 2 h) at the low dose; however, solubility- or dissolution-limited drug absorption at

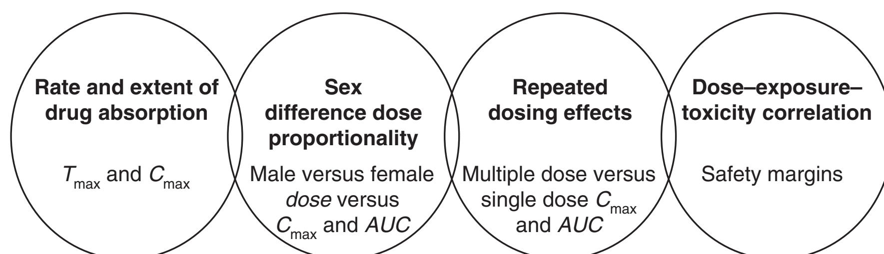

**FIGURE 2.3** *Applications of toxicokinetics in non-clinical toxicology studies.* Preclinical toxicokinetics data when generated along with toxicology studies may have multiple applications. The toxicokinetics data have many applications including the following: (1) rate and extent of drug absorption by knowing how fast a drug enters plasma and to what extent it achieves maximal concentrations; (2) sex differences in exposures help to interpret any potential sex differences in toxicity or differences in dose proportionality in exposures; and (3) repeated dosing effects on exposures by comparing single and multiple dose (typically at presumed at steady state) toxicokinetics (e.g. $C_{max}$ and *AUC*) (see text for additional discussion).

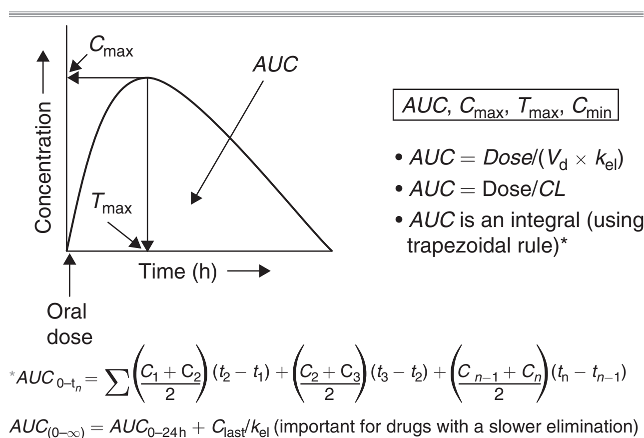

**FIGURE 2.4** *Basic toxicokinetics parameters*. In toxicokinetics studies, the assessment of toxicokinetics is often limited to the assessment of some very limited parameters, such as $C_{max}$, $T_{max}$, and *AUC*. This is due to limited blood sampling along with toxicity evaluation. The *AUC* is the most important pharmacokinetic parameter which can be estimated by statistical methods (trapezoidal rule) or by equations using $V_d$, $k_{el}$ (elimination constant), and drug clearance (*CL*). Because the correct estimate of $k_{el}$, $V_d$, and drug clearance is difficult to attain in oral toxicokinetics studies, it is a common practice to use trapezoidal rule to estimate the *AUC*.

the middle and high doses may lead to slower rise in concentration with longer $T_{max}$ and sustained concentrations. The rate of drug exposure has significant impact on overall safety profile of a drug. There are a large number of biological and drug derived factors that may impact the overall process of drug absorption (Curatolo, 1998). The total amount of drug circulating through blood relative to the administered dose in mg/kg is critical in interpreting the dose response in toxicity and establishing thresholds for adverse effects. Drugs that are poorly or incompletely absorbed due to solubility/dissolution-related problems may leave a large amount of unabsorbed drug in the GI tract. Chronic accumulation of large amounts of unabsorbed drug in the intestinal tract following chronic repeated oral dosing may result in adverse effects on GI homeostasis (e.g. nutrient absorption, GI emptying, changes in GI microflora, chronic GI irritation, and inflammation) and toxicity may arise secondary to these local adverse effects. The local untoward effects due to unabsorbed drug may not be relevant for humans because most drugs are administered at very-low-dosage strengths. In oral studies conducted at high doses for safety testing it is not possible to obtain information on percent bioavailability because of the lack of exposure data at relevant intravenous doses. The extent of absorption can be roughly estimated by comparing the ratio of $C_{max}$ to *AUC*; however, when the absorption is slow and sustained, it is difficult to know the extent of absorption. Drugs that have an effect on GI homeostasis, including pH, changes in gut microflora, gastric and intestinal secretions and enzymes, GI motility, and first-pass intestinal metabolism can substantially alter the rate and extent of drug absorption. Additionally, drug induced GI toxicity can also have a detrimental influence on the systemic availability of drug and its major metabolites. The time ($T_{max}$) to reach $C_{max}$ may be used to monitor certain adverse effects which may be peak concentration dependent and may include CNS adverse effects (e.g. tremors, convulsions), cardiovascular effects (e.g. ECG changes, blood pressure changes), and certain hormonal effects. For certain target organ toxicities that require a sustained presence of drug-related substances, it is critical to fully establish plasma concentration versus time profile and its relationship to target organ toxicity. This information is extremely important when oral dietary route of administration is chosen. Differences in treatment regimens, dosing schedules, or oral routes can produce differences in toxicities because of the mechanistic differences in patterns of drug exposures and adverse effects. Because of the advances in high throughout screening and tendency to generate metabolically stable molecules, newer drug molecules tend to be bulky and poorly soluble in water. Increasingly it is being recognized that these large lipophilic molecules are often poorly absorbed by animal species providing very limited drug exposure for toxicity testing.

Increases in solubility with lipophilic vehicles, including polyethylene glycols (PEG) 300/400, Imwitor, propylene glycol, sorbitol, Tween (polysorbate 80), acidified carboxymethyl cellulose, hydroxypropylcellulose/sucrose/sodium lauryl sulfate (SLS), cremophor, cyclodextrin, and span (sorbitan monoester), have been successfully obtained (Dressman, 1989; Crowley and Martini, 2001). Many of these lipophilic vehicles have been successfully used to enhance absorption for poorly soluble drugs. It is to be emphasized when attempting to enhance exposure maximum caution must be taken to assure that the selected vehicles and their dosing volumes will be well tolerated by preclinical animal species and the toxicity of the formulated drug will not be enhanced by the direct adverse effects of formulation other than what is expected from the increase in exposures.

The rate of drug elimination has an important effect on the extent of drug exposure. Because of the difficulty in knowing when absorption is complete and when elimination begins after oral dosing, it is often difficult to precisely calculate elimination half-life. Drug elimination can be semi-quantitatively estimated by examining the ratio of trough ($C_{min}$) and maximal concentration ($C_{max}$). Drugs with rapid elimination (e.g. short half-life, low $C_{min}/C_{max}$ ratio) generally tend to be less toxic; however, drugs with slower elimination (e.g. longer half-life, high $C_{min}/C_{max}$ ratio) can result in large accumulation of drug after repeated chronic dosing leading to unexpected toxicities. It is to be emphasized however, when a drug is largely cleared via metabolism and the

metabolite(s) is toxic, significant adverse effects can occur with a drug that has a short half-life.

### *Species-specific sex differences in metabolism leading to exposure differences*

It is not an uncommon finding in toxicology studies to have males and females responding to a drug differently. Therefore, it is usually of significant interest to find out if differences in toxicity are due to toxicokinetics differences or related to differences in susceptibility. Sex-related differences in drug metabolism are generally more common in laboratory rats than in other species, including humans, mice, dogs, and monkeys (Skett, 1988; DeBethizy and Hayes, 1994; Shapiro *et al.*, 1995). As early as 1937, Holck *et al.* demonstrated that female rats slept longer than male rats when given hexobarbital (Holck *et al.*, 1937). Subsequently it was proven that prolonged sleeping time was due to a slow metabolism of hexobarbital in female rats than in male rats. Generally, male rats tend to have more CYP per gram liver and greater rate of CYP-dependent metabolism than female rats which may markedly impact the metabolic clearance and overall exposure of the drug. Sex-related differences are developmentally regulated (Dressman, 1989) and appear more frequently in sexually mature rats. Generally, male rats have higher activities of certain important most abundant CYP enzymes than females; however, female rats have higher activities of certain specific CYP enzymes than males (Lin and Lu, 1997). For example, CYP2A2, CYP3A2, and CYP2C11 are male-dominant; however, CYP2A1, CYP2C7, and CYP2C12 are generally female-dominant (Holck *et al.*, 1937; Skett, 1988; Dressman, 1989; DeBethizy and Hayes, 1994; Shapiro *et al.*, 1995). Differential expression of sex-dependent CYPs leads to sex differences in drug exposure. The sexual dimorphic secretion pattern of growth hormone (constant low-level secretion in females versus pulsatile secretion in males) and sex hormones (e.g. testosterone and estrogen) directly regulates the expression of certain hepatic CYPs (CYP2C11 and CYP2C12) in male versus female rats (Kato and Yamazoe, 1990; Legraverend *et al.*, 1992a, b; Waxman *et al.*, 1985, 1990). It is also important to note that as male rats age, their metabolism declines to resemble young female rats (i.e. sexual dimorphism declines). This is due to changes in growth hormone patterns with older male rats exhibiting a sustained release of growth hormone (versus pustule pattern) similar to young female rats. When considering the fact that male rats predominately have higher activity of many CYP enzymes, it is not too surprising that male rats tend to have lower drug exposures than female rats and may show a reduced toxicity.

Other safety species show substantially less and infrequent sex-related differences in metabolism, including species like mice (Macleod *et al.*, 1987), ferrets (Ioannides *et al.*, 1977), and dogs (Dogterom and Rothuizen, 1993). Humans tend to show a relatively less frequent sex difference in drug metabolism. When sex differences in pharmacokinetics are observed in humans, these differences appear to be specifically related to anatomical and physiological differences (e.g. body weight, height, etc.) that may indirectly impact the ADME processes.

### *Dose proportionality in toxicokinetics*

A clear understanding of changes in systemic exposures with increasing doses is critical to interpreting the toxicity response. Given the species differences in rates and extent of ADME process, the comparison of systemic exposure versus doses administered is one of the most practical means of assessing margins of safety (exposure at NOAEL in animals/desired therapeutic exposure). In toxicity studies where doses may vary over several log orders of magnitude, the non-linearity in exposure with increasing doses is relatively a common finding. In interpreting dose proportionality, one also needs to carefully look at the variability across the mean or median values because preclinical animal species tend to vary a lot in ADME processes. These data are best compared when normalized for dose. For example, a dose comparison of AUC/dose will give the best assessment of dose proportionality.

Several possible scenarios may exist with regard to dose proportionality. In scenario A, the increase in exposure is proportional to increase in dose. This usually happens with drugs that follow a linear ADME process. A plot of dose versus AUC/dose will show no or little change with increasing doses. In case B, the increase in exposure is clearly greater than dose proportional and with increasing doses, AUC/dose will increase. This process generally occurs when the kinetics of the drug is dependent on one or multiple saturable processes. The saturable processes may include the following: (a) plasma and tissue protein binding; (b) metabolic enzymes, including saturation by substrate, depletion of cofactors, and product inhibition; (c) renal tubular secretion and tubular reabsorption; and (d) biliary excretion. All saturable processes typically follow Michaelis–Menton kinetics. With increasing concentrations the processes can get saturated (i.e. when concentration exceeds $K_m$ (plasma concentration needed to cause 50% saturation)), and the elimination follows a zero-order reaction ($dC/dt = V_{max}$). Under these circumstances, drug accumulation with high trough concentration may occur with increasing doses. When absorption is limited by dissolution and the saturable clearance occurs in parallel, a sustained plasma concentration versus time profile is often observed with increasing doses. In case C, with increasing doses there is a less than dose proportional increase in exposure. A plot of dose versus AUC/dose will decrease with increasing dose. With increasing doses, the rate and extent of absorption decreases and/or rate of elimination increases. The

absorption can decrease due to (1) poor solubility, (2) poor dissolution, (3) rapid transit time, and (4) saturation of active processes (i.e. influx transporters) (Schanker, 1960; Leahy and Lynch, 1989). In case D, the drug exposure remains similar with increasing doses showing a plateau in absorption. A plateau in exposure is usually observed with drugs that are poorly soluble in GI fluid and rate of dissolution is limited. To demonstrate toxicity at high doses, it is not an uncommon practice in toxicity studies to use doses between 1000 and 5000 mg/kg or 5% maximal in diet without a full understanding of dose proportionality in ADME processes. However, when the availability of drug to potential target sites is limited by poor absorption, the increasing amount of unabsorbed fraction of drug residing in GI tract could cause local GI toxicity (e.g. irritation, inflammation, interference with the absorption of nutrients and minerals) which may not be relevant for humans.

### *Duration of repeated dosing effects on toxicokinetics*

Duration of repeated-dosing-related effects on exposures/toxicokinetics is of considerable interest in toxicology. When toxicity develops during the progress or the end of subchronic or chronic dosing, it becomes important to know if toxicity is due to chronic repeated injury or due to changes in toxicokinetics leading to drug accumulation. Some toxic effects may decrease with repeated dosing due to induction of drug clearance or due to development of adaptive response to toxicity. Typically metabolic induction and a subsequent increase of clearance may occur with repeated dosing; however, in recent years, time-dependent effects on P-glycoprotein efflux transporters, renal tubular reabsorption/secretion, and biliary excretions have been identified as additional potential causes for changes in drug exposure with repeated dosing. Metabolic-induction-related decrease in exposure is normally accompanied by increase in metabolites levels formed due to the induction with the repeated dosing. In certain cases, autoinhibition of drug clearance may lead to drug accumulation that in turn may cause induction leading to a decrease in drug exposure. *Steady-state toxicokinetics* is an important concept in repeated dose toxicity studies. At steady state it can be expected that ADME processes are stable (rate of entry = rate of elimination) and there will be no further increase in exposures with duration of repeated dosing. For drugs following linear pharmacokinetics, 95% steady state can be expected to attained after 5 half-lives. For example, if the elimination half-life is 8 h, then the time to reach steady state will be $5 \times 8$ or 40 h. Therefore, if a drug is dosed every 8 h or three times daily, then steady state will be expected to be attained by 40 h or by fifth dose. Drugs with slower rate of elimination relative to dosing interval will accumulate with repeated dosing. When assuming linear kinetics and one compartment open model, the accumulation factor ($AF$) can be determined as follows:

$$AF = 1/1 - 2^{-e}$$

where $e$ is the dosing interval/half-life.

Therefore, if dosing interval and half-life are equal, a 2-fold accumulation is expected. If the values of $e$ (dosing interval/half-life) are 0.25, 5, 1, 2, 3, and 4, the $AF$ will be 6.3, 3.4, 2.0, 1.33, 1.14, and 1.07, respectively. In simplest terms, the extent of accumulation can be described as follows:

$$\begin{aligned} \text{Accumulation} &= 1/q^{\text{ue}} \times T(\text{doping } \textit{intervalle}); \\ q^{\text{ue}} &= \text{elimination constant} \\ &= 1/[0.693 \times t_{1/2}] \times T \\ \text{or } &= \frac{1.44 \times t_{1/2}}{T} \end{aligned}$$

### *Interanimal variability/genetic polymorphism in drug metabolism in preclinical species*

It is rare to find that all animals in a particular dose group will show a similar toxic response or lack of it when exposed to a test agent. The variability in toxic response has been observed in both inbred and outbred laboratory animals. When high variability in toxic response is observed, toxicokinetics data can help to assess if the variability in response is due to differences in metabolism/toxicokinetics properties or due to individual-based variability in toxicodynamic response. Genetic polymorphism in metabolism is not well characterized in preclinical species, although genetic polymorphism may be similar to humans, which include polymorphic enzymes and other targets. Given the small number of animals per group in toxicology studies, it is often difficult to assess polymorphism in metabolism or toxicodynamics; however, preclinical species can show significant metabolic polymorphism which may impact the assessment of systemic exposure and the interpretation of drug toxicity data. In the case of a celecoxib (anti-inflammatory agent), a polymorphism in the drug metabolism of beagle dogs was demonstrated (Paulson *et al.*, 1999). There were at least two distinct populations of dogs that cleared celecoxib from plasma at either a poor rate or fast rate. The poor metabolizers were designated as PM and extensive metabolizers were designated as EM. In a population of 242 beagle dogs and irrespective of sex, about 45.0% and 53.3% of the dogs were identified as the EM and PM phenotypes, respectively. The EM and PM phenotypes were attributed to be differences in the rate of metabolism of celecoxib by liver CYPs where a high correlation ($r > 0.90$) between *in vivo* clearance and *in vitro* hepatic metabolism rate of celecoxib was determined. In EM dogs, the mean elimination half-life and

clearance of celecoxib were 1.72 and 18.2 ml/min/kg, respectively. When compared to the EM dogs, the PM dogs had a longer half-life (5.18 h) and a slower clearance (7.15 ml/min/kg). Further studies identified CYP2D15 as an important CYP involved in the metabolic clearance of celecoxib. Interestingly four alleles of CYP2D15 designated as CYP2D15*2, CYP2D15*3, CYPD15WT2, and CYPD15 delta in beagle dogs have been identified by Roussel *et al.* (1998). Unlike dogs, CYP2C9 was identified as the major human CYP involved in the metabolism of celecoxib.

When a large interanimal variability in toxicokinetics and metabolism is observed in animals, individual values are relatively more important than mean values because they can be useful in the interpretation of the individual animal toxicity data. In some cases, appropriate statistical tests may be necessary to interpret dose proportionality, sex difference in toxicokinetics, and duration-dependent changes in toxicokinetics.

***Assessment of safety margins with toxicokinetics data***

Doses used in preclinical toxicity studies often utilize log orders of magnitude in excess doses in mg/kg than used in the clinical studies. Traditional approaches for estimation of safety margins have been based on a comparison of mg/kg doses or doses adjusted for species-specific surface area factor:

$$\text{Safety margin} = \frac{\text{No-observed-adverse-effect dose level in animals in mg/kg or mg/m}^{2*}}{\text{Maximal clinical efficacious dose level in humans in mg/kg or mg/m}^{2*}}$$

$$^{*}\text{mg/m}^2 = \text{dose in mg/kg} \times \text{species-specific body surface area factor.}$$

Although the above approach can often provide impressive safety margins, this approach fails to recognize the critical importance of quantitative species differences in ADME processes which are fundamental to the extrapolation of animal toxicology data for humans. ADME processes, especially metabolism, generally do not correlate well with the body weight or body surface area (Voisin *et al.*, 1990). Therefore, safety margins based on administered doses (mg/kg or mg/m$^2$) for drugs that are metabolized are likely to overestimate safety margins. Within the scope of this framework, it is assumed that equal plasma drug exposure will result in equal drug toxicity across species, including humans. This assumption, however, has some important limitations which are as follows: (1) species differences in susceptibility to adverse effects, (2) tissue retention of the drug poorly predicted by plasma concentrations, and (3) differences in elimination pathways. In some cases, the concentration of drug in urine may be more important than in plasma. This is best illustrated by the example of bumetanide, a potent diuretic. While dog and rat showed similar plasma concentrations, the diuretic effects were greater in dogs than in rats. This was due to a higher urinary excretion of unchanged drug in dogs than in rats which were likely to be in a better equilibrium at the site of action than plasma levels (Yu, 1999).

Despite the limitations of the classical toxicokinetics, plasma AUC is a powerful means to extrapolate toxicity from animal species to humans. Generally, plasma AUC is a good surrogate for all ADME processes and safety margins based on the ratio of animal AUC to the human AUC is a key endpoint in predicting the human safety of drug:

$$\text{Safety margin} = \frac{\text{Mean AUC at no-observed-adverse-effect dose level in animals}}{\text{Mean AUC at the maximal clinical efficacious dose level in humans}}$$

It is to be emphasized that for repeated dosing, the AUC should be measured at steady state within one interval of time and with same routes of administration. If routes of administration differ between animals and humans, it is critical to correct AUC for the differences in bioavailability. The AUC data should be assessed at a range of doses and the exposures should not be extrapolated from one dose to another without a full understanding of linearity in kinetic processes. A greater than dose proportional increase in exposure due to saturable metabolism can lead to gross underestimation of toxicity. Species differences in GI first-pass metabolism can lead to poor understanding of the risk of GI toxicity. For this assessment, it is important to consider the exposure to the total drug, including exposure to absorbed versus unabsorbed drug and potential precipitation in GI fluids as a cause for local effects.

Another important factor in interpretation of safety margins based on AUC margins is the impact of plasma protein binding. This is based on the fact that protein bound active substance is unlikely to cross cell membrane and the exposure based on total drug may not be a true representation of the drug at the active target site. Protein binding is a dynamic process and protein drug complexes often involving hydrophobic or hydrophilic interactions are often dissociable. Until a steady state is attained protein–drug complexes are subject to a dynamic process of dissociation and association dependent on total drug and unbound concentrations in tissues. To fully appreciate the value of protein binding it will be important to know the kinetics of association and dissociation of protein–drug complexes. Importance of plasma protein binding in the assessment of safety margins has been controversial since there is no good experimental way to determine the extent of protein binding "*in vivo*" as well as the kinetics of

protein binding and dissociation. Nevertheless, a correction for the protein binding may be necessary when protein binding is very high (e.g. >99%) and a clear species difference in protein binding exists. The AUC of free drug (unbound) can be calculated as follows:

$$AUC_f = AUC_t \times f_u$$

where $AUC_t$ is the total drug $AUC$ and $f_u$ the fraction unabsorbed.

$$\text{Safety margin} = \frac{\text{Mean } AUC_f \text{ at no-observed-adverse-effect dose level in animals}}{\text{Mean } AUC_f \text{ at clinical efficacious dose level in humans}}$$

In some cases of species differences in protein binding, safety margins based on unbound drug can be improved. Safety margins can be greatly improved by taking into consideration differences in protein binding across species. In contrast if protein binding saturates at low drug concentrations, higher doses can result in unexpected toxicity due to increase in free fraction of the drug. With 6,8,-diethyl-5-hydroxy-4-oxo-4*H*-1-benzopyran-2-carboxylic acid a saturable protein-binding-related increase in free drug systemic exposure occurred at doses exceeding saturable absorption and saturable protein-binding leading to unexpected hepatic toxicity (Lin and Yu, 1998). This stresses that an understanding of protein binding, especially at high plasma drug levels, is critical to interpretation of toxicity across species.

### *Application of toxicokinetics in species selection and dose selection for toxicity and carcinogenicity studies*

Good bioavailability and adequate exposure to parent drug and its major metabolites in preclinical species is an important goal of any well designed toxicology study. This helps to assure that toxicity was evaluated at multiples of human exposures in animals and adequate safety margins exist for potential adverse effects in humans. Preclinical animal species that have an adequate plasma half-life and/or clearance for a given drug are likely to show adequate bioavailability and adequate systemic exposures. Based on experience, drugs that are well absorbed and have a moderately sufficient half-life (e.g. 5–10 h) will likely provide an adequate systemic exposure. Because of the saturation of metabolic clearance and protein binding or in absorption, systemic drug bioavailability can change at high doses. Therefore, it is important to have the toxicokinetic exposure data at toxicologically relevant doses in one rodent and one non-rodent species prior to conduct of preclinical toxicology studies.

## SPECIES SELECTION FOR TERATOGENICITY

Evaluations should consider the adequacy of fetal exposure to the test drug and its major metabolites. The human safety evaluation of development and reproductive toxicity (DART) relies exclusively on preclinical animal developmental and toxicity data. One approach is to compare fetal and maternal plasma drug levels at specific stages of gestational development or at the end of gestation in pregnant animals. In practical terms, if fetal levels are at least 5–10% of the maternal levels, the selected species may be adequate for teratology testing. Similar to general toxicity studies, the information about similarity in metabolism between selected DART animal species and humans is necessary to justify the choice of species. Additionally, the adequacy of good systemic exposures relative to potential human exposures is necessary to justify the choice of species, study design, and dosing schedules for DART studies. Most importantly, the species selection for DART studies must consider the relevance of the selected species for identifying reproductive and developmental toxicities for humans. Generally, rats are preferred for fertility studies because of the practicality and a large body of information is available as a reference for reproductive toxicants in rats. Rats and rabbits are preferred species for teratology testing because of the existence of a large amount of background data and the suitability of these species for laboratory teratology studies. Monkeys and dogs have also been used for teratology testing; however, their use for teratology testing should be justified on the basis of specific objectives that cannot be met by standard teratology studies in rats and rabbits. From the regulatory perspective, one rodent and one non-rodent species are required for DART evaluation; however, in some cases a single specie may be sufficient if it can be shown that the selected species have relevance for humans on the basis of pharmacology, toxicokinetics/metabolism, and the biological characteristics.

## DOSE SELECTION FOR PRECLINICAL EARLY DOSE RANGE-FINDING TOXICITY STUDIES

Typically exploratory range-finding studies are conducted to assist in dose selection for the Food and Drug Administration (FDA) mandated Good Laboratory Practice (GLP) toxicity studies needed to support phase I clinical trials. For a large number of drugs, dose selection is difficult for the main toxicity studies, therefore, the dose range-finding studies are of a great value. These early studies

can be from a minimum of 5 to 15 days in duration and depending on the availability of drug typically three to five doses may be used. Selected doses may range from low doses to high doses ranging up to the limit dose of 2000 mg/kg/day. Typically, the low dose should be selected to provide a 2- to 5-fold multiples of the projected clinical efficacious exposure and the high dose should be high enough to produce some toxicity or at the limit dose of 2000 mg/kg/day. Early pharmacokinetic/toxicokinetic data can be very helpful in selecting dose levels, especially the low and middle doses. To conserve the drug, these studies can be conducted in a very small number of animals (5/group for rats) of one sex provided there are no sex-related differences in metabolism. In non-rodents, an ascending 5-day dosing may be conducted at 1 × (e.g. low dose corresponding to a 2- to 5-fold multiples of expected clinically efficacious exposures adjusted for differences in *in vitro* pharmacodynamic activity), 2.5×, 5×, 10×, 20×, etc. or until dose-limiting adverse effects are observed. Toxicity end points may involve histopathology of only major organs of toxicity (typically liver, kidneys, heart, pancreas, lung, brain, GI tissues, sex organs, limited primary and secondary immune organs), limited clinical pathology, and toxicokinetics investigations.

## DOSE SELECTION FOR REPEATED DOSE TOXICITY STUDIES

### High dose

Prior to exposing humans to a new drug entity, especially belonging to a new pharmacological mechanism and/or structure, it is critical to know what adverse effects may occur and if they are reversible. In principle, the high dose should be selected principally based on toxicological considerations. Ideally, the high dose should produce frank toxicity, identify target organ toxicity, and establish a positive correlation between clinical-pathology-based biomarkers and target organ toxicity. Identification of toxicity helps to formulate a better safety monitoring program in phase I–II clinical trials. This also provides assurance that if humans (healthy human volunteers and targeted sick patients) are more sensitive than animals to certain toxicities, appropriate safety monitoring is included in the clinical plans.

Given the dissimilarity in quantitative metabolism, pharmacological mechanisms, and sensitivity to certain toxicity, it is expected that preclinical safety species may not respond to certain pharmacological mechanisms. When toxic effects are not observed with increasing doses, toxicokinetics can be very useful in setting the high dose. If a drug is not getting absorbed with increasing doses, then the lowest dose that provides maximal exposure to drug and its metabolites can be considered as the high dose.

Saturable absorption- or dissolution-limited drug absorption can be demonstrated by establishing that systemic exposure to parent drug and major metabolites has plateaued over the range of doses. In practice, a plateau may be considered when the plasma AUC for the drug and each of its major metabolites does not increase by more than 20% with a 2-fold increase in dose. When there is a large interanimal variability in exposures with increasing insoluble doses, appropriate statistical tests may be necessary to establish a plateau in exposures. If saturable absorption cannot be demonstrated, then the high dose may be based on *maximal feasible dose* or the *limit dose* (generally not to exceed 2000 mg/kg/day).

### Middle dose

In designing the toxicity study, it is also important to fully understand the dose response in toxicity, including the threshold dose for inducing the toxicity. The middle dose selection should consider multiples of projected human maximally efficacious dose, threshold in toxicity response, pharmacodynamic response, and mechanisms of toxicity.

### Low dose

Given the importance of NOAEL in toxicity studies, the low dose should be selected to provide a NOAEL. Ideally, the low dose should be set to provide 2- to 5-fold safety margin over the estimated/projected maximal clinical efficacious dose/exposure.

## CARCINOGENICITY BIOASSAY STUDIES IN RODENTS

The conduct of the 2-year carcinogenicity bioassays remains a major challenge. The US FDA has placed a high importance to the process of dose election and protocol approvals for the carcinogenicity studies. The FDA document has provided details of the information that is needed to seek approval of dose selection and protocol approval prior to initiating carcinogenicity studies (McClain and Dammers, 1981) (Pharmacology/Toxicology, Procedural, Carcinogenicity Study Protocol Submissions). Additionally, the International Conference on Harmonization (ICH) has provided guidance on dose selection for the carcinogenicity studies.

### Use of systemic exposure margins in selecting the high dose for carcinogenicity bioassays

For drugs that are non-genotoxic and well tolerated, a maximum tolerated dose (MTD) may not be attained until excessive unrealistic doses are used. To alleviate the problem of selecting excessive doses, US FDA scientists analyzed carcinogenicity databases available from the US FDA, National Toxicology Program, International Agency for Research on Cancer (IARC), and scientists. Based on the evaluation of carcinogenicity studies of 35 compounds belonging to various pharmacological mechanisms, it was concluded that in the absence of an MTD, an exposure margin of at least 25-fold between systemic exposure in rodents and humans at the maximally recommended clinically efficacious dose will allow an adequate margin of safety. The ratio of 25 will likely allow the detection of a positive neoplastic response in the vast majority of 2-year bioassays for all IARC Class I definitive human carcinogen and 2A possible human carcinogens.

High-dose selection based on the 25-fold AUC margin should consider the following criteria: (1) the drug should have low degree of toxicity; (2) the drug must not be non-genotoxic; (3) the drug must be metabolized similarly in both rodents and humans; (4) if the protein binding is greater than 80%, the AUC should be corrected for protein binding in both humans and in animals; (5) exposure margins should be justified on the basis of the parent drug, parent drug plus major metabolite(s) or solely on metabolites; and (6) exposure data in humans must be attained at the maximum recommended human daily dose.

In practice, maximum recommended human dose (MRHD) is often not established at the time of selecting dose levels for the carcinogenicity studies. Under the conditions of the uncertainty in prediction of MRHD, it is advisable to select an uncertainty factor of 2–5 when using the 25-fold margin. If extrapolations to human suggest that the bioavailability will be good and drug will be metabolically stable, it will be practical to consider an AUC margin of 50- to 125-fold (2- to 5-fold greater than the targeted 25-fold) over the projected exposures at the MRHD. The factor of 2–5 may depend on the following factors: (1) medical need for the targeted therapy, (2) chronic exposure versus intermittent exposure, (3) chronic safety of drug in preclinical species, (4) previous experience with the class of drugs, (5) structure–activity relationship, and (6) inter-human variability in drug exposures.

When the systemic availability of the test drug does not increase with increasing doses, there will be very little benefit in testing the drug at high doses. There are multiples factors that can limit the exposure to drug-related substances, including limited solubility and poor dissolution rate in GI fluids, a very high first-pass metabolism, and saturation of influx transporters. In the vast majority of cases, the solubility and rate of dissolution are major limiting factors in drug absorption. In principle, the drugs that are poorly absorbed will likely attain a plateau in exposures and will offer no benefits to the use of high doses in carcinogenicity studies. The plateau in exposure to the parent drug must be demonstrated over the range of doses to assure that there is no substantial benefit (e.g. 20% or less increase in exposure with increasing doses) in testing the carcinogenicity of high doses. It is also important to establish that the limitations to the increase in exposure with increasing doses are not due to increased metabolic clearance. This can be demonstrated by showing a plateau in exposure to major metabolites with increasing doses.

## CONCLUSIONS

Classical toxicokinetics and drug metabolism studies when conducted to support non-clinical safety assessment studies have greatly reduced the uncertainty in interpretation of preclinical toxicity data and its utility in human health risk assessment. The classical non-compartmental toxicokinetics and drug-metabolism-based data have been particularly useful in selecting the dose levels for short- to long-term toxicity and carcinogenicity studies. Furthermore, these assessments have allowed great improvements in selection of relevant species, formulation, and doses for safety studies. The greatest utility of preclinical toxicokinetics data has been in the interspecies comparison of product toxicity. It is now widely accepted that toxic effects can be better extrapolated from animals to humans when these comparisons are based on toxicokinetics and disposition (absorption, distribution, metabolism, and excretion) data in preclinical species and humans. In this context, safety margin that is based on ratio of animal AUC at NOAEL to human AUC at an efficacious dose is the key predictor of human toxicity risk. It is generally accepted that when the AUC ratio to support safety margin is large, the expected risk of toxicity in humans is low. Although model independent or compartment-based plasma/blood toxicokinetics have served well as a practical means of assessing systemic exposure, they provide no information on the time course of exposure of target organs to drug or metabolites. Overall, toxicokinetics have greatly enhanced our understanding of interspecies differences in toxicity and significance of safety margins.

CHAPTER

# 3

# Physiologically based pharmacokinetic modeling

*Deon van der Merwe, Jennifer L. Buur, and Jim E. Riviere*

## INTRODUCTION

Physiologically based pharmacokinetic (PBPK) models are mathematical simulations of physiological processes that determine the rate and extent of xenobiotic chemical absorption, distribution, metabolism and excretion. Such models can be used for predicting internal doses at target organs and tissues due to their conformity to actual organs, tissues and physiological processes. Internal dose predictions are useful for dose–response analyses and risk assessment involving specific mechanisms and sites of toxicity. Successes in the application of PBPK models to predict xenobiotic concentrations at target sites have led to its acceptance as a modeling technique in risk assessments. It is also used in mechanistic studies of the underlying processes that determine pharmacokinetic profiles and dose-response relationships.

In veterinary toxicology PBPK methods can be used to improve the accuracy of predictions of toxicity across species by applying data obtained in one species to predictions in another species. It can be used to predict the effects of changes in physiological conditions, environmental conditions, activity levels and pathological changes on xenobiotic concentrations in target tissues. This allows for more accurate assessment of risk in varied individual animals and populations. PBPK approaches can be used to study and understand the effects of mechanisms that determine the internal exposure of animals to potential toxins – such as dermal absorption and xenobiotic metabolism. PBPK models can also be used to address problems associated with the exposure of food producing animals to drugs and chemicals that may result in potentially harmful or undesirable residues in meat, milk and other foods of animal origin (Brocklebank *et al.*, 1997; Riviere, 1999; Craigmill, 2003; Buur *et al.*, 2005, 2006; Van der Merwe *et al.*, 2006).

## BACKGROUND

Adverse effects due to exposure to potentially toxic xenobiotics are dependent on the rate and extent of absorption of the chemical into the body, its distribution to susceptible tissues and the specific interactions with biological targets. Predicting tissue concentrations over time is essential for the prediction of adverse effects (Andersen *et al.*, 2006).

Pharmacokinetic models describe the concentration/time profiles of chemicals in the body. Models are predictive tools that can be used to analyze risk due to xenobiotic chemical exposure. Models can also be used as an aid to understanding the mechanisms of chemical absorption, transport and elimination. Various types of pharmacokinetic models have been developed and the appropriateness of a specific model type depends on the available data and the model's purpose (Riviere, 1999). One of the key challenges to the successful use of PBPK models is identifying the appropriate conditions for its application.

The various membranes that form the body's interface with the environment and separates internal organs and tissues have to be permeable to a wide variety of chemicals so that nutrients can be absorbed and waste products eliminated. Depending on physical–chemical characteristics, concentration, solvent systems and environmental conditions; exposure to xenobiotic chemicals through dermal contact, ingestion and inhalation may lead to potentially harmful absorption of chemicals through permeable

*Veterinary Toxicology, Edited by Ramesh C. Gupta*

membranes. Living organisms are adapted to xenobiotic exposure through the development of transport and elimination mechanisms that prevent the build-up of harmful chemical concentrations in organs and tissues. Pharmacokinetic parameters, such as duration of internal exposure and tissue concentrations are useful for estimating risk values when the body's transport and elimination mechanisms are overwhelmed or inadequate to prevent the build-up of harmful chemical concentrations.

Traditional compartmental pharmacokinetic models describe the aggregate result of all the processes involved in determining the concentration/time curve of a compound in a reference compartment – most often the venous blood (also called the central compartment). It uses single or multiple compartments and first-order rate equations chosen to optimally describe experimental data, with no physiological relevance or implied fidelity to anatomical structure or physiology. The purpose of these models is to predict plasma concentrations after similar exposure conditions. PBPK models also make use of compartments, but the compartments are derived from mathematical descriptions of actual body compartments or tissues. Links between the compartments simulate physiological processes of partitioning, transfer, metabolism and excretion (Krishnan and Andersen, 2001). The concentration/time curves of chemicals in specific organs and tissues can be estimated. This offers an advantage over traditional compartmental models, because indirect estimations of concentrations in target organs/tissues based on administered dose, exposure conditions or concentration/time curves in a reference compartment may not be directly related to target organ/tissue concentrations and biological effects. Since PBPK model parameters are derived from actual physiological systems, differences in physiology, anatomy, environment, metabolism and the effects of chemical-induced changes and pathology can be simulated. Parameters can also be scaled to reflect different dose ranges, species, breeds, genetic polymorphism and life-stages.

The advantages of PBPK models are, however, often difficult to realize because the necessary anatomical and physiological parameters are not available and/or the relevant pharmacokinetic processes are not well understood. Ideal, complete PBPK models are not possible because complete knowledge of the modeled system is not attainable. Most PBPK models are, therefore, simplified representations of reality, based on assumptions regarding the most important processes and structures that determine the pharmacokinetic profile of the chemical in question. Typical PBPK models represent the body as a series of well-stirred compartments representing major organs and tissues of interest, a single dose and route of exposure and the major route of excretion. The compartments are linked by blood flow and the movement of chemicals between compartments is determined by tissue/blood partitioning and blood flow rates (Krishnan and Andersen, 2001). However, highly detailed, multiple compartment models can be constructed that include complex dosing regimens or exposure scenarios, detailed organ structures and physiological processes, as well as specific processes of metabolism and simulations of metabolite pharmacokinetics. Models of varying complexity focusing on specific organs and routes of absorption/elimination – such as the skin and respiratory organs have also been developed (McCarley and Bunge, 2001; Andersen *et al.*, 2002; Frederick *et al.*, 2002).

## MODEL CONSTRUCTION

The first step in the construction of a PBPK model is determining the purpose of the model and what internal tissue doses are needed to answer the specific scientific questions being asked. Once that is done, a schematic diagram is constructed that consists of each of the tissue compartments of interest, a plasma compartment, and a compartment or compartments that represent the rest of the system in question. It is often necessary to include more than one compartment to represent the remaining portions of the body to reflect the differences in high and low blood flow tissues. Tissue blocks can be further subdivided into vascular, extracellular and intracellular spaces (Colburn, 1988). Tissue blocks and their subcompartments can be combined as necessary to make the model as simple or as complex as needed. A schematic diagram for a generic whole body model is shown in Figure 3.1. Figure 3.2 depicts a generic tissue block with subcompartments as well as possible binding sites and sources of elimination. In contrast to the full body model, Figure 3.3 presents a schematic diagram used in the prediction of tissue residues for sulfamethazine (SMZ) in swine (Buur *et al.*, 2005). This model has several simplifications including the reduction of number of tissue blocks and the simplification of the tissue blocks into a single compartment. Since this model was designed for the prediction of SMZ drug residues in edible swine tissues, only the edible tissues of muscle, adipose, kidney and liver were incorporated into the model. The rest of the body was lumped into a single tissue block labeled carcass. Elimination is by renal filtration and is schematically diagramed using arrows that are not directed into the plasma compartment. The main metabolite is also modeled and the two xenobiotics are linked together via the liver tissue block. For the purposes of this model, the only tissue of interest for the metabolite is the liver, which is the site of the metabolic pathways. Thus the rest of the body is lumped into a single body component. This is a good example of how complexity can be added or removed from a model in order to accomplish specific scientific aims.

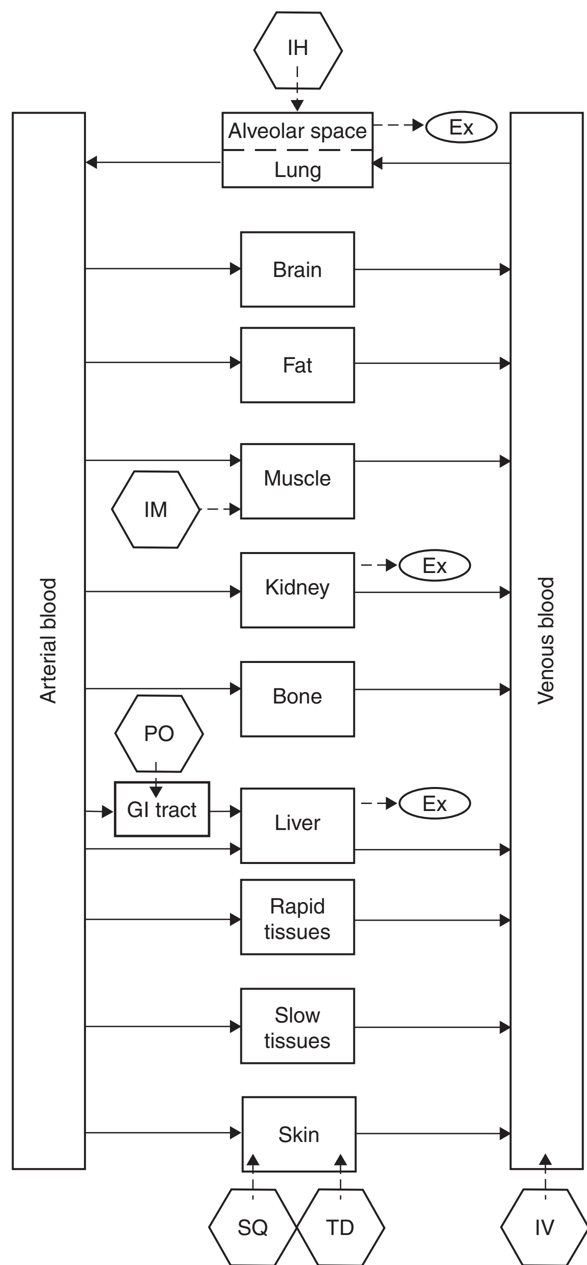

**FIGURE 3.1** Full body model for a generic mammal that includes standard dosing routes of intravenous (IV), intramuscular (IM), subcutaneous (SQ), transdermal (TD), inhalational (IH) and oral (PO). Ex represents excretion and removal of the xenobiotic from the body system. Solid line arrows represent blood flow. Dashed line arrows represent excretion processes. Dash-dot line arrows represent absorption processes.

After a schematic representation is achieved, the next step is to write mass balance equations that represent the changes in xenobiotic concentration in the tissues over time. In order to do this it must be decided if the rate-limiting step for xenobiotic partitioning is due to blood flow (flow-limited model) or diffusion through the cellular membrane (diffusion- or membrane-limited model). Flow-limited models are often for xenobiotics that are small and/

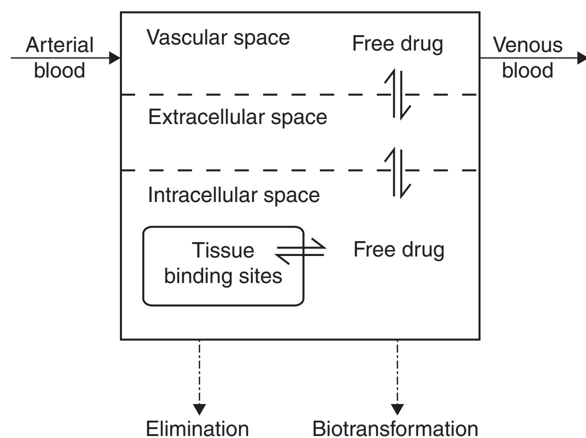

**FIGURE 3.2** Schematic diagram of a generic tissue block. Solid line arrows represent blood flow. Dashed line arrows represent excretion processes.

or lipophilic as well as for organ systems with small volumes or high blood flow to mass ratios. Membrane-limited models, on the other hand, often correspond to large molecules that are polar in nature or large volume organ

systems that have a small blood flow to mass ratio (Ritschel and Banerjee, 1986).

The basic mass balance equation for a flow-limited tissue compartment is:

$$V_t dC_t/d_t = Q_t\,(C_a - C_v) \qquad \textbf{3.1}$$

where $Q_t$, $V_t$ and $C_t$ are the blood flow, anatomic volume and concentration of the xenobiotic in tissue t and $C_a$ and $Cv$ are the concentration of the xenobiotic in the arterial and venous circulations perfusing tissue t, respectively. A basic assumption in flow limited models is that the xenobiotic is in instantaneous equilibrium and is homogenous throughout the tissue block. This is known as a well-mixed model and allows for the relationship between venous blood concentration and the vascular space to be defined according to the ratio:

$$C_v = C_t/P_t \qquad \textbf{3.2}$$

where $P_t$ is the tissue-to-blood partition coefficient for tissue t. Therefore, the final mass balance equation would be:

$$V_t\, dC_t/d_t = Q_t(C_a - C_t/P_t) \qquad \textbf{3.3}$$

This equation can be used in models where all tissue compartments are simplified into a single compartment, like that seen in our example model of SMZ. In contrast to that simplified model, a membrane-limited model does not assume that $C_v$ is in equilibrium with the vascular space. Instead it uses multiple subcompartments of extravascular and intracellular space. The assumption here is that the vascular space is assumed to be instantaneously in equilibrium with the extracellular space. The mass balance equation is then defined by rate of change in the extracellular space per unit of time and can be written as:

$$V_e\, dC_e/d_t = Q_t\,(C_a - C_e) - K_t\,(C_e - C_i) \qquad \textbf{3.4}$$

$$V_i\, dC_i/d_t = K_t\,(C_e - C_t/P_t) \qquad \textbf{3.5}$$

where $V_e$ and $C_e$ are the anatomic volume and xenobiotic concentration of the extracellular space in tissue $t$, $V_i$ and $C_i$ is the volume of the intracellular space and the concentration of xenobiotic in the intracellular space respectively, and $K_t$ is the membrane permeability coefficient for tissue t.

While the above equations do well for tissue blocks that do not alter the xenobiotic, further modifications are necessary for those tissue blocks that metabolize or excrete the xenobiotic. This is most often accomplished by the addition of a mass removal term, Rex. The mathematical definition of Rex can be a simple or as complex as needed and can include anything from a simple first-order equation to detailed Michaelis–Menton equations for multiple enzymes. The resulting equation for a flow-limited tissue block is:

$$V_t\, dC_t/d_t = Q_t\,(C_a - C_t/P_t) - \text{Rex} \qquad \textbf{3.6}$$

For example, if Rex is defined as the clearance of a specific organ the equation would be:

$$Vt\, dCt/dt = Qt(Ca - Ct/Pt) - Ct\, Cl_{organ} \qquad \textbf{3.7}$$

where $Cl_{organ}$ is the clearance of the eliminating organ.

Tissue blocks can be further refined in many cases by the addition of modification terms. You could add terms to describe processes such as protein binding, tissue binding, active transport, billiary excretion, enterohepatic circulation and metabolism.

For example, if Rex is governed by metabolism and the appropriate parameters of enzyme activity are available it may be described using Michaelis–Menton concepts and the equation would take the form of:

$$\text{Rex} = (V_m f_1)/(K_m + f_1) \qquad \textbf{3.8}$$

where $V_m$ is the maximum rate of metabolism, $K_m$ is the concentration at which the rate of metabolism is 50% of maximum and $f_1$ is the free blood concentration in the metabolizing organ.

Once mass balance equations have been written for tissue blocks, the final step is to write the mass balance equation for the plasma compartment. Recall that the inputs of xenobiotic into this compartment are from the venous blood streams from the various tissue blocks. The rate of change in the plasma space per unit of time is then:

$$V_p\, dC_p/d_t = \Sigma Q_t\, C_v - Q_p\, C_p \qquad \textbf{3.9}$$

where $V_p$, $Q_p$ and $C_p$ are the anatomic volume, the total blood flow, and the concentration of the xenobiotic in the plasma compartment respectively. $C_v$ represents the venous concentration of the xenobiotic from tissue t. You can also modify this compartment to incorporate such mechanisms as protein binding or partitioning into red or white blood cells by the addition of modification terms just like you would in the other tissue compartments. The final mass balance equations for the SMZ tissue blocks in our example model are listed in Table 3.1.

## PARAMETER ESTIMATION AND IDENTIFIABILITY

Accurate parameters are essential in PBPK models. As can be seen in the above equations, these parameters are often physiologic (blood flow, organ volume, vascular space,

**TABLE 3.1 Mass balance equations used in the SMZ PBPK model for the parent compound of sulfmethazine.**

| Tissue compartment | Equation |
|---|---|
| Muscle | $V_m \frac{dC_m}{dt} = [C_a - (C_m/P_m)]Q_m$ |
| Adipose | $V_{ad} \frac{dC_{ad}}{dt} = [C_{ad} - (C_{ad}/P_{ad})]Q_{ad}$ |
| Carcass | $V_c \frac{dC_c}{dt} = [C_a - (C_c/P_c)]Q_c$ |
| Kidney | $V_k \frac{dC_k}{dt} = [C_a - (C_k/P_k)]Q_k - (C_a CL_{renal})$ |
| Liver | $V_l \frac{dC_l}{dt} = [C_a - (C_l/P_l)]Q_l - (C_l CL_{acytlation}) + (C_{liver\ met} CL_{deacytlation})$ |
| Plasma | $Vp \frac{dC_p}{dt} = [(C_m/P_m)Q_m] + [(C_{ad}/P_{ad})Q_{ad}] + [(C_k/P_k)Q_k] + [(C_l/P_l)Q_l] + [(C_c/P_c)Q_m] + \text{IV dose} - (C_p Q_{tot})$ |

**V** is tissue volume; **C** is SMZ concentration; **P** is blood:tissue partitioning coefficient; **Q** is blood flow; **CL** is clearance; ***IV*** dose is total ***IV*** dose. Subscripts represent tissues (m: muscle; a: arterial; ad: adipose; c: carcass; k: kidney; l: liver; p: plasma), mechanisms (renal: renal clearance; acytlation; deacytlation), total blood blow (tot) or metabolite concentration (liver met).

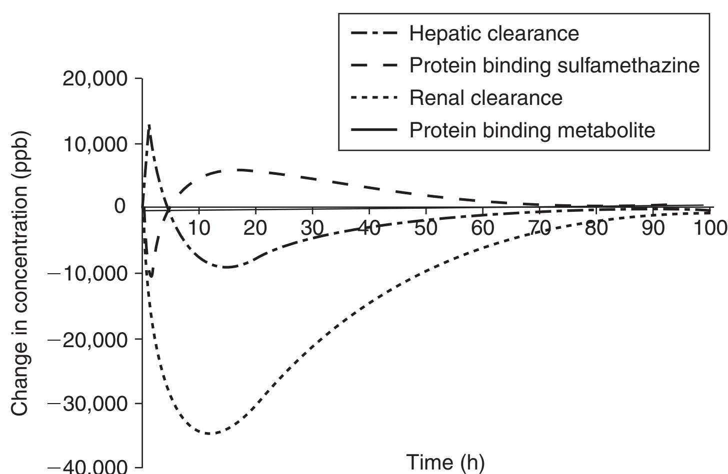

**FIGURE 3.4** Sensitivity analysis of a few parameters in the SMZ PBPK model showing the relative contributions to venous blood concentration of SMZ from protein binding of SMZ, hepatic clearance, renal clearance and protein binding of acetyl-SMZ.

etc.), physiochemical (partitioning coefficients, membrane permeability coefficients, rate of absorption, etc.) and even *in vitro* (protein binding, Michaelis–Menton constants, etc.) in nature. Most of the parameters can normally be found in the published literature with some degree of confidence. Some parameters can be derived using various *in vitro* and *in vivo* experimentation. However, there will be some parameters that are still not accounted for. In this case, you can estimate the value of those parameters using a curve fitting process against known data points (Sheiner, 1985). Several curve fitting software packages are available for this use and most use some function of a least likelihood ratio to estimate the parameters.

It is important to emphasize that a weakness of PBPK models is their dependence upon a large number of parameters. The large numbers of parameters also makes identifiability an issue in some cases. Identifiability is the ability to specifically determine a unique volume for each parameter based on an ideal data set. As you increase the number of tissue compartments, the ability to uniquely identify all parameters is diminished without the inclusion of additional data points. To correct this type of error, multiple tissue compartments can also be sampled. Thus it is not just the number of samples taken, but also the number of tissue compartments sampled that is important for accurate parameter estimation (Audoly *et al.*, 2001). When identifiability is a problem, you can decrease the number of parameters you are trying to estimate by using sensitivity analysis. A sensitivity analysis compares the relative contributions of a parameter to an output of interest (Evans and Andersen, 2000). For example, in the SMZ model above, you may look at the relative contributions to plasma disposition from the parameters of renal clearance, hepatic clearance and tissue partitioning coefficients. Figure 3.4

shows a sensitivity analysis of various parameters for the SMZ model. The parameters of protein binding, hepatic clearance and renal clearance have the greatest effect at early time points. If you have only enough data to identify two parameters, the sensitivity analysis can help narrow the scope of important parameters.

Parameters can also be estimated using statistical distributions rather than single numbers. Just like with single point estimations, the accuracy of the model is directly proportional to the accuracy of the distribution. In many cases, distributions of populations can be found in the literature. There are also several software programs that can estimate distributions given a shape (normal, log-normal, beta, etc.), mean and range.

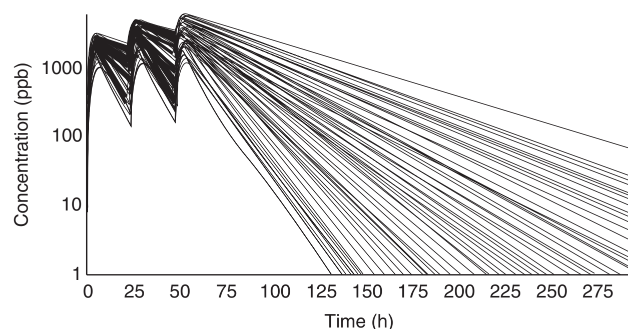

**FIGURE 3.5** Representative Monte Carlo analysis for SMZ PBPK model after multiple oral dosing. Parameters varied included gastric emptying time, absorption rate, protein binding of SMZ, protein binding of acetyl-SMZ and hepatic clearance.

## MODEL VALIDATION

The final step in building a PBPK model is confirming that your model can actually be predictive. This type of validation occurs by comparing model simulations to an external data set. It is important to exclude any data used in the estimation of parameters in your external data set. Simulations of the model are typically plotted along side observed data points (simulation plots); predicted values plotted versus observed values (correlation plots) and residuals plotted against time (residual plots). Results are then subjected to qualitative and quantitative analysis for goodness of fit. Unlike traditional pharmacokinetic modeling approaches, there is currently no standardized way to evaluate the goodness of fit for PBPK models. Often, a combination of visual examination of residual plots and simulation plots along with the quantification of regression correlation values ($R^2$ values) are used. In general, residual plots should have even distributions around zero without noticeable time bias. Correlation plots should have regression lines with $R^2$ values close to 1 and intercepts close to your starting value (in most cases, this is zero). Simulation plots also look for time and concentration bias.

If a complex model were created by the incorporation of population distributions, then model validation becomes even more qualitative in nature. In this case, a sampling method such as Monte Carlo or bootstrapping is used to generate specific numbers for the parameters in question. This is repeated a large number of times and the output becomes a set of simulations all plotted alongside each other. This gives a visual representation of what a population may look like (Thomas *et al.*, 1996; Sweeney *et al.*, 2001). Figure 3.5 shows a Monte Carlo analysis using the SMZ model after multiple oral dosing (Buur *et al.*, 2006). The parameters varied to get this output included oral absorption rate, rate of gastric emptying, protein binding and both renal and hepatic clearances. Validation of this data is performed by plotting the multiple simulation runs along side the external data points just like the simulation plots described above. However, confidence in the distributions and in the model is determined, not by correlation coefficients or residual plots, but by visual inspection alone. The more data points covered within the spread of the output, the higher the confidence in the predictive ability of the model.

## APPLICATIONS

PBPK models are most often used in toxicology to predict the concentrations of toxic chemicals and/or their toxic metabolites in target tissues. Target tissue concentrations predict the time course of toxic effects better than exposure concentrations or concentrations in a reference compartment such as venous blood. The adaptability of PBPK models makes them suitable for extrapolations across different exposure scenarios and routes, species, breed, age, physiological state, pathological changes and sex differences. PBPK models are also used in fundamental research to understand the effects and interactions between anatomical structure, tissue composition and physiological processes that influence the concentration/time course of xenobiotic chemicals.

Toxicologists are often faced with situations where the risk of chemical exposure must be estimated in the absence of observed data under the specific conditions of the exposure being analyzed. An advantage of PBPK models is that different exposure scenarios can be simulated using the same base model by varying the mathematical descriptions of the dosing regimen. These may include single, repeated or continuous oral ingestion, single or repeated intravenous boluses, constant intravenous infusion, single or repeated injections at various body sites, inhalation and topical exposures under various conditions.

When a good PBPK model is available, this approach result in more accurate predictions of risk compared to estimates based solely on exposure concentration and time (Simmons *et al.*, 2005).

Changes in physiological processes, environmental conditions, activity levels and pathological changes typically result in changes in the parameters used to describe a physiological system. If the extent and direction of parameter changes are known or predictable, those parameters can be altered in a PBPK model to simulate its effects on tissue xenobiotic concentrations. An example is the effects of body size, body fat content and sex on the pharmacokinetic behavior of trichloroethylene (Sato *et al.*, 1991). Similar approaches have been used to simulate the effects of pregnancy (Gabrielsson *et al.*, 1984), lactation (Fisher *et al.*, 1990) and species differences (Gabrielsson, 1991). The key requirement is that the parameters used, such as metabolic rate constants, physiological descriptors and partition coefficients, must be available or scaleable. It is also essential that the most important kinetic processes, such as pathways of metabolism, routes of excretion, active transport mechanisms and protein-binding potential, are similar or that the differences are well understood and describable.

PBPK models may be used to determine a minimum toxic dose in a species for which adequate data is not available based on toxicological data obtained in routine laboratory animal studies. This is achieved by linking tissue concentrations with pharmacodynamic effects. A dose metric, such as the area under the curve (AUC) of the tissue concentration over time, can be associated with a specific toxicological endpoint – such as a no-observed-adverse-effect level (NOAEL). Uncertainty factors can be applied to the dose metric to determine maximum acceptable exposure levels, also known as a reference dose, for risk assessment and regulatory purposes. The advantage of using well-validated PBPK models to obtain a reference dose is that PBPK models can eliminate some of the uncertainty associated with classical toxicological studies because variability associated with study design and interspecies variation can be accounted for. This can reduce the need for uncertainty factors while maintaining an acceptable margin of safety when estimating maximum acceptable exposure levels. An example of this process was the use of a PBPK model for a NOAEL of acetone in the rat and the human to increase the reference dose of human exposure to acetone (Gentry *et al.*, 2003). This was achieved by reducing uncertainty associated with pharmacokinetic, pharmacodynamic and interspecies variability. It resulted in a reduction of the uncertainty factor from 300 to 60. The new uncertainty factor retained a factor of 10 for human variability and a factor of 6 for the uncertainty associated with using a subchronic study to predict chronic effects. The new reference dose increased from 0.3 mg/kg/day, obtained from classical risk assessment methods, to 16 mg/kg/day.

The capacity of PBPK models to include non-linear processes, such as enzymatic processes typical of xenobiotic metabolism, makes it suitable for extrapolations across wide dose ranges. For example, the non-linear effects of high doses of ethylene oxide on DNA and hemoglobin adduct formation in the rat could be successfully simulated by using *in vitro* estimated rate and saturation parameters of hemoglobin and DNA binding, glutathione conjugation and hydrolysis (Krishnan *et al.*, 1992). However, predictions outside of the range of concentrations at which a model was validated may be misleading due to differences in xenobiotic metabolism rate parameters at widely varying concentrations. An example is the over-prediction of perchloroethylene metabolite excretion when the metabolism rates estimated using relatively high-dose exposures were used to predict rates of metabolism at the low concentrations relevant to cancer risk assessments. Some PBPK models overestimated rates of metabolite excretion at low parent compound concentrations 5–15-fold (Clewell *et al.*, 2005).

PBPK models can be applied to problems associated with the exposure of food-producing animals to potentially toxic chemicals and drugs and the resulting residues in meat, milk and other edible tissues of animal origin. Parameters describing the terminal phase of concentration/time curves are traditionally obtained using classical compartmental or non-compartmental pharmacokinetic methods. These parameters are then used to estimate residues at time points outside the time range of experimental data or below the detection limits of analytical techniques. These methods assume linearity outside the time and concentration ranges of experimental data. They also assume that the simulated exposure scenarios, study design and study animals are similar to that of the observed data used to obtain the parameters. Validated PBPK models, however, can overcome some of these disadvantages to provide more realistic and accurate predictions at lower concentrations and at extended time points. PBPK model predictions are less dependent on the dosage and route of administration used to validate the model and PBPK models can be adapted to account for variation in study designs and study animals. Monte Carlo analysis can be used to account for population variability in the food animal and can help to isolate sources of uncertainty in risk assessment.

Specific processes involved in the absorption, distribution, metabolism and elimination of xenobiotics can be isolated and modeled using PBPK methods. This approach makes it possible to describe specific processes and structures in greater and more physiologically accurate detail without the models being too cumbersome. To achieve the most benefit from this approach, degrees of freedom should be protected by estimating most parameter values independently from the concentration/time curve of observations in a reference compartment. When the

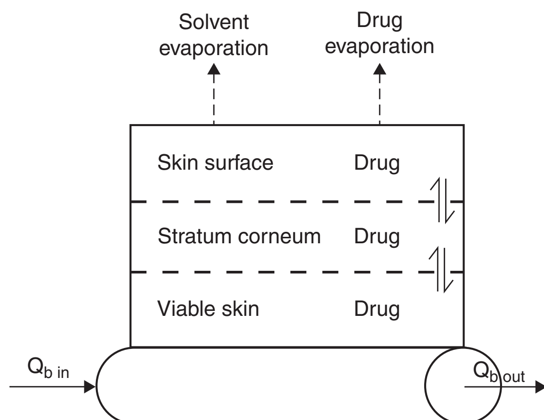

**FIGURE 3.6** A PBPK model of organophosphate pesticide dermal absorption in a flow-through diffusion cell (Van der Merwe *et al.*, 2006).

influence of any dependent parameters on the reference concentration/time curve can be reliably identified, the model can be used to simulate the effects of key parameters. It can also be used to do limited hypotheses testing related to key parameters. An example of this approach is the use of a PBPK model to describe the *in vitro* dermal absorption of organophosphate insecticides in flow-through diffusion cells (Figure 3.6) (Van der Merwe *et al.*, 2006). Extensive independent parameter estimations reduced the dependent parameters to three – each with an identifiable influence on the concentration/time curve in the receptor chamber of the flow-through cell. Sensitivity analyses were used to identify important parameters and to generate hypotheses regarding the effects of changes in the skin related to those parameters. For example, the number of cell layers in the stratum corneum was identified as an important parameter and the effect of varying numbers of cell layers was simulated. The simulation could then be verified by using skin with varying layers of cells in the stratum corneum in flow-through cell experiments.

## CONCLUSIONS

PBPK models provide a continuously evolving new frontier in toxicokinetic modeling. As our understanding of the systems and processes involved in toxicokinetics improve and expand – so does our ability to use new knowledge in PBPK models. It allows for the adaptability needed to simulate varied physiological processes and biological system conditions. PBPK models are likely to assume an ever more important role in our efforts to understand and predict the consequences of exposure to toxins and its application in veterinary toxicology can be expected to expand.

# Toxicological testing: *in vivo* and *in vitro* models

*Magda Sachana and Alan J. Hargreaves*

## INTRODUCTION

The large number of new chemical entities in human and veterinary pharmaceutical industry has led to increased demand for safety screening to ensure successful drug development. Part of this screening process includes the determination of the toxic potential of these new compounds by applying internationally recognized *in vivo* or *in vitro* toxicological tests. The importance of toxicological testing is critical, as many pharmaceutical and agrochemical products have to be assessed for their safety, before they become available for general use. Furthermore, in some cases, basic research can produce data that eventually leads to the ban of certain chemicals because they were proved to be unsafe.

Animal studies and validated *in vitro* models are extensively used for screening of agents in order to identify and predict potential ill-effects to humans, domestic and farm animals. Although the detection of adverse health effects of xenobiotics is the main objective of toxicity testing, it can be complemented by more sophisticated biomolecular approaches aimed at the elucidation of the mechanisms of action of certain chemicals.

Another area of veterinary interest regarding toxicological testing is the evaluation of the safety of veterinary drugs for food animals, as well as the safety assessment of veterinary drug residues in human food of animal origin, in order to determine the doses that cause non-observed effect level (NOEL) and consequently to establish the acceptable daily intake (ADI) in human diet.

Toxicological testing laboratories now have to comply with strict official controls and inspections on animal use at any time that can be reinforced by relevant legislation. In most European countries, veterinarians play a pivotal role in toxicity testing and are required by law to be employed by designated establishments that undertake experiments on animals, including toxicological studies. More specifically, a Named Veterinary Surgeon is responsible not only for the health and well being of laboratory animals but also to advise on the selection of adequate *in vivo* models and ensure that priority is given to the use of alternative methods during the local ethical review process. Furthermore, the refinement of experimental techniques and husbandry approaches should be one of the priorities of a veterinary surgeon working in animal units, especially where regulated procedures take place, and distressed animals should be kept under very close supervision by a veterinarian. A similar approach is used in the US, where all institutes are also obliged to establish an Institutional Animal Care and Use Committee (IACUC), where the participation of a trained and experienced veterinary surgeon is essential to ensure that all aspects of the 3 "R"s (replacement, reduction and refinement) (Russell and Burch, 1959) have been followed before approving animal use for toxicological studies.

A veterinarian with specific professional or scientific interest in toxicology should be aware of the alternative methods in toxicity testing, advise on replacement and refinement of laboratory animals used in toxicological studies and safeguard animal welfare. The main aims of this chapter are to outline the major aspects of *in vivo* and *in vitro* models in toxicity testing and to give a brief overview of endpoint determination. The principal focus will be to highlight some of the current *in vivo* and *in vitro* models available in toxicity testing and inform on new technologies and approaches used in this field.

# *IN VIVO* MODELS IN TOXICITY TESTING

## Introduction

With the continuous development of new chemicals and pharmaceutical products, laboratory animals have become important and well-established tools for the generation of *in vivo* toxicological data. Originally, *in vivo* experiments were aimed at the prediction of acute systemic toxicity usually in rodents. Currently more sophisticated, targeted and multi-species approaches with well-defined endpoints and experimental protocols are applied to toxicological studies, especially for regulatory testing.

As the science of toxicology evolves, an increasing number of *in vitro* alternative tests have been validated or they are currently under development. However, in some cases, animal models in toxicity testing are irreplaceable, especially in the tests required by the regulatory authorities to protect human and animal health. Furthermore, there is public demand to know the toxicity risks posed in every day life, which necessitates the use of animal models comparable to humans.

Although animals are relatively expensive experimental models compared to the alternative methods discussed later, there are several important reasons for their continued use. Firstly, there is extensive information available on their normal biochemical and physiological properties. Secondly, the published data from the measurement of toxicological endpoints *in vivo*, using models of relevance to humans and domestic/farm animals, makes animal testing a valuable tool to predict toxicity.

The animals that are most commonly used in toxicological testing are rodents and rabbits (Table 4.1). Cats and dogs are used less frequently in toxicity testing (and mostly in preclinical toxicology or phase I pharmacological studies), whereas non-human primates are rarely used and mainly to study metabolism of toxic compounds. In this table are not included the studies conducted on companion animals to determine safety limits in products that are directly applied to cats or dogs (EPA, 1998a). The interested reader is referred to some more specialized books regarding animal toxicity testing (e.g. Arnold *et al*., 1990; Gad and Gad, 2006) and some useful websites relevant to regulatory toxicological testing (e.g. http://www.epa.gov/opptsfrs/publications/OPPTS_H

## Animal welfare in toxicity testing

Animal welfare legislation is currently applicable in most countries to prevent misuse of animals in toxicological testing. In the US, the Animal Welfare Act as amended (7 USC, 2131-2156) provides guidelines and protection to animals used for scientific purposes including toxicity testing. In Europe, because of new developments in alternative approaches to animal testing and the increased public concern about animal welfare issues, Directives 86/609/EC and 2003/65/EC will be shortly amended or replaced by new directives, in order to upgrade the minimum standards for laboratory animals by introducing appropriate animal welfare indicators and better training and information for animal handlers. Furthermore, it is necessary that there is explicit and easy to follow documentation in each project licence involving toxicological testing in animals, where the steps followed in case of animal distress are described. Testing new chemical compounds on *in vivo* models can lead sometimes to pain, discomfort or animal distress. Animals exhibiting signs of suffering should be examined by a veterinarian or trained personnel and, if there is a good scientific reason to continue the study, administration of analgesics should be considered. Other options available are the euthanasia of the distressed animals and the decrease or the discontinuity of the test compound dose.

In general, there is a trend for improvements to enhance animal welfare, not only in animal housing (e.g. breeding, handling and feeding) but also in the same regulatory toxicity testing guidelines, by applying humane endpoints and decreasing the number of animals required (Combes *et al*., 2004).

Handling laboratory animals and administering toxicological compounds is a stressful procedure for both the animals and the designated personnel. In recent years, there has been an attempt to apply the highest ethical standards not only by introducing an excellent environment and a social and complex housing but also by reducing and improving any invasive techniques used on laboratory animals.

Implanted biosensors are now available that permit the continuous telemetric monitoring of physiological and biochemical parameters in experimental animals, and have been proved useful in toxicological studies to minimize not only the artefacts due to animal handling and restraint but also to improve animal welfare. In addition, non-invasive and currently expensive methods such as magnetic resonance imaging (MRI) and nuclear magnetic resonance spectroscopy are available for the visualization of pathological findings and determination of the distribution of a test chemical in laboratory animals, respectively, which contribute to improved animal welfare.

## Routes of test compound administration

Toxicity testing in animal models is most useful if it imitates the human or domestic/farm animal route of exposure to chemical agents. Based on the medium of exposure in human and domestic animals, it is possible to decide on which is the administration route of choice in animal toxicological tests (Table 4.2). Depending on the route of administration, experimental evaluation may differ because of variation in the absorption, metabolism and elimination of a compound. Oral exposure can lead to absorption by the digestive system and metabolism by the liver, whereas following inhalation a toxic compound is more likely to be absorbed by the respiratory system. Metabolism of xenobiotics can also occur in placenta, in the test dam and foetus. This can lead to changes in the balance of parent compound and metabolites, complicating the picture even more in case of developmental toxicity tests.

This metabolism of administered chemical should be relevant to human or domestic animals and is critical for risk assessment exercises. The final toxic effect will depend on a balance between the level of toxic agent reaching the target tissue and its rate of elimination and/or bioinactivation by mixed function oxidases, serum hydrolases or binding to serum proteins. Furthermore, there are interspecies differences regarding the metabolism of xenobiotics (Nebbia, 2001). For example, cats are at high risk to develop hepatotoxicity especially after paracetamol administration. This is due to differences in bioactivation of paracetamol, which occurs only in cats through *N*-hydroxylation with the help of cytochrome P450 2E1, during the oxidative reactions in phase I transformation (Nebbia, 2001). Ruminants are less susceptible to organophosphates (OPs) such as parathion than monogastrics, because the rumen microflora plays an important role by reducing the nitro group of OPs to an amino group (Nebbia, 2001).

The majority of toxicological studies commonly employ administration of the agent in animal feed or water or by

**TABLE 4.2 Proposed administration routes of test compounds in laboratory animals based on the medium of exposure**

| Medium of human and domestic/ farm animal exposure to toxicant | Administration route |
|---|---|
| Food commodities | Oral |
| Water | Oral |
| | Inhalation |
| | Dermal |
| Air | Inhalation |
| Household/environmental surfaces | Oral |
| | Dermal |

stomach intubation (i.e. by gavage) in order to imitate a known or potential human or domestic animal exposure. The use of oral gavage is commonly used in administration of high doses of xenobiotics and in developmental toxicity tests, but is less practical in case of long-duration studies. Inhalation is used when there is a need to duplicate industrial or environmental exposure to dusts, aerosols and fumes. In this case, nose, head or whole body exposure chambers are used, depending on the exposure time. For cutaneous administration, a toxic agent may be injected intradermally or simply applied topically on the skin or ears and sometimes covered with bandages. In case of experimental studies where the need for complete absorption of a tested compound is considered essential, parenteral routes of administration (intraperitoneal, intramuscular, intravenous and subcutaneous) are selected. However, the solubility and bioavailability of the tested agent can also influence the degree of absorption and how much of it is directly available in a laboratory animal.

Toxicokinetic and pharmacokinetic information on tested compounds and their comparison among laboratory animals and humans are also important to determine dosing parameters and improve the toxicological data obtained. The administered dose in toxicological studies should be decided taking into account many physicochemical parameters of chemical agents, biological differences between species, previously published data and after careful planning or preliminary experimentation.

## Reproductive toxicity tests

Reproductive toxicity testing is based on the measurement of reproductive functional and structural defects caused by toxic agents in both males and females. The toxicity endpoints most frequently studied in reproductive *in vivo* testing are summarized in Table 4.3. Rats and, to a lesser extent, mice are the species of choice in reproductive toxicological testing because they are considered inexpensive compared to bigger mammals (EPA, 2000; OECD, 2001a). On the other hand, small rodents need to be euthanized even for simple endpoints such as collection of sperm, whereas rabbits can be sampled regularly without being sacrificed, making them an alternative in reproductive toxicological tests (Foote and Carney, 2000). Some of the disadvantages of using rabbits are the higher cost due to greater amounts of chemical compounds administered and the increased cases of abortions because of the relatively high incidence of gastrointestinal dysfunction. For example, rabbits are poor models for veterinary residue testing and, more specifically, for antibiotics because these compounds have been found to cause diarrhoea and consequently abortion (Barlow *et al.*, 2002).

**TABLE 4.3 Selective endpoints applied to laboratory animals during reproductive toxicity testing**

| Female | Male |
|---|---|
| Reproductive tract morphology | Sperm structure/morphology |
| Reproductive tract receptors | Sperm motility/viability/count |
| Ovum properties | Sperm DNA integrity |
| Recovery of blastocysts | Hormonal balance/Receptor interactions |
| Hormonal balance/receptor | Fertility testing interactions |
| Length and normality of oestrus cycle | |
| Fertility testing | |
| Uterine condition | |
| Implantation | |
| Lactation | |
| Maternal behaviour | |

Dogs have been occasionally used for reproductive toxicity testing, because the physiology of their reproductive system in both sexes has been extensively studied, contributing to significant background knowledge (FDA, 1982). However, the dog is not the model of choice in reproductive toxicity testing because it is a rather expensive animal model and the number of litters is not as high as in rodents. The main difficulty in running reproductive toxicological tests is the requirement for an oestrous-synchronized population. Both the induction of ovulation by hormonal treatment and artificial insemination mainly in rabbits and dogs can overcome this problem and allow advanced planning for animal fertility studies.

Since exposure to chemicals can occur throughout life, a multi-generation study which extends over at least two generations, using a single type of laboratory rodent, is desirable in order to reveal reproductive toxicological data (OECD, 2001a; Barlow *et al.*, 2002), although this approach requires large numbers of animals and it is time consuming.

## Developmental toxicity testing

Developmental toxicity testing is primarily used to determine hazard regarding the potential effects of prenatal exposure on the developing foetus. These studies focus on functional and structural changes that can be observed throughout the development from zygote to neonate. The most important developmental phase is the organogenesis period that is always taken into account in developmental toxicity testing. Based on these studies, chemical compounds can be categorized as teratogenic and/or foetotoxic by recording structural malformations, developmental retardation and/or mortality, respectively. The vast majority it teratogenic chemical agents have been identified using rodent experimental models (EPA, 1998b, 2000;

OECD, 2001b). However, the failure of rodents to detect teratogenic signal on some occasions and the similarities in placentation and pregnancy physiology between humans and rabbits, led to the use of the rabbit as a second model for assessing the effects of toxic compounds on development (EPA, 1998b; Foote and Carney, 2000; OECD, 2001b). Furthermore, although non-human primates have been suggested as models for teratological testing (Buse *et al.*, 2003), they have several limitations such as a long gestation period, only single or twin offspring, high rates of abortion and ethical constraints.

The detection rates for veterinary pharmaceutical agents demonstrated to be teratogenic/foetotoxic were found to be 55–79% using individual species (Hurtt *et al.*, 2003). However, when the rat and rabbit data were both considered, there was a significant increase in detection rate to almost 100%, suggesting that in the absence of teratogenicity in rat, a second species developmental test in lagomorpha is required to provide high standards of public protection (Hurtt *et al.*, 2003).

## Cutaneous toxicity testing

The aim of *in vivo* assays for cutaneous toxicity is not only to assess potential acute local irritation but also to evaluate acute, subchronic and chronic systemic toxic effects. During cutaneous toxicity tests, animals are monitored for skin reactions/dermal effects, clinical, gross or microscopic pathological findings depending on the duration of a toxic compound administration and the observation period.

The albino rabbit has been until recently the animal model of choice because of the high permeability and sensitivity to toxic agents exhibited by its skin, which sometimes led to over-prediction showing little relevance to human irritation (Auletta, 2004). Currently, albino rats and occasionally guinea pigs are considered preferable species to assess local irritation. Traditionally, guinea pigs and mice have been used also to perform sensitization tests (EPA, 2003). On the other hand, long-term cutaneous toxicity studies usually require the use of a rodent (albino rat and mouse) as well as a non-rodent model. Minipigs have been proved to be a reliable non-rodent species because their skin demonstrates many physiological similarities with those of humans and pigs (Auletta, 2004). Other non-rodent models are dog and non-human primates, commonly used to test the metabolism of toxic agents and the safety of newly designed recombinant pharmaceutical products (Vail *et al.*, 1998; deBlois and Horlick, 2001).

## Genotoxicity testing

The aim of genotoxicity testing is to detect gene damage induced by the test compound, by measuring chromosome aberration and breakage, point mutation, and other DNA and chromosomal effects *in vivo*. The host-mediated assay is based on the inoculation of a microorganism into a rodent such as mouse, rat or hamster and subsequent assessment of the point mutations found in the microorganisms, after certain treatment of the rodents with the potential mutagen (Gabridge and Legator, 1969; Dhillon *et al.*, 1995; Loomis and Hayes, 1996). On the other hand, to identify chromosome breakage, male rodents are treated with the test compounds and, after mating with untreated females, foetal mortality and survival are recorded (OECD, 1984; EPA, 1998c).

The mouse spot test is capable of detecting somatic gene mutations and is based on *in utero* exposure to the tested chemical. This *in vivo* mutation test works by monitoring the appearance of coloured spots in the coat of the animal that may appear due to altered or lost specific wild-type allele in a pigment precursor cell (EPA, 1998h).

A popular *in vivo* test to identify genetic risks is the rodent bone marrow micronucleus test, although it is not the most sensitive test and it does not improve predictivity of rodent genotoxicity when combined with *in vitro* tests (OECD, 1997a; Zeiger, 1998). However, this *in vivo* test is widely used because it is relatively easy to perform. Another *in vivo* test that has been validated and recommended by Organisation for Economic Cooperation and Development (OECD, 1997b) is the rat liver unscheduled DNA synthesis (UDS) test. It is worth mentioning that none of the above approaches are suggested to be used individually to predict genotoxicity. Negative or positive results should always be confirmed first by *in vitro* or non-mammalian mutagenicity tests.

## Carcinogenicity tests

*In vivo* assays of carcinogenicity examine the possibility that a tested agent might cause tumours and other chemically related effects in one or more animal species. Currently available is the rodent carcinogenicity test which combines the use of F344 rats and B6C3F1 mice (OECD, 1981a, b). This test runs for up to 2 years and involves the use of three different concentrations, five different administration routes and both sexes. The results are based on clinical chemistry, gross and histopathological analysis of more than 40 tissues and organs in order to determine the site, the number and type of tumours (OECD, 1981a, b; Chhabra *et al.*, 1990).

One serious disadvantage of using mice in carcinogenicity testing is their tendency to present high incidence of spontaneous liver or lung tumours in some strains, leading occasionally to inconclusive results (Gad, 1998). Furthermore, because of the long duration of carcinogenicity tests and therefore the old age of laboratory animals, it means that the natural occurrence of tumours increases, making it difficult to distinguish between a real treatment and a background carcinogenic effect. In addition, the most

common mechanisms of tumour development in rodents may not be relevant to human carcinogenicity, posing limitations to any attempt to use *in vivo* data for carcinogen risk assessment.

Tumorigenic tests using dogs are limited because of the high cost and the long duration of the studies (up to 7 years). Furthermore, dogs demonstrate high susceptibility to aromatic amines and therefore care should be taken when using these animals for the evaluation of potential carcinogenic compounds of this category (Loomis and Hayes, 1996).

## Neurotoxicity

The neurotoxic potential of chemical compounds can be assessed by determining relevant effects on the autonomic or central nervous system (CNS), not only in adult but also in developing animals. Clinical signs including changes in behaviour (e.g. movement, motor co-ordination or reflexes, paralysis, tremor, learning and memory), neurochemical (e.g. activity of enzymes associated with neuropathies, cell signalling pathways, synthesis, release and uptake of neurotransmitters), neurophysiological (e.g. electroencephalography, nerve conduction velocity) and neuroanatomical effects are commonly explored.

Rodents are the most frequently used animal models and there is a considerable number of available guidelines to examine the neurotoxicity of xenobiotics on them (OECD, 1997c; EPA, 1998d, e). However, an important issue related to the selection of animal model in neurotoxicity testing is the delayed onset of effects manifested by toxic agents. For example, in the case of assessment of the potential of OPs to produce delayed neuropathy induced by organophosphate (OPIDN), as rodents are not the most sensitive models, the use of the hen model is recommended (OECD, 1995a, b). The two protocols used in the hen model involve either acute or repeated dosing for up to 28 days and determination of the enzymes acetylcholinesterase (AChE) and neuropathy target esterase (NTE), clinical observation and histopathology of the CNS (OECD, 1995a, b).

Furthermore, the need to address the specific risks of the developing nervous system has led to the application of more specific developmental neurotoxicity testing guidelines in rats (EPA, 1998f; OECD, 2003). Although rodents are the animal model of choice, the main problem using them in developmental studies is that the period of enhanced brain growth takes place during the first 10 days after birth, whereas in humans, dogs, guinea and mini pigs, this period is completed prenatally. In conclusion, for predicting developmental neurotoxicity risk in humans, the rat is the recognized model. However, dogs, guinea and mini pigs are also widely used to test pharmaceutical compounds that target children, due to the limitations of the rodent model (Kaufmann, 2003).

## Immunotoxicity

Immunotoxicity tests are designed to detect adverse effects of xenobiotics on the immune system including all the relevant cells, organs and mechanisms of immune response, whether or not there is a measurable disturbance in host resistance. Toxic substances can directly or indirectly cause immunotoxicity, either by inhibiting the enzymatic activity of esterases and serine hydrolases in the immune system or by chronic alteration in metabolism of organs in the immune and nervous system, respectively. Some of the approaches, tests and endpoints used to assess *in vivo* immunotoxicity are presented in Table 4.4 (OECD, 1995c; EPA, 1998g; Barlow *et al.*, 2002; Galloway and Handy, 2003).

Laboratory rodents, especially mice, are used in toxicological tests because basic immunological studies were mainly conducted in this species. The immune elements

**TABLE 4.4 Immunotoxicity endpoints, methods and approaches used for *in vivo* toxicity testing**

| Tests | Methods | Endpoints |
|---|---|---|
| Non-functional tests of immunotoxic response | Immunopathology | Lymphoid organ weight<br>Histopathology of lympoid tissues, including bone marrow |
| | Routine haematology | Immunocyte viability/differential count<br>Immunoglobulin levels |
| Functional tests of immunotoxic response | Measurement of humoral immunity | Antibody response<br>Antibody plaque forming |

| | Measurement of cell mediated immunity | Mitogen-induced cell proliferation<br>Natural killer cell activity<br>Mixed lymphocyte reaction<br>Delayed hypersensitivity |
| | Host resistance assays | Mortality and organ histopathology due to bacterial, virus and parasitic infection |

and interactions in rodents and humans are very similar and if the toxicokinetic properties of tested chemicals are close, then the use of mice or rats is recommended (IPCS, 1996; EPA, 1998g).

Chlorpyrifos, an OP with distinctive toxic effects on neurodevelopment, was reported to affect intracellular signalling cascades involved in differentiation and proliferation of T lymphocytes (Blakely *et al.*, 1999) and has recently been implicated as an endocrine disrupting chemical, thus possibly affecting endocrine-mediated immunity. In most experimental studies, cholinergic doses of OPs were shown to reduce immune activity whereas non-cholinergic ones resulted in an increased response, although there is still research to be done to this direction (Pruett, 1992; Galloway and Handy, 2003).

## Transgenic animals in toxicity testing

The recent advances in genetic engineering techniques led to the development of a number of transgenic *in vivo* models that can be used in toxicity testing, mainly in carcinogenicity and mutagenicity, as well as for the study of xenobiotic metabolism. These *in vivo* systems permit the study of toxicological effects of tested compounds on foreign genes of human or other origin that have been genetically transferred to produce transgenic animals, by transgenesis or targeted gene modification. From the point of view of toxicity testing, it is considered that such models will lead faster to results that are more representative of human response to xenobiotics. In addition, transgenic mice can bring significant animal welfare benefits, because they are able to reduce the group size needed in experiments and replace testing to other species, including non-human primates. Finally, these models are also excellent experimental systems and able to address and answer specific mechanistic questions in toxicology more efficiently (Valancius-Mangel and Doetschman, 1999). However, the use of "humanized" animal models in toxicological studies is an expensive process because it involves higher costs for their development and breeding. There is also concern that the human genome, once transferred to laboratory animals may express the same proteins, but it does not guarantee that the protein will have similar function with that found in humans. In addition, there is limited background information on transgenic animals, making the interpretation of data in toxicological studies difficult (Valancius-Mangel and Doetschman, 1999).

The main transgenic genotoxicity systems used in toxicology to follow up *in vitro* genotoxicity positives are the Muta Mouse and Big Blue rat/mouse models, in which the genome is "tagged" with the markers lacZ (β-galactosidase) and lacI, respectively (Gossen *et al.*, 1994; Winegar *et al.*, 1994; Wahnschaffe *et al.*, 2005a, b). Aflatoxin B1, a mycotoxin commonly found in human food and animal feed, has been tested in transgenic C57BL/6N mice and caused lacI mutation in animals' kidney and liver, proving the genotoxicity effect of the mycotoxin and demonstrating the usefulness of transgenic mice in toxicology because not only can this approach quantify mutant frequencies but it also identifies specific types of mutational events (Autrup *et al.*, 1996).

Several models are available to assess the carcinogenicity of a test compound: these include (a) inactivated tumour suppressor gene and DNA repair gene models such as p53+/− and XPA−/− knockout mice, and (b) oncogene activation models like the TgAC and the ras H2 transgenic mice (Valancius-Mangel and Doetschman, 1999).

Other important transgenic system with toxicological application that have been designed to express/lack one or more of the proteins involved in metabolism of xenobiotics and their use has led to a better understanding of metabolic activation and transformation. Most of these transgenic models express human cytochrome P450 (CYP1A2, CYP1B1) or are knock out mice (CYP2E1/CYP1A2 null mice) (Valancius-Mangel and Doetschman, 1999).

## Limitations and implications of animal use in toxicological testing

The closer a test is to the phylogenic species of concern, the more relevant the information obtained and the higher its predictivity. There are basic similarities in biology and xenobiotic metabolism between humans and the different mammalian species used in toxicity testing, making *in vivo* testing the most reliable approach in chemical safety assessment (Knudsen, 1999). However, because of species and strain variability in uptake, metabolism and elimination of xenobiotics, no single type of animal is an ideal model for predicting human or domestic animal toxicity. Consequently, multiple *in vivo* models are usually required to determine toxicity of agents and to contribute to more precise risk assessment, which may have ethical implications.

Currently there is a trend in using well-established inbred (immortal clones of genetically identical individuals) strains of rodents, in order to increase the sensitivity of animal experimentation in toxicological testing by maximizing the reproducibility of the results. While this approach can reduce animal numbers, the results may not be representative of a heterogeneous population; using a heterologous group of one species with low inbreeding may therefore be a more realistic approach reflecting the impact of a toxic compound on a broader spectrum of genes.

In the last three decades there has been an increased sensitivity to ethical issues involved in use of animals for toxicity testing. The tactics of mass demonstrations by animal protection and animal extremist groups has created an atmosphere where many institutions, organizations or companies and their employees are reluctant to

support or carry out any animal testing, before making sure that an alternative test does not exist. In addition, there are economic arguments against the use of animals in toxicity testing. Approaches using animals are undoubtedly more time consuming and more costly to run, compared to *in vitro* models. There are certain standards that should be maintained from laboratories undertaking toxicity testing experiments, such as Good Laboratory Practices (GLP), not only from an animal welfare prospective but also from experimental reproducibility approach, something that adds to the cost.

Furthermore, the quantity and quality of animal feed should also be considered because several studies demonstrated that the nutritional status can interfere with the reproducibility of the results obtained from animal models used in toxicity testing (Kacew, 2001). Other factors contributing to data quality are the health status of the animal stock (specific pathogen free, germfree or with ordinary microflora) and the laboratory experience in handling and caring for the stock. In conclusion, toxicological animal testing, although a valuable tool to predict human and domestic/farm animal toxicity of chemicals, is labour intensive, time and space consuming and raises important animal welfare concerns and uncertainties. For these reasons, there has been increasing interest in the development of *in vitro* alternatives that can help to reduce the use of animals in toxicity testing.

# *IN VITRO* MODELS OF TOXICITY TESTING

## Introduction

*In vitro* cellular models are relatively inexpensive and easy to maintain and manipulate compared to animal models. *In vitro* methods allow the study of direct cellular effects of toxins on specific cell or tissue types in a controlled environment.

However, the main disadvantage of *in vitro* systems over animal models is the lack of systemic effects such as an appropriate balance and supply of growth factors and a system of xenobiotic metabolism and elimination of toxins. The former can be at least partially addressed by adding appropriate growth factors and the latter can be addressed by the use of metabolic activation systems such as the introduction of nicotinamide adenine dinucleotide phosphate hydrogen (NADPH) activated microsomes or a hepatic cell line in a cell culture well insert fitted with a filter (Figure 4.1). The toxin is introduced into the insert and a mixture of metabolized and non-metabolized toxin (but not the microsomes or the hepatic cells) diffuses through the filter into the growth medium containing the target cells. Another

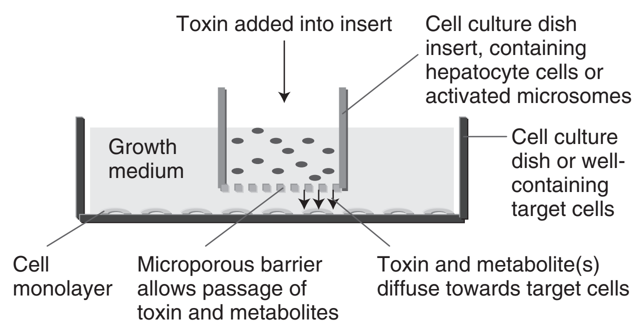

**FIGURE 4.1** Metabolic activation in cell culture systems.

disadvantage is that many cellular systems lack the complexity of cell:cell interactions in tissue, although this can be addressed to varying degrees using co-culture systems or organ culture, which are discussed later.

## Types of cell culture system used in toxicity testing

Before discussing the assays used in the *in vitro* systems it would be useful to discuss the principles, strengths and weaknesses of the main types of *in vitro* system. All cell cultures need to be prepared and maintained under sterile conditions in order to reduce microbial contamination. Cells are maintained under defined conditions of humidity, pH and temperature. They are grown in a specific growth medium, which may have a number of supplements, such as antibiotics, glutamine, serum, etc., which are different for each cell line. Growth conditions should be optimized prior to experimental work. Excellent reviews on practical aspects of cell culture can be found in the following sources (Cohen and Wilkin, 1996; Shaw, 1996; Masters, 2000; Davis, 2002; Gardner *et al*., 2004).

There are a number of types of cell culture available for *in vitro* testing that offer various degrees of complexity and relatedness to the *in vivo* situation. In order of increasing complexity and genetic similarity to the tissue of origin, these include permanent cell lines, primary cultures and organotypic cultures (Figure 4.2) (for reviews see, Noraberg, 2004; Spielmann, 2005; Sundstrom *et al*., 2005).

Permanent cell lines are mitotic and can be finite, established or clonal in nature. They have the advantage that they are relatively easy and inexpensive to maintain compared to animals and they are amenable to cryopreservation under liquid nitrogen. However, if maintained through high numbers of divisions, there is an increasing likelihood of genetic drift that might affect phenotypic properties of relevance to toxicity testing.

Finite cell lines are normally derived from primary cultures (see below) and can survive for 40–50 divisions before finally dying (e.g. fibroblasts). Established cell lines are effectively immortal, having been transformed with a virus, a mutagen or spontaneously. These are generally tumour

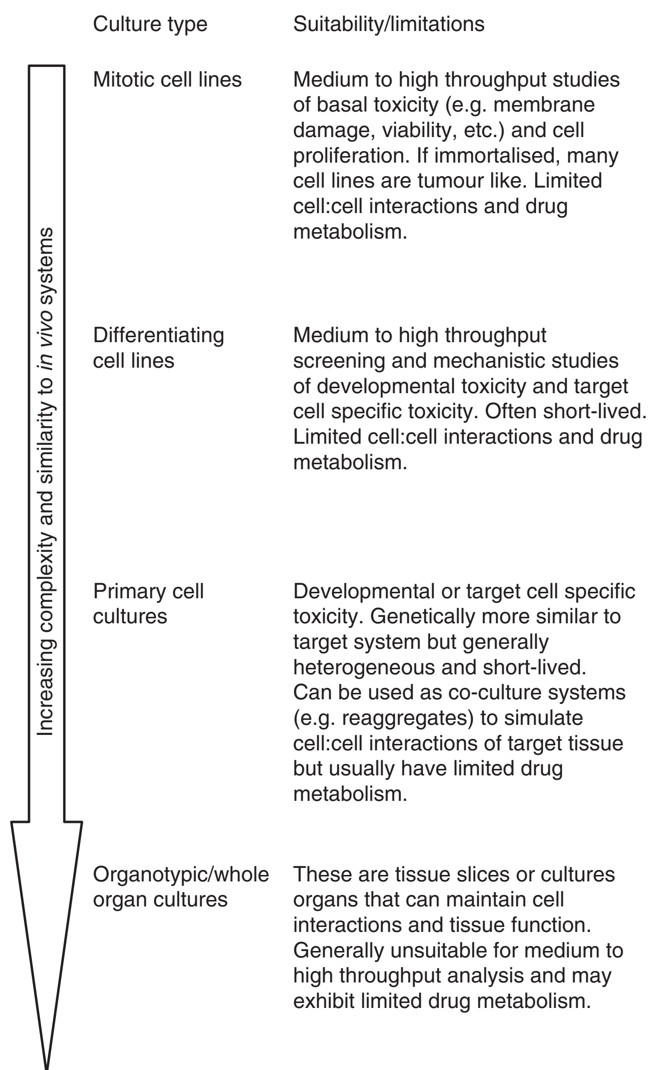

**FIGURE 4.2** Organization of a tiered system for *in vitro* toxicity testing.

like in nature; some widely used examples include mouse 3T3 fibroblasts, HeLa cells, Chinese hamster ovary (CHO) cells. However, several cell lines can be induced to differentiate, making them potentially useful models of specific stages of development, for example the use of nerve growth factor or retinoic acid to induce a neuronal phenotype in cultures of rat PC12 pheochromocytoma and human SH-SY5Y neuroblastoma cells, respectively (Fujita *et al*., 1989; Presgraves *et al*., 2004).

Clonal cell lines are derived from the mitotic division of a single cell seeded in a sterile microtitre plate by limiting dilution as used in the cloning of hybridoma cell lines. Thus, cell lines can be cloned to exhibit a specific trait (e.g. high levels of specific receptors, drug resistance, etc.). While a homogeneous response to toxin treatment might then be expected from such a cell line, there is the risk of losing other features of a more heterogeneous population. In some cases, clones of transfected cell lines provide useful tools for mechanistic studies of cell differentiation and/or toxicity. For example, some cell cultures have been transfected with the certain cytochrome P450 transgenes to make them metabolically more competent during long-term studies (Tzanakakis *et al*., 2002).

Primary cultures are derived by a combination of mechanical and enzymic disruption of the tissue of interest, which releases a collection of cells that resembles the tissue of origin closely both genetically and in terms of cell heterogeneity. It is then possible to enrich in specific cell types by using either selective culture media and/or cell growth inhibitors, immunomagnetic beads or fluorescence activated cell sorting (FACS). If a monoculture is desirable (i.e. predominantly one specific cell type), the resultant culture would then need to be screened for cell specific markers to determine purity/enrichment of the preparation, as a pure culture is rarely achieved. Typically, this would take the form of monitoring cultures for the expression of a unique morphological or molecular trait of the desired cell type to determine the level of enrichment. For example, expression of glial fibrillary protein (GFAP) and aster-like morphology would be good markers for astrocytic glial cells. Cells may be cultured as monolayers or, if a system simulating cell:cell interactions of the tissue of origin is required, cells may be cultured in suspension with mild agitation or using rolling cell culture. Under these circumstances, cells form clusters, spheroids or reaggregates that may continue to grow/proliferate over a period of several days or weeks, making them amenable to studies of long-term effects. For example, brain reaggregates prepared in this way have been maintained for up to several weeks and used in studies of pesticide toxicity (Sales *et al*., 2000). However, many primary cultures tend to be very short lived.

Also, as for established cell lines, such cell cultures do not necessarily exhibit identical cell:cell interaction patterns as those in the tissue of origin and cell types that divide more rapidly could become more predominant than they would be *in vivo*. This deficiency may be addressed by using organotypic cultures. In this case, tissue slices (typically 200 μm thickness) are cut from fresh tissue on a microtome, then subsequently rinsed and cultured in growth medium with agitation, as discussed above. Such slices maintain the complexity of cell:cell interactions and extracellular matrix composition of the original tissue and, in some cases can survive up to several weeks (Sundstrom *et al*., 2005). Nevertheless, even this kind of cellular system lacks the systemic interaction with the immune and circulatory systems that would occur *in vivo* and is not, therefore, a complete substitute for *in vivo* testing. However, using cell cultures as part of a tiered system of increasing complexity from *in vitro* to *in vivo* measurements would improve throughput, decrease costs and allow drastic reduction in the use of live animals in screening compounds for potential toxic effects. Some examples of *in vitro* toxicity testing systems in current use are indicated in Table 4.5.

**TABLE 4.5 Examples of cell culture systems used to model specific types of toxicity**

| Model | Description and comments |
|---|---|
| Neurotoxicity | Differentiating neural cell lines (e.g. human SH-SY5Y and rat PC12 neuroblastoma). Primary cultures, whole rat brain reaggregates and organotypic brain slice cultures (Sales *et al*., 2000). |
| Hepatic toxicity | Human hepatoma HepG2 cell line and subclones expressing CYP1A1, cell lines engineered to express single human or animal P450, primary hepatocyte cultures, longer term collagen sandwich cultures, liver slices and isolated perfused liver (Worth and Balls, 2002). |
| Developmental toxicity | Whole rat embryo cultures, rat limb bud reaggregates cultures and mouse embryonic stem cell lines (Liebsch and Spielmann, 2002). Standard operating procedures (SOPs) available on the ECVAM–INVITTOX databases. |
| Dermal toxicity | Keratinocyte and fibroblast cell lines. Excised rat skin models and human EPISKIN™ and EPIDERM™ skin models (Fentem *et al*., 2001). |
| Immunotoxicity | Antibody production and activation/proliferation of lymphocytes (Karol, 1998). |
| Genotoxicity | Mammalian cell gene mutation and chromosome aberration tests (EPA, 1998i, j). |

## Endpoint determination for *in vitro* testing systems

A good *in vitro* testing system should be sensitive but at the same time yield low levels of false positive and false negative results. It should have endpoint measurements that (i) show dose response relationships for a given toxin, (ii) reflect and are predictive of the *in vivo* pattern of toxicity for a given group of agents, (iii) are objective and reproducible, and (iv) have internal controls. It is also useful if the testing system involves rapid assays of toxicity, allowing medium to high throughput analysis and simultaneous testing of multiple compounds and/or doses. The testing system should also be relatively inexpensive and involve technology and skills that are easily transferable to other laboratory personnel. Importantly, for a testing system to be deemed reliable for the prediction of acute *in vivo* human systemic toxicity it should have been validated through a rigorous international multi-centre validation programme. For example, during the period 1989–1996, 97 international laboratories tested the same reference chemicals (which represent different classes of chemicals with varied human toxicity) in their own *in vitro* systems. The outcomes of these studies are available on an Internet database (URL http://www.cctoxconsulting.a.se/meic.htm) and various aspects of the overall study have been published in eight articles in Alternatives to Laboratory Animals. Over the past 10 years or so, recommendations governing validation of *in vitro* alternatives, including systems for measuring chronic effects, have been published and are regularly reviewed by international organizations such as ECVAM (European Centre for Validation of Alternative Methods), ICCVAM (The Interagency Coordinating Committee on the Validation of Alternative Methods) and OECD. The interested reader is referred to the following articles for more recent publications on validated systems for toxicity testing (Liebsch and Spielmann, 2002; Bhogal *et al*., 2005).

The best way to achieve something approaching an ideal testing system is to include a battery of endpoint measurements in order to minimize the occurrence of false negatives and false positive results. Endpoint determination should give an objective assessment of a cytostatic, cytotoxic or other functional effect. It should also be quantitative or reproducibly qualitative. The selection of endpoints chosen should enable the categorization of toxins in terms of their toxicity relative to other agents of the same or other groups, giving reproducible results in different laboratory settings.

Endpoints can take a variety of forms, including measurements of cell viability, metabolic activity, morphology, changes in protein and gene expression and/or altered subcellular distribution of markers of interest. Some of the main endpoints are summarized below and the reader is referred to other references for further background information (Masters, 2000) and the INVITTOX web site (http://embryo.ib.amwaw.edu.pl/invittox/) for further information and technical details about specific protocols used in toxicity testing *in vitro*.

### *Cell viability*

The traditional method of determining cell viability is to determine the cell density (cells/ml) in a haemocytometer chamber. While this is a very useful method for determining cell number for seeding in cell culture experiments, it does not distinguish between viable and non-viable cells following exposure to toxin. However, the proportion of non-viable cells can be determined in parallel by assessing the percentage of counted cells that take up the dye Trypan blue, which is excluded from viable cells. Though effective, this approach is not suited to high throughput, as measurement can be time consuming and is therefore best suited to small numbers of samples or treatments.

An alternative approach is to use dye uptake assays. For example, neutral red accumulates on the lysosomes of viable cells, after which it can be extracted from cells with an organic solvent and determined spectrophotometrically. A variation on this is to prelabel cells with the dye prior to treatment with toxin; reduced levels of absorbance compared to untreated control cells would be indicative of dye release due to membrane damage.

Appropriately equipped laboratories might choose to use a dual fluorescence assay to determine the proportion of live and dead cells. In one such system, fluorescein diacetate is taken up by viable cells and cleaved by esterases to release fluorescein producing green fluorescence in the cytoplasm, whereas propidium iodide only crosses the membrane of damaged cells and stains the nucleus (DNA) producing red fluorescence (Coder, 1997). Specimens are observed using a fluorescence microscope and quantification can be achieved by image analysis or by FACS analysis.

### Membrane leakage

Leakage of macromolecule through the plasma membrane into the culture medium is an effective means of detecting early or late stages of membrane damage. Cells can be incubated in the presence of $^{3}$H-thymidine, which is incorporated into DNA during cell proliferation. Subsequent loss of $^{3}$H-labelled DNA would be indicative of cell lysis. An alternative approach is to label cells in the presence of $^{51}$Cr which binds to many cellular proteins. Loss of labelled proteins from treated cells would be indicative of membrane leakage/cell lysis. In this sense the $^{51}$Cr release assay is more sensitive than that for $^{3}$H-labelled DNA as the former will detect signs of damage to the membrane at a much earlier stage than the latter.

An attractive alternative to radioisotopic methods is the release of lactate dehydrogenase (LDH) into cell culture medium, which is measured spectrophotometrically. The assay shows sensitivity comparable to the $^{51}$Cr release assay and is amenable to microtitre plate format, which would facilitate medium to high throughput analysis.

### Cell growth and proliferation

Cell growth or proliferation can be measured in a number of ways.

#### *Cloning efficiency*

In the absence of sophisticated equipment, perhaps the simplest method is that of cloning efficiency. In this case, cells would be plated at a density of 100–200 per culture vessel and assessed microscopically for their ability to produce viable colonies after a given period of incubation in the presence and absence of toxin. This is one of the most sensitive methods used for testing the effects of toxins on the growth of mitotic cells.

#### *Mitogenicity*

This can be determined in a number of ways. For example, the mitotic index of cell cultures can be determined by counting the percentage of mitotic figures following staining of DNA with haematoxylin. Alternatively, the proportion of cells in S-phase can be determined by immunohistochemical staining of cells incubated with the thymidine analogue 5-bromo, 2-deoxyuridine.

#### *DNA synthesis*

Another approach is the measurement of cell growth in toxin-exposed cells is via the incorporation of $^{3}$H-thymidine into DNA (Flaskos *et al.*, 1994). This method gives a good quantitative assessment of the effects of toxins on cell proliferation, as the radioisotope is incorporated into cells during S-phase of the cell cycle. High throughput analysis requires the use of a cell harvester to lyse cells and transfer radiolabelled DNA onto filters prior to detection by scintillation counting. Alternatively, cell proliferation can be measured by the incorporation of 5-bromo, 2-deoxyuridine incorporated into S-phase cultured cells, and subsequent quantification by enzyme-linked immunoabsorbent assay (ELISA) (Lanier *et al.*, 1989). Total DNA content can also be determined by detecting fluorescence after incubation of cells with DNA binding dyes such as Hoechst 33258, using a spectrofluorimetric microplate reader or by FACS analysis (Downs and Wilfinger, 1983).

#### *Protein synthesis*

Cell growth can also be measured by total protein content or by protein synthesis. Protein content can be estimated by a number of dye binding assays in microtitre plate format, such as the bicinchoninic acid (BCA) assay (Tuszynski and Murphy, 1990). More rapid analysis can be achieved by fixing and staining cells directly with Coomassie brilliant blue. After washing, the dye is solubilized and the absorbance of protein bound dye measured spectrophotometrically. As a measure of total protein synthesis, cells can be incubated in the presence of radiolabelled amino acids such as $^{35}$S-methionine or $^{14}$C-leucine and TCA precipitable protein assessed for radioactive content by scintillation counting. If an assessment of specific protein changes is required, protein extracts can be separated by polyacrylamide gel electrophoresis in the presence of sodium dodecyl sulphate (SDS-PAGE) and proteins stained with Coomassie blue or another protein staining dye. Changes in radiolabelled protein synthesis, which could be masked by the pre-existing protein pool, can be detected by autoradiography following exposure of dried gels onto X-ray film.

### Cell morphology

Changes in cell morphology can be measured microscopically and are very useful in studies of mechanisms of toxicity. However, medium to high throughput analysis of toxicity would require the use of image analysis software to produce more consistent data. Specialist techniques such as Allen video-enhanced contrast differential interference contrast (AVEC-DIC) microscopy facilitate analysis of effects on living cells. Furthermore, high throughput assays could be

developed that measure the underlying molecular changes determined from follow-up studies.

Morphological changes can take various forms, as indicated below.

*Cell volume*

An increase or decrease in cell volume could indicate osmotic changes or may represent the early stages of cell death by necrosis or apoptosis. Cell death or viability changes would then need to be made to confirm the type of cell death occurring, as indicated earlier.

*Cell shape*

Changes in shape may occur following exposure to a toxin. These could include rounding up, flattening, spreading or process outgrowth in cell culture monolayers. Such changes would give an initial indication of altered cell attachment, migration, proliferation or differentiation, indicating potential targets for follow-up molecular studies. For example, OP-induced changes in axon outgrowth in cultured neurons indicated possible changes in proteins associated with axon growth and maintenance, which were then targeted in molecular studies (Hargreaves *et al.*, 2006).

*Membrane integrity*

Changes in membrane integrity may be indicated by surface blebbing, which can occur as a result of cellular stress (e.g. oxidative stress) or during the early stages of apoptosis. These parameters could be measured further by biochemical methods to confirm the underlying molecular events associated with these morphological changes (e.g. free radical generation, lipid peroxidation, caspase activation, etc.).

*Growth patterns*

Growth patterns may change as a result of exposure to toxin. Thus, the proportion of cells growing in colonies or singly would indicate changes in cell:cell interactions and potential changes in cell adhesion proteins, which could be targeted in subsequent molecular studies.

**Metabolic assay**

*ATP levels*

ATP is an essential requirement for many energy dependent processes and its levels can be affected by a variety of toxins. It can be used as a marker for cell viability as it is present in all metabolically active cells and its levels decline rapidly when cells undergo apoptosis or necrosis (Kangas *et al.*, 1984). A number of reagents and kits suitable for high throughput screening are available. Typically, the amount of ATP in cell lysates is determined by the light released from firefly luciferase-catalysed oxidation of D-luciferin in the presence of ATP and oxygen. ATP and its major metabolites (ADP and AMP) in cell culture extracts can also be determined using an HPLC method (Yang and Gupta, 2003).

*Mitochondrial activity*

The activity of succinate dehydrogenase can be assayed by the reduction of the yellow methyl tetrazolium dye to its blue formazan reaction product. The reduced dye forms crystals in metabolically active cells and, after removal of growth medium, can be solubilized in an organic solvent such as dimethyl sulphfoxide and quantified spectrophotometrically in microtitre plate format, e.g. in assays of *in vitro* toxicity of OPs (Hargreaves *et al.*, 2006).

Although metabolic assays such as those indicated above are not direct measurements of cell viability, a significant fall in either measurement is normally taken to indicate a fall in cell viability or cell number.

**Calcium homeostasis**

Many toxins have a direct or indirect effect on mechanisms involved in the control of $Ca^{2+}$ homeostasis. Such effects could be related to a breakdown in plasma membrane integrity, which would also be detected by other methods discussed previously (e.g. leakage of LDH), or it may be the result of a selective effect on $Ca^{2+}$ channels or $Ca^{2+}$ ATPases that regulate $Ca^{2+}$ movements across cellular membranes. Changes in $Ca^{2+}$ flux can be measured using a variety of $Ca^{2+}$ binding dyes that fluoresce when bound to $Ca^{2+}$ (e.g. Quin 2 and Fura 2). Detection requires spectrofluorimetric analysis which is potentially applicable to high throughput analysis of average change for a given cell population. However, analysis of changes in $Ca^{2+}$ flux in individual cells requires a system that has an integrated microscope and image analysis software package.

**Cell or tissue specific markers of toxicity**

This approach is useful for targeting key proteins or enzyme activities involved in the normal function(s) of the target cells or tissues. It is particularly useful in sublethal/ chronic studies of exposure to toxin, in order to determine whether a potentially reversible functional deficit occurs. The principal approaches used at the protein level are those of antibody-based detection and enzyme assays.

*Antibody-based detection*

This involves mainly immunoblotting techniques such as Western blotting and dot blotting coupled with densitometric analysis of antibody reactivity with target antigens. In Western blotting the cell extracts are normally denatured, separated by SDS-PAGE and transferred electrophoretically onto nitrocellulose membrane filters (Towbin *et al.*, 1979) thus creating a replica of the gel pattern that is more accessible to antibody probes. By contrast, in dotblotting an

extract is applied direct in a circular dot onto the membrane filter, without chromatographic separation of proteins. Alternatively, experiments could be carried out on microtitre plates and the levels of antigens of interest determined in fixed cell monolayers by ELISA. Changes in the cellular or tissue distribution of antigens of interest can also be determined by immunohistochemical staining methods using enzyme conjugated or fluorophore-conjugated antibody detection systems in a light microscope or fluorescence microscope, respectively. In the case of fluorescence microscopy quantification of antigen levels or distribution can be done with the aid of image analysis software. These approaches have been used effectively in mechanistic studies of OP toxicity (Hargreaves *et al*., 2006).

*Enzyme assays*

Many cell and tissues can be monitored by the activity of enzymes that are known targets of the xenobiotics in question. For example, as discussed earlier, AChE activity is a good indicator of the acute neurotoxic effects of cholinesterase inhibitors such as OPs and carbamates *in vitro*, whereas NTE is a marker of the delayed neurodegenerative capability of OPs (Ehrich *et al*., 1997). There are also enzymes that provide useful markers of specific cell types, such as tyrosine hydroxylase for dopaminergic neurons (Kuhn and Geddes, 2000), 2′,3′-cyclic nucleotide 3′-phosphohydrolase for glial cells (McMorris, 1977) and alanine aminotransferase for hepatocytes (Amacher *et al*., 1998). Where possible, changes in expression of the enzyme should also be taken into account when interpreting specific activity data.

*Proteomic analysis*

This approach can be useful in mechanistic studies of toxicity as it helps to identify novel protein markers of toxicity. Techniques of this type include the use of two-dimensional PAGE, chromatographic or protein chip fractionation of proteins from cell/tissue lysates or subcellular in order to identify changes in specific protein levels following toxin exposure. Proteins of interest are then normally digested with trypsin and the tryptic fragments are initially identified by "peptide mass fingerprinting" in a matrix-assisted laser desorption ionization–time of flight (MALDI–TOF) mass spectrometer, followed by further confirmation using, e.g. tandem mass spectrometry (MS–MS) (Steen and Mann, 2004). Identification is facilitated by the use of freely available Internet-based gene and protein sequence databases such as MASCOT, SwissProt, etc.

*Genomic analysis*

Changes in the levels of specific proteins detected by proteome analysis could reflect changes in the regulation of protein turnover (i.e. how rapidly it is degraded once synthesized) or changes in gene expression. Furthermore, depending on the cell or tissue fractionation procedures adopted, changes in low abundance proteins that could be functionally important may not necessarily be detected by proteomic methods. Changes in gene expression following exposure to toxin can be determined by a number of methods including reverse transcriptase polymerase chain reaction (RT-PCR) and DNA microarray analysis (Koizimo and Yamada, 2003).

RT-PCR is a targeted approach involving the production of complementary DNA (cDNA), by treatment of cell or tissue RNA with RT. The resultant cDNA is then incubated with primers (probes) that recognize specific genes or DNA sequences of interest, followed by amplification of such sequences by the Taq polymerase reaction. Changes in the level of amplified target sequence would indicate corresponding changes in the expression of the target gene to which the primers are matched. This approach is only semi-quantitative although accuracy can be improved by continuous measurement of amplicon levels using real time RT-PCR. Levels of amplicon are normally compared to changes in household genes such as glyceraldehyde dehydrogenase, as an internal control.

A less targeted approach that, nevertheless, could help to identify novel changes in gene expression is that of DNA microarray analysis. In this technique, up to several thousand genes are immobilized on a template and probed with labelled RNA from control and treated cells or tissues. Image analysis software is then used to determine up- or down-regulation of genes due to toxin exposure. Controls usually involve averaged changes for a series of household genes. The researcher should be aware that a change in levels of gene expression does not necessarily indicate a corresponding change in protein levels or vice versa, as there are multiple levels of control. A multi-disciplinary approach is recommended to get an accurate overall picture of the chain of events following exposure to toxin.

## GENERAL SUMMARY AND CONCLUSIONS

A major issue facing toxicological science today is how to convert experimental data from *in vivo* and *in vitro* models into knowledge about molecular mechanisms of toxicity and safe levels of exposure to the agents tested. A number of animal models that have been used for many years for screening purposes, have been gradually refined with increasing emphasis on improved experimental design, animal welfare and reduced animal use. More recent developments in the area of *in vitro* toxicity testing have contributed significantly to the gradual reduction in animal use for toxicity screening and have helped to improve knowledge relating to mechanisms of cell- or

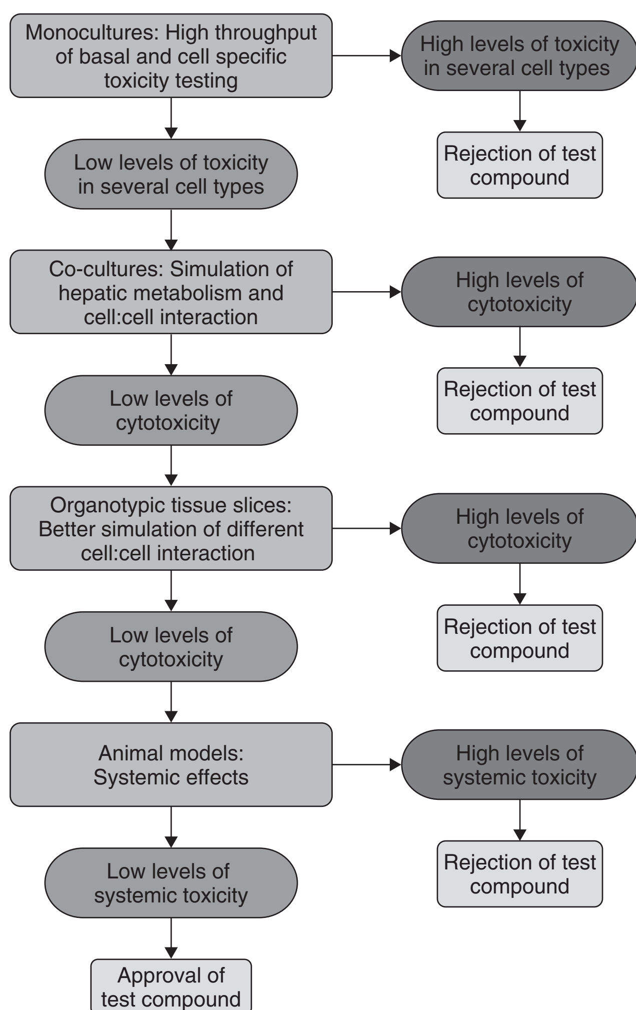

**FIGURE 4.3** Flow chart showing principles of multi-tiered approach to toxicity testing.

organ-specific toxicity. Veterinarians have played an important role in the development of legislation and guidelines relating to the use and replacement of laboratory animals in toxicity assessment.

The generally accepted approach to screening compounds for toxicity is to use a multi-tiered system starting with simple monocultures of specific cell types, followed by co-cultures that simulate metabolic effects and/or cell:cell interactions in the whole organism, before carrying out final testing on animals (Figure 4.3). In this way, it is possible to eliminate compounds that exhibit high levels of basal toxicity in several cell types and reduce unnecessary suffering in animals. In both *in vitro* and *in vivo* testing it is important to use a battery of appropriate endpoint measurements of both basal toxicity and cell/tissue specific toxicity at each level, in order to increase the reliability and predictive potential of the data produced.

*In vitro* toxicology has made significant advances in the last few decades, by improving and finding solutions to its limitations. For example, cell culture systems are now being designed to be metabolically competent and viable for several weeks, making them appropriate not only for short but for long-term toxicity testing (Bhogal *et al.*, 2005). Extending this approach to a wider range of cell culture systems will improve the prospect of using *in vitro* methods for studying a wider range of chronic toxicological phenomena. However, further development and validation of *in vitro* models is required if they are to be adopted on a much wider scale in order to secure further reduction, replacement and refinement of animal models. This will require further improvements in cell culture technology and growth conditions, such as the increased use of hollow fibre systems to facilitate continuous replenishment of media and supplements (Nussler *et al.*, 2001). The increased use of microsomal activation systems and/or established cell lines transfected with genes for mixed function oxidases is another approach that will help to increase the metabolic competence of *in vitro* models. Another promising *in vitro* approach involves the use of adult or embryonic stem cells of human or rodent origin. These cells can be either continuously cultured without being differentiated or they can generate a wide variety of functional mammalian cell types. In addition to its application in developmental toxicity testing, stem cell technology has been successfully used to study mechanisms of toxicity and to screen new pharmaceutical compounds for teratogenicity, genotoxicity, hepatotoxicity and cardiotoxicity (Davila *et al.*, 1998; 2004).

The development of medium to high throughput methods in proteomics, genomics and metabolomics, together with the revolution in bioinformatics, will lead to the accumulation of vast toxicological information, helping to elucidate mechanisms of toxicity in both *in vitro* and *in vivo* models (Bhogal *et al.*, 2005). These approaches will also help in the development and establishment of new biomarkers of effect or exposure.

In conclusion, although it is a desirable goal to replace all animal testing, animal-based toxicological testing is likely to continue for the foreseeable future. Further improvements in animal models will make them more reliable indicators of human toxicity, while the development of improved *in vitro* systems will eventually minimize the use of animals for toxicity studies. The veterinarian's role will therefore be to continue monitoring and improving the welfare of animals used in toxicity testing and to advise on issues relating to the development of *in vitro* alternatives.

# Epidemiology of animal poisonings

*Sharon M. Gwaltney-Brant*

## INTRODUCTION

Although animals are exposed to potentially toxic agents on a daily basis, actual poisoning cases are uncommon when compared to other conditions of veterinary concern (infectious disease, trauma, metabolic disease, neoplasia, etc.). Clients will often present their animal with a suspicion of poisoning, only for the veterinarian to determine that the animal is suffering from an unrelated ailment. When evaluating information regarding suspected poisoning cases, it is important to consider the full exposure and patient history before determining whether a particular exposure is related to a clinical syndrome, as temporal coincidence does not necessarily equal causality.

The fundamental rule of toxicology as stated by Paracelsus, considered to be the "Father" of toxicology, is "the dose makes the poison." Obviously the dose required to induce toxicosis will depend on a variety of factors, including the agent in question, species of animal exposed and route of exposure. Based on information from poison control centers, the majority of animal exposures to potentially toxic agents result in no signs developing (Hornfeldt and Murphy, 1992; Forrester and Stanley, 2004). However, animal poisonings *do* occasionally occur from exposures to natural or man-made hazards. Knowledge of the most common features of animal poisonings can aid in instituting measure that may help in minimizing exposures of animals to toxicants.

## DEMOGRAPHICS

Demographic information on animal poisonings has largely come from human or animal poison control centers that animal owners have contacted regarding potential exposures to toxic agents (Haliburton and Buck, 1983; Hornfeldt and Borys, 1985; Hornfeldt and Murphy, 1992, 1997, 1998; Forrester and Stanley, 2004) or from surveys of veterinary emergency centers or teaching hospitals (Osweiler, 1975; Cope *et al*., 2006). In all these reports, dogs and cats are the species that owners most frequently seek assistance with potential poisonings, accounting for 95–98% of all reported animal cases (Hornfeldt and Murphy, 1998; Xavier and Kogika, 2002; Forrester and Stanley, 2004; Giuliano Albo and Nebbia, 2004). Approximately 2–5% of reported cases involved other species of domesticated animals, exotic animals and wildlife. These percentages have changed considerably since the 1883, when dogs and cats accounted for 44% of calls to an animal poison control center, with production animals (bovine, porcine, ovine) and equines making up 35% of calls (Trammel *et al*., 1985).

Forrester and Stanley (2004) reported that exposures occurred more commonly in the summer, and this is consistent with data from the ASPCA Animal Poison Control Center's AnTox™ database (Figure 5.1), although a peak in December, associated with the holiday season, is also present in the APCC data (ASPCA Animal Poison Control Center, unpublished data, 2005). The majority (>90%) of animal poisonings are accidental and acute in nature and occur near or at the animal owner's home (Hornfeldt and Murphy, 1992, 1998; Khan *et al*., 1999). Malicious intent comprises less than 1% of all exposures to potentially toxic agents. The majority (70–95%) of exposures is due to acute ingestion, followed by acute dermal exposures (Hornfeldt and Murphy, 1992; Forrester and Stanley, 2004). Inhalation, envenomation, bites, ocular and parenteral routes of exposure account for less than 1% and chronic exposures comprise approximately 1% of all exposures. In 97% of exposures, a single agent is involved (Hornfeldt and Murphy, 1992, 1998).

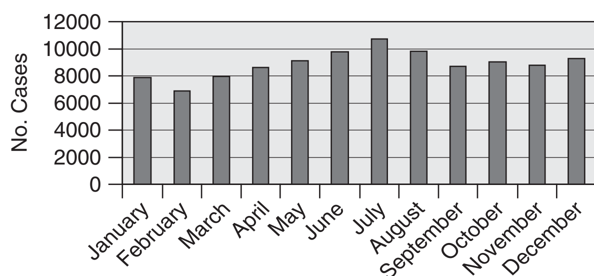

**FIGURE 5.1** Monthly distribution of cases managed by ASPCA Animal Poison Control Center in 2005 (unpublished data).

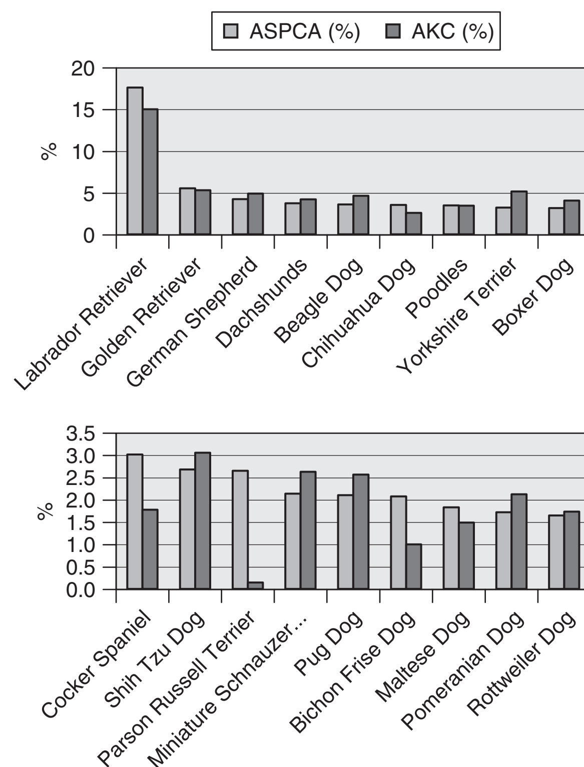

**FIGURE 5.2** Comparison of top twenty purebred dog breeds in relation to frequency of exposures to potentially toxic agents reported to the ASPCA Animal Poison Control Center with the relative popularity of the breed based on Registration Statistics from the American Kennel Club in 2006 (ASPCA Animal Poison Control Center, unpublished data, 2005).

## DOGS

Perhaps at least partly because of their inquisitive natures and willingness to investigate everything with their mouths, dogs far outrank other species when it comes to owners seeking aid for potential poisonings, making up 70–80% of all animal cases (Hornfeldt and Murphy, 1992, 1998; Xavier and Kogika, 2002; Forrester and Stanley, 2004).

There is a tendency in the veterinary community to consider certain breeds, such as Labrador retrievers, to be more prone to exposure to potentially toxic agents. However, to verify such an impression, one must take into account the relative popularity of a particular breed. In other words: Are there more poisoning cases with Labrador retrievers because they really are more inclined to misadventure, or is it just that there are more Labradors? A recent survey of the APCC database in 2005 (ASPCA Animal Poison Control Center, unpublished data, 2005) evaluated over 68,000 exposures of non-mixed breed dogs and compared the relative breed incidence to the 2005 Registration Statistics reported by the American Kennel Club, the oldest and largest purebred dog registry in the United States (American Kennel Club (AKC), 2006). The results of this comparison are displayed in Table 5.1 and the top 20 breeds are compared graphically in Figure 5.2. Labradors account for approximately 15% of AKC registered breeds, with almost three times more registered than the next most popular breed, the golden retriever. Labradors accounted for 17.5% of canine exposures in APCC cases, which was also three times more than the next most popular breed (the golden retriever) and which was not significantly different from the AKC statistics. In analyzing the data in Table 5.1, a few breeds do appear to be over-represented in regards to exposures to potentially toxic agents. For instance, the Bichon Frise ranks 26th in AKC registrations yet ranks 15th in the APCC data, occurring in APCC cases (2.1%) at twice the incidence of AKC (1%); Welsh springer spaniels make up 0.03% of AKC registered dogs, but account for 0.18% of APCC dogs. However, care must be taken when evaluating the data from certain breeds (such as greyhounds, border collies and Parson Russell terriers), as many individuals of these breeds are registered with their own independent breed registry rather than the AKC; this may be one reason all three of these dog breeds appear over-represented in APCC data.

Previous reports of poisoning cases in dogs have indicated no gender predisposition, and most reports indicate that adults are most commonly involved, with an average age of approximately 4 years (±3.6 years) (Khan *et al*., 1999; Cope *et al*., 2006). Given the wide age ranges in these studies (0.15–15 years) and the relatively low average age, it would appear that young adult dogs are most inclined to be exposed to potentially toxic agents.

## CATS

Due, perhaps, to their more discriminating habits and appetites, cats account for only 11–20% of reported animal exposures to potential toxicants, which is three times less frequent than dogs (Hornfeldt and Murphy, 1992, 1998;

ASPCA Animal Poison Control Center, unpublished data (2005) and American Kennel Club (2006).

Xavier and Kogika, 2002; Forrester and Stanley, 2004). In 2005, 72% of cats exposed to potential toxicants were identified as domestic shorthairs, 9% as domestic long-hairs and 5% as domestic mediumhairs (ASPCA Animal Poison Control Center, unpublished data, 2005). Excluding these types of cats due to the generic nature of their classification, the top 10 purebred cats were Siamese (28%), Persian (15%), Main coon (11%), Himalayan (9%), ragdoll (5%), Bengal (4%), Russian blue (3%), Abyssinian (3%), Manx (2%) and Burmese (2%). Of these, the Persian, Maine coon, Siamese, Abyssinian and ragdoll are listed in the 10 most popular breeds registered by the Cat Fancier's Association in 2005. As with dogs, no gender or age difference's in incidence of exposure have been noted. Cats may, due to their grooming habits, be more susceptible to toxicants that come into contact with their fur; this is especially problematic with agents to which cats are exquisitely sensitive (e.g. ethylene glycol).

## OTHER SPECIES

Demographic information on potential poisonings in animal species other than dogs and cats is largely lacking. Production animals are generally kept in large groups, meaning that when a toxicosis occurs, there is potential for a multiple animals of varying age and genders to be exposed. Most production animals are kept in some form of confinement, which limits the potential for exposure to toxic agents. However, mistakes in management, such as feed mixing errors or improper ventilation, may result in acute or chronic toxicosis in large numbers of animals.

Wildlife is almost continuously exposed to toxic agents in the environment, but specific demographic information is not available in most cases. Seasonality of poisoning incidences in wildlife would vary with the agent involved. For instance, avian botulism in waterfowl tends to be seasonal, with most cases occurring between the months of July and September (Locke and Friend, 1989).

## AGENTS INVOLVED

There is an unlimited number of agents by which exposed animals may become poisoned, and for the most part, which specific agents are involved in animal poisonings will be dependent upon what is available in the animals' environment, the potential or inclination for the animal to be exposed to the agent, the amount of agent to which

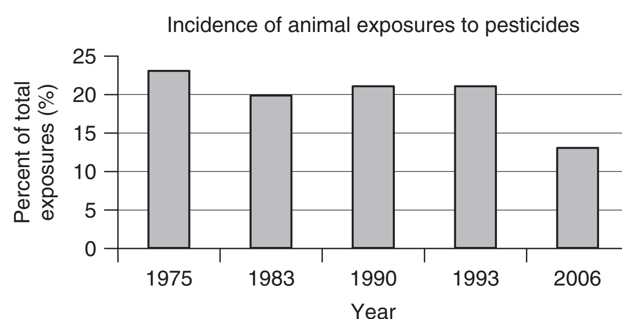

**FIGURE 5.4** Comparison of incidence of animal exposures to pesticides reported to human poison control centers and veterinary clinics (Osweiler, 1975; Haliburton and Buck, 1983; Trammel *et al*., 1985; Hornfeldt and Murphy, 1992).

the animal is exposed, and the individual sensitivity of the animal to the effects of the agent. The potential for exposure to specific agents may be uniform throughout the year or may be seasonal, depending on the agent and the species involved. For instance, exposures to lawn care products, such as herbicides and insecticides, would be expected to be more common during the seasons when these products are most in use (i.e. spring and summer).

Table 5.2 summarizes the most common agents involved in animal exposures reported to veterinary emergency referral centers and human or animal poison control centers in the United States. These exposures predominantly involve companion animals, particularly dogs and cats, and are consistent with the types of animal exposures reported by poison control centers in other countries (Xavier and Kogika, 2002; Giuliano Albo and Nebbia, 2004). Rodenticides, pharmaceuticals and chocolate make up the majority of agents in the most recent report summarized in Figure 5.3 (Cope *et al*., 2006). Rodenticides and chocolate made up approximately one quarter of all exposures, followed by pharmaceutical agents, which accounted for 22% of exposures. Pharmaceuticals exposures have increased since first reports in 1983 (Beasley and Trammel, 1994), likely due to the increased use of these agents in veterinary and human medicine over the past 20 years. The most common pharmaceutical agents associated with animal exposures are analgesics (primarily non-steroidal antiinflammatory drugs) and central nervous system drugs (sedatives, antipsychotics, stimulants, etc.) (Hornfeldt and Murphy, 1992, 1998). None of the reported data from poison control centers included information specifically on chocolate cases, but a veterinary emergency hospital reported that exposure of dogs to chocolate accounts for one in every four presentations for potential toxicosis (Cope *et al*., 2006). Pesticides have historically been responsible for large numbers of exposures and toxicoses in domestic animals (Beasley and Trammel, 1994), but the incidence appears to be declining (Figure 5.4). This may be due in part to the development of newer herbicides and insecticides that have a much higher margin of safety in mammals than those used in the past, as well as perhaps better public awareness of the potential hazards of these agents to pets.

Less information is available regarding exposure of non-canine and non-feline animals to potential toxicants. For livestock, plant poisoning causes tremendous economic losses to producers, estimated to exceed $350 million per year (Galey, 1996). Losses from poisonous plants are due to deaths as well as loss of productivity. Other agents reported to be responsible for significant livestock loss include mycotoxins, organophosphate and carbamate insecticides, nitrate and lead, although lead poisoning appears to be on the decline in livestock. For waterfowl, avian botulism is a concern, resulting in the loss of thousands to millions of birds each year (Locke and Friend, 1989). Lead toxicosis was once a significant cause of loss of waterfowl in the United States due to ingestion of lead shot left by hunters, but the incidence of lead toxicosis has decreased following an enforced ban on the use of lead shot on waterfowl (Gwaltney-Brant, 2004). However, lead intoxication still occurs in raptors that ingest upland prey that have shot embedded in their tissues. Wild animals ingesting the tissues of animals that have been euthanized with

barbiturates are at risk of toxicosis (Hayes, 1988), and toxicosis has been reported in a variety of species feeding on animals intentionally poisoned with pesticides (Stroud, 1998; Wobeser *et al.*, 2004). Intentional poisoning of wildlife with pesticides is most commonly accomplished using carbofuran and aldicarb, while accidental or secondary poisoning of wildlife by pesticides most often involves strychnine, famphur, fenthion and avitrol (Stroud, 1998). Oil spills near sea shores have resulted in significant loss of life of animals living in or around these areas, and industrial pollution from agricultural or industrial effluents have similarly cause deaths in a variety of wildlife species.

## SIGNS AND OUTCOMES

Based on poison control center statistics, the majority (57–63%) of animal exposures to potential toxicants result in no signs for the patient, either due to insufficient level of exposure or successful decontamination by animal caretakers (Figure 5.5). Mild signs developed in 25–27% of animal exposures to suspected toxicants, moderate signs developed in 7–8%, major signs developed in approximately 1% and death occurred in 2–3% of cases where outcomes were known (Hornfeldt and Murphy, 1992, 1998). Mild signs are those in which some clinical signs developed but are expected to be mild and self-limiting and not in need of treatment (e.g. hypersalivation, mild vomiting, etc.). Moderate signs are those in which signs that develop are more pronounced, prolonged or of a systemic nature and merit some form of treatment, although the signs would not be expected to be life-threatening (e.g. protracted vomiting, severe diarrhea, mild to moderate hypotension). No residual effects would be expected following recovery. Major signs are those in which life threatening conditions exist or there is potential for significant residual disability or disfigurement following recovery from the acute episode (e.g. seizures, renal injury, etc.).

Agents most frequently reported to be associated with mild to moderate signs in animals are pharmaceuticals (19%), pesticides (insecticides and herbicides, 14%), plants (10%), cleaning products (8%) and mushrooms (3%) (Hornfeldt and Murphy, 1998). Agents associated with major signs included pesticides (45%), pharmaceuticals (25%), plants (15%), rodenticides (9%) and cleaning products (8%). Deaths were most commonly associated with exposures to pesticides (24%), pharmaceuticals (17%), rodenticides (16%), plants (9%), automotive products (predominantly ethylene glycol, 9%) and cleaning products (8%). Organophosphate insecticides, ethylene glycol and long acting anticoagulant rodenticides were the top three agents responsible for deaths in animals.

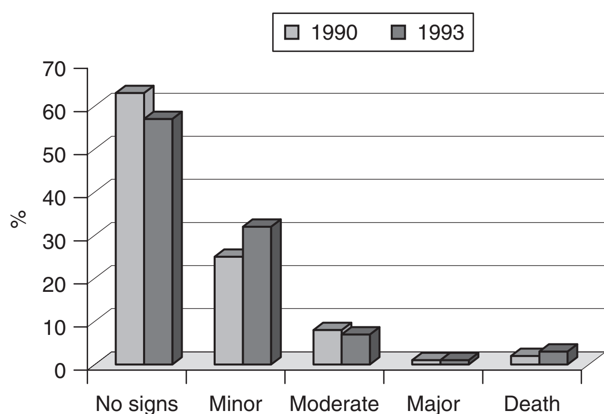

**FIGURE 5.5** Degree of illness in animals following exposure to potentially toxic agents (Hornfeldt and Murphy, 1992, 1998).

## CONCLUSIONS

Poisonings are a serious cause of morbidity and mortality in animals, particularly in dogs and cats. Based on information obtained by veterinary clinics and human and animal poison control centers the incidence of animal poisoning does not appear to be waning, although the agents to which animals are exposed does change with time. While significant pesticide exposures may be on the decline due to the development of newer and less toxic pesticides, exposures to other agents, such as chocolate and pharmaceutical agents may be on the rise. Knowing what agents have the potential to be involved in serious toxicoses should allow veterinarians to better educate their clients on means of preventing animal poisonings through the appropriate use of household products and the removal of potential hazards from the animals' environments.

# Chemicals of terrorism

*Tina Wismer*

## INTRODUCTION

Chemical agents may be chosen by terrorists as they can be dispersed over large areas and can eventually penetrate even the most well-defended positions. These agents can be deployed against specific targets, and depending on the agent used, the effects can be immediate or delayed. Chemical agents can cause incapacitation, disorientation, or death. Many of the more commonly used agents can be produced inexpensively and easily stored.

There are four basic types of military agents that can be used for chemical terrorism: choking agents (chlorine, phosgene), blister agents (mustard, Lewisite, phosgene oxime), blood agents (cyanide, hydrogen cyanide), and nerve agents (tabun, sarin, soman, VX). Chemical warfare agents can be delivered by a variety of methods: bomb, spray tanks, rockets, missiles, land mines, and artillery projectiles (USACHPPM, 2001a). Few indicators of a chemical attack may be evident at first. The initial observation of unusual signs and symptoms that correlate with nerve, vesicant, blood, or pulmonary agent exposures should raise immediate suspicion of poisoning.

The history of chemical warfare dates back to the beginning of the last century. The first chemical warfare agent of modern times was chlorine. It was used by the German army at Ypres in 1915 against the Allies. Experiencing some success, the Germans then began to mix chlorine with phosgene, or deployed phosgene alone as a weapon. Phosgene, arsenicals, blister agents, and mustard gas were estimated to be responsible for approximately 1.3 million casualties during the war, including at least 90,000 fatalities (Raffle *et al.*, 1994; Bingham *et al.*, 2001; HSDB, 2005). Phosgene accounted for 80% of all gas deaths.

Chemical warfare agents do not need to be lethal to be disruptive. Although the mortality rate was not as high as with phosgene, mustard gas was the number one cause of casualties in World War I (Raffle *et al.*, 1994). Mustard gas caused severe injuries, and due to its persistence, remained a hazard and barrier to troop movements.

Chemical weapons have been used in a few recent civil wars. Phosgene was used by Egyptian bombers against Yemeni royalist forces in the Yemeni Civil War in the 1980s (Evison *et al.*, 2002). The Iraqi military used both mustard gas and HCN against the Kurds leading to as many as 3000 deaths (Somani and Babu, 1989). Iraq also used "Yellow rain" (mixture of mycotoxins, mustard gas, and nerve agents) against Iran in 1984. The fatality rate was 20% (Drasch *et al.*, 1987).

With the changing political climate around the world, several terrorist groups have used chemical warfare to bring attention to themselves and further their cause. Aum Shinrikyo (Supreme Truth) has used several chemical attacks recently to promote their agenda. In June 1994, they attempted to assassinate three Japanese judges by releasing sarin gas in the community where they lived. Aum Shinrikyo had modified a truck with a special device to release the sarin gas. Seven people, but not the judges, died and 280 were injured. Emboldened by this partial success, on March 20, 1995, Aum Shinrikyo carried out a sarin gas attack on the Tokyo subway. The terrorists used sharpened umbrellas to puncture lunch boxes and bags filled with dilute sarin. Eleven people died and more than 5500 were injured (Kaplan and Marshall, 1996). On April 20, 1995, Aum Shinrikyo changed their chemical agent and released phosgene gas in a Yokohama train station, causing injuries to 300 people.

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

Chemical agents also have their problems as agents of terror. They are most effective in confined spaces. Chemical warfare agents dissipate quickly and degrade or adhere to surfaces. Attacks need to be well coordinated for dispersal of the agent and escape from the area of deployment.

Both livestock and pet animals can be exposed to chemical agents during a terrorist attack. Treatment of animals is secondary to treating human casualties. Humane euthanasia may be the only recourse due to financial or logistical concerns.

## CHLORINE GAS

### Background

Chlorine (Agent CL, $Cl_2$) has been used as a choking or pulmonary agent for military purposes under the name bertholite (Budavari, 2000). It is a greenish-yellow diatomic gas with an irritating, pungent, or suffocating odor (Lewis, 1997; Budavari, 2000; NIOSH, 2003). Chlorine gas is heavier than air and will settle in low areas.

### Pharmacokinetics/toxicokinetics

The initial effects of chlorine gas exposure can appear very rapidly, depending upon the concentration. Due to chlorine's water solubility and chemical reactivity, it can have a greater effect on the lower respiratory tract as a large percentage bypasses the upper airways. Respiratory, dermal, and ocular irritation starts immediately and acute lung injury peaks in 12–24 h.

### Mechanism of action

Chlorine gas is a strong irritant, or in concentrated amounts, may be corrosive to mucous membranes when inhaled or ingested. When chlorine combines with tissue water it produces hydrochloric acid, and reactive oxygen species. These free radicals are potent oxidizers, causing tissue damage. The damage to the respiratory epithelium leads to alveolar capillary congestion which is followed by high fibrinogen edematous fluid (Noe, 1963). Hypoxemia results from development of atelectasis, emphysema, and membrane formation. Death usually occurs within 48 h from cardiac arrest secondary to hypoxia (Decker, 1988).

### Toxicity

Inhalation is the main route of chlorine gas exposure. Chlorine gas is very irritating on contact and can be caustic to the eyes, skin, nose, throat, and mucous membranes. Ocular exposure can result in severe or permanent eye injury. Dermal exposure may cause erythema, pain, and irritation. Both liquid chlorine and high concentrations of gaseous chlorine can cause dermal burns (Raffle *et al.*, 1994). Signs of exposure to chlorine gas include rhinorrhea, ataxia, syncope, muscle weakness, dermatitis, dyspnea, tachypnea, pneumonia, bronchospasm, and acute lung injury. High concentrations may cause laryngospasm, cardiovascular collapse, tachycardia, and respiratory arrest (Noe, 1963). Respiratory symptoms may be immediate or delayed up to several hours depending on the concentration (Bingham *et al.*, 2001). Hypoxia is common and death may be rapid. See Table 6.1 for severity of signs expected after inhalation at certain parts per million (ppm) concentrations of chlorine gas.

Symptoms generally disappear within 6 h after mild exposures, but may continue for more than 24 h with severe exposures. Moderate or severe exposures can result in chronic respiratory dysfunction (Decker, 1988; Schwartz *et al.*, 1990).

Chlorine is both teratogenic and carcinogenic. Chlorine at 100 ppm when given to pregnant rats in their water caused both biochemical and metabolic effects in the newborns (RTECS, 2006). Carcinogenicity has only been

**TABLE 6.1 Different effects of exposure levels of chlorine gas**

| Values in ppm | Effect |
|---|---|
| 0.2–3.5 | Odor detection (some tolerance develops) |
| 1–3 | Mild mucous membrane irritation that can be tolerated for up to 1 h |
| 3 | Extremely irritating to the eyes and respiratory tract |
| 5 | Severe irritation of eyes, nose, and respiratory tract; intolerable after a few minutes |
| 14–21 | Immediate irritation of the throat; dangerous if exposed for 30–60 min |
| 15 | Irritation of the throat |
| 30 | Moderate irritation of the upper respiratory tract; immediate chest pain, vomiting, dyspnea, cough |
| 35–50 | Lethal in 60–90 min |
| 40–60 | Toxic pneumonitis and acute lung injury; dangerous for even short periods |
| 430 | Lethal over 30 min |
| 1000 | Fatal within a few minutes |

Lewis (2000), HSDB (2005), and Bingham *et al.* (2001).

demonstrated in chronic exposures (Morris *et al.*, 1992; RTECS, 2006).

## Treatment

Move animals into fresh air and monitor for respiratory distress. If coughing or dyspnea develops, evaluate for hypoxia, acidosis, respiratory tract irritation, bronchitis, or pneumonitis. Oxygen supplementation along with intubation and ventilation may be needed. Beta adrenergic agonists can help if bronchospasm develops (Guloglu *et al.*, 2002).

Flush eyes with copious amounts of room temperature 0.9% saline or water for at least 15 min. Fluorescein staining should be performed to check for corneal defects (Grant and Schuman, 1993). Animals should be bathed with copious amounts of soap and water. Chlorine blood concentrations are not clinically useful as it converts directly to hydrochloric acid in the lungs and in the tissues.

Animal models have suggested that corticosteroids can hasten recovery from severe chlorine gas poisoning (Traub *et al.*, 2002); however, administration of steroids to exposed humans has not been shown to provide any significant change (Chester *et al.*, 1977). Pigs exposed to chlorine gas responded best to a combination of aerosolized terbutaline and budesonide than to either therapy alone (Wang *et al.*, 2004). Another study in sheep exposed to chlorine gas and then nebulized with 4% sodium bicarbonate had decreased mortality and had improved arterial blood gas values (Chisholm *et al.*, 1989).

## Concluding remarks

Rescuers should wear self-contained breathing apparatus (SCBA) and have protective clothing when entering contaminated areas. Chlorine dissipates quickly in warm climates and does not leave an environmental residue (Munro *et al.*, 1999). The potential for secondary contamination is low, as the gas is not carried on contaminated clothing.

# PHOSGENE

## Background

Phosgene (Agent CG, carbonyl chloride, C—$Cl_2$—O) is classified as a choking agent. It is a colorless, noncombustible, and highly toxic gas. At room temperature phosgene is easily liquefied (NIOSH, 2003; Proctor and Hughes, 2004; ACGIH, 2005; CHRIS, 2005) and at high concentrations, the gas has an odor described as strong, suffocating, and pungent. Lower concentrations are referred to as smelling like green corn or "haylike" (Raffle *et al.*, 1994; Budavari, 2000; Pohanish, 2002). Phosgene will sink in water (Budavari, 2000; Bingham *et al.*, 2001).

## Pharmacokinetics/toxicokinetics

Dyspnea develops 2–6 h post exposure in most patients, but may be delayed up to 15 h (Borak and Diller, 2001). With high concentrations (>200 ppm), phosgene can cross the blood air barrier in the lung and cause hemolysis and coagulopathies (Sciuto *et al.*, 2001).

## Mechanism of action

Phosgene is a lower respiratory tract irritant. Due to its low water solubility and low irritancy of the upper respiratory system, phosgene is able to penetrate deeply into the lungs (Franch and Hatch, 1986). Phosgene gas contacts water in the lungs, where it is hydrolyzed into hydrochloric acid causing cellular injury (Murdoch, 1993). Phosgene also acylates sulfhydryl, amine, and hydroxyl groups (Borak and Diller, 2001). This results in protein and lipid denaturation, changes in membrane structure, and disruption of enzymes. Phosgene increases pulmonary vascular permeability, leading to increased fluid accumulation in the lung interstitium and alveolae. This fluid accumulation results in gas diffusion abnormalities and pulmonary edema (Diller, 1985; Ghio *et al.*, 1991). Phosgene also decreases energy metabolism and disrupts the glutathione redox cycle. Animals exposed to phosgene have elevated levels of leukotrienes and neutrophil chemotactic agents. Neutrophils congregate in the lung releasing cytokines and other reactive mediators which contribute to pulmonary injury (Ghio *et al.*, 1991; Sciuto *et al.*, 1995). Bronchiolar epithelium is damaged, resulting in local emphysema and partial atelectasis. Death is due to anoxia secondary to pulmonary edema.

## Toxicity

Most exposures to phosgene are from inhalation. The odor of phosgene gas is not sufficient to warn individuals of toxic levels and with high concentrations, olfactory fatigue can occur (Borak and Diller, 2001; ACGIH, 2005). The degree of pulmonary injury relates to the concentration and length of exposure (Bingham *et al.*, 2001) and initial symptoms are not considered to be a good indicator of prognosis (Diller, 1985).

Exposure to concentrations less than 3 ppm may not be immediately accompanied by symptoms, but delayed effects usually occur within 24 h of exposure. Concentrations as low as 3–5 ppm can cause immediate conjunctivitis, rhinitis, pharyngitis, bronchitis, lacrimation, blepharospasm, and

upper respiratory tract irritation and extended (170 min) exposure was fatal (Diller, 1985; Wells, 1985; Proctor and Hughes, 2004). A dose of 50 ppm for 5 min may cause pulmonary edema and rapid death (Chemstar, 1996; Borak and Diller, 2001; RTECS, 2006).

A lag time of 1–6 h before the onset of respiratory distress and pulmonary edema is common with acute, high-dose exposures (>50 ppm/min). Signs can be delayed for up to 24 h (most common) or 72 h with exposures to lower concentrations (Pohanish, 2002; Proctor and Hughes, 2004). Thoracic radiographs can show evidence of pulmonary edema within 1–2 h of high-dose exposure, 4–6 h after moderate exposure, and approximately 8–24 h after low-dose exposure (Diller, 1985).

Progressive dyspnea, productive cough, cyanosis, and hemoptysis are common initial signs following exposure (Wells, 1985; Borak and Diller, 2001). Hypoxemia and hypoventilation are common secondary to respiratory distress (Wells, 1985). Animals may develop secondary gastrointestinal (GI), hepatic, renal, or brain injury, due to lack of oxygenation. In a dog model, severe phosgene poisoning caused initial bradycardia followed by tachycardia and progressive hypotension (Patt *et al.*, 1946). Cardiac failure may occur secondary to severe pulmonary edema (Borak and Diller, 2001; Proctor and Hughes, 2004).

Direct contact with the liquefied material can cause dermal burns and severe eye irritation, corneal opacification, and frostbite (Proctor and Hughes, 2004). Corneal opacification has also been produced in cats exposed to highly concentrated phosgene gas (Grant and Schumann, 1993).

Prognosis is directly related to the extent of pulmonary injury. If the animal survives 24–48 h, the prognosis improves, as pulmonary edema begins to resolve after 2–3 days. Survivors may have suppressed natural killer cell activity and are more susceptible to infectious agents. Secondary infections may become evident 3–5 days after exposure. They may also have persistent exertional dyspnea, reduced exercise capacity, and abnormal pulmonary function tests (Borak and Diller, 2001).

## Treatment

If inhalation exposure occurs, remove animals to fresh air (higher ground) and monitor for respiratory distress. Exposed skin should be washed with soap and water. Exposed eyes should be flushed for 15 min with tepid water. Asymptomatic animals should be monitored for 12–24 h for development of pulmonary edema (Borak and Diller, 2001). Symptomatic animals should receive 100% oxygen. If arterial blood gases or $pO_2$ continues to fall, intubation and ventilation is recommended. Plasma phosgene levels are not clinically useful and there is no specific antidotal agent. Management of patients with pulmonary edema from phosgene is the same as for an ARDS (acute respiratory distress syndrome) patient. Diuretics are not indicated and can worsen volume depletion. Mechanical ventilation with oxygen and PEEP (positive end-expiratory pressure) is the mainstay of treatment.

Intravenous (IV) fluids can help with cardiovascular support, but monitor closely for signs of overhydration. Colloids are preferred as they will remain in the vascular space for a longer period of time. Most arrhythmias will resolve with adequate oxygenation.

Nebulized beta adrenergic agonists are recommended if bronchospasm occurs. In a rabbit inhalation study, animals exposed to toxic levels of phosgene were dosed with IV aminophylline and subcutaneous terbutaline. If given within 10-min post exposure, it prevented non-cardiogenic pulmonary edema (Kennedy *et al.*, 1989). *N*-acetylcysteine (Mucomyst®) administered intratracheally to rabbits 45–60 min after inhalational exposure to phosgene (1500 ppm/min) decreased pulmonary edema, production of leukotrienes, lipid peroxidation, and maintained normal glutathione levels as compared to rabbits exposed to phosgene only (Sciuto *et al.*, 1995). Ibuprofen was shown to protect against acute lung injury from phosgene in rats and rabbits (Guo *et al.*, 1990). Supplemental oxygen and sodium bicarbonate were beneficial in dog experiments (Mautone *et al.*, 1985). Aerosolized surfactant improved lung compliance in a dog model, but the effects of the surfactant on the development or resolution of pulmonary edema were not determined (Mautone *et al.*, 1985). Animal experiments also suggest that corticosteroids, prostaglandin E1, and atropine may be helpful in treating phosgene-induced pulmonary edema (Chemstar, 1996).

## Concluding remarks

Phosgene is heavier than air and will pool in low lying areas. This heavy vapor density, 3.4 times that of air, made phosgene practical for trench warfare. Phosgene is considered to be non-persistent in the environment. Air concentrations are reduced by atmospheric water, such as rain or fog (Borak and Diller, 2001). Rescuers should wear proper protective clothing when treating exposed patients. Fortunately, the potential for secondary contamination of rescue personnel is low, as the gas does not persist in fabric or leather. Phosgene is used extensively in industry as a chemical precursor and this widespread availability makes it an attractive agent for terrorist use.

# MUSTARD GAS

## Background

Mustard gas (Agent H, $C_4$—$H_8$—$C_{12}$—S) is a vesicant agent used in chemical warfare. It produces corrosion and

necrosis of the skin, eyes, and respiratory tract. It is an organic lipophilic sulfide which is a bifunctional alkylating agent (Borak and Sidell, 1992; Lewis, 1997). Mustard agent is a clear oily liquid in its pure state. Due to impurities, however, it is normally amber to black, or yellow to brown in color (Munro *et al*., 1999; USACHPPM, 2001b; HSDB, 2005). The liquid becomes aerosolized when dispersed by spraying or by explosive blast from a shell or bomb (USACHPPM, 2001a). Mustard gas has an odor resembling garlic, mustard, or horseradish. Systemic poisoning occurs more easily in warm climates than in temperate ones. Mustard gas is still considered a major threat by the US Military, as it is easily manufactured and is both incapacitating and lethal.

## Pharmacokinetics/toxicokinetics

Mustard gas is toxic by all routes of exposure (oral, inhaled, dermal, and ocular) (EPA, 1985b; Sidell *et al*., 1997; Lewis, 2000; Pohanish, 2002). Skin penetration of both the liquid and vapor is rapid, and mustard causes both localized cellular and systemic damage (NATO, 1973). Mustard penetrates down hair follicles and sweat glands within minutes. Dermal absorption of mustard varies by species. About 20% of a dermal dose is absorbed through human skin, while up to 75% was absorbed through the skin in rats (Smith, 1999; Hambrook *et al*., 1992). Ocular absorption also happens within minutes. The latent period for absorption is inversely related to the dose, temperature, and humidity (NATO, 1973). Lesions develop within 2–3 h with high-level exposures and 8–10 h after milder exposures (Requena *et al*., 1988).

The chemical reaction with biological tissue occurs rapidly, but symptoms are typically delayed by several hours (Grant and Schuman, 1993; Sidell *et al*., 1997). Dog studies show that equilibrium between blood and tissues was achieved within 5 min after inhalation (IARC, 1975). Once inside the body, mustard accumulates (in descending order) in fat, skin with subcutaneous fatty tissue, brain, kidney, muscle, liver, cerebrospinal fluid, spleen, and lung (Drasch *et al*., 1987; Somani and Babu, 1989). There are no measurable levels of mustard in the liquid from a skin blister (Drasch *et al*., 1987). Urine is the major route of excretion in rabbits, mice, and rats. After IV administration in rats and mice, the majority is excreted in 72–96 h (Maisonneuve *et al*., 1993; Dacre and Goldman, 1996). Only about 6% is eliminated in the feces (IARC, 1975). Bone marrow damage is not evident for 3–5-days post exposure. Leukopenia usually occurs at day 7–10 following exposures (Garigan, 1996).

## Mechanism of action

The mechanism of action for cellular damage by mustard is unknown, but four theories have been proposed: alkylation of deoxyribonucleic acid, oxidative stress upon cell components, depletion of glutathione, and an inflammatory response (Smith *et al*., 1995). Mustard gas is a bifunctional alkylating agent. It forms covalent cross-links between the double strands of DNA which inhibits DNA synthesis. Mustard-induced blistering appears to be correlated to DNA damage in the basal cells (Andreassi, 1991; Cowan *et al*., 1998). Mustard penetrates the skin, and damages the cells separating the epidermis from the dermis. Mustard disrupts the hemidesmosomes forming a blister between the two layers (Sidell *et al*., 1997). Skin biopsies from mustard gas blisters revealed a separation of the basal cells from one another and the development of multinucleated cells (Bismuth *et al*., 1995).

Mustard also causes oxidative stress on intracellular molecules. Mustard rearranges in the aqueous of the cytosol to form an electrophilic ethylene episulfonium intermediate (Smith, 1999). The episulfonium ion reacts with sulfhydryl groups leading to increased intracellular calcium. The increased calcium level breaks down the microfilaments needed to maintain cell integrity and induces apoptosis by activation endonucleases, proteases, and phospholipases (Smith *et al*., 1995).

Mustard gas may also exert its toxicity via depletion of glutathione. Without glutathione, reactive oxygen species react with membrane phospholipids causing loss of membrane function, fluidity, and integrity (Smith *et al*., 1995). Inflammation and sulfur mustard-increased proteolytic activity are also implicated in contributing to mustard pathology (Cowan *et al*., 1998).

## Toxicity

Mustard gas is a radiomimetic as it produces lesions similar to radiation (Andreassi, 1991; Sidell *et al*., 1997). Tissues with high cell turnover are the most affected. Being a vesicant, mustard gas can produce erythema, severe pruritus, blistering, ulceration, and necrosis of exposed skin (Borak and Sidell, 1992; ITI, 1995; Dacre and Goldman, 1996; Budavari, 2000; Pohanish, 2002). With dermal exposure, the skin initially appears pale and then becomes erythematous within a few hours of exposure (Requena *et al*., 1988). Blistering usually starts on the 2nd day and progresses for several more days. Erythema disappears in 3–7 days, while the ulcers take 6–8 weeks to heal (Garigan, 1996; Sidell *et al*., 1997). Brown or black hyperpigmentation usually occurs after resolution of the burns, especially in areas with thinner skin (Requena *et al*., 1988). Skin involvement is most severe at warm and moist sites (genitalia, perineal regions, groin, skin folds, and axillae). This is due to the high number of sweat glands in these areas. The smallest reported blister-causing dose on the skin is 0.02 mg of mustard (Smith *et al*., 1995).

The eyes are very sensitive to the effects of mustard gas (NATO, 1973; Borak and Sidell, 1992; Dacre and

TABLE 6.2 $LD_{50}$ for mustard gas

| Species | Route | $LD_{50}$ (mg/kg) |
|---|---|---|
| Human | Oral | 0.7 |
| | Dermal | 100 |
| Mouse | Dermal | 92 |
| | SQ | 20 |
| Rat | Oral | 17 |
| | Dermal | 5 |
| | SQ | 1.5 |

Lewis (2000) and RTECS (2006).

Goldman, 1996). Pain, lacrimation, corneal ulceration, along with photophobia, swelling, blepharospasm, and blindness can be seen (Garigan, 1996). Conjunctivitis appears early, developing 4–6 h after exposure. Eye lesions have been reported at a *Ct* (concentration × time) of 10 mg-min/m$^3$ (Sidell *et al.*, 1997). Porcelain-white areas in the episcleral tissues adjacent to the cornea and formation of large, tortuous, sausage-shaped varicose veins are pathognomonic signs of mustard gas poisoning (Grant and Schuman, 1993). Chronic conjunctivitis and keratopathy have been reported in people (Blodi, 1971).

The main non-dermal toxic effects are on the respiratory tract. Irritation or ulceration of the respiratory tract can occur (Vogt *et al.*, 1984; Borak and Sidell, 1992; ITI, 1995; Dacre and Goldman, 1996; Budavari, 2000). Cough, dyspnea, and pulmonary edema may occur up to 24 h after inhalation; 1 ppm in air is a lethal concentration for dogs and 0.650 ppm mustard results in a 33% mortality rate in rabbits (OHM/TADS, 2005). See Table 6.2 for $LD_{50}$ information in various species by multiple routes of exposure.

Mild pulmonary exposures produce rhinorrhea, sneezing, epistaxis, and cough within 12–24 h of exposure. Large exposures can cause pulmonary damage. In severe cases, arterial blood gases indicate hypoxia and respiratory acidosis. Seizures appear to occur only following extremely acute, high doses (Sidell *et al.*, 1997).

Leukopenia, thrombocytopenia, pancytopenia, and anemia have been reported due to depressed myelopoiesis from destruction of precursor cells in the bone marrow (Vogt *et al.*, 1984; Borak and Sidell, 1992; Dacre and Goldman, 1996). Bone marrow aplasia can be seen in severe cases. Secondary to bone marrow damage, overwhelming infection can result in death (Sidell *et al.*, 1997).

Mustard gas is a possible human and animal teratogen. It has been linked to an increased incidence of cleft lip and cleft palate in Iranian children born during the Iran–Iraq war (Taher, 1992). Abnormalities of the musculoskeletal system were observed in the offspring of rats orally dosed with mustard gas, but such effects may only occur at doses high enough to be toxic to the dams (Dacre and Goldman, 1996; RTECS, 2006). Other rat and rabbit studies showed no correlation (Hackett *et al.*, 1987). Mustard gas is considered both carcinogenic and neoplastic. Mustard gas has caused carcinomas in the skin, appendages, lungs, thorax, and blood (leukemia) of rats and mice via both inhalation and IV exposure (RTECS, 2006).

## Treatment

Move animal into fresh air. Do not induce emesis. Activated charcoal administration after oral ingestion is controversial. It appears to have some beneficial effects if administered within 1 h of ingestion. Sodium thiosulfate has been used as a "mustard scavenger" and giving 2% sodium thiosulfate solution orally may help in cases with ingestion exposures (Borak and Sidell, 1992; Dacre and Goldman, 1996). If signs or symptoms of esophageal burns are present, consider endoscopy to determine the extent of injury. Perforation and stricture formation could result.

Flush eyes with tepid water for at least 15 min. After flushing, instill 2.5% sodium thiosulfate to help neutralize the mustard. Time to decontamination is very important with ocular exposures. Mustard droplets disappear from the eye very quickly, and late flushing of the eye generally provides no benefit (Sidell *et al.*, 1997). Topical antibiotics and mydriatics should be used if corneal lesions are present (Sidell *et al.*, 1997). Corneal transplants have been performed on some human patients with good results and may be considered for some valuable animals (Blodi, 1971).

Bathe animals with copious amounts of soap and water. Dermal decontamination needs to be implemented quickly, as once mustard has reacted with the skin, it cannot be easily removed (Sidell *et al.*, 1997). A 2.5% sodium thiosulfate solution has been used to neutralize dermal mustard exposures (Garigan, 1996). Dilute (0.5%) hypochlorite solutions may also be used for skin decontamination (Borak and Sidell, 1992). Monitor for dermal effects, which are delayed and progressive. Dermal lesions behave like a chemical burn or radiomimetic effect. Topical silver sulfadiazine should be applied to all affected areas. In a mouse model, topically applied dexamethasone and diclofenac reduced inflammatory parameters when applied within 4 h (Dachir *et al.*, 2004). Healing can take weeks to months and infection is common (Borak and Sidell, 1992). Removal and debridement of closed blisters is controversial. Blisters should be left intact until they rupture spontaneously or unless they are extremely large or inhibit motion (Roberts, 1988). Tetanus toxoid should be given to all equine and ovine patients. Tetanus prophylaxis of other species should be determined on a case-to-case basis.

Monitor for coughing and respiratory distress. If respiratory abnormalities occur, monitor arterial blood gases and/or pulse oximetry, and thoracic radiographs. Thoracic radiographs may show an infiltrate within the first 2 days (Smith, 1999). Nebulization of 2.5% sodium thiosulfate

may help neutralize the mustard gas. *N*-acetylcysteine (Mucomyst®) is also a potential mustard gas antagonist (Garigan, 1996). A loading dose of 140 mg/kg should be given, followed by 40 mg/kg every 4 h for a total of 17 doses (Garigan, 1996). Administer oxygen and inhaled beta agonists if needed. Intubation and ventilation may be needed. Combinations of parenteral dexamethasone, promethazine, vitamin E, and heparin have shown protective effects against mustard gas poisoning in laboratory animals. (Vojvodic *et al*., 1985; Requena *et al*., 1988).

Monitor complete blood count (CBC) with platelets for 2 weeks after exposure. Leukopenia develops at 7–10 days following a severe acute exposure (Garigan, 1996). Prophylactic antibiotics are not recommended, but a broad spectrum antibiotic should be started if leukopenia develops (Sidell *et al.*, 1997). Antibiotic choice should be based on culture and sensitivity if possible.

Mustard can be detected in air, urine, and body tissues using different methods. Mustard gas or its thiodiglycol metabolite can be detected in urine up to a week after acute exposure using gas chromatography-mass spectrometry (GC-MS) (Vycudilik, 1985). Other than for confirming the diagnosis, measuring mustard gas levels is not likely to be of value in the management of the patient.

## Concluding remarks

Due to its low volatility, mustard is persistent in the environment. It persists for shorter periods of time in a hot climate, but reaches higher vapor concentrations more rapidly. In temperate areas mustard may persist for more than 1 week, but in desert conditions, persistence is reduced to about 1 day. Mustard will bind to vegetation for days to weeks (USACHPPM, 2001b). Detection tubes can be used to detect airborne levels of mustard gas (IARC, 1975).

The potential for secondary contamination is high. Rescue personnel must wear protective clothing, eye protection, and a respirator (HSDB, 2005). Mustard gas penetrates wood, leather, rubber, and paints. Medical personnel treating mustard-exposed patients have developed toxicity.

# LEWISITE

## Background

Lewisite ($C_2$—$H_2$—As—$Cl_3$) is a substituted arsine. Lewisite was first synthesized in 1918 by a research team headed by US Army Captain W.L. Lewis (Sidell *et al.*, 1997). It is an oily vesicant (blister-causing) liquid with potential terrorist use. Lewisite smells like geraniums. Pure Lewisite is colorless, but impurities and age cause the color to darken (amber to black or violet to brown, to olive-green) (HSDB, 2005). Lewisite remains a liquid at low temperatures and is persistent in colder climates. It hydrolyzes rapidly, making it difficult to maintain a biologically active concentration on a humid day (Sidell *et al.*, 1997; AAR, 2000; Lewis, 2000; HSDB, 2005). The synthesis of Lewisite involves adding arsenic trichloride to acetylene, using aluminum chloride as a catalyst. This results in a mixture of about 20% Lewisite, other arsine compounds, and an explosive component. Lewisite can be dispersed in air as a very fine droplet spray over a large distance (Grant and Schuman, 1993; Lewis, 2000).

## Pharmacokinetics/toxicokinetics

Lewisite can cause systemic signs when ingested, inhaled, or when absorbed dermally or ocularly (Sidell *et al.*, 1997; HSDB, 2005). Inhalation of vapor causes immediate pain and if high enough concentrations are inhaled, death can be seen within 10 min (DeRosa *et al.*, 2002). Dermal absorption occurs within 3–5 min, especially following liquid exposures (Sidell *et al.*, 1997). The volume of distribution of arsenic after Lewisite administration, is several liters/kilogram, indicating extensive tissue distribution (HSDB, 2005). A distribution study using rabbits revealed that the liver, lungs, and kidneys had the highest concentration of arsenic after Lewisite administration (>7 times blood concentration) (HSDB, 2005). Arsenic can cross the placenta and is passed into the milk, and nursing animals may be at risk (Barlow and Sullivan, 1982).

Animal studies showed that excretion of Lewisite oxidation products into the bile caused focal necrosis of the liver and necrosis of biliary vessel mucosa with peribiliary hemorrhages (Munro *et al.*, 1999). The same study in rabbits found that arsenic was eliminated with a half-life in blood of 55–75 h (HSDB, 2005). The excretion of oxidized Lewisite products into the bile by the liver may result in injury to the intestinal mucosa (Munro *et al.*, 1999).

## Mechanism of action

Besides being a vesicant, Lewisite is an arsenical compound which causes systemic effects. Lewisite directly effects enzyme systems. The exact mechanism of action is unknown, but it inhibits a variety of enzymes (pyruvic oxidase, alcohol dehydrogenase, succinic oxidase, hexokinase, and succinic dehydrogenase) (DeRosa *et al.*, 2002). Lewisite binds with thiol groups on these enzymes, resulting in decreased ATP production. Ocular injuries following Lewisite exposure are due in part to the liberation of hydrochloric acid. Deep penetration of Lewisite into the cornea and aqueous humor causes rapid necrosis (Goldfrank *et al.*, 1998).

Lewisite causes increased capillary permeability. Systemic absorption and increased permeability can cause a significant loss of blood plasma and is called "Lewisite shock" since it is similar to that of shock observed in severe burns. The leakage of fluid into the extravascular space results in hypotension (Sidell *et al.*, 1997). The exact mechanism of increased capillary permeability is not known. Theories include a capillary dilating material released from skin or tissue, or alternatively, enhanced permeability from an interference with the metabolism of capillary endothelial cells (Goldman and Dacre, 1989). Lung capillaries appear to be the most affected due to absorption via the respiratory tract and first pass through the lungs following dermal exposure. Pulmonary edema or ARDS can develop (Sidell *et al.*, 1997).

## Toxicity

Due to its method of dispersal (bursting charge of an explosive), the main routes of absorption are dermal and respiratory. Lewisite first acts as a vesicant, then as a pulmonary irritant, and finally as a systemic poison. Lewisite is similar to mustard gas in that it damages the skin, eyes, and airways; however, it differs in that its clinical effects appear within seconds of exposure and it is about 10 times more volatile than mustard gas (Budavari, 2000). Exposure to Lewisite is very painful, in contrast to mustard. See Table 6.3 for $LD_{50}$ of various species by different routes of exposure.

Dermal contact results in immediate pain. Both the vapor and liquid Lewisite can penetrate skin. Reddening of the skin becomes evident within 15–30 min after exposure (EPA, 1985a; Sidell *et al.*, 1997; Pohanish, 2002). Evidence of tissue destruction (grayish epithelium) will be present within minutes of skin contact (Goldman and Dacre, 1989; Sidell *et al.*, 1997). Severe blisters develop within 12 h after exposure (EPA, 1985a; Goldman and Dacre, 1989; Sidell *et al.*, 1997). The blisters may rupture, usually about 48 h after occurrence, with copious amounts of fluid seeping from the site (Goldman and Dacre, 1989). With dermal exposure, as little as 0.5 ml may cause severe systemic effects and 2 ml may be lethal. Severe edema can be seen due to the Lewisite's increased capillary permeability. Dermal burns are generally deeper than those with mustard gas. Healing occurs much faster than with sulfur mustard-induced lesions and is generally complete within 4 weeks (Goldman and Dacre, 1989; Sidell *et al.*, 1997).

**TABLE 6.3 $LD_{50}$ for Lewisite**

| Species | Route | $LD_{50}$ (mg/kg) |
|---|---|---|
| Mouse | Dermal | 12 |
| Rat | Dermal | 15 |
| | Subcutaneous | 1 |
| | Oral | 50 |
| Human | Dermal | 30 |

RTECS (2006), Sidell *et al.* (1997), and DeRosa *et al.* (2002).

Ocular contact causes immediate pain, lacrimation, and blepharospasm. Permanent blindness may occur if eye exposure occurs for more than 1 min without rapid decontamination (EPA, 1985a; Pohanish 2002). A small droplet (0.001 ml) can cause perforation and loss of vision (Sidell *et al.*, 1997).

Inhalation of the Lewisite vapor may result in irritation to nasal passages and profuse nasal discharge and violent sneezing (HSDB, 2005). Inhalation of 6 ppm can be lethal (USACHPPM, 2001c). Following inhalation of vapor, coughing and hemoptysis commonly occur (Sidell *et al.*, 1997; HSDB, 2005). Lesions following Lewisite inhalation are similar to the lesions produced by mustard gas exposures (Sidell *et al.*, 1997). Dogs that inhaled lethal doses died of necrotizing pseudomembranous laryngotracheobronchitis (Goldman and Dacre, 1989). A thick membrane was noted in the nostrils, larynx, and trachea with purulent bronchitis. Edema, hemorrhage, and emphysema were seen in the lungs (Goldman and Dacre, 1989). Death can be seen within 10 min with high concentrations (EPA, 1985a).

Unlike arsenic or mustard gas, Lewisite does *not* cause damage to the bone marrow or immunosuppression (Sidell *et al.*, 1997). Even though Lewisite is a substituted arsine, it also does not appear to directly cause hemolysis of the red blood cells (RBC) (HSDB, 2005). Hypovolemia, secondary to fluid loss, can be severe enough to cause renal dysfunction (Sidell *et al.*, 1997). Arrhythmias may occur as a result of hypovolemia rather than a direct toxic effect of Lewisite on the myocardium (Sidell *et al.*, 1997). Lewisite was fetotoxic to rats and rabbits, but not teratogenic (Goldman and Dacre, 1989; RTECS, 2006). It is a suspected carcinogen due to its arsenic content (Goldman and Dacre, 1989). Lewisite blood levels are not clinically useful, but an arsenic blood level below 7 $\mu$g/100 ml is considered normal.

## Treatment

Move animals to fresh air and monitor for coughing and respiratory distress. Monitor blood gases and $SpO_2$ in patients with significant exposures. If coughing or difficulty breathing develops, administer oxygen and assist ventilation as needed. Bronchospasm should be treated with inhaled beta agonists and possibly corticosteroids. Monitor electrolytes and packed cell volume (PCV) as animals can become hemoconcentrated. Crystalloids should be given with caution not to overhydrate the patient (Goldfrank *et al.*, 1998). Consider urinary alkalinization and maintain good urine output. Monitor for liver and kidney failure and secondary infection.

Emesis is not recommended due to the irritant and vesicant nature of Lewisite. Dilute oral ingestions with milk or water. Activated charcoal is of unknown benefit in Lewisite ingestion and as severe irritation or vesication (blistering) of the esophagus or GI tract is likely to occur it is not recommended. Endoscopy may be used to determine the extent of injury. Perforation and stricture formation may occur after ingestion.

Flush eyes with copious amounts of tepid water for at least 15 min. A 5% BAL (dimercaprol, British Anti-Lewisite) compounded ophthalmic ointment applied within 2 min may prevent a significant reaction. Treatment at 30 min will lessen the ocular reaction but does not prevent permanent damage (Goldfrank *et al.*, 1998).

Animals should be rinsed with copious amounts of water. A 5% solution of sodium hypochlorite (diluted liquid household bleach) should be used as soon as possible on contaminated skin. Topical application of a 5% BAL ointment within 15 min of an exposure has been reported to be effective in diminishing the blistering effects of Lewisite (Smith, 1999). Wash BAL ointment off after 5 min. The ointment may cause stinging, itching, or urticaria. Burns should be managed as discussed previously under mustard gas. Pain control is very important.

Chelation is indicated if there is coughing, dyspnea, pulmonary edema, or skin burns larger than palm size (Goldfrank *et al.*, 1998). BAL is an effective arsenic chelator, but requires painful deep intramuscular injections and has numerous side effects (hypertension, tachycardia, vomiting, lacrimation, sweating). BAL will increase the clearance rate of arsenic, but it is contraindicated in animals with liver damage (Goldfrank *et al.*, 1998). 2,3-Dimercaptosuccinic acid (DMSA, Succimer®) appears to be a very effective arsenic chelator in animals (Graziano *et al.*, 1978). DMSA is an oral agent and is relatively nontoxic. It may be used following BAL. 2,3-Dimercapto-1-propanesulfonic acid (DMPS) is related to DMSA and is used for heavy metal poisoning, especially in Europe. It has been effective in protecting rabbits from the lethal effects of Lewisite (Aposhian *et al.*, 1982).

Urine arsenic levels may be tested using several methods. Urinary arsenic levels of less than 100 μg are considered normal (Proctor and Hughes, 2004). Concentrations between 700 and 1000 μg/l (0.7–1.0 mg/l) indicate a potentially harmful exposure (Proctor and Hughes, 2004).

### Concluding remarks

Lewisite can remain in the environment for about 1 day. It reacts with water to yield a solid arsenoxide that also has vesicant properties. When in contact with strong alkalis, Lewisite is decomposed to less harmful substances. The potential for secondary contamination is high and material spilled on clothing may be transferred to rescuers or medical personnel. Lewisite is considered a terrorist threat as it is easy to produce and has a quick onset of signs. Carcasses should be buried deeply (away from water supplies), rendered, or incinerated to insure safety of the food supply.

## PHOSGENE OXIME

### Background

Phosgene oxime (Agent CX, "Nettle Rush," CH—$Cl_2$—NO) is a halogenated oxime used as a blistering agent in chemical warfare. Other halogenated oximes include diiodoformoxime, dibromoformoxime, and monochloroformoxime, but phosgene oxime is the most irritant of the group and the only one considered a terrorist warfare threat. Phosgene oxime can be found as a liquid or as a colorless, low melting point crystalline solid, readily soluble in water. The solid form can produce enough vapor to cause symptoms (Sidell *et al.*, 1997). Phosgene oxime has an unpleasant, peppery, and irritating odor. Phosgene oxime is not a true vesicant as it does not cause skin blisters but it does have a rapid dermal corrosive effect. It can be dispersed as a liquid or vapor causing almost immediate tissue damage upon contact (Sidell *et al.*, 1997).

### Pharmacokinetics/toxicokinetics

Absorption in both dermal and inhalational exposures is complete and rapid (within seconds) (Sidell *et al.*, 1997). Dermal lesions form within seconds. As phosgene is soluble in water, it will dissolve in sweat and move to other non-exposed areas of the body (DeRosa *et al.*, 2002). Pulmonary edema can be evident on thoracic radiographs within 2 h of high-dose exposure, 4–6 h of moderate exposure, and approximately 8–24 h after low-dose exposure (Sidell *et al.*, 1997).

### Mechanism of action

The exact mechanism of action is unknown, but it has been proposed that phosgene oxime reacts with SH and $NH_2$ groups (US Army, 1996; Sidell *et al.*, 1997). Phosgene oxime exerts its greatest effects in the first capillary bed it encounters (Sidell *et al.*, 1997).

### Toxicity

Both liquid and vaporous phosgene oxime cause intense, immediate pain, and local tissue destruction on contact

with skin, eyes, and mucuous membranes (Sidell *et al.*, 1997). Damage to the eyes, skin, and airways is similar to that caused by mustard gas. Following dermal contact with either the liquid or vapor, grayish tissue damage may be seen within several minutes. The damaged areas are erythematous and extremely painful. Within 1 h, the area becomes edematous. Browning of the skin and blistering occurs the next day. In about 3 weeks, desquamation, necrosis, crust formation, and purulent exudate occur (US Army, 1996; Sidell *et al.*, 1997). Pain can last for several days. Skin irritation begins at 0.2 mg/min/$m^3$ (12 s) for humans and is intolerable 3 mg/min/$m^3$ (1 min) (USACHPPM, 2001d).

Phosgene oxime is very irritating to the eyes. Very low concentrations can cause lacrimation, inflammation, and temporary blindness and high concentrations can cause permanent corneal lesions and blindness (US Army, 1996; Sidell *et al.*, 1997; USACHPPM, 2001d). Inhalation or oral absorption may cause respiratory tract irritation, dyspnea, and pulmonary edema. The non-cardiogenic pulmonary edema may occur after a several hour delay. Death is due to respiratory arrest.

## Treatment

There is no antidote for phosgene oxime exposure. Move animals into fresh air. Emesis is not recommended after oral ingestion because of the irritant and corrosive effects of phosgene oxime. Immediately dilute oral ingestions with milk or water. Activated charcoal is also not recommended after ingestion, since the primary toxicity is expected to be a local corrosive injury rather than systemic effects from absorption. Charcoal may also obscure endoscopy findings and induce emesis.

Flush eyes with tepid water until pH returns to neutrality and remains so for 30 min after irrigation is discontinued (Brodovsky *et al*., 2000). Decontamination after ocular exposure is critical since phosgene oxime is absorbed within seconds. Corneal ulcers should be treated with mydriatic cycloplegics to prevent synechia development (Grant and Schuman, 1993; Brodovsky *et al*., 2000). For more severe corneal lesions, topical steroids, citrate, ascorbate, and tetracycline or doxycycline may be used to aid in re-epithelialization (Grant and Schuman, 1993).

The skin should be flushed with large volumes of water and mild soap. As phosgene oxime reacts so quickly with tissue, decontamination is not expected to be entirely effective after pain has been produced. Chloramine and phenol towelettes are ineffective for dermal decontamination. Isotonic sodium bicarbonate or 0.5% hypochlorite may remove phosgene oxime that has not yet reacted with tissue. Ulcerated skin lesions should be treated just like a thermal burn. Topical silver sulfadiazine is recommended (Roberts, 1988). Healing of dermal lesions can take from 1 month to over a year (US Army, 1996; Sidell *et al*., 1997). Both sheep and horses should receive tetanus prophylaxis. Other species should be vaccinated at the veterinarian's discretion. Large amounts of opioid analgesics may be needed to help control pain.

Monitor arterial blood gases, pulse oximetry, and thoracic radiographs in patients following significant exposures. Non-cardiogenic pulmonary edema may take 12–24 h to develop. If dyspnea develops, administer 100% humidified oxygen, perform endotracheal intubation, and provide assisted ventilation as required. Beta adrenergic agonists may help if bronchospasm develops. Administer IV fluids but ensure that the animal does not become over hydrated (Hoffman, 2002).

## Concluding remarks

Phosgene oxime is considered non-persistent in the environment. It hydrolyzes rapidly in aqueous alkaline solutions. The potential for secondary contamination is high. Veterinary personnel should wear aprons, rubber gloves, and masks when treating un-decontaminated patients to avoid self-contamination. Phosgene oxime is of interest to terrorists as it penetrates garments and rubber much more quickly than other chemical warfare agents. Phosgene oxime can also be mixed with other chemical warfare agents (e.g. VX). The phosgene oxime will cause skin damage which will increase the dermal absorption of the second agent (Sidell *et al*., 1997).

# CYANIDE AND HYDROGEN CYANIDE

## Background

Cyanogen and cyanogen halides (cyanogen bromide, cyanogen chloride, and cyanogen iodide) have been used historically as military chemical warfare agents (Barr, 1985; ACGIH, 2005). Today cyanide is most likely to be used for a terrorist weapons in the form of hydrogen cyanide or cyanogen chloride.

Hydrogen cyanide (Agent AC, HCN, prussic acid) is a colorless gas with a faint bitter almond-like odor (ACGIH, 2005). Hydrocyanic acid is the liquefied form of hydrogen cyanide (Lewis, 1997). Cyanogen chloride (Agent CK, ClCN) is either a colorless irritant gas or liquid with a pungent odor (ACGIH, 2005). It was developed to be slightly heavier than air and to have greater environmental persistence. It can release hydrogen chloride and hydrogen cyanide when it contacts water, acids, or by thermal decomposition. The water-soluble salt forms (calcium cyanide, sodium cyanide, and potassium cyanide) will form HCN gas when mixed with a strong acid.

Animals with cyanide poisoning may have an odor of bitter almonds in their gastric or ruminal contents or expired breath. The ability to smell the bitter almond-like odor of cyanide is genetically determined, and 20–60% of the population cannot detect its presence (Hall and Rumack, 1986). Cyanide and related compounds are classified as blood agents.

## Pharmacokinetics/toxicokinetics

Cyanide and hydrogen cyanide can be absorbed by inhalation, ingestion, ocularly, and through intact skin (Ballantyne, 1983; Hall and Rumack, 1986). Cyanide rapidly diffuses into tissues and irreversibly binds to its target sites. Dermal absorption of significant amounts of hydrogen cyanide gas has not been reported. There have been no reports of systemic poisoning in humans ocularly exposed to cyanide; however, rabbits have died following ocular exposure to NaCN, KCN, and HCN (Ballantyne, 1983).

Cyanide is distributed to all organs and tissues. The concentration of cyanide in red cells is greater than that in plasma by a factor of 2 or 3 (HSDB, 2005). Cyanide accumulates in neural tissue. It preferentially accumulates in the hypothalamus, with levels about 40% higher compared to the hippocampus, cerebellum, and cortex (Borowitz *et al*., 1994). In acute cyanide intoxication, there are no specific pathological changes.

Cyanide is metabolized by rhodanase in the liver to thiocyanate (Hall and Rumack, 1986). This reaction complexes cyanide with endogenous sulfur or sulfur supplied from the sodium thiosulfate antidote. Once thiocyanate is formed it is excreted mainly in the urine. Half-life for the metabolism of cyanide to thiocyanate is 20 min to 1 h (Feldstein and Klendshoj, 1954). In animals, the dose of cyanide that produces signs is very close to the lethal dose and death can occur within seconds to minutes.

## Mechanism of action

Cyanide causes its toxicity by forming a stable complex with ferric iron ($Fe^{3+}$) in cytochrome oxidase enzymes. Since oxygen is unable to re-oxidize the reduced cytochrome a3, this inhibits cellular respiration, oxygen utilization, and ATP production, resulting in deprivation of oxygen to the body at the cellular level (Way *et al*., 1988). In the brain, cyanide decreases oxidative metabolism, increases glycolysis, and inhibits brain glutamic acid decarboxylase, thereby decreasing gamma aminobutyric acid (GABA) (Bingham *et al*., 2001). The corpus callosum, hippocampus, corpora striata, and substantia nigra are commonly damaged in cyanide poisoning (Grandas *et al*., 1989).

Early in cyanide toxicosis, central nervous system (CNS), respiratory, and myocardial depression also contribute to decreased oxygenation of the blood and decreased cardiac output (Hall and Rumack, 1986). There is also evidence of lipid peroxidation by measurement of elevated levels of conjugated dienes in mouse brain and kidneys at 15 and 30 min after cyanide exposure (Ardelt *et al*., 1994). Cyanide salts are irritating upon ingestion and can cause corrosion of the oral, esophageal, or gastric mucosa (HSDB, 2005).

## Toxicity

Signs following acute cyanide exposure include syncope, or CNS stimulation, dizziness, dyspnea, seizures, paralysis, apnea, and coma (Vogel *et al*., 1981; Hall and Rumack, 1986). Tachypnea and hyperpnea are followed rapidly by respiratory depression. Signs of severe hypoxia without cyanosis can suggest the diagnosis. Signs in birds are similar to those in mammals. Chickens will pant, and have rapid eye blinking, excess salivation, and lethargy (Wiemeyer *et al*., 1986). Mydriasis is common in severe poisonings and blindness may occur from cyanide-induced damage to optic nerves and retina (Vogel *et al*., 1981; Grant and Schuman, 1993). Nausea, vomiting, and abdominal pain may occur, especially after ingestion of cyanide salts (Vogel *et al*., 1981; Hall and Rumack, 1986; Singh *et al*., 1989). Metabolic acidosis and lactic acidosis are frequent metabolic derrangements associated with cyanide poisoning. Blood gases show a decreased arterial–venous oxygen saturation difference due to the cellular inability to extract oxygen (Paulet, 1955; Graham *et al*., 1977).

The blood, both arterial and venous, becomes cherry red from accumulated oxyhemoglobin (Lewis, 2000; Bingham *et al*., 2001). The skin may also be a bright pink color from the high concentration of oxyhemoglobin in the venous return (HSDB, 2005). On funduscopic examination, retinal arteries and veins will appear equally red. The arterialization of venous blood gases occurs early in the process of cyanide poisoning (Hall and Rumack, 1986). Tachycardia and hypertension may be seen in the initial phases of cyanide poisoning followed by bradycardia and hypotension in the late phases (Vogel *et al*., 1981; Hall and Rumack, 1986). Cyanide exposure can produce death within minutes. See Table 6.4 for $LD_{50}$ of HCN by various routes.

Cyanide can be measured in blood. No symptoms are expected at concentrations less than 0.2 mg/l, tachycardia can be seen at 0.5–1.0 mg/l, obtundation at 1.0–2.5 mg/l, coma and respiratory depression at levels greater than 2.5 mg/l, and death with blood levels greater than 3 mg/l (Graham *et al*., 1977). No adverse reproductive studies were found for cyanide or hydrogen cyanide, but in

**TABLE 6.4 $LD_{50}$ for hydrogen cyanide**

| Species | Route | $LD_{50}$ (μg/kg) |

ACGIH (2005), Bingham *et al.* (2001), Budavari (2000), HSDB (2005), ITI (1995), Lewis (2000), OHM/TADS (2005), and RTECS (2006).

laboratory animals, cyanide compounds did cause resorptions, malformations, and teratogenic effects in offspring (Willhite, 1983).

## Treatment

Move animals to fresh air. Emesis is not recommended due to the rapid progression of the clinical signs and potential for seizures, coma, or apnea. Activated charcoal may be beneficial if administered immediately after ingestion as the absorption of cyanide is rapid. Flush eyes for at least 15–20 min with tepid water. Wash all contaminated animals thoroughly with soap and water.

Monitor arterial blood gases and serum electrolytes (Vogel *et al.*, 1981; Hall and Rumack, 1986). Administer 100% humidified oxygen with assisted ventilation if needed to maintain an elevated $pO_2$. Hyperbaric oxygen therapy is approved for cyanide poisoning by the Undersea Medical Society (Myers and Schnitzer, 1984). It has been suggested to improve clinical outcome, but experimental animal studies have been questionable (Way *et al.*, 1972). For severe acidosis ($pH < 7.1$) administer sodium bicarbonate, but acidosis may be difficult to correct prior to administration of antidotes in cyanide toxicosis. Control seizures with benzodiazepines or barbiturates.

Cyanide toxicosis usually occurs and progresses so rapidly that treatment is rarely administered soon enough to be effective. Antidotal agents should be used if the animal is in respiratory distress or a coma. Treatment for cyanide poisoning includes several steps. Sodium nitrite should be given IV over 15–20 min, as soon as vascular access is established. Quick administration can cause hypotension. Sodium nitrite reacts with hemoglobin in the RBC forming methemoglobin. The methemoglobin will combine with free cyanide to form cyanomethemoglobin. If possible, monitor methemoglobin levels during nitrite administration. The goal is to maintain methemoglobin levels below 30% (Hall and Rumack, 1986).

Follow sodium nitrite with IV administration of sodium thiosulfate. Sodium thiosulfate supplies sulfur for the rhodanase reaction (Hall and Rumack, 1987). Thiocyanate is formed and excreted in the urine. Oxygen, combined with traditional nitrite/thiosulfate therapy, provides better results than thiosulfate alone (Way *et al.*, 1972). It is believed that oxygen may reverse the cyanide–cytochrome oxidase complex and aid in the conversion to thiocyanate following thiosulfate administration (Graham *et al.*, 1977).

Hydroxocobalamin, a vitamin B12 precursor, is a cobalt containing chelator. It is the chelator of choice in Europe and Australia. Hydroxocobalamin is not approved for use in the United States. Hydroxocobalamin reverses cyanide toxicosis by combining with cyanide to form cyanocobalamin (vitamin B12) (Hall and Rumack, 1987). It has been shown to be effective in treating cyanide-poisoned laboratory animals and has the advantage of producing neither methemoglobinemia nor hypotension, as sodium nitrite does. Dicobalt–EDTA (Kelocyanor®) is also highly effective in chelating cyanide. It is used clinically in Europe, Israel, and Australia, but it is not available in the United States (Hillman *et al.*, 1974). Another methemoglobin-inducing agent used in some European countries is 4-dimethylaminophenol hydrochloride (4-DMAP). It has a more rapid onset of methemoglobin production than sodium nitrite. Methemoglobin peaks at 5 min after 4-DMAP versus 30 min after sodium nitrite. 4-DMAP is coadministered with thiosulfate. Excessive methemoglobin production can be a major complication and hemolysis may occur with therapeutic doses (van Dijk *et al.*, 1986; Weger, 1990).

Animal studies to identify alternate cyanide antidotes have tested stroma-free methemoglobin solutions, alpha-ketoglutaric acid, chlorpromazine, hydroxylamine, phenoxybenzamine, centrophenoxine, naloxone hydrochloride, etomidate, para-aminopropiophenone, and calcium-ion-channel blockers (Ashton *et al.*, 1980; Amery *et al.*, 1981; Dubinsky *et al.*, 1984; Leung *et al.*, 1984; Ten Eyck *et al.*, 1985; Johnson *et al.*, 1986; Bright and Marrs, 1987; Yamamoto, 1990; Budavari, 2000). These antidotes have shown some promise in the laboratory setting, but have not been tried during actual poisoning situations.

Blood cyanide levels can be useful in confirming the diagnosis. However, unless the results are available within a reasonable time, it is not clinically useful. Cyanide can be measured by several methods but most take several hours to complete. Biological specimens can be tested using spectroscopy, GC, gas–liquid chromatography, paper chromatography, ion specific electrode, fluorimetric, microdistillation, and paper strip (Groff *et al.*, 1985; Fligner *et al.*, 1992; HSDB, 2005). Cyanide and thiocyanate levels can be measured in timed urine collections to provide information on cyanide clearance, but it is rarely done clinically. Handling of samples is very important due to the volatile nature of HCN. The loss of cyanide from specimens can be minimized by rapid analysis after death, collection of blood from a closed source, storage in a fluoride–oxalate tube with minimal dead space, and frozen at −20°C (Bright *et al.*, 1990).

## Concluding remarks

Because HCN is lighter than air, it has a long half-life in air. However, HCN is rapidly dispersed and diluted to non-toxic concentrations. Cyanide does not concentrate in soil or plant material, but can mix with water. Water converts HCN gas to HCN liquid. Treat contaminated water with ozone, hydrogen peroxide, or calcium or sodium hypochlorite bleach. The potential for secondary contamination of rescue personnel is high. Boots, gloves, googles, full protective clothes, and a self-contained positive pressure breathing apparatus are needed (AAR, 2000).

As a chemical warfare agent, cyanide is not easy to disseminate; however, it is widely available which increases the chances of its use in terrorist activities (Burklow *et al.*, 2003). Cyanide works much better as a terrorist weapon in an enclosed space.

# MILITARY NERVE AGENTS

## Background

Military nerve agents are probably the most poisonous of the known chemical warfare agents and are sufficiently toxic that even a brief exposure may be fatal. They were originally synthesized by the Germans during World War II in search of alternatives to the embargoes against insecticidal nicotine. Military nerve agents are rapidly acting, anticholinesterase organophosphate (OP) compounds. Military nerve agents are more potent than OP insecticides and military nerve agents contain a C—P bond that is unique and very resistant to hydrolysis, except in highly alkaline solutions. At ambient temperatures, nerve agents are viscous liquids, not gases.

Military nerve agents are generally divided into "G" and "V" agents. The "G" agents (tabun, sarin, soman) were developed during World War II and are called "G" agents because they were first synthesized in Germany. The "G" agents are very volatile and present a vapor hazard. The vapors are denser than air, thus they stay close to the ground (Garigan, 1996). Tabun (Agent GA, $C_5$—$H_{11}$—$N_2$—$O_2$—P) was first of the "G" agents to be synthesized in 1936, followed by sarin (GB, $C_4$—$H_{10}$—F—$O_2$—P) in 1938 and soman (GD, $C_7$—$H_{16}$—F—$O_2$—P) in 1944 (Sidell *et al.*, 1997).

Tabun is the easiest of the "G" agents to manufacture. It is a fruity-smelling (like bitter almonds) combustible colorless to brownish liquid. Contact with bleaching powder generates cyanogen chloride (EPA, 1985c). It may also undergo hydrolysis in the presence of acids or water, releasing hydrogen cyanide (Munro *et al.*, 1999; Budavari, 2000; HSDB, 2005). Sarin is a colorless liquid with almost no odor in its pure state (Budavari, 2000). Soman is a colorless liquid with a fruity or camphor odor (Budavari, 2000). Soman can release hydrogen fluoride when in contact with acids (EPA, 1985c).

The "V" agents ("V" for venomous) were developed in 1954 in the United Kingdom and are more stable than the "G" agents (Sidell *et al.*, 1997). "V" agents, such as VX, contain a sulfur group and are alkylphosphonothiolates, they are more toxic and persistent on surfaces than G-series agents. VX ($C_{11}$—$H_{26}$—N—$O_2$—P—S) is a nonvolatile, amber colored, odorless liquid (Sidell *et al.*, 1997).

## Pharmacokinetics/toxicokinetics

Nerve agents can be absorbed following ocular exposure, oral ingestion, inhalation, and dermal contact (HSDB, 2005; RTECS, 2006). These nerve agents are absorbed without producing any irritation or other sensation on the part of the exposed person or animal (HSDB, 2005). Inhalation of military nerve agents will have initial effects on the airways within seconds. Inhalation of a large amount of the vapor will result in sudden loss of consciousness, apnea, flaccid paralysis, and seizures within seconds to 2–3 min (Sidell *et al.*, 1997). Peak effects are seen within 20–30 min and death is usually due to respiratory failure (Berkenstadt *et al.*, 1991). Dermal exposures to nerve agents have a slower onset of action. Following exposure to a large drop or more will result in clinical effects within 30 min but with small drops, a delay of up to 18 h can be seen (Sidell *et al.*, 1997). With an ingestion, initial symptoms begin in 20–30 min and are usually GI. There is no taste to solutions containing nerve gas agents (Grob, 1956).

Distribution in the body is slightly different for each of the nerve agents. Distribution of sarin is to the brain, liver, kidney, and plasma of mice (Little *et al.*, 1986). Radiolabeled soman was evenly distributed throughout the mouse brain after IV administration, with higher levels in the hypothalamus (Wolthuis *et al.*, 1986). Tabun was also found in high concentrations in the hypothalamus after IV administration in mice (Hoskins *et al.*, 1986). An unusual feature of soman toxicity is its apparent storage in body "depots" and release over time. This results in eventual death in animals who survive the initial dose of soman (Wolthuis *et al.*, 1986).

The military nerve agents differ from other OPs in the rapidity of "aging" of the OP–enzyme complex. "Aging" is thought to be due to the loss of an alkyl group, whereby the inhibitor–enzyme complex becomes resistant to reactivation (Young *et al.*, 1999). The half-life ($T_{1/2}$) of aging: soman within minutes, sarin about 5 h, tabun and VX both greater than 40 h (Garigan, 1996).

The nerve agents are hydrolyzed by plasma and tissue enzymes to their corresponding phosphoric and phosphonic acids. Oxidative enzymes are also involved in metabolism (HSDB, 2005). Sarin is hydrolyzed in the body to isopropyl-methylphosphonic acid (IMPA). IMPA in mice

studies was generally present at 20-fold higher concentrations than sarin in most tissues, exceeding sarin by 4 times in the brain (Little *et al.*, 1986). In mice studies, the majority of administered radioactive sarin was detoxified and excreted by the kidneys (Little *et al.*, 1986). Mouse studies reveal that approximately 50% of injected soman is converted to free pinacolyl-methylphosphonic acid within 1 min, and the half-life of this metabolite is less than 1 h (Reynolds *et al.*, 1985). Soman is mainly eliminated via enzymatic hydrolysis, in competition with binding to target acetylcholinesterase (AChE) (HSDB, 2005).

**TABLE 6.5** $LD_{50}$ (mg/kg) for various nerve agents

| Species | Route | Sarin | Soman | Tabun | VX |
|---|---|---|---|---|---|
| Mouse | IP | | | | 0.050 |
| | Dermal | 1.08 | 7.8 | 1 | |
| | IM | | 0.089 | | |
| Rat | SQ | | | 0.162 | 0.012 |

| | Dermal | | | 18 | |
| | IM | | 0.062 | | |
| Human | Dermal | 28 | 5 | 14 | 0.14 |

RTECS (2006) and Sidell *et al.* (1997).

## Mechanism of action

OPs competitively inhibit AChE by binding irreversibility to its esteric site (phosphorylation). Inhibition of the AChE enzyme results in accumulation of acetylcholine and excessive stimulation at muscarinic, nicotinic, and CNS cholinergic sites. Increased acetylcholine at autonomic neuroeffector junctions results in increased smooth muscle contractions and secretions, but its effect at skeletal muscle junctions is partly stimulatory (fasciculations) and partly inhibitory (muscle weakness, paralysis) (Garigan, 1996). The effects on the sino-atrial node of the heart is inhibitory, causing bradycardia (Namba *et al.*, 1971). Acetylcholine accumulation in the CNS can cause ataxia, seizures, and coma. These high levels induce massive neuronal deaths in various brain areas, particularly in limbic and cortical structures. Death from nerve agents is due to paralysis of the diaphragm, airway obstruction from increased bronchial secretions, or depression of the CNS respiratory center (Garigan, 1996).

VX is also thought to possibly react directly with receptors of other neurotransmitters, such as norepinephrine, dopamine, and GABA. VX appears to have CNS effects that are unrelated to AChE activity and these agents may produce prolonged effects following convulsive doses (Young *et al.*, 1999).

## Toxicity

Symptoms of acute exposure to OPs may include muscarinic, nicotinic, and CNS signs. The muscarinic effects include sweating, hypersalivation, increased bronchial secretions, miosis, bradycardia, hypotension, vomiting, and diarrhea, bronchoconstriction, and urinary and fecal incontinence. The nicotinic effects include fasciculations and weakness of muscles (including the diaphragm), tachycardia, hypertension, and mydriasis. The CNS effects of nerve agents include restlessness, anxiety, headaches, seizures, and coma (Garigan, 1996). Effects after inhalation begin within seconds to minutes post exposure (Sidell *et al.*, 1997; HSDB, 2005). Death can occur within minutes from inhibition of AChE function.

The "G" nerve gases do not readily penetrate intact skin, but toxicity significantly increases if the skin becomes permeable. Dermal toxicity of VX is high, even through intact skin as the liquid does not evaporate quickly (Berkenstadt *et al.*, 1991; Sidell *et al.*, 1997). With dermal exposures, a very small drop on the skin may cause sweating and fasciculations at the site, starting within 18 h of exposure. A larger drop may cause loss of consciousness, seizures, apnea, and flaccid paralysis, with effects beginning within 30 min. Liquid tabun in the eye can result in death nearly as quickly as an inhalational dose (EPA, 1985c).

On a weight basis, toxicity in descending order is VX > soman > sarin > tabun. As used, sarin is the most potent of the "G" nerve agents and VX is about 3 times more potent a respiratory agent as sarin (HSDB, 2005). VX is 300 times more lethal than tabun on skin (Sidell *et al.*, 1997). See Table 6.5 for $LD_{50}$ of the various nerve agents.

Plasma cholinesterase values usually recover in a few days or weeks, due to the irreversible nature of OP inhibition. RBC AChE recovers more slowly (several days to 4 months) depending on the severity of the depression (Grob, 1956). Delayed neurotoxicity has not been reported in humans following nerve agent exposure. However, delayed peripheral neurotoxicity has been reported in animal studies. Soman, at a dose of 1.5 mg/kg, produced severe delayed neuropathy in the atropinized hen assay (Willems *et al.*, 1984). No prenatal mortality or fetal toxicity was noted in soman-poisoned rats or rabbits, even at doses producing significant maternal toxicity, but other nerve gases showed post-implantation mortality and fetotoxicity (HSDB, 2005; RTECS, 2006).

## Treatment

Remove animal from the toxic environment. Administer oxygen if needed. Intubation and ventilation may be necessary if signs progress. Flush eyes with copious amounts of tepid 0.9% saline or water for at least 15 min. Wash all exposed animals 3 times with soap and water. The use of a dilute bleach solution (1:10 with water), ethanol, or tincture of green soap may be more efficacious (Cancio, 1993).

Military personnel carry skin decontaminating kits and towelettes impregnated with an alkaline chloramine and phenol mixture which can break down nerve agents (M291 Skin Decontaminating Kit, Rohm and Haas). The kit has been tested for safety and efficacy against mustard vesicant agents and OP nerve agents. A topical skin protectant (IB1) has also been tested as a pretreatment for exposure to sulfur mustard and VX (Kadar *et al*., 2003).

Emesis is not recommended in oral ingestion due to the rapid development of signs. Activated charcoal might provide benefits even after a topical exposure. Control seizures with diazepam, methocarbamol, or barbiturates as needed before proceeding with other treatments.

Atropine sulfate is reversal agent. It is used for the treatment of muscarinic effects of nerve agent poisoning, and will not reverse nicotinic effects (muscular weakness, diaphragmatic weakness, etc.). Atropine does not affect the AChE–insecticide bond, but blocks the effects of accumulated acetylcholine at the synapse. Atropinization should be continued until the nerve agent is metabolized (Midtling *et al*., 1985). Effects of overdosing with atropine include hyperthermia, tachycardia, inspiratory stridor, irritability, and dilated and unresponsive pupils (Meerstadt, 1982).

Pralidoxime chloride (2-PAM) can be used to treat the nicotinic signs. Pralidoxime is probably most effective when administered in the first 1–3 h. Pralidoxime is not as effective in the treatment of soman poisoning, due to the quick "aging" (within minutes) of the compound (Sidell *et al*., 1997). Since VX-inhibited cholinesterase ages slowly, administration of 2-PAM chloride is effective in reactivating the enzyme for up to 48 h after exposure (Sidell and Groff, 1974).

In Belgium, Israel, The Netherlands, Scandinavia, Portugal, and West Germany, obidoxime dichloride (Toxogonin, LUH6) is the favored oxime. It may be a less toxic and more efficacious alternative to pralidoxime in poisonings from OPs containing a dimethoxy or diethoxy moiety (De Kort *et al*., 1988). HI-6 is an alternative oxime that has excellent AChE regenerating action with VX and very good action with sarin (GB). It has a good response to soman, but provides poor to no response following tabun exposures (Hoffman, 1999). HI-6 is given in conjuction with atropine and diazepam (Kusic *et al*., 1991).

With human exposures to nerve agents, autoinjectors (AtroPen®, Mark I®, Combopen MC®) are available for use. Most available autoinjectors combine atropine and pralidoxime. Autoinjectors are not used in veterinary medicine as they are not adaptable for different sized patients.

The "G" agents have been detected in urine and water using capillary GC and GC-MS (Okudera *et al*., 1997; Kientz, 1998). Immunoassay has been used to detect VX in biological samples (Ci *et al*., 1995). Nerve agent detection is not as clinically relevant as the measuring of AChE. AChE activity can be used as a diagnostic indicator or a screening test. The test can be run on plasma, serum, or whole blood. AChE activity that is less than 50% of normal is generally associated with severe symptoms (Midtling *et al*., 1985). Blood AChE does not always correlate well with clinical signs and poisoning has been diagnosed in patients with "normal" values.

## Concluding remarks

The "G" agents evaporate and disperse over several hours, they are non-persistent in the environment (Garigan, 1996). In contrast, VX is an oily liquid that can remain in the environment for weeks or longer after being dispersed (Garigan, 1996; Sidell *et al*., 1997; Munro *et al*., 1999; Budavari, 2000). Environmental persistence is estimated to be 0.5–1 day for tabun, 1–2 days for soman, 5 days for sarin, and several weeks for VX. Environmental cleanup of OP spills depend on changing the pH to promote hydrolysis to inactive phosphate diester compounds (EPA, 1978). Contaminated soil can be treated with either alkaline substances (sodium carbonate, sodium bicarbonate, calcium hydroxide, and calcium carbonate) or chlorine-active compounds (sodium hypochlorite or calcium hypochlorite) (EPA, 1975).

Veterinarians and staff can be dermally exposed to contaminated animals. Rubber gowns, aprons, and gloves along with respiratory protection must be worn. Once the animals are bathed, the risk of secondary contamination is low. Leather absorbs OPs and is extremely difficult to decontaminate. Leather collars, muzzles, and other items should be disposed of by incineration.

The production of nerve agents is beyond the capabilities of most terrorist groups. Production requires a significant background in chemistry and outlay of capital. The production of sarin by the Aum Shinrikyo cult was estimated to take 1 year to make, involved 80 persons led by a PhD level scientist, and cost about $30 million (Leitenberg, 1999).

# Regulatory considerations in veterinary toxicology

*Lynn O. Post*

## INTRODUCTION

This chapter is organized into six sections: Section I: Food and Drug Administration and the Center for Veterinary Medicine; Section II: Environmental Protection Agency; Section III: US Department of Agriculture; Section IV: Drug Enforcement Administration; Section V: Occupational Safety and Health Administration; and Section VI: Statues, Regulations, and Guidelines. Sections I through V describe the federal agencies that are important to animal health, including processes, organizational structure and mission, and selected programs. Testing methods and pharmacovigilance for the Center for Veterinary Medicine, the Environmental Protection Agency, and the US Department of Agriculture are described in Sections I through III. Pharmacovigilance is the emerging area of monitoring for unintended harmful effects of marketed animal health products.

This chapter is an overview to a complex and dynamic area that is under the constant influence of competing interests (consumer groups, industrial groups, and professional organizations), new legislation, and legal precedents, as well as a new generation of animal health products and issues. Appropriate Internet addresses are included in the list of references for the reader to consult more complete and/or updated information from Internet home pages of the respective federal agencies and other reliable organizations.

## SECTION I. FOOD AND DRUG ADMINISTRATION AND THE CENTER FOR VETERINARY MEDICINE

### Creation and organization of the FDA and CVM

Animal drugs and medical devices are regulated by the Food and Drug Administration's (FDA) Center for Veterinary Medicine (CVM) under the Federal Food, Drug, and Cosmetic Act (FFDCA). The FFDCA and FDA are widely recognized as the preeminent regulatory legislation and agency in the nation. The first Federal Food and Drug Act was passed in 1906. It prohibited interstate shipment of adulterated or misbranded food, drink, and drugs, and was administered by the US Department of Agriculture's (USDA) Bureau of Chemistry. In 1938 landmark broader legislation was passed requiring manufacturers to provide evidence of product safety before distributing new drugs. This legislation also provided authority to conduct manufacturing site inspections, establish tolerances for unavoidable contaminants and use court injunctions as enforcement tools. In 1940, FDA was transferred from USDA, ultimately becoming part of the Department of Health, Education and Welfare (DHEW), which became the Department of Health and Human Services (DHHS). During the early 1950s, a veterinary branch was established within the FDA's Bureau of Drugs. Subsequently, two major amendments to the

*Veterinary Toxicology, Edited by Ramesh C. Gupta*

FFDCA were passed. The Food Additive Amendments of 1958 expanded FDA's authority over animal food additives and drug residues in animal-derived foods. The Kefauver–Harris Drug Amendments of 1962 brought major changes to the FFDCA, requiring manufacturers to test new drugs for effectiveness before marketing them, and to report adverse drug events promptly to FDA. These requirements were also applied through a modified process to products already on the market. Recognizing the importance of animal health products the FDA established the Bureau of Veterinary Medicine (all Bureaus became Centers in 1984) in 1965. However, animal drugs were still regulated under three different sections of the FFDCA, either as new drugs, antibiotics, or if labeled for food-animals, as food additives. Because this situation produced a regulatory scheme for animal drugs that was confusing and more complex than for human drugs, the Animal Drugs Amendments of 1968 were passed consolidating the various sections of the FFDCA that applied to animal drugs in one section (512) of the FFDCA. More complete discussions of the history of the FFDCA and CVM are available (Teske, 1995; FDA Center for Veterinary Medicine, 1999). More recent animal health product-related amendments to the FFDCA are given in Table 7.1 (FDA Center for Veterinary Medicine, 2000).

**TABLE 7.1 Recent major animal health product-related amendments to the FFDCA**

| Amendment | Summary of changes |
|---|---|
| Generic Animal Drug and Patent Term Restoration Act (GADPTRA) | Enacted 1988.<br>Provides for approval of generic copies of animal drug products that have been previously approved and shown to be safe and effective.<br>Provided for prescription status for animal drugs. |
| Animal Drug Use Clarification Act of 1994 (AMDUCA) | Allows veterinarians to prescribe extra-label uses of approved animal drugs and approved human drugs for animals under certain conditions.<br>Allows FDA to restrict extra-label use in certain circumstances.<br>Allows FDA to establish a safe level for a residue for such extra-label use by regulation or order and require the development of analytical methods for residue detection. |
| Animal Drug Availability Act of 1996 (ADAA) | Amended the definition of substantial evidence of effectiveness.<br>Created a new category of drugs – "Veterinary Feed Directive Drugs".<br>Permitted a range of doses to appear on animal drug product labeling, rather than one optimum dose.<br>Provided for Licensing of Feed Mills and eliminated the requirement for Medicated Feed Applications. |

FDA is an agency within the DHHS. The senior official within FDA is the FDA Commissioner. The agency is organized by product responsibility into Centers: Center for Veterinary Medicine (CVM); Center for Drugs Evaluation and Research (CDER); Center for Biologics Evaluation and Research (CBER); Center for Devices and Radiological Health (CDRH); and the Center for Food Safety and Nutrition (CFSAN). The FDA is also organized geographically into Regional Offices and component Districts where field staff are assigned.

## Approving and monitoring animal drugs

Under the FFDCA, the CVM is responsible for ensuring that animal drugs and medicated feeds are safe and effective for their intended uses and that food from treated animals is safe for human consumption. To accomplish its mission, the CVM is organized into pre-market review, post-market monitoring, and research components. In addition, FDA field staff conduct inspections of FDA-regulated animal health industries and products. Prior to a product being marketed it must have an approved New Animal Drug Application (NADA). In order for an NADA to be approved there must be substantial evidence that the new animal drug is effective and safe for its intended uses under the conditions of use prescribed, recommended, or suggested in the proposed labeling. In addition, methods, facilities, and controls used for the manufacturing, processing, and packaging of the drug must be shown to be adequate to preserve its identity, strength, quality, and purity (Good Manufacturing Practices, 21 CFR 210 and 211). For food-animal products safety includes safety of drug residues in animal-derived food. Tolerances for residues of new animal drugs in food may be found in 21 CFR 556. Safety would also include an assessment of the effects of the proposed animal drug on the environment and on human health. Following approval products are monitored to ensure safety and effectiveness and maintained under actual conditions of use.

## Testing methods for animal drugs

FDA has developed extensive detailed guidelines for the conduct of studies required to obtain approval to market products. This section provides a brief description of the animal safety and efficacy studies and human safety studies that may be performed. They are provided to familiarize the student with the general scope of information required for product approval, not to provide guidance in designing studies for product approval. The specific pertinent agency guideline should be consulted prior to designing a study protocol.

### CVM *target animal safety and product efficacy testing requirements*

*Introduction*

A veterinary drug sponsor must show that a drug is safe to use as described in the proposed labeling (21 CFR 514.1(b)(1) and 512(d) of the FFDCA; FDA Center for Veterinary Medicine, 1989). The information needed to determine a products safety in the target species depends on several factors: proposed use, type of product, chemistry, intended species, breed, and class of animal (calves versus mature ruminants), claims and previous use history. Existing data collected from previous studies are used to develop and refine protocols for toxicity studies. While the CVM target animal safety guideline is intended to provide general directions for acquiring essential information, all the data requirements for a standard target animal safety study are not required for every product, and special circumstances may require the collection of additional data that is not specified for the standard study.

*Good laboratory practices and general study requirements*

Laboratory studies in animals are conducted according to Good Laboratory Practice (GLP) regulations (21 CFR Section 58). Target animal safety studies are also subject to GLP regulations. The GLP regulations ensure that methods and procedures for collecting, processing, and reporting data are standardized and verified for the entire study. GLPs ensure an adequate level of accuracy and quality control. Many GLP requirements are inherent in any well-designed scientific study. On the other hand, adherence to GLP standards does not guarantee the scientific validity of the study.

Since animal husbandry requirements often differ for laboratory animals and domestic animals, domestic animals utilized in clinical studies are not maintained under GLP conditions. Appropriate diagnostic tests, vaccinations, prophylactic, and therapeutic treatments are completed prior to the treatment phase of the study. During this initial phase a complete physical examination is performed and baseline data are collected by a qualified person. The test product formulation must be identical to the proposed marketed product. The route of administration should be the same as the proposed labeling, however, the toxicity or nature of the product may require a different formulation. For example, due to feed refusal, a drench of a product may be required instead of delivery of the drug through a medicated feed.

Data are collected at predetermined intervals during the trial. Clinical observations are recorded at specified intervals, usually twice a day, 7 days a week during the entire study or modified according to the study protocol. During the study appropriate clinical pathology procedures are conducted in all test groups, usually only half of the animals selected at random from each group at predetermined intervals. Histopathologic examinations may be required from all or a portion of the animals. Tissues from the highest treatment and control groups must be examined. If microscopic lesions are observed, corresponding tissues from the next lower treatment group are examined until a no observable effect level (NOEL) is established.

*Drug tolerance test*

Under controlled conditions, the target animal response to a toxic dose is characterized by clinical signs. Clinical signs include changes in behavior and appearance and gross lesions in animals that die during the study. Clinical pathology and histology data reveal physiological functions that are most readily affected by the drug. The duration of the toxicity studies may range form acute to chronic.

Target animal safety studies require systemic testing for new products or new chemical entities and additional animal species. They are not required for drugs administered locally, such as otic, ophthalmic, intra-mammary, and intra-articular preparations. This does not apply to generalized dermal or topical drugs that may act systemically. The market formulation of a drug must be administered according to the proposed conditions of use. If volume or palatability becomes a limiting factor for administration, gavage, intravenous, multiple sites, or incremental doses may be used. A vehicle control group must be included in the experimental design.

Usually, up to ten times (10×) the maximum proposed clinical dose is administered. The toxic dose (10×) may be reduced or increased in order to manifest toxic signs without causing death. The main purpose of the tolerance test is to characterize toxic signs which can be used to develop toxicity study protocols at lower doses (1×, 3×, and 5×). The toxicity studies are used to design the clinical efficacy study protocol.

*Toxicity study*

The objective of toxicity studies in target animal species are (1) to demonstrate safety of the drug product under condition of use, (2) to demonstrate signs and effects associated with toxicity, and (3) to demonstrate a margin of safety at 5× or below (FDA Center for Veterinary Medicine, 1989). If the drug has a narrow margin of safety with an intended use in debilitated animals, safety studies in diseased animals may be necessary. This may require more animals per treatment group because of greater variability. Special studies may be requested by FDA, such as lameness, reproductive, dermal irritation, specific routes of administration, tissue disposition, and combination drugs.

### *FDA-required toxicological testing in food-producing animals*

*General considerations*

Studies must be conducted according to GLPs. For compounds used in food-producing animals, FDA is concerned with intermittent and chronic exposure of people to relatively low concentrations of residues. FDA tailors the type of toxicological testing needed to show safety for a specific compound. Factors, which are considered, include the proposed use, the potential human exposure of the parent compound and/or its residues, as deduced by structure–activity relationships. Some compounds need only a minimum of testing; others may need very extensive studies in a number of diverse biological systems.

The purpose of the toxicology studies is to define the biological effect(s) of the sponsored compound and its quantitative limits. FDA generally asks that the sponsor (owner of the NADA), at a minimum, to determine a dose of the compound that produces an adverse biological effect in test animals and a dose that does not produce any significant toxicological or pharmacological effect (NOEL). The spacing of the doses should provide an assessment of the dose–response relationship (FDA Center for Veterinary Medicine, 2005).

*Testing requirements*

FDA recommends the following studies as the minimum necessary for each sponsored compound:

- A battery of genetic toxicity tests.
- A 90-day feeding study in both a rodent species (usually the rat) and a non-rodent mammalian species (usually the dog).
- A two-generation reproduction study with a teratology component in rats. Two litters should be produced in each generation. If toxicity occurs at a lower dose, with a higher incidence, or with greater intensity in the second generation as compared to the first, then the study should include a third generation.

FDA may require the following additional studies, which should be conducted using an approved protocol:

- Chronic bioassays for oncogenicity in each of two rodent species when indicated by positive results in genetic toxicity tests.
- One-year feeding studies in a rodent species (usually the rat) and in a non-rodent species (usually the dog) are needed, when human residue exposure exceeds 25-μg/kg body weight/day. This daily intake is equivalent to 1 part per million in total solid diet of 1500 g, normally consumed by a 60-kg human subject. The FDA will calculate permissible exposure, when evidence indicates that the residue bioaccumulates in the tissues of target animals.
- A teratology study in a second species when the compound is structurally related to a known teratogen, when the compound has hormonal activity that may affect the fetus, or when the compound shows adverse effects in the reproduction/teratology study indicating that the compound may be a teratogen.
- Other specialized testing if necessary to define the biological effect of the compound. Examples of specialized studies include testing for neurotoxicity, for immunotoxicity, for hormonal activity, for toxicity following *in utero* exposure, or for toxicity from a "biomass" product.

If the testing shows that the sponsored compound is a carcinogen, FDA will apply the "no-residue" requirement of Section 409(c)(3)(A), 512(d)(1)(H), or 706(b)(5)(B) of the Act as operationally defined in 21 CFR subpart E of Part 500. FDA will calculate the concentration of residue giving no significant risk of cancer from the tumor data using a statistical extrapolation procedure. In the absence of information establishing the mechanism of carcinogenesis for a particular chemical, FDA will use a non-threshold, linear-at-low-dose extrapolation procedure that determines the upper limit of the risk (Gaylor and Kodell, 1980; Farmer *et al.*, 1982). In the extrapolation FDA will use the upper 95% confidence limit on the tumor data and a permitted maximum lifetime risk to the test animal of 1 in 1 million.

*Acceptable daily intake and safety factors*

For other toxicological endpoints, FDA will calculate the acceptable daily intake (ADI) from the results of the most sensitive study in the most sensitive species. From that study the ADI is the highest dose showing NOEL divided by the appropriate safety factor (Table 7.2).

*Sex steroids*

Although not all sex steroids are demonstrated carcinogens, the evidence supports FDA's conclusion that all endogenous sex steroids and synthetic compounds with similar biological activity should be regarded as suspect

**TABLE 7.2 CVM: human food safety studies and safety factors**

| Type of study | Safety factor |
|---|---|
| Chronic | 100 |
| Reproduction/teratology<br>(100 for a clear indication of maternal toxicity, 1000 for other effects) | 100 or 1000 |
| 90 days | 1000 |

carcinogens, and that the endogenous sex steroids are not genotoxic agents. If these compounds produce an oncogenic response in experimental animals, the mechanism of action is not related to a direct chemical interaction with DNA. Specifically, tumor development is a consequence of hyper-proliferation of endocrine-sensitive tissue resulting from persistent over-stimulation of the hormonal system.

The safety of endogenous sex steroids and their simple ester derivatives can be assured without additional animal study data. Large quantities of these compounds are produced by *de novo* synthesis in people and food-producing animals. The FDA has concluded that no physiological effect will occur in individuals ingesting animal tissues that contain endogenous steroids equal to 1% or less of that produced daily in the population with the lowest production. In the case of estradiol and progesterone, prepubertal boys synthesize the least; in the case of testosterone, prepubertal girls synthesize the least. The daily production values and the calculated increase permitted above the amount naturally present in untreated target animals are listed in Table 7.3. The product is considered safe within the meaning of the Act, if data acceptable to the FDA demonstrate that under the proposed conditions of use, the residue concentration of the endogenous sex steroid in treated food-producing animals does not exceed the permitted increase at the time of slaughter.

*Synthetic sex steroids*

In addition to the standard requirements, FDA recommends the following additional tests:

- A 180-day study in rhesus monkeys or another suitable subhuman primate is required to assess the effect of the sponsored compound on various parameters including ovulation, menstrual cycle, and circulating levels of gonadotropins, and sex steroids. The study should establish a dose that gives a no observed hormonal response.
- FDA will also normally use a safety factor of 100 for the study in subhuman primates. If a carcinogenic response is observed in a non-endocrine-sensitive tissue, FDA will determine the dose that will satisfy the "no-residue" requirement of the act using the tumor data from that tissue and a statistical extrapolation procedure.

**TABLE 7.3 CVM: human food safety and endogenous sex steroids**

| Sex steroids | Daily production (μg) | Permitted increased exposure (μg) |
|---|---|---|
| Estradiol | 6 | 0.06 |
| Progesterone | 150 | 1.50 |
| Testosterone | 32 | 0.32 |

## Animal efficacy studies

Efficacy studies are clinical studies. The purpose of an efficacy study is to evaluate the response of the test article under actual conditions of use. Clinical studies to establish efficacy are also important to the overall safety assessment of the product. GLP regulations do not apply because clinical studies are conducted in a clinical environment under actual conditions of use, rather than in a rigorously controlled laboratory setting. For example, veterinary practitioners may enroll their client's dogs in a non-steroidal anti-inflammatory study and food-animal producers may participate in a production drug study. In efficacy studies, special care must be exercised in handling animals to avoid undue stress which may alter the response to the drug, greatly affecting the study results. If there is a need to collect samples for laboratory analysis that is unrelated to the collection of efficacy data, all animals are sampled at specified times in order to minimize bias.

The design of the efficacy trial is flexible and depends on the species, breed, drug, class of production animal, and data endpoints. In some instances, such as for production drugs, many animals are required per treatment group for the efficacy trial because of variability due to environmental conditions and in the test animals. For typical therapeutic products, the number of subjects required for an animal drug clinical trial is about 5–10% of the number required for an equivalent human drug clinical trial. Additionally, while toxicity is not the objective of these studies, animals are observed periodically (usually daily) for clinical signs and abnormalities. These observations give valuable information for designing additional safety study protocols or reveal information that would appear in the safety information on the product label. Some animals may be necropsied at the end of the study if animals exhibit signs of toxicity. On the other hand, the drug may also be discontinued in an animal exhibiting toxic signs.

Even though the efficacy studies are non-GLP, the test methods and procedures for administering the test article are verified and monitored throughout the study. This ensures that the drug is being delivered to the animals according to the protocol. For example, an oral drug may administer with or without food, or the mixing procedure for dispersing a production drug in feed must be periodically validated.

After all requirements have been met, FDA approval of the product allows it to be legally marketed and promoted as a new animal drug. The label must contain the product claim(s), pharmacology, side effects, precautions, and warnings. After approval, the drug is monitored through periodic and special industry drug experience reports (DERs) to CVM. These reports include adverse experiences and may result in label changes related to product safety.

### *Regulatory requirements for reporting animal adverse drug events*

#### *Introduction*

CVM does not evaluate complaints for pesticides and animal vaccines. These complaints should be sent to the Environmental Protection Agency (EPA) or the USDA. The CVM will accept safety information for animal feeds, animal devices, human drugs used in animals, and approved animal drugs. Mandatory reporting of safety complaints by the company are only required for approved animal drugs to include medicated feeds. Animal medicated feeds may be mixed incorrectly or given to the wrong species, such as monensin intended for cattle is fed to horses. Alternately, animals feeds may be contaminated with natural or man-made toxins, such as aflatoxin and polychlorinated biphenyls (PCBs), with the potential for serious consequences in humans and the target species.

Although, there are no regulatory requirements for the firm to report post-approval safety information for animal devices, CVM will take regulatory action when necessary. Pre-market approval is not required: the FDA does not require formal pre-market approval for devices used in veterinary medicine (510(k) of the FFDCA). Firms that manufacture radiation emitting devices need to register their products under the radiological health regulations, administered by the Center for Devices Radiological Health. FDA does have regulatory oversight over veterinary devices and can take appropriate regulatory action if a veterinary device is misbranded, mislabeled, or adulterated. It is the responsibility of the manufacturer and/or distributor of these articles to assure that these animal devices are safe, effective, and properly labeled.

The Center for Drug Evaluation and Research does not require the pharmaceutical company to report safety complaints from extra-label use of human drugs in animals. CVM will process and evaluate the complaints concerning the extra-label use of human drugs in animals, such as methimazole use for hyperthyroid cats.

#### *Pharmacovigilance*

Pharmacovigilance consists of the means and methods for monitoring and ensuring the safety and efficacy of marketed medicinal products. (*Note*: For the purpose of this section, the term "pharmaco-" is used to encompass not only drugs, but all types of medicinal products.) Pharmacovigilance is made necessary by the limitations of pre-approval or pre-registration studies for animal medicinal products. Economic and practical considerations limit the number of animals included in safety and efficacy studies. Further, many of the animals utilized during the testing phase consist of experimental animals that are homogenous in age, breed, and genetics. More variation is obtained when the drug is tested in clinical studies, but these types of studies generally have few animals. Thus, while premarketing studies may be adequate in demonstrating efficacy and common adverse drug reactions, they generally have limited power to detect less frequently occurring adverse events that may occur when the product is finally utilized under actual conditions of use in the general veterinary community.

Veterinary pharmacovigilance within the federal government is typically based on the receipt of spontaneous reports involving complaints of product performance. Spontaneous refers to reports that are voluntarily submitted by veterinarians, animal producers, and animal owners. The reports may be submitted by mail, phone, fax, or e-mail. The reports may be originally submitted to either the drug company involved or directly to CVM. Product complaints might involve a suspected animal injury, failure of the product to perform (or ineffectiveness), or a product defect.

The key to understanding the spontaneous AER (adverse event report) reporting process is in recognizing and appreciating the word "suspected". Any complaint must start with the establishment of an actual AER. The pharmacoepidemiologist understands that any one spontaneously reported AER might be misrepresented, or perhaps not existed at all. A certain level of bias is automatically introduced when the reporter associates the AER with the administration of a specific drug. Lacking evidence that unquestionably documents and supports the AER occurrence, information criteria must be established for accepting an AER into a pharmacovigilance system. This information should include an identifiable reporter, an identifiable animal, an identifiable product, and an adequately described adverse event.

In the case of the existence of an actual AER, a reporter lodges a complaint in the form of an AER. The AER is the mechanism through which all relevant aspects of the AE are described. The main goal of the pharmacovigilance program receiving an AER should be to ensure that all needed data elements are accurately and fully described. In many cases, follow-up information may be needed to augment the original AER. Even if the most accurate information is obtained for an AER, the possibility of one or more alternative non-drug-related explanations for the AE occurrence cannot be discounted.

This type of system establishes some level of assurance that the drug under question was "associated" with the reported AER. Strength of association is often determined by utilizing objective-based guidelines termed algorithms. The main strength of the spontaneous reporting system is in detecting the occurrence of drug-related adverse effects that are uncommon and cannot be detected by premarketing studies, which generally have low statistical power. Once a trend or suspected adverse reaction is detected, other methods may be used to investigate the suspected AER and determine the most appropriate course

of action. For instance, the drug company may be requested to provide more information or to conduct studies investigating the specific issue, or expert opinions may be sought from relevant veterinary specialists. Recommended actions might include labeling changes, the recall of specific batches of product, or even the removal of the product from the market.

#### *FDA/CVM adverse drug event reporting system for approved animal drugs*

The regulations that specifically address the spontaneous reporting obligations of the drug sponsors of FDA-approved animal drugs are contained in "Records and reports concerning experience with new animal drugs for which an approved application is in effect" (21 CFR 514.80). Reporting of AERs is mandatory for the pharmaceutical industry. It is voluntary for veterinarians and consumers.

For industry reporting, the regulations categorize AERs into three categories: significant product defect reports that should be submitted to an FDA District Office within 3 days (21 CFR 514.80(b)(1)); AERs involving unexpected animal injury and unexpected product ineffectiveness that should be submitted within 15 working days to CVM (21 CFR 514.80(b)(2)); and the remaining types of AERs and product defects which should be submitted at periodic intervals to CVM (21 CFR 514.80(a)(4)). All categories of complaints are required to be submitted by the drug sponsor on the OMB-approved Form FDA 1932 ("Veterinary Adverse Drug Reaction, Lack of Effectiveness, and Product Defect Report").

Significant product defects are those involving either label mix-ups or a significant departure of the product form approved specifications, where the product defect may result in immediate harm to animals. Corrective action is accomplished through the FDA Field Office responsible for the manufacturing site.

AERs requiring 15-day submissions are serious and unexpected (21 CFR 514.3 and 514.80):

- fatal or life threatening;
- require professional intervention;
- causes an abortion, or stillbirth, or infertility, or permanent disability disfigurement;
- unexpected AERs are not on the current label or may be pathophysiologically related to an AER on the label.

Unexpected refers to either information that is not contained either on product labeling or as part of the approved FDA application. Regulations further require reporting of unexpected adverse events that are associated with either clinical use, studies, investigations, or tests, whether or not determined to be attributable to the suspected drug. A key phrase is whether or not determined to be attributable to the suspected drug. CVM expects the drug sponsor to submit all AERs rather than only those reports the firm believes are associated with the AER. CVM considers selective report submission (filtering) to introduce a bias that confounds the evaluation of submitted AERs.

All AERS submitted to CVM are evaluated by a staff of veterinarians assigned to this task. All relevant information is extracted from the AERs and entered into the appropriate fields of a relational database, using standard terminology. A six-step algorithm, evaluation process is utilized to assign a score that represents the strength of the veterinarian's opinion that the use of the drug was associated with the adverse clinical sign.

The database is utilized by product manager, veterinarians assigned to monitor the safety and efficacy of specific products. In the event that a potential problem is identified, the Monitored Adverse Reaction Committee (MARC) is convened to assist in evaluating information related to the potential problem. The MARC also recommends appropriate regulatory action, in the event the problem is considered significant. AER information is released to the public by means of summary report publication on the CVM website. Additional requests for AER information can be made through the Freedom-of-Information officer.

AER submission is required only from companies marketing FDA-approved animal drugs. There are no requirements for submitting AERs for human drugs used in animals or unapproved products labeled for animals. CVM will accept reports directly from consumers and veterinarians regarding extra-label use of human drugs and unapproved animal drug products. CVM has limited ability to monitor the performance of these drugs in animals.

Veterinarians are encouraged to report AERs directly to the manufacturer/sponsor. The manufacturer should record the information and send a report of their investigation to CVM. Another reporting option is to call the CVM AER hotline (1-888-FDA-VETS) to report AERs. An FDA veterinarian will return the phone call. The reporter can also either call or write the CVM to obtain a pre-postage-paid reporting form.

AER reporting to CVM has significantly increased over the last decade. During the early 1990s, the CVM received approximately 1000 AERs each year. CVM received about 33,000 AER reports for the year 2005. Reasons for the increase are numerous, but include the new types of drugs approved for use in companion animals, label information provided for contacting drug companies, and the interest of the public in reporting perceived product problems.

#### ***The future of global pharmacovigilance reporting***

The USDA and FDA are participants in the construction of a global AER platform. The reporting format for AERs will be standardized but not the causality assessment, evaluation of risk for each AER, and the pharmacoepidemiologic approach that may include a mathematical analyses.

Standardized evaluation of AERs is impractical because conditions of use for a drug vary from country to country. Spontaneous reporting does not readily lend itself to classical epidemiologic analyses because the numerator (number of animals) is under-reported and the denominator (number of doses) is unknown. Therefore, it is extremely difficult to calculate a true incidence.

Global harmonization of reporting requirements for AERs is no small task. It must be kept in mind that, unlike human AERs, veterinary medicine deals with multiple species which adds more complexity to a complicated process. In addition, reporting requirements differ substantially from country to country because missions, goals, resources, administrative procedures, and AER sources vary considerably. The variations reflect the fundamental differences in the worldwide agencies and the laws they administer. The International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products (VICH, 2005) is a trilateral (EU–Japan–USA with two observer countries: Australia and Canada) program aimed at harmonizing technical requirements for animal medicinal product registration to include pre-approval review and post-approval monitoring (International Cooperation on Harmonization of Technical Requirements for Registration of Veterinary Medicinal Products). In 1996, at the inception of VICH, one goal was the harmonization of pharmacovigilance reporting requirements: definitions, data elements, electronic submission protocols, and medical dictionaries.

Successful efforts of VICH will lead to the timely transmission of AER information between all parties and organizations involved in animal pharmacovigilance. Electronic reporting standards would also available to consumers and veterinarians who could report directly to the regulatory agency rather than the company. The standardized AER information will be disseminated worldwide for examination and analysis by all interested parties.

# SECTION II. ENVIRONMENTAL PROTECTION AGENCY

## Creation of the EPA

During the 1960s activists became increasingly effective in focusing attention on environmental and public health issues. Rachael Carson's book, Silent Spring (1962), provided a worldwide view of the effects of indiscriminate use of pesticides. By 1969, the word "ecology" had become part of American culture. Under criticism that his environmental committees were largely ceremonial bodies, President Nixon appointed a White House Committee in December of 1969 to consider whether there should be a separate environmental agency. About the same time, Congress sent the National Environmental Policy Act (NEPA) to the president and he signed NEPA on January 1, 1970.

It was against the background of environmental activism that Reorganization Plan No. 3 was sent to Congress by the Nixon Administration. Under Reorganization Plan No. 3, the EPA was formed in 1970 to establish and enforce environmental protection standards; to conduct environmental research; to provide assistance to other agencies in combating environmental pollution; and to assist in developing and recommending new policies for environmental protection. The regulatory activities for environmental protection were consolidated from 15 components of five executive departments and independent agencies into a single agency, the EPA. Certain pesticide regulatory functions were transferred from FDA and USDA to EPA. The enactment of major new environmental laws and important amendments since 1970 have expanded and refined the role of the EPA (Table 7.4).

The EPA is organized into major Offices headed by assistant EPA administrators which develop and implement EPA's policies and programs. For instance the Office of Prevention, Pesticides and Toxic Substances (OPPTS) develops national strategies for toxic substance control and promotes pollution prevention and the public's right to know about chemical risks. A component Office, the Office of Pesticide Programs (OPP), regulates the use of all pesticides in the United States and establishes maximum levels for pesticide residues in food. The EPA also has geographically organized regions. Each EPA Regional Office is responsible, within selected states, for the execution of the Agency's programs, considering regional needs and the implementation of federal environmental laws (USEPA, 2000b).

## Pesticides and the Federal Insecticide, Fungicide, and Rodenticide Act

The Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) has a major impact on the practice of veterinary medicine because it provides EPA the authority to regulate pesticide use in animals. Under FIFRA the term pesticide includes products, such as insecticides, fungicides, rodenticides, insect repellants, weed killers, antimicrobials, and swimming pool chemicals. Pesticides are intended to prevent, destroy, repel, or reduce pests of any sort. If a pesticide can be used with "reasonable certainty of no harm", it is granted a "registration" that permits its sale and use according to requirements set by EPA to protect human health and the environment. During its evaluation of a proposed pesticide the EPA considers the toxicity of the pesticide, the quantity and frequency of pesticide application, and the amount of pesticide that remains on the food by the time it is marketed.

**TABLE 7.4 Major statutes that form the basis for the programs of the EPA**

| Statute or law | Description |
|---|---|
| Federal Food, Drug, and Cosmetic Act, Delaney Clause (1958) | FFDCA prohibited any man-made chemical in food that caused cancer in any animal, including man. |
| National Environmental Policy Act (1969) | NEPA is the basic national charter for protection of the environment. |
| Clean Air Act (1970) | CAA is the comprehensive federal law that sets standards regulates air emissions from area, stationary, and mobile sources. |
| Occupational Safety and Health Act (1970) | OSHA ensures worker and workplace safety from hazards, such as exposure to toxic chemicals, excessive noise levels, mechanical dangers, heat or cold stress, or unsanitary conditions. |
| Federal Insecticide, Fungicide, and Rodenticide Act (1972) | FIFRA provided federal control of pesticide distribution, sale, and use and required users (farmers, utility companies, and others) to register when purchasing pesticides. |
| Endangered Species Act (1973) | ESA provides a program for the conservation of threatened and endangered plants and animals and the habitats in which they are found. |
| Safe Drinking Water Act (1974) | SDWA was established to protect the quality of drinking water in the United States. |
| Resource Conservation and Recovery Act (1976) | RCRA gave EPA the authority to control hazardous waste during the generation, transportation, treatment, storage, and disposal of hazardous waste. |
| Toxic Substances Control Act (1976) | TSCA gave EPA the ability to track about 75,000 industrial chemicals produced or imported into the United States. |
| Clean Water Act (1977) | CWA gave EPA the authority to set effluent standards on an industry basis (technology based) and continued the requirements to set water quality standards for all contaminants in surface waters. |
| Comprehensive Environmental Response Compensation and Liability Act (1980) | CERCLA created a tax on the chemical and petroleum industries and provided broad federal authority to cleanup abandoned hazardous waste sites (Superfund). |
| Emergency Planning and Community Right-to-Know Act (1986) | EPCRA was enacted by Congress as the national legislation on community safety. |
| Superfund Amendments and Reauthorization Act (1986) | SARA amended CERCLA and reflected EPA's experience in administering the complex Superfund program. |
| Pollution Prevention Act (1990) | PPA encouraged industry to control toxic emissions by using cost-effective changes in production. |
| Oil Pollution Act (1990) | OPA streamlined and strengthened EPA's ability to prevent and respond to catastrophic oil spills through a tax on oil. |
| Food Quality Protection Act (1996) | FQPA amended FIFRA and FFDCA. |

The FIFRA was enacted in 1947 as a consumer protection statute to regulate the manufacture, sale, distribution, and use of pesticides. The USDA administered FIFRA. Pesticide registration was required before marketing in interstate commerce, and the pesticide product had to bear a label with the manufacturers name and address, name brand and trademark of the product, net contents, ingredient list, warning statements to prevent injury, and directions for use. Subsequent amendments added more product classes including nematicides, plant regulators, defoliants, and desiccants (1959); and a requirement that all pesticide labels contain a Federal Registration Number and safety information words, such as "warning", "danger", "caution", and "keep out of reach of children"(1964).

In 1970, authority for FIFRA was transferred from the USDA to the newly created EPA. Another amendment in 1972 provided the EPA with authority to regulate pesticides to prevent unreasonable adverse effects on the environment. The 1972 amendment changes included requirements to follow the label, heavy fines for violations, classification of pesticides as "restricted use" or "general use", state certification, manufacturer registration and inspection by EPA, and scientific evidence that the product is effective and safe for humans, crops, and animals. Subsequent clarifying amendments provided for significant changes to improve the registration process including generic standards for the active ingredient rather than for each formulated product, re-registration of all products registered prior to 1975, conditional registration where efficacy data may be waived, state enforcement authority and defined the phrase: "to use any registered pesticide in a manner inconsistent with its labeling".

In 1988, the EPA was required to re-register existing pesticides that were originally registered before current scientific and regulatory standards were formally established. The Food Quality Protection Act (FQPA) of 1996 is the most recent significant amendment to FIFRA.

## Pesticide residues in foods

When pesticides are used in producing food, they may remain in small amounts called residues. To protect the public from potentially harmful effects caused by pesticide residues on food, the EPA regulates the amount of each pesticide that may remain on or in each food. EPA regulates pesticides under two major federal statutes. Under the FIFRA, EPA registers pesticides for use in the United States and prescribes labeling and other regulatory requirements to prevent unreasonable adverse effects on health or the environment. Under the FFDCA, EPA establishes tolerances (maximum legally permissible levels) for pesticide residues in food. Tolerances are established as part of the pre-market registration process. Exceeding the tolerance initiates enforcement actions where the commodity may be subject to seizure. Tolerance limits apply to both domestic and imported food. Some foods do not require tolerances because the exposure and toxicity data show that the food is safe when the pesticide is used according to the directions on the label.

Several other government agencies enforce EPA's pesticide tolerances in food. The FDA tests food produced in the United States and imported food. State agencies also test food produced in the United States. The USDA tests milk, meat, and eggs. The USDA and FDA have programs designed to develop statistically valid information on pesticide residues in foods. This information is provided to EPA for use in risk assessments for pesticides. When the USDA detects violations of tolerances in their data collection program, they notify FDA.

EPA has responded to both large and small environmental disasters during the past 30 years. Less visible but just as important is EPA's present effort to reassess all the pesticide and other ingredient tolerances and exemptions that were in effect as of 1996 when the FQPA of 1996 was passed. It amended both the FIFRA and the FFDCA. These amendments changed the way EPA regulates pesticide residues. Examples of FQPA changes include a single residue safety standard of "a reasonable certainty of no harm"; requirement for an explicit determination that pesticide tolerances are safe for children (includes an additional safety factor); limits consideration of benefits when setting tolerances to non-threshold (such as carcinogenic) effects; requirement to review existing pesticide tolerances within 10 years; authorization to require new data, including potential endocrine effects; imposition of civil penalties; and expedites review of safer pesticides.

## EPA companion animal safety testing

Companion animal safety studies for EPA registered pesticides apply only to dogs and cats because of widespread use of these external products for pests (USEPA, 1998). The companion animal safety study is required for pesticide registration. Companion animal safety studies for pesticide formulations for the treatment of external pests are intended to demonstrate that an adequate margin of safety exists with overuse or misuse (40 CFR Section 792 and 40 CFR 160, GLP Standards). Data from companion animal safety studies for pesticides serve as a basis for product labeling. The study can be compared to an acute dermal toxicity study, and is limited because an NOEL is not required. External pesticide products include collars, sprays, dips, shampoos, and spot treatments.

The design of a companion animal safety study should reflect the product label: method of administration, species and age group, and frequency of application. The criteria for use of the product should be used in the study. A control group should receive a concurrent vehicle at the 5× level. The vehicle should contain the inert ingredients at the maximum levels that would appear in the 5× formulation. Negative (untreated) controls may occasionally be employed to determine whether adverse effects are due to the inert ingredients in a formulation. The test formulation is applied to several groups of (six/sex) experimental animals at the label dose and multiples of this dose (3× and 5×). For exaggerated doses (3× and 5×), products specifically prepared for this type of study that contain higher concentrations of the active ingredient are preferred. If the drug cannot be formulated at the 3× or 5× concentration, due to volume constraints, multiple treatments at frequent intervals may be necessary. If the high-dose level (at least 5×) produces no evidence of drug-related toxicity, a full study (three-dose levels) may not be necessary. Multiple pesticides formulated into a single product may also be evaluated. Depending on the severity of clinical signs of toxicity, products with less than 5× margin of safety may be considered for registration. The route of administration of these product studies should be topical. The skin or hair should not be prepared in any manner unless such directions appear on the label. If the product label recommends several treatments, multiple treatments at frequent intervals are included in the study design based on label claims and instructions for use.

The species recommended for treatment on the product label is included in the study. Studies are preformed on representative classes of healthy dogs and cats by size, weight, sex, and age based on label claims. For instance, if only adults over 6 months of age are the label population of animals to receive treatment, only adults are enrolled in the study. If the product is registered for puppies and kittens, the label should state a minimum age for this group and this class should be included the study.

An equal number of animals per sex are used at each dosage level. Animals are appropriately examined and prepared during the acclimation period.

Clinical observations are conducted at hourly intervals for at least 4 h after the last treatment, and twice daily for the duration of the study. If adverse reactions are observed, the observation period on the day of treatment is extended to a time at which no toxic signs are observed. Observations should include all systems. Special attention is directed to observations of central nervous system signs of seizures, tremors, and salivation; and gastrointestinal signs of vomiting and diarrhea. Observations and measurements are reported for a minimum of 14-day post-treatment and longer if appropriate. Various samples and measurements are collected throughout the study. Individual body weights and food consumption are measured during the acclimation and periodically during the study. Animals that die or are euthanized in a moribund state are subjected to a gross necropsy and abnormal tissues are examined histopathologically to determine the cause of death. Routine post-study necropsy is not required. Clinical pathology samples including red cell cholinesterases, when appropriate, are assessed prior to treatment, 24-h post-treatment, and on day 7 of treatment.

## Chronic toxicity testing: pesticides in animal-derived food

### *Introduction*

The USEPA requires a variety of toxicity testing prior to registration of pesticides. The 870 Series Final Guidelines describe study protocols that meet testing requirements of the FIFRA and the Toxic Substances Control Act (TSCA): Reproduction and Fertility (870.3800) and Combined Chronic Toxicity/Carcinogenicity (870.4300) (USEPA, 1998, 2000a).

### *Reproduction toxicity testing*

The two-generation reproduction study provides information on the effects of a test substance on the male and female reproductive systems. The study should be conducted in accordance with the GLP Standards stipulated in 40 CFR Part 160 (FIFRA) and 40 CFR Part 792 (TSCA). The test substance is administered to parental (P) animals prior to and during their mating, during the resultant pregnancies, and through the weaning of their F1 offspring. The substance is then administered to selected offspring during their growth into adulthood, mating, and production and weaning of a subsequent generation. The rat is the most commonly used species for testing. Each control group should contain a sufficient number of mating pairs to yield approximately 20 pregnant females. Each test group should contain a similar number of mating pairs. At least three-dose levels and a concurrent control should be used. The dose levels should be spaced to produce a gradation of toxic effects. The highest dose should be chosen to induce some reproductive and/or systemic toxicity but not death or severe suffering. The intermediate-dose levels should produce minimal observable toxic effects. The lowest-dose level should not produce any evidence of either systemic or reproductive toxicity. The highest dose tested should not exceed 1000 mg/kg/day (or 20,000 ppm in the diet), unless potential human exposure data indicate the need for higher doses. A concurrent control group should be used. The test substance is usually administered by the oral route (diet, drinking water, or gavage). The animals should be dosed with the test substance on a daily basis. Daily dosing of the parental males and females should begin when they are 5–9-week old, and that of the offspring should begin at weaning. Daily dosing should begin at least 10 weeks before the mating period and continue until termination.

The endpoints measured should provide data regarding the performance of the male and female reproductive systems including gonadal function, the estrous cycle, mating behavior, conception, gestation, parturition, lactation, and weaning, and on the growth and development of the offspring. The study may also provide information about the effects of the test substance on neonatal morbidity, mortality, target organs in the offspring, and preliminary data on prenatal and postnatal developmental toxicity and serve as a guide for subsequent tests. Additionally, since the study design includes *in utero* as well as postnatal exposure, it provides the opportunity to examine the susceptibility of the mature/neonatal animal. For further information on functional deficiencies and developmental effects, additional study segments can be incorporated into the protocol, utilizing the guidelines for developmental toxicity or developmental neurotoxicity (USEPA, 1996).

### *Combined chronic toxicity/carcinogenicity testing*

The objective of the combined chronic toxicity/carcinogenicity study is to determine the effects of a substance in a mammalian, species following prolonged and repeated exposure. If chronic/carcinogenic effects are detected in the first mammalian species, usually the rat, further long-term studies may be conducted in another species, usually the dog. The design and conduct should allow for the detection of neoplastic effects and a determination of the carcinogenic potential as well as general toxicity, including neurological, physiological, biochemical, and hematological effects and exposure-related morphological (pathology) effects.

Preliminary studies providing data on acute, subchronic, and metabolic responses should be conducted. The rate of exposure is generally oral, dermal, or inhalation. For the

combined chronic toxicity/carcinogenicity study, the rat is the species of choice for oral and inhalation studies, whereas the mouse is species of choice for the dermal route. The choice of the route of administration depends on the physical and chemical characteristics of the test substance and the product exposure in humans. The duration of studies should be at least 18 months for mice and hamsters and 24 months for rats. The following general requirements apply to all combined chronic toxicity/carcinogenicity studies regardless of the route of administration. Testing should be started with young healthy animals as soon as possible after weaning and acclimatization, but no later than 8 weeks of age. At commencement of the study, the weight variation of animals used should be within 20% of the mean weight for each sex. At least 100 rodents (50 males and 50 females) should be allotted randomly to each dose level and concurrent control group. At least 20 additional rodents (10 males and 10 females) should be used for satellite dose groups and the satellite control group. The purpose of the satellite group is to allow for the evaluation of chronic toxicity after 12 months of exposure to the test substance. The number of animals in any group should not fall below 50% during the course of the study at 15 months in mice and 18 months in rats, so that a meaningful and valid interpretation of negative results can be achieved. Survival in any group should not fall below 25% at 18 months in mice and 24 months in rats.

#### *Organization for Economic Cooperation and Development*

The Organization for Economic Cooperation and Development (OECD) carried forward recommendations of an international expert group and questioned the value of clinical pathology findings, including hematology, clinical chemistry, beyond 12 months in chronic, and combined chronic/carcinogenicity studies (Weingand *et al.*, 1996). As a result, hematology and clinical chemistry measures beyond 12-month period have been eliminated. The observational and functional tests on nervous system and behavior have also been revised per OECD. Recently, the requirement for the 6-month long-term studies in the dog has been modified. Long-term studies (6 months or longer) in the dog will not be conducted unless warranted by findings in long-term rat studies.

## EPA adverse effects information reporting

At EPA, regulatory responsibilities for pesticides are centralized at the OPP. Regulatory authority is derived from Section 6(a)(2) of the FIFRA. The regulations that specifically address reporting of adverse effects of pesticides are contained in Reporting Requirements for Risk/Benefit Information (40 CFR Section 159). Reporting of AERs is mandatory for industry.

Pesticides are broadly defined to include insecticides, herbicides, fungicides, and various other substances that are not animal drugs used to control pests. A pesticide is also any substance or mixture of substances intended for use as a plant regulator, defoliant, or desiccant. The EPA collects information on pesticide use, whether intended or unintended. Adverse effects information may include information on human or animal injury, plant injury, or environmental contamination. All adverse effects information is accepted regardless of the registered label use of the product.

Specific industry reporting requirements for adverse effects information depends on the category of the information. Reports of human death should be submitted within 15 calendar days as an individual report. A variety of other information, including suspected product defects, human epidemiology and exposure studies, and pest resistance reports should be submitted within 30 calendar days as individual reports. Reports involving major and moderate human injury, major injury to plants and wildlife, water contamination, and public health product ineffectiveness should be submitted after a 1-month accumulation as individual reports.

Animal reports receive less priority than human reports. Reports involving any type of domestic animal injury, and some minor types of human, plant, and wildlife injury, should be reported within 2 months, after a 3-month accumulation of reports. The information may be submitted in an aggregate format. An aggregate report for a specific time period includes a count of domestic injuries within categories of assessed seriousness. Information concerning the specific details of each individual AER is not included in an aggregate. The EPA, however, may request additional information for any AERs that involved the death of an animal.

The EPA/OPP gathers adverse effects information from other sources. Information may result from complaints made directly to the EPA. This AER information is entered into the EPA Incident Database. Information may also be obtained through the National Pesticide Communications Network, based at Oregon State University, and other sources. Much of this information may be entered into the EPA Incident Data System. Some aggregate reports may also be entered into the system.

Various product divisions within OPP review the AER information. A complete review of product-related information is performed when it is being considered for re-registration. A Special Review may be set in motion when EPA has reason to believe that the use of a pesticide may result in unreasonable adverse effects, including acute toxicity to domestic animals. Subsequent regulatory actions may range from removal of the product from the market to changes in permitted uses.

Since the EPA/OPP regulates all pesticides, jurisdictional AER issues resulting from extra-label use are not a

consideration. Further, the mission of OPP is to monitor the safety of pesticides in humans and animals regardless of the intended use. Evaluation of domestic animal AERs involving pesticides labeled for therapeutic use on animals is given the same attention as a pesticide labeled for use on plants. Intended use is more likely to affect what regulatory actions may be subsequently taken to improve the overall safety of product use.

# SECTION III. US DEPARTMENT OF AGRICULTURE

## Regulatory authority and mission

The authority for regulating veterinary biologics in the United States is provided in the Virus–Serum–Toxin Act (VSTA), enacted in 1913 and amended in 1985 (USDA APHIS Center for Veterinary Biologics, 2005a). It requires, with some exceptions, that all veterinary biologics be licensed. The Licensing and Policy Development (LPD) unit in the Center for Veterinary Biologics (CVB), Veterinary Services, Animal and Plant Health Inspection Service (APHIS), and US Department of Agriculture (USDA) enforces the VSTA. The Act authorizes the Secretary of USDA to prescribe regulations governing the preparation and marketing of veterinary biologics shipped into, within, or from the United States. The VSTA makes it unlawful to sell worthless, contaminated, dangerous, or harmful veterinary biologics or to ship veterinary biologics in or from the United States unless they are prepared in a licensed establishment in compliance with USDA regulations. It requires the issuance of a permit by USDA prior to the importation of a veterinary biological product and gives the department the authority to test veterinary biological products prior to importation. In case of violation, the Act permits USDA to remove or suspend establishment and/or product licenses and permits. It also gives authority for detention, seizure, and condemnation of products and injunctions against products or establishments.

## Definition and functions

The regulations in 9 CFR 101.2(w) define veterinary biological products to be all viruses, serums, toxins, and analogous products of natural or synthetic origin that are intended for use in the diagnosis, treatment, or prevention of diseases of animals. The products include diagnostics, antitoxins, vaccines, live or killed microorganisms, and their antigenic or immunizing components. The LPD reviews license applications for production facilities and biological products and for importation. It reviews production methods, labels, and supporting data involved in the licensing and permit process and issues licenses and permits. An exemption from this licensing provision is given for products prepared by (1) a person solely for administration to that person's own animals; (2) a veterinarian for use in his or her own licensed practice under a veterinarian–client–patient relationship; and (3) a person operating a State licensed facility solely for distribution of product within the State of production in a State that has the State regulatory USDA-approved control program for veterinary biologics. The VSTA provides for the issuance of conditional or special licenses for products in order to meet an emergency condition.

A proposed rule to amend the VSTA (9 CFR Parts 101 and 116) was published in the Federal Register on August 17, 2005 (Vol. 70, No. 158, p. 48325) (USDA APHIS Guidance Documents, 2005b). The proposed rule requires veterinary biologics licensees to record specific information concerning adverse events associated with the use of biological products that they produce or distribute and to compile and submit those records in a summary report to the APHIS every 12 months for products licensed for 1 year or more; for newly licensed products. A summary report would have to be submitted at 6-month intervals during the first year of the product license and at 12-month intervals thereafter. The VSTA did not explicitly require licensees to maintain records of adverse events associated with the use of veterinary biologics, nor do the regulations in Part 116.5 provide specific guidance in determining whether an adverse event should be considered an indication that raises questions regarding the purity, safety, potency, efficacy, preparation, testing, or distribution of biologics.

Adverse event and AER are defined as follows:

- As any observation in animals, whether or not the cause of the event is known, that is unfavorable and unintended and that occurs after any use (on or off label) of a biological product.
- For products administered to animals, this would include events related to a suspected lack of expected efficacy.
- AER: as a communication concerning the occurrence of an adverse event from an identifiable first-hand reporter that includes at least the following information: an identifiable reporter; an identifiable animal; an identifiable biological product; and one or more adverse events.

### *Animal immunobiologic vigilance program*

Regulation of animal immunobiologics is centralized within the APHIS and CVB. Regulatory authority is derived from the VSTA. Animal immunobiologics modulate the immune system for the prevention, treatment, or diagnosis of disease in animals. Animal immunobiologics typically include

vaccines, toxoids, and serum derivatives, which may be used in diagnostic test kits.

Immunobiologic vigilance (or vaccinovigilance) may in some respects be more complicated than monitoring the safety of animal drugs, or even therapeutic animal pesticides. Vaccines are generally utilized for the prevention of disease. The real or perceived failure of a vaccine to perform may be dependent on a number of factors and difficult to assess. Suspected vaccine failure in individuals is particularly difficult to assess. Further, assessing AERs involving adverse events that are manifested some time after vaccine administration can be complicated. In addition to the "active ingredient", vaccines can include other ingredients, such as preservatives, stabilizers, and adjuvants, which can affect the product performance. Vaccinovigilance is a particularly challenging discipline that may require substantially more information from formal studies in order to verify suspected problems.

Until the proposed rule is finalized to amend the VSTA, USDA currently has no regulations that require the immunobiologic industry to routinely submit AERs to CVB. Since the immunobiologic industry does not submit AERS, the CVB has limited ability to monitor AERs involving animal safety. USDA may at times request companies to voluntarily submit AERs that are related to a particular safety issue. Although, the USDA does not presently mandate specific AER record keeping practices, the USDA does have the ability to conduct investigations at the immunobiologic manufacturing site.

At present, modest levels of CVB resources are allocated to direct vaccinovigilance activities. However, CVB can direct resources, as needed, to safety issues. While regulatory actions may be more likely to result in the removal of the registered product from the market, other actions may include manufacturing changes or label revisions.

## Animal care and welfare requirements

Researchers who conduct studies funded by the federal government are subject to a number of requirements imposed by various federal agencies. The Animal Welfare Act (AWA) is administered by the USDA APHIS Animal Care Program (USDA APHIS Animal Care Program Publications, 2000). It applies specifically to dogs, cats, and a number of other listed species as well as to any other warm-blooded animals designated by the Secretary. It requires covered facilities to register and comply with AWA regulations. Examples of types of requirements established to implement AWA include living space, lighting, heating, ventilation, drainage, transportation, feeding and watering, and veterinary care. It establishes the requirement for an Institutional Animal Care and Use Committee, which must include a veterinarian and an external member. This committee reviews the program and inspects the facility periodically and reviews protocols for research conducted within the facility. It does not apply to animal agriculture or non-research horses. It does apply to dealers and exhibitors. Federal agencies such as National Institutes of Health (NIH) may impose additional requirements.

As a practical approach to ensuring that their programs and facilities meet these requirements, many organizations participate in the Association for Assessment and Accreditation of Laboratory Animal Care (AAALAC) International's accreditation process (Association for Assessment and Accreditation of Laboratory Animal Care, 2005). AAALAC was founded in 1965 to address laboratory animal welfare issues. AAALAC International is a non-regulatory, non-profit corporation. Its mission is to promote high standards for animal care, use, and welfare and enhance life sciences research and education through its accreditation process.

# SECTION IV. DRUG ENFORCEMENT ADMINISTRATION

## Mission and public health impact

Illegal drug use is a widespread problem in the United States. In 1998, an estimated 13.6 million Americans used an illicit drug at least once during the 30 days prior to being interviewed. During the same period, nearly 1 in 10 youths aged 12–17 years was an illicit drug user, and 130,000 were current users of Heroin. The Drug Enforcement Administration (DEA) was established on July 1, 1973. Its mission is to enforce the controlled substances laws and regulations of the United States and to bring to the criminal justice system, or any other competent jurisdiction, those organizations and principal members of organizations who are involved in the growing, manufacture, or distribution of controlled substances in the United States.

## Illicit veterinary drugs of public health concern

Approved veterinary scheduled drugs, which are illicitly used in humans, include boldenone (Equipoise), ketamine, stanozolol (Winstrol), and trenbolone (Finajet). Veterinary products containing anabolic steroids that are exclusively intended for administration through implants to cattle or other non-human species and which have been approved by the CVM, US FDA are excluded from all schedules (Drug Enforcement Agency: 21 CFR Parts 1300–1316, List of Scheduling Actions and Controlled Substances, 1999b; Drugs of Abuse, 1997).

Ketamine hydrochloride, known as "special k" and "k", is a general anesthetic for human and veterinary use.

Ketamine produces effects similar to pentachlorophenol (PCP) with the visual effects of lysergic acid diethylamide (LSD). Ketamine sold on the streets comes from diverted legitimate supplies, primarily veterinary clinics. Its appearance is similar to that of pharmaceutical grade cocaine, and it is snorted, placed in alcoholic beverages, or smoked in combination with marijuana. The incidence of ketamine abuse is increasing. Ketamine was placed in Schedule III of the Controlled Substances Act (CSA) in August 1999 (Drug Enforcement Agency: 21 CFR Parts 1300–1316, Schedules of Controlled Substances, 1999a).

Concerns over a growing illicit market and prevalence of abuse combined with the possibility of harmful long-term effects of steroid use led Congress in 1991 to place anabolic steroids into Schedule III of the CSA. The CSA defines anabolic steroids as any drug or hormonal substance chemically and pharmacologically related to testosterone (other than estrogens, progestins, and corticosteroids) that promotes muscle growth. Most illicit anabolic steroids are sold at gyms, competitions, and through mail operations. For the most part, these substances are smuggled into this country. Those commonly encountered on the illicit market include boldenone (Equipoise), ethlestrenol (Maxibolin), fluoxymesterone (Halotestin), methandriol, methandrostenolone (Dianabol), methyltestosterone, nandrolone (Durabolin, DecaDurabolin), oxandrolone (Anavar), oxymetholone (Anadrol), stanozolol (Winstrol), testosterone, and trenbolone (Finajet). Physical side effects include elevated blood pressure and cholesterol levels, severe acne, premature balding, reduced sexual function, and testicular atrophy. In males, abnormal breast development (gynecomastia) can occur. In females, anabolic steroids have a masculinizing effect, resulting in more body hair, a deeper voice, smaller breasts, and fewer menstrual cycles. Several of these effects are irreversible. In adolescents, abuse of these agents may prematurely stop the lengthening of bones, resulting in stunted growth (Drug Enforcement Agency: 21 CFR Parts 1300–1316, List of Scheduling Actions and Controlled Substances, 1999b).

## DEA regulatory requirements for veterinarians

Federal DEA regulations are contained in 21CFR 1300 and 1316 (US Department of Justice, 2005). Clinicians who are authorized to prescribe controlled substance may do so for legitimate medical purpose in the context of a valid veterinary-client–patient relationship. Under these regulations the prescribing practitioner is held responsible in case the prescription does not conform to the regulations for records and reports (21 CFR 1304), submitting proper ordering forms (21 CFR 1305), and for meeting the requirements for prescriptions (21 CFR 1306 (1)). Requirements for prescribing Schedule II drugs are much more stringent than those are for Schedules III, IV, and V. For example, an oral order or refilling of the prescription for Schedule II drugs is prohibited under the CSA. DEA has divisional offices in various regions, including in Atlanta, Boston, Chicago, Dallas, Denver, Detroit, El Paso, Houston, and Los Angeles. In addition, each division has several district offices.

# SECTION V. OCCUPATIONAL SAFETY AND HEALTH ADMINISTRATION

## Organization and mission

Harmful chemical compounds in the form of vapors, fumes, mists, gases, liquids, and solids are encountered in the workplace by inhalation, absorption (through direct skin contact), or to a lesser extent by ingestion. Airborne chemical hazards have great occupational health significance. The degree of worker risk from exposure to any given substance depends on the nature and potency of the chemicals toxic effects and the duration and intensity of exposure (Occupational Safety and Health Administration, Informational Booklet on Industrial Hygiene, 2005c).

In 1970 Congress passed the Occupational Safety and Health Act to assure so far as possible every worker in the nation safe and healthful working conditions (Occupational Safety and Health Administration, The Occupational Safety and Health Act of 1970, 2005a). The Act requires employers to maintain a safe workplace and created the Occupational Safety and Health Administration (OSHA). This agency's mandate includes regulatory responsibility for establishing mandatory occupational exposure standards, as well as related research, training and education and enforcement. OSHA is part of the Department of Labor and is headed by the Assistant Secretary of Labor for Occupational Safety and Health. Major OSHA programs are administered through Directorates such as the Directorate for Safety Standards Programs which provides workplace standards and regulations to ensure safe working conditions.

*Offices and District Offices*. Under the Act many states have OSHA-approved occupational safety and health programs which function *in lieu* of OSHA programs or standards. OSHA has broad workplace safety responsibilities which pertain to physical hazards such as electromagnetic radiation, temperature, noise and vibration; ergonomic hazards such as repeated motions or heavy lifting; and biological hazards including bacterial and viral pathogens, in addition to the chemical hazards that are the primary subject of this section. The Act also established the National Institute for Occupational Safety and Health (NIOSH) within the (DHHS). NIOSH is authorized to develop and establish recommended occupational safety and health standards by conducting research and

experimental programs for the development of new and improved occupational safety and health standards.

### Exposure limits

OSHA limits occupational exposure to hazardous chemicals by establishing exposure limits and directing changes in employer work processes or equipment, or when that is not feasible requiring personal protective equipment. Unlike drugs, biologics, pesticides, or food additives, industry does not need to provide evidence of safety, or obtain an approval prior to manufacturing and marketing new products which may entail occupational exposure to hazardous chemicals. Thus, exposure limits may be adopted after the chemical has entered the occupational environment. The Act specifies that for regulating toxic chemicals OSHA must adopt standards which most adequately assure, to the extent feasible, on the basis of the best available evidence, that no employee will suffer material impairment of health or physical capability. Thus, some consideration must be given to the issue of technological achievability for industry in promulgating standards.

OSHA standards are called permissible exposure limits (PELs). They are legal standards that may not be exceeded. PELs have been controversial and susceptible to successful legal challenges. Thus, many chemicals do not have PELs. In the absence of OSHA PEL's employers utilize recommended occupational exposure limits established by acknowledged sources in order to meet OSHA's requirements for worker safety. NIOSH has recommended exposure limits (RELs). The American Conference of Governmental Industrial Hygienists Threshold Limit Values (TLVs) for Chemical Substances and Physical Agents in the Work Environment are very widely utilized (National Oceanographic and Atmospheric Administration, 1998). TLVs refer to airborne concentrations of substances and represent conditions under which it is believed that nearly all workers may be repeatedly exposed day after day without adverse health effects. There are three categories of occupational exposure limits:

1 *Time-weighted average (TWA)*: The TWA concentration for a conventional 8-h workday and 40-h workweek, to which it is believed that nearly all workers may be repeatedly exposed, day after day, without adverse effect.
2 *Short-term exposure limit (STEL)*: The concentration to which it is believed that workers can be exposed for a short period of time without suffering from irritation, tissue damage, or narcosis, it is not a separate exposure limit but supplemental to the TWA and limited to a 15-min TWA.
3 *Ceiling*: The concentration that should not be exceeded during any part of the working exposure (The American Conference of Governmental Industrial Hygienists, 2005).

The OSHA Hazard Communication Standard (29 CFR 1910.1200), also called the Right-to-Know Law, ensures that the hazards of all chemicals are evaluated and the information concerning their hazards is transmitted to employers and employees. It requires chemical manufacturers and importers to obtain or develop a material safety data sheet (MSDS) for each hazardous chemical they produce or import. Distributors are responsible to insure that their customers are provided a copy of these MSDSs. An MSDS must contain information describing the physical and chemical properties, health hazards, routes of exposure, precautions for safe handling and use, emergency procedures, and control measures. The MSDS has become a well-established document for disseminating health and safety information about chemical products (Occupational Safety and Health Administration, Technical Center Brochure, 2005b). The NIOSH Pocket Guide to Chemical Hazards is another useful document for health and safety information about hazardous chemicals (National Institute for Occupational Safety and Health, 1997).

## SECTION VI. STATUTES, REGULATIONS, AND GUIDELINES

The three federal agencies (FDA, EPA, and USDA), which are responsible for regulating animal health products all maintain surveillance programs for monitoring products after they are marketed. The laws, which provide regulatory authority, and thus the regulatory goals, regulations, and approach by these three agencies are different. By extension, the pharmacovigilance programs utilized for monitoring the safety and effectiveness of marketed animal medicinal products are different. Thus, they have some common and some different statues, regulations, and guidelines.

### Notice and comment rulemaking procedures and access to agency records

Statutes are legislation passed by congress and signed by the president. They are the laws that provide the authority for regulatory agencies to operate. Regulations are basic tools for achieving a regulatory agency's goals, such as consumer or environmental protection. Regulations inform the affected industries and the public of statutory requirements and the agencies procedures. Regulations interpret the law and spell out the details needed to implement the general

provisions in the statutes. Regulations also describe the product approval process for many individual products or set forth required standards of product composition or performance.

Change is constant and agencies must issue new regulations and amend or revoke old ones. All regulations must be authorized by statute, and the rulemaking procedures must conform to requirements of the Administrative Procedures Act which applies to all executive branch departments and agencies of the federal government. The administrative process for establishing regulations used is referred to as "Notice and Comment Rulemaking".

New and amended regulations and other notices are disseminated by publication in the Federal Register which is issued daily by the Federal Government (Federal Register). Regulations are codified in the Code of Federal Regulations (CFR) which is updated annually. Preparing and issuing a regulation is a complex and lengthy process because agencies must be sure any new rule is needed and well conceived. Stakeholders such as affected industry, and consumers generally must be given an opportunity to participate through the notice and comment rulemaking process. Ordinarily, this is done by publishing in the Federal Register a notice of proposed rulemaking and inviting comments, within a specified time frame, typically 60 or 90 days. In appropriate cases public hearings are also held. The written and public hearing comments then must be reasonably responded to before issuing a final regulation. After reviewing all comments an agency publishes the final rule in the Federal Register and announces the effective date of the regulation. The regulation then becomes part of the CFR.

Guidelines establish practices of general applicability and do not include decisions or advice on specific situations. Guidelines are not legal requirements, but may be relied on with the assurance that it is an acceptable procedure or standard. A guideline represents the formal position of the agency on a matter and obligates the agency to follow it until it is amended or revoked. The guideline development process is similar to the regulation publication process. Draft guideline availability and request for comment is typically announced in the Federal Register and comments are considered when developing final guidelines.

## Freedom of information and public access to regulatory agency records

The Freedom of Information Act (FOIA) went into effect in 1967. It provides access to information in government files and requires that each government agency publish descriptions of its operations and procedures. Each agency must also make available opinions, orders, and statements of public policy that affect the public. Any person can obtain information through an FOIA request. Certain types of information are not available under FOIA. For example, national security-related, trade secrets and commercial information and personnel and medical files are exempt. Agencies are given a certain period of time to process requests, typically within 20 days of receipt. The key to obtaining the desired information is to make the request sufficiently detailed and specific to allow identification of the record(s). Information that would be important to veterinarians would include adverse reaction information for animal drugs, regulatory letters written by the agency, Compliance Policy Guidelines (to direct FDA field staff in enforcement activities), and Guidelines implementing regulations. Fortunately most of this information is now available on federal agency Internet home pages. For instance, Warning Letters to manufacturers for violations of Good Manufacturing Practices, and livestock producers or veterinarians involved in causing violative drug residues may be viewed on FDA's FOIA site. Summary information on reports of adverse drug reactions is available on the FDA CVM's home page.

CHAPTER

# 8

# Toxicology and the law

*Michael J. Murphy*

## INTRODUCTION

Much of the law of admissibility of scientific expert testimony arises from toxic tort cases. Consequently, the discipline of toxicology has strongly influenced the legal standards by which scientific expert testimony is admitted in a legal venue.[1]

This chapter uses a hypothetical example of legal issues that may arise in an animal toxicosis case to illustrate application of the law to a feed case. It is intended to introduce toxicologists, and other scientists, to a broad overview of some of the legal issues that may arise when a medical case become a "legal case." This chapter is not, and is not intended to be, a comprehensive review of the law. Neither it is intended to provide an outline of steps to take for a particular case in a particular jurisdiction.[2]

This chapter primarily relies on the Federal Rules of Evidence, and limited case law, to identify issues[3] that may arise when the findings of a medical diagnosis are used in the courtroom. It focuses on the admissibility of expert testimony in a legal proceeding. However, the reasons for conducting toxicology analyses, jurisdiction, standard of proof, and evidence, are briefly summarized to provide a foundation for the role of the expert testimony. The chapter concludes with some questions to consider when analyzing a toxicology case.

[1]The particular county, or geographical area, in which a court with jurisdiction may hear and determine a case. Black's Law Dictionary.

[2]It is the power of the court to decide a matter in controversy and presupposes the existence of a duly constituted court with control over the subject matter and the parties.

[3]A single, certain, and material point, deduced by the allegations and pleadings of the parties, which is affirmed on the one side and denied on the other.

## REASONS FOR CONDUCTING TOXICOLOGY ANALYSES

Toxicology has been defined as the scientific *study of adverse effects of chemicals on living organisms* (Eaton and Klaassen, 2001). A toxicologist is one trained to examine the nature of those effects and assess the probability of their occurrence (Eaton and Klaassen, 2001). Exposure, dose response, and variability of that response are fundamental principles in the science of toxicology (Eaton and Klaassen, 2001). A showing that the toxicologist offered as an expert witness has applied these fundamental principles to the facts of the case at hand will likely be useful in the determination of whether the toxicologist's testimony will or will not be admissible as evidence. The factors that the judge uses to make this determination are discussed in the expert witness section at the end of this chapter.

A toxicologist relies on analytical toxicology analyses in many toxicology cases. In most instances, it is known at the time the sample is submitted for analytical chemistry analysis that the results of that analysis will be used for legal purposes. Racing chemistry laboratories are one example in the veterinary profession where it is known from the outset that the results of the analytical chemistry testing performed will be used in a legal enforcement setting. In some instances however, the purpose to which the results will be applied is not known at the time of sample submission, or, more commonly, that purpose changes after the testing is completed.

### *When the reason for testing the sample is known*

Samples are analyzed for the presence of chemical toxins for many reasons and in many settings. Analyses may take place in academic, governmental, or private laboratories. Analyses performed in these laboratories may each

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

serve a different purpose, such as research, enforcement actions, preclinical testing, or clinical diagnoses.

Toxicology analyses in academic settings are primarily conducted to support one's research or scholarly efforts. One example is the development of new analytical methods. Another example is the characterization of adverse effects of a particular dose of a particular chemical in a given species. Similarly, researchers may observe the clinical signs and adverse effects of animals exposed to chemicals, then compile these effects in retrospective or prospective case reports in peer-reviewed literature. Such literature may be useful to support a general causation[4] argument in a legal case. However, the medical case itself or even the analyses performed on that medical case may not be admissible in court because of insufficient documentation supporting authenticity. Other laboratories may provide such documentation.

Veterinary diagnostic laboratories normally have some government support to assist in the clinical diagnosis of diseased animals. Such analyses are normally aimed at assisting in the determination of whether an animal may or may not have been exposed to a particular chemical, and if so, whether the animal has or has not experienced a toxicosis as a result of that exposure. These chemical analyses may give qualitative, semi-quantitative, or quantitative results.

Many contemporary analytical chemistry procedures, performed in each of the above laboratory types, allow detection of the presence of chemicals in biological samples that represent only "background" or "normal" exposure to that chemical. One example is micronutrients, such as vitamins A and E, copper, iron, magnesium, selenium, and zinc. Similarly, lead may be detected at "background" concentrations in blood, liver, or kidney by many analytical toxicology methods available today. Consequently, the detection of the chemical is not "diagnostic" for toxicosis due to that chemical, but merely indicates exposure. Information beyond the concentration of a chemical in tissues is often required to reach a toxicosis diagnosis. The distinction between "exposure to" and "toxicosis from" a chemical is fundamental in a legal venue.

Samples are received from many sources. Most diagnostic laboratories accept samples from veterinarians, animal owners, animal industries, and others. The circumstances of the collection and handling of the sample prior to submission in the diagnostic laboratory are rarely known with certainty. Similarly, routine protocols in a diagnostic laboratory may be different than those in an enforcement laboratory, particularly with respect to sample tracking, documentation, and disposal.

Some government and some private laboratories focus on performing chemical analyses in support of legal enforcement actions. Examples of such laboratories include racing chemistry laboratories, and State or Federal Departments of Agriculture or Health. Many of these laboratories have inspectors who insure proper sample collection and transport to the laboratory. In addition, sample tracking, control, retention, and disposal are generally better documented in laboratories devoted to enforcement action, than those devoted to research or routine diagnostic testing. The analytical methods used in an enforcement setting have often been validated by AOACI,[5] or a similar entity. This validation often demonstrates that the method has been shown to be reliable in multiple laboratories for quantifying the concentration of an analyte or a group of analytes in a specific matrix.

The analytical methods useful in a diagnostic setting may be different from those in an enforcement or research setting. The analytical methods used to support a diagnostic case are often influenced by cost and turn-around-time. On the other hand, those in an enforcement setting may be more influenced by reliability of the results reported. These factors directly and indirectly influence the collection of the original sample, tracking of the sample in the laboratory, sample retention, document retention, and sample disposal protocols. Protocols appropriate for the development of a method in a research laboratory may not be appropriate for use in an enforcement setting. These factors should be taken into account and samples sent to the appropriate laboratory when the reason for the analysis is known. The reason is not always known.

#### *When the reason for testing the sample is not known or changes after testing*

Problems are more likely to occur if the purpose for which the sample is tested is not known at the time of testing, or changes after the testing is completed. These problems may give rise to angst on the part of the toxicologist, counsel, and others. This angst may occur if sample collection, tracking, analysis, and interpretation have not been documented in a way that supports proof of reliability in a legal venue. Questions of authenticity and reliability are more likely to arise in analyses performed in a research, routine clinic, or diagnostic laboratory setting than those collected and performed by enforcement personnel. Medical samples submitted and tested for one purpose may not be reliable if used for another purpose. In short, the lack of sample tracking or chain of custody documentation may seriously erode the admissibility of laboratory results. A diagnosis may not be supported without laboratory results and a legal case may not succeed without the diagnosis. Put more bluntly, insufficient sample collection, retention, and chain of custody documentation can be a

[4] The fact of being the cause of something produced or of happening. The act by which an effect is produced.

[5] Association of Official Analytical Chemists International.

huge problem for a plaintiff or prosecutor in a legal venue. A hypothetical case may help illustrate the application of a number of the following legal issues.

### *Hypothetical case*

A hypothetical individual employee of a feed additive manufacturer intentionally adds a foreign chemical to a feed premix during a step in the manufacturing process. The feed premix is distributed to many states. Many local mills purchase the premix and incorporate it into the feed in appropriate amounts. The mill then delivers that feed to its customers – animal owners. These animal owners offer that finished feed to their animals in appropriate amounts. These animals ingest the feed, then develop adverse effects. An adverse effect in one of the animals is death. An animal that died after ingesting this feed is submitted to a local diagnostic laboratory by the animal owner. The owner of the animal has not made any association between the new feed and the death of the animal, so the feed is not delivered when the animal is, and the new feed delivery is not part of the history provided to the diagnostic laboratory. The laboratory does a routine necropsy and case work up. A feed additive is mentioned to the animal owner as one of the possible differential diagnostic causes for the lesions seen at necropsy. The owner then takes a grab sample of feed out of the total mixed ration mixer and has her teenager drive it down to the diagnostic laboratory. The chemical is detected in the feed at concentrations sufficiently high to cause the lesions observed in the dead animal.

Various types of legal claims[6] could arise from this case. The results of diagnostic testing may be offered as fact by the animal owner, feed manufacturer, State and Federal agencies, or some combination thereof, against one or more parties. An insurance claim and government enforcement action are discussed very briefly before continuing with issues that arise in civil or criminal litigation.[7]

The results of a routine diagnostic case may now be offered as fact in an insurance claim. The animal owner will claim that the feed provided by the distributor caused the toxicosis experienced by the owner's animals. The animal owner may file a claim against the distributor of the feed for the harm done to her animals. The distributor, or the distributor's insurance company, may settle the claim with the animal owner if all agree. If all do not agree, a civil suit may be filed. The issues that arise in the civil suit are discussed in the next section.

[6] A cause of action. To demand as one's own or as one's right, to assert, to urge, to insist. Means by or through which claimant obtains possession or enjoyment or privilege or thing.

[7] A lawsuit. Legal action, including all proceedings therein. Contest in a court of law for the purpose of enforcing a right or seeking a remedy.

The dispute[8] between the animal owner and the feed distributor involves private parties. The case may also give rise to an enforcement action. These actions may be on the part of one or more agencies in one or more States, the Federal government, or any combination of State and Federal government. One or more agencies of the State in which the animal was harmed may have statutory authority to protect the health of animals, humans, or both. These agencies may include the State Department of Agriculture, the State Department of Health, the State Department of Natural Resources, or the State Board of Animal Health. A state agency may choose to take enforcement action against the feed distributor, premix manufacturer, or both in order to protect the health of animals or humans in its state.

The state agency may collect its own samples, and perform its own analyses prior to taking any enforcement action. The agency may determine that the concentration of chemical in the feed is greater than a published tolerance or action level for that chemical in that feed. This agency action may end with a fine, recall, or other administrative action, if both sides agree.

If both sides do not agree, the feed distributor and premix manufacturer may "appeal" the agency's decision. This appeal may go to an administrative law judge, or a similar official within, or outside, the agency, depending on the administrative structure of that particular agency. If the feed manufacturer or premix manufacturer agrees with the ruling of the administrative law judge, the dispute is finished. If all do not agree, the distributor or manufacturer of the feed may choose to appeal the decision of the administrative law judge to a district civil court. This puts the dispute in a venue similar to a civil suit as discussed below.

Agencies are given deference at the district court level, making this an increasingly difficult, but not insurmountable, argument to win. The specialty of Administrative Law is devoted to the details of administrative procedure that arises in such actions. Administrative Law is beyond the scope of this chapter.

Federal agencies may also have an interest in the animal case. The Federal Food and Drug Administration (FDA) may have an interest in the case because the feed additive impacted interstate commerce when it crossed state lines and impacted the health of the public when it caused toxicosis of a food animal. The FDA has authority to protect the public health. It has authority to take administrative action against the manufacturer of the feed similar to that discussed for the state agencies above.

Although agency decisions are normally given deference in the courtroom, regulations developed by agencies may not always address the issue of causation. Agency

[8] A conflict or controversy, a conflict of claims or rights, an assertion of a right, claim, of demand on one side, met by contrary claims or allegations on the other.

regulations are often promulgated to protect populations rather than individuals.[9] The effect on an individual referred to as specific causation is discussed below. The distinction between enforcement actions taken by agencies to benefit the public as a whole and legally admissible specific causation in an individual is not always appreciated.

This distinction may be illustrated by a hypothetical example. A bulk tank load of milk is tested in the receiving bay and found to be positive for the presence of beta-lactam antibiotics using a test kit marketed and validated for this purpose. The entire load of milk is dumped and the producer whose individual sample is positive is charged for the load of milk. Paying for the tanker load of milk in this situation is a contractual agreement between the milk producer and the bulk milk buyer.

The test kit is approved and validated for use in administrative action. That action is to assist in the public policy of preventing exposure of humans to beta-lactam antibiotics to prevent allergic reactions and to reduce the likelihood of developing strains of bacteria that are pathogenic to humans and resistant to beta-lactam antibiotics. The test kit is sufficient to support the administrative action of preventing these antibiotics from entering the human food supply.

It may not be sufficient, however, for litigation aimed at prosecuting one for the source of the beta-lactam. Further analytical chemistry analysis may be required to distinguish, penicillic acid, from penicillin G from, from ticarcillin, as an extreme example. This distinction may be important because of the implication raised as to the potential source of the antibiotic in the bulk tank – feed, versus a treated cow, versus "spiking" the bulk tank. In short, a test that is entirely acceptable for agency action may not be acceptable for a specific type of litigation. This concept is expanded upon in the section on specific causation below. See Dr. Post's chapter on Regulatory Veterinary Medicine for a further discussion of agency issues.

The results of diagnostic testing may rarely be offered as fact in a criminal case. Animal poisoning cases have rarely risen to the level of criminal action. The addition of the chemical to the feed with the intention of causing a toxicosis may be a crime based on animal cruelty or chemical terrorism statutes. The executive branch of government would then prosecute the case. The state – often through its Attorney General's office – may choose to prosecute under an animal cruelty statute. Similarly, the Department of Justice may file criminal prosecution charges if the act is considered to be one of chemical terrorism. In these instances the state or federal government is a direct party in the case.

This discussion of legal venue is not exhaustive. The purpose of this section is merely to indicate how a routine clinical or diagnostic case could become involved in a variety of legal venues including, insurance claims, administrative action, civil and criminal litigation at the state and federal levels.

In summary, those samples used for the purpose known at the time of submission to a laboratory can, with some reasonable care, be handled, analyzed, interpreted, and stored in a manner consistent with that purpose. Angst may arise on the part of the animal owner, veterinarian, laboratory personnel, counsel, and others, in those instances where the application of results of testing is used in a venue not anticipated at the time of sample submission, particularly in those laboratories not accustomed to litigation work. This angst may rise when the documentation of laboratory results is found not to be sufficiently authentic or reliable to support a legal case. The importance of authenticity and reliability is discussed in the Evidence section below, immediately after a brief discussion of jurisdiction and standard of "proof."

## JURISDICTION – WHAT ARE THE RULES IN THIS FIGHT AND WHO DECIDES THE WINNER?

Ok, the parties have met, discussed, and agreed to disagree on reaching a settlement[10] on the insurance claim. They decide to take the case "to court." The owner of the animals will normally be the plaintiff,[11] and the distributor of the feed will normally be the defendant,[12] in this legal case. The manufacturer of the premix is also likely to be named as a defendant. The animal owner may be a natural person or may have formed a legal entity[13] such as a family farm corporation. The feed manufacturer and premix manufacturer may be businesses organized as sole proprietorships, partnerships, corporations, or other legal entities.

A question arises as to "which court" will decide the dispute. The state and federal governments already have authority to rule on disputes between their citizens. This authority ultimately arises from the respective constitutions.

[9] See e.g. *Troy Corp*, *AFL-CIO,* and *Simpson.*

[10] Payment or satisfaction. In legal parlance, it implies meeting of the minds or parties to transaction or controversy, an adjustment of differences or accounts, a coming to an agreement.

[11] A person who brings an action; the party who complains or sues in a civil action and is so named on the record. A person who seeks remedial relief.

[12] The person defending or denying; the party against whom relief or recovery is sought in an action or suit to the accused in a criminal case.

[13] A real being. An organization or being that possesses separate existence for tax purposes.

State constitutions most commonly delegate authority to the state judicial system to enforce the laws passed by the state legislature. Many state judicial systems have a three tiered structure composed of district courts, courts of appeals, and a Supreme Court, each with increasing authority. Similarly, the federal constitution authorizes the federal judicial system which has district courts, courts of appeals, and the Supreme Court.

Most civil suits that are filed in the United States do not actually go to trial. A settlement is reached in the vast majority of civil cases. This settlement may be reached by the parties on their own, after mediation or arbitration, or even after litigation has begun, but before a judgment is entered.

Mediation and arbitration are two forms of "alternative dispute resolution" (ADR). An outcome reached after ADR may or may not be disputed later in court depending on the final agreement of the parties in the ADR process. Judges often encourage ADR even when civil litigation is filed. Authority may be given by contract. Disputing parties may have agreed to not litigate at all but rather to use ADR. ADR is increasingly used to settle disputes between companies because it can be faster and cheaper than litigation, and because both parties have more control over the outcome of the dispute. Two parties who agree to submit themselves to ADR must grant authority to the mediator or arbitrator at the outset of the deliberation by way of contract. This authority prevails for as long as the contract between the parties is in force. Authority already exists for the government.

Parties with an ongoing relationship may have made a contractual agreement to argue any disputes that arise under that contract according to the laws of a particular state. For example, the manufacturer of the feed additive and the manufacturer of the final feed may have agreed to argue any dispute they may have under that contract according to the laws of Minnesota. One reason for this may be that both parties agree that the cost of arguing jurisdiction for a distributor with outlets in many states, and a manufacturer with plants in many states, is not in the economic best interest of either company.

The parties will need to decide on the state in which the dispute – lawsuit – will be litigated if they have not already made this decision by prior contract. Individuals, and particularly companies, may be citizens of more than one jurisdiction; consequently parties may need to decide which judicial system they choose to "sue out" the case in. This decision may influence the outcome of the dispute because of differences in laws on a particular issue between states. Similarly, federal law on a particular point may be different than that of state law on the same point, so one party may prefer to argue in federal court and the other in state court. The choice of venue may then become a significant part of the dispute that must be decided before the merits of the case can be argued. This jurisdictional decision will normally be made by the judge in the venue where the case was originally filed.

Each state has rules governing the procedures to be followed in conducting a civil trial; and procedures to be followed in conducting a criminal trial. Although these procedural rules may have many similarities between states, they are not uniform across all states. The Federal rules are more consistent nationwide.

The federal judicial system also has rules governing Civil Procedure and those governing Criminal Procedure. These rules are the same across states, although they may be interpreted differently in different federal judicial districts. In short, administrative rules guide administrative actions, state rules guide state civil or state criminal actions, and federal rules guide federal civil and criminal actions.

In our hypothetical example, the manufacturer of the premix and the manufacturer of the feed may have agreed to argue any disputes that arise under their business contract according to the laws of Minnesota. The animal owner who chooses to sue the manufacturer of the feed may choose to sue in state court in the state in which the owner fed the feed to their animal, or perhaps in the federal court representing the same geographic area. One argument that may be used to argue that the case belongs in the federal court system is that the feed crossed state lines and therefore impacted interstate commerce. Other elements that may be required to establish federal jurisdiction are beyond the scope of this chapter.

A judgment will be entered by the judge if the dispute goes all the way through trial. Thus the animal owner may receive compensation at the insurance claim, settlement, or judgment level of this dispute if the animal owner prevails.

The point of this section is primarily to indicate that the procedures by which the dispute is handled may be different between states for an insurance claim, arbitration, mediation, or litigation. These distinctions between state court systems are beyond the scope of this chapter. On the other hand, the Federal Judicial system has procedures that are generally applied across the country. They are more similar nationwide, so they are described below to indicate some procedural issues that may arise in toxicology cases. Although many disputes involving animal toxicoses are not tried in federal courts, the Federal procedural rules provided below illustrate issues that are likely to be similar across the country.

## STANDARD OF PROOF – HOW SURE DO I NEED TO BE?

One party needs to persuade the other party once a dispute develops. This need is normally referred to as the

burden of persuasion in a legal setting.[14–16] The burden of persuasion is colloquially referred to as a "burden of proof" – a phrase that toxicologists may find familiar. This burden of persuasion is different in civil cases than it is in criminal cases. Both legal burdens may be different than that of a routine medical diagnosis. The level of medical certainty needed to treat is often presented by quoting the Hippocratic Oath "first do no harm." The degree of medical certainty required to treat a disease may only be that needed to give appropriate general and supportive treatment, but not that which would be required to reach an etiological diagnosis. Reaching an etiological diagnosis to any degree of medical certainty is not always done in clinical practice.

Similarly, routine cases in a diagnostic laboratory may not reach an etiological diagnosis to any degree of medical certainty either. In many instances reaching an etiological diagnosis is limited by time, cost, and the needs of the animal owner and veterinarian. This need may be merely to have guidance for providing supportive treatment. Other limits on the ability to provide an etiological diagnosis may be the available samples, the condition of the samples, the willingness of the owner to spend the money required to reach such a diagnosis, and other factors.

This distinction between a medical diagnosis and a "legal" diagnosis is appreciated by the court system. This distinction is summarized in *Wynacht*:

> There is a fundamental distinction between Dr. Z ...'s ability to render a medical diagnosis based on clinical experience and her ability to render an opinion on causation of W..'s injuries. Beckman apparently does not dispute, and the Court does not question, that Dr. Z is an experienced physician, qualified to diagnose medical conditions and treat patients. The ability to diagnose medical conditions is not remotely the same, however, as the ability to deduce, delineate, and describe, in a scientifically reliable manner, the causes of these medical conditions. Wynacht v. Beckman Instruments, Inc. 113 F. Supp. 2d 1205, 1209 (E.D. Tenn., 2000).

In short, the diagnosis reached in a routine medical clinic is not always sufficient to meet a legal burden of persuasion. Similarly, the diagnosis reached in a routine veterinary clinic may not meet this burden either.

The legal burden of persuasion is different in civil and criminal cases. The burden in civil cases is usually either a preponderance of the evidence or clear and convincing evidence. A preponderance of the evidence is also referred to as a "more likely than not" standard. Juries are sometimes instructed that this is a 51% persuasion standard. In a civil case, the plaintiff has the burden of persuading the finder of fact – judge or jury – that his or her claim is valid with a preponderance of the evidence. Similarly, the defense has the burden of persuading the finder of fact that their defense is valid with a preponderance of the evidence.

The burden of persuasion in criminal cases is much higher. Here, the burden of persuasion is "beyond a reasonable doubt." The prosecutor has the burden of persuading the fact finder – judge or jury – beyond a reasonable doubt, that the crime was committed by the defendant. Conversely, the defendant raises "reasonable doubt" that the prosecution has met this burden. The merits of both civil and criminal cases are argued based on evidence. Some evidence will require interpretation. Interpretation of facts is the role of the expert. The role and types of evidence follow.

## EVIDENCE

Legal cases are decided based on an application of the law to the facts of a particular case. A dispute about facts themselves or interpretation of those facts arises in many legal cases. Disputes of fact are decided by the trier of fact. The trier of fact is the judge in a bench trial. The trier of

[14] Article III. Presumptions in Civil Actions and Proceedings.
Rule 301. Presumptions in General in Civil Actions and Proceedings

In all civil actions and proceedings not otherwise provided for by Act of Congress or by these rules, a presumption imposes on the party against whom it is directed the burden of going forward with evidence to rebut or meet the presumption, but does not shift to such party the burden of proof in the sense of the risk of non-persuasion, which remains throughout the trial upon the party on whom it was originally cast.

[15] Rule 302. Applicability of State Law in Civil Actions and Proceedings

In civil actions and proceedings, the effect of a presumption respecting a fact which is an element of a claim or defense as to which State law supplies the rule of decision is determined in accordance with State law.

[16] Rule 1101. Applicability of Rules:

(a) Courts and judges: These rules apply to the United States district courts, the District Court of Guam, the District Court of the Virgin Islands, the District Court for the Northern Mariana Islands, the United States Courts of Appeals, the United States Claims Court, 1 and to United States bankruptcy judges and United States magistrate judges, in the actions, cases, and proceedings and to the extent hereinafter set forth. The terms "judge" and "court" in these rules include United States bankruptcy judges and United States magistrate judges.

(b) Proceedings generally: These rules apply generally to civil actions and proceedings, including admiralty and maritime cases, to criminal cases and proceedings, to contempt proceedings except those in which the court may act summarily, and to proceedings and cases under title 11, United States Code.

fact is the jury in a jury trial. The trier of fact learns of these facts largely through evidence.

All facts are not admissible as evidence. The judge must determine which facts are admissible as evidence and which are not as a preliminary matter in the case. Specifically, the judge must determine "the qualifications of a person to be a witness", and "the admissibility of evidence."[Rule 104 (a)] The weight and credibility of the evidence is not determined at this preliminary stage. Rather "evidence relevant to weight or credibility" is normally "introduce[d] before the jury."[Rule 104 (e)]

The major factor used to determine the admissibility of evidence is relevance. "Relevant evidence" and "material fact" are two phrases that are often used synonymously. "Relevant evidence" is "evidence having any tendency to make the existence of any fact that is of consequence to the determination of the action more probable or less probable than it would be without the evidence."[Rule 401] "[A]ll relevant evidence is admissible" with few exceptions.[Rule 401] "Evidence which is not relevant is not admissible."[Rule 402] For example, testimony that the sky is blue may not be admitted as relevant, because the color of the sky has no tendency to indicate that the feed did or did not cause the toxicosis in the animals.

The judge decides which facts are admissible as evidence and which are not. The factors that influence the judge's decision on admissibility vary with the type of fact. Documents, specimens and testimony are three sources of fact that a party may desire to enter into evidence in toxicology cases.

### Documents

Documents require authentication before they can be considered as evidence. Document authentication is of increasing interest in many laboratories revisiting record retention procedures. Authentication of documents is covered by Rule 901 of the Federal Rules of Evidence.[17] Subsections of this rule specify the procedure for authenticating public[18] or ancient[19] documents. A laboratory will likely have additional influence on its record keeping. For example, veterinary diagnostic laboratories are adopting ISO standards, contract research laboratories adhere to Good Laboratory Practice standards,[20] many state agencies have state specific data practices requirements. While the specific requirements may vary, the general purpose is to authenticate the accuracy of the final report.

The case report and the documents supporting that case report may be required to authenticate that report in a legal proceeding. Authentication of case documents is one reason that many laboratories have established record retention procedures. A document and its underlying support is retained for 7 years in some diagnostic laboratories. The specimens themselves are also important in these proceedings.

### Specimens

Specimens are often relevant in toxicology cases. Toxicologists are well aware of the importance of accurate sample identification to establish the relevance of the results of testing a particular sample. Laboratories involved in racing chemistry, regulatory enforcement, and GLP studies often have significant sample tracking documents to establish that the result of a test can be tracked to the original specimen. These sample tracking or chain of custody documents are often needed to establish that the sample tested does, in fact, relate to the case report. The absence of sample tracking or such chain of custody data may eviscerate a legal claim. The federal judicial system is aware of this as well. It considers as relevant evidence "Comparison by the trier of fact or by expert witnesses with specimens which have been authenticated."[Rule 901 (3)] Split sample testing in racing chemistry is an example of comparison by an expert witness with authenticated samples. Such split sample testing may be desirable in toxicology cases that reach an insurance claim, civil or criminal case level.

Toxicologists are aware of the potential for different results when different analytical methods are used. This awareness has given rise over the years to recognition of the need to "validate" tests and test results. The federal judicial system is also aware of this need. It requires "[e]vidence describing a process or system used to produce a result and showing that the process or system produces an accurate result."[Rule 901 (9)] AOACI is an example of an entity that validates an analytical method for a particular matrix. The plaintiff has the burden of persuading the judge that the analytical results go with the correct sample, and the results of that sample's testing are on the correct report. Authenticating sample results for such proceedings are one reason for standard operating procedures, quality assurance samples, method validation, split sample testing, and other such procedures.

---

[17] Rule 901. "The requirement of authentication or identification as a condition precedent to admissibility is satisfied by evidence sufficient to support a finding that the matter in question is what its proponent claims."

[18] Rule 901 (7). "Evidence that a writing authorized by law to be recorded or filed and in fact recorded or filed in a public office, or a purported public record, report, statement, or data compilation, in any form, is from the public office where items of this nature are kept."

[19] Rule 901 (8). "Evidence that a document or data compilation, in any form, (A) is in such condition as to create no suspicion concerning its authenticity, (B) was in a place where it, if authentic, would likely be, and © has been in existence 20 years or more at the time it is offered."

[20] 21 CFR 58.

Analytical toxicologists know the limits of interpretation of the results of a given test. However, some who see these reports may not be aware of these limits. So toxicologists may take care in the wording of interpretive comments made.

*Testimony*

Testimony is the third means of introducing evidence. Testimony is often gathered during the discovery portion of a legal case by taking the deposition of witnesses. Testimony may also be given orally at trial. Witnesses are under oath both at the deposition and at trial. Testimony given in a deposition may be entered into evidence at trial. This is sometimes done because the witness is not available on the trial date. Testimony may be given in a deposition, then again at trial by the same person on the same subject.

Testimony is given by both "lay" witnesses and expert witnesses. Admission of testimony from a lay witness is evaluated differently than that of an expert witness. A lay witness must have personal knowledge of the facts to which she or he is testifying. Specifically, "[a] witness may not testify to a matter unless evidence is introduced sufficient to support a finding that the witness has personal knowledge of the matter. Evidence to prove personal knowledge may, but need not, consist of the witness' own testimony. …"[Rule 602]

Lay witnesses must testify to their personal knowledge. This personal knowledge is their recollection of the event. For example, the animal owner in our hypothetical example may testify that she did purchase the feed, that she fed it to her animals, that she observed certain clinical signs in her animals, and that she delivered a dead animal to the veterinary diagnostic laboratory.

The animal owner may be cross-examined to help verify details of the events. The animal owner's recollection may be refreshed by referring to a written document pursuant to Rule 612.[21]

Examples of a writing to which the animal owner may refer are a receipt and a case report from the diagnostic facility or veterinary clinic. The receipt could be used to refresh the memory of the animal owner as to precisely when and where the feed was purchased. The case report could be used to refresh the memory of the animal owner as to when the animal died, when the diagnostic testing was performed, and the results of the testing. An expert witness may be required, however, to interpret the laboratory report.

## ADMISSIBILITY OF EXPERT TESTIMONY

The lay witness is not the only source of testimony. Lay testimony is a source of facts. Some of these facts must be interpreted, which is the role of the expert. Expert testimony is the other main form of introducing testimonial evidence. Expert testimony is commonly used at trial and has become the topic of a number of evidentiary rules. Federal Rules of Evidence 701 through 706 follow in their entirety.[22–27]

Expert testimony must not only be relevant as with a lay witness, but it must also be *reliable*. Discussion of this reliability factor constitutes most of the remainder of this

[21] Except as otherwise provided in criminal proceedings by section 3500 of title 18, United States Code, if a witness uses a writing to refresh memory for the purpose of testifying, either:

(1) while testifying, or

(2) before testifying, if the court in its discretion determines it is necessary in the interests of justice, an adverse party is entitled to have the writing produced at the hearing, to inspect it, to cross-examine the witness thereon, and to introduce in evidence those portions which relate to the testimony of the witness. … If a writing is not produced or delivered pursuant to order under this rule, the court shall make any order justice requires, except that in criminal cases when the prosecution elects not to comply, the order shall be one striking the testimony or, if the court in its discretion determines that the interests of justice so require, declaring a mistrial. Rule 612. As amended March 2, 1987, eff. October 1, 1987.

[22] Rule 701. Opinion Testimony by Lay Witnesses

If the witness is not testifying as an expert, the witness' testimony in the form of opinions or inferences is limited to those opinions or inferences which are (a) rationally based on the perception of the witness, and (b) helpful to a clear understanding of the witness' testimony or the determination of a fact in issue, and (c) not based on scientific, technical, or other specialized knowledge within the scope of Rule 702. (As amended March 2, 1987, eff. October 1, 1987; April 17, 2000, eff. December 1, 2000.)

[23] Rule 702. Testimony by Experts

If scientific, technical, or other specialized knowledge will assist the trier of fact to understand the evidence or to determine a fact in issue, a witness qualified as an expert by knowledge, skill, experience, training, or education, may testify thereto in the form of an opinion or otherwise, if (1) the testimony is based upon sufficient facts or data, (2) the testimony is the product of reliable principles and methods, and (3) the witness has applied the principles and methods reliably to the facts of the case. Rule 702. (As amended April 17, 2000, eff. December 1, 2000.)

[24] Rule 703. Bases of Opinion Testimony by Experts

The facts or data in the particular case upon which an expert bases an opinion or inference may be those perceived by or made known to the expert at or before the hearing. If of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence in order for the opinion or inference to be admitted. Facts or data that are otherwise

chapter. In virtually all legal cases, the judge makes preliminary rulings that determine whether the expert may testify at all, and if so, upon which opinions. Reliability is the primary factor in the judge's determination of admissibility of expert testimony. Two approaches to determine the reliability of expert testimony have evolved, namely the "*Frye* test" and the "*Daubert* test."

### *Frye*

The *Frye* test is the original standard of reliability for expert testimony, and it remains in several state court systems, including Minnesota (see Table 8.1). The *Frye* test is often summarized as the "general acceptance" standard. A brief history of *Frye* may illustrate its use in a legal setting.

In 1923, a defendant was convicted of second degree murder (*Frye*, 1923). The defendant appealed the trial court's ruling because the court[28] did not allow the defendant to offer expert testimony. The expert testimony would have used a precursor to the "lie detector test" known as the "systolic blood pressure deception test" ("SBPD test"). The defendant's expert claimed that the SBPD test could prove whether or not a person being examined by the SBPD was attempting to deceive the examiner or conceal his guilt with regard to the crime. The judge did not allow this testimony, and the defendant was convicted. The ruling was appealed.

**TABLE 8.1 Test of admissibility of expert testimony in some states.[1]**

| *Frye* test | *Daubert* (all three cases) | *Daubert* and *Kumho* only |
|---|---|---|
| Alabama | Arkansas | Kentucky |
| Arizona | Delaware | New Hampshire |
| California | Louisiana | North Carolina |
| Florida | Massachusetts | Ohio |
| Illinois | Mississippi | Rhode Island |
| Kansas | Nebraska | South Dakota |
| Maryland | Oklahoma | |
| Michigan | Texas | |
| Minnesota | Wyoming | |
| Missouri | | |
| New Jersey | | |
| New York | | |
| North Dakota | | |
| Pennsylvania | | |
| Washington | | |

[1] Modified from Bernstein, David E, Jackson, Jeffrey D. Jackson, The Daubert Trilogy in the States, 44 Jurimetrics J 351 (2004).

The court of appeals held that when "admitting expert testimony deduced from a well-recognized scientific principle or discovery, the thing from which the deduction is made must be sufficiently established to have gained general acceptance in the particular field in which it belongs" (*Frye*

inadmissible shall not be disclosed to the jury by the proponent of the opinion or inference unless the court determines that their probative value in assisting the jury to evaluate the expert's opinion substantially outweighs their prejudicial effect.Rule 703. (As amended March 2, 1987, eff. October 1, 1987; April 17, 2000, eff. December 1, 2000.)

[25] Rule 704. Opinion on Ultimate Issue:

(a) Except as provided in subdivision (b), testimony in the form of an opinion or inference otherwise admissible is not objectionable because it embraces an ultimate issue to be decided by the trier of fact.

(b) No expert witness testifying with respect to the mental state or condition of a defendant in a criminal case may state an opinion or inference as to whether the defendant did or did not have the mental state or condition constituting an element of the crime charged or of a defense thereto. Such ultimate issues are matters for the trier of fact alone. (As amended October 12, 1984.)

[26] Rule 705. Disclosure of Facts or Data Underlying Expert Opinion

The expert may testify in terms of opinion or inference and give reasons therefore without first testifying to the underlying facts or data, unless the court requires otherwise. The expert may in any event be required to disclose the underlying facts or data on cross-examination. (As amended March 2, 1987, eff. October 1, 1987; April 22, 1993, eff. December 1, 1993.)

[27] Rule 706. Court Appointed Experts

(a) Appointment: The court may on its own motion or on the motion of any party enter an order to show cause why expert witnesses should not be appointed, and may request the parties to submit nominations. The court may appoint any expert witnesses agreed upon by the parties, and may appoint expert witnesses of its own selection. An expert witness shall not be appointed by the court unless the witness consents to act. A witness so appointed shall be informed of the witness' duties by the court in writing, a copy of which shall be filed with the clerk, or at a conference in which the parties shall have opportunity to participate. A witness so appointed shall advise the parties of the witness' findings, if any; the witness' deposition may be taken by any party; and the witness may be called to testify by the court or any party. The witness shall be subject to cross-examination by each party, including a party calling the witness.

(b) Compensation: Expert witnesses so appointed are entitled to reasonable compensation in whatever sum the court may allow. The compensation thus fixed is payable from funds which may be provided by law in criminal cases and civil actions and proceedings involving just compensation under the fifth amendment. In other civil actions and proceedings the compensation shall be paid by the parties in such proportion and at such time as the court directs, and thereafter charged in like manner as other costs.

(c) Disclosure of appointment: In the exercise of its discretion, the court may authorize disclosure to the jury of the fact that the court appointed the expert witness.

(d) Parties' experts of own selection: Nothing in this rule limits the parties in calling expert witnesses of their own selection.
(As amended March 2, 1987, eff. October 1, 1987.)

[28] The judge is referred to as "the court" in legal writing.

at 1013). This holding is commonly abbreviated as the "general acceptance" test. The trial court decision held, because the defendant had insufficient proof that the SBPD test had gained "general acceptance." Consequently, the defendant's expert was not allowed to testify, so this expert testimony was not entered into evidence, and this evidence was then not available to support an argument to overturn the defendant's conviction.

*Frye* was a federal criminal case, but the holding was later adopted in federal civil cases. Over time, *Frye* was adopted by most state courts for both civil and criminal proceedings. Minnesota reaffirmed its use of *Frye* in *Goeb* v. *Tharaldson*. Minnesota Supreme Court cases on the subject are briefly summarized to illustrate differences with the *Daubert* test below.

Minnesota adopted *Frye* in 1952 in the case of *State* v. *Kolander*. In 1980, Minnesota added an analysis to decide that testimony developed through hypnosis was inadmissible (*State* v. *Mack* at 768–69). Consequently, the Minnesota test for admissibility of novel scientific evidence has evolved into a two-prong *Frye–Mack* standard. The *Frye* prong first requires that a novel scientific technique be generally accepted in the relevant scientific community, then the *Mack* prong requires that the particular evidence derived from that test have a foundation that is scientifically reliable (Goeb at 814, see also State v. Anderson, State v. Jobe, State v. Moore).

The Minnesota Supreme Court reconsidered the *Frye–Mack* two-prong test after *Daubert* passed the United States Supreme Court.[29] It rejected *Daubert* and sustained *Frye–Mack*, stating:

> Having reviewed the cases and the commentary surrounding this issue, we reaffirm our adherence to the Frye–Mack standard and reject Daubert. Therefore, when novel scientific evidence is offered, the district court must determine whether it is generally accepted in the relevant scientific community. See Moore, 458 N.W.2d at 97–8; Schwartz, 447 N.W.2d at 424–26. In addition, the particular scientific evidence in each case must be shown to have foundational reliability. See Moore, 458 N.W.2d at 98; Schwartz, 447 N.W.2d at 426–8. Foundational reliability "requires the 'proponent of a * * * test [to] establish that the test itself is reliable and that its administration in the particular instance conformed to the procedure necessary to ensure reliability.' " Moore, 458 N.W.2d at 98 (alteration in original) (quoting State v. Dille, 258 N.W.2d 565, 567 (Minn., 1977)). Finally, as with all testimony by experts, the evidence must satisfy the requirements of Minn. R. Evid. 402 and 702 – be relevant, be given by a witness qualified as an expert, and be helpful to the trier of fact. (See State v. Nystrom, 596 N.W.2d 256, 259 (Minn., 1999).)

The Minnesota Supreme Court has held that the Frye–Mack standard for admission "facilitates more objective and uniform rulings" and reduces the "undesired element of subjectivity * * * [in] evidentiary rulings" *Schwartz*, at 424 that may occur with *Daubert*. The Minnesota approach requires that an appellate court review a novel scientific or non-scientific technique for reliability before an expert may offer it (*State of Minnesota* v. *DeShay*) including DNA testing by PCR-STR (*State of Minnesota*, v. *Nose*). With very rare exceptions, a layperson may not testify in the form of opinions or inferences (*Ray* v. *Miller Meester*).

However, *Frye* is no longer the standard in federal cases. The *Frye* test was superseded in federal courts by the enactment of the Federal Rules of Evidence (*Daubert* at 589). The *Frye* test has also been replaced by the *Daubert* test in many state court systems (see Table 8.1). The remainder of this section is devoted to *Daubert* since it has been adopted by the federal courts and many state court systems to determine whether expert testimony is, or is not, admitted into evidence today.

### *Daubert*

*Daubert* is one of three United States Supreme Court cases addressing the issue of admissibility of expert testimony. In addition, the Federal Court system has published a Reference Manual on Scientific Evidence to assist judges in applying these rulings. This Reference Manual contains a section devoted to toxicology and a separate section devoted to medical testimony. Much of the material below is summarized from these sources.

Three cases with rulings on the admissibility of expert testimony have reached the United States Supreme Court in recent years. The cases are *Daubert* v. *Merrell Dow Pharmaceuticals*, Inc 509 U.S. 579 (1993), *General Electric Co* v. *Joiner*, 522 U.S. 136 (1997), and *Kumho Tire Co* v. *Carmichael*, 119 S. Ct. 1167 (1999). Both *Daubert* and *General Electric* were toxic tort cases. *General Electric* and *Kumho* are discussed first.

The holdings in *General Electric* and *Kumho* are of legal review and admission of testimony from non-scientists as experts, so they are summarized briefly. The holding in

[29] There have been no developments in Minnesota since Mack and Schwartz to convince us that the Frye–Mack standard is now incompatible with those same rules of evidence in existence at the time of these decisions. Cf. Leahy, 882 P.2d at 328 (reasoning that by applying the Frye standard after the adoption of the evidence code, the California Supreme Court had concluded Frye was compatible with the code); State v. Copeland, 922 P.2d 1304, 1314 (Wash. 1996) (noting that by adopting the rules of evidence and continuing to adhere to Frye, the Washington Supreme Court "signaled that Frye and the evidence rules coexist as the law of th[e] state [of Washington]").

*General Electric* is primarily of legal interest. In *General Electric*, the Supreme Court held that the correct standard for an appellate court to apply in reviewing a district court's evidentiary ruling is an "abuse of discretion" standard. This holding most commonly has the effect of strengthening the decision made by the district court whether it is to admit or to not admit the expert testimony. Of interest to toxicologists and other scientists, is the urging by Justice Breyer in *General Electric* that judges avail themselves of court appointed experts (General Electric at ...). *Kumho Tire* is not directly on point for toxicologists either.

The Supreme Court held in *Kumho Tire* that the phrases "technical" and "other specialized" knowledge in the Federal Rule of Evidence 702, allows testimony from those with "skill" or "experience" based expertise and not just "science" based expertise. The Supreme Court held that an expert in tire failure analysis could testify as an expert even though his expertise was "skill" or "experience" based, rather than "science" based *(Kumho* at 1171). The *Frye–Mack* test in Minnesota offers very few exceptions to the rule that lay witnesses may not give expert testimony. The holdings in *Daubert* are of most direct interest to toxicologists, and other scientists.

Expert testimony is different from lay testimony. One difference is the possibility that "junk science" may be used to confuse, rather than assist, the trier of fact. Consequently an additional test of admissibility is applied to expert testimony. Such testimony must not only be relevant, but it must also be *reliable*. This concept is explained in the *Daubert* case. Justice Breyer, "believe[s] there is an increasingly important need for law to reflect sound science" (Justice Breyer, in the Reference Manual on Scientific Evidence, p. 5). Justice Breyer also writes in the Manual on Scientific Evidence:

> The judge is the evidentiary gatekeeper (*General Electric Co* v. *Joiner*, 522 U.S. 136 (1997); *Daubert* v. *Merrel Dow Pharms Inc*, 509 U.S .579 (1993)). "The judge, without interfering with the jury's role as trier of fact, must determine whether purported scientific evidence is "reliable" and will "assist the trier of fact" thereby keeping from juries testimony that, in Pauli's sense, isn't even good enough to be wrong. Justice Breyer, in Manual on Scientific Evidence, p. 6.
>
> The purpose of Daubert's gatekeeping requirement "is to make certain that an expert whether basing testimony upon professional studies or personal experience, employs in the courtroom the same level of intellectual rigor that characterizes the practice of an expert in the relevant field." *Kumho Tire Co* v. *Carmichael*, 119 S. Ct. 1167 (1999) at 1176. See also, *Rosen* v. *Ciba-geigy Corp*, 78 F.3d 316 (7th Cir) cert denied, 519 U.S. 819 (1996) at 318.

Clearly, the United States Supreme Court in *Daubert* assigned the trial judge a "gatekeeping" responsibility. This responsibility is to make a "preliminary assessment of whether the reasoning or methodology underlying the testimony is scientifically valid and whether that reasoning or methodology properly can be applied to the facts in issue" (*Daubert* at 589). The "gatekeeper" function requires district court judges to screen proffered expert testimony (*Daubert* at 589). This screening is intended to ensure that expert testimony "is not only relevant, but reliable" (*Daubert* at 589). To be relevant, the testimony "requires a valid scientific connection to the pertinent inquiry as a precondition to admissibility" (*Daubert* at 591–2). Much has been written about the reliability portion of this screening.

To meet the reliability standard, the judge must determine whether testimony is "grounded in the methods and procedures of science" (*Daubert* at 590). Consequently, an expert must account for "how and why" he or she reached the expert opinion (Kumho at note 27). The judge's determination is "flexible" (*Daubert* at 594), so the trial judge has broad latitude to determine *how* to test an expert's reliability (Kumho at 1176), and this determination may be different in a criminal case than in a civil one (Kumho at 1176). Nevertheless, guidelines for determining the reliability of expert testimony exist.

Four factors were presented in *Daubert* to assist the judge in determining whether a theory or technique has been derived by the scientific method (*Daubert* at 593–94). These four factors are used to determine the theory's testability (*Carmichael* at 1522), because "[w]hether [a theory or technique] can be (and has been) tested" is the "methodology [that] distinguishes science from other fields of human inquiry" (*Daubert* at 593). In short, the four factors are testability, peer review or publication, the existence of known or potential error rates, and standards controlling the techniques' operation (*Daubert* at 593).

In summary, the trial judge decides whether or not expert testimony is allowed. The means by which the judge makes this decision is flexible, but the judge often tests both the credentials of the expert and the opinion that expert offers. The expert's opinion must meet "the same standard of intellectual rigor" inside the court room as outside of it (*Kumho* at 1176). This showing of intellectual rigor requires that the expert demonstrate both "how and why" the opinion was reached. This may be done by satisfying four factors, namely (1) whether the theory or technique can be tested, (2) whether it is published or peer reviewed, (3) whether it has known or potential error rates, and (4) what the control standards are.

These factors may be applied to both the analytical and interpretive portions of a toxicology case. Both *Daubert* and *General Electric* were toxic tort cases. This may be one reason that a chapter devoted to toxicology appears in the Reference Manual for Scientific Evidence. This Manual

offers some questions to be asked of purported toxicology experts.

Three questions may be asked in the evaluation of a toxicology expert to determine whether the expert's testimony is reliable – and therefore admissible. These questions may be reduced to (1) is the expert qualified, (2) has general causation been established, and (3) has specific causation been established?

### *Is the expert qualified?*

The individual wanting to be allowed to testify as an expert must be "qualified as an expert by knowledge, skill, experience, training, or education, …"[Rule 702] Toxicologists are often argued to be experts based on education, board certification, and other means. Although "… no single academic degree, research specialty, or career path qualifies an individual as an expert in toxicology. … A number of indicia of expertise can be explored, …" (Reference Guide on Toxicology at 415).

1 *Has the person been trained and educated in the discipline of toxicology?*

An advanced degree in toxicology presumptively supports the argument that the person has been trained and educated in the discipline of toxicology. One may go to the credentialing and other means portions of the analysis if the person possesses an advanced degree in toxicology. Not all toxicologists possess such a degree, however.

Many well-qualified toxicologists do not have an advanced degree in toxicology, but do have an advanced degree in related disciplines such as pharmacology, biochemistry, environmental health, industrial hygiene, or other similar fields (Reference Guide on Toxicology at 415). However, not all individuals in possession of these related degrees are toxicologists. So further evidence of training and education is often required of those who do not have an advanced degree in toxicology but do have an advanced degree in a related discipline.

This training and education is often in the form of college level course work or continuing education programs. The number of required courses in toxicology cannot be stated, but one such course is not enough. Specifically, "a single course in toxicology is unlikely to provide sufficient background for developing expertise in the field" (Reference Guide on Toxicology, p. 415). "A physician without particular training or experience in toxicology is unlikely to have sufficient background to evaluate the strengths and weaknesses of toxicological research (see Mary Sue Henifin). "[M]ost physicians have little training in chemical toxicology and lack an understanding of exposure assessment and dose–response relationships"(Mary Sue Henifin). The same is true for veterinarians, and many other health care professionals. So, while the number of college courses, continuing education, or other training programs required to support an argument that one is a toxicologist is not established, one such course is most likely too few. Consequently, an MD or DVM without an advanced degree in toxicology may well be found to not be a toxicologist based on training and education if they have only a course in professional school to support the claim. Certification is another way to support the argument that one is a toxicologist.

2 *Has the person been certified as a toxicologist?*

Some professions have a subspecialty in toxicology with a board certification. Physicians may be certified by the American Board of Medical Toxicology.[30] Veterinarians may be certified by the American Board of Veterinary Toxicology.[31] The American Board of Toxicology (ABT) was established to provide certification of individuals trained and experienced in toxicology without consideration of whether the individual has a professional Medical or Veterinary Medical degree.[32] However, individuals with an MD or DVM degree may also take the ABT certifying examination. A very few individuals are certified by more than one of these boards. Certification by other boards may be relevant for a particular legal case. A person with an advanced degree in toxicology and board certification has strong support for an argument that they are a toxicologist. This may be one reason that the American Association of Veterinary Laboratory Diagnosticians (AAVLD) requires a board certified toxicologist be on staff for an accredited laboratory. A person with an advanced degree but no board certification, or board certification but no advanced degree, may have other criteria to support a finding that they are a toxicologist.

3 *Do other criteria support an argument that the person is a toxicologist?*

Such other criteria may be membership in one or more toxicology organizations, peer-reviewed or other publications, research grants, scientific advisory panels, university appointments, and the like (Mary Sue Henifin p. 418). These criteria are often documented in one's resume or curriculum vitae.

So, a person with a professional degree, plus an advanced degree in toxicology, plus board certification in toxicology, plus membership in one or more toxicology organizations, peer-reviewed toxicology literature, grants, service on scientific advisory panels, and a university appointment has very strong support for an argument that they are an expert in toxicology. On the other hand, a person with a professional degree, no advanced degree in toxicology, no board certification in toxicology,

[30] A list of approved medical subspecialties is available at: http://www.abms.org/approved.asp

[31] www.abvt.org

[32] www.abtox.org

and no other publications, grants, and the like has a very weak argument, if any, that they are an expert in toxicology. The courts recognize the distinction between a professional degree and expertise required in a legal setting. This distinction is aptly described in *Wynacht* v. *Beckman Instruments*.

> There is a fundamental distinction between Dr. Z…'s ability to render a medical diagnosis based on clinical experience and her ability to render an opinion on causation of W…'s injuries. Beckman apparently does not dispute, and the Court does not question, that Dr. Z is an experienced physician, qualified to diagnose medical conditions and treat patients. The ability to diagnose medical conditions is not remotely the same, however, as the ability to deduce, delineate, and describe, in a scientifically reliable manner, the causes of these medical conditions.

Many combinations of education, certification, and other criteria that fall between the two above extremes are possible for toxicology experts. These would, of course, be decided by the judge in a specific case. Once found to be an expert, the toxicologist will most likely be asked to give an opinion on general causation.

## General causation

"[T]he methodology prescribed by both the World Health Organization (WHO) and the National Academy of Sciences (NAS) for determining whether a person has been adversely affected by a toxin" have been described in *Mancuso* v. *Consolidated Edison Co*. as a three step procedure. Scientific validity may be argued in three steps "(1) the validity of the underlying principle, (2) the validity of the technique applying the principle, and (3) the proper application of the technique on a particular occasion." (Paul C. Giannelli)

> First, the level of exposure of plaintiff to the toxin in question must be determined; second, from a review of the scientific literature, it must be established that the toxin is capable of producing plaintiff's illness – called "general causation" – and the dose/response relationship between the toxin and the illness – i.e. the level of exposure which will produce such an illness – must be ascertained; and third, "specific causation" must be established by demonstrating the probability that the toxin caused this particular plaintiff's illness, which involves weighing the possibility of other causes of the illness – a so-called "differential diagnosis." (*Mancuso* at 399)
>
> Toxicologists may arrive at an expert opinion in a variety of ways. "The basis of the toxicologist's expert opinion in a specific case is a thorough review of the research literature and treatises concerning effects of exposure to the chemical at issue. To arrive at an opinion, the expert assesses the strengths and weaknesses of the research studies. The expert also bases an opinion on fundamental concepts of toxicology relevant to understanding the actions of chemicals in biological systems." (Manual on Scientific Evidence at 415)

Two key legal concepts of causation have emerged as courts have attempted to keep junk science out of the courtroom. These concepts are general causation and specific causation. The discussion of specific causation follows in the next section.

"Causation is frequently a crucial issue in toxicology cases. Establishing causation means providing scientific evidence from which an inference of cause and effect may be drawn" (Reference Manual on Scientific Evidence at 32). The Manual goes on to describe the process of arriving at general causation.

> Once the expert has been qualified, he or she is expected to offer an opinion on whether the plaintiff's disease was caused by exposure to a chemical. To do so, the expert relies on the principles of toxicology to provide a scientifically valid methodology for establishing causation and then applies the methodology to the facts of the case.
>
> "An opinion on causation should be premised on three preliminary assessments. First, the expert should analyze whether the disease can be related to chemical exposure by a biologically plausible theory. Second, the expert should examine if the plaintiff was exposed to the chemical in a manner that can lead to absorption into the body. Third, the expert should offer an opinion as to whether the dose to which the plaintiff was exposed is sufficient to cause the disease." (Reference Guide on Toxicology at 419)

Courts define general causation as "the capacity of a product to cause injury" (Siharath). General causation is a scientifically established cause-and-effect relationship. To satisfy this burden, sufficient testing must be done to establish that a disease or condition can arise after exposure to a certain substance. Peer-reviewed literature of epidemiology studies, case reports, *in vitro*, and animal studies may be used to support a general causation argument.

A toxic tort plaintiff must first show that the substance to which he was allegedly exposed is capable of causing his injury – general causation (see e.g. Raynor 7). General causation asks whether exposure to a substance causes harm to anyone (see Navigating Uncertainty).

In short, is the alleged chemical capable of causing the disease observed at any dose or exposure? In our hypothetical above, has the chemical that was added to the feed additive been shown to cause the clinical signs and lesions observed in the species of animal in this case? If not, the expert's testimony may not be allowed in the case. If so, an analysis of specific causation would be required.

## SPECIFIC CAUSATION: THE DIFFERENTIAL DIAGNOSIS

General causation answers the question of whether the chemical in question may cause the disease observed. Specific causation is aimed at answering the question of whether the chemical in question did in fact cause the disease in the specific case at hand. This concept has been stated in a variety of ways. Specific causation is "proof that the product in question caused the injury of which the plaintiff complains" (*Siharath*). It is a tendency to show that the person's alleged exposure, in fact, caused his or her condition (*Siharath* at see also DT Ralston). In other words, it is a showing that the said exposure was the actual cause of the injury (see e.g. Raynor). An analysis of specific causation answers the question of whether exposure to the specific chemical in question did or did not cause the disease experienced by the plaintiff, or in the hypothetical, plaintiff's animals. The specific causation analysis requires consideration of other potential causes of the disease.

Consideration of other causes of the disease is termed differential diagnosis. Differential diagnosis is a common occurrence in the practice of medicine. Differential diagnosis evidence is often crucial to show specific causation (see Lennon). Without some evidence that the substance in question caused the specific injury to the specific plaintiff, courts are likely to grant the defendant summary judgment. Courts generally agree that, whenever there are different causes for the plaintiff's disease, an expert must perform a differential diagnosis before testimony will be admitted (see Gianelli). Courts accept the general validity of the technique of differential diagnosis (US versus Downing). An expert opinion based on a properly performed differential diagnosis analysis is not likely to be inadmissible (*Westberry* at 263). More specifically, "[t]o the extent that a doctor utilizes standard diagnostic techniques in gathering this information, the more likely we are to find that the doctor's methodology is reliable" (In *re* Paoli, at 758).

Put differently, "[a]n expert who opines that exposure to a compound caused a person's disease engages in deductive clinical reasoning. … The opinion is based on an assessment of the individual's exposure, including the amount, the temporal relationship between the exposure and disease, and other disease-causing factors. This information is then compared with scientific data on the relationship between exposure and disease. The certainty of the expert's opinion depends on the strength of the research data demonstrating a relationship between exposure and the disease at the dose in question and the absence of other disease-causing factors (also known as confounding factors)." (Reference guide at 422–3, see also Joseph Sanders).

However, simply stating that a differential diagnosis was performed is not enough. This issue was discussed in *Viterbo*:

> We do not hold, of course, that admissibility of an expert opinion depends upon the expert disproving or discrediting every possible cause other than the one espoused by him. Here, however, Dr. Johnson has admitted that Viterbo's symptoms could have numerous causes and, without support save Viterbo's oral history, simply picks the cause that is most advantageous to Viterbo's claim. Indeed, Dr. Johnson's testimony is no more than Viterbo's testimony dressed up and sanctified as the opinion of an expert. Without more than credentials and a subjective opinion, an expert's testimony that "it is so" is not admissible. (*Viterbo* v. *Dow Chemical*)
>
> This formulation is repeated by Judge Becker in *United States* v. *Downing.*
>
> The process of differential diagnosis is undoubtedly important to the question of "specific causation." If other possible causes of an injury cannot be ruled out, or at least the probability of their contribution to causation minimized, then the "more likely than not" threshold for proving causation may not be met. But, it is also important to recognize that a fundamental assumption underlying this method is that the final, suspected "cause" remaining after this process of elimination must actually be capable of causing the injury. That is, the expert must "rule in" the suspected cause as well as "rule out" other possible causes. And, of course, expert opinion on this issue of "general causation" must be derived from a scientifically valid methodology. (*Cavallo* v. *Star Enterprise*)

The order of proving causation is important. General causation should be proven first, then the specific causation differential diagnosis analysis. In virtually all cases, differential diagnosis does not provide general causation – it can only provide specific causation.[33] This may be part of the reasoning that argues that epidemiological data

[33] See generally, *Raynor* v. *Merrell Pharmaceuticals*, 101 F.3d 129, 138–39 (D.C. Cir. 1996). See also, *Kelly, Grimes, Rutigliano, Hall*, In *re* Breast Implant, National Bank of Commerce and Wynacht.

is rarely determinative in a specific causation analysis, and is most commonly used in the general causation argument.

To show that said exposure was the actual cause of the injury, toxic tort plaintiffs must prove the admissibility of their expert testimony in both general causation and specific causation context by a preponderance of proof (*Daubert* at 593). A successful plaintiff must not only show that, more likely than not, the substance can cause the injury in question, but also that, more likely than not, the plaintiff's specific injury was in fact caused by the substance (*DeLuca*, Ronald J. Allen).

A *Daubert* analysis should be performed. In fact, "a trial court that fails to justify its decision not to use *Daubert* factors risks reversal" (*Black* v. *Food Lion*). *Daubert* factors may be used when assessing the admissibility of clinical medical testimony (*Moore*). This opinion is because reliable opinions are reached using the "methods and procedures of science." Scientific validity is the foundation of "*evidentiary reliability*" (*Daubert* at 590, see also, Bert Black *et al.*).

So the expert in our case must not only rule in the chemical added to the feed additive as the cause of the clinical signs and lesions observed, but must also rule out other diseases that cause these clinical signs or lesions in that species of animal.

## APPLICATION OF DAUBERT IN TOXICOLOGY CASES

The application of these legal rules to specific toxicology cases may be useful. Testimony may be weakened if there is no Daubert inquiry at all (Goebel, 2000).

The differential diagnosis portion of analyzing specific causation is important. Expert testimony from a forensic toxicologist has been properly excluded for insufficient proof to rule in the chemical in question and to rule out other diseases (Wills, 2004). The testimony of a toxicologist was properly excluded because the toxicologist was not a medical doctor and therefore not qualified to offer reliable differential diagnosis analysis (Plourde, 2003) On the other hand, testimony was properly allowed from two marine biologists who each performed a differential diagnosis analysis in a case involving marine animals (Clausen, 2003).

Dose is important in toxicology cases. Testimony of a treating physician, toxicologist, and industrial hygienist were excluded, and the exclusion affirmed because the literature did not support a finding of general causation at the relevant exposure (Amorgianos, 2002). Testimony of a toxicologist was properly excluded because he performed no dose assessment and showed no statistically significant link between the chemical and the type of cancer present (Burleson, 2004).

Reliance on peer-reviewed literature is also important. A toxicologist's testimony was excluded, but the exclusion was reversed, because the toxicologist's testimony was supported by peer-reviewed literature (Bocanegra, 2003).

## SOME QUESTIONS TO CONSIDER WHEN USING LABORATORY RESULTS IN A LEGAL CASE

1 Was the legal aspect of the case known at the time the samples were submitted? If not, is the sample tracking or chain of custody sufficiently well documented to establish each relevant step of the analysis? Can the relevance of the documents be authenticated? Does chain of custody or sample tracking documentation exist?
2 What type of legal venue is the work to be used in? Administrative enforcement, civil litigation, criminal litigation? What standard of persuasion is appropriate for this venue?
3 Can the relevance of the analytical results be authenticated? What documentation exists that the samples were collected from the appropriate animal? What documentation exists to demonstrate proper sample identification throughout the laboratory testing process? What documentation exists to demonstrate that the process used produces an accurate result – what validation processes are in place? Is the interpretation of the test results accurate for the type of analytical test performed?
4 Is the testimony to be as a lay – or fact – witness?
5 Is the testimony to be as an expert witness?
   A Is the expert a toxicologist?
   B Does the scientific literature support an argument of general causation?
   C Was a differential diagnosis performed by the laboratory?
      - Rule-in:
         – Can the expert provide reliable testimony that the sample received by the laboratory is representative of the diseased animals?
         – Can the expert provide reliable testimony that the animals were in fact exposed to a toxic dose of the chemical in question? To what degree of certainty does the analytical methodology demonstrate exposure of the animal to the chemical in question?
         – Can the expert provide reliable testimony that the animals experienced the disease expected from exposure to a toxic dose of the chemical in question? Is reliable testimony of the clinical signs and lesions available?

- Rule-out:
  - Can the expert provide a differential diagnosis list?
  - Can the expert provide reliable testimony that diseases other than the purported one were ruled out? Can the expert explain how and why these other diseases were ruled out? Were scientifically valid methods used to rule out these diseases?

## ACKNOWLEDGMENT

My sincere appreciation to Kevin Conard, Drs. Roger McClellan, Richard Huston, Beth Thompson, Judith Kashman, Betsy Aird, and federal employees who asked to not be named, for reviewing this chapter and providing their valuable insight.

## Organ Toxicity

*This page intentionally left blank*

CHAPTER

# 9

# Neurotoxicity

*Donna Mensching and Petra A. Volmer*

## INTRODUCTION

Neurotoxicants abound. Some of the most potent, well-known neurotoxicants are "all natural" and all around us. The toxin of the anaerobic bacterium *Clostridium botulinum*, for instance, is popularly considered to be the most toxic natural substance on the planet. Just 1 ng is lethal to a human (Kotsonis *et al*., 2001). Strychnine, a rodenticide commercially available in some geographic regions today, is a toxic alkaloid first isolated from the seeds of *Strychnos nux vomica* and *S. ignatii* hundreds of years ago (Talcott, 2006). The deadly venom of the brilliant Australian blue-ringed octopus (*Hapalochlaena maculosa* and *H. lunulata*) contains tetrodotoxin (TTX) which causes respiratory paralysis and death within minutes of a sting via blockade of sodium channels (Scheumack *et al*., 1978; White, 1995).

Many toxicants of human historical significance affect the nervous system. One of the most notorious toxicoses occurred in Minamata Bay, Japan, in the 1950s and for decades to follow when thousands of people were affected with neurologic deficits due to the ingestion of fish contaminated with mercury. The bay had been contaminated by the Chisso Corporation, which used the mercury in the manufacture of acetaldehyde, a plastic intermediate. Over time, the mercury bioaccumulated in the fish causing neurologic deficits in the people and animals that ingested them. Due to their advanced cerebellar ataxia, resident cats that subsisted on these fish were described as "suicidal" and were often seen falling into the water (Smith and Smith, 1975; Francis, 1994). Mercury toxicosis has invaded popular culture as well. The phrase "mad as a hatter" did not originate with Lewis Carroll's *Alice in Wonderland* (1865) but was popularized years prior. It stemmed from the bizarre behavior of hat manufacturers who used mercury in the curing process of the felt and ultimately suffered neurotoxic effects from the occupational exposure (Francis, 1994).

In addition to the plethora of "all natural" neurotoxicants, a multitude of synthetic pesticides (insecticides, rodenticides, etc.) directed at the nervous system of target species has been developed. One example of historical significance was the delayed neuropathy associated with the intentional contamination of Jamaican ginger alcohol ("Jake") with tri-*ortho* cresyl phosphate (TOCP), an organophosphorus (OP) compound, during the Prohibition years. The TOCP was present in lindol, a substitute solvent added to the Jake in 1929 by Hub Products Corporation president, Harry Gross, to cut costs. The resulting upper motor neuron spasticity and paralysis affected more than 50,000 people and were irreversible (Woolf, 1995).

The efficacy of such compounds, natural or manmade, against non-target species, unfortunately, underscores the importance of a thorough understanding of neurotoxic mechanisms in veterinary medicine. Because of its unique anatomy, specialized functions, and high-metabolic requirements, the nervous system is highly susceptible to toxic effects, often despite adaptations to protect itself (i.e. the blood–brain barrier). The following discussion addresses the basic structural and functional causes of neurotoxicity.

## STRUCTURAL TOXICOSES

Structural changes caused by neurotoxicants can be further divided into those that cause a neuronopathy, an axonopathy, or a myelinopathy.

## Neuronopathy

A neurotoxicant that results in neuronopathy directly targets the neuronal cell body, resulting in cell death and secondary axonal degeneration. Gliosis, proliferation of astrocytes and/or microglial cells, is a common response to loss of neurons (Anthony *et al.*, 2001). With few exceptions, this type of injury is irreversible. Examples of such toxicants include the aforementioned methyl mercury which preferentially targets the cell bodies of the occipital cortex and the cerebellum via an unproven mechanism. Blindness and motor incoordination are common manifestations of lesions in these areas. Atchison (2005) postulates that the selective toxicity to cerebellar granule cells is due to the stimulation of $M_3$ muscarinic acetylcholinergic receptors and inhibition of $GABA_A$ (gamma aminobutyric acid) receptors. In veterinary medicine, methyl mercury intoxication is most likely seen in animals that subsist on a diet of contaminated fish, as with the "dancing" cats of Minamata Bay.

A second example of a neuronotoxicant is the heavy metal, trimethyltin [$(CH_3)_3Sn$], used as a plasticizer and antifungal agent (Anthony *et al.*, 2001). It causes diffuse injury, but the pyramidal cells of CA1, CA3, and CA4 regions of the hippocampus are most sensitive. Signs experimentally produced in rats include aggression, increased irritability, tremors, seizures, and hyperactivity (Shin *et al.*, 2005). Like methyl mercury, the mechanism of trimethyltin neuronopathy is not well understood.

A third example of a toxicant that can directly target neurons of particular relevance in veterinary medicine is the anthracycline glycoside antineoplastic agent, doxorubicin (Adriamycin®). Its potential for bone marrow suppression and cardiac toxicity with veterinary use, however, is much greater than its neurotoxic potential (Anthony *et al.*, 2001; Plumb, 2005). Although doxorubicin exerts its antineoplastic effect via interference with transcription, the neurons of the dorsal root ganglia and autonomic ganglia are most susceptible to injury. The selectivity of the effect is thought to be due to a lack of blood–tissue barrier within the ganglia (Anthony *et al.*, 2001).

Domoic acid, the neurotoxicant responsible for amnesic shellfish poisoning (ASP) in people and wildlife, is produced by the diatom *Pseudo-nitzschia* spp. Popular belief holds that Alfred Hitchcock's 1963 movie, "The Birds" was inspired by an outbreak of domoic acid poisoning among California seabirds in 1961. The toxin is thought to exert its excitatory and cytotoxic effects on hippocampal cells due to its high affinity for binding to the kainate receptor, which is a glutamate receptor subtype. Cellular excitation ensues, resulting in an influx of $Ca^{2+}$ ions, upregulation of the c-Fos gene, and cell death (Jeffery *et al.*, 2004).

A large animal example of neuronotoxicosis is yellowstar thistle (*Centaurea solstitialis*) ingestion by horses which occurs typically in the dry summer and fall. It results in neurologic signs including involuntary lip and tongue movements, difficulty in prehending food, tremors, writhing, possible circling, persistent slow movements (dystonia), and significant weight loss. The disease is also called nigropallidal encephalomalacia as a result of the areas of the brain that are uniquely affected (the globus pallidus and the pars reticularis of the substantia nigra). These regions and the clinical signs draw a striking similarity to Parkinson's disease in people (Burrows and Tyrl, 2001; Sanders *et al.*, 2001) which has been associated with selective loss of dopaminergic neurons (van den Munckhof *et al.*, 2006). Several guaianolide sesquiterpene lactones have been isolated from *Centaurea* species. *In vitro* ranking of their toxicity in order of most to least reveals repin, subluteolide, janerin, cynaropicrin, acroptilin, and solstitialin. Cynaropicrin and an analog of solstitialin are cytotoxic in primary cultures of rat substantia nigra cells, and thus raise further suspicion for their role in the toxicosis. Aspartic and glutamic acids, two excitatory amino acid neurotransmitters, are also present in *Centaurea* (Burrows and Tyrl, 2001). Their role, if any, in the mechanism of nigropallidal encephalomalacia has yet to be determined.

A final example of a neuronopathic toxicant is currently a common drug of abuse called methylenedioxyamphetamine (MDMA) or "Ecstasy." MDMA selectively targets serotonergic and dopaminergic cells depending on the species exposed, and long-term, irreversible effects may be seen (Gouzoulis-MayFrank and Daumann, 2006). Acute physiologic effects in people include tachycardia, hypertension, euphoria, heightened sexual awareness, urinary urgency, nausea, chills, sweating, and hyperthermia, among others. Signs consistent with serotonin syndrome (hyperactivity, agitation, mental confusion, hyperthermia, tachycardia, and tremors) have been observed in experimentally exposed rats (Easton and Marsden, 2006). Further research is indicated to define species-specific effects, particularly the extent to which serotoninergic or dopaminergic neurons are involved. Veterinary practitioners should be aware of the potential for accidental exposure to small animals.

## Axonopathy

The second class of structural lesions caused by neurotoxicants is axonopathy. With damage to the axon, the neuronal cell body remains intact, but the portion of the axon distal to the lesion degenerates, resulting in a "chemical transection" distal to the lesion that is functionally identical to a physical transection of the axon. This is also known as Wallerian or axonal degeneration. Changes in the Nissl substance, the protein synthetic material comprising of free polyribosomes and rough endoplasmic reticulum, become evident histologically in response to this degeneration. These changes include chromatolysis

(dissolution of the Nissl substance) as well as margination of the Nissl and the nucleus to the periphery of the cell body. Not surprisingly, those neurons with axons of greatest length are most susceptible to axonal damage. To highlight the susceptibility of distal axons, a subclassification of axonopathy affecting these axons has been termed "central peripheral distal axonopathy." This is in contrast to "central peripheral proximal axonopathy" which involves axons proximal to the spinal cord (Anthony *et al.*, 2001). A third subclassification of axonopathy has been termed "dying back axonopathy." The latter represents progressive death of the axon toward the cell body with time and continued injury. In the peripheral nervous system (PNS), the prognosis for at least partial regeneration is good, but this is less true in the central nervous system (CNS). Secondary demyelination is also possible with axonal injury (Mandella, 2002). Both sensory and motor axons can be affected.

Many agents cause axonopathies, yet a few are particularly relevant to veterinary medicine. The first example, commonly used as an antineoplastic drug, is the vinca alkaloid, vincristine, which is derived from the periwinkle plant, *Vinca rosea* or *Catharanthus rosea*. Vincristine exerts its therapeutic effect by binding to tubulin, inhibiting microtubular formation, disrupting the formation of the mitotic spindle, and arresting cell division at metaphase (Burrows and Tyrl, 2001; Roder, 2004a). Neurotoxicity in the form of axonal degeneration can occur as a result of disruption of fast axonal transport (rate of 400 mm/day normally) which relies on functional integrity of the microtubules (Anthony *et al.*, 2001). Cats are more sensitive to the neurotoxic potential of vincristine. With discontinuation of therapy and appropriate supportive care, animals exhibiting signs of peripheral neuropathy may improve over several weeks to months (Roder, 2004a). Colchicine, an antimetabolite derived from the autumn crocus (*Colchicum autumnale*) and the glory lily (*Gloriosa* spp.), also inhibits spindle formation (Burrows and Tyrl, 2001; Roder, 2004a). It is used in veterinary medicine for the treatment of amyloidosis associated with Shar Pei fever (Loeven, 1994). Although reported rarely in humans, no published reports of peripheral neuropathy in veterinary patients were found.

A more common yet fortunately still rare cause of neurotoxicosis in veterinary medicine is metronidazole. A nitroimidazole antibacterial and antiprotozoal agent used to treat *Giardia* and anaerobic intestinal bacterial overgrowth in small animals (Plumb, 2005), metronidazole can result in a sensory peripheral neuropathy manifesting as proprioceptive deficits (Gupta *et al.*, 2000) as well as CNS effects including ataxia, nystagmus, head tilt, and seizure activity (Plumb, 2005). Myelinated fibers are most commonly affected (Anthony *et al.*, 2001). The mechanism is unknown for both peripheral and central effects.

A final example of a class of agents that can cause axonopathy are the organophosphorus compounds (OPs), commonly used as insecticides, that can result in signs of neuropathy 7–10 days post-exposure, termed OP-induced delayed neuropathy or OPIDN. An example is the previously described TOCP contamination of Ginger Jake (Woolf, 1995). In addition to humans, hens have also been shown to be very sensitive to OPIDN (Damodaran *et al.*, 2001). The neuropathy associated with OPs is thought to involve slow axonal transport macromolecules such as actin and tubulin (Zhao *et al.*, 2005) which involves movement of the neuronal cytoskeleton at a rate of 1–4 mm/day (Anthony *et al.*, 2001).

## Myelinopathy

Myelin is produced by the oligodendrocytes of the CNS and Schwann cells of the PNS. It is composed of lipid and forms a sheath around certain axons, namely those of the cranial and spinal nerves. It functions to increase the speed of impulse conduction by creating isolated areas of heightened electrical excitability, termed nodes of Ranvier (Spencer, 2000). Myelin gives white matter its characteristic appearance. Toxicants that result in myelinopathy may affect the myelin itself or target the cells that produce myelin. The insult may result in loss of myelin (demyelination) or edema of the myelin sheath and subsequent separation of myelin lamellae. Remyelination of segmentally demyelinated areas can occur more so in the PNS than the CNS. When peripheral nerves are remyelinated, the process involves more Schwann cells compared to the initial myelination. As a result, the nodes of Ranvier in remyelinated peripheral nerves are closer (Anthony *et al.*, 2001).

Two examples of toxicants that result in intramyelinic edema and separation of the myelin lamellae are hexachlorophene and bromethalin. The former is an antibacterial agent commonly marketed decades ago as pHisoHex® and still commercially available for the treatment and prevention of *Staphylococcal* infections. The latter is a relatively new rodenticide that has been available for roughly 20 years now and is marketed under a variety of tradenames including Assault®, Sudden Death®, and Vengeance.® The mechanism by which hexachlorophene and bromethalin cause intramyelinic edema is due to the uncoupling of oxidative phosphorylation (Anthony *et al.*, 2001; Dorman, 2004). This uncoupling results in decreased $Na^+/K^+$-ATPase activity, weakened ion gradients, and retention of water in the myelin lamellae (van Lier and Cherry, 1988). The use of mannitol or diuretics early in the course of the disease may reverse mild changes, but continued swelling of the lamellae results in a dramatic increase in intracranial and cerebrospinal fluid (CSF) pressure that is typically unresponsive to therapy. Clinical signs in an acute toxic exposure include muscle tremors, hyperthermia, generalized seizures, hyperexcitability, hyperesthesia, and death within several hours of ingestion (4–18 h) for bromethalin.

Cats are more sensitive to bromethalin than dogs with a minimum lethal oral dose of 0.45 mg/kg versus 2.5 mg/kg in the dog (Dorman, 2004). At lower dosages, hind limb ataxia and paresis can develop in dogs and cats within 2–7 days of ingestion. Signs may include decreased or absent proprioception, loss of response to deep pain, upper motor neuron bladder paralysis, patellar hyperreflexia, and varying degrees of CNS depression. These sublethal effects may be spontaneously reversible with time (1–2 weeks). Histologic lesions consistent with bromethalin and hexachlorophene toxicosis include spongy degeneration (diffuse vacuolation) of the white matter of the CNS. Confirmation of a fatal bromethalin toxicosis can be accomplished by identifying the parent compound and/or its more toxic metabolite, desmethylbromethalin, in the liver. Due to their relative inability to metabolize bromethalin into desmethylbromethalin, guinea pigs are resistant to its toxic effects. Treatment of exposed susceptible species is largely aimed at initial decontamination via induction of emesis (in those species that can vomit) and administration of multiple doses of activated charcoal prior to the onset of clinical signs (Dorman, 2004).

Another toxicant which results in myelinopathy is inorganic lead. The peripheral neuropathic manifestation of lead intoxication is secondary to the segmental degeneration of myelin in distal motor fibers and is most commonly seen in veterinary medicine with chronic intoxication of horses. Sensory function is spared. Clinical signs may include dysphagia and secondary weight loss, ataxia, dysphonia, laryngeal paralysis ("roaring"), and facial nerve deficits. The CNS and other organs may be affected resulting in seizures, depression, secondary aspiration pneumonia, colic, and death (Gwaltney-Brant, 2004).

## FUNCTIONAL TOXICOSES

Most neurotoxicants exert their functional effects via the exquisitely orchestrated mechanisms involved in neurotransmission yet leave no structural footprint of their activity. This can occur at all levels within the nervous system including the CNS, PNS, and autonomic nervous system (ANS). Nervous impulses are chemically mediated across synapses by the release of neurotransmitters from the pre-synaptic terminal. These neurotransmitters then move across the synaptic cleft, bind to their post-synaptic target receptor, and effect either an excitatory or inhibitory response in the post-synaptic neuron or muscle (Anthony *et al.*, 2001). Functional neurotoxicants may exert their action by preventing synthesis, storage, release, binding, reuptake, or degradation of the neurotransmitter. Interference with axonal transmission via sodium, potassium, chloride, or calcium channels and subsequent alteration of action potentials can also result in functional toxicoses (Spencer, 2000; Hansen, 2006). The lack of structural lesions in these circumstances in no way minimizes the resulting pathology.

Examples of neurotransmitters include acetylcholine; the catecholamine neurotransmitters dopamine, norepinephrine, and epinephrine; the amino acid derivatives serotonin (5-hydroxytryptamine; 5-HT), GABA, glycine, histamine, aspartic acid, and glutamic acid; and various neuropeptides including enkephalins, substance P (a neurokinin), orexins, endorphins, vasopressin (antidiuretic hormone, ADH), and thyroid releasing hormone (TRH) (Beasley, 1999; Spencer, 2000). The complex array of neurotransmitters provides many targets for neurotoxicity, both intentional as with organophosphate insecticides and unintentional as with serotonin syndrome after an acute overdosage of a selective serotonin-reuptake inhibitor (SSRI) by the family dog. A more detailed discussion follows regarding some of the more common neurotransmitters involved in neurotoxicoses.

### Acetylcholine

Acetylcholine (ACh) is the neurotransmitter that mediates effects at the neuromuscular junction, at the pre-ganglionic neurons of both the parasympathetic and sympathetic nervous systems of the ANS, and at many of the post-ganglionic neurons of the parasympathetic nervous system. It is the target neurotransmitter of OP and carbamate insecticides, which have been marketed since the 1970s and now widely available commercially for home and agricultural use (Meerdink, 2004b). Acetylcholinesterase (AChE) is the enzyme that degrades ACh to choline and acetic acid once it is no longer needed to effect transmission. OP and carbamate insecticides bind to AChE, the former by phosphorylating the enzyme, the latter by carbamylating the enzyme, and prevent its degradative action on ACh. This results in an excess of ACh in the synaptic cleft and continued binding to the post-synaptic receptors. Examples of OPs include disulfoton, malathion, terbufos, phosmet, chlorpyrifos, tetrachlorvinphos, and parathion. Examples of carbamates include carbaryl, carbofuran, aldicarb, methomyl, and propoxur. The onset of action and severity of signs vary widely among these agents. OPs with a sulfur linkage need to be activated by p450 enzymes in the liver prior to exerting their toxic effects, a process which may take just minutes. Carbamates are active upon absorption but some of them are less likely to cross the blood–brain barrier than the more fat soluble OPs. Cholinergic effects are mediated by both muscarinic and nicotinic receptors. Classic muscarinic effects include excess *s*alivation, *l*acrimation, increased *u*rination, *d*iarrhea, *d*yspnea (due to increased bronchial secretions), and *e*mesis (abbreviated as the mnemonic SLUDDE or the alternative DUMBELS which stands for *d*iarrhea, *u*rination, *m*iosis, *b*ronchospasm,

*e*mesis, *l*acrimation, and *s*alivation). Nicotinic effects include tremors, weakness, and paralysis. CNS effects can range from coma and depression to hyperactivity and seizures (Blodgett, 2006).

The main distinction between the OPs and carbamates is the reversibility of the bond between the insecticide and AChE. OPs phosphorylate the esteratic site of the enzyme. At variable times depending on the type of OP bound, the carbon groups attached to the phosphorus are hydrolyzed and replaced by hydrogen. This process is classically referred to as "aging" and represents the point at which there is no possible functional recovery of that enzyme. The use of pralidoxime (2-PAM) as an antidote to preferentially bind the OP is useful only before the aging process has occurred. In contrast, the affinity of carbamates for AChE is much more labile and aging does not occur with carbamylation of the enzyme. Therefore, the bond between AChE and carbamates is spontaneously reversible with time ($t_{1/2} = 30$–40 min) and precludes the use of 2-PAM. Provided the receptor effects are not life threatening in the meantime, the prognosis for carbamate toxicoses is generally good. With potent carbamates such as methomyl, however, the signs may be severe enough and the duration of effect long enough for the outcome to be fatal. Management of life-threatening bradycardia and/or dyspnea due to bronchospasm and excess bronchial secretions with sufficient atropine (0.1–0.5 mg/kg intravenous (IV), intramuscular (IM), or subcutaneous (SC) to effect) to competitively inhibit the ACh at the muscarinic receptor is indicated in severe cases (Blodgett, 2006).

In addition to the chronic OPIDN (discussed under *Axonopathy*) and the acute toxicosis with SLUDDE effects, there is an intermediate syndrome that is most commonly seen with more liphophilic OPs and classically with chlorpyrifos exposure in cats. It is thought to arise from a down-regulation of muscarinic receptors with sublethal, prolonged exposures. The clinical signs as a result are predominantly nicotinic in nature because those receptors are not down-regulated. Signs which typically appear within 3–10 days of exposure include generalized weakness (including ventroflexion of the neck due to the cat's lack of a nuchal ligament), anorexia, muscle tremors, seizures, depression, and/or death (Blodgett, 2006).

Another toxicant with muscarinic effects is the mycotoxin, slaframine, produced from the fungus *Rhizoctonia leguminicola*, and primarily associated with clovers (*Trifolium* species). It is a cholinergic agonist which is responsible for the clinical picture of profuse salivation or "slobbers" in affected animals (Meerdink, 2004a). Mushrooms of the genera *Inocybe* and *Clitocybe*, among others, contain the toxic principle muscarine which, not surprisingly, results in clinical signs consistent with muscarinic stimulation (Turner and Szczawinski, 1991). Anatoxin-$a_{(s)}$, a neurotoxin produced by the cyanobacteria *Anabaena* sp., *Aphanizomenon* sp., and *Oscillatoria* sp., inhibits AChE in the PNS. Like slaframine, the toxin does not cross the blood–brain barrier (Roder, 2004c).

Several examples of neurotoxicants exist that antagonize muscarinic effects as well. The classic poisonous plant, *Atropa belladonna*, or deadly nightshade, is the source of atropine, a racemic mixture of the tropane alkaloids, D- and L-hyoscyamine (Burrows and Tyrl, 2001). Other belladonna alkaloids include scopolamine and hyoscine. *Datura* sp., commonly known as jimsonweed, thorn apple, or devil's trumpet, contains scopolamine and hyoscyamine. Excessive anticholinergic action can result in sinus tachycardia, a dry mouth manifesting as increased thirst, dilated pupils, visual disturbances, ileus, urinary retention, restlessness, muscular twitching, incoordination, delirium (as a result of crossing the blood–brain barrier and entering the CNS), respiratory paralysis, and death (Burrows and Tyrl, 2001; Pickrell *et al*., 2004).

Nicotinic cholinergic receptors are also involved with neurotoxicoses. Nature has provided several poisonous plants that stimulate these receptors including *Nicotiana* sp. (varying types of tobacco), *Conium maculatum* or poison hemlock, and *Lobelia* or Indian tobacco. The numerous alkaloids present in these plants (Table 9.1) as well as the cyanobacterial toxin, anatoxin-a, most commonly produced by *Anabaena flos-aquae* (Roder, 2004c), exert their neurotoxic effects by initially stimulating nicotinic cholinergic and neuromuscular junction receptors but ultimately resulting in a persistent neuromuscular blocking effect. Signs include muscular weakness, tremors, nausea, vomiting, ataxia, tachypnea, tachycardia, hypertension, mydriasis, staggering, seizures, respiratory failure, and death (Panter, 2004a,b,c,). Treatment is symptomatic and supportive. Prognosis is good except in cases of large overdoses.

**TABLE 9.1 Alkaloids exerting nicotinic effects (Panter, 2004a,b,c)**

Many snake toxins are nicotinic receptor antagonists. Envenomation can result in muscular paralysis and death. They include the following $\alpha$-neurotoxins: erabutoxin (of the sea snake, *Laticauda semifasciata*), $\alpha$-cobratoxin (of the cobra, *Naja naja siamensis*), and $\alpha$-bungarootoxin (of the many-banded krait, *Bungarus multicinctus*).

Imidacloprid (Advantage®) is a chloronicotinyl nitroguanide insecticide marketed for flea control in pets and which exerts its effects via possibly both agonist and antagonist actions at the nicotinic ACh receptor. Death of the insect is effected via the same clinical signs as previously described above, yet imidacloprid has a wide margin of safety in mammals due to its poor systemic absorption when applied dermally (as labeled) and due to the higher affinity of imidacloprid for insect nicotinic receptors versus mammalian receptors. Acute oral ingestions are usually limited to nausea, salivation, and vomiting (Wismer, 2004).

Another mechanism by which ACh can be involved in toxicoses is the lack of release of the neurotransmitter from the pre-synaptic terminal as a result of the action of the botulinum toxin, produced by the anaerobic bacterium, *Clostridium botulinum*. Sources of the toxin include ingestion of food contaminated with either preformed toxin or clostridial spores, contamination of a puncture wound with spores, and ingestion of spores from the environment. Exposure can be oral, inhaled, or absorbed cutaneously through devitalized skin (Bailey, 2006). The toxin consists of a 100 kD heavy chain and a 50 kD light chain linked by disulfide and non-covalent bonds. Upon ingestion of the toxin, its heavy chain binds synaptotagmin, a pre-synaptic vesicle protein. Once the toxin is internalized within the pre-synaptic terminal, its disulfide bonds are cleaved, releasing the light chain. The free light chain is then available to cleave proteins that are responsible for the docking and release of ACh vesicles into the synapse.

Seven different botulinum toxins (A–G) have been described. Types C and D are most commonly associated with veterinary species (type C is most common in dogs); types A, B, E, and F have caused disease in humans. Although differences exist regarding which proteins are cleaved by each toxin type, the end result is the lack of ACh in the synaptic cleft of the neuromuscular junction (Roder, 2004b). The clinical result is a progressive flaccid paralysis which results in death within 3–10 days. Signs are symmetric and progress from the pelvic limbs toward the thoracic limbs. Cranial nerves may be affected, possibly resulting in megaesophagus, decreased jaw tone, facial paralysis, and/or a decreased gag reflex. Autonomic functions may be affected as well (Coleman, 1998). For obvious reasons, the disease is called limber neck in affected birds. In patients fortunate enough to be supported with artificial respiration, the duration of effect can persist for 6–8 months (Kotsonis *et al.*, 2001).

The prognosis for severely- affected animals is at best guarded but more realistically poor. Treatment can include debridement of wounds, penicillin therapy, and antitoxin (5 ml IV or IM) within the first 5 days of exposure. Administration of the antitoxin does not reverse the clinical signs attributed to neurons already affected by the toxin. Due to its equine source and antigenicity, an intradermal test dose is recommended prior to full administration IV or IM. For individuals already severely affected, assisted ventilation is indicated until the patient can breathe spontaneously, yet the duration of therapy required may not be practical in veterinary medicine. Extreme supportive care including assisted feeding, physical therapy, manual evacuation of the bladder, and intermittent manipulation of body position to prevent hypostatic congestion is critical. Some laboratories can confirm the diagnosis with analysis of serum, gut contents, and/or feed for the preformed toxin (Roder, 2004b; Bailey, 2006).

## Catecholamine neurotransmitters

The synthesis of catecholamine neurotransmitters begins with the amino acid, L-tyrosine. The enzyme tyrosine hydroxylase, present in the cytosol of neurons, converts L-tyrosine to L-dopa. The removal of a carboxyl group from L-dopa, aided by the enzyme L-dopa decarboxylase, forms dopamine. The enzyme dopamine $\beta$ hydroxylase then converts dopamine to norepinephrine which is packaged into synaptic vesicles and released from the pre-synaptic terminal via a $Ca^{2+}$-dependent mechanism (Spencer, 2000). Norepinephrine is also stored in the adrenal medulla and released into the blood with sympathetic stimulation (Capen, 2001). *N*-methylation of norepinephrine forms epinephrine, an adrenal hormone which is only nominally present in the brain. Catecholamines are inactivated by monoamine oxidase (MAO) and catechol-*O*-methyltransferase (COMT) enzymes. MAO-A deaminates norepinephrine and serotonin while MAO-B metabolizes dopamine (Beasley, 1999; Spencer, 2000).

In addition to its role at post-ganglionic sympathetic neurons, norepinephrine also mediates effects in the CNS. Adrenergic receptors include $\alpha_1$, $\alpha_2$, $\beta_1$, and $\beta_2$ receptors. Stimulation of $\alpha_1$ adrenergic receptors, present peripherally, results in vasoconstriction and mydriasis. Stimulation of $\alpha_2$ adrenergic receptors, present in the CNS, mediates inhibition of norepinephrine, resulting in effects opposite those of $\alpha_1$ stimulation, namely hypotension. Stimulation of $\beta_1$ receptors, located predominantly in the heart but also in the kidney, adipose, skeletal muscle, and eye, results most notably in an increase in the rate and force of cardiac contraction. Other effects include increased renin release, lipolysis, tremors, and increased production of aqueous humor. The $\beta_2$ adrenergic receptors present in skeletal muscles; in the smooth muscle of the bronchi,

vasculature, and uterus; and also in the liver mediate vasodilation, bronchodilation, uterine relaxation, and enhanced glycogenolysis in the liver (Landsberg and Young, 2001).

Examples of adrenergic toxicosis involving overstimulation of the $\alpha_2$ receptors include accidental ingestion of brimonidine, the active ingredient in Alphagan® eye drops used in the treatment of glaucoma; ingestion of Preventic® collars, and overdosage of the sedative/analgesic, xylazine. Exposures involving Alphagan® typically involve puncturing of the bottle with sparing amounts actually ingested. Clinical signs for all three toxicoses include profound hypotension and bradycardia, which can be specifically reversed with either of the $\alpha_2$ antagonists, yohimbine or atipamezole (Antisedan®). The half-life of the latter is longer in dogs and may require less frequent administration (Plumb, 2005).

An example of adrenergic toxicosis involving overstimulation of the $\beta_2$ adrenergic receptors involves the accidental puncture of pressurized albuterol inhalers. Albuterol is a $\beta_2$ adrenergic agonist used therapeutically to treat the bronchoconstriction associated with asthma. When excessive $\beta_2$ stimulation occurs, profound hypotension, a reflex tachycardia, and subsequent release of catecholamines can occur. Clinical signs usually include tachycardia with possible ventricular premature contractions (VPCs), tachypnea, hyper- or hypotension (depending on the timeframe relative to exposure and the predominating neurotransmitter effect), behavioral changes including restlessness, agitation, anxiety, largely due to secondary catecholamine release, weakness later in the course, and hypokalemia, sometimes severe, due to an intracellular potassium shift. Treatment is largely supportive with fluid therapy, management of severe tachycardia with a $\beta$ blocker such as propranolol, supplementation of potassium as needed, and diazepam to address behavioral changes due to secondary norepinephrine release (Rosendale, 2004).

Apomorphine, a commonly used emetic in veterinary medicine, mediates its effect by stimulating dopamine receptors in the chemoreceptor trigger zone. Particularly when administered via the IV route, vomiting is rapid and predictable. It can also be administered intramuscularly and within the conjunctival sac to effect emesis. Adverse effects associated with overdoses, in particular, include CNS depression or stimulation, cardiac and respiratory depression, and protracted vomiting. Administration into the conjunctival sac allows decontamination via saline lavage if such effects are seen. Otherwise, naloxone, an opiate antagonist, may be given to reverse the depressive effects. Protracted vomiting may be ameliorated with phenothiazine tranquilizers via their anti-dopaminergic properties (Plumb, 2005).

Sympathomimetics such as amphetamines, cocaine, pseudoephedrine, phenylpropanolamine, and ma huang mediate dopaminergic and norepinephrine-induced neurotoxic effects including hypertension, hyperexcitability, tachycardia, tremors, seizures, mydriasis, hyperesthesia, head-bobbing, piloerection, and death (APCC, 2006). Phenothiazine tranquilizers such as acepromazine and chlorpromazine are the mainstay of sympathomimetic overdose therapy due to their post-synaptic blocking effects of dopamine as well inhibition of its release and increase in its turnover in the CNS. Phenothiazines also block $\alpha$ adrenergic and cholinergic activity and are antihistaminic (Plumb, 2005).

## Serotonin

The synthetic pathway for the CNS neurotransmitter, serotonin, begins in serotonergic neurons with the amino acid, tryptophan. It is converted by tryptophan hydroxylase to 5-hydroxytryptophan (5-HTP), which is then converted to serotonin by aromatic amino acid decarboxylase. The various physiologic roles of serotonin include serving as an effector in gastrointestinal and cardiovascular smooth muscle, promoting platelet aggregation, and various roles in regulating sleep, mood, cognition, appetite, and behavior (Gwaltney-Brant *et al*., 2000; Spencer, 2000). Due to the popularity of SSRIs and over-the-counter supplements containing 5-HTP for the treatment of depression in humans, accidental exposures resulting in signs consistent with excess serotonin are fairly common in veterinary medicine. Examples of SSRIs include fluoxetine (Prozac®), fluvoxamine (Floxyfral®, Luvox®), paroxetine (Paxil®), and sertraline (Zoloft®) (PDR, 2006). The seeds of the West African legume, *Griffonia simplicifolia*, contain 6–10% free serotonin (Spencer, 2000). The collective neurologic signs of serotonin excess, termed serotonin syndrome, include tremors, seizures, depression (rarely to the point of coma), disorientation, vocalization, hyperesthesia, ataxia, and apparent blindness. Tachycardia and hypertension have also been seen (APCC, 2006). A majority of affected dogs exhibit vomiting or diarrhea. Other gastrointestinal signs such as hypersalivation, abdominal pain, flatulence, and bloat may be seen but are less common (Gwaltney-Brant *et al*., 2000). Treatment of the clinical patient is largely symptomatic and supportive. The specific serotonin antagonist, cyproheptadine, mediates the effects of serotonin syndrome. The drug can be given orally or crushed, mixed with water or saline, and administered rectally (Gwaltney-Brant *et al*., 2000; APCC, 2006).

## Glycine

Like serotonin, glycine is also an amino acid neurotransmitter. It is synthesized from serine, a reaction catalyzed by serine hydroxymethyltransferase. Glycine acts predominantly in interneurons (Renshaw cells) of the brainstem

and spinal cord as well as in spinal sensory, auditory, and visual pathways where it effects inhibitory functions. Two well-known toxicants, tetanus and strychnine, act by inhibiting glycine's inhibitory effects. Tetanospasmin, a biotoxin produced by the anerobic bacterium, *Clostridium tetani*, is responsible for the prevention of the $Ca^{2+}$-dependent release of glycine from CNS neurons in victims of tetanus (Spencer, 2000; Roder, 2004b). The lack of inhibition by glycine results in unchecked muscle contraction, largely of the powerful extensor muscles of the limbs and the masseter muscles. The stereotypical sawhorse stance and "lockjaw" result within 5–10 days of wound infection. Less severe signs include elevation of the nictitating membrane, which may be the earliest indication of toxicosis in the horse, the most sensitive species (Coleman, 1998). Contracture of facial muscles may result in abnormal wrinkles in the skin, erect ears, or an abnormal expression, sometimes referred to as a sardonic grin. Progression of the disease results in an inability to rise and possible seizures. Severe muscular contraction or seizures may be induced by external stimuli. Death is due to an inability of the muscles of respiration to relax and subsequent hypoxia (Roder, 2004b).

Diagnosis of tetanus is based on characteristic clinical signs, history of a wound in which the organism could have proliferated, and anerobic culture of an infected wound. Treatment includes penicillin, antitoxin administration, and debridement of the wound. Like botulinum toxin, the tetanus antitoxin is ineffective for toxin that is already bound and will not reverse existing clinical signs. Its administration can be repeated in 7–10 days. The dose for horses and cattle is 10,000–50,000 units SC or IM and 3000–15,000 units for sheep and swine (Roder, 2004b). Contrary to popular belief, the antitoxin may be extremely cost effective. At the time of this writing, the Colorado Serum Company (Denver, CO) sells 15,000 units for $12.95 (US) (www.colorado-serum.com). Muscle spasms and seizure activity can be managed by minimization of external stimuli as well as with tranquilizers and muscle relaxants such as acepromazine, diazepam, barbiturates, and methocarbamol (Coleman, 1998). The prognosis for severely affected individuals is poor.

Another antagonist of glycine is the neurotoxicant, strychnine. As mentioned earlier in this chapter, it is an alkaloid derived from the *Strychnos nux vomica* and *S. ignatii* trees. It binds with high affinity to the glycine receptor and blocks its effects as a result. Extreme muscle rigidity occurs as in the tetanus-intoxicated patient and can rapidly progress to intermittent or continuous seizures within 10–120 min of strychnine ingestion. Anxiety, apprehension, nervousness, and tachypnea also may be part of the clinical presentation due to this rapid progression. Death occurs due to hypoxia as a result of contracture of the diaphragm and abdominal and intercostal muscles. The oral $LD_{50}$ is 0.5–1.2 mg/kg for dogs; 0.5 mg/kg for horses and cows; 2 mg/kg for cats; and 0.5–1 mg/kg for pigs (Talcott, 2006). In the exposed but asymptomatic patient, aggressive decontamination is warranted. Treatment of the symptomatic patient is limited to symptomatic and supportive care. The agents used to treat muscle spasms, seizures, and anxiety in the tetanic patient may also be used in the strychnine-intoxicated patient. The prognosis for symptomatic patients is grave.

## GABA

GABA serves as the predominant inhibitory neurotransmitter in the brain of mammals and is synthesized from glutamic acid. Two main receptor subtypes, $GABA_A$ and $GABA_B$, exist. $GABA_A$ has atleast seven subunits ($\alpha$, $\beta$, $\gamma$, $\delta$, $\varepsilon$, $\theta$, and $\rho$) which combine with a chloride channel to form a receptor/ionophore complex. The complex contains binding sites not only for GABA but also for drugs such as the anticonvulsant benzodiazepines and barbiturates. Stimulation of these receptors results in CNS depression, somnolence, fatigue, lethargy, ataxia, and muscular incoordination. Paradoxical hyperactivity, excitement, or aggression can also occur. In overdoses, CNS and respiratory depression may be extreme leading to hypotension, hypoxia, hypothermia, and death (Rudolph *et al.*, 2001; Spencer, 2000).

Drugs of the avermectin class are commonly used in veterinary medicine for the prevention of heartworm disease (*Dirofilaria*) in dogs and cats and the treatment of endoparasitism (strongyles, ascarids, bots, threadworms, lungworms, stomach worms, and summer sores (*Habronema*, *Draschia* species) and ectoparasitism (*Sarcoptes*, *Demodex*). Examples of avermectins include ivermectin (Heartgard®), selamectin (Revolution®), milbemycin (Interceptor®), moxidectin, and abamectin. Their mechanism of action on target species was originally thought to be due to the enhanced release of GABA at pre-synaptic neurons, causing parasite paralysis and eventual death (Plumb, 2005). Mealey (2006), however, reports more recent evidence that suggests the target effects to be mediated via glutamate-gated chloride channels in the CNS. Such channels are not present in the mammalian brain, allowing for a wide margin of safety of these drugs in the host animal. P-glycoprotein, part of the blood–brain barrier, is present in the apical membrane of brain capillary epithelial cells, and serves as an efflux pump to remove certain drugs from the brain. In addition to the avermectins, other such drugs include loperamide (Imodium®), ondansetron (a $5\text{-}HT_3$ antagonist), digoxin, quinidine, tacrolimus (a macrolide immunosuppressant), cyclosporine A, doxorubicin, and the *Vinca* alkaloids (vincristine, vinblastine). In dogs with an MDR1 (multi-drug resistance) gene defect, classically the collie and other herding breeds, p-glycoprotein is not functional, allowing far greater concentrations of these drugs

to accumulate in the brain. Drugs such as cyclosporine A, ketoconazole, verapamil, and tamoxifen can inhibit p-glycoprotein action and can result in a toxicosis of substrate drugs even in an animal without a genetic p-glycoprotein defect (Mealey, 2006).

Once access to the GABAergic pathways in the brain is obtained, the clinical signs of an acute or chronic avermectin toxicosis in a p-glycoprotein deficient dog can be profound. They include ataxia, CNS depression (potentially to the point of coma), recumbency, disorientation, mydriasis/apparent blindness, muscle tremors, seizures, respiratory depression, hypothermia, bradycardia, hypoxia, and death. Signs may persist for weeks. The duration of effect is often difficult to predict based on the severity of signs. Extreme supportive care is indicated for the comatose patient. Assisted ventilation may be necessary. Repeated doses of activated charcoal can be of significant benefit due to the enterohepatic recirculation of avermectin drugs. If treated aggressively, severely affected dogs can recover without long-term sequelae (APCC, 2006; Mealey, 2006). The duration of therapy and intensity of supportive care required in such cases, however, is often a limiting factor in veterinary medicine. Confirmation of exposure can be accomplished by detecting the drug in the liver, adipose tissue, or blood. Because signs are due to concentrated amounts of the drug in the brain, serum, or plasma levels may not correlate well with clinical signs. The College of Veterinary Medicine at Washington State University can confirm the presence of the mutant MDR1 gene with polymerase chain reaction (PCR) analysis of a swab from a suspect dog's oral mucosa (Mealey, 2006). Otherwise, diagnosis is largely based on a history of exposure and consistent clinical signs.

## Glutamate/aspartate

The primary excitatory neurotransmitters of the brain are the non-essential amino acids, glutamate and aspartate. Their synthesis in the brain from glucose and other molecules is tightly regulated. The blood–brain barrier excludes excesses of these excitatory neurotransmitters except in areas of the hypothalamus (arcuate nucleus) and retina where acute cellular degeneration may occur as a result. Three main receptor subtypes exist for glutamate: AMPA (DL-α-amino-3-hydroxy-5-methyl-4-isoxazole), kainic acid (KA), and NMDA (*N*-methyl-D-aspartate) receptors. As previously mentioned (see *Neuronopathy* section), domoic acid is an example of a toxicant that stimulates kainate receptors, resulting in ASP (Jeffery *et al.*, 2004).

The potential role of glutamate and aspartate in the pathogenesis of yellowstar thistle intoxication in horses is not well defined (Spencer, 2000). The plant is known to contain both excitatory amino acids in addition to several unstable guaianolide sesquiterpene lactones which may degrade to the former to exert their neurotoxic effects (Burrows and Tyrl, 2001).

Ketamine, a dissociative anesthetic used commonly for induction of general anesthesia in veterinary medicine, blocks the open NMDA ion channel by binding to it. Seizures, due to elevation of CSF pressure, are a potential sequela of ketamine use at therapeutic doses. The anesthetic is a congener of phencyclidine (Plumb, 2005), also known as PCP or angel dust, which not only binds to NMDA receptor channels but also acts as an antagonist of nicotinic cholinergic receptors. Overdose with PCP can result in a variety of signs including delirium, aggression, coma, seizures, and death (Spencer, 2000).

## Histamine

Histamine is a physiologically active amine that is both a neurotransmitter as well as a mediator of peripheral effects relating to allergic reactions and gastric acid secretion. It is formed from the decarboxylation of L-histidine. The roles of histamine in the CNS are thought to include regulation of arousal, blood pressure, water metabolism, and nausea. Peripherally, histamine receptors are of two subtypes: $H_1$ and $H_2$. The former mediate allergic reactions in which histamine is released from the granules of mast cells, resulting in dilation and increased permeability of capillaries (wheal and flare reaction) and constriction of bronchial smooth muscle. The $H_2$ receptor stimulation increases gastric acid secretion (Beasley, 1999). Common $H_2$ blockers used in veterinary medicine to decrease gastric acidity include cimetidine, ranitidine, and famotidine (Plumb, 2005). Of the $H_2$ blockers, cimetidine is more likely to cross the blood–brain barrier. Adverse neurologic effects reported in people include confusion, slurred speech, flushing, sweating, dizziness, and delirium. Administration of these drugs may result in fever, which spontaneously resolves within 48–72 h after discontinuation. The mechanism is thought to be due to CNS receptor antagonism (Poisindex®, 2006).

Antagonists of $H_1$ receptors are commonly used to treat acute and chronic allergic reactions, to prevent mast cell degranulation during surgical excision, as well as to minimize motion sickness in veterinary and human medicine. They are divided into first- and second-generation antagonists. The first-generation antihistamines can both stimulate and depress the CNS while the second-generation antihistamines are considered non-sedating due to their exclusion from the brain at therapeutic dosages (Murphy, 2006). $H_1$ antihistamines can be further divided into piperazine, ethanolamine, ethylenediamine, propylamine, and piperidine derivatives. Examples of the piperazine derivative antihistamines include the first-generation hydroxyzine HCl (Atarax®) and meclizine HCl (Dramamine®, Bonine®) and the second-generation piperazine-derivative

antihistamines, cetirizine HCl (Zyrtec®). The first-generation ethanolamine-derivative antihistamines include diphenydramine (Benadryl®), dimenhydrinate (Dramamine®), and clemastine (Tavist®). Ethanolamine-derivative antihistamines are strictly first generation and include pyrilamine and tripelennamine (Pelamine®). The first-generation propylamine-derivative antihistamines include brompheniramine maleate (Dimetapp®) and chlorpheniramine maleate (Chlor-trimeton®). The second generation includes tripolidine HCl (Actifed®). The final class, piperidine-derivative antihistamines, are entirely second generation and include drugs such as loratadine (Claritin®), astemizole, and levocabastine HCl. Other antihistamines that do not fall neatly into the aforementioned categories include fexofenadine (second generation) and cyproheptadine (first generation). At therapeutic doses and with mild overdosages, particularly with the first-generation antihistamines, CNS depression and hypotension may be seen. Epinephrine is contraindicated for management of hypotension in these patients. Paradoxical CNS excitation including restlessness, hyperactivity, tachycardia, tremors, and seizures may also occur and the potential for it varies largely with the individual. Large overdoses can result in extreme CNS and cardiovascular (CV) stimulation to the point of seizure activity, cardiac arrhythmias, hypertension, and death. Seizures, tremors, and hyperactivity may be treated with diazepam (APCC, 2006; Murphy, 2006).

Scombrotoxism, the clinical toxicosis caused by ingestion of poorly preserved scombroid fish (tuna, mackerel, bonito, anchovies, sardines), results from bacterial production of histamine. Histidine-rich muscle is decarboxylated with the enzyme histidine decarboxylase to form histamine and imparts a peppery taste to the fish. Clinical signs include vasodilation, abdominal pain, nausea, vomiting, diarrhea, generalized erythema and urticaria, intense pruritus, tachycardia, bronchoconstriction, respiratory distress, shock, and possible death. Treatment includes antihistamines that are both $H_1$ and $H_2$ receptor antagonists (Mebs, 1995; Ludolph and Spencer, 2000).

## Mixed neurotransmitter effects

Many agents exert their effects via multiple neurotransmitters or pathways. Tricyclic antidepressants such as amitriptyline (Elavil®) and clomipramine (Clomicalm®) are structurally similar to phenothiazines and exert their effects via blocking the reuptake of norepinephrine and serotonin (Plumb, 2005). Inhibitors of MAOs (selegeline, Anipryl®), used in veterinary medicine for cognitive dysfunction, prevent the metabolism of neurotransmitters (Spencer, 2000; Plumb, 2005).

Accidental overdosage of certain human prescription drugs can result in excessive norepinephrine and serotonin effects. Venlafaxine (Effexor®), a bicyclic antidepressant, e.g. blocks the reuptake of norepinephrine and serotonin and to a lesser extent, that of dopamine. Neurologic effects from overdoses include depression, lethargy, tremors, vocalization, disorientation, mydriasis, ataxia, seizures, hyperactivity, and death. Other possible effects include tachypnea, tachycardia, hypersalivation, and retching. Treatment is symptomatic and supportive. Cyproheptadine may help alleviate signs (see *Serotonin* section; APCC, 2006).

**TABLE 9.2 Ergot alkaloids (Evans *et al.*, 2004)**

| Ergopeptine alkaloids | Ergoline alkaloids |
|---|---|
| Ergotamine | Lysergic acid |
| Ergocristine | Lysergol |
| Ergosine | Lysergic acid amide |
| Ergocrytpine | Ergonovine |
| Ergocornine | |
| Ergovaline | |

Another neurotoxicosis that involves multiple neurotransmitters is that induced by the ergot alkaloids produced by fungi of the *Claviceps* genus. The mycotoxins can be further divided into ergopeptine and ergoline alkaloids (Table 9.2). The alkaloids exert their toxic effects via effects on dopaminergic, serotonergic, and adrenergic pathways. Successful recovery is aimed at early diagnosis, when signs such as ataxia and confusion are reversible, and removal of the contaminated feed source (Evans *et al.*, 2004). The effects of the ergoline alkaloids, in particular, can also be seen with ingestion of the seeds of *Ipomoea* or morning glory and are very similar to those of the related street drug, lysergic acid diethylamide, also known as LSD (Burrows and Tyrl, 2001).

$\alpha$-latrotoxin, the toxin in the venom of the black widow spider (*Latrodectus*), has mixed neurotransmitter effects. Binding of the toxin to neurexins and $Ca^{2+}$-*i*ndependent *r*eceptor for $\alpha$-*l*atrotoxin (CIRL; latrophilin) results in the release of catecholamines and also ACh, GABA, and glutamate. The toxin mediates its catecholamine effects by forming a transmembrane pore through which $Ca^{2+}$ can influx, allowing release of pre-synaptic vesicles containing neurotransmitters. Clinical signs associated with a bite from *Latrodectus* species include abdominal pain, ataxia, muscle fasciculations, muscle rigidity, and flaccid paralysis, which can ascend to involve the respiratory muscles. Cats are more sensitive than dogs to the effects of $\alpha$-*l*atrotoxin, but all mammalian species are susceptible. Antivenin is commercially available for black widow spider bite victims. Like all products derived from equine serum, a test dose should be administered intradermally to determine if hypersensitivity to the product exists. If none exists, the contents of the antivenin vial (2.5 ml) can be diluted 4–20 $\times$ (10–50 ml) with sterile saline and administered slowly intravenously over approximately 15 min (Roder, 2004d; PDR®,

2006). A slow, IV injection of 10% calcium gluconate may be given to treat the muscle fasciculations and weakness as well. Aggressive pain management with opioids or benzodiazepines is indicated (Roder, 2004d).

## ION CHANNELS

The propagation of an impulse along an axon depends on an electrochemical gradient that is intricately regulated by various ion channels in an excitable membrane. Initiation of action potentials, release of neurotransmitters, axonal transport, and healthy muscle activity rely on control of ions such as sodium, potassium, chloride, and calcium (Spencer, 2000). Specific examples follow regarding the variety of natural and synthetic toxicants that target the ion channels of the nervous system.

### Sodium channels

The sodium channel of mammals is made up of three protein subunits, the largest of which is the transmembrane alpha ($\alpha$) subunit which contains the $Na^+$ pore and which is flanked by two smaller $\beta$ subunits. The pores are voltage-gated, allowing sodium ion entrance into the cytoplasm only when charge-dependent conformational changes occur. Nature provides us with several examples of neurotoxicants which affect the sodium channel. The TTX present in various puffer fish (*Tetraodon, Fugu, Lagocephalus, Sphaeroides, Arothon, Chelonodon, and Amblyrhynchotes* species), and in the venom of the blue-ringed octopus (*Hapalochlaena maculosa* and *H. lunulata*), among many other creatures, exhibits a profound binding affinity for the sodium channel peptide complex. Whereas the $Na^+$ ion reversibly binds to peptide complex for just nanoseconds, TTX enters, binds to the external surface of the peptide ion channel, and remains bound for tens of seconds, an eternity with respect to nerve conduction, halting the action potential. Four grades of TTX poisoning have been described in humans. The first grade, evident within minutes, involves numbness around the mouth with or without nausea. The second involves numbness of the tongue, face, and skin and early motor paralysis and incoordination manifested as slurred speech. The third grade involves more widespread paralysis resulting in dyspnea, hypotension, the inability to speak, and fixed and dilated pupils. The final grade is characterized by severe paralysis involving the respiratory muscles, hypoxia, hypotension, and cardiac arrhythmias. Consciousness may be lost followed by death due to respiratory failure as early as 17 min after ingestion but up to 24 h. Treatment is aimed at decontamination and symptomatic and supportive care (Kaku and Meier, 1995).

Saxitoxin, the causative toxin for paralytic shellfish poisoning (PSP), is produced by several dinoflagellates, most notably *Alexandrium* and *Pyrodinium* species, and causes a similar clinical picture as that of TTX toxicosis also due to its binding to the sodium ion channel (Smart, 1995).

Local anesthetics exert their pharmacologic effects by binding to the fast sodium channel complex when it is inactive, inhibiting its recovery after depolarization. Lidocaine, as an example, rapidly dissociates from the sodium channel complex and is also rapidly metabolized in the liver. Consequently, adverse events associated with therapeutic dosages are rare. In an overdose situation, however, CNS depression, ataxia, seizures, and circulatory collapse can occur (Welch, 2000; Plumb, 2005). Dibucaine HCl is 10 times more potent than lidocaine and much more likely to result in adverse effects as a result. Cats are especially susceptible to the methemoglobinemic potential of local anesthetics (Welch, 2000).

Several toxins affect the sodium ion channel by enhancing its activity, resulting in repetitive and prolonged neurotransmission. Brevetoxins, produced by the dinoflagellates *Karenia brevis* and *Gymnodinium breve*, prolong the opening of the sodium ion channels, perpetuating the propagation of the action potential, particularly in the parasympathetic and adrenergic nerves. Bossart *et al*. (1998) implicated the toxin in the death of a minimum of 149 manatees along the southwest coast of Florida in 1996. Ciguatoxins are produced by dinoflagellates and are bioaccumulated by herbivorous, and then piscivorous, fish. They mediate their toxic effect by enhancing $Na^+$ permeability through the ion channel (Spencer, 2000). The hallmark clinical sign of ciguatera fish poisoning (CFP) in people is a paresthesia (tingling sensation) in the extremities as well as a perception of heat with cold stimuli ("dry-ice phenomenon") (Kaplan, 2000). The neurologic signs are attributable to edema of the adaxonal Schwann cell cytoplasm and can persist for weeks. Gastrointestinal pain and diarrhea are also typical, particularly in the early course of the disease (Glaziou *et al*., 1995; Spencer, 2000).

Other examples of toxicants that block inactivation of sodium channels include batrachotoxin, a steroid alkaloid isolated from the skin of *Phyllobates aurotaenia*, a South American frog (Spencer, 2000); grayanotoxins, diterpene alkaloids from the plants of the *Rhododendron, Kalmia, Pieris, Leucothoe*, and *Lyonia* genera (Puschner, 2004); aconitine, present in monkshood (*Aconitum* species); and veratridine from *Veratrum album* (Spencer, 2000). The $\alpha$ scorpion toxins stabilize $Na^+$ channels in the open state and allow neuronal hyperexcitation. The $\beta$ scorpion toxins bind to a different site in the complex and allow repetitive firing. Toxins of the Sydney funnel web spider (*Atrax robustus* and *Hadronyche* species; $\delta$-atracotoxin, atraxotoxin, robustoxin) also block sodium channel inactivation (White *et al*., 1995; Spencer, 2000).

TABLE 9.3 Representative pyrethrins and pyrethroids (Volmer, 2004)

| Pyrethrins | Type 1 pyrethroids | Type II pyrethroids |
|---|---|---|
| Pyrethrin I | Allethrin | Cyfluthrin |
| Pyrethrin II | Bifenthrin | Cyhalothrin |
| Cinerin I | Permethrin | Cypermethrin |
| Cinerin II | Phenothrin | Deltamethrin |
| Jasmolin I | Resmethrin | Fenvalerate |
| Jasmolin II | Sumithrin | Flumethrin |
| | Tefluthrin | Fluvalinate |
| | Tetramethrin | Tralomethrin |

Pyrethrins, natural organic esters isolated from the flower of the *Chrysanthemum cinerariaefolium*, have natural insecticidal properties as a result of their ability to bind to $Na^+$ ion channels and slow their inactivation. The lack of environmental contamination and relative wide margin of safety of pyrethrins to mammals are advantages of these compounds. One disadvantage of the natural compounds is their relatively short duration of action, resulting in a quick knock down effect of the insect followed by recovery. Synthetic pyrethroids were developed as of 1977 to address this issue. Table 9.3 lists both natural and synthetic (pyrethroids) pyrethrins. Type I pyrethroids do not have a cyano group in the $\alpha$ position of the molecule, a characteristic of type II pyrethroids which affords the latter greater insecticidal potency. Type I compounds cause repetitive firing of the affected nerves whereas type II pyrethroids are associated with membrane depolarization. Because of their relatively rapid metabolism, pyrethrins and pyrethroids are often marketed with synergists such as MGK-264 or piperonyl butoxide to inhibit enzymes which degrade them (mixed function oxidase and esterase), thereby prolonging their insecticidal action (Volmer, 2004).

Fish and cats represent the most susceptible animals to pyrethroids. Fish typically die acutely when exposed to pyrethroids. Cats are most commonly presented to the veterinarian as a result of exposure to the highly concentrated (45–65%) spot-on permethrin products labeled for use in dogs. Within 12–18 h of application or accidental exposure, affected cats will exhibit hyperesthesia, generalized tremors, hyperthermia, seizures, and possible death. The prognosis for complete recovery, however, is excellent provided that appropriate care is administered including control of tremors with IV methocarbamol, decontamination with a warm bath using a liquid dishwashing detergent, thermoregulation, seizure management (with diazepam, barbiturates, propofol, and/or inhalant anesthetics), and supportive care. The body temperature may become critically elevated with continued tremors and seizures or subnormal following a bath. Secondary adverse effects due to hyperthermia and enhanced toxicosis of pyrethroids at lower body temperatures may complicate the clinical course and should be avoided. Other species may have dermal hypersensitivity reactions or local paresthesia effects from topical application of pyrethroids. Steady resolution with this clinical picture is expected once the dermal residue is removed with a bath and liquid dishwashing detergent (Volmer, 2004; Hansen, 2006).

## Potassium channels

Potassium channels are largely involved with repolarization of the neuron following $Na^+$-induced depolarization. The opening of these potassium channels is voltage dependent and allows $K^+$ to leave the cell, thereby restoring the resting potential of the axonal membrane. Several subtypes of potassium channels exist, the details of which exceed the scope of this text. Neurotoxicants that block $K^+$ channels include 4-aminopyridine (Avitrol®), quinidine (derived from the *Cinchona* tree; class 1A antiarrhythmic), PCP ("angel dust"), mast cell degranulating peptide in the venom of the bee, *Apis mellifera*; venom of the gaboon viper, *Bitis gabonica*; and leuirotoxin 1 from the scorpion *Leuirus quinquestriatus hebraeus*. Neurologic clinical signs of potassium channel blockage include rapid onset of seizures progressing to death as in intoxication with Avitrol® (Schell, 2004); depression, confusion, and seizures with quinidine overdose (Plumb, 2005); and pain, urticaria, and erythema as a result of an *Apis mellifera* sting. Because of the array of potassium channel functions and their various regulatory pathways (voltage, calcium, sodium, ATP, increased cell volume (Spencer, 2000)), the clinical effects of potassium channel blockade are widely varied.

## Chloride channels

As opposed to sodium and potassium channel neurotoxicants, relatively few toxicants have been identified that affect the chloride channel. Chloride ions can passively diffuse down their concentration gradient out of the neuron. Chloride ion channels regulate the entrance of chloride into the neuron and affect the membrane potential as a result. Normal resting membrane potential is $-70$ mV. Threshold potential, the potential at which an action potential is propagated, is roughly $-50$ mV. Membranes can be hyperpolarized by allowing entrance of negative chloride into the neuron and making it more difficult to reach threshold potential. Both benzodiazepines and barbiturates mediate their effects via $GABA_A$ receptors which are chloride ionophore complexes (Crystal and Schaumburg, 2000). Minute details regarding binding sites, duration, and frequency of chloride channel opening effected by barbiturates and benzodiazepines have been extensively studied (Hobbs *et al.*, 1996; Crystal and Schaumburg, 2000; Maytal and Shinnar, 2000), yet the exact mechanism remains unclear. Ultimately, the two classes of drug inhibit excitatory

neurotransmission by increasing chloride conductance into the neuron. This can occur both pre-synaptically or post-synaptically (Harrison *et al.*, 2006).

The use of potassium bromide for chronic management of idiopathic epilepsy in veterinary patients is based on the competition of the bromide ion with chloride ions for transport across cell membranes. The therapeutic action relies on hyperpolarization of the neuronal membrane and a decrease in the propagation of epileptic discharges. Bromide blood levels should be monitored routinely in treated animals and particularly in those animals exhibiting signs of bromide toxicity. Neurologic signs consistent with a bromide toxicosis include ataxia, tremors, and sedation to the point of stupor in veterinary species (Plumb, 2005). Headache, mood alterations, hallucinations, speech abnormalities, and visual disturbances have also been reported with human bromism (Spencer, 2000). Because bromide has a longer half-life than chloride, the latter is preferentially excreted by the kidney. In animals with a deficiency of dietary salt, the half-life of bromide is prolonged, enhancing the chances of neurotoxicity. Conversely, the epileptic patient with a high-dietary salt intake may have seizure activity that is poorly managed with potassium bromide treatment (Plumb, 2005).

## CONCLUSION

The health of the nervous system, and largely that of the individual, relies on the system's structural and functional integrity. From specialized nerve cells and anatomic structures to axonal transport, myelination, neurotransmitter synthesis, storage, release, binding, and degradation as well as the regulation of action potentials, maintenance of nervous system integrity is a complex task requiring significant energy expenditure. This functional complexity and structural specialization provide a plethora of targets for neurotoxicant action. The scope of this chapter precludes a detailed discussion of every known neurotoxicant. Many more mechanisms exist by which neurotoxicants exert their effects. Table 9.4 provides a more extensive, yet certainly not exhaustive, list of neurotoxicants grouped by mechanism or site of action, where known.

The extent to which a neurotoxicant exerts its effects depends on a variety of factors including species, age, genetics, underlying diseases, drug therapy, diet, stress, and concurrent toxicoses. Neurologic effects may be potentiated by a combination of two or more of these factors. Veterinary practitioners should be aware of these underlying susceptibilities and the most common mechanisms by which neurotoxicants act so that toxicoses may be avoided or appropriately diagnosed and successfully treated when they do occur.

**TABLE 9.4 Miscellaneous neurotoxicants arranged by mechanism of action (Beasley, 1999; Spencer, 2000; Burrows and Tyrl, 2001; Schulze, 2002; Plumlee, 2004)**

| |
|---|
| *Mediation by acetylcholine* |
| Amanita (muscarinic) |
| *Atropa belladonna* |
| Atropine |
| Botulism |
| Carbamates |
| *Datura* (jimsonweed) |
| Imidacloprid (nicotinic) |
| Kentucky coffee tree (*Gymnocladus dioica*) |
| Organophosphorates |
| Slaframine |
| *Producing acidosis* |
| Aspirin |
| Ethanol |
| Ethylene glycol |
| Metaldehyde |
| Methanol |
| *Stimulating cannabinoid receptors* |
| Marijuana (*Cannabis sativa*) |
| *Effect on chloride channel* |
| Avermectins |
| Picrotoxin (antagonizes GABAergic transmission) |
| Potassium bromide |
| *Mediation by GABA* |
| Avermectins (glutamate-gated ion channels in insects) |
| Baclofen (centrally acting skeletal muscle relaxant; *p*-chlorophenyl derivative of GABA) |
| Barbiturates |
| Benzodiazepines |
| Bicuculline (antagonist) |
| Fipronil (antagonist) |
| Flumazenil (antagonist) |
| *Cicuta*/water hemlock |
| Cyclodiene organochlorines (competitive inhibition) |
| *Mediation by glutamate/aspartate* |
| Domoic acid |
| +/− Yellowstar thistle (*Centaurea solstitialis*) |
| *Mediation by glycine* |
| *Calycanthus* sp. (Bubby bush) |
| Strychnine |
| Tetanus |
| Tremorgenic mycotoxins (penitrem A and roquefortine) |
| *Producing hepatic encephalopathy* |
| Acetaminophen |
| Alsike clover (horses) |
| Blue-green algae |
| Cycad palms (*Cycas, Macrozamia species*) |
| *Lantana* |
| DL-methionine |
| Non-protein nitrogen |
| NSAIDs |
| Pyrrolizidine alkaloids – *Senecio, Crotolaria, Heliotroprium* (giant hog weed), *Amsinckia* (fiddle neck, tarweed), *Symphytum* (comfrey) |
| *Mediation by histamine* |
| Brompheniramine |
| Chlorpheniramine |
| Cetirizine |

(*Continued*)

**TABLE 9.4 (Continued)**

Cimetidine
Cyproheptadine
Dimenhydrinate
Diphenhydramine
Famotidine
Fexofenadine
Hydroxyzine
Loratadine
Ranitidine
Scombroid fish poisoning

*Causing hypoglycemia*
Cocklebur (*Xanthium*)
Xylitol

*Mediation by norepinephrine*
Albuterol (β adrenergic agonist)
Atipamezole (α adrenergic blocker)
Brimonidine (α adrenergic agonist)
Doxazosin (α adrenergic blocker)
Phentolamine (α adrenergic blocker)
Phenoxybenzamine (α adrenergic blocker)
Tamsulosin (α adrenergic blocker)
Terazosin (α adrenergic blocker)
Yohimbine (α adrenergic blocker)
Atomoxetine (norepinephrine reuptake inhibitor)
Metoprolol (β adrenergic blocker)
Propranolol (β adrenergic blocker)
TCAs
MAOIs
Venlafaxine (norepinephrine/dopamine reuptake inhibitor)

*Mediation of opioid receptors*
Butorphanol
Buprenorphine
Fentanyl
Naloxone
Loperamide
Morphine
Meperidine
Heroin
Hydromorphone
Oxymorphone
Codeine
Oxycodone
Tramadol
Horse chestnut (*Aesculus hippocastanum*)

*Effect on potassium channels*
4-Aminopyridine
Organochlorines (inhibit $K^+$ efflux)

*Mediation by serotonin*
Canary grass poisoning
*Griffonia*/5-HTP supplements
*Phalaris* staggers
*Psilocybe* mushrooms
SSRIs
Tryptamine alkaloids

*Effect on sodium channels*
Ciguatoxin
Local anesthetics
Organochlorines (inhibit $Na^+$ influx)
Pyrethroids/permethrin
Saxitoxin
Sodium intoxication
Tetrodotoxin

*Sympathomimetics/catecholamines*
Amphetamines (bind to carrier)
Pseudoephedrine
Ma huang (*Ephedra*)
Phenylpropanolamine
Adderal® (amphetamine–dextroamphetamine)
Cocaine
MDMA/"Ecstasy"
Tricyclic antidepressants (inhibit transport)
Monoamine oxidase inhibitors (MAOIs)
+/− yellowstar thistle (*Centaurea solstitialis*)

*Thiamine deficiency/thiaminase excess*
*Equisetum*
*Pteridium* species (Bracken fern)
Raw fish diet
Excess dietary sulfur

*Uncoupler of oxidative phosphorylation*
Bromethalin
Trialkyltin
Hexachlorophene

*Multiple/miscellaneous MOAs*
*Astragalus/Oxytropis* (locoweed; miserotoxin – causes demyelination of the posterior spinal cord resulting in incoordination, hypermetria, ataxia, and clicking of the dewclaws – "cracker heels"; swainsonine – affected animals exhibit ataxia, emaciation, staggering, and proprioceptive deficits, belligerence or violent startling in horses)
Bovine bonkers (ammoniated feed)/4-methylimidazole
Cycad palm (*Cycas* species: β-*N*-methylamino-L-alanine; *Macrozamia* species: β-*N*-oxalylamino-L-alanine)
5-Fluorouracil/1080 (antimetabolite antineoplastic agent; forms suicide complex with thymidine synthetase)
Lead
Mercury
Methylxanthines, *Guarana* (adenosine receptor antagonists)
Sudan grass (β cyanoalanine)
Phenothiazines (anticholinergic, antihistaminic, α adrenergic blocking effects)
Yesterday, today, and tomorrow plant (*Brunfelsia*; brunfelsamidine)

*Unknown etiology/MOA*
Tick paralysis
Macadamia nuts
Diethyltoluamide (DEET)
Nitrofuran
Desert spike
Sleepy grass
White snakeroot
Essential oils
Hydrocarbons
Indoxacarb

*Metabolic*
Carbon monoxide
Cyanide
Zinc phosphide

CHAPTER

# 10

# Liver toxicity

*Karyn Bischoff and Shashi K. Ramaiah*

## INTRODUCTION

There is continued interest concerning the higher incidence of liver toxicosis caused by prescription/injectable drugs, over-the-counter medications, or dietary supplements that are often combined with special diets and alcohol consumption, in addition to environmental chemicals/xenobiotics (Watkins and Seeff, 2006). Though alcohol consumption is not a major risk factor in most veterinary patients, other factors such as toxic pasture or house plants, cyanobacteria, pollutants, fungal toxins, and household waste may come into play. An incomplete list of hepatotoxins is found in Table 10.1. Complicating matters is the increasing population of geriatric veterinary patients, preexisting liver disease must be considered with the patient exposed to liver toxicants.

The liver is a remarkable organ that usually protects the individual against injury from foreign substances. It is very robust in its capacity to regenerate and repair the damage (Ramaiah *et al.*, 2004; Mehendale, 2005). However, if the ability to regenerate is not adequate, or if injury to the liver is very severe, liver damage may progress to liver failure and death. Chemical/drug-induced liver injury has become the most frequent cause of acute liver failure in humans in the United States and around the world, exceeding all other causes combined (Watkins and Seeff, 2006). Toxic liver disease also remains the major single reason for regulatory actions concerning drugs. Such actions may include failure of approval, withdrawal from the market, restrictions on use, and warnings to physicians (Watkins and Seeff, 2006).

Xenobiotic-induced liver injury is encountered in a variety of circumstances. Some natural toxins such as the peptides of *Amanita phalloides*, the pyrrolizidine alkaloids, the toxin of the cycad nut, and other phytotoxins are hazards posed by the environment. They may be ingested by the curious or very hungry veterinary patient. Others, such as mycotoxins, are ingested unknowingly because of feed contamination due to climatic conditions favorable to fungal growth. A striking example of this phenomenon is the recent contamination of dog food with aflatoxin resulting in dozens of canine deaths in late 2005 and early 2006. Other circumstances of exposure to hepatotoxins in the home or farm include accidental food or feed contamination with industrial chemicals or pesticides, e.g. a human outbreak of hepatic porphyria in Turkey in 1955 caused by ingestion of wheat to which the fungistatic agent, hexachlorobenzene, had been added.

Research in the last decade has focused on understanding the different mechanisms for chemical-induced liver injury. Researchers have attempted to understand the molecular basis for injury and contribution of individual cell types to ultimate hepatic pathology. Recently, techniques such as microarray-based toxicogenomics, 2D gel electrophoresis-based proteomics and metabolomics, have attempted to further design novel hypotheses to test the molecular players involved in liver damage. Idiosyncratic drug reactions remain a mystery.

The goal of this chapter is to provide a basic understanding of the liver pathophysiology and general concepts of liver injury, and to expand on the commonly occurring drug/chemical toxicoses in veterinary medicine.

## STRUCTURAL AND FUNCTIONAL ORGANIZATION OF THE LIVER

The structural and functional organization of the liver has been described by the hepatic lobule and hepatic acinus

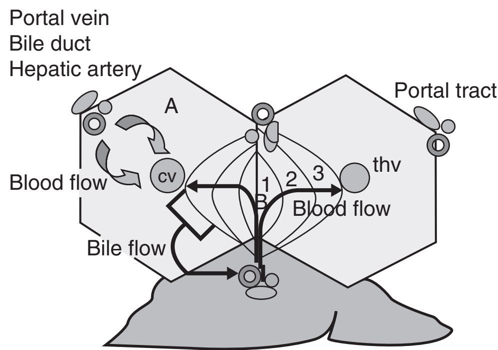
| | | *Nolina texana* | Plant | Herbivores, ruminants |
| Other | Pyrrolizidine alkaloids | *Amsinkia* spp.<br>*Crotolaria* spp.<br>*Cynoglossum* spp.<br>*Echium* spp.<br>*Erechtites glomerulata*<br>*Senecio* spp. | Plant | Herbivores |
| | Glycosides of methylazocymethanol | *Cycas* spp. | Plant | Dogs |
| | Carboxyatractyloside | *Xanthium* spp. | Plant | Swine, herbivores |
| | Triterpenes | *Lantana* spp. | Plant | Herbivores |
| | Amatoxins | *Amanita* spp. | Mushroom | All |
| | Microcystins | *Microcystis* spp. | Cyanobacteria | All |
| | Nodularins | *Nodularia* spp. | Cyanobacteria | All |
| | Phenolics and coal tar derivatives | Disinfectants, clay pigeons | Household | All |
| Idiosyncratic | Sulfonamides | Antimicrobial | Drug | Dogs |
| | Carprofen | Anti-inflammatory | Drug | Dogs |
| | Diazepam | Sedative | Drug | Cats |

models. The hepatic lobule is defined histologically as a hexagonal region of parenchyma surrounding the central vein. Six portal triads, composed of branches from the portal vein and hepatic artery as well as bile ductules, border the edge of the lobule. One-cell-thick plates or cords of hepatocytes are arranged radially around the central vein and blood sinusoids form between them. The hepatic parenchyma is divided into three zones based on proximity to the central vein. The area around the central vein is termed *centrilobular*, the area closer to the portal triads is *periportal*, and the area between the centrilobular and periportal parenchyma is termed *midzonal*.

Alternately, Rappaport defined the hepatic acinus as the smallest structural and functional unit in the liver based on the microcirculation in the liver. The simple hepatic acinus is defined as a parenchymal mass organized around the portal triad (Figure 10.1). Within the acinus, blood drains from the portal triad through the sinusoids into the central hepatic vein. The cells of the acinus are arbitrarily divided into three zones: *zone 1* corresponds to the periportal zone, *zone 2* corresponds to the midzonal parenchyma, and *zone 3* corresponds to the centrilobular zone. The blood supply is mainly from the portal tract vessels: 60–80% from branches of the portal vein supplying nutrients and toxins from the gastrointestinal tract, and 20–40% from the hepatic artery supplying oxygen (Treinen-Moslen, 2001). This blood is mixed in the penetrating vessels then enters the sinusoids. Blood flows sequentially through zones 1, 2, and 3 before draining via the terminal hepatic vein (central vein) (Figure 10.1). A consequent of this structure, hepatocytes in zone 1 receive blood that is 9–13% oxygenated whereas zone 3 is relatively hypoxic, the blood is 4–5% oxygenated (Treinen-Moslen, 2001). Blood entering zone 3 is relatively nutrient depleted (Sturgill and Lambert, 1997).

Hepatocyte stem cells, termed oval cells, are located in the canals of Hering where bile canaliculi from the hepatic cords converge on bile ductules of the portal triad. New hepatocytes progress down hepatic cords to replace the aging zone 3 hepatocytes.

Sinusoids, which are located between cords of hepatocytes, are larger than capillaries and lined by specialized



Comparative terminology for hepatic functional units

| Classic lobule (A) | Acinus concept (B) |
|---|---|
| Periportal, peripheral | Zone 1, periportal |
| Mid-zonal | Zone 2 |
| Central, centrilobular | Zone 3, perivenular |
| Panlobular | Panacinar |
| Multilobular | multiacinar |

Adopted from Veterinary Laboratory Medicine, Meyer and Hervey (eds), 2nd edition, 1998, p. 159, with permission

**FIGURE 10.1** Lobular versus acinar concept in liver architecture. The hepatic lobule is defined histologically as a hexagonal region of parenchyma surrounding the central vein. The blood flows from the portal vein and hepatic artery and mixed in the penetrating vessels, and enter the sinusoids. The hepatic parenchyma is divided into centrilobular, midzonal and periportal areas based on the proximity to the central vein. The acinus represents the functional unit in the liver wherein the parenchyma is organized around the portal triad and the triads represent the corners of the acinus triangle. In this concept, blood drains from the portal triad through the sinusoids into the central hepatic vein. The cells of the acinus are divided into zone 1 which corresponds to the periportal zone; zone 2 corresponds to the midzonal parenchyma, and zone 3 corresponds to the centrilobular zone.

endothelium. The endothelial lining is discontinuous and endothelial cells have fenestrae to allow movement of fluid and molecules less than 259 kDa (Watkins, 1999; Treinen-Moslen, 2001; Plumlee, 2004). This material enters the space of Disse, located between the endothelium and the hepatocytes. Within the space of Disse, hepatocytes contact free and protein bound molecules which may be absorbed by diffusion or active transport (Watkins, 1999).

The liver is a functionally diverse organ. Blood from the gastrointestinal tract, via the portal vein, is filtered for endotoxin, ammonia, other bacterial products, and xenobiotic (Treinen-Moslen, 2001; Plumlee, 2004). The liver is directly involved in nutrient homeostasis, including glucose regulation (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004); cholesterol synthesis and uptake (Treinen-Moslen, 2001); synthesis of proteins such as clotting factors, albumin, and very low-density lipoprotein (Treinen-Moslen, 2001; Plumlee, 2004); storage of glycogen, lipids, minerals, and vitamins (Plumlee, 2004); and metabolism and excretion of such things as hemoglobin breakdown products (Plumlee, 2004), steroid hormones (Brown, 2001), and drug metabolites.

There is remarkable metabolic diversity of the hepatic zones in order to accommodate its numerous functions. The liver is a predominant organ for the metabolism of xenobiotics, compounds that are foreign to the body. Hepatocytes of zone 3 in particular are rich in enzymes. These enzymes are divided into two main categories although phase III transporters are recently implicated in drug metabolism and transport (Xu *et al.*, 2005). Phase I enzymes are involved in oxidation, reduction, and hydrolysis reactions, and phase II enzymes are involved in conjugation reactions. These enzymes will be described in more detail later. Recently it has been shown that pretreatment with several inducers alter the expression of phase III transporters, alters the excretion of xenobiotics, and provides an important means to protect the body from xenobiotic insults. Zone 3 hepatocytes are involved in glycolysis and lipogenesis (Plumlee, 2004), and zone 1 hepatocytes are mitochondria rich (Treinen-Moslen, 2001; Plumlee, 2004). Functions of zone 1 hepatocytes include bile salt extraction, fatty acid oxidation, gluconeogenesis, and protein synthesis (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004; Plumlee, 2004). Zone 1 hepatocytes have the highest levels of glutathione (GSH) (Treinen-Moslen, 2001).

Bile secretion is a major function of the liver. Bile is composed of bile salts, bilirubin, GSH, phospholipids, cholesterol, proteins, organic anions, metals, and conjugated xenobiotics (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004). Bile salts and bilirubin enter bile canaliculi via active transport through hepatocyte membranes (Treinen-Moslen, 2001). Canaliculi are dynamic structures located between hepatocytes and formed by hepatocyte membranes (Treinen-Moslen, 2001; Plumlee, 2004). Energy-dependent transport exists for certain hormones, drugs, and other xenobiotics (Treinen-Moslen, 2001). These include a group of multiple drug resistance *p*-glycoproteins that transport lipophilic cationic drugs, estrogens, and phospholipids, and canalicular multiple organic anion transporters involved in movement of molecules conjugated to GSH, glucuronide, and sulfate (Treinen-Moslen, 2001). Metal and mineral transport is important for mineral homeostasis and occurs through facilitated diffusion and receptor-mediated endocytosis across the sinusoidal membrane. Lysosomes are involved in storage and export of metals and minerals into canaliculi (Treinen-Moslen, 2001).

Canaliculi enter canals of Hering in the portal triad and lead to intrahepatic bile ducts which coalesce to form the hepatic bile duct. Most species have a gall bladder for bile storage, but many that eat frequently lack a gall bladder, including pigeons, rats, deer. Ratites lack a gall bladder, as do many parrots. Horses and related species, the rhinoceroses and tapirs, lack a gall bladder, as do elephants, camels (New and Old World), and porcupines. Most carnivores have a gall bladder, the exception being dolphins and other cetaceans. Gall bladders may or may not be present in some species such as the giraffe and hippopotamus

(Oldham-Ott and Gilloteaux, 1997). The gall bladder stores and concentrates bile and then empties into the duodenum. Bile that is excreted into the small intestine enhances nutrient uptake, protects enterocytes from oxidation, and facilitates excretion of xenobiotics and endogenous waste in the feces (Treinen-Moslen, 2001).

Seven intrinsic cell types have been identified in the liver: the parenchymal cells or hepatocytes, and the oval cell or hepatocytic stem cells, both described above, and four types of non-parenchymal cells. As well as the endothelial cells lining sinusoids and bile duct epithelium, mentioned above, the non-parenchymal cells include the Kupffer cells, which are resident macrophages, the stellate cells, also called ito cells or fat storing cells, and the pit cells or large granular lymphocytes. In the rat, hepatocytes represent for about 60% of the total cell number and 80% of hepatic tissue volume. Non-parenchymal cells in the rat are estimated to constitute about 30% of total cellular population, but comprise only 6–7% of tissue volume due to their small size relative to hepatocytes (Jones, 1996).

Kupffer cells represent 80% of the fixed macrophages in the body (Treinen-Moslen, 2001). These cells are mostly located within the sinusoidal lumina in close association with endothelial cells. Kupffer cells function as phagocytes, ingesting foreign material which may arrive through the portal circulation (Treinen-Moslen, 2001; Plumlee, 2004) as well as apoptotic or necrotic hepatocytes. Kupffer cells have other immune functions in that they act as antigen presenting cells and secrete various cytokines (Treinen-Moslen, 2001; Plumlee, 2004). They are involved in destruction of metastatic neoplastic cells (Plumlee, 2004). Kupffer cells may store minerals and are also involved in the pathogenesis of a variety of liver diseases induced by toxins such as ethanol (Laskin, 1990; Thurman *et al*., 1998).

Stellate cells are located within the sinusoids and store fat and vitamin A (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004; Plumlee, 2004). When there is liver injury, stellate cells may become activated to myofibroblast-like cells (Plumlee, 2004; Maddrey, 2005). Activated stellate cells produce collagen and play a role in hepatic fibrosis (Treinen-Moslen, 2001; Plumlee, 2004).

Pit cells are natural killer cells which have antineoplastic actions (Treinen-Moslen, 2001; Plumlee, 2004). They are also involved in granuloma formation (Plumlee, 2004).

# FACTORS INFLUENCING TOXIC LIVER INJURY

## Uptake and concentration

The liver has a dual blood supply as noted above. The hepatic artery brings material from the systemic circulation and the portal blood flow brings material directly from the gastrointestinal system. The portal system is involved in what is described as the "first pass effect", meaning that nutrients and xenobiotics that are absorbed from the stomach and intestines are filtered through the liver before entering the systemic circulation (Treinen-Moslen, 2001).

The space of Disse allows close contact between circulating plasma, plasma proteins, and hepatocytes, allowing for rapid diffusion of lipophilic compounds across the hepatocyte membrane (Treinen-Moslen, 2001). Some compounds are specifically taken up by sinusoidal transporters, including phalloidin from several species of mushrooms in the genus *Amanita*, microcystin produced by the cyanobacteria *Microcystis aeruginosa*, and bile acids (Treinen-Moslen, 2001).

Liver cells may accumulate high levels of metals and vitamins, which can lead to toxic injury. Excessive storage of vitamin A in stellate cells acutely leads to engorgement, activation, and proliferation of these cells (Treinen-Moslen, 2001). Chronic high levels lead to hepatic fibrosis and portal hypertension, precipitating increased fibrosis (Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004; Maddrey, 2005). Cadmium is sequestered by hepatic metallothioneins but may produce pathology when storage capacity is exceeded (Treinen-Moslen, 2001). The liver is also responsible for iron homeostasis. There is receptor-mediated uptake of iron from the sinusoids and sequestration in storage proteins such as ferritin. High levels of iron cause lipid peroxidation of zone 1 hepatocytes (Treinen-Moslen, 2001). Of veterinary relevance is the copper-mediated liver damage noted in certain breeds of dogs (Bedlington terriers, Dobermans, and Dalmatinans) where copper is stored within the lysosomes of hepatocytes resulting in progressive accumulation of copper resulting in liver necrosis (Rolfe and Twedt, 1995). Sheep are also particularly susceptible to elevated hepatic copper levels.

## Bioactivation and metabolism

Most xenobiotic agents absorbed by the small intestine are highly lipophilic. Renal excretion is the primary mechanism of removal for xenobiotics, but renal excretion of lipophilic compounds, which are frequently protein bound in the circulation, is poor (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Watkins, 1999). Such lipophilic compounds must be metabolized to increase their water solubility for excretion (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Zimmerman, 1999). Enzymes within the liver add functional groups or conjugate xenobiotics to water-soluble molecules to promote excretion. While these reactions often function in the detoxification of compounds, there is significant potential for toxification (Zimmerman, 1999). Phase I reactions involve oxidation, reduction, and hydrolysis, and are ubiquitous in mammals (Brown, 2001). Phase I enzymes, which are predominantly located in zone 3, may produce active metabolites.

Many hepatic enzymes are present in the smooth endoplasmic reticulum of the hepatocyte. When liver tissue is homogenized, the endoplasmic reticulum breaks down into small vesicles known as microsomes, thus these enzymes are termed microsomal enzymes. Many of the phase I enzymes are microsomal enzymes. As a rule, microsomal enzymes require oxygen and NADPH to function (Dahm and Jones, 1996; Brown, 2001).

Most phase I enzymes contain heme, giving them a red coloration, and they absorb light at a wavelength of 450 nm. These enzymes are known as cytochrome P450s, the P for pigment and 450 for the wavelength of absorbed light. Most cytochrome P450s act as mixed function oxidases (MFOs). Genes for cytochrome P450s are highly conserved in mammals. There are 3 gene families, CYP1, CYP2, and CYP3, and more than 36 cytochrome P450 isoenzymes have been identified in animals (Dahm and Jones, 1996; Watkins, 1999).

Oxidation is the major phase I reaction produced by the group of cytochrome P450s known as MFOs. Important substrates include steroid hormones and lipid soluble drugs (Brown, 2001). Oxidative reactions frequently lead to the formation of highly reactive epoxides (Watkins, 1999). These toxic metabolites are very transient and usually detoxified rapidly by phase II conjugation or other mechanisms, such as microsomal epoxide hydrolases (Watkins, 1999; Piñeiro-Carrero and Piñeiro, 2004). If an individual is exposed to the xenobiotic in doses too high for these mechanisms to compensate reactive phase I metabolites are not removed quickly enough to prevent injury (Watkins, 1999).

Non-cytochrome P450 enzymes may be involved in oxidative reactions. One such enzyme is alcohol dehydrogenase whose substrates include vitamin A, ethanol, and ethylene glycol. Aldehyde dehydrogenase is another.

Most reduction reactions also involve microsomal enzymes, with the exception of ketone reduction. Nitro compounds are reduced to amines and volatile anesthetics undergo dehalogenation by microsomal enzymes. Hydrolysis reactions are involved in metabolism of compounds with amide bonds or ester linkages, as in the conversion of aspirin to salicylate (Brown, 2001).

Phase II enzymes may be cytosolic or microsomal (Dahm and Jones, 1996; Brown, 2001). Phase II enzymes are predominantly involved in conjugating phase I metabolites or xenobiotics with functional groups. Phase II metabolites are rarely reactive, but there are exceptions, such as the glucuronide of the non-steroidal anti-inflammatory drug (NSAID) diclofenac and the GSH conjugate of $\alpha$-napthothiourea (ANIT). Phase II enzymes conjugate a polar group to the substrate at a hydroxyl group, carboxyl group, amino group, or sulfhydryl group that may have been produced through the actions of phase I enzymes. Polar molecules that are added to the substrate include glucuronic acid, sulfate derived from sulfuric acid ester, acetate, GSH, methyl groups derived from methionine, and amino acids such as glycine and cysteine. These polar groups enhance water solubility of the substrate and allow renal or biliary excretion. Disruption of phase II reactions may lead to accumulation of reactive phase I metabolites (Sturgill and Lambert, 1997).

Glucuronidation is the most common phase II reaction in humans, though it is deficient in the neonate and, of significant veterinary importance, in cats (Sturgill and Lambert, 1997; Brown, 2001; Piñeiro-Carrero and Piñeiro, 2004). Substrates with an atomic mass greater than 500 amu frequently undergo glucuronidation. Such substrates include steroid hormones, thyroxin, and bilirubin as well as many drugs, including salicylates and acetaminophen (Brown, 2001). Glucuronyl transferases are microsomal enzyme that catalyzes the transfer of glucuronide from uridine 5′-diphosphate (UDP) (Watkins, 1999). UDP may be depleted in patients overdosed with acetaminophen or other drugs that undergo this detoxification pathway. Products of glucuronidation may be excreted in the bile or urine. Those excreted in the bile may undergo hydrolysis in the intestine, which leads to reabsorption of the parent compound in a phenomenon called enterohepatic cycling (Brown, 2001). Some agents induce glucuronyl transferases, such as phenobarbital (Sturgill and Lambert, 1997).

Sulfation is the primary conjugation reaction for substrates with phenol groups or aliphatic alcohols (Sturgill and Lambert, 1997; Brown, 2001). These reactions are catalyzed by sulfotransferases in the cytoplasm. Agents that undergo sulfation include acetaminophen, morphine, ascorbic acid, and endogenous compounds like chondriotin, heparin, and some steroids. The pool of available sulfates may become saturated in drug overdoses (Brown, 2001).

Drugs with amine and hydrazine groups may be conjugated to acetate (Sturgill and Lambert, 1997). Sulfonamides often undergo acetylation (Brown, 2001). *N*-acetyltransferase is an enzyme in the cytoplasm involved in acetylation reactions.

GSH and cysteine both have sulfhydryl groups which readily bind many phase I metabolites (Brown, 2001). GSH is a free radical scavenger that prevents membrane damage from reactive metabolites. These reactions may be spontaneous or catalyzed by GSH peroxidases and selenium-dependent enzymes. Because these enzymes are cytosolic, damaged membrane phospholipids must be released by phospholipase A2 for detoxification. GSH is also involved in reduction and recycling of other antioxidants such as vitamins E and C (Dahm and Jones, 1996). When oxidized, GSH forms a dimer which must be reduced by GSH reductases, NADPH-dependent enzymes (Dahm and Jones, 1996). GSH may be depleted in the overdosed patient or due to fasting (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Piñeiro-Carrero and Piñeiro, 2004). *N*-acetylcysteine is frequently used to replenish GSH.

Significant species differences exist in phase II enzymes. Glucuronyl transferase is deficient in cats, which significantly affects their ability to detoxify certain compounds including acetaminophen (Brown, 2001). Swine have reduced sulfate conjugation abilities (Brown, 2001). Dogs do not have the ability to acetylate aromatic groups (Brown, 2001; Trepanier, 2004). This may interfere with their ability to metabolize sulfonamide antimicrobials (Trepanier, 2004).

In addition to phase I and II biotransformation enzymes, studies suggests the involvement of hepatic transporter systems involved in drug efflux from hepatocytes as a means for the liver to rid itself of foreign chemicals. This is termed phase III transporter systems. Several transporter families which mediate uptake of chemicals into liver and excretion of chemicals from liver into blood and/or bile have been cloned and identified. In general, the Organic anion transporting polypeptide family (Oatps) along with Organic cation transporter 1 (Oct1) and organic anion transporter 2 mediate uptake of a large number of xenobiotics from blood into liver. Conversely, Multidrug resistance proteins (Mdrs), Multidrug resistance associated proteins (Mrps), and Breast cancer resistance protein (Bcrp) mediate efflux of xenobiotics from liver into bile or blood (Klaassen and Slitt, 2005).

Reactive metabolites of phase I or occasionally phase II processes might act as free radicals, substances with unpaired electrons. Free radicals act by the generation of reactive oxygen species such as superoxide ($O_2^-$), hydroxyl radicals (OH) and hydrogen peroxide ($H_2O_2$) through interactions with other molecules. Free radicals reacting with phospholipids of the plasma membrane, endoplasmic reticulum membrane, or mitochondrial membranes cause a self-propagating chain reaction that may lead to cell death (Dahm and Jones, 1996; Watkins, 1999).

Electrophiles are molecules with electron seeking properties, often epoxides. They form covalent bonds with nucleophilic molecules, often binding to thiol groups on proteins (Dahm and Jones, 1996; Watkins, 1999; Zimmerman, 1999). Electrophiles produced by phase I reactions may cause cell death by damage to critical proteins, such as calcium transport proteins in membranes (Dahm and Jones, 1996). Aflatoxin $B_1$ binds to guanine residues in the DNA, which may lead to defects in protein transcription and cell death, or to carcinogenesis (Dahm and Jones, 1996).

# TYPE OF CHEMICALLY MEDIATED LIVER INJURY

## Hepatic steatosis/fatty liver

Hepatic steatosis is simply the accumulation of fat vacuoles within the hepatocytes. Steatosis is a common response noted with a variety of liver toxicants and represents a potentially reversible injury to hepatocytes (Treinen-Moslen, 2001). Grossly, the affected liver will be swollen with rounded edges, friable, and light brown to yellow in color. Due to the fat accumulation, sections of the affected liver will float in formalin (Plumlee, 2004). Compounds that produce prominent steatosis associated with mortality include the antiepileptic drug valproic acid and the antiviral agent fialuridine. Other toxins that may cause hepatic steatosis include aflatoxin and white or yellow phosphorus. Although steatosis has been considered a benign and reversible situation, there are recent reports that suggest that several biochemical alterations occur during the steatosis stage resulting in steatohepatitis, fibrosis and cirrhosis (Apte *et al.*, 2004; Ramaiah *et al.*, 2004). Recently, there is a syndrome noted in obese individuals, who are often type II diabetics, called non-alcoholic fatty liver disease (NAFLD) where hepatocytes are markedly steatotic and there is marked inflammatory component (Diehl 2002). Other disorders that result in fatty livers include ethanol and carbon tetrachloride. It should be noted however that several endocrine abnormalities result in steatosis, thus assigning the cause to a specific etiology should be done with caution. Serum transaminase levels during steatosis are usually variable and a mild to moderate increase in serum transaminase is not unexpected. Hepatic steatosis can cause cholestasis if lipid accumulation is severe.

Steatosis is termed microvesicular if the fat droplets are small and do not displace the nucleus. Microvesicular steatosis often indicates a slow lipid accumulation (Bastianello *et al.*, 1987; Plumlee, 2004). This form of steatosis may indicate a deficiency in mitochondrial $\beta$-oxidation of fatty acids. It is a relatively severe form of steatosis and has been associated with some toxins including aflatoxin in primates and dogs (Bastianello *et al.*, 1987; Zimmerman, 1999) and valproic acid in humans (Sturgill and Lambert, 1997; Zimmerman, 1999).

Macrovesicular steatosis describes hepatocytes containing large, usually single fat droplets that displace the hepatocyte nucleus to the periphery of the cytoplasm. This is the more common form of steatosis in domestic animals (Plumlee, 2004). Macrovesicular steatosis indicates an imbalance between fatty acid uptake and the secretion of very low-density lipoproteins. This may be due to increased triglyceride mobilization, decreased fatty acid oxidation, decreased synthesis of very low-density lipoproteins, or other metabolic anomalies (Sturgill and Lambert, 1997; Zimmerman, 1999; Treinen-Moslen, 2001; Plumlee, 2004). Macrovesicular steatosis has been reported in dogs with subacute aflatoxicosis (Bastianello *et al.*, 1987). Zone 1 macrovesicular steatosis is reported with yellow phosphorus toxicosis (Zimmerman, 1999). Macrovesicular steatosis is relatively common in veterinary medicine and occurs with a variety of metabolic diseases. Steatosis is common in obese cats with anorexia and preparturient cattle due to mobilization of lipids.

## Steatohepatitis

Steatohepatitis is the accumulation of lipid and the presence of inflammatory cells within hepatic parenchyma. Steatohepatitis is usually the next stage of steatosis if untreated (Lieber, 1994; Bautista, 2002; French, 2003). The inflammatory cells are usually neutrophils and mononuclear leukocytes. There is no specificity noted with this pathologic stage and the distribution of lipidosis and inflammation is random and multifocal. Conditions usually associated with steatohepatitis are alcoholic liver disease, NAFLD and endotoxemia secondary to intestinal disease. Any toxic compounds that cause steatosis can also result in steatohepatitis if condition is left untreated. It should be noted that steatohepatitis may progress to fibrosis/cirrhosis and hepatocellular carcinoma if the inciting cause is not removed or treated (Diehl, 2002). The clinical biochemistry alterations of the liver usually include elevated serum transaminases.

## Cell death

Two forms of cell death are described, apoptosis and necrosis. Apoptosis is often called "programmed cell death" and is a normal physiologic process. Individual cells are affected (Dahm and Jones, 1996), cell death is not associated with inflammation, and normal architecture of the hepatic parenchyma is maintained allowing regeneration (Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004). Apoptotic cells undergo cell shrinkage, nuclear condensation, and pyknosis (Dahm and Jones, 1996; Treinen-Moslen, 2001), but mitochondrial function is maintained (Piñeiro-Carrero and Piñeiro, 2004) and the cell membrane remains intact (Zimmerman, 1999). Apoptotic cells are occasionally seen in the centrilobular area but are rapidly phagocytized by macrophages and other hepatocytes (Plumlee, 2004). Apoptosis may be induced by xenobiotics due to oxidative stress (Piñeiro-Carrero and Piñeiro, 2004), decrease in apoptotic suppressors, or enhanced expression of apoptosis genes (Dahm and Jones, 1996).

Necrosis is the predominant form of cell death in most toxic insults. The term "necrotic" is used to describe "dead and dying" cells which are often identified by homogenous eosinophilic cytoplasm on hematoxylin and eosin (H&E) stained liver sections with variable loss of nuclear and cellular detail. Degenerative changes to the hepatocyte may precede necrosis. Microscopically evident changes may include ballooning degeneration, hyaline degeneration, and the presence of Mallory bodies (Zimmerman, 1999). Cells lose osmotic homeostasis and there is swelling of hepatocytes on a microscopic basis and organelles on an ultrastructural basis (Dahm and Jones, 1996; Treinen-Moslen, 2001). Energy production fails due to loss of calcium homeostasis (Dahm and Jones, 1996; Zimmerman, 1999). Eventually there is rupture of the cell membrane and leakage of cell contents (Dahm and Jones, 1996; Zimmerman, 1999; Treinen-Moslen, 2001). Typically, necrosis results in elevation of serum transaminases such as alanine transaminase (ALT), aspartate transaminase (AST) and sorbitol dehydrogenase (SDH). Depending on the extent of liver necrosis, the liver function may or may not be affected.

Necrosis is often initiated by damage to membranes, either the plasma membrane of the cell or the membranes of organelles, particularly the mitochondria (Zimmerman, 1999). Cell membrane damage is often caused by peroxidation of membrane phospholipids (Zimmerman, 1999). Damage to the plasma membrane interferes with ion regulation, damage to the membranes of the mitochondria interfere with calcium homeostasis and energy production, and damage to the smooth endoplasmic reticulum membrane diminishes the ability of that organelle to sequester calcium (Zimmerman, 1999). Inhibition of protein synthesis is an alternate mechanism that may cause cell necrosis. Toxins that act in this way include phalloidin and related mushroom toxins, which inhibit the action of RNA polymerase and therefore mRNA synthesis (Piñeiro-Carrero and Piñeiro, 2004).

Necrotic liver injury can be focal, zonal, bridging, or massive and panlobular. Focal necrosis is randomly distributed and involves hepatocytes either individually or in small clusters (Treinen-Moslen, 2001). Zonal necrosis is common and usually occurs in zone 3, the centrilobular zone (Zimmerman, 1999; Treinen-Moslen, 2001; Plumlee, 2004). Grossly, the liver will have a reticulated pattern with dark red central areas separated by brown to yellow areas (Plumlee, 2004). Bridging necrosis describes confluent zones of necrosis that extend between zones of the lobule and between lobules (Treinen-Moslen, 2001). Panlobular or massive necrosis denotes hepatocyte loss throughout the lobule with loss of lobular architecture (Treinen-Moslen, 2001; Plumlee, 2004). The liver is grossly swollen and friable with panlobular injury (Plumlee, 2004).

Although necrosis and apoptosis are considered separate entities, an alternate view is emerging that apoptosis and necrosis are frequently the consequence of the same initiating factors and signaling pathways. Rather than being separate entities, apoptosis and necrosis in their pure form may represent extremes on a continuum of cell death. Thus necrosis resulting from oncotic event or oncosis is termed "oncotic necrosis" and that originating from apoptosis is termed "apoptotic necrosis" (Levin *et al.*, 1999; Jaeschke *et al.*, 2004; Malhi *et al.*, 2006).

The nature of the lesions can tell us something about the mechanism of injury. Several drugs/chemicals such as carbon tetrachloride ($CCl_4$), acetaminophen, thioacetamide, allyl alcohol and ethanol result in hepatocyte oncotic necrosis. Carbon tetrachloride, acetaminophen, and thioacetamide cause centrilobular necrosis, a commonly seen

pattern while the necrosis caused by allyl alcohol may fit the more rarely seen midzonal pattern. Recently, we have identified midzonal necrosis in a rat model of endotoxin-mediated hepatitis. Ethanol ingestion results in multifocal, random hepatic necrosis. Necrosis may be a primary event such as that caused by reactive intermediates (e.g. acetaminophen, thioacetamide and carbon tetrachloride), or may be a secondary event following infiltration of inflammatory cells as seen with ethanol.

## Pigment accumulation

Various substances may accumulate within hepatocytes or Kupffer cells. These substances may be visible by microscopy as pigment. Occasionally, these pigments lend a grossly visible tint to the liver. Bile pigment may accumulate in canaliculi and bile ducts, particularly in zone 3, leading to a yellow to green color (Zimmerman, 1999; Plumlee, 2004). Iron in the form of hemosiderin is stored in the liver as a yellow-brown pigment which may be visualized using Pearl's Prussian Blue (Plumlee, 2004). Copper may be yellow-brown and is visualized using Rhodenase (Plumlee, 2004). Lipofuscin may be present within hepatocytes as a senile change. This yellow-brown pigment represents lipid accumulation within lysosomes (Plumlee, 2004).

## Cholestatic liver injury

Cholestasis may be transient or chronic (Treinen-Moslen, 2001). If severe, bile pigments give the liver a grossly yellow to yellow-green tint (Plumlee, 2004). Cholestasis may be subdivided into canalicular cholestasis and cholangiodestructive cholestasis.

Canalicular cholestasis can be produced by drugs/chemicals that damage the bile canalicular structures and function. Cholestasis may be primary or secondary. A key component of bile secretion involves several ATP-dependent export pumps such as the canalicular bile salt transporter that moves bile salts and other transporters that export bile constituents from the hepatocyte cytoplasm to the lumen of the canaliculus. Some of the drugs bind these transporter molecules resulting in the arrest of bile formation or movement within the lumen of the canalicular system (Klaassen and Slitt, 2005). Secondary bile injury can result if there is cholestasis due to the detergent action of bile salts on the biliary epithelium or hepatocytes in areas of cholestasis. Cholestasis can occur simply as a result of physical obstruction of canaliculi within the liver parenchyma (intrahepatic) or outside the liver (extrahepatic). Causes of cholestasis may include hepatobiliary tumors, endotoxemia, hepatocyte swelling, and intraductal crystals such as calcium salts of plant saponins, e.g. those found in *Tribulus* spp. Disruption of actin filaments within the hepatocyte may cause cholestasis by preventing the normal pulsatile contractions that move bile through the canalicular system to the bile ducts. Drugs that bind to actin filaments such as phalloidin, those that affect cytoskeletal assembly such as microcystin, and those that affect calcium homeostasis and cellular energy production can generate this type of injury. Cholestatic disorders typically result in elevation of serum alkaline phosphatase, $\gamma$-glutamyl transferase and elevation in serum bilirubin. Toxic hepatopathies may be primarily cholestatic, necrotic, or mixed.

Cholangiodestructive cholestasis is caused by bile duct obstruction which may be intrahepatic or extrahepatic. Bile duct injury may lead to sloughing of epithelial cells into the lumen, cell edema, and inflammation, which may contribute to obstruction (Treinen-Moslen, 2001; Plumlee, 2004). Chronic lesions associated with cholangiodestructive cholestasis typically include bile duct proliferation and periductular fibrosis (Treinen-Moslen, 2001; Plumlee, 2004). Vanishing bile duct syndrome, characterized by a loss of bile ducts, has been seen in chronic cholestatic disease in humans (Zimmerman, 1999; Treinen-Moslen, 2001) and has been produced experimentally in dogs (Uchida *et al.*, 1989).

## Hepatic fibrosis/cirrhosis

Fibrosis is a non-specific lesion which usually results from chronic inflammation. Chronic inflammation can be the result of continuous exposure to a variety of hepatotoxic chemicals such as organic arsenicals, vinyl chloride, or high doses of vitamin A (Zimmerman, 1999), chronic ethanol ingestion and NAFLD. Fibrosis usually occurs around the portal area, in the space of Disse, and around the central veins. This results in loss of liver architecture and function. The hepatocytes are replaced with fibrous material and thus there is hepatocyte loss. Periportal fibrosis may lead to portal hypertension (Zimmerman, 1999).

## Cirrhosis

Hepatic cirrhosis is typically the end stage liver disease. Cirrhosis describes irreversible changes characterized by accumulation of excessive collagen deposition in the form of bridging fibrosis which disrupts the hepatic architecture (Treinen-Moslen, 2001). Hepatocytes entrapped by fibrosis undergo random mitosis and growth, termed nodular regeneration. Cirrhosis may be micronodular or macronodular depending on the amount of fibrosis and tissue regeneration. The surface of a liver with micronodular fibrosis will have a cobblestone appearance. The liver will be firm and difficult to cut with a knife.

When the liver reaches this stage, the serum transaminase enzymes are usually low due to the lack of functional

hepatocytes and the liver function parameters such as bile acids and ammonia are highly elevated. Prognosis for recovery is poor. Liver transplantation is the only solution to restore adequate liver function in human medicine.

## Hepatic neoplasia

Chemically induced tumors can originate from hepatocytes, biliary epithelium and very rarely from endothelium of hepatic sinusoids. Neoplasias occur months to years after toxin exposure (Plumlee, 2004). If a toxin causes direct damage to DNA, a single exposure may lead to neoplastic changes (Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004). Aflatoxin $B_1$ is an agent that acts by alkylating DNA and is associated with hepatocellular carcinoma in humans infected with hepatitis B virus. Aflatoxin B1 has also been implicated in liver cancers in trout and laboratory animals (Newberne and Butler, 1969). Non-genotoxic agents must be given at high doses for long periods of time to induce cancer (Piñeiro-Carrero and Piñeiro, 2004). Examples of non-genotoxic agents include phthalate esters in plasticizers, phenoxy acid herbicides, and hypolipidimic drugs (Piñeiro-Carrero and Piñeiro, 2004).

Hepatic adenomata are benign neoplasms of the hepatocytes that have been associated with contraceptive steroid use in humans (Zimmerman, 1999). Hepatocellular carcinomata are of more concern. These malignant neoplasms of the hepatic parenchyma may be induced by various chemical and botanical toxins. They have been found in humans affected with hepatitis B virus and exposed to aflatoxin $B_1$, as noted above, and associated with anabolic steroid abuse (Zimmerman, 1999). Other risk factors for hepatocellular carcinomata include viral hepatitis C and D, ethanol abuse, and microcystin exposure.

Biliary carcinomata or cholangiocarcinomata are not commonly associated with exposure to drugs/chemicals. Biochemical indicators noted include normal, elevated or low levels of serum transaminases and loss of liver function resulting in increased bile acids and ammonia levels.

Angiosarcomata or hemangiosarcomata derives from sinusoidal epithelium (Zimmerman, 1999; Treinen-Moslen, 2001; Plumlee, 2004). This neoplasm is rare but rapidly lethal and has been associated with exposure to vinyl chloride, inorganic arsenics (Zimmerman, 1999), and Thorotrast, a form of radioactive thorium dioxide once used in radiographic contrast studies.

# MECHANISMS OF LIVER DAMAGE

Mechanisms of liver injury have been divided into two classifications, intrinsic and idiosyncratic. Intrinsic injury may lead to steatosis, necrosis, cholestasis, or a mixed form of damage, often with minimal inflammation (Cullin and Ruenber 1991; Sturgill and Lambert, 1997). Intrinsic liver injury is a predictable, reproducible, dose-dependent reaction to a toxicant (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004). A threshold dose exists for xenobiotics causing intrinsic liver injury (Sturgill and Lambert, 1997). There is commonly a predictable latent period between the time of exposure and clinical evidence of liver injury (Dahm and Jones, 1996). This type of liver injury accounts for the vast majority toxic liver injury and is often caused by reactive products of xenobiotic metabolism, most commonly electrophiles and free radicals. A few drugs cause intrinsic liver injury without bioactivation (Zimmerman, 1999). An abbreviated summary of mechanisms of intrinsic liver injury is illustrated in Figure 10.2.

Idiosyncratic responses are, by contrast, unpredictable responses to a drug or other toxicant. They are rare, non-dose dependent, and often associated with extrahepatic changes (Sturgill and Lambert, 1997; Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004; Shenton *et al.*, 2004).

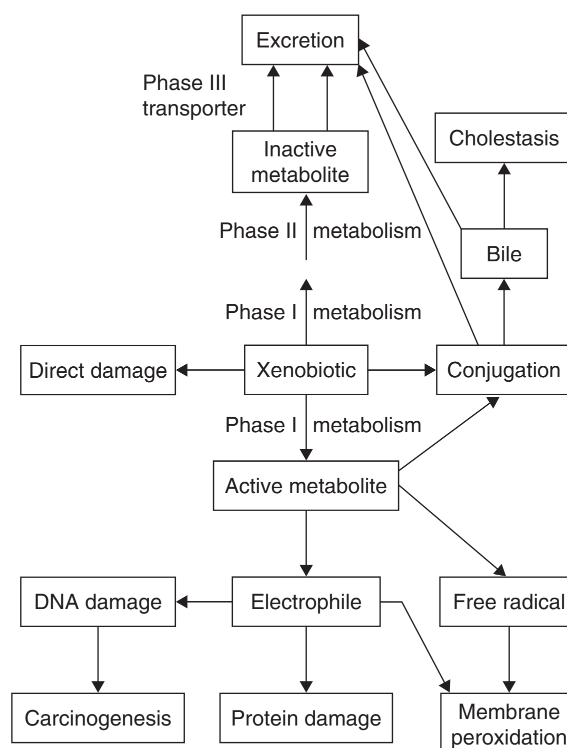


**FIGURE 10.2** Basic mechanisms of hepatic injury showing the relationship between multiple pathways for metabolism and toxicity for any compound. The liver metabolizes xenobiotics (and some endogenous compounds) to form water-soluble products appropriate for urinary or biliary excretion. Some compounds are activated through these metabolic processes to free radicals, electrophiles, or other toxic products that may induce hepatic injury.

Idiosyncratic drug reactions often occur after sensitization followed by reexposure to a drug (Sturgill and Lambert, 1997; Dahm and Jones, 1996; Zimmerman, 1999; Treinen-Moslen, 2001). There is usually a delay of 1–5 weeks (Zimmerman, 1999), and occasionally several months, between the time of the first dosing and the time clinical signs become evident, but onset is expedited with rechallenge (Dahm and Jones, 1996; Sturgill and Lambert, 1997; Watkins, 1999). Hepatic changes associated with idiosyncratic drug reactions include necrosis, cholestasis, or both, and there is often an inflammatory response involving macrophages and eosinophils (Sturgill and Lambert, 1997). Extrahepatic clinical signs may include pyrexia, rash, and peripheral eosinophilia (Sturgill and Lambert, 1997; Watkins, 1999; Zimmerman, 1999; Piñeiro-Carrero and Piñeiro, 2004). Some idiosyncratic drug reactions resemble serum sickness (Zimmerman, 1999).

Liver injury can also be classified as acute or chronic. Acute responses to liver toxins may be cytotoxic, cholestatic, or both. These classifications are also present in chronic hepatotoxin responses, with the addition of veno-occlusive disease, often associated with thrombosis of the hepatic vein (Piñeiro-Carrero and Piñeiro, 2004).

Mechanisms of liver injury are described in more detail below.

## Oxidative stress mediated by free radicals

Free radicals are generated from within hepatocytes in several ways, such as ionizing radiation, oxidative metabolism by cytochrome P450, reduction and oxidation (redox) reaction that occur during normal metabolism, transition metals such as iron and copper, and from nitric oxide (NO) generated by variety of inflammatory cells. The reactive species generated result in lipid peroxidation of membranes, oxidative modification of proteins and lesions within DNA (Crawford, 1999).

Free radicals have unpaired electrons, making them highly reactive. They may be formed by one electron oxidation or reduction reactions, leading to cationic or anionic radicals, respectively (Dahm and Jones, 1996). Alternately, hemolytic bond scission leads to neutral radical formation (Dahm and Jones, 1996). Oxygen free radicals result from metabolic processes, leukocytic respiratory burst, or to the effects of ionizing radiation. Hydroxyl radicals, superoxide-radicals, and hydrogen peroxide are major reactive oxygen species (Dahm and Jones, 1996). The free radical NO, an important cell-signaling agent released by leukocytes, may react with superoxide to form peroxinitrite.

Free radicals cause peroxidation of phospholipids within the plasma membrane of the cell as well as the membranes of the mitochondria and endoplasmic reticulum. The radicals act by removing a proton ($H^+$) from a methylene carbon within a polyunsaturated fatty acid, forming a lipid free radical. This lipid free radical may then abstract a proton from a neighboring polyunsaturated fatty acid, generating more lipid free radicals. It is estimated that this can occur 4–10 times per initiation (Dahm and Jones, 1996). Effects of lipid peroxy radicals on the cell membrane include increased permeability, decreased fluidity, and inactivation of membrane proteins (Dahm and Jones, 1996). Additionally, mitochondrial membranes lose polarity (Watkins, 1999).

Lipid peroxy radicals can react with metal ions stored within the hepatocyte, generating more lipid radicals. It is estimated that propagation by this mechanism can occur in 4–10 steps per initiation (Dahm and Jones, 1996).

The most frequent mechanism of free radical production leading to hepatocellular injury involves phase I metabolism of xenobiotics and the cytochrome P450 system. Phase I metabolism may lead to bioactivation of the substrate to a high-energy reactive intermediate molecule in preparation for phase II conjugation reactions. However, in circumstances such as overdosage, phase I products may accumulate. Lesions produced by these compounds are mostly centrilobular because the cytochrome P450s responsible for metabolism is mostly situated in the centrilobular areas of the liver.

The classical examples of this process are cell death resulting from acetaminophen (Figure 10.3) and carbon tetrachloride (Figure 10.4) toxicosis. Acetaminophen is a widely used analgesic that rarely induces clinical signs at therapeutic doses, except in the particularly susceptible feline species, where acute liver failure oxidation of hemoglobin, and methemoglobinemia occur.

Acetaminophen has a hydroxyl group that can undergo immediate phase II conjugation reactions. Indeed, at therapeutic doses 90% of this substrate undergoes glucuronide or sulfate conjugation in humans (Mitchell *et al.*, 1973; Court and Greenblatt, 1997; Sturgill and Lambert, 1997). These are major metabolic pathways in most species, but glucuronyl transferase deficiency in cats in part explains the sensitivity of felines to this drug (Court and Greenblatt, 1997).

Acetaminophen itself is not considered toxic. Cellular injury is caused by the unstable metabolite, *N*-acetyl-*p*-benzoquinone imine (NAPQI). Under normal conditions in humans, 5% of a dose of acetaminophen is oxidized to NAPQI, which is rapidly neutralized by conjugation with GSH (Sturgill and Lambert, 1997; Maddrey, 2005). Toxic levels of NAPQI may accumulate under certain conditions, as when large amounts of substrate are available for metabolism due to either large ingestions or inadequate glucuronidation. Metabolism of acetaminophen to NAPQI is increased in individuals who regularly consume alcohol or take medications that induce microsomal enzymes, e.g. antiepileptic therapy. The hepatic pool of GSH becomes overwhelmed and depleted permitting the accumulation of NAPQI. Possible additional risk factors that lower the

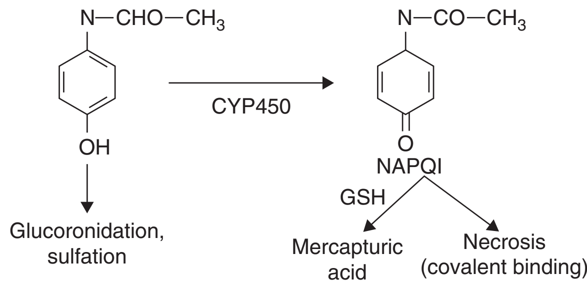

**FIGURE 10.3** Metabolism and mechanism of acetaminophen toxicity. Bioactivation of acetaminophen by P450 enzymes results in the formation of the reactive intermediate (NAPQI) which form covalent protein adducts with GSH which is then converted to mercapturic acid. When the amount of the reactive metabolite formed exceeds the GSH available for binding, the excess metabolite binds to tissue molecules resulting in centrilobular hepatic necrosis.

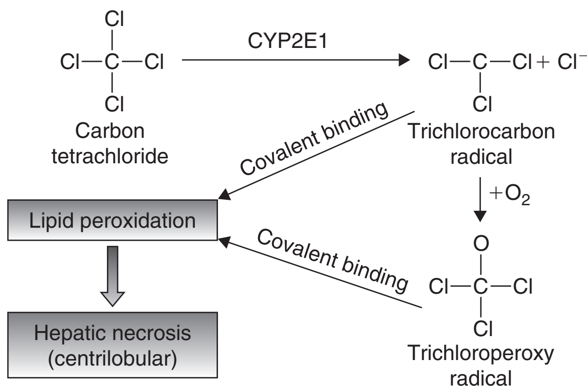

**FIGURE 10.4** Metabolism and mechanism of carbon tetracholoride toxicity. Carbon tetrachloride metabolism by CYP450 leads to free radicals such as trichlorocarbon and trichloroperoxy radical that initiates lipid peroxidation. The centrilboular location of CYP2E1 enzyme is mainly responsible for carbon tetrachloride metabolism and contributes to centrilobular necrosis similar to acetaminophen toxicity.

threshold for hepatotoxicity have been identified and include fasting and malnutrition, which deplete GSH reserves (Dahm and Jones, 1996; Sturgill and Lambert, 1996; Treinen-Moslen, 2001; Piñeiro-Carrero and Piñeiro, 2004).

The reaction that produces NAPQI generates superoxide anions as a by-product. Interactions of NAPQI with other cellular molecules also generate reactive oxygen species, leading to oxidative stress on the hepatocyte (Dahm and Jones, 1996; Zimmerman, 1999). The role of calcium and Kupffer cell activation have been implicated as contributing factors for acetaminophen-induced liver injury by producing reactive nitrogen species (Treinen-Moslen, 2001).

NAPQI also acts as an electrophile, targeting the mitochondria in particular. This reactive metabolite forms covalent adducts with cellular molecules, particularly proteins with thiol groups. Other targets besides mitochondrial proteins include plasma membrane proteins involved in calcium homeostasis and adenine nucleotides (Dahm and Jones, 1996; Sturgill and Lambert, 1997).

## Disruption of calcium homeostasis and cell membrane damage

Calcium ions ($Ca^{2+}$) are important for the mediation of hepatic injury. Cytosolic free calcium is maintained at relatively low concentrations compared to the extracellular levels. The majority of intracellular calcium is sequestered within the mitochondria and endoplasmic reticulum. Membrane associated calcium and magnesium ATPases are responsible for maintaining the calcium gradient (Farrell *et al.*, 1990). Significant and persistent increases in the intracellular calcium result from non-specific increases in permeability of the plasma membrane, mitochondrial membranes, and membranes of the smooth endoplasmic reticulum. Calcium pumps in the mitochondrial membrane require NADPH, thus depletion of available NADPH can cause calcium release from mitochondria (Cullen, 2005; Jaeschke and Bajt, 2006).

Elevated cytoplasmic calcium activates a variety of enzymes with membrane damaging effects. The major enzymes that are involved in activation by calcium include ATPases, phospholipases, proteases, and endonucleases. Thus increased calcium causes increased mitochondrial permeability and induction of apoptosis and necrosis. Calcium is required for maintenance and function of the cytoskeleton as well (Dahm and Jones, 1996; Delgado-Coello *et al.*, 2006).

Although cell injury results in increased calcium, which causes a variety of damaging effects, the cause and effect relationship of calcium in cell damage is not known. The chemicals that cause liver damage by this mechanism include quinines, peroxides, acetaminophen, iron, and cadmium.

## Mitochondrial injury

Mitochondria function in production of energy, in the form of ATP, for the cell by oxidative phosphorylation. Hepatocytes are highly metabolically active and require a continuous supply of ATP. Hepatocytes active in detoxification or replacement of damaged tissue have higher ATP requirements still (Dahm and Jones, 1996). Compounds that may disrupt mitochondrial oxidative phosphorylation include bile acids and amiodarone. Mitochondria are also critical to modulation of cell redox status, osmotic regulation, pH control, cytosolic calcium homeostasis and cell signaling. Mitochondria are important targets for virtually all types of injurious stimuli, including hypoxia and toxins. Mitochondria are targeted by oxidants, electrophiles,

lipophilic cations, and weak acids. Damage is often precipitated by increases in cytosolic calcium.

Hepatic injury is frequently accompanied by morphological change in mitochondria. Mitochondrial changes evident as structural abnormalities include greatly increased size and the development of crystalline inclusions. These changes are usually regarded as pathologic, reflecting either as a protective or degenerative response to injury. Mitochondrial damage may results in the formation of high conductance channels, the so-called mitochondrial permeability transition, in the inner mitochondrial membrane. This is an irreversible change and, because membrane potential is critical for mitochondrial oxidative phosphorylation, constitutes a deathblow to the cell.

Oxidative phosphorylation produces reactive oxygen species (Watkins, 1999). These are deactivated by antioxidants present within the mitochondrion. GSH is present within mitochondria as a scavenger for peroxides and electrophiles. Synthesis of GSH requires ATP and takes place outside of the mitochondrion. Greater than 90% depletion in GSH reserves decrease the ability of the mitochondrion to detoxify reactive oxygen species produced by oxidative phosphorylation (Watkins, 1999). GSH *S*-transferase, the enzyme required for recycling of GSH, may become overwhelmed by toxicants and reactive metabolites (Dahm and Jones, 1996).

Xenobiotics may cause cell death by their effects on mitochondrial DNA. Some antiviral dideoxynucleoside analogs can disrupt mitochondrial DNA synthesis through the inhibition of DNA polymerase gamma, leading to depletion of mitochondria and consequent hepatocyte death (Houten *et al*., 2006).

Chemicals that damage mitochondrial structure, enzymes, or DNA synthesis can disrupt $\beta$-oxidation of lipids and oxidative energy production within hepatocytes. Prolonged interruption of $\beta$-oxidation leads microvesicular steatosis which can progress to macrovesicular steatosis. This sequence of events has been noted with alcoholic and non-alcoholic steatohepatitis. The role of mitochondria has been extensively studied with NAFLD, a major issue in human medicine. Alcoholic steatosis and other forms of hepatic steatosis have been linked to impairment of ATP homeostasis and mitochondrial abnormalities have been reported in a growing body of literature.

Investigations of animals dosed with ethanol for one to several months have shown that the mechanisms of liver injury caused by ethanol ingestion are numerous and this indicates that the pathogenesis of alcoholic liver disease is complex and multifactorial (Figure 10.5) (Lieber and DeCarli, 1976). The role of CYP2E1, fatty acid metabolism, oxidative damage, endotoxin, Kupffer cell, and neutrophil infiltration has been extensively investigated in literature (DiLuzio, 1966; Bardag-Gorce *et al*., 2000; Kono *et al*., 2000; Hoek and Pastorino, 2002). Studies have shown that progression of the disease correlates well with the dose of ethanol consumed daily and the duration of alcohol consumption. Alcoholic hepatic steatosis, steatohepatitis, fibrosis, and cirrhosis represent a sequential progression in the alcoholic liver disease following ethanol ingestion. Women are more sensitive to ethanol-induced liver effects than men and experience higher incidence of liver injury (Banerjee *et al*., 2006). The histologic changes noted include fatty change, cholestasis, and inflammation. Inflammation is predominantly neutrophilic with the regions of necrosis and Mallory body formation. Although many of these changes have been observed in experimental models of alcoholic hepatitis, progression to cirrhosis has been seen only rarely.

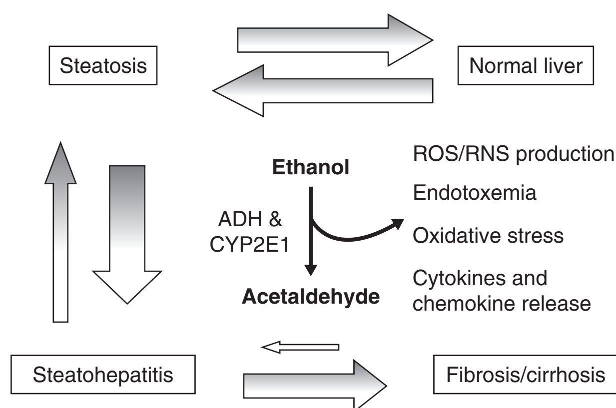

**FIGURE 10.5** Progression of alcoholic liver disease. Consumption of ethanol produces hepatic pathology in a sequence ranging from steatosis (fatty liver) on one extreme to fibrosis/cirrhosis on the opposite end of the spectrum. Steatosis and steatohepatitis represent acute stages of alcoholic liver disease. ROS = reactive oxygen specie; RON = reactive nitrogen specie

There are several drugs that inhibit $\beta$-oxidation of fatty acids in mitochondria leading to lipid accumulation, such as aspirin, valproic acid, tetracyclines.

## Disruption of cytoskeleton

Changes in intracellular calcium homeostasis produced by active metabolites of xenobiotics may cause disruption of the dynamic cytoskeleton. There are a few toxins that cause disruption of the cytoskeleton through mechanisms independent of biotransformation. Microcystin is one of these toxins. Microcystin is produced by the cyanobacterium *Microcystis aeruginosa*. Similar toxins are produced by other species of cyanobacteria. The hepatocyte is the specific target of microcystin, which enters the cell through a bile acid transporter. Microcystin covalently binds to serine/threonine protein phosphatase, leading to the hyperphosphorylation of cytoskeletal proteins and deformation of the cytoskeleton (Treinen-Moslen, 2001).

Phalloidin and related toxins found in some mushrooms, including *Amanita phalloides*, act by binding tightly to actin filaments and preventing cytoskeletal disassembly (Treinen-Moslen, 2001).

## Cholestasis

Sinusoidal transporters and canalicular transporters are involved in the movement of bile salts from the sinusoids into the canaliculi. Within the hepatocyte, transcytosis is mediated by cytoskeletal transport mechanisms. Bile is moved within the canaliculi through actions of the hepatocyte cytoskeleton causing contraction of the canalicular lumina (Treinen-Moslen, 2001). Xenobiotics acting on any of the above systems may influence bile transport and secretion.

Most chemicals that cause cholestasis are excreted in the bile, including the mycotoxin sporodesmin which concentrates 100-fold in the bile (Treinen-Moslen, 2001).

ANIT is a hepatotoxicant that damages bile duct epithelium and hepatocytes. The drug is used experimentally in rodents as a model of intrahepatic cholestasis. A single dose of ANIT induces acute cholangitis; prolonged exposure causes bile duct hyperplasia and biliary fibrosis. Although the biochemical and histological features of ANIT toxicity are well documented, the mechanism by which ANIT causes liver injury remains uncertain. *In vivo*, ANIT does not cause liver damage until it appears in bile (Jean and Roth, 1995).

This drug is initially detoxified in hepatocytes by conjugation with GSH. ANIT–GSH complexes are secreted into bile, but they are unstable and rapidly dissociate. This exposes biliary cells to high concentrations of the parent compound, which presumably causes direct cytotoxicity. The reappearance of ANIT in bile also leads to enterohepatic cycling, reuptake of the drugs in the intestine and repetitive rounds of GSH conjugation and secretion. This not only delays elimination of the drug but depletes GSH progressively from hepatocytes and leads to hepatocellular damage. In addition ANIT is also known to cause hepatotoxicity by neutrophil- and platelet-dependent mechanisms (Jean and Roth, 1995).

## Hepatogenous photosensitization

Cholestatic diseases in herbivores, and ruminants in particular, may lead to dermal photosensitization. The presentation of photosensitization is similar in appearance to that of sunburn, but it is more rapid onset and associated with different wavelengths of light (Rowe, 1989). Photosensitization is caused by circulation of photoactive compounds. There are three classifications of photosensitization. Primary photosensitization involves ingestion or dermal absorption of a photodynamic compound which enters the circulation. An example is hypericin from *Hypericum perforatum*, or St. John's wort. Aberrant pigment synthesis occurs when the photoactive compound is produced by the body, as is the case with inherited porphyria. The third type of photosensitization is hepatogenous photosensitization.

Hepatogenous photosensitization occurs secondary to bile stasis. Herbivores ingest large quantities of chlorophyll. Metabolism of chlorophyll by bacteria in the gastrointestinal tract produces the photoactive compound phylloerythrin. Absorbed phylloerythrin is readily excreted in the bile with minor urinary excretion (Rowe, 1989; Burrows and Tyrl, 2001). Upon exposure to light of wavelengths 320–400 nm, singlet oxygen is generated causing lipid peroxidation in areas of skin unprotected by hair or melanin (Burrows and Tyrl, 2001). Not all causes of cholestasis produce photosensitization, thus icterus may occur in the absence of photosensitization (Rowe, 1989).

Hepatocyte swelling may lead to cholestasis. Agents that may cause photosensitization through hepatocyte damage include the toxic plant *Lantana camera* which causes steatosis, and subacute poisoning by microcystin. Because significant hepatocyte damage must occur before the individual presents with photosensitization, damage of this type usually carries a poor prognosis (Rowe, 1989).

Agents that act by damage to the bile duct include the mycotoxin sporodesmin and sapongenins from the plant *Tribulus terrestris*. Sporodesmin, produced by *Pithomyces chartarum* and associated with ryegrass pastures in Australia and New Zealand, acts by direct damage to the biliary epithelium leading to cell necrosis and degeneration. Bile ducts become occluded with cell debris and inspissated bile. Periductular fibrosis also occurs and may further occlude the bile ducts (Rowe, 1989).

Several plant species cause bile stasis through precipitation of calcium salts of sapogenic glucuronide within bile ducts. The major toxic sapongenins from *T terrestris* are diosgenin and yamogenin. These compounds are hydrolyzed in the gastrointestinal tract to sapongenins which are further metabolized before glucuronidation in the liver (Burrows and Tyrl, 2001). The sapogenins cause cholestasis through direct occlusion of the bile duct and damage to the canalicular membrane. It should be noted that while *T terrestris* poisoning is reported with some frequency in South Africa and Australia, it is believed that the toxic sapogenins are absent or present in much lower levels in *T terrestris* present in the United States (Burrows and Tyrl, 2001).

## Inhibition of tissue repair response

Tissue repair is a dynamic response involving compensatory cell proliferation and tissue regeneration which is stimulated in order to overcome acute toxicity and recover hepatic structure and function. Extensive evidence in rodent models using structurally and mechanistically diverse hepatotoxicants such as acetaminophen, carbon tetrachloride, chloroform, thioacetamide, trichloroethylene, and allyl alcohol have demonstrated that tissue repair plays a critical role in determining the final outcome of toxic insult, i.e. recovery from injury and survival or

progression of injury leading to liver failure and death (Mehendale, 2005).

Thioacetamide, originally used as a fungicide, is a potent hepatotoxicant. Studies have shown that this compound is bioactivated by cytochrome P450 and/or flavin-containing monooxygenase (FMO) systems to sulfine (sulfoxide) and sulfene (sulfone) metabolites, which cause centrilobular necrosis. Studies suggest that thioacetamide sulfoxide, a relatively stable intermediate of thioacetamide metabolism, is obligatory for the hepatotoxic effects of this compound, indicating that it is the penultimate reactive metabolite. Accordingly, it has been reported that the hepatotoxic effects of thioacetamide are only expressed after metabolic conversion to thioacetamide *S*-oxide, which undergoes further metabolic conversion to an as yet unidentified metabolite, probably the reactive unstable thioacetamide sulfone. Recently, it has been reported that thioacetamide bioactivation is primarily mediated by the cytochrome P450 enzyme CYP2E1. The reactive intermediate of thioacetamide binds to liver proteins with the formation of acetylimidolysine derivatives that are responsible for thioacetamide-induced hepatotoxic effects. The progression of thioacetamide-induced liver injury has also been attributed to inhibited tissue repair response. Studies have shown that diet restriction increases the liver injury of thioacetamide by diminishing tissue repair response (Ramaiah and Mehendale, 2000).

Tissue repair is a complex process governed by intricate cellular signaling involving a number of chemokines, cytokines, growth factors, and nuclear receptors leading to promitogenic gene expression and cell division. Tissue repair also encompasses regeneration of hepatic extracellular matrix and angiogenesis, the processes necessary to completely restore the structure and function of the liver tissue lost to toxicant-induced initiation, progression of injury. New insights have emerged over the last quarter century indicating that tissue repair follows a dose response. Tissue repair increases with xenobiotic dose until a threshold dose is reached beyond which repair is delayed and impaired due to inhibition of cellular signaling. This may result in runaway secondary events causing tissue destruction, organ failure, and death. Prompt and adequate tissue repair response to toxic injury is critical for recovery from toxic injury. Tissue repair is modulated by a variety of factors including species, strain, age, nutrition, and disease condition causing marked changes in susceptibility and toxic outcome (Ramaiah *et al.*, 1998; Mehendale, 2005).

## Idiosyncratic reactions

Many idiosyncratic drug reactions are believed to be immune mediated. Neoantigens may result from adducts formed from the interaction of reactive drug metabolites with cellular proteins. These neoantigens may be processed by Kupffer cells or other antigen presenting cells, transported to the cell surface, and presented as antigens (Reynold and Moslen 1980). Cell and antibody-mediated immune response may cause severe liver damage. Various drugs are believed to cause immune-mediated idiosyncratic reactions in humans, including halothane, diclofenac, phenytoin, and sulfonamides (Sturgill and Lambert, 1997; Watkins, 1999; Zimmerman, 1999; Treinen-Moslen, 2001). The idiosyncratic reaction to halothane has been well studied (Figure 10.6). A few compounds have been implicated in idiosyncratic reactions in domestic animals, as will be described below.

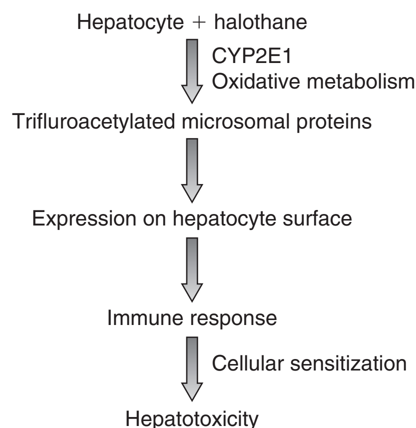

**FIGURE 10.6** Postulated mechanism of immune-mediated halothane hepatotoxicity. Halothane-mediated hepatitis is the best example for immune-mediated liver damage. Oxidative pathway yields trifluoroacetylchloride, which can react with microsomal proteins to form a neoantigen which then can generate immune response leading to hepatic injury.

Liver injury can be a result of both direct cytotoxicity and antibody-dependent cellular toxicity. Alcoholic liver disease is another example of possible immune-mediated damage. Acetaldehyde, produced by metabolism of ethanol, forms adducts with hepatic proteins similar to halothane, resulting in higher antibody titers to which some of the liver damage following ethanol ingestion may be attributed (Ramaiah *et al.*, 2004). However, the role of immune-mediated liver damage following ethanol ingestion is minimal compared to other known mechanisms of alcohol liver damage.

A few idiosyncratic drug reactions have been reported in veterinary medicine. The most well known is probably carprofen in dogs, as characterized by MacPhail *et al.* (1998). Carprofen is a non-steroidal anti-inflammatory agent. Clinical signs of idiosyncratic reaction to carprofen occur 20 days on average following the first exposure to the drug and include anorexia, vomiting, and icterus. Signs do not correlate with drug dose. Affected dogs have elevated ALT, AST, ALP, and serum total bilirubin. There is mild to severe bridging degeneration and necrosis with evidence of apoptosis. Mild to moderate periportal

inflammation is reported. Spayed female dogs are over-represented amongst those affected (MacPhail *et al*., 1998).

Other idiosyncratic reactions of veterinary importance include diazepam in cats (Center *et al*., 1996) and sulfonamides in dogs (Trepanier *et al*., 2003; Shenton *et al*., 2004; Trepanier, 2004). The clinical presentation associated with diazepam in cats is similar to that described with carprofen in dogs. Idiosyncratic reactions to sulfonamides in dogs may occur in 0.25% of dogs and a variety of organ systems may be affected. Hepatopathy is the third most reported reaction to sulfonamides and other effects may include polyarthropathy, which may predominate in Doberman pinchers, thrombocytopenia, pyrexia, and dermal drug eruptions (Trepanier, 2004).

## ON THE HORIZON

With the advent of "omics" approaches such as genomics, proteomics and metabolomics, there is increasing interest in the detection of novel genes, proteins, and metabolites associated with hepatotoxic chemicals. This technology has recently resulted in the generation of novel set of hypotheses for mechanism of action of hepatotoxic agents. Furthermore similar approaches have also led to identify signature biomarkers to diagnose hepatotoxicosis. For example serum proteomic analysis data recently revealed increased levels of vitamin D-binding protein, malate dehydrogenase and purine nucleoside phosphorylase in several models of chemically induced hepatotoxicants. These enzymes were elevated in the serum before increases in conventional serum markers such as ALT, AST and histopathology (Amacher *et al*., 2005). Therefore these proteins may of potential predictive value in early diagnosis of liver disease in the future although these markers have not been validated in veterinary or human medicine. Further, research involving transgenic and knock out models are continuing to provide insight into understanding mechanistic and molecular basis of liver injury. Development of animal models to investigate idiosyncratic drug hepatotoxicity is another area of intense investigation. Clearly there is progress in the area of liver toxicology which will continue to yield new information. This is especially true with the growing trends in research collaborations between individuals from multiple disciplines relevant to drug and chemical hepatic injury.

CHAPTER

# 11

# Renal toxicity

*Manu M.Sebastian, Steven I. Baskin, and Steven E. Czerwinski*

## INTRODUCTION

Kidney plays an important role in the total body homeostasis by multiple functions. The important functions include excretion of metabolic waste products and foreign chemicals, regulation of water and electrolyte balances, regulation of body fluid osmolality and electrolyte concentrations, regulation of arterial pressure, regulation of acid–base balance, secretion, metabolism and excretion of hormones and gluconeogenesis. A toxic insult to the kidney can disrupt any or all of these functions and result in acute or chronic toxic effect on body.

## ANATOMY

The kidneys in mammals are paired organs that lie ventral and adjacent to the lumbar vertebrae. Carnivores and horses have unilobar or unipyramidal kidneys. Kidneys of pigs and cattle are multilobar or multipyramidal. Bovine kidneys have external lobation. The medial side of each kidney contains an indented region called the hilum through which pass the renal artery and vein, lymphatics, nerve supply and ureter which carries the final urine from kidney to bladder. The kidney is surrounded by a tough fibrous capsule that protects its inner structures. If the kidney is bisected from top to bottom, the two major regions that can be visualized are the outer cortex and the inner region referred as the medulla. The corticomedullary ratio is usually approximately 1:2 or 1:3 in domestic animals. Normally the cortex appears dark brown and medulla has a pale gray color except in mature cats, in which the cortex is often yellow because of the large lipid content of tubular cells. Medulla is divided into multiple cone-shaped masses of tissues called renal pyramids. The base of each pyramid originates at the border between the cortex and medulla and terminates in the papilla which projects into the renal pelvis, a funnel-shaped continuation of the upper end of the ureter. The outer border of the pelvis is divided into open-ended pouches called major calyces that extend downward and divide into minor calyces, which collect urine from the tubules of each papilla. The walls of the calyces, pelvis and ureter contain contractile elements that propel the urine toward the bladder (Ellenport, 1975).

The functional unit of the kidney is the nephron and components of the nephron include Bowman's capsule, proximal tubule, Loop of Henle, distal tubule and the collecting duct. Each kidney (human) contains approximately 1 million nephrons and each of it is capable of forming urine. The nephron consists of a tuft of glomerular capillaries called the glomerulus, through which large amounts of fluid are filtered from the blood, and a long tubule in which the filtered fluid is converted into the urine. The glomerulus is made up of a network of branching and anatomizing capillaries and these capillaries have high hydrostatic pressure compared to other capillaries in the body. These capillaries are composed of endothelial cells that have attenuated and fenestrated cytoplasm which allow the passage of molecules. Those compounds up to a molecular weight of about 60,000 Da pass through the glomeruli into the tubular lumen to be excreted with urine. The glomerular capillaries are covered by epithelial cells and the total glomerulus is encased in Bowman's capsule with a space which is called the Bowmen's space. Fluid filtered from the glomerular capillaries flow into

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

Bowman's space and then into the proximal tubule. The fluid collected in the proximal tubule flows into the loop of Henle, which dips into the renal medulla. Each loop is made up of an ascending and descending limb. The walls of the descending limb and the lower end of the ascending limb are very thin and are called the thin segment of the loop of Henle. After the ascending limb of the loop has returned partway back to the cortex, its walls become much thicker and is called the thick segment of the ascending limb. Approximately 25% of the filtered $Na^+$ and $K^+$ and 20% of the filtered water are reabsorbed by these segments of loop of Henle.

Macula densa which regulates the glomerular filtration rate (GFR) by signaling arteriolar constriction is composed of specialized cells located between the end of the thick ascending limb and the early distal tubule with close proximity to the afferent arteriole. The function of macula densa is to prevent massive losses of fluid/electrolytes in impaired tubular resorption. The fluids after passing this area enter distal tubule which lies in renal cortex, and move to the connecting tubule which leads to the cortical collecting tubule. The initial parts of 8–10 collecting ducts join to form a single larger collecting tubules that runs downwards into the medulla and becomes the medullary collecting duct. The collecting ducts merge to form progressively larger ducts that eventually empty into the renal pelvis through the tips of renal papillae.

Blood flow to the two kidneys is approximately 22–25% of the cardiac output. The kidney is supplied by the renal artery which enters the kidney through the hilum and then branches progressively to form the interlobar arteries, arcuate arteries, interlobular arteries (also called radial arteries) and afferent arterioles, which lead to the glomerular capillaries. The distal ends of each glomerulus coalesce to form the efferent arteriole, which leads to a secondary capillary network, the peritubular capillaries which surround the renal tubules. The cortex receives approximately 90% of the blood flow compared to the medulla or papilla and so blood-born toxic molecules reaching the kidney have more toxic effect on the cortex compared to medulla or renal papillae. The interstitial space is occupied by the fenestrated peritubular capillaries and a small number of fibroblasts-like cells. Increase in thickness of interstitial space in pathological conditions is due to edema, proliferation of fibrous tissue or infiltration of inflammatory cells (Guyton and Hall, 2006; Kriz and Bankir, 1998).

## BIOTRANSFORMATION AND EXCRETION

The xenobiotics which are absorbed through the gastrointestinal (GI) tract, lungs, skin and other special routes of administration (e.g. intravenous) eventually reach the blood. After entering the blood toxicant is distributed throughout the body. The rate of distribution to organs or tissues is depended on the blood flow and the rate of diffusion out of the primarily capillary bed into the cells of a particular organ. Hence kidney is exposed to several toxicants. Xenobiotics are often concentrated in specific sites which may be the site of their toxic action or at sites other than target organs which can be considered as a storage depot. Kidney along with liver are the two important organs in the body which concentrate toxicants. A classic example is metallothionein, a protein which binds to cadmium and zinc with high affinity in kidney and liver (Rozman and Klaassen, 2001). Kidney is a target organ for many toxicants both primary and their metabolites which are distributed through blood as it receives approximately a quarter of the cardiac output. Xenobiotics can induce their toxicity on an organ by the action of their parent compound or through the metabolite as a result of bioactivation via metabolism (biotransformation). The nephrotoxicity can be induced by the parent compound (e.g. gentamicin), the biotransformed molecules in extra renal organs like liver (e.g. hepatic biotransformation of haloalkene) and by biotransformation in kidney (e.g. chloroform). Biotransformation reactions are catalyzed by Phase I and Phase II enzymes which convert the parent compounds to more polar and hydrophilic metabolites, thereby excreted more rapidly or convert them to reactive chemical species which can induce toxicity. The important Phase I enzymes present in the kidney are cytochrome P450, prostaglandin synthase and reductases. The important Phase I enzyme cytochrome P450 is present in the kidney, but the concentration is only approximately 10% of that in liver. The enzyme is found in the highest concentration in the renal cortex (majority in the proximal tubular epithelial cells), although small amounts are found in medulla. The compounds which are biotransformed by cytochrome P450 in the kidney are acetaminophen (acute overdosage), cephaloridine, chloroform and ochratoxin (partially). Prostaglandin synthase another Phase I enzyme is found primarily in the medullary interstitial and collecting duct cells. Chronic acetaminophen nephrotoxicity is attributed to the prostaglandin H synthase biotransformation. Phase I enzymes capable of catalyzing reduction reaction (reductases) are also present in the kidney and are involved in the reduction of 5-nitro group in 5-nitrofurans to reactive chemical species leading to nephrotoxicity. The important Phase II enzymes present in the kidney are UDP-glucuronosyltransferases (UGT), sulfotransferases and glutathione-*S*-transferases. Liver possess the highest UGT concentration and kidney has much lower concentration. UGT may contribute to acute or chronic toxicity associated with clofibrate, diclofenac (a nonsteroidal antiinflammatory agent (NSAID)) and other NSAIDs. The substrates for glutathione-*S*-transferases

include haloalkenes, acrolein, etc. (Rankin and Valentovic, 2004).

Kidney is the most important organ for the excretion of xenobiotics. The different mechanisms by which the toxicants are removed by the kidney are glomerular filtration, tubular excretion by passive diffusion and active tubular secretion. The xenobiotics which enter the blood reach the kidney where they are filtered through the large pores of the glomerular capillaries (70 nm size) and reach the tubular lumen and eventually excreted through the urine. Those compounds up to a molecular weight of about 60,000 are filtered through the glomeruli into the tubular lumen to be excreted with urine. The removal of toxicants through kidney tubule is mainly depended on the water solubility of the toxicant. Those xenobiotics which are biotransformed to more water soluble products (more polar) are excreted with the urine while those toxicants with high lipid solubility (high lipid/water partition coefficient) are reabsorbed across the tubular cells into the blood stream. Toxicants can be excreted by passive diffusion through the tubules and flow of urine is important for maintenance of concentration gradient necessary for this process. Toxicants are also excreted into urine by active secretion by a transporter which is an active transport process. These transporters are localized in the proximal tubules. The important transporters are organic anion transporter (oat) which is localized at the basolateral membranes of the proximal tubular cells and organic cation transporter (oct) which are involved in uptake of organic acids and some cations, respectively, into the renal tubular cells. Multidrug resistant protein (mdr) and multiresistant drug protein (mrp) move xenobiotics from the proximal tubule cells into the lumen. The organic action transporter (octn2) and peptide transporter (PEP2) are involved in the reabsorption of chemicals from the tubular lumen into the proximal tubular cells. A classic example of the action of active transport is the difference in susceptibility of the cephaloridine in adult and newborn animals. In newborn animals the active uptake of cephlaoridine is not well developed and hence it is not absorbed and concentrated in the tubular cells to result in toxicity (Rozman and Klaassen, 2001). Thus tubules play an important role in the excretion of toxicants and a toxic insult to those cells will result in accumulation of toxicants in the body (Figure 11.1).

The proximal tubule can be divided into three discrete segments. The S1 segment (pars convoluta) is the initial portion of the proximal convoluted tubule, S2 the transition between the pars convoluta and the pars recta which consists of the end of the convoluted segment and initial portion of the straight segment, and S3 the pars recta which consists of distal portion of the proximal segment (Figure 11.1).

The toxic effect of many xenobiotic compounds in kidney is specific to the anatomical locations as proximal tubules, glomeruli, medulla/papilla or loop of Henle (Figure 11.1). The site selective injury which is observed in human when exposed to many compounds is similar to that in domestic animals. The proximal tubule is the specific target for several antibiotics, mycotoxins, some antineoplastic drugs and heavy metals. Medulla/papilla is the target site for analgesics like phenylbutazone in horses. Loop of Henle is target for fluoride ion and glomeruli for immune complexes. The cause of these site specific target injury is multifactorial and may include detoxification mechanisms, regenerative ability, difference in blood flow, transport and accumulation of the chemicals and their metabolites, etc. Proximal convoluted tubule is the most common site of toxin induced injury and there are multiple reasons for this site specific action. These reasons include cytochrome P450 and cysteine conjugate β-lyase activity localization in this area (those agents requiring bioactivation by these enzymes induce toxicity in this region, e.g. chloroform), selective accumulation of xenobiotics in this area due to a relative loose epithelium compared to distal tubules which allows compounds to get into the cells easily, increased transport of several molecules like organic anions, cations and heavy metals resulting in increased accumulation in this area and increased susceptibility of proximal convoluted tubular epithelial cells to ischemic injury. Compared to the proximal tubules, distal tubules are less affected by toxicant injury (Schnellmann, 2001). The other anatomical location which is commonly affected by toxicant injury is the renal papillae and the classic example is the renal papillary necrosis by analgesics in horses. The important factors for this site specific injury are due to high concentration of prostaglandin H synthase activity in this area (they metabolize analgesics to reactive intermediate compounds which bind to cellular macromolecule), high papillary concentration of the toxicants, inhibition of the vasodilatory prostaglandins which result in ischemia to this area (Schnellmann, 1998).

## TOXIC EFFECTS ON KIDNEY

### Acute renal failure

Toxicants produce their effect on the different components of the kidney by affecting the tubules, glomeruli, vessels and the interstitium. Toxicants are an important cause of both acute and chronic renal failure with majority of the toxicants manifesting their effect by acute renal failure. The most important manifestation of acute renal failure is the decrease in GFR which leads to an excess of urea or other nonprotein nitrogenous component in the blood (azotemia). The decrease in GFR can be due to prerenal, renal or postrenal causes. Renal toxicity generally leads to renal or sometimes postrenal azotemia. Postrenal

**TABLE 11.1 Toxicants that adversely affects renal system**

| Toxicant | Species | Site and action |
|---|---|---|
| *Metals* | | |
| Mercury | All species | Tubules, tubular degeneration and necrosis |
| Arsenic | All species | Tubules, tubular degeneration and necrosis |
| Copper | All species | Tubules, degeneration and necrosis |
| Cadmium | All species | Tubules, tubular degeneration and necrosis |
| Lead | All species | Tubules, tubular degeneration and necrosis |
| Fluorine | All species | Tubules, tubular degeneration and necrosis |
| Zinc | All species | Tubules, tubular degeneration and necrosis |
| *Mycotoxins* | | |
| Ochratoxin | All species | Tubules, tubular degeneration and necrosis |
| Citrinin | All species | Tubules, tubular degeneration and necrosis |
| Oosporein | Avian | Tubules, tubular degeneration and necrosis |
| *Plants* | | |
| Oxalate in plant | Ruminants predominantly | Tubules, tubular degeneration and necrosis by crystals |
| Halogeton | | |
| Rhubarb | | |
| Sorrel, dock (*Rumex* spp.) | | |
| Oak | Ruminants | Tubules, tubular degeneration and necrosis |
| Amaranthus | Cattle and swine | Tubules, tubular degeneration and necrosis |
| Bracken fern | Cattle | Urinary bladder, hemorrhage, neoplasms |
| Easter lily | Cat | Tubules, tubular degeneration and necrosis |
| Red maple | Equine | Tubules, tubular degeneration and necrosis |
| White snake root | Equine and ruminants | Tubules, tubular degeneration and necrosis |
| Vitamin D/analog plants | Ruminants and horses | Tubules, arteries, mineralization |
| Cestrum diurnum | | |
| *Solanum* spp. | | |
| *Trisetum* spp. | | |
| *Sorghum* spp. | Ruminants | Urinary bladder, necrosis |
| *Antifungals* | | |
| Amphotrecin B | Dogs and cats mostly | Tubules, tubular necrosis by vasoconstriction |
| *Antibacterials* | | |
| Neomycin | | |
| Gentamicin | | |
| Tetracycline | Ruminants, dogs, cats, snakes | Tubules, tubular degeneration and necrosis |
| Sulfonamide | Ruminants | Tubules, tubular degeneration and necrosis by crystals |
| Furazolidone | Goat | Tubules, tubular degeneration |
| *NSAIDs/analgesics* | | |
| Phenyl butazone | Horse | Renal papillae, necrosis by vasoconstriction |
| Flunixin meglumine | | |
| Multiple NSAIDs and analgesics | Dogs, cats and avian | Tubules and renal papillae, necrosis |
| *Antineoplastics* | | |
| Cisplastin | Dogs | Tubules, degeneration and necrosis |
| Cyclophosphamide | Dogs | Urinary bladder, necrosis |
| *Rodenticides* | | |
| Diquat/paraquat | All species | Tubules, degeneration and necrosis |
| Zinc phosphide | All species | Tubules, degeneration and necrosis |
| Cholecalciferol rodenticide | All species | Tubules, arteries, mineralization |
| *Miscellaneous* | | |
| Ethylene glycol | Dogs and cats predominantly | Tubules, tubular degeneration and necrosis by crystals |
| Pine oil | Cats | Tubules, tubular degeneration and necrosis |
| Vitamin K3 | Horses | Tubules, tubular degeneration and necrosis |
| Cyclosporine | Dogs and cats | Tubules, glomerulus |
| Blister beetle | Mostly horses, but cattle also | Urinary bladder, necrosis |
| Raisin | Dogs | Tubules, tubular degeneration and necrosis |
| Snake venom | All species | Glomerulus, mesangiolysis |

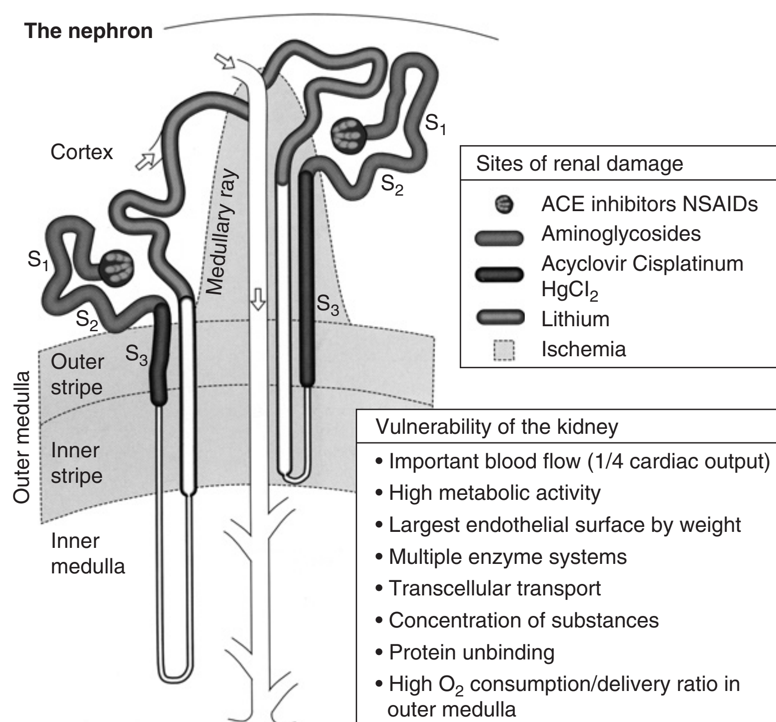

**FIGURE 11.1** Sites of renal damage, including factors that contribute to the kidney's susceptibility to damage. ACE: angiotensin converting enzyme; NSAIDs: nonsteroidal antiinflammatory drugs; $HgCl_2$: mercuric chloride (adapted from Berl and Bonaventure 1998, with permission).

azotemia is usually observed in conditions due to obstruction of renal out flow or post renal leakage. The toxic effect of chemicals acting on kidney results in reduced GFR leading to azotemia. The different mechanisms by which toxins/chemicals induce renal failure are: (1) tubular epithelial damage leading to formation of tubular casts which leads to tubular blockage, (2) tubular epithelial necrosis which leads to reabsorption of glomerular filtrate, (3) renal vasoconstriction which leads to hypoxia resulting in necrosis and (4) changes in the glomerular ultrafiltration barrier. Majority of the chemicals induce renal failure by direct action on the tubules.

The ultrastructural changes which lead to acute renal failure are due to the loss of cell-to-cell adhesion, and cell-to-matrix adhesion which eventually lead to a loss of tubular integrity.

The clinical signs associated with acute renal failure are nausea, vomiting, GI bleeding, esophagitis, gastritis and colitis which are all associated with azotemia. When azotemia is associated with a constellation of clinical signs and symptoms and biochemical abnormalities it is called uremia. There is secondary involvement of GI tract (uremic gastroenteritis), peripheral nerves (peripheral neuropathy) and sometimes heart (uremic fibrinous pericarditis).

## Chronic renal failure

Chronic renal failure is associated with long-term exposure to the toxins and is mostly related to the secondary pathological changes triggered by the initial injury. These secondary changes are compensatory mechanisms to maintain the function of the whole kidney but eventually result in reduced glomerular function leading to tubular and interstitial changes. Once the chronic changes are initiated it progresses to an end stage kidney.

Clinical signs of chronic renal failure are primarily (1) edema which is due to reduced renal perfusion leading to stimulation of renin–angiotensin system, which stimulates aldosterone secretion leading to retention of sodium and water, (2) hypocalcemia with compensatory parathyroid activity and osteodystrophy and (3) reduced red blood cell counts due to reduced synthesis of erythropoietin as a result of damage to juxtaglomerular cells.

## Pathological correlates

The kidney has extensive reserve capacity and hence renal diseases may be present with or without any clinical signs or clinicopathological abnormalities. Renal failure occurs or is manifested after substantial loss of the functional unit, the nephron. Renal failure represents clinical signs or laboratory abnormalities as a result of reduced renal function. Hence measurement of renal function will aid in diagnosing a toxic insult to the renal tubules or glomeruli. The various renal functions which can be measured to evaluate a toxic insult include urine concentration, blood urea nitrogen (BUN), urea excretion, serum creatinine, uric acid in birds, GFR, urine electrolyte clearance ratios, changes in blood levels of calcium, phosphorus,

magnesium, sodium and potassium as these elements are either due to loss or reduced excretion.

Urine analysis is one of the keys to evaluate the kidney function and to interpret the injury to the various component of the kidney. Urine analysis involves multiple physical and chemical parameters and sediment analysis. The different physical characters which are evaluated to assess the kidney function include volume, color, transparency and odor. The different chemical characters evaluated include ketones, protein, glucose, bilirubin, blood, urobilinogen, nitrate and enzymes. The different sediments which help to evaluate a toxic insult to the urinary system include epithelial cells, erythrocytes, leukocytes, casts and crystals. The important abnormal sediments which help in diagnosing an acute failure include renal epithelial cells, pigments casts (myoglobin, hemoglobin) and crystalluria (uric acid).

The other important parameters which can be measured to evaluate the function of the kidney include urine specific gravity, BUN, serum creatinine, uric acid excretion (in birds), GFR and levels of calcium and phosphorus in the serum. A reduced urine specific gravity, increased BUN (azotemia) increased serum creatinine concentration, hyperuricemia (in birds), altered GFR and altered serum calcium and phosphorus levels are all indicators of renal damage. Because of the high reserve capacity of kidney, many of these alterations are observed only when more than two third of the nephrons are damaged (Gregory, 2003).

The gross findings in renal damage are not that evident in acute damage and may include swollen cut sections, pale renal parenchyma and reddish discoloration. Mineralization and crystal deposits will be manifested by linear pale streaks in cortex and medulla with gritty consistency (mineral). Papillary necrosis is characterized by pale discoloration in the papilla and renal crest. The gross observations observed in chronic renal failure are reduced size, irregular subscapular surface, hard to section with gritty consistency. The important histopathological observations associated with renal damage are necrosis and degeneration of tubular lining epithelium mostly in the proximal convoluted renal tubular epithelium, regeneration, casts (protein, degenerated cells, globin) in the lumen, mineralization of the basement membranes of tubules, glomeruli tufts, its capsule and blood vessels, necrosis of the renal papillae, necrosis of the glomerular matrix with hemorrhage and increased cellularity of the glomerular tufts (proliferative glomerulonephritis) (Confer and Panciera, 2001).

# NEPHROTOXIC AGENTS

Specific nephrotoxic agents include mercury, cadmium, ochratoxin A, citrinin, oosporein, ethylene glycol, aminoglycosides, sulfonamides, tetracyclines, amphotericin B, cyclosporine, cisplatin, NSAIDs, Easter lily, pigweed, oak, oxalate containing plants and raisins. Other agents mentioned in this section produce toxic effects in multiple organs including kidneys.

## Mycotoxins

Ochratoxin is a mycotoxin produced by the toxic strains of *Penicillium* and *Aspergillus* spp. mostly related to improper storage conditions of grain, coffee, etc. Three different ochratoxins have been isolated and characterized (ochratoxins A, B and C). Of these ochratoxin A is the most commonly detected and most toxic among the three. The subchronic and chronic effects of this toxin are more of concern compared to the acute toxicity. Pigs are the most common species to be affected by ochratoxicosis. Clinical pathological changes include increased BUN values, reduced creatinine clearance and urine specific gravity. The gross pathological changes observed in experimental studies of pigs include enteritis, pale tan discoloration of liver, edema and hyperemia of the mesenteric and other lymph nodes. The microscopic findings are mostly confined to the kidney and GI tract which include necrosis of the renal tubular epithelium most frequently affecting the proximal convoluted tubules, dilation of the tubules, necrotizing enteritis in multiple locations, fatty degeneration of liver and focal necrosis of lymphocytes in the germinal center of the lymph nodes (Szczech *et al.*, 1973a; Zomborszky-Kovacs *et al.*, 2002). The renal pathological changes observed in experimental studies of dogs are similar to that observed in the porcine studies and included necrosis and desquamation predominantly in the proximal convoluted tubules, eosinophilic granular casts in proximal and distal convoluted tubules (Szczech *et al.*, 1973b; Szczech, 1975).

Ochratoxicosis has been reported commonly in avian species. Experimental studies in young broilers with ochratoxin A show renal edema and tubular necrosis (Wyatt *et al.*, 1975; Duff *et al.*, 1987). Chronic exposure of ochratoxin A is considered as an etiology in Balkan endemic nephropathy and urothelial tumors in human beings.

Citrinin is a benzopyran metabolite produced by the toxic strains of *Penicillium* sp. and *Aspergillus* spp. Some hepatotoxic effects have been reported for citrinin but the lethal effects are largely due to the nephrotoxic effects. The specific mechanism of action in kidney is not known. Primary effect is on the kidney and leads to acute tubular necrosis. In pigs, rats and rabbits, the proximal segments are affected. Histopathological findings in different species of animals include necrosis and desquamation of the proximal renal epithelium, basement membrane thickening, tubule dilation and proliferation of cells in interstitium (O'Brien and Dietrich, 2004). Experimental studies show that citrinin induces renal damage in turkeys and ducklings

along with hepatic degeneration and lymphoid necrosis (Mehdi *et al.*, 1984).

Oosporein which is produced primarily by *Oospora colorans* and *Caetomium trilaterale* is observed in feed stuff, cereals and peanuts. It has been reported to be toxic in poultry resulting in nephrotoxicity, visceral and articular gout. The pathological observations in oosporein toxicity include necrosis of the tubular epithelial cells in the proximal tubules with basophilic casts, hyaline casts in the distal tubules with fibrosis and interstitial pyogranulomatous inflammation, urate deposits in various tissues and proventricular enlargement with mucosal necrosis (Pegram and Wyatt, 1981; Brown *et al.*, 1987).

Fumonisin is a mycotoxin produced by the fungus *Fusarium moniliforme* primarily in corn. Brain, liver and lung are the target organs in horses and pigs. In rats and rabbits, kidney is the target organ. Histopathological changes primarily affect the renal tubular epithelium at the junction of cortex and medulla. Toxicity leads to apoptosis of epithelial cells of proximal convoluted tubules (Bucci *et al.*, 1998).

# DRUGS

## Aminoglycosides

The most important toxic effects manifested by aminoglycosides are nephrotoxicity, ototoxicity and neuromuscular blockade. Aminoglycosides accumulate in the proximal tubular epithelial cells where they are sequestered in the lysosomes and interact with ribosomes and mitochondria resulting in cellular damage by altered mitochondrial function and inhibition of protein synthesis.

Gentamicin toxicity has been reported in dogs. Grossly the kidney appears pale. Histopathological changes include tubular epithelial necrosis with regeneration and mineralization. Predominantly the proximal tubules are affected. Lesions will progress from hyaline droplet degeneration with dilated lumen to necrosis of the renal tubular lining epithelium (Sprangler *et al.*, 1980). Gentamicin toxicity has also been reported in snakes. In experimental studies conducted on gopher snakes, proximal tubules showed hydropic degeneration and this progressed to tubular necrosis 1 week after the gentamicin was discontinued. In the same experiment the snakes also developed visceral gout with urate crystals in multiple visceral organs (Montali *et al.*, 1979).

Neomycin toxicosis has been reported in calves. Experimental exposure of neomycin in calves has reported both nephrotoxicity and totality (demonstrated clinically). The clinical pathological observations included granular casts in urine, proteinuria and low specific gravity of urine, azotemia, decreased creatinine clearance, polyuria and polydipsia. The histopathological findings included renal tubular epithelial degeneration and necrosis (Crowell *et al.*, 1981).

Amphotericin B is an antifungal agent and is a drug of choice for systemic mycosis. Toxicosis of this drug can happen at recommended dosage rates. Nephrotoxicity may be related to a decrease in intrarenal blood flow associated with arteriolar vasoconstriction, a subsequent decrease in GFR and impaired tubular function. Dogs and cats are the common species affected with more susceptibility in cats. The common histopathological finding includes renal tubular necrosis, dilation of the tubules and mineralization with mild lesions in the interstitium and glomeruli (Rubin *et al.*, 1989).

## Cisplatin

Cisplatin is an antineoplastic drug which causes toxic changes in kidney, intestines and bone marrow. Cisplatin or its metabolites are eliminated through urine. Cisplatin may directly damage tubules and lead to tubular degeneration and necrosis or cause vasoconstriction leading to tubular necrosis. The exact mechanism of toxicity is not known and may involve the metabolites of cisplatin and not the platinum atom itself. The pathological findings associated with cisplatin treatment in dogs include mild renal tubular atrophy and tubular necrosis (Choie *et al.*, 1981; Forrester *et al.*, 1993).

## NSAIDs and other analgesics

NSAIDs are the most widely used analgesics in veterinary medicine, and all have some toxic potential. The common species affected are the dogs, cats and horses. NSAIDS cause toxicity of the GI tract, kidneys and liver. NSAIDs cause renal toxicity mainly by the inhibition of prostaglandin synthesis and renal blood flow resulting in renal papillary necrosis. The hepatic toxicity is mostly attributed to idiosyncratic reaction. Renal tubular or papillary necrosis is also reported in a limited number of cases in dogs (Jones *et al.*, 1996).

Horses are susceptible to phenylbutazone toxicity especially when dehydrated and the target organ is kidney. The most common gross observation in experimental studies conducted in horse dosed with phenylbutazone and deprived of water was yellow green radial streak in the renal papillae. The microscopic observations include sloughing of the renal pelvic epithelium including the terminal lining of collective ducts with coagulation necrosis of the underlying papillary interstitium, mineralization of the calyx necrotic papillary interstitium contain nuclear debris and hemorrhage and dilation of collecting ducts and cortical tubules in wedge-shaped segment of the kidney tissue above area of necrotic papillae. Other lesions observed in experimental studies of horses include ulceration and

erosions of the glandular portion of the stomach, submucosal edema of the small intestine, erosions and ulcers of the large colon, ulceration of the gastric mucosa and tongue. Pathological findings in experimental studies of horses exposed to flunixin meglumine (aminonicotinic acid) were glandular mucosal erosion and ulcer of the stomach (Gunson and Soma, 1983; MacAllister *et al.*, 1993).

Large doses of acetaminophen can cause renal toxicity along with hepatotoxicity in rats and mice. Toxicity is characterized by renal tubular necrosis in the proximal tubules (Schnellmann, 2001). Recently report of vulture mortality was reported from the Indian subcontinent related to NSAID toxicity. Diclofenac is an NSAID widely available veterinary drug in the Indian subcontinent, used in domestic livestock. Vultures were exposed to the drug when they consumed carcasses of cattle that were treated with diclofenac shortly before death. Experimental studies of this drug in vultures showed marked nephrotoxicity. The gross observations were primarily deposits of urate on the surface of internal organs related to renal failure. Histopathological finding were acute necrosis of the proximal renal tubular epithelium with minimal inflammatory response and deposits of urate crystals (Oaks *et al.*, 2004; Meteyer *et al.*, 2005). Aspirin, ibuprofen and acetaminophen are the important analgesics which are reported to cause toxicosis in veterinary medicine. Generally, toxicosis is a result of large overdoses and affects liver. Renal lesions including renal tubular necrosis and papillary necrosis have been reported in dogs.

## Sulfonamides

Renal toxicity associated with sulfonamides is rare as most of the current pharmaceutical preparations are relatively highly soluble at the pH normally occurring in the kidney. Toxicity occurs due to very high overdosage. Sulfonamides can cause both acute and chronic toxic effects. The most important organ affected in toxicity is the kidney. Animals with renal toxicity will show elevated levels of BUN and creatinine. In some animals sulfonamide crystals are observed in the renal pelvis as a gross finding and kidneys are gritty in texture when cut. Histopathological observation is primarily renal tubular epithelial degeneration and necrosis due to the direct action of the crystals and these crystals are visible with polarized light only if the kidney is processed to prevent the dissolution (Jones *et al.*, 1992).

## Tetracyclines

Tetracyclines have been reported to cause toxicity, and kidneys are the primary organs affected. Renal tubular necrosis is the common pathological finding. Animals with renal toxicity will show oliguria, marked azotemia, moderate proteinuria, tubular casts in urinary sediment with inability to concentrate urine (Lairmore *et al.*, 1984; Vaala *et al.*, 1987).

## Vitamin K3 (menadione sodium sulfate)

Toxicity is commonly reported in horses. In experimental studies the gross lesion observed was enlargement and paleness of the kidney. The microscopic lesions include diffuse or multifocal tubular necrosis and dilation with proteinaceous and cellular debris from red blood cells and neutrophils and casts, diffuse interstitial edema and lymphocytic infiltration regeneration of the tubular epithelium. In animals which survived for 3 months renal tubules showed degeneration, necrosis and dilation. In chronic renal failure following vitamin K3 administration, the kidneys were reduced in size, the capsule adherent, and pale streaks of connective tissue may be grossly apparent. Microscopic findings include connective tissue proliferation with mononuclear cell infiltration, moderate hypercellularity of glomeruli with few sclerotic glomeruli. The tubules are dilated but the lining epithelium appears normal with mineral, cellular and proteinaceous cast which may be seen in many tubules (Rebhun *et al.*, 1984).

## Cyclosporine

Cyclosporine is a macrolide antibiotic and has been used as an immunosuppressive agent. Cyclosporine can cause both renal and nonrenal toxicity. Clinically renal toxicity consists of four discrete syndromes which include acute reversible renal functional impairment, delayed renal allograft function, acute vasculopathy and chronic nephropathy with interstitial fibrosis. Proximal tubular epithelium is uniquely sensitive to the toxic effect. The toxic effect is characterized by isometric cytoplasmic vacuolations (equally sized several small vacuoles in cytoplasm), necrosis with or without subsequent mineralization, inclusion bodies (giant mitochondria) and giant lysosomes. Acute vasculopathy consists of vacuolization of the arteriolar smooth muscles and endothelial cells leading to necrosis. In some cases thrombotic microangiopathy develops characterized by thrombosis of the renal microvasculature. Long-term treatment with cyclosporine results in chronic nephropathy with interstitial fibrosis (Charney *et al.*, 2004).

## Furazolidone

Furazolidone renal toxicity has been reported in goats. The gross observations included congestion in brain, livers and kidneys. The histopathological findings included degenerative changes in the renal tubules, hepatocyte

necrosis and degeneration in the centrilobular areas (Ali *et al.*, 1984).

## METALS

### Mercury

Fungicides, preservatives and fixatives are the main sources of mercury toxicosis. Often toxicosis is related to accidental ingestion of obsolete mercury products. The lesions of mercury toxicosis are distributed in the GI tract, kidney and sometimes in the brain (alkyl organic mercury). Inorganic mercurial salts accumulate in renal cortex and are excreted primarily in urine. Inorganic mercurial salts cause direct tissue necrosis and renal tubular epithelial necrosis by two mechanisms. Mercuric ion binds covalently with sulfur and inhibits sulfhydryl containing enzymes in microsomes and mitochondria. The mercurial salts may bind to protein as mercaptides. Death occurs in acute toxicity, and oliguria and azotemia are observed in animals surviving acute exposure (Osweiler, 1996). Gross lesions include gastric ulcers, congestion of the intestinal mucosa, pale swollen kidney and pale liver. Histopathological findings in kidney are primarily renal tubular degeneration and necrosis especially in the proximal tubular epithelium. In chronic exposure glomerulonephritis is observed due to antigen–antibody complex deposition (Jones *et al.*, 1996).

Diagnosis and confirmation can be made by analytical estimation in the kidney. Differential diagnoses include toxicosis by lead, thallium, phenylarsonic feed additive and ethylene glycol toxicosis, encephalitis, polioencephalomalacia, hog cholera (pigs) and erysipelas (pigs).

### Cadmium

The other metal which is associated with rare cases of renal toxicity in domestic animals is cadmium. Cadmium exposure is by ingestion of cadmium–nickel batteries. Cadmium is concentrated in the renal tubules and to a lesser degree in hepatocytes. Cadmium induces metallothionein production and forms cadmium–metallothionein complex. This complex is filtered freely by the glomerulus and is reabsorbed by proximal tubules. Inside the tubules renal metallothionein is formed and once the renal metallothionein pool is saturated free cadmium ion initiates renal tubular injury (Osweiler, 1996; Schnellmann, 2001).

### Arsenic

Toxicosis is mostly reported in cattle and dogs by accidental exposure but all species of domestic animals can be affected. Trivalent arsenicals inhibit cellular respiration and cause capillary dilation and degeneration. Pentavalent inorganic arsenicals cause uncoupling of oxidative phosphorylation leading to cellular energy deficiency. In acute toxicosis the pathological changes are mostly limited to the GI tract. Subacute toxicity is by exposure to low dose for several days. In subacute cases kidneys are affected. The clinical signs associated with subacute toxicity are oliguria and proteinuria followed by polyuria. Watery diarrhea exhibited in acute poisoning will also be observed. Death results due to dehydration, acidosis and azotemia (Osweiler, 1996). The gross findings include pale swollen kidney and pale liver. Renal damage affects all portions of the nephron leading to severe renal tubular necrosis. Histopathological lesions consist of dilation of the vessels, submucosal congestion and edema, necrosis of the intestinal epithelium, renal tubular necrosis and fatty degeneration of the hepatocytes (Jones *et al.*, 1996). Diagnosis is by correlating the case history, pathological findings and analytical estimation of arsenic in liver, kidney and other tissues (hair). Differential diagnosis of pathological lesions includes infectious agents affecting kidney and NSAID exposure.

### Copper

Acute copper toxicosis results from accidental ingestion or administration of copper containing formulations like anthelmintics, feed additives, foot baths used for livestock, pesticides including fungicides and algaecides at a toxic dose. Copper toxicosis is a problem observed frequently in the sheep as they are sensitive to excessive accumulation of copper. Sheep accumulate copper in the liver in proportion to intake, where there is slow build up of the copper and then there is sudden release which results in excess copper in the circulation. This excess copper in the circulation oxidize the erythrocyte membrane resulting in intravascular hemolysis. Clinical signs in sheep are due to acute anemia and include weakness, anorexia, fever, pale mucous membranes and dyspnea. Grossly the kidney has a dark red or bluish black color (gun metal kidneys) and the liver will be pale yellow and friable. Microscopic findings include necrosis of renal tubular epithelium and hemoglobin casts (Osweiler, 1996; Maiorka *et al.*, 1998). Diagnosis is by correlating liver copper values with pathological findings and case history.

### Fluoride

Fluoride toxicosis can be acute or chronic and acute toxicosis is by exposure to insecticides/rodenticides and exposure to volcanic dust exposure. Fluoride is metabolized via renal excretion and is preferentially deposited in bones

and teeth. Acute fluoride intoxication produces clinical signs and lesions of gastroenteritis and renal tubular necrosis. In a study conducted in sheep exposed to fluoroacetate, the microscopic findings in acute toxicosis included degeneration and necrosis of myocardial fibers. In a study conducted in sheep poisoned by sodium fluoride the pathological findings included necrosis of the proximal tubular epithelial cell, necrotizing rumenitis, reticulitis and abomasitis (Shupe, 1980; O'Hara *et al*., 1982; Maylin *et al*., 1987).

## Lead

Lead toxicosis is caused by exposure to lead paint, lead containing objects like toys foils, etc., plumbing material, tiles and linoleum. Lead toxicosis affects hemoglobin synthesis by inhibiting the enzymes delta-aminolevulinic acid synthetase and ferrochelatase resulting in anemia. Clinical signs include signs of central nervous system involvement, anorexia, anemia and proteinuria. Clinical pathological findings suggestive of lead toxicosis are basophilic stippling of erythrocytes and metarubricytosis with minimal polychromasia. Anemia may be microcytic hypochromic to normocytic normochromic (Prescott, 1983). Animals dying of acute lead poisoning have very few microscopic lesions other than mild degenerative neuronal necrosis in the cerebral cortex and mild renal epithelial degeneration.

In chronic cases the kidney histopathological changes are characterized by degeneration and necrosis of the renal tubular epithelium which may show regeneration. Degenerative changes of the renal epithelial cells and hepatocytes have been reported in chronic lead poisoning in dogs. Intranuclear inclusions may be visible in the renal tubular epithelial cells, but their absence do not rule out lead toxicosis (Jones *et al*., 1996; Osweiler, 1996).

In birds especially water fowls, lead toxicosis has been reported and the lead shots may be found in the gizzard. The birds are generally emaciated with extensive muscle wasting with atrophy of the breast muscles. Changes in the kidney are primarily renal tubular degeneration or necrosis (with or without intranuclear inclusions) (Locke and Thomas, 1996). Diagnosis is by analytical estimation and history of exposure. Liver and kidney are the preferred samples for analysis of lead.

## Zinc

Zinc toxicosis has been reported in dogs as a result of ingestion of zinc containing hardwares, pennies which contain zinc, drinking water, acidic food material from galvanized tanks and containers. Severe intravascular hemolysis is the most prominent clinical pathological finding associated with zinc toxicosis in dogs. The gross observation in dogs and cats exposed to zinc includes splenomegaly, icterus, enlarged diffused red kidney with hemorrhage, and histopathological observations in the kidney are renal tubular necrosis (Luttgen *et al*., 1990; Osweiler, 1996). In experimental studies conducted in sheep exposed to zinc, renal lesions observed were degeneration of the tubular lining epithelium along with pancreatic lesions (Smith and Embling, 1993).

The renal histopathological changes observed in experimental studies in veal calves include multifocal renal cortical fibrosis with necrosis in convoluted tubules and loops of Henle and intratubular mineralization (Graham *et al*., 1988). Diagnosis is by correlating case history, pathological findings and analytical estimation in liver, kidney and pancreas.

# PESTICIDES

## Paraquat and diquat

Paraquat is one of the two widely used bipyridyl broad-spectrum herbicides (the other being diquat). The most common route of intoxication is ingestion. Among domestic animals toxic exposure has been reported in cattle, sheep, horses, pigs, poultry and dogs. Paraquat primarily affects the lungs. Kidney and liver may also be affected and the histopathological change is renal tubular epithelial degeneration. Diquat toxicity results in intracerebral hemorrhage and acute renal failure (Dungworth, 1993). Diagnosis is by correlating history of exposure with pathological findings.

## Cholecalciferol/vitamin D3

Vitamin D3 toxicity in veterinary medicine is by overdosage of vitamin supplements or exposure to rodenticide. Dogs and cats are the common species affected but any species can be affected. The common clinical pathological finding is rapid increase in plasma phosphorus in acute cases and followed by an increase in plasma calcium levels. Histological findings include mineralization in multiple organs including the kidneys, lungs, myocardium, stomach and vessels. In kidneys mineralization of arteries as well as mineral deposition in the tubular basement membranes are observed. Diagnosis is by chemical evaluation of serum, plasma, bile, urine and kidney for PTH/25-hydroxycholecalceferoland correlating pathological findings (Gunther *et al*., 1988; Fooshee and Forrester, 1990; Talcott *et al*., 1991). Differential diagnosis includes ethylene glycol toxicity, hypercalcemia of malignancy, chronic renal failure and other causes of hypercalcemia.

## Zinc phosphide

Toxicosis can happen by animals feeding directly on bait or by eating tissues of zinc phosphide-poisoned animals. All domestic animals can be affected and reports are common in dogs. Zinc phosphide releases phosphine gas when in contact with acid contents of the stomach. Both phosphine and intact zinc phosphide are absorbed from the GI tract. The phosphine is believed to cause the majority of acute signs, while the intact phosphide may cause hepatic and renal damage later. Histopathological findings in kidney include renal tubular degeneration and necrosis (Casteel and Bailey, 1986). Diagnosis is by analysis of stomach contents/vomitus/liver and kidney for phosphine gas and the samples have to be submitted frozen in air-tight containers.

# PLANTS

## Easter lily

Cats are the most common species affected. The aqueous extracts of leaves and flowers are proven to be nephrotoxic and pancreatoxic. The renal tubular epithelial cells are damaged resulting in anuric renal failure. Clinical signs start with GI disturbances followed by isosthenuria, polyuria, dehydration, anuria, weakness and recumbency. The clinical pathological changes include an elevated creatinine and BUN with glucosuria, proteinuria with numerous tubular epithelial casts in urine sediment. The significant histopathological findings include acute necrosis of proximal convoluted tubules and degeneration of pancreatic acinar cells. The tubular epithelial cells show loss, degeneration and regeneration. Tubular lumen contains protein casts and cellular debris. Renal ultrastructurally changes include swollen mitochondria, megamitochondria, edema and lipidosis (Langston, 2002; Rumbeiha *et al*., 2004). Diagnosis is by correlating the clinical signs with histopathological examination and case history.

## Oxalate containing plants

### *Rheum, Halogeton, Rhubarb*

The common plants which contain toxic level of soluble oxalates are Rhubarb (*Rheum rhaponticum*), Halogeton (*Halogeton glomerulatus*) and Grease wood (*Sarcobatus vermiculatus*), beets and dock (*Rumex* spp.) and lamb quarters (*Chenopodium* spp.).

The toxic principles are oxalic acid, sodium and potassium oxalates, which complex with calcium forming calcium oxalate and crystallize in the kidney when they are excreted. Sheep, cattle and swine are the common species affected. Hypocalcemia is observed due to formation of calcium oxalate. Increased BUN values are observed in chronic cases with nephritis. The gross lesions consist of radially arranged white streaks in the kidney and hemorrhages in the GI tract. The common microscopic findings are hemorrhagic rumenitis in sheep associated with deposits of calcium oxalate in the walls of blood vessels, oxalate nephrosis characterized by irregular rhomboid crystals which are visible in sharply reduced or polarized light, protein casts in tubular lumen with varying degrees of renal tubular epithelial degeneration and necrosis (Dickie *et al*., 1978; Panciera *et al*., 1990).

## *Amaranthus* spp.

The toxic principles include an unknown agent which causes perirenal edema and nephrosis. The most common species affected are cattle and swine. The significant clinical pathological findings include increased BUN, proteinuria, CK and creatinine.

The most striking gross lesion is retroperitoneal edema in the perirenal connective tissue. Edema is often present in the ventral abdominal wall and per rectal area. Kidneys are normal or small in size and pale with subcapsular petechiae. In calves free straw colored fluid is observed in thoracic and peritoneal cavities. Histopathological findings include degeneration and necrosis of the tubular epithelium of the proximal tubules with interstitial edema, dilation of the renal tubules with protein casts and some may have oxalate crystals (Stuart *et al*., 1975; Kerr and Kelch, 1998). Diagnosis is by evidence of consumption of the plant material with appropriate clinical signs and pathological findings.

## Oak (*Quercus* spp.)

Oak (*Quercus* spp.) poisoning has been reported from many regions of the world, and more than 60 species of oak have been identified in North America, Tannins and their metabolites (digallic acid, gallic acid and pyrogallol) are responsible for the toxicity. High levels of toxic component are in young leaves and the shells of green acorns. Cattle and horses are the common species affected with reports more common in cattle.

Kidney is the target organ with pathological findings also in GI tract. Oak causes GI irritation which manifests in the early course of toxicosis, characterized by anorexia, constipation and colic. After a few days, constipation is followed by diarrhea, and fragments of acorns may be present within stools.

The gross findings include swollen pale kidney with petechial hemorrhage, perirenal edema, hemorrhage and

ulcers in the GI tract (can extend from pharynx to the lower intestinal tract). The histopathological findings include degeneration and necrosis of tubular epithelium, regeneration of tubular epithelium, dilated tubules with erythrocytes, homogenous and granular casts and sloughed necrotic tubular epithelial cells and neutrophil infiltration. The renal interstitium has multifocal areas of hemorrhage and edema. Secondary lesions related to uremia and renal failure may also be observed in stomach and tongue. Oak toxicosis has high mortality due to renal failure (Anderson *et al*., 1983; Plumlee *et al*., 1998). Diagnosis is by evidence of consumption of the plant material with appropriate clinical signs and pathological findings.

## Red maple (*Acer rubrum*)

The most common species affected is equine. An unidentified toxin creates an acute hemolytic anemia associated with methemoglobinemia and/or Heinz body formation. Clinical pathological findings are hemolytic anemia and blood smears may show eccentrocytes, spherocytes, anisocytes and Heinz bodies. It produces generalized icterus, spleenomegaly and enlarged liver with pale centrilobular areas, dark brown black discolored kidney, increased pleural and pericardial fluid, petechiae and ecchymosis in the serosal surfaces. The histopathological findings in kidney include renal tubular epithelial degeneration with hemoglobin casts (Figure 11.2) (George *et al*., 1982; Stair *et al*., 1993). Diagnosis is by evidence of consumption of the plant material with appropriate clinical signs and pathological findings. Differential diagnosis includes nitrate toxicosis, equine infectious anemia and Babesiosis.

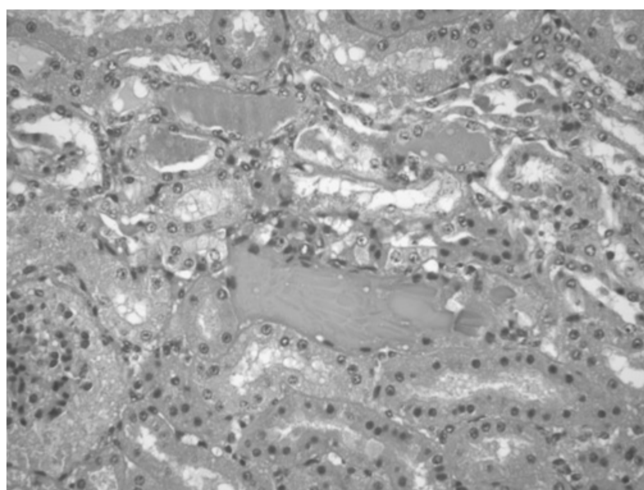

**FIGURE 11.2** Red maple poisoning, equine kidney, tubules are dilated and lined by degenerate epithelium. The tubular lumen is filled with casts. H&E stain 40×. This figure is reproduced in color in the color plate section.

## Vitamin D containing plants

The most common plants which contain calcitriol that accounts for pathogenesis are *Cestrum diurnum*, *Trisetum flavescens* and *Solanum malacoxylon*. The toxicityin Cestrum is attributed to 1,25-dihydroxy-vitamin D-glycoside and that in *Solanum malacoxylon* to a molecule similar to or identical to 1,25-dihydroxy vitamin D. The plant (*Cestrum diurnum*) is seen in warmer parts of the USA like Florida and is grown as an ornamental plant. *Solanum* spp. is seen in Brazil and Argentina, and *Trisetum* spp. is seen in Germany and Austria. The common species affected are cattle and horses. *Solanum malacoxylon* toxicity is commonly reported in sheep and cattle. Other animals are susceptible experimentally. Adult cows are more susceptible than calves. The clinical pathological observation in the early stage is hypercalcemia and hyperphosphatemia and later the levels decrease resulting in normal calcium and phosphorus levels. The gross findings include white to tan gritty foci in multiple organs including kidney. In cattle the microscopic findings include cardiac mineralization commonly in the endocardium of left atrium, mineralization of the aorta primarily involving tunica intima and media. Mineralization is observed in several major and minor blood vessels. Other locations in which microscopic evidence of mineralization are observed include kidneys, alveolar septa of lung, bronchiolar epithelium, muscles of the intestine and stomach. Diagnosis is by correlating history of exposure, pathological findings and estimation of 1,25-dihydroxy cholecalciferol levels in serum (Jones *et al*., 1996).

## White snake root (*Eupatorium rugosum*)

The common species affected by white snake root (*Eupatorium rugosum*) are cattle, horses, sheep and goats. The toxic component is tremetol and has been described as a fat soluble, high molecular weight alcohol. The toxic principle is a cumulative poison and repeated exposure to small amounts results in intoxication. Clinical pathological changes associated with liver and muscle damage is observed. Myoglobinuria or hemoglobinuria is also observed. The gross findings are observed primarily in heart and skeletal muscles with congestion in kidneys. Histopathological changes in the kidney consist of degeneration and regeneration of the tubular epithelium with hemoglobin or myoglobin casts and congestion (Olson *et al*., 1984; Jones *et al*., 1996). Diagnosis is made by correlating clinical signs, history of exposure, pathological findings and chemical analysis of the toxin in liver and kidney. The differential diagnosis includes ionophore toxicity, selenium/vitamin E deficiency and oleander toxicity.

## MISCELLANEOUS AGENTS

### Ethylene glycol

Intoxication with ethylene glycol is caused by consumption of antifreeze solution which contains up to 95% ethylene glycol. Mostly cats and dogs are the affected species but there are rare reports of intoxication in other species. The common clinical pathological findings in cats and dogs include neutrophilia, lymphopenia, azotemia, hyperphosphatemia, hypocalcemia, hyperglycemia and decreased whole blood bicarbonate. The common findings in urine analysis include proteinuria, glucosuria, hematuria, calcium oxalate and hippurate crystalluria, and the presence of renal epithelial cells, white blood cells and granular and cellular casts in the urine sediment.

Grossly the kidneys are firm with pale streaks at the corticomedullary junction. In some cases pulmonary edema and hyperemia of the gastric and intestinal mucosa are observed. The microscopic findings include marked renal interstitial fibrosis (in cases which survive for long), mild lymphocytic infiltration in the interstitium, atrophy, degeneration and necrosis and of the renal tubular epithelium with birefringent crystals (Figure 11.3), mineralization and glomerular atrophy in some cases. Microscopic demonstration of birefringent crystals in renal tubules using polarized light (Figure 11.4) is pathognomonic for ethylene glycol toxicity in dogs and cats (Jones *et al*., 1996). The antemortem diagnosis is by clinical pathological evaluation (increased anion and osmolal gaps, suggestive), colorimetric test kit, glycolic acid assay in serum and postmortem diagnosis is by pathological evaluation or chemical analysis of kidneys.

### Snake bite

Most of the poisonous snakes in USA are of Crotalidae family which includes the rattle snakes, water moccasins and copper heads. The Crotalidae family produces venoms which are mostly necrolytic and hemolyzing. Hemorrhagins in crotalid venom are toxic to the vessels and hence cause hemorrhage and edema at the wound site, in addition to systemic hemorrhage and shock. Marked anemia is observed due to hemolysis and extravasations. Disseminated intravascular coagulation is observed in some cases. The common initial clinical pathological changes include echinocytosis, thrombocytopenia, leukocytosis and prolonged activated clotting time. Generally edema and erythema along with fang marks (Crotalidae family) may be observed at the site of bite although it is tough to identify due to thick hair coat in animals. Major route of venom excretion is through the kidneys and hence kidney failure is observed in many cases of crotalid snake bites characterized by renal tubular necrosis with protein casts, hemorrhage and necrosis in the glomeruli (mesangiolysis). Mesangial proliferative glomerulonephritis is observed in patients who survive (Dickinson *et al*., 1996; Sitprija and Chaiyabutr, 1999; Hackett *et al*., 2002).

### Raisins

Grape and raisin ingestion has been reported to cause renal toxicity in dogs. The specific mechanism is not known. Clinical pathological findings include hypercalcemia, hyperphosphatemia, increased Ca $\times$ $PO_4$ product elevated BUN and serum creatinine concentrations, all related to renal damage.

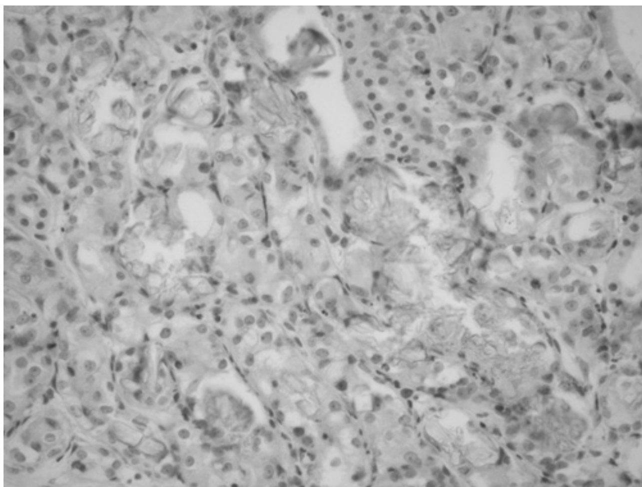

**FIGURE 11.3** Ethylene glycol poisoning, canine kidney, tubules are lined by degenerate epithelium and multiple tubules contain crystalline material. H&E stain 40×. This figure is reproduced in color in the color plate section.

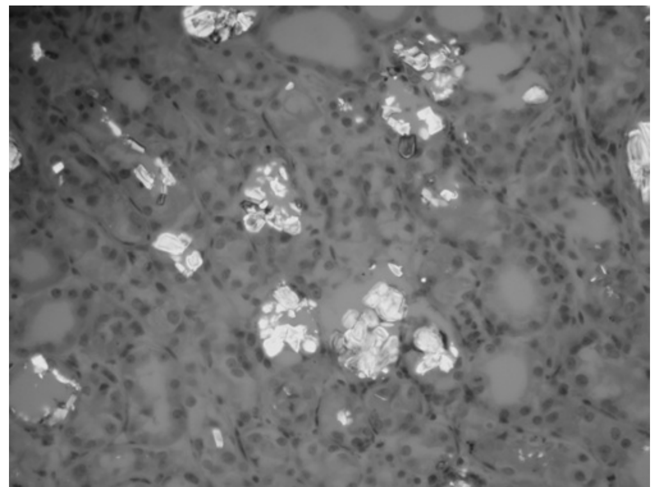

**FIGURE 11.4** Ethylene glycol poisoning, canine kidney, multiple tubules contain birefringent crystalline material. H&E stain 40× under polarized light. This figure is reproduced in color in the color plate section.

Gross lesions are absent and microscopic findings include degeneration and necrosis of proximal renal tubular epithelium with intact basement membrane, regeneration of the tubular epithelium and mineralization. The tubules contain granular and protein casts. In few animals fibrinous arteritis of the large colon were also observed (Eubig *et al.*, 2005; Morrow *et al.*, 2005).

## Pine oil

It is a component of many house hold cleaners and disinfectants. Renal toxicity has been reported in cats exposed to pine oil. The histopathological findings include renal cortical necrosis and centrilobular necrosis (Rousseaux *et al.*, 1986).

## Lower urinary tract

The anatomical components of this area include the ureters, urinary bladder and urethra. Only very few agents are reported to induce damage to these areas. Transitional epithelium lines these areas and the reduced toxic insult to this area may be due to reduced metabolic activity of transitional epithelium and reduced time of exposure to these cells as urine is excreted rapidly except for the time retained in the urinary bladder. The important agents which induce changes in the lower urinary tract are blister beetle, bracken fern, *Sorghum* spp. and cyclophosphamide.

## Black blister beetle (*Epicauta* spp.)

Toxicosis is due to ingestion of blister beetle itself. Toxicity occurs primarily when beetles are present in alfalfa hay mostly in southwestern US and occasionally in Eastern and Midwestern states of United States. The toxic principle is cantharidin, bicyclic terpenoid, which is contained in the hemolymph, genitalia and other tissues of beetle. This is a very stable compound and remains toxic even in dead beetle. Ingested cantharidin causes irritation of oral and GI mucosa leading to colic. Horses are the most common species affected.

Clinical pathological findings include hemoconcentration, neutrophilic leukocytosis and hypocalcemia. Lesions are confined to GI tract, urinary tract and heart. Gross lesions are rare and may include ulceration and hyperemia in the entire GI tract and urinary bladder. Histopathological findings include ulceration and necrosis of the mucosal epithelium in the esophagus, stomach, urinary bladder and myocardial necrosis (Schoeb and Panciera, 1979; Schmitz, 1989; Helman and Edwards, 1997). Diagnosis is by clinical signs, pathological findings confirmed by analysis of urine and gastric contents for cantharidin.

## Bracken fern (*Pteridium aquilinum*)

Most common species affected are horses and cattle. Several toxic principles are recognized and poisoning in nonruminants is due to presence of thiaminase that leads to thiamine deficiency. In ruminants the toxins include a bone marrow toxin and the suspected carcinogen ptaquiloside which induce the bladder tumors in cattle.

In cattle different clinical manifestations of the poisoning by bracken fern are reported. When large amount of plants are consumed in a short period of time aplasia of the bone marrow develops and results in mortality. Thrombocytopenia, neutropenia and anemia develop and early myeloid cells are destroyed. Those animals consuming less quantity for longer period develop hematuria and are called enzootic hematuria. They also develop urinary bladder tumors and squamous cell carcinoma in the GI tract. All these lead to death due to anemia and chronic wasting. The pathological findings include widespread petechial and ecchymotic hemorrhage in intestines, serosal surfaces of several internal organs including urinary bladder, gall bladder, heart, subcutaneous tissue and muscles. Some animals develop abomasal ulcers. Hyperplasia and hemorrhage are observed in the urinary bladder and also ureter or renal pelvis. Chronic cystitis with hemangiomas develops which bleed resulting in hematuria. Adenocarcinomas, transitional cell carcinomas, squamous cell carcinomas, papillomas, fibromas and adenomas are reported in the urinary bladder, renal pelvis and ureters, related to exposure of bracken fern. Tumors in the GI tract are mostly squamous cell carcinomas located in pharynx, base of tongue, esophagus and rumen (Pamukcu *et al.*, 1976; Jones *et al.*, 1996; Gava *et al.*, 2002; Carvalho *et al.*, 2006). Diagnosis is by evidence of consumption of the plant material with appropriate clinical signs and pathological findings.

## *Sorghum* spp. (Equine Cystitis Ataxia syndrome)

In horses, especially females, a syndrome of cystitis and ataxia has been associated with the consumption of hybrid strain of *Sorghum* spp. Gross observations include edema and hemorrhage in the bladder mucosa with occasional ulceration of the mucosa. Histological findings include focal necrosis and ulceration of the urinary bladder mucosa, degeneration of axons and demyelination with gitter cells in cervical, thoracic, lumbar and sacral spinal cord segments. Fetal malformations associated with hybrid

sudan are mentioned in the reproductive system section (Adams *et al*., 1969; Morgan *et al*., 1990).

### Cyclophosphamide

The common pathological manifestation of adverse reaction of cyclophosphamide therapy in dogs and cats is sterile hemorrhagic cystitis characterized by ulceration, edema and necrosis. Toxic effects of cyclophosphamide in the urinary bladder are by the action of acrolein, a metabolite of cyclophosphamide. Acrolein causes submucosal, edema, necrosis, hemorrhage and fibrosis of the urinary system epithelia (Dhaliwal and Kitchell, 1999; Charney *et al*., 2003).

## CONCLUSION

The primary functions of the kidney are get rid of the body waste materials that are either ingested or produced by metabolism and to control the volume and composition of the body fluids. The toxins absorbed by the different routes are biotransformed and enter the blood which is eliminated through the urine, feces and air. Since kidney receives approximately a quarter of the cardiac output it is an important organ for the exposure of toxicants and their metabolites.

CHAPTER

# 12

# Respiratory toxicity

*John A. Pickrell*

## INTRODUCTION

Inhalation toxicology refers to a route of exposure; toxic chemicals inhaled have a potential to produce lung disease and if the chemical is trans-located to other organs disease in those organs as well. Contrast this to pulmonary toxicity which rather than being a route is more of a target organ toxicity. The environment in which animals live is distinctly different than where humans live, with respect to quality of shelter, as well as square and volume of living areas (Pickrell, 1991). Thus, it is not surprising if both inhalation and pulmonary toxicity differ from animal to man. Air pollution is a reflection of and a description of the presence of chemicals in the air all of the time (Zemp *et al.*, 1999 cited in Witschi and Last, 2001).

To better understand environmental lung disease we need (1) more precise knowledge and an understanding about toxic doses of inhalation toxicants delivered to specific sites of the lung; and (2) the extent of chronic low-level exposures which may trigger and facilitate development of progressive lung disease. Many lung diseases have their beginnings with increases in oxidative burden or stress to the lung. There is strong evidence that oxidative burden to lung may initiate and favor development of lung diseases such as chronic bronchitis, asthma, and interstitial lung disease (Witschi and Last, 2001).

Lung toxicology requires interdisciplinary collaboration between anatomists, physiologists, immunologists, pathologists, molecular biologists, epidemiologists, clinicians and many other shared disciplines. Adaptation of pulmonary function tests to animals has led to an elucidation of mechanisms related to respiratory toxicology in both man and animals. In fact, the comparison of human and animal data especially in more than one species, provides data more relevant to mechanisms than any from individual species. Recent molecular measurements have brought home how closely tied many of these diseases are to specific protein synthesis, how complementary protein and RNA synthesis are. Such molecular analyses help to pinpoint specific molecular reactions to specific cell types. In addition, they help us describe the more relevant influence of each cell on the others in the near neighborhood. Tissue culture, organ minces and *in vivo* animal exposure studies especially with bronchoalveolar lavage washings further elucidate such interaction.

## LUNG STRUCTURE AND FUNCTION

### Nasal passageways normal function

The nasopharynx is lined by pseudo-stratified columnar ciliated epithelium with goblet cells (Dungworth, 1993). Abundant lymphoid nodules are present in the submucosa. The eustachian Tubes extend from the middle ear to the nasal cavity (Dungworth, 1993). Many animals, especially horses and small laboratory rodents, are obligate nose breathers. Other animals can breathe with either their nose or mouth. Dogs are blessed with a keen sense of smell relative to humans. Basset hounds or beagles primarily hunt by scent rather than sight.

These dogs specialize in following a smell or scent. Most of these breeds have longer, drooping ears; one theory says that this helps to collect scent from the air and keep it near the dog's face and nose. They also have large nasal cavities to better process scent. Their typically loose,

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

moist lips also trap scent particles. This scent can be tracked for considerable time after it is made – sometimes even across water. They are most happy when being afforded the chance to track scents. For these reasons, they can become valuable after being trained to sniff out specific chemicals. For example, dogs are quite efficient at sniffing illegal drugs, if trained properly (Natural History, 2006).

Dogs have many more olfactory (smell) receptors than humans do – approximately 25 times more (Natural History, 2006). These receptors occur in special sniffing cells deep in a dog's snout; dogs can smell much more acutely than humans. In fact, dogs can sense odors at concentrations nearly 100 million ($10^8$) times lower than humans can. As an example, we can detect a drop of blood (0.05 ml). Dogs can detect one drop of blood in five quarts of water; $10^8$-fold lower.

As a second example, tertiary butyl mercaptan (TBM) has an odor threshold where a human can just sense its unpleasant odor at or near 0.1 parts per billion ($10^{-10}$) in air. If a dog is more sensitive by approximately a factor of $10^8$; that dogs odor threshold would be more like $10^{-18}$; a picogram of TBM (~0.01 pmol) in 800,000 l of air (800 $m^3$ of air; a cube ~ 9 m [~30 ft] on a side if well mixed) or 10 pmol (0.01 μmol) in 800,000,000 l of air (800,000 $m^3$ of air; a cube ~300 ft; 100 yd on a side). We usually don't get much information from sniffing the bare sidewalk, but the same action yields much information to a trained dog. It may be dropped food, or the scent of that poodle next door.

When a dog breathes normally, air laden with scent doesn't pass directly over the smell receptors. But when the dog takes a big sniff, air travels to the smell receptors, near the back of the dog's snout. To sniff deeply is to smell and track efficiently (Natural History, 2006). Wild dogs smell to hunt and to read smells left by other dogs. Domesticated dogs can be trained to sniff deeply and to smell certain odors (Natural History, 2006). The author has been told that dog sniffing parked cars is not legally a search, but it can be the basis for search for further physical evidence if a warrant is issued.

### *Epistaxis*

Circulatory disturbances such as epistaxis (nasal hemorrhage) or pulmonary hemorrhage can cause nosebleed and subsequent obscuring of vision. Obscured vision has the greatest consequences in horses performing in races. At necropsy, blood stained foam indicates terminal congestion, edema, and hemorrhage of the lung. Breakdown of blood vessels can have a traumatic, inflammatory, or neoplastic cause. It may be part of hemorrhagic diatheses or mycotic in origin. Infrequently it may be caused by elevated blood pressure – horses performing in races.

Although commonly caused by intense exercise, cases have been associated with envenomation by rattle snakes (Dickinson *et al.*, 1996). These horses have fever, tachycardia, cardiac arrhythmia, thrombosis, and hemorrhage, including epistaxis. Acutely bitten horses have 19% mortality. Since horses are often bitten on the nose and are obligate nose breathers, the nostril may swell. The nostril and airway must be kept patent (Dickinson *et al.*, 1996). Airborne reactive oxygen substances (ROS) can destroy the capillary barrier and reduce vasoactive nitric oxides; both actions increase the likelihood of equine exercise-induced pulmonary hemorrhage (EIPH) caused by exercise (Manohar *et al.*, 1993; Mills and Higgins, 1997).

High doses of ethylene glycol (>10 mg/kg) produced bovine epistaxis and hemoglobinuria (Crowell *et al.*, 1979). Both fungal cultures and brodifacoum can be a source of hemorrhage from the beak (Rabie *et al.*, 1975). Fungal rhinitis can cause epistaxis in cats (Whitney *et al.*, 2005).

### *Anosmia: hyposmia*

Pace and Lancet (1986) have shown that olfactory responses may be mediated by a GTP-binding protein (G protein); they have identified it in dendritic membranes (olfactory cilia preparations) of chemosensory neurons from three vertebrate species. The G protein is shown to mediate the stimulation by odorants of the highly active adenylate cyclase in these membranes. Its alpha subunit (42,000 Da) undergoes ADP-ribosylation catalyzed by cholera toxin that leads to adenylate cyclase activation. Signal amplification may be responsible for the unusual acuity of the sense of smell (Pace and Lancet, 1986).

Olfactory testing helps establish the presence or absence of such adverse influences to sense of smell. In the future, production animals may be tested to detect reasons for disability compensation and monitor function of smell (Doty, 2006). We expect attempts will be made to relate optimal production to a healthy sense of smell as a group and then individually. Numerous toxins, including environmental toxins, particularly heavy metals, influence the ability to smell. It is hoped that modern advances in technology, in conjunction with better production medicine practices, will make it possible to reliably monitor and limit occupational exposures to hazardous chemicals and their potential adverse influences on the sense of smell. Alternatively, hyposmia occurs in dogs following laryngectomy; these data suggest that both loss of airway and connections to the olfactory cortex may cause hyposmia (Netzer *et al.*, 2002; Doty, 2006).

## Conducting airways normal function

Upper (conducting) airways (bronchi, progressively smaller generations of bronchioles and terminal bronchioles) are lined with pseudo-stratified columnar epithelial cells with a few goblet cells interspersed. Their support tissue contains fibrous connective tissue and cartilaginous plates

(Dungworth, 1993). Animals performing for speed have progressively larger diameter airways to accommodate additional airflow needed.

Normal mucociliary clearance requires coordination of both the gel–sol mucus and beating of cilia to clear particles (Dungworth, 1993). Goblet mucus cells, submucous glands, and serous secretory cells coordinate to mix the mucus to lubricate exit flow. Mucus allows cilia to coordinate help clear particles. Non-ciliated (Clara) epithelial cells have P-450 monoxygenase systems that can actively metabolize foreign (xenobiotic) chemicals and active inflammatory compounds such as prostaglandins. Bronchial epithelial cells produce their intercellular adhesion molecule (ICAM 1).

Upper airways (bronchi and bronchioles) have bronchial associated lymphoid tissue (BALT); this tissue is similar to gut associated lymphoid tissue (GALT) (Dungworth, 1993). BALT is responsible for local immunity in the lung. As bronchioles become progressively smaller, resistance to airflow increases. In these small conducting airways, diseases reflecting altered airflow resistance are said to be diseases of small airways or small airway resistance. As the airways narrow, the epithelium changes from pseudostratified ciliated columnar cells with goblet cells to simple columnar epithelium, reflecting the form, function, and stresses of these smaller airways. The smallest bronchioles may collapse near the end of expiration, unless there is sufficient collateral circulation to keep them open.

### *Toxic diseases of the conducting airways*

Instillation of ragweed caused decrease in nasal cavity volume and minimal cross-sectional area without adverse systemic effects (Rudolph *et al*., 2003). Allergic rhinitis, that clinically resembles hay fever in humans, can occur in horses and cats in addition to dogs (Dungworth, 1993). Nasal granuloma is a chronic form of allergic rhinitis. Degranulation of mast cells and sensitization by albumin provide evidence that allergic stimulation is an underlying cause.

Constant exposure to dust through litter use or upper respiratory tract infections were blamed as likely causes of feline upper airway inflammation. However only certain cats become clinically ill; all cats are potentially exposed to similar conditions. These data suggest varying degrees of hypersensitivity to stimulating antigens in cat populations (Dye, 1992). The results of this study suggest that there is a different metabolic response as indicated by heart rate, blood lactate, $PaO_2$ to exercise in poor equine performers compared to good performers (Courouce-Malblanc *et al*., 2002).

Cattle, especially the channel island breeds, and occasionally sheep have a seasonal allergy that resembles this condition (Dungworth, 1993). Cattle are believed to be allergic to pollen antigens. Histologically, the epithelium is hyperplastic, eroded, and/or infiltrated with eosinophils. Seasonal eosinophilia in hamsters is believed to have a similar origin, although details are lacking.

Nasal granuloma is the chronic form of allergic rhinitis. Because this is moderately common in Jersey cattle, breed sensitivity is proposed. Less commonly, allergic rhinitis may have a fungal origin (Dungworth, 1993). Horses with chronic obstructive pulmonary disease have high transpulmonary pressures (Ammann *et al*., 1998).

A very high prevalence of inflammatory gastrointestinal tract problems in brachycephalic dogs that presented with upper respiratory problems was observed clinically, endoscopically, and histologically (Poncet *et al*., 2005). Histologic inflammatory lesions were observed that were not macroscopically visible at endoscopy. Respiratory and digestive signs correlated closely in French bulldogs, males and heavy brachycephalic dogs. These observations show a correlation between upper respiratory and gastrointestinal tract problems in brachycephalic breeds with upper respiratory disease (Poncet *et al*., 2005). Systemic inflammatory disease led to secondary pulmonary infiltration and inflammation (Bedenice *et al*., 2003). Lobeline induced highly reproducible respiratory hyperpnea without any apparent adverse effects; it may be useful in the investigation of pulmonary function in healthy horses and those with airway disease (Marlin *et al*., 2002).

Moderate smoke inhalation injury to the upper airway is usually independent of temperature damage; after as little as 1 h increases endothelin-1 in cells that line the airway increases (Cox *et al*., 2001). Such changes may contribute to the airway inflammation, mucus secretion, pulmonary hypertension, increased airway resistance, and decreased lung compliance, in our ovine model of smoke inhalation injury (Cox *et al*., 2001).

### *Therapeutic approaches to conducting airway dysfunction*

Oral pseudoephedrine or chlorpheniramine was reported to block the ragweed-induced nasal congestion. This canine model may be used to study upper airway diseases such as allergic rhinitis and to evaluate activity of nasal decongestants (Rudolph *et al*., 2003).

Steroid inhalation reduces the pressures to within the range of apparently normal horses; resistance and arterial oxygen tension became more normal (Ammann *et al*., 1998), suggesting an acute improvement of pulmonary function. Interferon alpha reduced the indication of upper airway inflammation (neutrophils and lymphocytes) in horses without affecting the proportion of lymphocytes that contain CD4-, CD5- and CD8-surface protein (Moore *et al*., 1998).

Tannin is a poly-dispersed poly-phenol from cotton bracts that can be inhaled by dogs near a cotton processor and inhibit acute inflammation's (phorbol myristic acid, PMA) activation of protein kinase C. Tannin inhibits

chloride secretion in airway epithelial cells in part by inhibiting protein kinase C (Cloutier and Guernsey, 1995).

## Gas exchange region

### *Introduction*

Pulmonary parenchyma is divided into units of structure and function called acini (Dungworth, 1993). An acinus is the gas exchange unit of the lung and of pulmonary parenchyma. The acinus includes all branches of respiratory bronchioles, alveolar ducts, and alveoli associated with ventilation; in addition, it contains the vasculature associated with perfusion. Lobules are many acini grouped together and surrounded by connective tissue; in cattle, sheep, and horses they form lobules visible at autopsy. In other species lobules are less obvious on macroscopic examination. Cells most important to the gas exchange are epithelium (type II epithelial corner cells and type I epithelial cells). Fibroblasts provide connective tissue and structural support for the alveolus; vascular endothelial cells line the pulmonary capillaries.

In birds there are many morphologic, physiologic, and mechanical differences between the bird's lung-airsac respiratory system and the mammalian bronchoalveolar lung (Brown *et al.*, 1997). The gas exchange unit is the parabronchus. Oxygen is extracted from air passing through the conducting airways to the gas exchange unit and on to the airsacs. The airsacs provide an auxiliary source of air moved back out to give the parabronchus an opportunity to extract oxygen. Because the extraction is countercurrent, air circulation is from the dorsal and ventral bronchi, the gas exchange area is about the same, and the gas exchange membrane is thinner, oxygen is extracted about twice as efficiently as in mammals. Airsacs and air membrane spaces provide a reduction in density to birds; reduced density is often helpful in staying aloft. Peak oxygen consumption measured in hovering hummingbirds is limited not by metabolic capacity, but by wing aerodynamics secondary to a low density atmosphere. The large mass-specific gas uptake by the avian respiratory system, at rest and especially during exercise, could be exploited as a very sensitive monitor of air quality. An example of this is the canary in the mine that predicts toxicity to the miners (Brown *et al.*, 1997).

### *Ventilation*

Tidal volume has a contribution from dead volume: the volume in the conducting airways that does not exchange gas (West, 2000a, b). Anatomic dead space measures the volume of the conducting airways to where oxygen becomes diluted, e.g. Fowler's method. Physiologic dead space measures the portion of the airways that do not exchange carbon dioxide ($CO_2$) (Bohr's method). The more rapid and shallow the breathing pattern, the higher the percentage of the non-contributing dead volume in each breath.

In addition the tidal volume has a contribution from the alveolar (acinar) volume (the volume in the alveolus that does exchange gas). Although we assume that all regions of the lung are ventilated equally, positional differences are seen in humans (West, 2000a, b). Such differences are minimized when humans are in the supine position. The anterior main bronchi receive more ventilation than do the rear ones in dogs.

Ozone and oxides of nitrogen and sulfur were modeled for absorption throughout the respiratory tract (Tsujino *et al.*, 2005). All three gases had higher concentration in the airways. For example, ozone was 3–12 times higher at the fifth generation bronchus. Sensitivity analysis indicated that tidal volume, respiratory rate, and surface area of the upper and lower airways significantly affected the results. Kinetics of inhaled gaseous substances vary substantially among animals and humans, and such variations are, at least partially, the result of anatomical and physiological differences in their airways.

Two anesthetized, spontaneously breathing ducks inhaled a non-toxic iron oxide aerosol with an aerodynamic mass mean diameter = $0.18\,\mu m$ at $460\,mg/m^3$ for 1.75 h; two awake, resting ducks inhaled a 10-fold less concentrated aerosol ($38\,mg/m^3$) for 6 h on two consecutive days (Stearns *et al.*, 1987). We found iron oxide particles trapped within the substance that coats the atria and infundibula; within epithelial cells of the atria and initial portions of the infundibula; and within interstitial macrophages. Only occasionally, small amounts of particles were found in the air capillaries. Both epithelial cells and interstitial macrophages phagocytized particles in avian lungs and transported them to the atria and the initial portions of the infundibula (Stearns *et al.*, 1987; Brown *et al.*, 1997).

### *Perfusion*

There are two different types of blood supply to the lung: nutrient vessels that provide nutrition for the lung and pulmonary vessels that specialize in exchanging alveolar oxygen onto the hemoglobin to be carried around and exchanged to the target organs (West, 2000a, b). Both gas exchanges operate on an oxygen gradient and occur between alveoli and capillaries. The capillaries are just large enough to admit erythrocytes and they are very short. Visualization of multiple short segments is misleading; blood really flows as a sheet, and the network of capillaries is said to resemble a miniature underground parking garage.

### *Diffusion*

Diffusion is driven by the properties of the blood gas barrier, not by the amount of blood available. Thus, diffusion of certain gases (e.g. carbon monoxide (CO)) is said to be

diffusion limited. In certain other gases such as nitrous oxide which do not bind to or are taken up by the red blood cell, diffusion occurs rapidly and is said to be dependent on blood volume. Oxygen takes the middle road so that some of its diffusion is a characteristic of the blood gas barrier (diffusion limited) and some portion of its diffusion is dependent on blood volume (perfusion limited).

Chickens and rabbits die from high doses of *Crotalia* in 10–20 min; death in rabbits is delayed for 10 h. Phospholipase–crotapotin (PC) paralyzes the contractile response of isolated phrenic-hemidiaphragms of rats. A latency period 20–100 min preceded the paralysis (Breithaupt, 1976).

Thus, if the barrier becomes abnormally thick, diffusion of oxygen is said to limit gas exchange. Although this is an easily understood and therefore an attractive concept to think of a thick barrier, this is less frequent. Alternatively, a failure to match ventilation with perfusion is the cause of poor gas exchange. If the blood flow changes relative to air or air relative to blood flow a mismatch of ventilation (availability air and oxygen) with perfusion (availability of blood) is said to have occurred (West *et al.*, 2000).

If, for example, the lung is heavily perfused with minimal ventilation because of a blocked airway, the amount of oxygen that can be exchanged is limited by the mismatch of poor ventilation with good perfusion. Alternatively, if the lung is efficiently ventilated portion with little or no perfusion, gas exchange is limited, because of the lack of blood and there is said to be a mismatch of good ventilation with poor perfusion (West *et al.*, 2000).

#### *Mismatch of ventilation with perfusion*

Beta-blocker intoxication causes dose dependent decreases of myocardial contractility in laboratory animals (Langemeijer *et al.*, 1992). Calcium probably causes direct negative inotropy of the myocardium, decreased parathormone production, and centrally mediated hypotension. In addition toxic doses of beta blockers can lead to central nervous system mediated respiratory arrest and death. To prevent death, early initiation of ventilation, as well as administration of beta-antagonist can be essential to correct the drop in serum calcium concentration. Phosphodiesterase inhibitors and glucagon are given to improve myocardial contractility (Langemeijer *et al.*, 1992).

Dogs inhaling smoke from a burning charcoal tip, where tobacco does not burn, developed the same coronary artery narrowing as if they had inhaled smoke from tobacco (Gering and Folts, 1990).

Dogs that inhaled 1% nitric acid on alternate days for 4 weeks had increased pulmonary resistance and decreased dynamic compliance. Anatomically, there was bronchial obstruction, diffuse chronic airway inflammation, slight epithelial changes, slight peribronchiolar fibrosis, and an increase in smooth muscle (Peters and Hyatt, 1986).

#### *Allergic lung disease in swine and poultry confinement operations*

Raising pigs and poultry indoors in large confinement facilities is increasingly common. High endotoxin, ammonia ($NH_3$), dust and endotoxin levels caused both the human caretakers and animals in those buildings to develop bronchitis and asthma exacerbation (Von Essen and Donham, 1999; Jones *et al.*, 1984).

## GENERAL PRINCIPLES IN THE PATHOGENESIS OF LUNG DAMAGE CAUSED BY CHEMICALS

### Oxidant burden

Oxidant burden in the lung is frequently associated with airborne pro-oxidants such as nitrogen dioxide, sulfur dioxide, oxidants such as ozone, free radicals, tobacco smoke, or an overzealous defense by phagocytic cells (Pickrell *et al.*, 1987; Pickrell and Mageed, 1995; Witschi and Last, 2001). Free radical damage in lung is provided by varied sources of evidence. Exposure to oxidants can lead to changes in lung structure and biochemistry (Pickrell *et al.*, 1987; Witschi and Last, 2001). Pivotal roles have been established for superoxide, pro-oxidant peroxy nitrites, and hydroxyl radicals. Responses depend on the oxidant burden in combination with the glutathione or biological antioxidant concentration. For example, in the presence of significant oxidant burden but high glutathione lung defensive metabolic enzymes are activated. At intermediate glutathione levels, inflammation is activated using nuclear factor kappa beta. At lower levels of glutathione, mitochondrial enzymes are activated. The relation of programmed cell death (apoptosis) to mitochondrial enzyme activation is being investigated (Nel *et al.*, 2006). Among animal cells, macrophages, monocytes, and neutrophils efficiently generate free radicals and oxidants; this is believed to relate to phagocytosis. With sufficient dose and depletion of glutathione, all lung toxins have an inflammatory disease component.

### Toxic inhalant gases and dose

#### *Chlorine*

Chlorine and chlorinated chemical toxicities in humans are thought to originate from manufacture of pulp, paper, plastics, and chlorinated chemicals (Witschi and Last, 2001). Animals exposed to pulp, paper, and plastics manufacture are generally considered to be small in number. Somewhat more frequently, animals are exposed to chlorine by chemical spills.

Chlorine gas is irritating to the upper airways and can cause hemoptysis, dyspnea, tracheobronchitis, or even bronchopneumonia in animals inhaling sufficient concentrations as a result of accidents and spills (Witschi and Last, 2001). Chlorine is a respiratory toxin. Symptoms from sensory irritation include bronchospasm, cellular changes to bronchioles and alveoli, to development of pulmonary disease. Full recovery from such injuries is likely; permanent loss of function is possible in cases of exposure to very high levels of chlorine (Winder, 2001). Chlorine escaping from rail car accidents leads to upper airway irritation (LeVecchio *et al.*, 2005). Complaints included shortness of breath, eye irritation, nasal complaints, cough, and skin complaints in animals and their caretakers near the chemical spill. Peak symptoms were reached in 30–90 min. Patients only infrequently required more than monitoring and rudimentary support measures (LeVecchio *et al.*, 2005). Humans exposed to similar atmospheres had a limitation of forced expiratory volume to forced vital capacity that was less than that found in normal subjects (Mehta *et al.*, 2005). This limitation is frequently reversible and less than that of seasonal allergic rhinitis (Shusterman *et al.*, 2004).

#### *Ammonia*

$NH_3$ occurs frequently in swine confinement facilities to both animals and caretakers (Carson, 2004). At greater than 100 ppm, $NH_3$ irritates eyes and respiratory membranes. $NH_3$ affects the course and intensity of microbial or parasitic infections in animals in these facilities. The degree to which it reduces growth rate in addition to infectious or parasitic disease varies from minimal to modest reductions. In poultry, $NH_3$ predisposes chickens to respiratory infections. Eye irritation causes them to close their eyes, become listless, and grow more slowly. Levels greater than 60 ppm $NH_3$ cause kerato-conjunctivitis in broilers; reduced bacterial clearance, and enhanced sensitivities to bacterial infections are shown in turkeys (Carson, 2004). High levels of $NH_3$ found in poultry houses have about the same level of toxicity to birds as they would in other animals (Brown *et al.*, 1997).

#### *Anhydrous ammonia*

Anhydrous $NH_3$ is injected from pressurized tanks into the ground as a fertilizer nitrogen source. It can be released in sufficient quantity to be lethal to animals and man if pressurized tanks used to apply fertilizer to farms are breached or large containers are spilled in transit (Carson, 2004). $NH_3$ goes to the first moisture it encounters to form a vapor cloud which can either remain for several hours or disperse efficiently, depending on atmospheric parameters such as wind velocity or humidity. In animals and man, the eyes and upper respiratory tract are prime targets. If $NH_3$ is higher than 5000 ppm, it can cause a fatal apnea, or laryngeal edema. Survivors may be blinded by corneal lesions and sloughed epithelium. Removal of animals is important if the cloud has not dispersed. Supportive therapy may be curative in moderate exposures (Carson, 2004). Loss of olfactory ability was associated with exposure to anhydrous $NH_3$, a history of wheezing and asthma, and of flu-like illness after farm work in humans (Snyder *et al.*, 2003); the extent of such illness in animals has yet to be explored.

#### *Carbon dioxide*

$CO_2$ is well tolerated at 50,000 ppm, stimulating the rate and depth of respiration (Carson, 2004). It is being explored as a novel human stressor (Kaye *et al.*, 2004). Because it is heavier than air it collects in the lower portion of animal facilities and may be an asphyxiant at 400,000 ppm (Carson, 2004). It is used as an euthanasia agent in some laboratory animal species.

#### *Carbon monoxide*

CO is a product of incomplete combustion of hydrocarbon fuels. It has background levels of about 0.02 ppm in rural areas, 13 ppm in urban areas, and 40 ppm in areas of high urban traffic. Improperly vented heaters, space heaters, or improperly adjusted heaters are frequent sources of CO. Fires especially those burning more coolly are also a good source.

CO binds about 250 times as tenaciously to hemoglobin as oxygen, forming carboxyhemoglobin (COHb). Oxygen is displaced from CO, limiting ability to take up oxygen and give off $CO_2$, the main function of lungs. Because of their high respiratory exchange efficiency, birds are unusually sensitive to CO (Brown *et al.*, 1997). Often they have smaller sizes and more active metabolism, requiring more oxygen. CO binds hemoglobin more tenaciously than oxygen, displacing it from hemoglobin and limiting hemoglobin's ability to carry oxygen.

CO forms COHb in blood; measurement of COHb is diagnostic of intoxication (Carson, 2004). In humans, $<3\%$ COHb is considered normal; 6–8% causes drifting of attention; 10–20% headaches, 20–30% dizziness; 30–60% tachypnea, tachycardia, and confusion; and 60% fatality. Birds respond more acutely than mammals because of their more efficient gas exchange. For this reason, canaries have been used as sentinels for miners (Brown *et al.*, 1997; Carson, 2004). Treatment requires a minimum fresh circulating air; 100% oxygen may be lifesaving. Prognosis depends on the amount of COHb and the hypoxic brain damage. Monitor cardiac and pulmonary function for at least 2 weeks and in some cases 6 weeks. Attention to outside ventilation connections can often be lifesaving. Aging *"white"* (unventilated) space heaters are often an unnoticed source of problems (Carson, 2004).

### *Methane*

Methane ($CH_4$) becomes asphyxiant at >85%; it is an explosion hazard at 10–15%. It is substantially lighter than air and will flow above water in a swamp source (Carson, 2004).

### *Hydrogen sulfide*

Hydrogen sulfide ($H_2S$) is heavier than air and insoluble in the water of manure pits (Carson, 2004). Thus it will exist as bubbles in swine manure pits waiting to gas animals or humans on agitation. Since $H_2S$ is insoluble in water, it may expose the deepest recesses of the lung; at 50–150 ppm $H_2S$ causes pulmonary edema (Carson, 2004). *In vitro*, $H_2S$ induces apoptosis of aorta smooth muscle cells, which is potentiated by the endogenous $H_2S$ level. Externally regulated mitogen associated protein kinase (ERK-MAPK) mediating $H_2S$-induced apoptosis of smooth muscle cells by activating caspase-3. These findings may help reveal novel mechanisms for many diseases linked to $H_2S$-related abnormal cellular proliferation and apoptosis (Yang *et al.*, 2004). $H_2S$ is less toxic to birds than to other animals; 2000–3000 ppm will change respiratory rate and depth, while 4000 ppm will kill them. The mechanism for this decreased sensitivity is not defined, but may relate to the greater efficiency of parabronchi at transferring oxygen (Brown *et al.*, 1997).

$H_2S$ ability to paralyze the respiratory tract is its greatest danger to animals and man (Carson, 2004). Above 500–2000 ppm, animals are said to take the second, but not the third, breath. Above 500 ppm, it begins to cause permanent neurologic change. Data from rats trained to run a reversed contingency maze suggested that $H_2S$ may impair learning by increasing the animals' susceptibility to interference from irrelevant stimuli (Partlo *et al.*, 2001).

$H_2S$ is readily detectable as a rotten egg smell. Humans and presumably animals can detect $H_2S$ at 0.025 ppm (Carson, 2004). Above 200 ppm $H_2S$ paralyzes the olfactory apparatus so it may not be detectable by smell. Higher concentrations seem to paralyze more rapidly. Thus, animals or man may have only a very brief instant to smell $H_2S$ at high concentrations; it is dangerous to discount the smell because it is so brief. People or animals not breathing can be dragged outside. Breathing is not re-established spontaneously, but if some artificial respiration is given, they may spontaneously recover (Carson, 2004).

### *Nitrogen dioxide and ozone*

Nitrogen dioxide ($NO_2$) is considered with ozone ($O_3$), because $NO_2$ is a pro-oxidant and $O_3$ an oxidant. In agriculture, $NO_2$ can come from relatively airtight ensilage; $NO_2$ is usually found at the top of silos (Carson, 2004). Indoor air $NO_2$ and $O_3$ can come from second hand cigarette smoke. Nitrogen dioxide exposure from newly opened silage bags may modestly affect hungry cattle if exposure levels are unusually high (i.e. in large confined animal feeding operations (CAFO) dairies), but usually they are more likely to affect caretakers in upright silos. Nitrogen dioxide can pass through the upper airway and permanently damage pulmonary parenchyma where residence times are longer. At ambient $NO_2$ (2–3 ppm) there is little damage or clinical signs. At higher levels, e.g. 20 ppm, $NO_2$ animals have coughing, some fluid in the lungs, death of type I epithelial cells significantly enlarged air spaces and an increased collagen production but no morphologic evidence of fibrosis (Gregory *et al.*, 1983; Mauderly *et al.*, 1987; Pickrell *et al.*, 1987a; Carson, 2004). Animals that die at varying times after exposure have evidence of pulmonary edema and emphysema (Carson, 2004).

Birds are unusually sensitive to $NO_2$ and $O_3$ depending on exposure level. Caged pet birds may be sensitive to second hand cigarette smoke, especially in a kitchen. Newly hatched chickens die after 5 days exposure to 1–4 ppm $O_3$; exposure to 0.3–0.7 ppm $O_3$ causes pulmonary hemorrhage in these chickens (Brown *et al.*, 1997). Pulmonary hemorrhage in mammals is typical of acute high-level oxidant exposure of a somewhat more intense nature than pulmonary edema (Pickrell *et al.*, 1987a).

## Particle size and clearance

### *Particle size and deposition mechanisms*

Inhaled aerosol particles are frequently of multiple sizes (polydispersed) (Witschi and Last, 2001). The distribution is described by geometric mean and the scatter by geometric standard deviation. Although this sounds complicated, it is even more complicated than one might imagine, because geometric mean and geometric standard deviation can be for particle number (count median), for geometric mean for mass (mass median), geometric mean for volume (volume median), and lately, for surface area (geometric surface area median). An example of this is shown for aluminum nanoparticles (NP) where you can read number (count), surface area, and volume medians from a single chart (Figure 12.1).

In this figure, number (count) median would be approximately 150–200 nm, surface area median would be approximately 700–800 nm, and volume median would be approximately 10 μm (10,000 nm) in diameter. These numbers represent varying degrees of agglomeration of the aluminum NP; NP have large surface areas relative to mass and aggregate readily (Powers *et al.*, 2006).

Particles of different aerodynamic sizes deposit in different anatomic areas of the mammalian avian respiratory tracts. In mammalian lungs, particles 5–30 μm travel mostly by momentum (inertia); they do not turn corners well and they deposit by inertial impaction in the nasopharyngeal region (Witschi and Last, 2001). Inertial impaction in bird

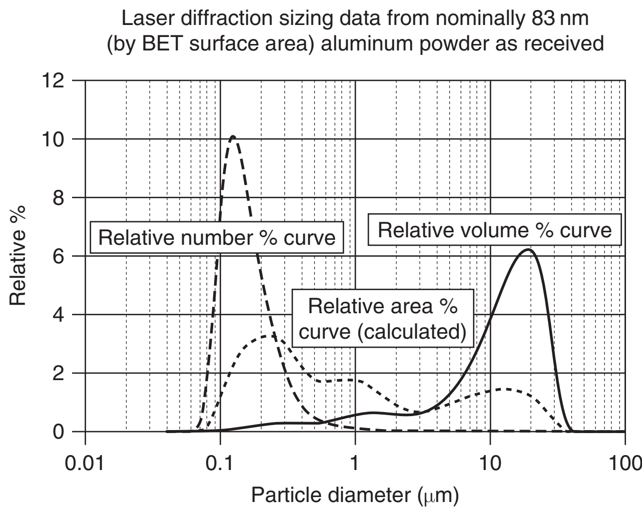

**FIGURE 12.1** Laser diffraction size data for "nanoscale" aluminum powder used for *in vitro* toxicity experiments. Note the apparent difference in size when depicted as a number distribution versus an area or volume distribution. This occurs because volume scales as the cube of the particle diameter and calculated area scales as the square. Each curve, if presented alone, would give an incomplete picture of the particle size distribution/state of agglomeration of the sample. The three curves will overlay only for an ideal spherical, monodisperse, unagglomerated system. By comparing changes in particle size distribution to that of an "ideal" dispersion, a qualitative assessment of the degree of agglomeration can be made (Reproduced with permission of Powers *et al*., 2006).

respiratory tracts is influenced by flow rate and Reynolds numbers (*Re*) (trachea 100 cm/sec at $Re = 700$; primary bronchi 130 cm/sec and $Re = 600$; narrowed primary bronchus 200 cm/sec and $Re = 550$). The expected sites of inertial impaction in birds are similar to those in mammals (Brown *et al*., 1997).

Slightly smaller particles (1–5 μm in diameter) deposit in the conducting airways – the trachea, bronchi, and bronchioles deposit by sedimentation. In the human lung, sedimentation is an important mechanism for deposition at sizes greater than 0.2 μm in diameter (Witschi and Last, 2001). In birds, deposition probability is a product of (residence time) × (aerodynamic diameter)$^2$. In parabronchi where flows are as low as 3 cm/s ($Re = 2$) and residence times may be up to 1 min for complete change of airsac volume at rest, deposition probabilities can be quite high (Brown *et al*., 1997). Diffusion, like sedimentation, is most important in the parabronchi and airsacs where residence time is long.

Particles <1 μm in aerodynamic diameter have a good probability to deposition by Brownian diffusion (Witschi and Last, 2001). The probability of diffusion increases with decreasing particle size, so that those particles whose aerodynamic diameter is less than 0.5 μm is largely by diffusion. Breathing pattern can be important. During exercise impaction of larger particles that acquire higher velocity, momentum and inertia at levels higher up the respiratory tract may occur. Alternatively, breath holding causes more deposition by gravitational sedimentation and diffusion. Brownian diffusion in birds is a function of (residence time ($t$)/spherical volume with the same diffusion displacement as the particle ($D_{te}$)). Diffusion, like sedimentation, is most important in the parabronchi and airsacs where residence time is long (Brown *et al*., 1997). The influence of greater numbers and volumes of ultra-fine particles has not as yet been defined, but it is expected that deposition in bird parabronchi may occur.

### *Particle clearance*

Particle clearance in mammals is important to the defense of the lung (Witschi and Last, 2001). Rapid clearance lessens exposure time and extent of injury. Clearance of intact particles depends heavily on pulmonary alveolar macrophages and the mucociliary escalator – mucus and movement by the cilia of epithelial cells of the upper airway. Particles can leave the lung and enter the vascular system, causing a risk to organs downstream from the lung (Nemmar *et al*., 2001; Kendall *et al*., 2002; Borm *et al*., 2006). Alternatively particles soluble in aqueous media can dissolved, especially small (fine and ultra-fine) particles. Ultra-fine (nano) particles with much of their mass in contact with the surface are especially subject to such dissolution. Factors affecting this solubility are quite complex; they include but are not limited to composition of the aqueous fluid, particle size, chemical particle composition, effect of curvature, steepness of concentration gradient, effect of agglomeration aspect ration (Nemmar *et al*., 2001; Kendall *et al*., 2002; Borm *et al*., 2006).

Bicarbonate in lung simulant fluid can influence solubility in particles moderately soluble in aqueous media. Solubility and chemical reactivity are thought to be a function of environment; they should be measured in an environment as near to that of the biological environment as possible. This can sometimes be accomplished with *in vitro* conditions closely simulating biological solutions (Powers *et al*., 2006). Solubility is thought to be a function of chemical activity, specific surface area, radius and curvature, agglomeration, and specific chemicals that are adsorbed to the nano-sized particles (NSP) (Borm *et al*., 2006). It is important to consider not just solubility in water, but also in fluids that bear significant resemblance to that of the epithelial lining fluid (ELF). ELF is the fluid that lines the epithelial cells in the respiratory tract. A minimal volume is predicted –40 to 100 ml for mature humans. pH varies from 6.9 at the end of inspiration to 7.5 at the end of expiration. Bicarbonate is a major buffer; the variation is caused by removing $CO_2$ from expiration (Langmuir, 1965). Bicarbonate concentration in lung simulant fluid increases the solubility of magnesium oxide (MgO) (Pickrell *et al*.,

2006). Stoichiometry of the likely chemical species suggests a conversion of MgO to magnesium hydroxide ($Mg(OH)_2$) in aqueous media and a subsequent conversion to the hydrated carbonate (nesquehonite; Langmuir, 1965; Pickrell *et al*., 2006).

In chickens, small amount of dust was found trapped in the respiratory epithelial cell trilaminar substance; that material was assumed to be a surfactant (Brown *et al*., 1997). No particles were found in the vascular system, kidneys, and heart, suggesting that at least this size particle does not leave the vascular system. After 1 h 54% of the particles remained, while after 36 h approximately 36% remained, suggesting that appreciable clearance took place. The mechanism of the clearance is not completely clear. However, parenchymal respiratory epithelial cells could have focused particles toward the pulmonary interstitium. Particles in the mammalian lung too small to be efficiently phagocytized were also focused into the lung's interstitium. In bird lungs, there was a virtual absence of phagocytes; the absence may have caused the epithelial cells to take a larger role. Following experimental introduction of Sephadex or Freund's adjuvant, phagocytes with physiological features similar to macrophages can enter the bird's pulmonary spaces. We do not as yet quite know what to make of the fact that they can survive in bird lung parenchymal spaces, but are not naturally found there. This raises the question, do macrophages appear in bird conducting airways and parenchyma only when needed, or do other cells perform this function?

Birds living in dusty environments – kiwis near the desert with abundant sand and poly-dispersed loose dust or birds living near or flying over volcanic ash – show significant pathology and signs after only short exposures. CAFO with poultry raised in high population densities often show reduced production and pathology at necropsy (Brown *et al*., 1997). It is not clear whether a lack of phagocytes or a delay in their introduction best correlates to heightened sensitivity of birds to small dust after relatively short exposures.

## ACUTE RESPONSES OF THE LUNG TO INJURY

### Airway reactivity

Mammalian airway reactivity is bounded by the large conducting airways surrounded by bronchial smooth musculature (BSM; Witschi and Last, 2001). BSM tone is balanced by the autonomic nervous system. Reflex contraction occurs after stimulation by irritants (air pollutants and second hand cigarette smoke – the major indoor air pollutant); bronchoconstriction can be provoked by cholinergic drugs. This stimulation is used in diagnosis as a basis to assess the "*twitchiness*" of BSM – at how low a level the bronchi can be induced to constrict. These agents bind to receptors and trigger increased intracellular cyclic monophosphates – adenosine and guanosine, respectively (cAMP and cGMP). Histamine, prostaglandins, nitric oxide, and leukotrienes also influence bronchoconstriction (Witschi and Last, 2001).

### Pulmonary edema

Pulmonary edema is exudative; it signals acute lung injury (Witschi and Last, 2001). Edema has leakage or interruption as well as thickening of the alveolar capillary membrane. Edema fluid creates a thicker diffusion barrier or causes a mismatch of ventilation to perfusion. The mismatch limits the rate of oxygen exchange from the air of the alveoli to the blood of the alveolar capillaries, even if the alveolar capillary unit is normal in all other ways.

Pulmonary edema is a less common complication in lower airway disease in the horse (Wilkins, 2003). Even something as innocent as hyperhydration prior to overexertion in horses in a field trial can cause arterial hypoxemia during the intense exercise phase was some degree of pulmonary edema, from the extravasation of the administered fluid. Hyperhydration prior to exercise may be detrimental to respiratory function (Sosa *et al*., 2002).

Fatal *Taxus* (Japanese yew) poisoning in horses led to pulmonary congestion, hemorrhage, and edema (Cope *et al*., 2004). Very high levels of fumonisin (>100 ppm in diet) caused fatal pulmonary edema in pigs 1–4 h after exposure (Marasas, 2001). A human took 3 times the dose of monensin (a sodium–potassium ionophore) that was fatal to cattle (Caldeira *et al*., 2001). Calves given *Nerium oleander* (Oleander) clippings developed tachycardia, pulmonary edema, and died suddenly (Galey *et al*., 1996). Dogs and cats with non-cardiogenic pulmonary edema resulting from airway obstruction were the most abnormal on radiograph; others with cranial trauma, seizures, or electric shock also had fatal pulmonary edema (Drobatz *et al*., 1995).

Even brief edema may compromise the alveolar capillary structure, damaging or denuding epithelium or endothelium or both (Witschi and Last, 2001). Frequently, very intense pulmonary edema will include some evidence of small pinpoint pulmonary hemorrhage. As an example, small Teflon particulates from frying pans overheated in the last 1–5 min often cause caged companion birds in the same room to die with pulmonary edema and hemorrhage (Brown *et al*., 1997). Laboratory rodents receiving very high doses of paraquat may die with pulmonary edema and hemorrhage.

Some toxic agents, such as alloxan which denude the alveolar capillary unit, reduce the likelihood of recovery (Witschi and Last, 2001). Such denuding may lead to significant collagen deposition (Pickrell and Villegas (1994), *Research Communication*). If the changes are intense and

architecture is severely compromised, less frequently pulmonary fibrosis may result. From some insults (histamine) an uneventful recovery may result. Several other insults (paraquat) cause sufficient injury to lead to healing by secondary intent (fibrosis) which depending on dose and intensity either fails to interrupt pulmonary architecture and is beneficial because it heals with only modest increases in collagen and little if any change in pulmonary function. Alternatively, with more severe injuries and edema, pulmonary architecture is interrupted, anatomic structure changed, increased total lung collagen causing more extensive and irreversible pulmonary fibrosis developed with detrimental consequences.

We determined the extent of pulmonary edema by relating lung wet weight to body weight (Witschi and Last, 2001). Since pulmonary edema may lead to weight loss in experimental animals, this ratio may slightly overestimate the extent of the edema, but is considered to be a useful indicator. Alternatively, lungs, lobes, or slices can be weighed before and after drying. The accuracy of the second procedure is limited by the uniformity of the edema, but again, this may be a useful indicator. Both of these methods have been compared to morphometric estimates under certain conditions.

Acute respiratory distress, particularly acute pulmonary edema, is treated with diuretics such as furosemide, intranasal oxygen, bronchodilators, corticosteroids, and alleviation of the underlying cause (Foreman, 1999). It is especially important to address the underlying cause in many of these conditions. Furosemide was formerly used in North America as a race-day preventative for EIPH. The difficulty with using furosemide as a preventive was that recent data have shown that furosemide may also be a performance-enhancing agent in addition to its therapeutic action.

## Mechanisms of respiratory tract injury

### *Nasal and upper airway reactivity*

Upper airway irritant gases such as formaldehyde will react differently with nasal epithelium in rats (Witschi and Last, 2001). Rats are much more heavily dependent on scent than are humans; they have more than 10-fold greater cross-sectional areas ($mm^2$) in their nasal epithelium than do humans. Thus, rats can attract much greater masses of formaldehyde in the water of their linings. Scent hounds have roughly the same area and capability, but exercise it intermittently, reducing the amount of water their linings can attract (Natural History, 2006). When this enhanced sensitivity is exercised, it warns and allows strategic shielding action such as tucking the nose under an armpit. Alternatively, identifying an odor allows considerable desensitization to it; the effect of the desensitization on strategic shielding action is continuing to be investigated.

Upper airway irritant gases and particulates, especially ultra-fine particulates with greatly increased surface area, stimulate nasal (trigeminal) nerve endings (Witschi and Last, 2001). These also elicit strategic avoidance reactions. The relation to the nasal cross-sectional area supplied by trigeminal nerve endings has not been defined. Phosphine ($PH_3$) is liberated after ingesting zinc phosphide rodenticide; $PH_3$ irritates nasal and upper airway nerve endings resulting in a different sort of strategic avoidance reaction in dogs, cats, or pigs consuming it. Breath holding and subsequent paroxysmal breathing are unusual enough strategies that they are of value in diagnosing exposure to zinc phosphide (Knight, 2006). Other agents, HCl, $NH_3$, $NO_2$, and phosgene ($COCl_2$), appear to bombard the epithelial barrier in lung for several hours and initiate leakage from the serum. Toxicity to either type I epithelial cells or endothelial cells or both is thought to play a role.

Highly reactive molecules cause their reactions in a different manner (Witschi and Last, 2001). It is unlikely that ozone can penetrate fluid layers to cause direct toxicity; it is more likely that reactive molecules initiate a cascade of ROS such as aldehydes and hydroperoxides. ROS are thought to be formed by ozonolysis of substances in the lung's ELF (e.g. lipids, fatty acids, and other chemical substrates). In addition, ROS have been implicated in oxygen, paraquat, bleomycin, and asbestos toxicities.

Metabolism of xenobiotics (substances foreign to the body) mostly reduces their toxicity; alternatively, in some instances they become more toxic, more carcinogenic, or are transformed into substances that can avoid further metabolism and cause harm to the respiratory tract (Witschi and Last, 2001). The lung contains most of the detoxifying P450 isoenzymes often at lower concentrations than in the rest of the body. These P450 isoenzymes are highly inducible. Activation of these enzymes is an initial defensive reaction which may heal the lung in the presence of relatively high amounts of antioxidants (Nel *et al.*, 2006). Although these isoenzymes are clearly activated after exposure, it is not clear whether the response is sufficiently linear to use them as a biomarker of the exposure. Cytochrome P450 2B1, the isoenzyme that metabolizes phenobarbital, is not inducible in lung. Glutathione-*S*-transferase and glutathione peroxidase are present in lung. In fact, the lung has been found to contain several forms of glutathione-*S*-transferase.

## Mediators of lung toxicity

Studies measuring releases of cytokines (tumor necrosis factor alpha (TNF$\alpha$ ), transforming growth factor B (TGF-B), and interleukin 1B (IL-1B)) in lavage fluid were used to guide the design of the culture whole lung tissue and of

specific lung cells (lung epithelial cells and fibroblasts) (Witschi and Last, 2001). These experiments were designed to elucidate the release of specific molecules signaling toxicant-induced lung damage. For example TNF$\alpha$ and IL-1B signaled acute lung injury. TGF-B and the cytokines signaling acute lung injury were both part of the pathogenesis of pulmonary fibrosis. IL 1, IL 2, IL 5, and IL 8 are thought to be essential components of epithelial lung cell injury. Finally, IL 4, IL 5, and IL 13 are thought to be associated with allergenic responses. Cytokines were thought to be so potent that they must be compartmentalized to control healthy lung responses.

### Cell proliferation

Toxicants can cause either reversible or irreversible changes in lung (Witschi and Last, 2001). Toxic changes that cause major alterations in lung architecture usually cause irreversible lung injury. Severe tissue injury is followed by either tissue loss (emphysema) or healing by secondary intent (fibrosis). We do not know how the lung repairs or attempts to repair itself in a post exposure period when animals inhale filtered air.

When type I lung epithelial cells are injured and die following exposure to an oxidant gas, or some toxicant that causes a high oxidant load, the type II lung epithelial cells associated with them proliferate, begin to flatten and stretch to cover the void left by the type I lung epithelial cell death. Clara cells proliferate following type II proliferation to fill the epithelial void left by type I cell death (Witschi and Last, 2001). Migration of blood monocytes across the alveolar capillary barrier may trigger responses from other cells in the parenchymal lung unit, e.g. interstitial fibroblasts, myofibroblasts, and endothelial cells. The lung may heal with a relatively normal appearance, a higher total lung collagen, and minimal if any alteration of pulmonary function (Witschi and Last, 2001).

## CHRONIC RESPONSES OF THE LUNG TO INJURY

### Fibrosis

Healing by secondary intent, often called pulmonary fibrosis, may be either reversible or irreversible depending on the degree of injury that is required to heal the lung. When lung injury is too high, intense, or persists too long to heal spontaneously e.g. with high levels of paraquat, fibroblasts will attempt to fill the role of lung epithelial cells. Specifically they will normally proliferate to fill the void caused by type I epithelial cell death. Fibroblast proliferation would be expected to impair gas exchange – ventilation and perfusion – making the lung less functional than would be expected by epithelial proliferation. In addition, there would be expected to be greater alteration of pulmonary architecture and increased numbers of interstitial fibroblasts. Increased fibroblasts making normal amounts of collagen would be expected to collectively make more collagen. If minimal to moderate alterations in pulmonary architecture are present the lung will spontaneously resolve (Pickrell *et al.*, 1983). If greater alterations have been made to pulmonary architecture in response to high levels of alveolar damage, the interstitial fibrosis may become irreversible and form dense fibrous scars. The lung becomes stiffer and its movement is restricted. While it is possible to produce fibrosis experimentally in laboratory rodents and dogs, there are few examples of models in nature that have been studied (Pickrell, 1991; Pickrell *et al.*, 1983; Witschi and Last, 2001).

There are at least 19 genetically distinct collagen types in animal and man. Collagen types I and III are major interstitial collagens in the lung. Type III collagen is more compliant than type I; thus, an increase in type I relative to type III which has been shown in experimental models of fibrosis caused by paraquat and asbestos would make a stiffer lung even more stiff than if only an increased amount of collagen was present and the ratios of type I to type III collagen were unchanged (Pickrell, 1991; Witschi and Last, 2001).

Fibrosis is associated with compensatory emphysema. This association illustrated that injury was often local and heterogeneous. If doses were sufficiently low, the lung healed normally. In an adjacent area where injury was somewhat higher fibroblast proliferation and the excess production of collagen resulted in fibrosis. In a still higher level of injury, even fibroblasts could not effectively fill the void and healing by secondary intent failed, cells died and lung tissue was lost, and emphysema was formed. Loss of an inability to produce the collagen needed to heal by secondary intent. We do not fully understand the extent to which this varied response is related to variations in local dose, the reserve of biological antioxidants, or the balance of proteinase–antiproteinase (Pickrell *et al.*, 1983; Pickrell *et al.*, 1987a, b; Pickrell, 1991).

### Emphysema

Emphysema has been defined as enlarged air space with tissue destruction (Witschi and Last, 2001). Loss of gas exchange membrane, specifically alveolar capillary membrane, causes a reduction in gas exchange area; as the alveoli collapse, air spaces become distended, irregular, and the possibility of trapping air increases. This makes it difficult to get enough air (sometimes called air hunger) and even more difficult to expel the air once the air is in the distended alveoli. In horses with emphysema from hay contamination or in humans with developing emphysema,

the patients become emaciated, have increasingly forced expirations and develop heave lines, signifying the difficult expirations (Lowell, 1990). *Nerium oleander* produced widespread congestion and hemorrhage as well as pulmonary emphysema. By the time death occurred at 3–14 days, liver and kidney pathology was most important (Ada *et al.*, 2001).

Some humans have alpha 1 antitrypsin deficiencies that shift the balance of proteinolysis to antiproteinase toward lung tissue digestion, loss of membranes (tissue damage) with distension (enlargement) of air spaces. We know of no natural model of alpha 1 antiproteinase deficiency. Mice with deficiencies in processing (modifying) collagen or elastin develop emphysema (O'Byrne and Postman cited in Witschi and Last, 2001). These data suggest that elastin synthesis may be important to the development of emphysema and that the elastase–antiproteinase model alone cannot explain the development of emphysema (Pickrell *et al.*, 1987a; Witschi and Last, 2001).

In experimental elastase-induced emphysema, instillation of fibroblast growth factor 2 (or injection by microsphere) restored vascularity to lung and caused it to attain normal physiological function (Morino *et al.*, 2005).

## Asthma

In asthma, small conducting airways can be made to constrict at lower irritant concentrations than in normal lungs (Witschi and Last, 2001). Bronchoconstriction reduces airway diameter with a reciprocal increase in small airway resistance. Persisting increased resistance allows our patients to speak to us with symptoms of persistent cough, wheeze, and progressive dyspnea. Irritant gases with moderate solubility also provoke these symptoms.

Guinea pigs are believed to be a natural animal model of human bronchial asthma. Stated alternatively, guinea pigs are perhaps the most sensitive of the species to upper airway irritation and to subsequent development of bronchial asthma. In addition, horses, dogs, and cats develop symptoms like those of asthma (Padrid, 2000; Davis and Rush, 2002; McCue *et al.*, 2003; Pirie *et al.*, 2003; Reinero *et al.*, 2006). Diagnostic approaches are being standardized (Padrid, 2000). Inhaled endotoxin and organic dust particulates were synergistically related to heaves in horses (Pirie *et al.*, 2003).

Potentially detrimental effects of airborne endotoxins on the welfare and exercise performance of stabled horses can be reduced by maintaining horses in "low dust" stables or at pasture, since these environments had significantly lower airborne dust and endotoxin (McGorum *et al.*, 1998). Specific allergen immunotherapy is a potential cure for allergy. No studies have evaluated its efficacy in feline allergic asthma (Reinero *et al.*, 2006). Reinero demonstrated that Rush Immunotherapy (RIT) blunted eosinophilic airway inflammation in experimental feline asthma. British anti-lewisite (BAL) cytokine profiles favoring a Th2 response developed after giving Bermuda grass antigen. RIT shifted the response to increased IFN-g and IL-10 thereafter. The mechanism of RIT may involve changes in allergen-specific immunoglobulins, induction of hyporesponsive lymphocytes, or alteration of cytokine profiles.

Bird fancier's disease is a hypersensitivity pneumonitis in the caretakers of companion birds; care must be taken to differentiate this from aspergillus exposure or from exposure to a humidifier containing mold in its water (Zacharisen and Schoenwetter, 2005). Animal poultry farmers had significantly higher incidences of chronic bronchitis (Radon *et al.*, 2002). The major risk factor for respiratory symptoms was shown to be the adequacy of ventilation of the animal houses; intervention studies are testing the effectiveness of improved ventilation on caretaker respiratory health. Airborne endotoxin can cause flu-like symptoms in birds; this condition must be differentiated from infectious avian influenza, a potential pandemic (Joseph and Subbarao, 2005).

## Lung cancer

Lung cancer was an extremely rare disease in humans at the beginning of the 20th century. In laboratory animals, spontaneously occurring malignant pulmonary tumors are rare, except for very old animals. If lung tumors do develop in laboratory rodents, they are generally peripheral adenomas instead of the more central tumors seen in humans. Adenomas usually originate from type II pulmonary epithelial cells or Clara cells. These adenomas rarely have sufficient time to develop into carcinomas. Occasionally a different kind of injury causes bronchogenic adenocarcinoma that is an unusual lung tumor in cats; it has metastasized to the digits and to the abdominal wall. Average survival time for tumors metastasizing to the digits is only ~5 weeks (van der Linde-Sippman and van den Ingh, 2000; Petterino *et al.*, 2005).

Certain mouse strains (strain A and Swiss-Webster mice) with mutations in the K-ras genes similar to human carcinomas develop adenomas that increase in incidence after the inhalation of some inhalation toxicants or carcinogens. These mice are being studied to see how close they model the pathogenesis of human lung carcinogenesis (Witschi and Last, 2001).

Rat lungs occasionally contain lesions of epithelial cells surrounding material identified as keratin (Witschi and Last, 2001). The cells may compress lung parenchyma and occasionally invade it. These lesions are found more frequently in long term tests of animals exposed to substances not considered to be carcinogens such as carbon black, titanium dioxide, and certain man-made fibers. Controversy exists as to whether these are cysts filled with keratin or can be classified as tumors.

In humans, it has been estimated that 80–90% of all lung tumors are caused by inhaling cigarette smoke (Witschi and Last, 2001). Dogs are companion animals that live with their owners over long periods of time. The most frequent tumors in dogs are mammary tumors which may metastasize to the lung. Spontaneous lung tumors in companion animals such as dogs are less frequent. Although infrequent, some dogs developed either nasal or lung tumors, after being exposed to owner's second hand cigarette smoke (Reif *et al.*, 1992). In both cases, the tumors were carcinomas – epithelial in origin and malignant. Dogs with long noses (dolocephalic breeds) tended to deposit the tumor causing (carcinogenic) particles in the nasal cavity and develop nasal carcinomas. Alternatively dogs with shorter noses (brachycephalic breeds) tended to allow the cigarette smoke particles to deposit in the upper airways and develop bronchogenic carcinomas.

# AGENTS KNOWN TO PRODUCE LUNG INJURY IN ANIMALS

## Airborne agents that produce lung injury in animals

### *Urea*

When a flock of goats consumed 4.2% urea, 18 of 54 goats showed acute respiratory embarrassment and sounds suggestive of pulmonary edema from $NH_3$ toxicosis (Ortolani *et al.*, 2000). Ten goats died within 1 h; while five with convulsions recovered when given vinegar and saline, diuretics, and atropine. Three goats with mild signs recovered spontaneously within 1 h without treatment. Generalized congestion, intense pulmonary edema, and slight tubular nephrosis were found in three surviving goats at necropsy. No more cases occurred when the diet was removed. Approximately 200 chickens inadvertently given zinc phosphide were found dead with no clinical signs after the flooring of a slat-and-litter house was breached (Tiwary *et al.*, 2005). Gross necropsy revealed intense congestion of the viscera; histopathologic examination revealed severe pulmonary edema and congestion of the chickens' lungs, hearts, livers, and kidneys.

### *Smoke*

Cardiac dysfunction after the combined burn and smoke injury in sheep had an initial depression was mostly related to hypovolemia from burns; this was improved by a large amount of fluid resuscitation. The later myocardial contractile dysfunction seemed to be correlated with smoke inhalation injury (Soejima *et al.*, 2001). In normal (control) chickens, the adjacent parabronchi were separated by a minimal septal space (Weidner and Kinnison, 2002). Comparatively, in "volume-loaded" birds, the inter-parabronchial septal spaces were measurably thickened and engorged as a result of hydrostatic pulmonary edema, similar to the effect of hydrostatic pulmonary edema in mammals. Under similar conditions, airsacs thickened; microvilli had increased density (Weidner, 2000).

Environmental tobacco smoke (ETS) from the burning of tobacco indoors can cause a health hazard for companion animals; because its aerosol can contain more than 4000 toxicants into the airway (Sullivan *et al.*, 2006). Some of them are carcinogens; the EPA has classified ETS a group A carcinogen, meaning that there is sufficient evidence to indicate that it will produce cancer in humans.

Inhaled cigarette smoke often did not cause significant increases in numbers of malignant respiratory tumors in rats, mice, hamsters, dogs, or non-human primates even when experimentally exposed for long periods of time to very high concentrations of mainstream cigarette smoke. The results are different from the epidemiological evidence in human smokers. It is difficult to reconcile this major difference between observational studies in humans and controlled laboratory studies.

Dogs living for protracted periods of time in a home with a smoker tended to get more lung cancer than those in homes of non-smokers (odds ratio: 1.6, 95% confidence interval: 0.7–3.7). No relation to increasing the number of packs of cigarettes smoked per day or the proportion of time the dog spent within the home was found. However, dog breeds with short and medium length noses had an increased tendency to get lung cancer (odds ratio: 2.4, 95% confidence interval: 0.7–7.8). Dogs living for protracted periods of time in the homes of owners that smoke have a greater chance of getting lung cancer (Reif *et al.*, 1992).

### *Naphthalene*

Naphthalene, a miscellaneous indoor toxicant, occurs in tars, petroleum, tanning preparations, and mothballs (Witschi and Last, 2001; Oehme and Kore, 2006). It is also released in cigarette smoke and from termites parasitizing houses. The lowest canine lethal dose is 400 mg/kg, but cats are more sensitive. Mothballs weigh near 2.7 or 4 g. Exposed animals have naphthalene scented breath, methemoglobinemia, Heinz body anemia, red blood cell lysis, hepatic injury, and possible nephrosis from red blood cell debris. Dogs and cats can be treated with emesis and if needed charcoal. Dogs can be given 4 mg and cats one dose of 1.5 mg of 1% methylene blue. Intravenous bicarbonate containing saline will help reduce hemoglobin or possibly cell debris precipitation in kidney tubules. Other causes of hemolysis in small animals include zinc (from pennies), onion and copper poisoning, and rattlesnake bites. Prognosis is good if no liver or kidney damage can be detected (Oehme and Kore, 2006; Talcott, 2006).

### *Overheated frying pans*

Exposure of caged birds in the room with overheated cookware has been shown to result in a high percentage of deaths (Brown *et al.*, 1997). Most of these birds have pulmonary edema and hemorrhages. Birds in adjacent rooms, even at the same level of mass exposure have only minimal pulmonary reactions. The mechanism of these reactions is not known at this time. Best guesses suggest that the overheating may imbue unique surface characteristics to the teflon or polytetrafluoroethylene aerosols. Alternatively, aerosols in the same room are less than 25 nm in diameter, where those in adjacent rooms are nearly 100 nm in diameter. Thus, birds in the same room would be exposed to >10-fold more surface areas per unit mass than those in adjacent rooms. Additionally, concentrations would be expected to reduce with diffusion to adjacent rooms. Finally, surface characteristics of the teflon particles would change.

### *Tryptophan–3 methyl indole: perilla mint*

Tryptophan toxicity is associated with cattle consuming tryptophan in lush green forages *per os* (Pickrell and Oehme, 2004). The rumen converts tryptophan to 3 MI which is metabolically activated by cytochrome P450 to a reactive compound that is concentrated in the lung and is pneumotoxic. Perilla ketone and 4-ipomeanol from Perilla frutescens damage endothelial cells and type I pulmonary epithelium (Nicholson, 2004; Pickrell and Oehme, 2004).

At high doses, 3 MI leads to pulmonary edema, emphysema, and death within 6–24 h after the onset of clinical signs (Pickrell and Oehme, 2004). Several pounds of green forage containing 4-ipomeanol may be fatal to a cow within 1–2 days (Nicholson, 2004). At lower exposure levels, animals may have respiratory signs (depression, respiratory grunt, wheeze, and froth flowing out of the nostrils), but will recover over 24–72 h. These animals will recover in 24–72 h which have minimal to no physiological impairment. However, proliferation of type II alveolar cells may persist with no demonstrable physiological consequences, if they die of other causes. If exercised, cattle with intermediate signs can be pushed into the acute syndrome; they will worsen rapidly, develop significant lung edema, and die (Kerr LE cited in Pickrell and Oehme, 2004).

## ACKNOWLEDGMENTS

The author would like to thank Dr. Larry Erickson, Chemical Engineering Kansas State University, for his support in this effort and Dr. Frederick W. Oehme Comparative Toxicology Laboratories, Department of Diagnostic Medicine/Pathobiology, Kansas State University, for his support and for critically reading the manuscript.

# Cardiovascular toxicity

*Steven I. Baskin, Steven E. Czerwinski, Jaime B. Anderson, and Manu M. Sebastian*

## INTRODUCTION

Drugs, chemicals, or plants can produce toxic effects on the whole animal as well as on the heart. Twenty chemicals and drugs were selected to show that there is no specific uniform toxicity effect across animal species. It is noted from the graphics displayed (Figures 13.1–13.3) that there does not appear to be one species that is more or less sensitive to drugs or chemicals overall. It is recognized that certain chemicals are much more or

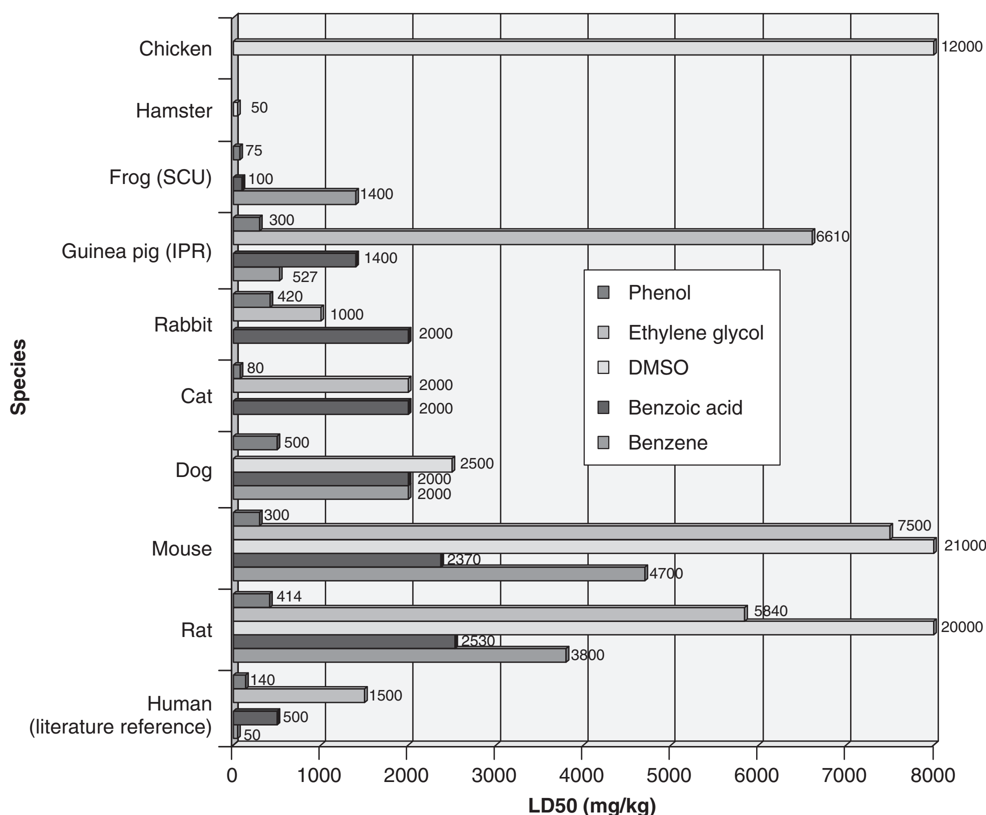

**FIGURE 13.1** Toxic effects of selected organic chemicals.

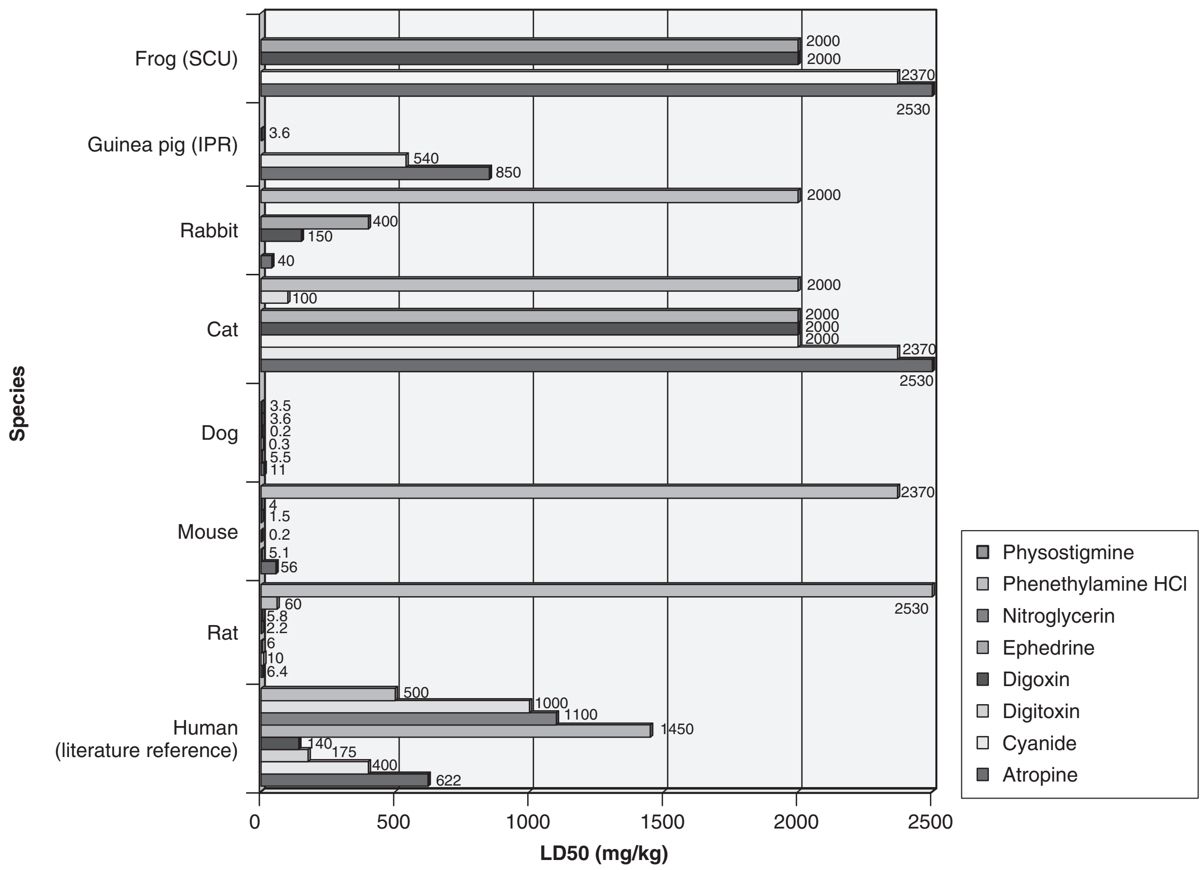

**FIGURE 13.2** Toxic effects of selected drugs.

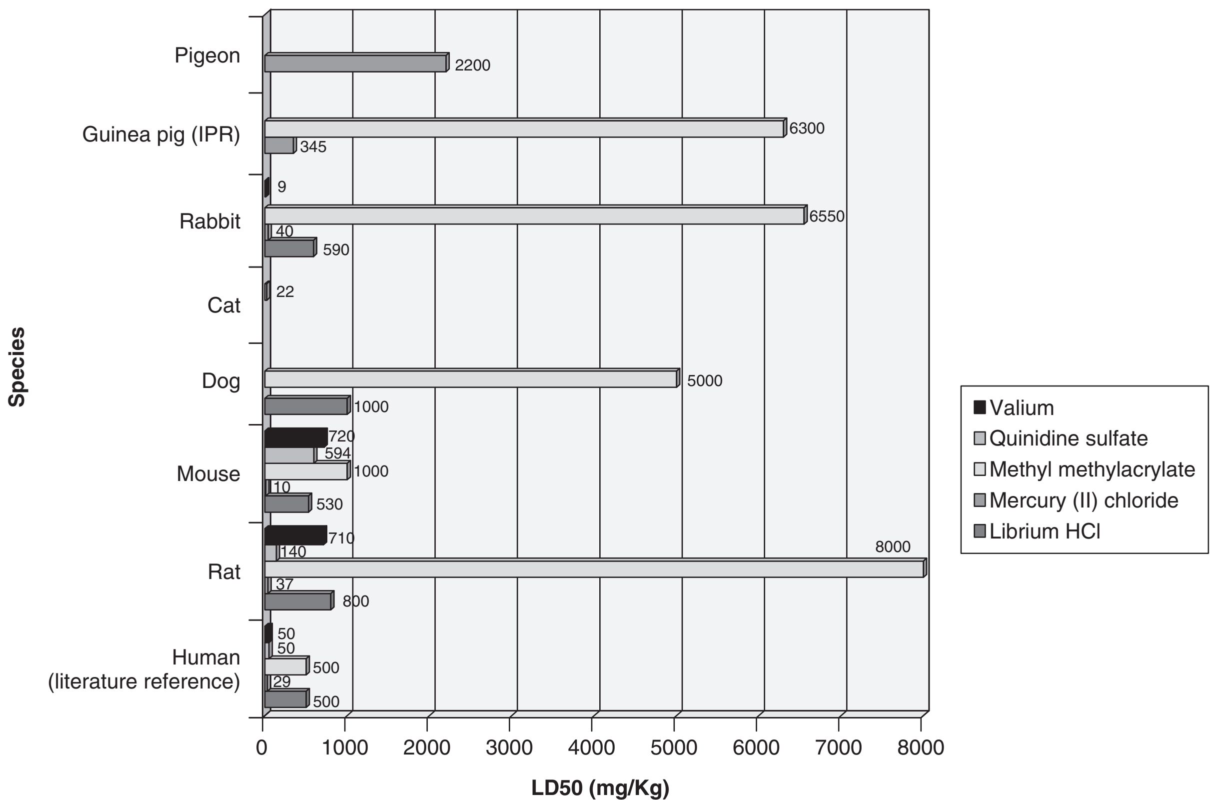

**FIGURE 13.3** Toxic effects of selected chemicals.

less toxic than others because of their inherent mechanism. Botulinum toxin, for example, is toxic because it interacts with specific protein receptors in the body. Some of the drugs that are recognized as antidotes for toxic chemicals are in and of themselves toxic. For example, *physostigmine* (Figure 13.2) (which protects against anticholinesterase agents) and *Valium*® (Figure 13.3) (both of which has anti-arrhythmic and anti-convulsant properties versus a variety of agents) also display a varied toxicity pattern across species.

## TOXIC PLANTS AFFECTING THE CARDIAC SYSTEM

Over the course of time, animals learn that certain plants should be avoided because they can induce unwanted toxic effects (Table 13.1), as in the learned experience from ingesting the bitter monarch butterfly which contains cyanogenic glycosides. Alternately, it has been proposed that certain animals will selectively graze a particular plant specifically for its medicinal effects. Many toxic plants are relatively palatable and may be the only green plants available in the pasture during certain times of the year. Toxic plants may also be hidden within hay and inadvertently fed to the livestock.

The toxicity of plants may be derived from their alkaloid compounds, proteins and amino acids (enzymes, glycoproteins), glycosides, oxalates, resins, tannins, and phenol compounds. Most plant toxins affecting the heart fall into the alkaloid and glycoside groups.

An alkaloid is a nitrogen base containing organic compound that has a pharmacologic effect in animals and humans. The alkaloid groups are now normally classified based on their common precursors if known. Historically, they have been grouped under the names of similar known compounds or by the plants or animals from which they were isolated. The toxic alkaloid compounds derived from plants usually form heterocyclic rings and generally affect the passage of ions across membranes leading to various disturbances in cardiac arrhythmia. Toxic alkaloid compounds are present in 0.0001–10% of all plants, and in general fairly evenly distributed within the plant with variable total concentrations depending on stage of growth and maturity. The alkaloid compounds present a bitter taste and so are not selectively grazed unless other more palatable forage is unavailable. Some of the alkaloids that exert an affect on the cardiovascular (CV) system are polycyclic diterpene alkaloids, steroidal alkaloids, glycoalkaloids, and alkaloid-like compounds such as tryptamine alkaloids and tropane alkaloids. Common plants containing alkaloid toxins include Larkspurs, Monkshood, Yew, Ground hemlock, and Death Camas.

A glycoside is any molecule in which a sugar group is bonded through its anomeric carbon to another group via an *o*-glycosidic bond or an *s*-glycosidic bond. Cardioglycosides exert their pharmacologic effects by inhibiting the ATPase activity of a complex of transmembrane proteins that form the sodium–potassium ATPase pump ($Na^+/K^+$-ATPase). Inhibition of the $Na^+/K^+$-ATPase in turn causes a rise not only in intracellular $Na^+$, but also in calcium, which in turn results in increased force of myocardial muscle contractions which is an indicated treatment for heart failure. However, these cardiac glycosides have steep dose–response curves; therefore minute increases in the dosage can be fatal. Table 13.1 shows a listing of some plants that contain cardiac glycosides. Cardiac glycosides produce positive ionotropy and cardiac arrhythmias by inhibition of the $Na^+/K^+$-ATPase of the heart. Table 13.1 shows milkweed, avocado, digitalis, oleander, and lily of the valley but there are many other plants containing cardiac glycosides. Cardiac glycosides from various plants show different lipophilic properties and different affinity for the $Na^+/K^+$-ATPase (Sodium Pump). There is a direct relationship across animals between inhibition of $Na^+/K^+$-ATPase and positive ionotropy (Akera *et al.*, 1973). The animals ingesting the different cardiac glycosides may present with various degrees of a rapid and weak pulse resulting from arrhythmias and ventricular fibrillations. There are differences between members of the same genus but different species could have different cardiac glycosides that have different toxic effects and time course for different animal species (i.e. Digitalis purpurea). For toxicity of digitalis, digibind is used but to act effectively against other cardiac glycosides digibind is much less effective because of its specificity.

Asclepias syriaca (courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

**TABLE 13.1 Plants affecting the heart**

| Name | Common name | Animals typically effected | Clinical signs | MOA |
|---|---|---|---|---|
| *Asclepias* spp. | Milkweeds | Grazing animals (cattle, sheep, horse) | Trembling, staggering, pulse rapid and weak, dyspnea, salivation, bloating, mydriasis, respiratory depression, and death | Interfere with the $Na^+/K^+$-ATPase enzyme in cardiac fibers resulting in decreased intracellular $K^+$ and increased intracellular $Na^+$ causing various degrees of heart block. |
| *Persea americana* | Avocado | Grazing animals and birds | Nonspecific in pet birds, reduced activity, failure to perch, fluffed feathers, and dyspnea, death 24–48 h post exposure, | Interfere with the $Na^+/K^+$-ATPase enzyme in cardiac fibers resulting in decreased intracellular $K^+$ and increased intracellular $Na^+$ causing various degrees of heart block. |
| *Digitalis purpurea* | Foxglove | Grazing animals | Trembling, staggering, rapid weak pulse, dyspnea, salivation, bloating, mydriasis, respiratory depression, and death | Interfere with the $Na^+/K^+$-ATPase enzyme in cardiac fibers resulting in decreased intracellular $K^+$ and increased intracellular $Na^+$ causing various degrees of heart block. |
| *Convallaria majalis* | Lily of the valley | Grazing animals, pets | Vomiting, diarrhea, nausea, anorexia, abdominal cramps, delayed onset of cardiac signs for days; persistent intoxication for up to 3 weeks; paces and ventricular tachycardia may occur. Large doses cause mental confusion, weakness, depression, CV collapse, and death | Interfere with the $Na^+/K^+$-ATPase enzyme in cardiac fibers resulting in decreased intracellular $K^+$ and increased intracellular $Na^+$ causing various degrees of heart block. |
| *Apocynum* spp. | Dogbane, Indian hemp | Grazing animals | Either tachy- or bradycardia, fever, cold extremities, mydriasis, GI upset, and death | Interfere with the $Na^+/K^+$-ATPase enzyme in cardiac fibers resulting in decreased intracellular $K^+$ and increased intracellular $Na^+$ causing various degrees of heart block. |
| *Nerium* spp. | Oleander | Grazing animals | Onset 1–24 h after ingestion. Vomiting, diarrhea (diarrhea may be bloody), trembling, ataxia, weakness, cold extremities, dyspnea, paralysis, coma, and death | Interfere with the $Na^+/K^+$-ATPase enzyme in cardiac fibers resulting in decreased intracellular $K^+$ and increased intracellular $Na^+$ causing various degrees of heart block. |
| *Delphinium* spp. | Larkspurs | Grazing animals | Sudden death, especially in cattle, nervousness, staggering, falling, salivation, tremors, bloating, vomiting, abdominal pain, irregular tachycardia, respiratory paralysis, and death | Methyllycaconitine functions as a potent NM blocking agent. |
| *Aconitum* spp. | Monkshood | Grazing animals | CV disturbance including hypotension, myocardial depression, superventricular tachycardia, conduction disturbances, CNS involvement; oral irritation, nausea, dizziness, severe vomiting, diarrhea, slow/weak heartbeat, weakness, salivation, dyspnea; bloating, prostration, blenching, frothy salivation, convulsions, and death | Methyllycaconitine functions as a potent NM blocking agent. |

TABLE 13.1 (Continued)

| Name | Common name | Animals typically effected | Clinical signs | MOA |
|---|---|---|---|---|
| *Rhododendron* spp. | Azalea and rhododendron | Cattle, sheep, goats. rarely horses | Onset within 6 h of acute digestive upset, salivation, epiphora, anorexia, depression, projectile vomiting, frequent defecation; weak, ataxias, paralysis of limbs, stupor, depression of CV, CNS depression; aspiration of vomitus common in ruminants; coma, death; survival >2 days may recover | MOA similar to cardioglycoside |
| *Kalmia* spp. | Lambkill, calfkill, laurel | Grazing animals | Onset 3–14 h post ingestion, weakness, abdominal pain, salivation, epiphora, vomiting; dyspnea, bradycardia, depression, prostration; convulsions, paralysis of limbs, coma, and death within 12–14 h of onset | MOA similar to cardioglycoside |
| *Taxus* spp. | Yew | Grazing animals | Onset 1–48 h post ingestion; trembling, dyspnea, incoordination, collapse, bradycardia followed by acute cardiac failure; sub-acute meningitis, diarrhea | Inhibit conduction of depolarization through the myocardium and GI irritant |
| *Veratrum* spp. | Hellebore, Skunk cabbage | Grazing animals | Sheep: acute intoxication, onset 2–3 h post ingestion (200–400 g of stems or leaves), hypersalivation, ataxia progressing to paresis, rapid/irregular heartbeat progressing to bradycardia, dyspnea, emesis, diarrhea, diuresis, and death | Increased activity from pressor receptors inhibiting sympathetic outflow and augments vagal influence resulting in hypotension and bradycardia. Veratrum extracts are potent ruminatorics, emetics, and cause hypotension, bradycardia, increased peristalsis and hypercalcemia. Inhibition of mitosis at the neural plate development stage in embryogenesis |
| *Zygadenus* spp. | Death camas | Grazing animals | Onset 1.5–8 h post ingestion, salivation, hyperpnea, tremors, vomiting, sub-normal temperature, weak/irregular pulse, dyspnea, cyanosis, collapse, coma, and death (high mortality) | MOA similar to nonteratogenic effects of veratrum |

MOA: mode of action. *Source*: Casteel (1989).

**Asclepias** species (milkweeds) is a perennial herb 1–3-ft tall with milky sap that is classified in the subfamily Asclepiadaceae of the dogbane family Apocynaceae. There are over 140 broad and narrow leaf varieties. Most of these species occur in the United States. The plant contains cardiac glycosides that are most concentrated in the roots and shoots. Grazing animals (cattle, sheep, goats, and horse) are susceptible to intoxication. The plant is not very palatable but may be grazed during drought and retains toxicity in dried form such as in hay. Clinical signs of intoxication include trembling, staggering, rapid weak pulse, dyspnea, salivation, bloating, mydriasis, respiratory depression, and possibly death. Treatments consist of activated charcoal lavage followed by saline cathartic. Seizures are controlled symptomatically.

*Persea americana* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

***Persea americana*** (Avocado) is a tree native to Central America and Mexico and is grown commercially in the United States. It is classified in the flowering plant family, Lauraceae. The avocado toxin is lethal in pet birds (canaries, budgerigars, and cockatiels) with death occurring 24–48 h post ingestion preceded by clinical signs of reduced activity, failure to perch, fluffed feathers, and dyspnea. Nonseptic mastitis can be induced in cattle, horses, sheep, goats, and rabbits. Large doses may be lethal in goats. The toxin occurs in the fruit, bark, leaves, and seeds. However, the most likely circumstance of poisoning is the owner supplementing their pet bird's fruit and vegetable diet with avocado fruit. Cardiotoxic lesions in pet birds include hydropericardium with subcutaneous edema, and generalized congestion.

***Digitalis purpurea*** (Foxglove) is an herbaceous biennial flowering plant in the family Plantaginaceae that is originally native to most of Europe but has since become a common garden plant and now can be found throughout the United States. The leaves, flowers, and seeds of this plant are poisonous to humans and some animals and can be fatal if eaten due to the presence of the cardiac glycoside digitoxin, digoxin, and others. Dogs, cats, rabbits, and livestock are susceptible to intoxication. The plant retains toxicity in a dried form. Treatments consist of activated charcoal lavage followed by administration of a cathartic. Seizures are controlled symptomatically. Attention should be given to insure the animal maintains an adequate hydration status.

***Delphinium spp.*** (Larkspurs) is a genus of about 250 species of annual, biennial, or perennial flowering plants in the buttercup family Ranunculaceae, native throughout the Northern Hemisphere and also on the high mountains of tropical Africa. Many species are cultivated as

*Digitalis purpurea* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

*Delphinium elatum* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

garden plants. All parts of the plant contain polycyclic diterpene alkaloids such as delphinidin and methyllycaconitine which are potent neuromuscular (NM) blocking agents. Clinical signs may vary from sudden death, especially in cattle to nervousness, staggering, falling, salivation, tremors, bloating, vomiting, abdominal pain, irregular tachycardia, respiratory paralysis culminating in death. Treatment consists of administering an activated charcoal and magnesium sulfate lavage. Treat cardiac signs as a cardioglycoside intoxication. Treat NM blocking effects with physostigmine.

*Aconitum variegatum* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

**Aconitum spp.** (Monkshood) is a genus of flowering plant belonging to the buttercup family (Ranunculaceae). There are over 250 species of *Aconitum*, commonly known as aconite, monkshood, or wolfsbane. These herbaceous perennials are chiefly natives of the mountainous parts of the Northern Hemisphere. Many species of *Aconitum* are cultivated in gardens. All parts of the plant are toxic but especially the roots and seeds which contain polycyclic diterpene alkaloids such as aconitine, acinine, and others. Clinical signs consist of gastrointesinal (GI) upset, CV disturbance (to include: hypotension, myocardial depression, superventricular tachycardia, and conduction disturbances), central nervous system (CNS) involvement; oral irritation, nausea, dizziness, severe vomiting, diarrhea, slow/weak heartbeat, weakness, salivation, dyspnea; bloating, prostration, blenching, frothy salivation, convulsions, and death. Treatment is symptomatic which consist of activated charcoal lavage followed by administration of a cathartic.

***Taxus* spp.** (Yew) is a genus of yews, small coniferous trees or shrubs, the yew family Taxaceae. All species of

*Taxus baccata* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

yew contain the highly poisonous alkaloid taxine, with some variation in the exact formula of the alkaloid between the species. All parts of the tree except the arils contain the alkaloid. The arils are edible and sweet, but the seed is dangerously poisonous; unlike birds, the human stomach can break down the seed coat and release the taxine into the body. This can have fatal results if yew "berries" are eaten without removing the seeds first. Grazing animals, particularly cattle and horses, are sometimes found dead near yew trees after eating the leaves. Deer are able to break down the poisons and will eat yew foliage freely. Clinical signs occur 1–48 h post ingestion and consist of: trembling, dyspnea, incoordination, collapse, bradycardia followed by acute cardiac failure; subacute meningitis and diarrhea potentially culminating in death. Treatment is symptomatic which consist of activated charcoal lavage followed by administration of a cathartic.

*Helleborus niger* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

***Veratrum spp.*** (Hellebore, Skunk Cabbage) is a genus of 15 species of herbaceous perennial flowering plants in the family Ranunculaceae. Hellebores are widely grown in gardens for decorative purposes. Clinical signs in sheep occur 2–3 h post ingestion and consist of: hypersalivation, ataxia progressing to paresis, rapid/irregular heartbeat progressing to bradycardia, dyspnea, emesis, diarrhea, diuresis, and death. Treatment is symptomatic which consist of activated charcoal lavage followed by administration of a cathartic.

*Zgadenus fremontii* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

***Zygadenus spp.*** (Death Camas, Star Lily) is a genus of flowering plant, the family Melanthiaceae. Death Camases are perennial plants growing from a bulb or rhizome. Members of the genus are found in North America and Asia. All members of the genus are unpalatable to livestock. As the name Death Camas suggests, some are seriously toxic to both animals and humans. Clinical signs occur 1.5–8 h post ingestion and consist of: salivation, hyperpnea, tremors, vomiting, sub-normal temperature, weak/irregular pulse, dyspnea, cyanosis, collapse, coma, and death (high mortality). Treatment is symptomatic which consist of activated charcoal lavage followed by administration of a cathartic.

***Convallaria majalis*** (Lily of the Valley) is native throughout the temperate Northern Hemisphere in Asia, Europe and North America. It is the sole member of the genus

*Convallaria majalis* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

*Convallaria* in the flowering plant family Rosaceae. It is a popular garden plant. The leaves and flowers contain cardiac glycosides that have been used in medicine for centuries. All livestock, pets, and humans are susceptible. Clinical signs consist of vomiting and diarrhea, nausea, anorexia, abdominal cramps; onset of cardiac signs may be delayed. Heart condition progresses to hyperirritability with premature ventricular complexes (PVCs) and ventricular tachycardia. Large doses cause mental confusion, weakness, depression, CV collapse, end death. Treatment is symptomatic which consists of activated charcoal lavage followed by administration of a cathartic.

*Apocynum cannabinum* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

***Apocynum*** (Dogbane and Indian Hemp) is a genus in the Apocynaceae family. The genus occurs throughout most of the temperate Northern Hemisphere, except for Western Europe. It is a perennial plant 1–5-ft tall with milky sap. Cattle, sheep, and horses are susceptible. The plant retains its toxicity in dry form. Clinical signs consist of GI upset, CV disturbance including hypotension, myocardial depression, supraventricular tachycardia, conduction disturbances, CNS involvement, oral irritation, nausea, dizziness, severe vomiting, diarrhea, slow/weak heartbeat, weakness, salivation, dyspnea, bloating, prostration, blenching, frothy salivation, convulsions, and death. Treatment is symptomatic which consists of activated charcoal lavage followed by administration of a cathartic.

*Nerium oleander* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

***Nerium oleander*** (Oleander) is an evergreen shrub or small tree from 5 to 25-ft tall containing gummy sticky sap in the dogbane family Apocynaceae. It flowers in the spring or summer with white, pink, yellow, or red large clusters. All parts of the plant are toxic. Toxicity is retained in dried form. Clinical signs are seen 1–24 h after ingestion with vomiting and diarrhea (diarrhea may be bloody), trembling, ataxia, weakness, cold extremities, dyspnea, paralysis, coma, and death. Treatment is symptomatic which consists of activated charcoal lavage followed by administration of a cathartic. Attention should be given to insure the animal maintains an adequate hydration status.

***Rhododendron spp.*** (Azalea and Rhododendron) is a genus of flowering plants in the family Ericaceae. It is a large genus with over 600 species. They may be either evergreen or deciduous, and most have flower displays.

*Rhododendron ponticum* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

It includes the plants known to gardeners as azalea. Rhododendron is a very widely distributed genus, but a major concentration of diversity occurs in Asia. Several species also occur in North America and a few in Europe, and some tropical species occur as far south as Borneo and New Guinea. Many Rhododendrons have a toxin called grayanotoxin in their pollen and nectar. People have been known to become ill from eating honey made by bees feeding on rhododendron and azalea flowers. Clinical signs consist of onset within 6 h of acute digestive upset, salivation, epiphora, anorexia, depression, projectile vomiting, frequent defecation; weak, ataxias, paralysis of limbs, stupor, depression of CV, CNS depression; aspiration of vomitus common in ruminants; coma, and death; animals that survive more than 2 days may recover. Treatment is symptomatic which consists of activated charcoal lavage followed by administration of a cathartic.

*Kalmia angustifolia* (Courtesy of Wikipedia.com). This figure is reproduced in color in the color plate section.

***Kalmia spp.*** (Lambkill, Calfkill, Laurel) is a genus of about seven species of evergreen shrubs in the family Ericaceae. They are native to North America (mainly in the eastern half of the continent) and Cuba. Kalmias are popular garden shrubs, grown for their decorative flowers. The foliage is toxic if eaten, with sheep being particularly prone to poisoning, hence the name "lambkill" used for some of the species. Clinical signs occur 3–14 h post ingestion and consist of: weakness, abdominal pain, salivation, epiphora, vomiting; dyspnea, bradycardia, depression, prostration; convulsions, paralysis of limbs, coma, death within 12–14 h of onset. Treatment is symptomatic which consists of activated charcoal lavage followed by administration of a cathartic.

## PESTICIDES AND ECONOMIC POISONS AFFECTING THE CARDIAC SYSTEM

Organophosphates are used on crops and weeds all over the world. Their use provides many financial positives and negatives. Their uses allow for greater abundance of crops as well as more beautiful lawns and gardens. It is known that organophosphates can accumulate in animals and man, and can produce cardiac arrhythmias that can lead to death. The commercial organophosphates can produce atrial and/or ventricular arrhythmias which is dose dependent. The mechanism of action is the inhibition of acetylcholinesterase (AChE). The result is an increase in acetylcholine (ACh) which can depolarize the cells of the heart. It is believed one of the more sensitive areas affected is the Purkinje fibers which act to carry electric messages through the heart. ACh shows a diurnal cycle with the highest levels during 3:00 a.m. which suggests why many acute cardiac disorders seem to occur during the overnight hours. Some of the anti-arrhythmics can reduce the release of ACh which may, in part, serve as the mechanism for the anti-arrhythmic effects. Secondly, ACh does affect the passage of ions across cardiac membranes such as calcium, potassium, chloride, and sodium.

## SOLVENTS AFFECTING THE CARDIAC SYSTEM

A number of organic solvents apparently produce a negative ionotropic effect in animals. A mixture of organic solvent and a catecholamine can produce a serious arrhythmia. For example, chloroform and epinephrine or another catecholamine has been used as a model for cardiac arrhythmia. Stimulating sites such as the sinus-arterial (SA) node appear to be more sensitive than other sites. Organic solvents such as benzene (Figure 13.1) and organic chemicals such as benzoic acid, dimethyl sulfoxide (DMSO), ethylene glycol, phenol, or *o*-cresol have been shown to produce variable toxicity across different species. It is well established that the cardiac system is sensitive to organic solvents.

## DRUGS AFFECTING THE CARDIAC SYSTEM

There have been many reviews on drugs which produce cardiac toxicity (Baskin, 1991). The figures in this chapter show that there are marked differences in lethality between animals. It should be easy to guess that many different drugs have different effects including dose–response on the heart. Chemicals which are basic (Figure 13.1) can show different effects. Many chemicals exert their action through a anti-cholinergic mechanism such as atropine (Figure 13.2) and physostigmine or adrenergic mechanisms such as ephedrine or phenethylamine. Mechanical (pump) function, electrical function, endocrine function, and flow function can be changed by drugs. Certain species are sensitive or insensitive to a certain type of drug. Drugs such a cardiac glycosides, digitoxin, and digoxin often have different effects in different species. The rat heart is not very sensitive to digoxin but rat brains are sensitive to cardiac glycosides. The dog heart and brain are both sensitive to cardiac glycosides. The pigeon and frog are more sensitive to cyanide, nitroglycerin, and many other toxic gases. Historically, caged birds have been used in the mines as sentinel warning species because it is more sensitive than humans. This is just another example of species sensitivity.

CHAPTER

# 14

# Reproductive toxicity and endocrine disruption

*Tim J. Evans*

## INTRODUCTION

Reproduction is a critical biological process in all living systems and is required for species survival. Toxicant-induced abortions, congenital defects and infertility can have devastating effects on livestock production. Wildlife species living in environments contaminated by industrial and/or agricultural chemicals have experienced impaired fertility and declining populations. There is growing concern within the scientific community and amongst government regulatory agencies about the effects of occupational and environmental exposures to reproductive toxicants on human fertility.

For the purposes of this chapter, the term "reproduction" will be used primarily in reference to vertebrate species of animals (especially mammals) and will be inclusive of "development", which is sometimes treated as a separate topic in toxicology texts. This particular book chapter will emphasize the interactions between toxicants and the male and female reproductive tracts, as well as xenobiotic-induced effects on the growth, maturation and sexual differentiation of the embryo and fetus. Since "endocrine disruption" (see definition below) is an extremely common mechanism of action for xenobiotics associated with impaired reproductive function, reproductive toxicity and endocrine disruption will be discussed together in this chapter. Efforts will be made to clarify the currently used terminology related to reproductive toxicity and endocrine disruption and to introduce the reader to normal reproductive anatomy and physiology, as well as important concepts associated with embryonic and fetal development. Endocrine disruption in wildlife species and humans and the effects of xenobiotics, including endocrine disrupting chemicals (EDCs), on reproductive function in domestic animals will be discussed along with a brief description of proposed mechanisms of action and observed effects of some selected reproductive toxicants.

Unfortunately, space constraints limit the amount of information which can be presented in this chapter, and many of the presented topics cannot be discussed at great length. There are a number of recently published textbooks and issues of journals which cover some of these subjects in greater detail and provide information which is complementary to what is presented in this chapter (Burrows and Tyrl, 2001; Plumlee, 2004; Naz, 2005; Golub, 2006a; Hood, 2006; Jobling and Tyler, 2006; Jørgensen *et al.*, 2006b; Mukerjee, 2006). The reader is directed to these publications and the other references cited in this chapter in order to gain additional insight into specific areas of reproductive function and toxicology.

It is important that the reader understand that the areas of toxicology involving reproductive toxicity and endocrine disruption, in particular, are in continual flux. New data and exceptions to "classical" mechanisms of action are being reported on a regular basis, and there continues to be ongoing debate about the various aspects of normal as well as xenobiotic-induced abnormal reproductive function. Every effort has been made to accurately represent what is currently understood about the topics of discussion in this chapter. Controversial topics or those currently still subject to debate within the scientific community have been noted wherever possible.

# IMPORTANT DEFINITIONS AND CONCEPTS

## Reproduction

Reproduction in domestic, wild and laboratory vertebrates encompasses the wide range of physiological processes and associated behaviors and anatomical structures involved in the production of the next generation and the survival of a given species of animal (Senger, 2003). The physiological processes involved in reproduction generally include the following: (1) gametogenesis (production of sperm or ova) and the pre- and peri-pubertal changes leading up to its onset; (2) release of gametes [i.e. sperm transport and maturation, penile erection and ejaculation of sperm (mammals), copulation between a male and a female of the same species (several vertebrate classes) and ovulation of oocytes]; (3) formation of the zygote (i.e. sperm storage, capacitation and other processes leading to fertilization, or union, of a single sperm with an egg); (4) embryonic and fetal development during the incubation process in egg-bearing vertebrates or, especially in the case of mammals, during pregnancy (gestation) [i.e. activities related to the initiation and progression of zygote cleavage, blastocyst formation, separation of the germ layers, placentation (mammalian species), neurulation and organogenesis (including sexual differentiation)] and finally (5) "birth" of a single or multiple offspring (hatching in oviparous vertebrates). In the conventional sense, the reproductive process culminates with birth or parturition (mammals); however, the initiation and maintenance of milk production (lactation) for the postpartum nutrition of offspring can also be considered a critical aspect of mammalian reproduction (Evans *et al.*, 2007).

## Reproductive toxicity

For the purposes of this chapter, "reproductive toxicity" will refer to any manifestations of xenobiotic exposure reflecting adverse effects on the physiological processes and associated behaviors and/or anatomical structures involved in animal reproduction or development. This is a fairly broad definition which encompasses developmental toxicity, as well as any toxic effects of post-pubertal exposures to xenobiotics on either male or female reproduction. "Developmental toxicity" refers to any adverse effect on the developing organism associated with either pre-conception parental exposures to toxicants or post-conception xenobiotic exposures to the embryo, fetus or pre-pubertal offspring (Hodgson *et al.*, 2000; Eaton and Klaassen, 2001). Adverse effects associated with developmental toxicity of xenobiotics might not necessarily be observed until after the affected individuals have reached sexual maturity (Eaton and Klaassen, 2001).

### *Teratogenesis*

The term "teratogenesis" is derived from the Greek word for monster ("teras") and is a form of developmental toxicity (Rogers and Kavlock, 2001; Panter, 2002). "Teratogenesis" refers specifically to developmental defects induced by toxicant exposures occurring between conception and birth (Hodgson *et al.*, 2000; Eaton and Klaassen, 2001; Rogers and Kavlock, 2001). The types of abnormalities that are typically associated with teratogenesis include embryonic or fetal death; morphological, functional and/or neurobehavioral abnormalities and decreased growth rate and/or birth weight (Rogers and Kavlock, 2001; Panter, 2002).

#### *Wilson's general principles of teratology*

With respect to teratogenesis, there are six basic tenets of teratology, first defined by Wilson in 1959, which need to be kept in mind whenever gestational exposure to a teratogenic xenobiotic is suspected or when a chemical is being evaluated for its teratogenic potential. As stated by Wilson in the *Handbook of Teratology* (1977), the general principles of teratology are as follows:

1. Susceptibility to teratogenesis depends on the genotype of the conceptus and the manner in which it interacts with environmental factors.
2. Susceptibility to teratogenic agents varies with the developmental stage at the time of exposure.
3. Teratogenic agents act in specific ways (mechanisms) on developing cells and tissues to initiate abnormal embryogenesis.
4. The final manifestations of abnormal development are death, malformation, growth retardation and functional disorder.
5. The access of adverse environmental influences to developing tissues depends on the nature of the influences (agent).
6. Manifestations of deviant development increase in degree as dosage increases from no effect to the totally lethal level.

### *Mechanisms of reproductive toxicity and teratogenesis*

There are a wide range of specific mechanisms of action by which xenobiotics can adversely affect reproductive function, including embryonic and fetal development. In general, many of these mechanisms are the same as those for toxicants affecting other organ systems and essentially involve some sort of toxicant-induced cellular dysregulation and alterations in cellular maintenance which, when possible, the body attempts to repair, either successfully or unsuccessfully (Gregus and Klaassen, 2001). Oxidative damage and interference with normal enzymatic reactions are two common mechanisms by which xenobiotics

can cause the dysregulation and altered maintenance of cells within various organs and tissues.

Normal reproduction and development require, by their very nature (see review in this chapter), signaling within and between a variety of diverse organs. In sexual reproduction and mammalian pregnancy, critical communication even takes place between distinctly different organisms (i.e. male and female and mother and offspring, respectively). The dependency of reproductive function on signaling pathways inclusive of gene transcription makes this physiological process especially prone to adverse effects associated with xenobiotic-induced disruption of or interference with cell-to-cell, organ-to-organ and/or even animal-to-animal communication. Many of the mechanisms which interfere with physiological signaling activity can be classified as forms of "endocrine disruption", which will be discussed in much greater detail in this chapter.

There is a great deal of overlap between the various different mechanisms for reproductive toxicity. The level of exposure to a particular toxicant is an important determinant of what toxic effects are observed. Xenobiotics which "disrupt" endocrine pathways can do so without interactions with endogenous receptors, using mechanisms of action which can cause other forms of toxic insult at various dosages.

#### *Reproductive toxicants and teratogens*

Any xenobiotic associated with adverse effects on development or male or female reproductive function can be classified as a "reproductive toxicant". Xenobiotics capable of inducing teratogenesis are referred to as "teratogens". Although any chemicals adversely affecting animal well-being have the potential to have a negative impact on development and reproductive function, this chapter will attempt to focus on mechanisms of actions and toxicants which specifically target normal embryonic or fetal growth and maturation or have a direct effect upon the male and/or female reproductive tract.

## Hormones and hormone receptors

The term "hormone" classically refers to a substance which is secreted into the circulation by a ductless gland and which alters the function of its target cells (Hodgson *et al.*, 2000). While the traditional "endocrine" aspect of hormone action involves organ-to-organ signaling (and in the case of mammalian pregnancy animal-to-animal signaling), it is recognized that hormones can also be involved in "paracrine" (cell-to-cell) communication and signaling pathways within the same cell in which they were produced ("autocrine" function) (Evans *et al.*, 2007). In vertebrates there are a wide variety of different hormones involved in reproductive function. The major reproductive hormones are generally grouped according to their basic molecular structure and include amino acid derivatives [e.g. dopamine or prolactin inhibitory factor (PIF) and melatonin]; peptides [e.g. oxytocin, adrenocorticotropin hormone (ACTH), corticotropin releasing factor or hormone (CRF or CRH), gonadotropin releasing hormone (GnRH) and thyrotropin releasing hormone (TRH)]; proteins [e.g. activin, inhibin, insulin-like growth factors, prolactin and relaxin]; glycoproteins [e.g. follicle-stimulating hormone (FSH), luteinizing hormone (LH) and thyroid stimulating hormone (TSH or thyrotropin)]; steroids (e.g. androgens, estrogens and progestins) and eicosanoids, which include prostaglandins (Evans *et al.*, 2007).

The actions of hormones on their targets are generally mediated through receptors which initiate or inhibit some sort of signal transduction pathway or are required for hormone-induced alterations in gene expression. Hormone–receptor interactions can be modulated by a number of factors including the amount of hormone present, the affinity of the hormone for the receptor, receptor density and occupancy and interaction with other hormones, receptors and hormone–receptor complexes, as well as a variety of endogenous co-activators and inhibitors (Genuth, 2004a; Bigsby *et al.*, 2005). It should be clear by the end of this chapter that various xenobiotics are also capable, under certain exposure conditions, of modulating the interactions between endogenous hormones and their receptors.

#### *Gonadal steroid hormones and their "nuclear" receptors*

The primary gonadal steroids [i.e. androgens and estrogens (some references also include progesterone)] are also referred to as the "sex" steroids, and the imitation and/or inhibition of the actions of these hormones by xenobiotics is what was first referred to as "endocrine disruption" (Krimsky, 2000; McLachlan, 2001). The major androgens [testosterone and dihydrotestosterone (5$\alpha$-reductase conversion product of testosterone in the testes and selected non-gonadal tissues)], estrogens (estradiol and estrone) and progesterone and endogenous progestins facilitate the development and regulation of reproductive function in animal species, in large part, by interacting with (i.e. functioning as ligands for) receptors which are members of the steroid/thyroid ("nuclear") receptor superfamily, the largest family of transcription factors in eukaryotic systems (Tsai and O'Malley, 1994; Genuth, 2004a). Receptors in this superfamily are large oligomeric proteins (Genuth, 2004a), which generally consist of five domains (A/B, C, D, E and F) (Tsai and O'Malley, 1994). Although specific portions of the gonadal steroid nuclear receptor molecules can interact with a variety of co-activators as well as inhibitors, the most important domains of these receptors are generally considered to be those involved in transactivation (*N*-terminal A/B domain; also C-terminus in

estrogen receptors (ERs)); DNA-binding and hormone–receptor complex dimerization (middle portion containing two helical zinc fingers; C domain) and hormone (ligand) binding (C-terminus; E domain) (Genuth, 2004a; Bigsby *et al.*, 2005). While androgen, estrogen and progesterone receptors, which are members of the steroid/thyroid superfamily, are often thought of as being exclusively nuclear in their location, these receptors can also be located in the cytoplasm of some cells (Tsai and O'Malley, 1994; Genuth, 2004a). Cytoplasmic and nuclear gonadal steroid receptors can be bound to a variety of different heat shock proteins, which interact with the receptor's hormone-binding domain. Heat shock proteins can act as "blocking" molecules and are displaced by hormones binding to the receptors (Genuth, 2004a; Bigsby *et al.*, 2005) or as "chaperones" involved in receptor turnover and "trafficking" of these receptors between the nucleus and the cytoplasm (Pratt and Toft, 1997).

There is reportedly a single type of androgen receptor which is a member of the steroid/thyroid superfamily. In contrast, there are two types of nuclear ERs (ER$\alpha$ and ER$\beta$), which are the products of distinct genes on separate chromosomes (O'Donnell *et al.*, 2001). ER$\alpha$ and ER$\beta$ differ in their amino acid structure, tissue distribution, affinity for selective ER modulators (SERMs) and their role in female (Britt and Findlay, 2002) as well as, somewhat surprisingly, male fertility (O'Donnell *et al.*, 2001; Hess, 2003). The nuclear progesterone receptor also has two isoforms, progesterone receptor A and progesterone receptor B (PRA and PRB, respectively), which differ slightly in their amino acid sequences and their interactions with co-activators. However, unlike ER$\alpha$ and ER$\beta$, PRA and PRB are the products of a single gene (Brayman *et al.*, 2006).

#### *Genomic and non-genomic mechanisms of action of gonadal steroid hormones*

Traditionally, the receptor-mediated reproductive effects of gonadal steroids were thought to occur almost exclusively through interactions between homodimers of the hormone–nuclear receptor complexes and specific regions of DNA upstream from the basal promoter of a given gene, referred to as hormone-response elements (HREs) or, more specifically, androgen and estrogen-response elements (ARE and ERE, respectively) (Tsai and O'Malley, 1994; Genuth, 2004a). It is now understood that these "genomic" effects of gonadal steroids and their nuclear receptors, which involve alterations in gene transcription, can, in some instances, involve heterodimers of different nuclear steroid–receptor complexes, indirect binding of hormone–receptor complexes to DNA via proteins within a preformed transcriptional complexes and even ligand (hormone)-independent "activation" of nuclear gonadal steroid receptor molecules (O'Donnell *et al.*, 2001; Bigsby *et al.*, 2005; Thomas and Khan, 2005). In addition, it is also apparent that gonadal steroids can affect cellular function by non-genomic mechanisms of action involving changes in intracellular concentrations of ions, cAMP and its second messengers, and the mitogen-activated protein (MAP) kinase pathway. These non-genomic mechanisms are independent of the somewhat "time-consuming" alterations in gene expression traditionally associated with gonadal steroids and occur rapidly within seconds or minutes (O'Donnell *et al.*, 2001; Thomas and Khan, 2005). While the rapid, non-genomic effects of gonadal steroids most likely involve receptors bound to the plasma membrane, the specific identity and classification of these receptors remain unclear and might involve a number of different receptor types (Razandi *et al.*, 1999; O'Donnell *et al.*, 2001; Thomas and Khan, 2005; Warner and Gustafsson, 2006).

## Endocrine disruption

"Endocrine disruption" is a developing, multidisciplinary area of research, involving aspects of both toxicology and endocrinology (McLachlan, 2001). "Endocrine disruption" is also a potential mechanism of action for many toxicants, and this term has been defined in a variety of different ways, depending on the circumstances and the intended audience. Some of these definitions can be fairly "broad", such as the one which will be used in this chapter (see below). However, "endocrine disruption" can also be defined fairly narrowly with respect to toxicant origin (synthetic versus naturally occurring); source or site of toxicant exposure (environmental contamination versus occupational exposure); xenobiotic mechanism of action [receptor agonism and/or antagonism (see definition below) versus other mechanisms independent of direct interactions between xenobiotics and receptors]; and/or the timing of exposure (prenatal versus postnatal exposures) (Krimsky, 2000, 2001). It is critically important for one to carefully define the context in which "endocrine disruption" is being used in order to clearly and accurately discuss one's research findings or opinions with toxicologists, physiologists, wildlife biologists, medical professionals, regulatory personnel, the popular press and/or the general public (McLachlan, 2001).

Although the imitation and/or inhibition of the actions of androgens and, especially, estrogens by xenobiotics is what was first referred to as "endocrine disruption", both the multidisciplinary area of study and mechanism of action generally referred to as "endocrine disruption" have evolved over the years to encompass a wide range of specific mechanisms of action which can ultimately result in adverse effects on invertebrate and/or vertebrate animals (McLachlan, 2001). As scientists continue to investigate the effects of xenobiotics on biological systems, the paradigm of endocrine disruption will continue to "shift", and a willingness to "step out of the box" and discuss endocrine

disruption in a broader context will be necessary in order to participate in scientific discussions, to design future experiments and/or to make informed, medical or policy decisions based on "good" science (McLachlan, 2001; Guillette, 2006). For the purposes of this chapter "endocrine disruption" will refer to the effects of any synthetic or naturally occurring xenobiotic which can affect the endocrine system of exposed individuals (i.e. the balance of normal hormonal functions) and, as a result of exposure, cause physiological alterations (Keith, 1997; Hodgson *et al.*, 2000). Within the broad scope of this definition, reproduction, including prenatal and pre-pubertal development, certainly would be expected to be one of the physiological functions most profoundly affected by chemicals capable of endocrine disruption. In fact, it could be argued that the majority of reproductive toxicants interfere with endocrine function in one way or another. However, adverse effects on other, "non-reproductive" endocrine systems can also be associated with exposures to xenobiotics, and these "non-reproductive" effects need to be taken into consideration as well when describing the endocrine disruption associated with exposure to a given chemical (Guillette, 2006) (see below).

### *Mechanisms of endocrine disruption*

Endocrine disruption encompasses a wide range of mechanisms of action which can ultimately result in adverse effects on animal species. The mechanisms of action of involved in endocrine disruption can include effects which are mediated directly by interactions between the xenobiotic and an endogenous hormone receptor (i.e. the xenobiotic functions as a ligand for an endogenous receptor and a receptor–ligand complex is formed), as well as those adverse effects which alter hormonal functions without direct interactions between the toxicant and an endogenous receptor (Keith, 1997). In addition, it should be noted that some xenobiotics are capable of causing endocrine disruption by functioning as an endogenous hormone receptor ligand, as well as by mechanisms of action which are independent of the formation of a xenobiotic (ligand)–receptor complex.

#### *"Classic" receptor-mediated endocrine disruption*

"Classic" endocrine disruption can involve imitation or mimicry of the interactions between cellular receptors and endogenous hormones (i.e. receptor agonism) and/or a blockade or inhibition of the formation of receptor–hormone complexes (i.e. receptor antagonism) (McLachlan, 2001). With respect to gonadal steroids, both genomic and non-genomic physiological responses can be affected by this mimicry or blockade of endogenous hormone receptor-mediated activity (Thomas and Khan, 2005). Xenobiotics which mimic the actions of endogenous androgens or estrogens (i.e. gonadal steroid receptor agonists) are referred to, respectively, as being either "xenoandrogens" or "xenoestrogens". Conversely, reproductive toxicants which inhibit or block endogenous estrogens or androgens from interacting with their respective receptors (i.e. gonadal receptor antagonists) are generally classified as "antiandrogens" or "antiestrogens". Progestins" ("progestogens" or "progestagens" in some literature) is a generic term for endogenous or synthetic compounds which interact with progesterone receptors, and there is evidence of increasing environmental contamination with these types of EDCs.

Some xenobiotics can act as receptor agonists or antagonists, depending on the circumstances or tissues involved. "Selective ER modulators" or "SERMs" refer to a class of xenobiotics which, although originally classified as antiestrogens, can function as either ER agonists or antagonists, depending on the tissue in which estrogen-dependent responses are being discussed (Dutertre and Smith, 2000; Katzenellenbogen and Katzenellenbogen, 2000). SERMs are particularly relevant with respect to observed differences in their binding affinities to ER$\alpha$ or ER$\beta$ and their development as therapeutic agents for different types of estrogen-responsive neoplasia.

#### *Endocrine disruption independent of receptor-mediated interactions*

Endocrine disruption which is independent of interactions between xenobiotics and endogenous hormone receptors can occur in a variety of different ways. Xenobiotic exposure can result in alterations in the number of hormone receptor sites (up- or downregulation) or can cause direct or indirect hormone modifications which alter hormonal function (Keith, 1997). Xenobiotics can change the rate of synthesis or destruction of endogenous hormones and can alter how hormones are stored, how they are released into and/or transported within the circulation or even how they are eventually cleared from the body (Keith, 1997; Sikka *et al.*, 2005). Any xenobiotic which is toxic to organs or tissues producing hormones (e.g. testis and ovary) has the potential to decrease hormone synthesis and thereby indirectly cause endocrine disruption (Devine and Hoyer, 2005). It should also be noted that some of these mechanisms of endocrine disruption are not necessarily exclusive of one another. A given xenobiotic can potentially disrupt the normal balance of hormonal function by more than one mechanism which is independent of direct interactions between the toxicant and an endogenous hormone receptor.

### *"Androgenic" and "estrogenic" effects of xenobiotics*

The terms "androgenic" and "estrogenic" and their antonyms, "antiandrogenic" and "antiestrogenic" have been used in a number of different contexts. Some authors have used these terms to refer specifically to the agonistic

and antagonistic receptor interactions of xenobiotics (Hodgson *et al.*, 2000). Because the precise mechanism of endocrine disruption of a given toxicant might not always be known or might involve multiple mechanisms of action, these terms have also been used in a more general sense, especially in livestock and wildlife species, to refer to phenotypic changes which were similar to or the opposite of the effects which would be expected with exposure to endogenous androgens or estrogens (Guillette, 2006). This type of general usage can be helpful in some instances but can also be confusing, given that xenoandrogens and progestins frequently have the opposite phenotypic effects as xenoestrogens. For instance, the effects of estrogenic xenobiotics can be described as antiandrogenic or antiprogestagenic in some instances, while the effects of xenoandrogens and progestins can be referred to as being antiestrogenic in nature. Further confusion can be associated with exposures to mixtures of chemicals having different phenotypic effects, as is often the case in instances of environmental contamination, or with exposures to xenobiotics having mixed antiestrogenic and antiandrogenic effects mixed effects (i.e. methoxychlor). When the terms "androgenic", "estrogenic" or their antonyms are used within this chapter, an attempt will be made to clearly denote the intended specific or general meaning of the terms in the context in which they are used. The discretionary use of the terms "feminization" and "masculinization", as well as "defeminization" and "demasculinization", can also, in some instances, help to clarify and/or describe the phenotypic effects of a chemical suspected endocrine disruption.

### *Endocrine disrupting chemicals, endocrine disruptors and hormonally active agents*

Any reproductive toxicant capable of endocrine disruption can be considered an "EDC" or an "endocrine disruptor". Obviously, this includes a large number of xenobiotics which are used in commercially available industrial, agricultural and pharmaceutical products, as well as naturally occurring toxicants produced by plants and fungi. An effort will be made later in this chapter to discuss some of the xenobiotics most often associated with endocrine disrupting mechanisms of action.

Another term frequently used with respect to endocrine disruption, especially regarding xenobiotics which interact with endogenous hormone receptors, is "hormonally active agent" or "HAA". In most instances, "endocrine disrupting chemical", "endocrine disruptor" or "hormonally active agent" can be used interchangeably to discuss the actions of a given xenobiotic. However, whereas "endocrine disrupting chemical" and "endocrine disruptor" generally have negative connotations and imply, by virtue of the inclusion of the term "disrupt", something "dangerous" and the likelihood of adverse or toxic effects, the term "hormonally active agent" is more benign and only indicates that a given xenobiotic has the potential to affect a hormonal pathway in an animal (Krimsky, 2001). As pointed out by Krimsky (2001), a mechanism rather than a specific pathology is inferred by "hormonally active", and "hormonally active agent" is the nomenclature preferred by the National Research Council (Knobil, 1999), especially when referring to xenobiotics which interact with endogenous hormone receptors.

The circumstances and intended audience will often dictate the terms used to describe xenobiotics associated with or suspected of being having endocrine activity. "Environmental hormone" and "environmental signal" have also been used, along with "HAA", "EDC" and endocrine disruptor, to describe xenobiotics capable of interacting with endogenous hormone receptors (McLachlan, 2001; McLachlan *et al.*, 2006). However, the context in which these two terms have been routinely used generally implies environmental contaminants with documented adverse endocrine effects on animals or humans. In some instances, the term "HAA" might be more "politically correct" (Krimsky, 2001) than "EDC", "endocrine disruptor", "environmental hormone" or "environmental signal" when discussing chemicals with a suspected hormonal activity that has not been clearly associated with adverse effects on animals in a research and/or clinical setting.

### *Aryl hydrocarbon receptor-mediated endocrine disruption*

Endocrine disruption mediated by the aryl hydrocarbon receptor (AhR) is a relatively complex, species- and tissue-dependent phenomenon, involving several of the previously described mechanisms of EDC action and interactions with many important, environmentally persistent compounds. Some aspects of AhR-mediated endocrine disruption are reminiscent of the ligand-induced transcription associated with gonadal steroid receptor function. However, the unique nature of the endogenous AhR and its interactions with primarily xenobiotic agonists warrants further discussion.

#### *Aryl hydrocarbon receptor agonists*

The major agonists for the AhR protein belong to the class of environmental contaminants referred to collectively as "halogenated" or "polyhalogenated aromatic hydrocarbons" (HAHs or PAHs, respectively) and includes many highly stable and lipophilic organochlorine industrial chemicals [e.g. polycyclic aromatic hydrocarbons (PAHs), polychlorinated biphenyls (PCBs), polychlorinated dibenzo-*p*-dioxins (PCDDs) and polychlorinated dibenzo-difurans (PCDFs)], as well as their metabolites (Safe, 2005). In addition, other organic compounds, such as polycyclic aromatic hydrocarbons (PAHs) [e.g. 3-methylcholanthrene and benzo[a]pyrene) (BaP)] and flavones (e.g.

$\beta$-naphthoflavone), have also been shown to be AhR agonists (Parkinson, 2001).

*Mechanisms of aryl hydrocarbon receptor-mediated endocrine disruption*

Many of the mechanisms of action mediated by AhR–ligand interactions have been elucidated using 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) as a prototypical AhR agonist (Parkinson, 2001; Safe, 2005). TCDD is considered by many to be the most toxic of all of the HAHs, and it is reported to have the highest AhR-binding affinity of any of the xenobiotics in that class of chemicals (Safe, 2005). The AhR, also referred to as the "dioxin receptor", is located in the cytoplasm bound to heat shock proteins (Parkinson, 2001). Following ligand (i.e. TCDD) binding and the subsequent disassociation of the heat shock proteins, the AhR is activated by phosphorylation (Parkinson, 2001) and the activated ligand–AhR complex undergoes a rapid sequence of events involving interactions with the AhR nuclear translocator protein (Arnt) and relocation of the ligand–AhR–Arnt complex into the nucleus (Safe, 2005).

Within the nucleus, the liganded AhR/Arnt heterodimer can facilitate a variety of endocrine disrupting mechanisms. This activated heterodimer complex can interact with dioxin/xenobiotic-response elements (DREs/XREs), which function in much the same way as the previously discussed HREs, and with various co-activators to increase the expression of selected genes (Parkinson, 2001; Safe, 2005). Depending on the animal species and the tissue, multiple phase I drug-metabolizing enzymes [e.g. cytochrome P450 (CYP) enzymes (CYP1A1, CYP1A2 and CYP1B1)] and enzymes involved phase II drug-biotransformation reactions (e.g. glutathione-*S*-transferase and glucuronosyl transferase), are induced by TCDD (Safe, 2005).

Although the antiandrogenic and antiestrogenic properties of TCDD have been associated with the ability of HAHs to induce enzymes involved in androgen and estrogen metabolism, TCDD can interact with androgen-, estrogen- and progestin-modulated pathways in a number of ways, including interference with neuroendocrine development (Petersen *et al.*, 2006). AhR-mediated effects of TCDD can interfere with the biosynthesis of testosterone by a mechanism which alters the regulation of the synthesis and release of LH (Sikka *et al.*, 2005). It has also been shown in cell cultures that TCDD can disrupt testosterone signal transduction pathways (Jana *et al.*, 1999). The liganded AhR/Arnt heterodimer appears to be able to interact with inhibitory DREs (iDREs) in selected tissues to suppress the expression of some genes induced by estrogens (Safe, 2005), as well as be able to actually block the ability of estrogen–ER complexes to bind to their HREs (Kharat and Saatcioglu, 1996; Thomas and Khan, 2005). It is likely that a variety of other means of crosstalk between TCDD- and estrogen-mediated signaling pathways exist, and, in fact, TCDD has actually been shown to have the potential for estrogenic activity through interactions between liganded AhR/Arnt heterodimers and unliganded ERs (both ER$\alpha$ and ER$\beta$) (Ohtake *et al.*, 2003; Bigsby *et al.*, 2005; Thomas and Khan, 2005). Ohtake *et al.* (2003) have reported that these novel interactions resulted in the recruitment of unliganded ERs and p300 co-activator to gene promoters which are responsive to estrogens. Based on the results of the various experiments performed with TCDD, it is important to remember that the effects observed following exposure to HAHs and EDCs, in general, can be dependent on animal species involved, as well as the type of tissue, organ or physiological response being evaluated.

***Epigenetic mechanisms of action of endocrine disrupting chemicals***

In recent years there has been increasing interest in the association between prenatal exposures to some reproductive toxicants and the postnatal development of neoplasia (cancer) involving the reproductive tract, as well as the occurrence of transgenerational or vertically transmitted adverse reproductive effects (Crews and McLachlan, 2006). These two phenomena are not mutually exclusive of one another, and, in fact, there is increasing evidence of vertically transmitted neoplasia involving reproductive organs (McLachlan *et al.*, 2006). Both tumor formation and transgenerational reproductive abnormalities can occur because of "genetic" mutations or alterations in the genotype (i.e. DNA sequence) or as a result of "epigenetic" changes where there are heritable modifications in the properties of a cell which do not represent genetic changes (inherited phenotypic alteration without genotypic change) (Lewin, 1998; McLachlan, 2001; Crews and McLachlan, 2006).

Epigenetic changes are a normal part of development and most likely represent one means for heritable environmental adaptation (Crews and McLachlan, 2006). One of the more common mechanisms of epigenetic modification in mammals is DNA methylation of CpG nucleotides in the promoter regions of genes, which results in methylated genes being "turned off" and unmethylated or demethylated genes being "turned on" (McLachlan, 2001; Anway and Skinner, 2006). Patterns of DNA methylation are generally established during development at the gastrulation stage (i.e. lineage-specific pattern in somatic cells) and after sex determination (i.e. germ line-specific lineage pattern in the gonad) (Anway and Skinner, 2006). DNA methylation can facilitate "genomic imprinting", a form of epigenetic gene regulation resulting in the expression of the allele from only one parent (i.e. monoallelic expression) (McLachlan, 2001; Anway and Skinner, 2006). The ability of developmental exposures to xenobiotics to provide a basis for adult disease, such as neoplasia, might very likely involve epigenetic changes involving methylation or demethylation of the promoters for specific

genes (Newbold *et al.*, 2006). Epigenetic modification by alterations in DNA methylation patterns in the germ line might be one mechanism for observed xenobiotic-induced transgenerational (vertically transmitted) effects associated with infertility and tumor susceptibility in rodents (Anway and Skinner, 2006; Newbold *et al.*, 2006).

#### *Disruption of "non-reproductive" endocrine systems*

Although it can be argued that almost all endocrine systems are "reproductive" to some extent, there are multiple systems with primary functions which are not directly related to reproduction, and several of these systems have also been identified as potential targets of EDCs. In addition, gonadal steroids and xenobiotics which mimic these endogenous hormones can have "non-reproductive" effects. The synthesis of triiodothyronine ($T_3$) and thyroxine ($T_4$) by the thyroid gland can be decreased by chemicals which inhibit the uptake of iodine (e.g. perchlorate and thiocyanate) and also by xenobiotics which inhibit thyroperoxidase (e.g. thiourea, propylthiourea (PTU), some sulfonamides, methimazole, carbimazole, aminotriazole and acetoacetamide) (Capen, 2001). Polybrominated diphenyl ethers (PBDEs) have been shown to have antithyroidal activity (Guillette, 2006), and thyroid hormone secretion can be inhibited by exposure to excessive amounts of iodine or lithium (Capen, 2001). Xenobiotics, such as the *o,p′*-DDD metabolite of dichlorodiphenyltrichloroethane (DDT), can interfere with glucocorticoid metabolism (Guillette, 2006), and there has been increasing interest in the relationship between gestational and neonatal exposures to xenoestrogens and the development of obesity (Cooke and Naz, 2005; Newbold *et al.*, 2005, 2006). Some EDCs (e.g., organotin compounds) have recently been described as "obesogens" because of their ability to affect adipogenesis by several different mechanisms, including interactions involving the isoforms of 11β-hydroxysteroid dehydrogenase (11β-HSD) which play key roles in glucocorticoid metabolism (Grün and Blumberg, 2006). Because of increased societal concerns about obesity, there is likely to be greater future interest in organotins and other EDCs with similar "obesogenic" activities.

## NORMAL ANIMAL REPRODUCTION

Reproduction is a complex and dynamic process involving precise coordination and integration of the functions of multiple organs within the body. The production of viable and functional gametes and their transport and union to form a zygote which develops into a healthy and fertile individual require that many stringent physiological and metabolic needs be met. A thorough understanding of the mechanisms involved in reproduction is absolutely essential in order to recognize which steps in the reproductive process are most susceptible to the adverse effects of potential toxicants. It is critical that one be able to understand the pathophysiological basis for reproductive abnormalities. In addition, it is necessary, from a clinical perspective, to identify what constitutes "normal" reproduction in order to recognize abnormal reproductive behaviors and morphological changes in both domestic and wild animals. Impaired reproductive function in domestic animals, which is associated with exposure to toxic amounts of xenobiotics, necessitates the use of diagnostic, prognostic and therapeutic procedures which require a thorough knowledge of normal reproductive anatomy and physiology.

Normal reproduction will be reviewed in this chapter to provide a basis for discussion concerning specific reproductive toxicants. Although the emphasis will be on mammalian reproduction, many of the principles will be applicable to other classes of vertebrates. If additional information is needed, textbooks are available which provide a comprehensive overview of animal reproduction (Hafez and Hafez, 2000; Senger, 2003), as well as general veterinary anatomy (Dyce *et al.*, 2002). Other references can be consulted for descriptions of various aspects of normal reproduction in species of domestic or laboratory animals, which might be of particular interest to the reader (Johnston *et al.*, 2001; Hedrich and Bullock, 2004; Suckow *et al.*, 2006; Youngquist and Threlfall, 2007).

### Neuroendocrine control of reproduction

In humans and animals alike, visual, olfactory, auditory and other sensory data are integrated within the brain and are reflected in endocrine events. The neuroendocrine functions of the pineal gland, hypothalamus and pituitary gland play an important role in the integration and endocrine regulation of the body's physiological processes and are potential targets for many reproductive toxicants (i.e. dioxins). These structures within the brain and proper function of the hypothalamic–pituitary–gonadal axis facilitate development of the reproductive tract and endocrine regulation of spermatogenesis in the male and the estrous or menstrual cycle in the female. The onset of puberty and sexual behavior in males and females, the ability to achieve erection and ejaculation in males, and the normal progression of gestation, parturition and lactation in females are all affected by the secretions of the hypothalamus and pituitary gland, as well as interactions between these structures and the reproductive tract (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007).

The hormones involved in the neuroendocrine control of reproduction are produced in several regions of the brain. Melatonin is produced in the pineal gland. The major hormones of reproductive interest which are of hypothalamic origin are dopamine, CRF, GnRH and TRH. Oxytocin is released from the posterior pituitary (neurohypophysis), and ACTH, FSH, LH, prolactin and TSH are synthesized

and released from the anterior pituitary (adenohypophysis) (Ginther, 1992; Evans *et al.*, 2007). The production and release of these hormones are regulated by various positive and negative feedback loops, which are potentially susceptible to the effects of hormonally active xenobiotics.

## Puberty

### *The onset of puberty*

Puberty in male and female offspring implies reproductive competence and corresponds to the onset of normal spermatogenesis in the male and reproductive cyclicity in the female. Puberty can be indicated in the female by the age at first estrus or ovulation or even the age at which pregnancy can be maintained safely (Senger, 2003; Evans *et al.*, 2007). In the male, the age at the time of preputial separation and the acquisition of the ability to ejaculate or the age at the first appearance of spermatozoa in the ejaculate or urine, as well as the production of threshold concentrations of fertile sperm in the ejaculate, have all been used as indicators of puberty (Senger, 2003). Species, nutritional status, environmental and social factors, pheromones and photoperiod in short- or long-day breeders can all influence the age of onset of puberty in animal species (Senger, 2003; Evans *et al.*, 2007).

### *The endocrinology of puberty*

From an endocrine perspective, puberty is associated with the ability of the hypothalamus to release enough GnRH to induce gonadotropin production by the anterior pituitary gland (Senger, 2003). This endocrine milestone is brought about by the postnatal developmental changes which allow the hypothalamus to overcome the negative feedback of testicular androgens and estrogens in males and which facilitate the ovary's ability to produce sufficient estrogens to induce the preovulatory surge of GnRH in females (Senger, 2003; Evans *et al.*, 2007). Many of the endocrine changes which come into play with the onset of puberty are also involved in the transition from anestrus to the ovulatory season in seasonally polyestrous female animals (Evans *et al.*, 2007).

### *The susceptibility of the pubertal process to reproductive toxicants*

While puberty is often described simply in terms of a single, initial reproductive event (e.g. first estrus, ovulation or ejaculation), the attainment of reproductive competency is actually a process which is susceptible to the affects of reproductive toxicants. Xenobiotics can interfere with important physiological and morphological transformations necessary for the normal stepwise progression toward reproductive competency. Pre-pubertal follicular development, as well as the onset of the preovulatory LH surge in the female and the transition in testicular estrogen synthesis from the Sertoli cell to the Leydig cell in the males of many species, in addition to the postnatal proliferation of Sertoli cells in some mammals, are all potentially susceptible to the adverse effects of xenobiotics. Pre- or peri-pubertal exposure to hormonally active xenobiotics, such as anabolic steroids and antiandrogens, can interfere with postnatal reproductive development and function and can impair an animal's ability to reach its maximum reproductive potential (Monosson *et al.*, 1999; Evans *et al.*, 2007).

## Normal male reproductive anatomy and physiology

### *Reproductive anatomy of the male*

Anatomical structures associated with reproduction in the male usually include, especially in mammals, paired testes (male gonads) positioned outside the abdominal cavity in most species; an excurrent duct system (i.e. efferent ductules, paired epididymidies, vas deferens and urethra); accessory sex glands (i.e. ampullae, seminal vesicles, prostate and bulbourethral glands); a scrotum and its associated thermoregulatory functions to protect the testes from mechanical and thermal insult and some form of copulatory organ or penis with a mechanism for protrusion, erection, emission of glandular secretions and ejaculation of sperm. The primary functions of the testis (testicle) are spermatogenesis [production of male gametes (sperm or spermatozoa)] and steroidogenesis (production of androgens and estrogens). Unlike the female in which oogonia are no longer replicating and the full complement of potential oocytes are present at birth, spermatogonia are proliferating and differentiating into spermatozoa continuously, and the testis is organized in such a way as to maximize sperm production (Senger, 2003).

#### *Testicular structure*

The parenchyma of the testis is divided into the tubular and interstitial compartments (Senger, 2003) (Figure 14.1a). The structural and functional units of the testis are the seminiferous tubules within the tubular compartment and the Leydig (interstitial cells) within the interstitial compartment. Depending on the species, it is estimated that the seminiferous tubules comprise approximately 80% of the adult testis, with the interstitium comprising most of the remaining 20% (Genuth, 2004b). Seminiferous tubules form highly convoluted loops (tubulus contortus) which begin and end with straight portions (tubulus rectus) that connect to the rete tubules (Thomas and Thomas, 2001; Senger, 2003; Genuth, 2004b). In some species, the rete tubules coalesce in a fibrous region of the testis referred to as the mediastinum, which joins with septal projections of

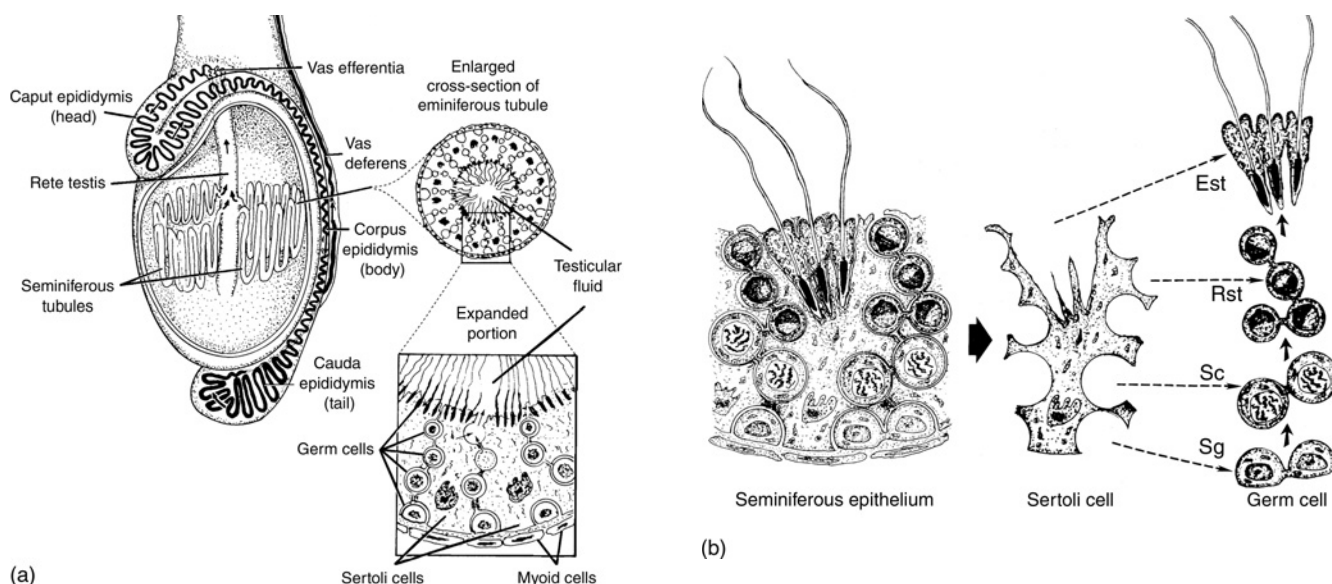

**FIGURE 14.1** Loops of the seminiferous tubules, rete testis and excurrent duct system (i.e. efferent ductules (vas efferentia), epididymidis (epididymis) and ductus deferens (vas deferens), as well as a cross-section of a seminiferous tubule showing the microanatomy of the seminiferous epithelium in a "typical" mammalian testis, are shown in (a). Mature spermatozoa follow the pathway denoted by arrows. Testicular fluid is secreted by the Sertoli cell into the lumen of the seminiferous tubule. The portion of the testicular parenchyma outside of the seminiferous tubules is the interstitium. The predominant cell type within the interstitium is the Leydig or interstitial cell. The complex nature of the association between Sertoli cells and developing germ cells within the seminiferous epithelium in a "typical" mammalian testis is shown in (b). The Sertoli cell and germ cells are shown schematically disassociated to demonstrate how spermatozoal precursors occupy spaces between adjacent Sertoli cells. Spermatogonia, spermatocytes, round spermatids and elongate spermatids are denoted by Sg, Sc, RSt and ESt, respectively. This figure was adapted, with permission, from Garner DL, Hafez ESE (2000) In *Reproduction in Farm Animals*, 7th edn, Hafez ESE Hafez B (eds). Lipincott Williams & Wilkins, Philadelphia, PA (modifications and artwork courtesy of Don Connor and Howard Wilson).

the tunica albuginea, part of the testicular capsule (Senger, 2003). The rete tubules join with the efferent ductules which attach to the epididymidis.

Within the seminiferous tubules are germ cells at various stages of differentiation and Sertoli cells which provide germ cells with structural support and nutrients, as well as regulatory and paracrine factors (Thomas and Thomas, 2001) (Figure 14.1b). Tight junctions (junctional complexes) between adjacent Sertoli cells divide the seminiferous epithelium into basal and adluminal compartments, with Sertoli cells anchored to the basement membrane and surrounding the developing populations of germ cells (Thomas and Thomas, 2001; Senger, 2003; Genuth, 2004b). The seminiferous tubules are surrounded by peritubular myoid cells, which in combination with the junctional complexes, form the "blood–testis barrier" to prevent free exchange of large proteins and some xenobiotics between the blood and the fluid within the seminiferous tubules (Thomas and Thomas, 2001; Senger, 2003).

Within the interstitial compartment are the Leydig (interstitial) cells, as well as capillaries, lymphatic vessels and connective tissue (Senger, 2003). The Leydig cells are homologous to the theca interna cells in the ovary and produce testosterone (also estrogen in some species). There are species differences with respect to the abundance of Leydig cells in the interstitium, and these differences are important to recognize when reporting Leydig or interstitial cell hyperplasia in response to toxicant exposure. It should also be noted that Leydig and, to a lesser extent, Sertoli cells contain enzymes involved in xenobiotic biotransformation, and the synthesis of toxic metabolites can actually occur within the testis, in close proximity to the target cells for a given reproductive toxicant (Thomas and Thomas, 2001; Creasy and Foster, 2002).

*Excurrent duct system*

The excurrent duct system consists of the efferent ductules, the epididymal duct and the ductus deferens. This duct system functions to conduct spermatozoa, rete fluid and some testicular secretory products away from the testis and eventually into the pelvic urethra (Senger, 2003). The reabsorption of fluid by a species-variable number of efferent ductules is essential for normal testicular function (O'Donnell *et al.*, 2001; Hess, 2003), and these tubules terminate by joining a single highly coiled epididymal duct, commonly referred to as the epididymidis or epididymis. Depending on the species, the epididymidis is generally subdivided into the initial segment, head (caput), body (corpus) and tail (cauda), with the various portions sometimes being further subdivided (França *et al.*, 2005). The primary functions of the epididymidis are transport and

sustenance of sperm, reabsorption and secretion of fluid (initial segment and head, respectively); spermatozoal acquisition of motility and fertile potential (i.e. sperm maturation); recognition and elimination of defective spermatozoa; sperm storage prior to ejaculation and secretory contributions to the seminal fluid (Sutovsky *et al.*, 2001). The epididymal transit time varies somewhat with species, but is generally approximately 7–14 days in length, depending on several factors including ejaculation frequency. The ductus deferens conducts spermatozoa matured in the epididymidis to the pelvic urethra which helps to form the penis.

*Accessory sex glands*

There are a number of accessory sex glands (the complement of which varies with species) that contribute to the composition of the seminal fluid in mammals. These glands include the ampullae, seminal vesicles (vesicular glands), prostate and bulbourethral glands (Senger, 2003). Laboratory rodents (i.e. mice and rats) have an additional gland referred to as the preputial gland, which appears to have a role in the production of pheromone (Creasy and Foster, 2002). These accessory sex glands in the male are generally considered to be androgen dependent, with conversion of testosterone to DHT occurring in the prostate and seminal vesicles of many species) (Creasy and Foster, 2002; Senger, 2003). The weights of the accessory sex glands can be used as an indirect measure of testosterone concentrations or exposure to antiandrogens (Thomas and Thomas, 2001; Senger, 2003).

*External genitalia*

The external genitalia of the male consist of the copulatory organ or penis, the prepuce, which protects the penis from environmental and mechanical injury, and the scrotum for testes positioned outside of the abdominal cavity. Penile structure is extremely species variable, with some species even having a special penile bone (i.e. os penis), but the shaft of the penis generally consists of erectile tissue (corpus cavernosum and corpus spongiosum) which surrounds the pelvic urethra. The glans penis is homologous to the female clitoris, and stimulation of the glans is the primary factor involved in the initiation of ejaculation (Senger, 2003). The scrotum protects the testes from mechanical injury and, in conjunction with the tunica dartos, cremaster muscle and pampiniform plexus, plays a major thermoregulatory role with respect to temperature sensitive, testicular spermatogenesis. In some species of wildlife (e.g. elephants and marine mammals), the testes are positioned intra-abdominally. Xenobiotics, which cause hyperthermia (i.e. ergopeptine alkaloids) or which induce fever, have the potential to adversely affect spermatogenesis.

***Spermatogenesis***

Spermatozoa are highly specialized haploid cells equipped with a self-powered flagellum to facilitate motility, as well as an acrosome to mediate penetration of the zona pellucida. Spermatogenesis takes place within the seminiferous tubules and consists of all the changes germ cells undergo in the seminiferous epithelium in order to produce adequate numbers of viable spermatozoa each day and to continuously replace spermatogonial stem cells (Thomas and Thomas, 2001; Senger, 2003). Spermatogenesis provides for genetic diversity and ensures that germ cells are in an immunologically favored site (Senger, 2003). The duration of spermatogenesis varies with species but generally ranges between 4 and 8 weeks (approximately 30–60 days) in domestic and laboratory animals and is approximately 75 days (almost 11 weeks) in humans. It is important to keep in mind the durations of spermatogenesis and epididymal sperm transport in a given species, as well as the normal, species-specific number of spermatozoa produced daily by the testes, when determining the period of toxicant exposure relative to the appearance of abnormal spermatozoa in an ejaculate and when assessing the severity and reversibility of toxicant-induced damage to sperm precursors within the testes.

Spermatogenesis can be subdivided into three phases or stages referred to as "proliferation", "meiosis" and "differentiation". During each of these phases, sperm precursors or male germ cells (spermatogonia, spermatocytes or spermatids) undergo specific, stepwise changes as they develop into spermatozoa which will eventually be released into the excurrent duct system. Each of these phases involves a different type of germ cell undergoing a different developmental process, and, as such, these phases have the potential to differ in their susceptibility to the mechanisms of action of various reproductive toxicants.

*Proliferation (mitosis or spermatocytogenesis)*

The "proliferation" phase of spermatogenesis has also been referred to as "mitosis" or "spermatocytogenesis" and occurs within the basal compartment of the seminiferous tubule. Proliferation denotes all of the mitotic divisions involving spermatogonia (Senger, 2003). A large number of B-spermatogonia result from the mitoses of several generations of spermatogonia (e.g. $A_1$, $A_2$, $A_3$, $A_4$ and I; some species variations in nomenclature) (Senger, 2003; Genuth, 2004b). Stem cell renewal is accomplished during proliferation by the reversion of some spermatogonia to more primitive germ cells (Senger, 2003). Germ cell mitosis during spermatogenesis ends with the transformation of B-spermatogonia into primary spermatocytes, and this process is particularly susceptible to toxicants, such as chemotherapeutic agents and radiation, which target rapidly dividing cells.

### Meiosis

"Meiosis" takes place within the adluminal compartment of the seminiferous tubules and involves the participation of primary and secondary spermatocytes in a total of two meiotic divisions. The chromosomal reduplication, synapsis and crossover, as well as cellular division and separation, which occur during this phase of spermatogenesis, are extremely complex and guarantee genetic diversity (Senger, 2003; Genuth, 2004b). The meiosis phase of spermatogenesis is considered by some to be most susceptible to toxic insult (Thomas and Thomas, 2001) and ends with the production of haploid round spermatids (Senger, 2003).

### Differentiation (spermiogenesis)

Spermatozoa have been aptly characterized as "sophisticated, self-propelled packages of DNA and enzymes" (Senger, 2003). "Differentiation" or "spermiogenesis" involves all the changes occurring within the adluminal compartment, which transform round spermatids into spermatozoa possessing an acrosome for penetration of the zona pellucida and a tail or flagellum to facilitate motility (Genuth, 2004b). Differentiation can be subdivided into the "Golgi", "cap", "acrosomal" and "maturation" phases, which correspond respectively to acrosomal vesicle formation; spreading of the acrosomal vesicle over the nucleus; elongation of the nucleus and cytoplasm and final assembly involving the formation of the post nuclear cap organization of the tail components (Senger, 2003). Following the nuclear and cytoplasmic reorganization which characterizes the changes to germ cells during spermiogenesis, differentiated spermatozoa are released from Sertoli cells into the lumen of the seminiferous tubules by a process referred to as "spermiation". The complex signaling pathways and genomic imprinting involved in regulating the differentiation of round spermatids into spermatozoa are potential targets for EDCs.

### The cycle of the seminiferous epithelium

In most sexually mature mammals, spermatozoa are produced continuously, with the entry of germ cells into the proliferation phase of spermatogenesis occurring in a coordinated cyclic manner (Genuth, 2004b). Spermatogonia A in a given region of the seminiferous tubule commit to proliferate in a synchronous manner, with cohorts of their progeny germ cells (cellular generations) connected by intercellular bridges and developing and differentiating in unison (Thomas and Thomas, 2001; Senger, 2003). Including spermatogonia A, four or five generations or concentric layers of sperm precursors are present in each cross-section of the seminiferous tubules (Figure 14.1) (Thomas and Thomas, 2001; Creasy and Foster, 2002; Senger, 2003). The cycle of the seminiferous epithelium in most mammals is characterized by germ cells in each spermatogenic phase associating with contiguous generations in a repeatable pattern of specific cellular associations or "stages" (Thomas and Thomas, 2001; França *et al.*, 2005). There is generally only one stage per seminiferous tubular cross-section in subprimates (França *et al.*, 2005), and each stage transitions into the next at predictable intervals (Senger, 2003). At any given point along a seminiferous tubule, the entire cycle of the seminiferous epithelium occurs over a set time interval closely associated with the spermatogonial turnover rate for that particular mammalian species (Thomas and Thomas, 2001; Creasy and Foster, 2002). The number and duration of the various stages of the cycle of the somniferous epithelium vary with species (Senger, 2003), and various classification schemes have been used, based on the morphological characteristics of the spermatid nucleus or the development of the acrosomic system (França *et al.*, 2005). In subprimates, sequential stages are arranged along the length of the seminiferous tubule in consecutive order, forming a "spermatogenic wave" (Creasy and Foster, 2002; Senger, 2003). The progeny of one spermatogonium A will progress through approximately 4.5 cycles of the seminiferous epithelium before being released into the lumen of the seminiferous tubule and progressing through the rete testis into the excurrent duct system (Thomas and Thomas, 2001). An understanding of the cycle of the seminiferous epithelium is very useful for the evaluation of the effects of xenobiotics on spermatogenesis and for the determination of populations of germ cells most susceptible to a given toxicant.

## *Male reproductive physiology*

### Gonadal steroid synthesis in the testes

The endocrine events which regulate spermatogenesis and sexual behavior in males are very distinct from those which take place in females (see below). The primary gonadal steroids produced by the testes are androgens [testosterone and DHT (also produced from testosterone in selected non-gonadal tissues)] and estrogens (primarily estradiol in most species), which are now recognized as playing essential roles in male reproductive development and function (O'Donnell *et al.*, 2001; Hess, 2003). Leydig cells in the interstitium synthesize pregnenolone and then progesterone from cholesterol and convert progesterone to testosterone under the influence of LH (Senger, 2003; Genuth, 2004b). The site of estrogen synthesis (i.e. aromatase activity) varies with the age and species of animal. In the male fetus, postnatal immature male and, in some species, the adult male, Sertoli cells within the seminiferous tubules play a major role in the aromatase-mediated conversion of testosterone to estradiol under the influence of FSH (O'Donnell *et al.*, 2001; Senger, 2003). In many mammals, Leydig cells in the fetal testis and, especially, the postnatal immature testis gradually

begin to synthesize estrogens, and, at sexual maturity, a major portion of the estrogens in these species is produced by aromatase activity in the Leydig cells, under the influence of LH rather than FSH (O'Donnell *et al.*, 2001; Hess, 2003). More recently, germ cells have been identified as another potential source of estrogens in the testis, and it is possible that germ cell-derived estrogens play major roles in regulating male reproductive function (Hess, 2003).

*Endocrine regulation of spermatogenesis*

While the female hypothalamus has both fully developed tonic and surge centers for GnRH release (especially prior to ovulation), the hypothalamic GnRH surge center in the male is diminished, and the anterior pituitary gland of the male does not experience surges in GnRH stimulation (Senger, 2003). This gender-specific alteration in the hypothalamus facilitates the normal endocrine milieu which maintains continuous spermatogenesis and stimulates normal sexual behavior (Figure 14.2). The tonic pulsatile release of GnRH induces the anterior pituitary to produce pulses of LH and FSH several times during the day and facilitates adequate LH-dependent testosterone production and, depending on the species, normal FSH-dependent Sertoli function, both of which are essential for spermatogenesis to occur continuously in the seminiferous tubules (Senger, 2003; Genuth, 2004b). In some species, FSH is primarily required for the onset of puberty and the initiation of spermatogenesis, with many of the functions of FSH in the immature male being taken over by testosterone in the sexually mature animal (Creasy and Foster, 2002).

Testosterone stimulates Sertoli cells to produce several androgen-regulated proteins, including androgen-binding protein, which are required for spermatogenesis (Creasy and Foster, 2002; Senger, 2003). Interference with this testosterone-mediated effect by antiandrogens (e.g., vinclozolin) which prevent interactions between testosterone and the androgen receptor or by the inhibition of testosterone synthesis by excessive glucocorticoids (e.g., chronic stress, alterations in endogenous glucocorticoid metabolism or the administration of xenobiotics with glucocorticoid-like activities) has the potential to adversely affect Sertoli cell function, and, therefore, spermatogenesis. Estrogens are required for various aspects of the normal development and function of Sertoli cells and germ cells within the seminiferous tubules (O'Donnell *et al.*, 2001; Hess, 2003). Xenobiotics which mimic or inhibit the actions of estradiol within the testis can disrupt normal spermatogenesis.

*Positive and negative feedback loops involved in male reproduction*

Positive and negative feedback mechanisms help maintain an endocrine environment which if conducive to normal male reproductive function (Figure 14.2). The Sertoli cell can produce activin and inhibin which respectively

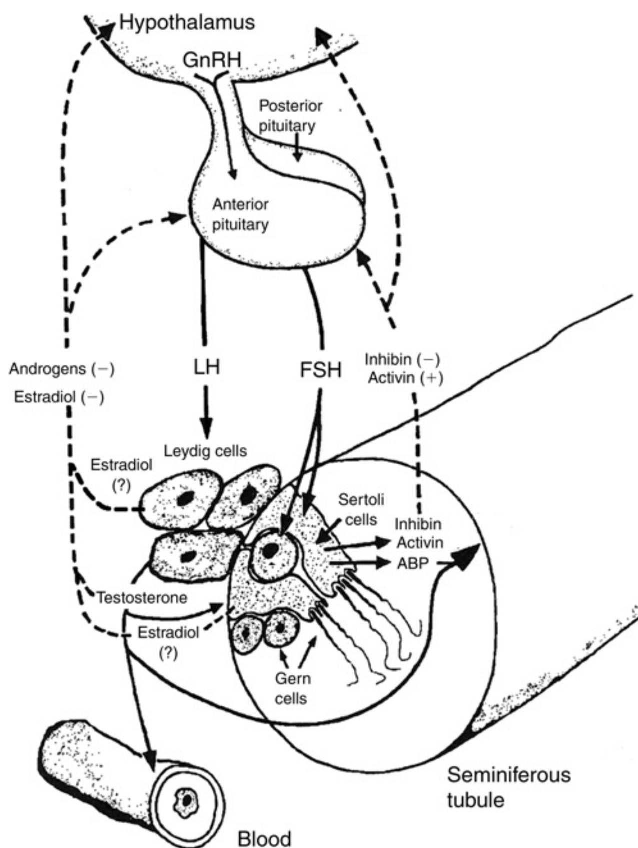

**FIGURE 14.2** The relationship between the tubular and the interstitial compartments of the testicular parenchyma and the endocrine regulation of testicular function in mammalian species is shown. Solid lines indicate positive feedback mechanisms, and dashed lines denote negative feedback pathways. The question mark associated with the production of estradiol by the Sertoli cells and Leydig cells is used to indicate that this hormone, as well as other estrogens, can be produced in the testis by either primarily Sertoli or Leydig cells, depending on the species and stage of development. Although not shown, it should be kept in mind that DHT also provides negative feedback to the hypothalamus and anterior pituitary and germ cells can also aromatize testosterone and produce estradiol. This figure was adapted, with permission, from Garner DL, Hafez ESE (2000) In *Reproduction in Farm Animals*, 7th edn, Hafez ESE, Hafez B (eds). Lipincott, Williams & Wilkins, Philadelphia (modifications courtesy of Don Connor and Howard Wilson).

increase and decrease the secretion of FSH by gonadotropes and, in some species, GnRH release from the hypothalamus (Creasy and Foster, 2002). Testosterone, DHT and estradiol all provide negative feedback to the hypothalamus with respect to GnRH release, and testosterone can also directly inhibit LH secretion by gonadotropes (Creasy and Foster, 2002; Senger, 2003). Xenoestrogens and xenoandrogens have the potential to disturb the hypothalamic–pituitary–gonadal axis (O'Donnell *et al.*, 2001). It is currently thought that antiandrogens and a variety of other xenobiotics can interfere with these feedback loops and possibly other endocrine pathways, resulting in Leydig or interstitial cell hyperplasia (O'Connor *et al.*, 2002; Thomas and Thomas, 2001).

*Epididymal and accessory sex gland function*

Epididymal development and function are dependent on the proper balance of androgenic and estrogenic stimulation and are required for normal male reproductive function and fertility. The accessory sex glands are considered to be primarily androgen dependent, and the secretions of these glands, as well as those of the epididymidis are important components of seminal fluid. Conversion of testosterone to DHT can generally occur in the epididymidis, prostate and seminal vesicles. Hormonally active xenobiotics which alter the normal endocrine events associated with epididymal and accessory gland development and function can have adverse effects on male fertility.

*Sexual behavior, erection, emission and ejaculation*

Sexual behavior is mediated by estradiol in postnatal males and females. The conversion of the steadily produced testosterone in the male to estradiol in the brain (plus the effects of estrogens of testicular origin) results in the male being sexually receptive most of the time (Senger, 2003). Adequate libido and sexual receptivity, as well as adequate concentrations of testosterone, are necessary for erection of the penis, which is required for intromission during copulation (Sikka *et al.*, 2005). Olfactory (detection of pheromones), auditory and visual stimuli play roles in facilitating cholinergic and NANC (non-adrenergic/non-cholinergic) parasympathetic neuron-mediated penile erection, which, depending on the species, involves various degrees of nitric oxide-associated vasodilation and vascular engorgement (Senger, 2003; Sikka *et al.*, 2005). During copulation, the events which lead to emission of the secretions of the accessory sex glands and the ejaculation of spermatozoa generally involve tactile stimuli to the glans penis (Senger, 2003) and stimulation by sympathetic neurons (Sikka *et al.*, 2005).

## Normal female reproductive anatomy and physiology

### *Reproductive anatomy of the female*

Although there are some distinct morphological differences between species (e.g. simplex uterus in primates, duplex cervices in rabbits), the female reproductive tract generally consists of paired ovaries and the "tubular genitalia", which include the paired oviducts (uterine tubes) and uterine horns contiguous with a uterine body and cervix, vagina, vestibule and vulva (Senger, 2003; Evans *et al.*, 2007). The organs involved in female reproductive function are physiologically and morphologically dynamic and function to produce the oocyte, facilitate its fertilization, provide an environment for embryonic and fetal development, and transport the fetus from the maternal to the external environment. Variations in size, appearance, location and function of the female reproductive organs depend on the endocrine milieu dictated by the effects of sexual maturation, stage of the estrous or menstrual cycle, gestational hormone production of maternal, fetal and/or placental origin, exposure to exogenous HAAs and seasonal influences (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007).

The primary functions of the ovary are oogenesis [production of female gametes (oocytes or ova)] and steroidogenesis (production of estrogens and progesterone). The ovaries of most domestic mammals consist of a peripheral parenchymatous zone (cortex), containing various stages of follicular and luteal gland development and a central vascular zone (medulla), comprised of collagenous connective tissue rich in blood vessels (Senger, 2003) (Figure 14.3). The structural and functional unit of the ovary is the follicle. Follicles are classified as primordial, primary (some become atretic), secondary and tertiary (antral) follicles based on their stage of development (Evans *et al.*, 2007).

A primary oocyte surrounded by a single, flattened cell layer is a primordial follicle. A basal lamina separates the single layer of what will become granulosa cells from the adjacent stromal tissue which eventually develops into the theca cells (theca interna and theca externa). The granulosa cells homologous to the Sertoli cells in the testis, and the theca interna cells are the female equivalent of the Leydig cells (Senger, 2003). Following the appropriate endocrine stimulation, primordial follicles are recruited to undergo possible further differentiation into estrogen-producing antral follicles and ultimately ovulation, which results in the release of a secondary oocyte (primary oocyte in dogs) and formation of a corpus luteum (CL) which produces progesterone (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007).

### *Female reproductive physiology*

Females are born with a finite pool of primordial follicles (up to hundreds of thousands), and reproductive cyclicity (i.e. estrous or menstrual cycles) provides females with repeated opportunities for the establishment of pregnancy. The majority of mammalian species (subprimates) have estrous cycles, which reflect the physiological changes occurring between successive ovulations and/or periods of sexual receptivity (estrus) (Senger, 2003). Humans and non-human primates experience menstrual rather than estrous cycles and don't have defined periods of sexual receptivity (i.e. estrus). Unlike the estrous cycles in subprimates, the reproductive cycle in menstruating animals is divided into phases (i.e. menses, proliferative and secretory phases), which are defined based on the physiological state of the uterine endometrium, rather than on the predominant ovarian structures (Senger, 2003; Genuth, 2004b).

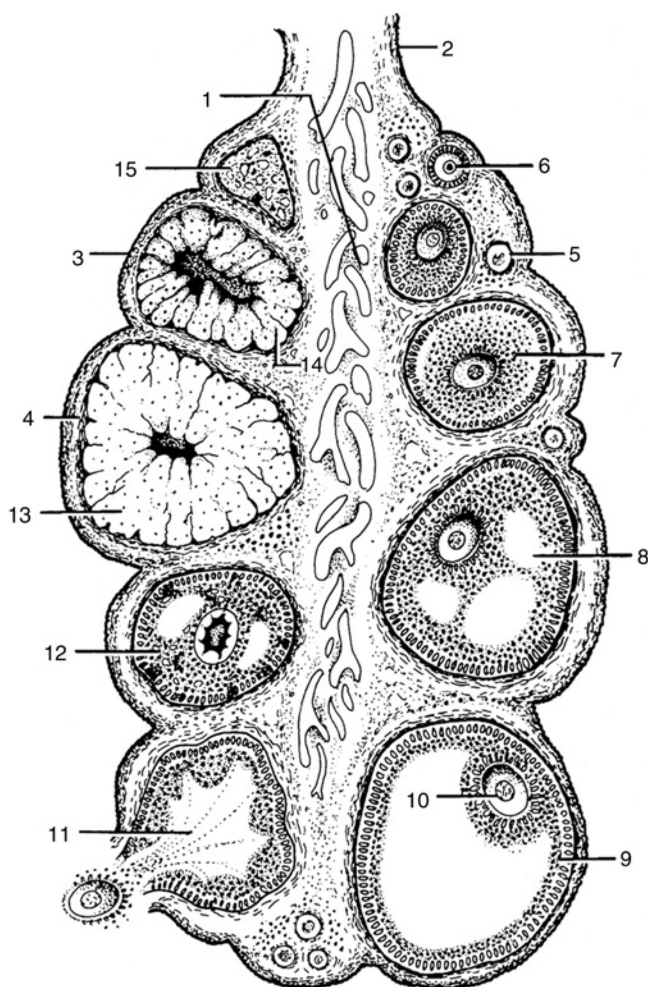

**FIGURE 14.3** Although there is some interspecies variation with respect to ovarian structure, a schematic representation of a "typical" mammalian ovary is shown to demonstrate the major ovarian structures: (1) medulla; (2) mesovarium; (3) surface epithelium; (4) tunica albuginea, which is poorly developed in the ovary as compared to the testis; (5) primordial follicle; (6) primary follicle; (7) secondary follicle; (8) early tertiary or antral follicle; (9) mature antral follicle; (10) oocyte; (11) ruptured follicle and ovulated secondary oocytes (except for the dog); (12) atretic follicle; (13) CL; (14) atretic CL; (15) corpus albicans. This figure was adapted, with permission, from Dyce *et al.* (2002) (modifications courtesy of Don Connor and Howard Wilson).

*The estrous cycle*

The follicular and luteal phases of the estrous cycle describe the predominant ovarian structures and the corresponding gonadal steroid concentrations which result from the follicular secretion of estrogens or the luteal secretion of progesterone, respectively (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007). Both the follicular and luteal phases can generally be further subdivided into two stages each, proestrus and estrus (sexual receptivity) for the follicular phase and metestrus and diestrus (sexual non-receptivity) for the luteal phase (Senger, 2003). Proestrus represents the period of transition from the diestrus dominance of progesterone to the dominance of estrogens during estrus, while metestrus represents the opposite shift in the endocrine milieu (estrogen dominance to progesterone dominance) (Senger, 2003; Evans *et al.*, 2007).

The durations of the various stages of the estrous cycle vary with species and can, depending on the animal in question, either occur throughout the year, multiple times within an ovulatory season that is dependent on photoperiod (long-day or short-day polyestrous animals) or only once a year (Senger, 2003). The domestic bitch does not have a metestrus and, in fact, is actually most receptive to copulation when estradiol is declining and there is a unique, preovulatory surge in progesterone. This endocrine environment predisposes the bitch to cystic endometrial hyperplasia and pyometra following exposure to some xenoestrogens and progestins. Felids, which are induced (reflex) ovulators, like ferrets, mink, camelids and rabbits, the period of time following an estrus in which copulation has not occurred has been described as post-estrus rather than metestrus because there is no increase in progesterone secretion following the end of sexual receptivity (Senger, 2003). Anestrus is the time period during which reproductive cyclicity ceases and can be seasonal (estradiol and progesterone production are at basal levels) or can be associated with various endocrine milieus related to species of animal, pregnancy, lactation, stress and/or pathological conditions, some of which can be induced by xenobiotics.

*Follicular development*

The general sequence of endocrine and morphological changes occurring during the estrous cycle involves a variety of positive and negative feedback loops affecting the hypothalamic–pituitary–gonadal axis and leads to the development of antral follicles, the primary source of estrogens, and, eventually, the formation of corpora lutea, which produce progesterone (Figures 14.3 and 14.4). During the time of year when females are exhibiting reproductive cyclicity, there are cyclic alterations in the pattern of hypothalamic GnRH secretion from the tonic and surge centers, which interact with the anterior pituitary to influence the relative amounts of FSH and LH secreted by anterior pituitary gonadotropes. Over the course of the ovulatory season, many (up to several hundred or more) primordial follicles leave the reserve pool in a cyclic fashion (under the influence of FSH) and enter the active pool of follicles (primary follicles) undergoing growth and differentiation (folliculogenesis) and eventually atresia or ovulation (Senger, 2003; Evans *et al.*, 2007). The oocyte in the developing follicle grows in size, the zona pellucida is formed and the granulosa cells surrounding the oocyte undergo mitosis and further differentiation

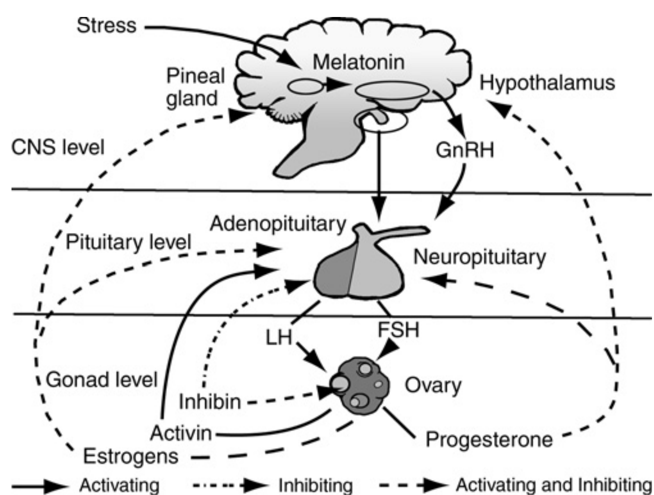

**FIGURE 14.4** The endocrine regulation of ovarian function and the feedback loops for the hypothalamic–pituitary–gonadal (ovarian) axis in the female are depicted. This figure was adapted, with permission, from Wilker and Ellington (2006) (modifications courtesy of Don Connor and Howard Wilson).

(Senger, 2003). A primary follicle is transformed into a secondary follicle when there are several layers of granulosa cells. Preantral follicles (primary and secondary follicles) become antral (tertiary) follicles, when fluid from the granulosa cells of secondary follicles coalesces to form an antrum (Evans *et al.*, 2007).

Cyclic increases in FSH concentrations facilitate recruitment antral follicles. Granulosa cells can produce activin which is thought to provide positive feedback to the anterior pituitary, further increasing gonadotropic FSH secretion (Figure 14.4) (Senger, 2003; Wilker and Ellington, 2006). Recruited antral follicles, which are gonadotropin sensitive, undergo several waves of follicular development beginning in metestrus and ending in proestrus (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007). The final wave of one or more dominant follicles, destined for ovulation, rather than atresia, produces the large amounts of estrogens typical of estrus and required for sexual receptivity and the preovulatory estrous surges in GnRH and LH secretion (Senger, 2003).

*Ovarian follicular synthesis of estrogens*

The production of estrogens (predominantly estradiol) by antral follicles is accomplished by a mechanism termed the "two-cell or two-gonadotropin model", which can vary somewhat between species (Senger, 2003; Evans *et al.*, 2007). Cells from the theca interna and/or granulosa cells (depending on the species) produce progesterone from pregnenolone synthesized from cholesterol and, under the influence of relatively low concentrations of LH, theca interna cells convert this progesterone into androgens and, ultimately, testosterone (Evans *et al.*, 2007). In granulosa cells (reportedly theca interna cells in some species), the release of FSH from the anterior pituitary induces aromatase-mediated conversion of testosterone produced in the theca cells into estradiol (Senger, 2003; Evans *et al.*, 2007). Stimulation of aromatase activity by xenobiotics can have an overall estrogenic effect on exposed animals (increased production of estradiol).

*The effects of estrogenic feedback on the hypothalamic–pituitary–gonadal axis*

Increasing concentrations of estrogens associated with estrus alter the hypothalamic GnRH secretory pattern and decrease pituitary secretion of FSH, while greatly increasing the amount LH produced and released by the anterior pituitary gland (preovulatory LH surge) (Senger, 2003; Evans *et al.*, 2007). Although inhibin produced by granulosa cells further decreases FSH secretion, dominant follicles surviving to estrus do not undergo atresia because of an enhanced sensitivity to basal FSH levels (Senger, 2003; Wilker and Ellington, 2006). Xenoestrogens have the potential to either imitate or inhibit these estradiol feedback mechanisms in sexually mature females, depending on amount estrogenic xenobiotic, the endocrine milieu at the time of the exposure and the relative binding affinity of the xenobiotic for ERs.

*Ovulation*

The granulosa cells in the one or more dominant estrous follicles (Graafian follicles) cease to divide shortly prior to ovulation and undergo further differentiation, with increased numbers (upregulation) of LH receptors which will be responsive to the estrogen-induced preovulatory LH surge (Senger, 2003; Evans *et al.*, 2007). As LH increases, granulosa cells (theca interna cells in some species) continue to convert pregnenolone to progesterone, but estradiol production decreases, resulting in a slight preovulatory decline in estradiol (Evans *et al.*, 2007). The preovulatory LH surge is associated with increased follicular pressure, degeneration of theca cells and weakening of the follicular wall, completion of the first meiotic division within the oocyte (end of meiotic inhibition except in dogs and foxes) and, finally, ovulation of a secondary oocyte arrested in metaphase II (Senger, 2003; Evans *et al.*, 2007). In felids, ferrets, mink, camelids and rabbits, the preovulatory LH surge is induced by copulation (intromission or vaginal stimulation in most induced ovulators; seminal fluid in camelids). Toxicants which interfere with copulation or sexual contact in these species can interfere with the ovulatory process.

*Formation and function of a CL*

Following ovulation, a cascade of endocrine changes takes place in the female subprimate which facilitates the

transition from sexual receptivity to non-receptivity. Once an ovulation occurs, blood concentrations of follicular estradiol and inhibin return to their basal levels, and granulosa cells continue their growth, differentiation and increased production and release of progesterone (luteinization) under the influence of LH (Evans *et al.*, 2007). The functional ovarian structure which eventually develops from each ovulated follicle is a CL, which is comprised of large and small luteal cells derived form the granulosa and theca interna cells (granulosa cells in horses), respectively (Senger, 2003; Evans *et al.*, 2007). In most species, luteal cells are responsive to LH and produce progesterone until, shortly before the usual end diestrus in non-pregnant animals, the CL undergoes luteolysis mediated by oxytocin-stimulated production of prostaglandins $F_{2\alpha}$ ($PGF_{2\alpha}$) (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007). While luteolysis is an intraovarian event in primates, oxytocin-stimulated endometrium produces the luteolysin ($PGF_{2\alpha}$) in subprimates (Senger, 2003). Xenobiotics, which can cause endometritis or mimic the actions of oxytocin or $PGF_{2\alpha}$ [e.g. endotoxin or lipopolysaccharide (LPS)] can be associated with premature luteolysis. Conversely, toxicants with the opposite oxytocin/$PGF_{2\alpha}$-related effects would be expected to disrupt normal reproductive cyclicity by prolonging the lifespan of the CL and causing a prolonged diestrus or pseudopregnancy (e.g. xenoestrogens in swine).

Species of animals can vary in the number of fertile ovulations and, therefore, CLs, which are characteristically associated with each estrous cycle. Monotocous mammalian species usually only ovulate a single secondary oocyte each estrous cycle. The ovaries of litter-bearing (polytocous) mammals generally develop multiple follicles which mature, ovulate and form functional CLs.

#### *Summary of the effects of estrogens and progesterone during the female reproductive cycle*

The endocrine changes which occur during the estrous cycle are reflected in behavior and the size, morphology, position and function of the tubular genitalia. Estrogens have a multiple effects on the female reproductive tract with include: the previously discussed interactions with the hypothalamus and anterior pituitary to alter the patterns GnRH and gonadotropin secretion, which govern follicular development and ovulation; facilitation of sexual receptivity; increased blood flow, genital swelling, leukocytosis, mucosal secretion and myometrial tone; altered tissue electrical conductivity and initiation of the growth of endometrial and mammary glands (Senger, 2003). Like estrogens, progesterone also has several effects on the reproductive tract of the female, but the effects of progesterone generally oppose those of estrogens, favoring pregnancy maintenance and sexual non-receptivity over ovulation and appropriately timed sexual receptivity associated with estrogenic stimulation (Ginther, 1992; Senger, 2003; Evans *et al.*, 2007). Progesterone is generally associated with negative feedback to the hypothalamus and anterior pituitary gland which limits GnRH and gonadotropin secretion (Senger, 2003; Evans *et al.*, 2007). Sexual receptivity and myometrial contractility and tone are diminished in an endocrine environment dominated by progesterone, while mammary and endometrial gland development and secretion are promoted (Senger, 2003). Toxicants which disrupt the communication and coordination between the ovary and the other parts of the reproductive tract (e.g. xenoestrogens, xenoandrogens and antiestrogens) will alter the appearance and function of the reproductive organs and can interfere with survival of the oocyte, embryo and/or fetus.

## Oocyte/sperm transport, normal capacitation of sperm and fertilization

### *Transport of the ovulated oocyte*

The primary reproductive organs involved in the transport of ovulated secondary oocytes (primary oocytes in the bitch) are the oviducts or uterine tubes. Each oviduct consists of an infundibulum, isthmus and ampulla, which have some distinct differences in structure, as well as function (Evans *et al.*, 2007). The ovulated ovum enters the funnel-like opening to the infundibulum and is transported through the isthmus to the ampulla or ampullary–isthmic junction for fertilization. Unlike spermatozoa which can generally survive for several days in the oviduct, secondary oocytes usually, depending on the species, are viable for 12–24 h (Genuth, 2004b). The appropriate endocrine environment is required for adequate oviductal entry and transport of ovulated oocytes to the site of fertilization. Delayed transport of oocytes within the uterine tubes can result in the death of ova before contact can be made with fertile spermatozoa.

### *Transport and capacitation of spermatozoa*

#### *Transport of spermatozoa*

During mammalian copulation, mature sperm stored in the caudae epididymidies travel through the vas deferens and penile urethra to be ejaculated into the anterior vagina, cervix or uterine body of the female reproductive tract, depending on the species. Spermatozoa can be lost from the female reproductive tract by retrograde loss and phagocytosis by leukocytes (Senger, 2003). Contractions of the smooth muscle within the tubular genitalia (muscularis), as well as interactions involving components of the seminal fluid and luminal secretions of the female reproductive tract, facilitate the transport of sperm to the oviducts (uterine tubes) where, depending on the species, fertilization takes place in the ampulla or at the junction

of the ampulla and the isthmus (ampullary–isthmic junction) (Senger, 2003; Genuth, 2004b). While sperm can be rapidly transported to the ampullary–isthmic junction or ampullae of the oviducts within minutes of natural or artificial semination, the relatively slow, sustained transport of motile sperm from reservoirs of spermatozoa in the cervix and uterotubal junctions is the primary mechanism by which the viable sperm that can participate in fertilization actually enter the oviducts (Senger, 2003). Xenobiotics which interfere with the endocrine milieu required for appropriate muscularis contractility and the cervical and uterine mucosal secretions which facilitate sperm transport (e.g. phytoestrogens) can prevent spermatozoa from getting to the site of fertilization in a timely manner.

#### *Capacitation of spermatozoa*

Spermatozoa can generally survive in the oviducts for several days following insemination. Ejaculated sperm are not competent to either bind to the zona pellucida or to undergo the acrosomal (acrosome) reaction, both of which are required for fertilization of ova by mature spermatozoa. Sperm must be capacitated in order interact with the ovum. The capacitation process involves calcium influx and biochemical changes to the sperm plasma membrane which result in the "removal" or modification of epididymal and seminal plasma proteins and the exposure of the surface molecules required for spermatozoal binding to the zona pellucida of the ovulated secondary oocyte (Senger, 2003; Genuth, 2004b). Depending on the species and, to some extent, the site of their deposition, spermatozoa become capacitated within the cervix, uterus and/or the oviduct (Senger, 2003).

### *Fertilization*

Fertilization of secondary oocytes by capacitated sperm is a complex process involving a cascade of events which prevents fertilization of an ovum by more than one sperm (polyspermy) and ends in the fusion of the male and female pronuclei (syngamy) (Senger, 2003). In the oviductal ampulla or at the ampullary–isthmic junction, the motility of capacitated sperm becomes hyperactive, facilitating the precise sequence of events which includes the following in their respective order: (1) sperm binding to the zona pellucida of the oocyte involving interactions between species-specific sperm and oocyte proteins; (2) the sperm acrosomal reaction, which results in the release of acrosomal enzymes and exposure of the equatorial segment of the sperm plasma membrane; (3) acrosomal enzyme-associated penetration of zona pellucida by a single spermatozoon; (4) fusion of the plasma membrane of the sperm at its equatorial segment with the plasma membrane of the oocyte; (5) membrane fusion-associated sperm engulfment and the oocyte cortical reaction, which prevents additional oocyte zona binding and membrane fusion (i.e. polyspermy prevention); female pronucleus formation and completion of meiosis; decondensation within the sperm nucleus and male pronucleus formation and, finally, the fusion of male and female pronuclei or syngamy which produces a zygote ready to undergo embryogenesis (Senger, 2003; Genuth, 2004b). From the complexity of the fertilization process, it be apparent that toxicants which result in subtle aberrations in sperm and oocyte formation and maturation can have profound effects on gamete function.

## The endocrinology of pregnancy and placentation

### *Gestational hormones*

Pregnancy begins with fertilization of the oocyte within the oviduct, followed by the first cleavage of the zygote, and terminates with parturition. Although the endocrine physiology and duration of mammalian pregnancy are very species specific and are characterized by a great deal of interspecies variation, the overall goals during the entire gestation for all pregnant mammals, their embryo(s) and, eventually, the maternal–fetal–placental unit are the same. A uterine environment conducive to embryonic and fetal development must be facilitated and the pregnancy (pregnancies in multitocous animals) must be maintained for the entire normal gestational length. The primary hormones involved in establishing the proper uterine environment and maintaining pregnancy are progesterone secreted by the maternal ovary and/or the placenta, as well as, in some species, a variety of placental progestins. In addition, a variety of other endogenous hormones of maternal, fetal and/or placental origin (depending on the species and gender of the offspring), including androgens, estrogens, prolactin, placental lactogen, equine and human chorionic gonadotropins (eCG and hCG, respectively) and relaxin, also have important gestational functions. Normal embryonic and fetal development require that gestational hormones, especially endogenous androgens and estrogens, be synthesized and secreted in sufficient quantities and at the appropriate time during pregnancy. The proper reproductive development of the female fetus is primarily dependent on exposure to estrogens at specific times during gestation. However, the male fetus must have appropriately timed exposure to normal amounts of both androgens and estrogens for normal development of the reproductive tract and optimal adult reproductive performance (Hess, 2003). Depending on the timing of exposure, EDCs, especially those which function as gonadal steroid receptor agonists and antagonists, can potentially interfere with normal gestational signaling and sexual differentiation.

### *Maternal recognition of pregnancy*

The embryo generally enters the uterus several days after fertilization. One of the first endocrine events which must occur in most mammalian species, other than those for which the timing of luteolysis and duration of pregnancy are very similar to one another (i.e. dogs and cats), is the prevention of luteolysis (i.e. entry into the next estrus or period of sexual receptivity) and the maintenance of luteal phase progesterone concentrations (Senger, 2003; Evans *et al.*, 2007). The mechanism for this embryo–endometrium interaction in subprimates (intraovarian event in primates), also referred to as "maternal recognition of pregnancy", has been elucidated in several species and involves embryonic production of species-specific interferon-$\tau$ in ovine and bovine species (o-IFN-$\tau$ and b-IFN-$\tau$, respectively), estradiol secretion by porcine embryos, intrauterine embryonic migration in equids and placental chorionic gonadotropin (hCG) in humans (Senger, 2003; Genuth, 2004b). The timing of "maternal recognition of pregnancy" is species specific and in subprimates generally corresponds to the time period spanning the normal oxytocin-mediated synthesis and release of $PGF_{2\alpha}$ by the endometrium, as well as transport of the luteolysin to the ovary. Xenobiotics which interfere with embryonic and, in the case of humans, placental development or those toxicants which mimic the actions of the luteolysin (e.g. endotoxin) can terminate early pregnancies. Some species of mammals, such as dogs, cats, camelids, goats, swine and rabbits, depend solely on luteal progesterone secretion for the maintenance of pregnancy (Senger, 2003). The placenta takes over progesterone-associated pregnancy maintenance in sheep at approximately 50 days post-conception and between the 6th and 8th month of gestation in cattle (Senger, 2003). The uterofetoplacental unit of the mare begins to produce a unique assortment of progestins classified as 5$\alpha$-pregnanes, beginning at about day 70 of pregnancy (Ginther, 1992; Evans *et al.*, 2007). A number of toxicants (e.g. ergopeptine alkaloids) have been found to interfere with normal progestin metabolism in the mare (Evans, 2002).

### *Placentation*

Most mammalian species are "eutherian" and, during pregnancy, form a placenta comprised of both fetal and maternal components, which acts as an attachment between the fetal and the maternal systems, functions as a transient endocrine organ and plays essential roles in the exchange of gases, nutrients and metabolic wastes between the maternal and the fetal circulations (Ginther, 1992; Senger, 2003). The yolk sac, chorion, amnion and allantois are the extraembryonic membranes formed by the pre-attachment mammalian embryo (Senger, 2003). While the yolk sac in most mammalian species normally undergoes regression, the allantois and chorion generally fuse to form the allantochorion, and the fluid-filled amnion provides a shock absorbing, aquatic environment to facilitate fetal development and transport (Ginther, 1992; Senger, 2003). The allantochorionic membrane is the fetal contribution to the placenta and the chorionic villi are the structures which interdigitate with the maternal endometrium (Senger, 2003).

#### *Types of placentas*

Mammalian placentation can be classified according to the degree of intimacy between the maternal and the fetal circulations (i.e. the number of tissue layers separating maternal and fetal blood) and by the pattern of distribution of the chorionic villi on the surface of the placenta facing the maternal endometrium (Senger, 2003). Epitheliochorial placentas (placentae) have a total of six layers separating the maternal and fetal circulations and are observed in variety of species, including equids and swine. Ruminant placentation is described as syndesmochorial because of the transient erosion and regrowth of the maternal epithelium, which results in the intermittent exposure of maternal endothelium (capillaries) to chorionic epithelium (Senger, 2003). Canine and feline placentas are classified as endotheliochorial, and the hemochorial placentation observed in rodents and primates has essentially only chorionic epithelium separating the maternal blood from that of the fetus. The placenta of each species is associated with a typical distribution of the chorionic villi, classified as being either diffuse (e.g. equids and swine), cotyledonary (e.g. ruminants), zonary (e.g. dogs and cats) or discoid (e.g. rodents and primates). Some species, such as the rabbit, have variations in their placentation over the course of gestation, and what begins as an epitheliochorial placenta has transformed into an endotheliochorial type of placentation by the end of pregnancy (Rozman and Klaassen, 2001).

#### *Placental function*

In multitocous species, each fetus has its own placenta, with the previously described endocrine functions, which "attaches" the fetus to the endometrium and facilitates the exchange of gases, nutrients, metabolic wastes and xenobiotics between the fetal and the maternal circulations. Although the term "implantation" is frequently used to describe the appropriately timed attachment of the placental membranes to the endometrium, only the conceptuses of rodent and primate species undergo true implantation (Senger, 2003). Placental exchange involves the processes of simple (passive) diffusion, facilitated diffusion and active transport, as well as pinocytosis and phagocytosis of some nutrients (Senger, 2003).

The passage of materials across the placenta has been traditionally thought of as primarily a function of the intimacy (i.e. number of tissues layers) between the maternal and the fetal circulations, especially with respect to maternal immunoglobulins which cross hemo- and endotheliochorial

placentas but not those types placentae having more layers. However, since most xenobiotics cross the placenta by simple diffusion, it is currently thought that molecular size and solubility are the most important determinants of the ability of potential teratogens in the maternal circulation to cross the placenta into the fetal circulation (Rozman and Klaassen, 2001; Senger, 2003). Some toxic xenobiotics can be actively transported by mechanisms intended for structurally similar endogenous molecules (Rozman and Klaassen, 2001), and it is thought that transplacental transport of lead can mimic that of calcium (Evans *et al.*, 2003).

*The "placental barrier"*

Because the placenta "blocks" the ability of very large molecules to cross from the maternal circulation into the fetal circulation, the term "placental barrier" has been used to describe this protective function of the placenta. Given that a large number of potential toxicants diffuse across the placenta and reach the fetus, the term "barrier" might be somewhat of a misnomer. However, multidrug resistance protein and enzymes involved in biotransformation of xenobiotics have been found in the placenta (Rozman and Klaassen, 2001), and regardless of its relative inefficacy as a "barrier" between the maternal and fetal circulations, with respect to at least some xenobiotics, the nutritional and endocrine functions of the placenta are essential for successful completion of the mammalian pregnancies. Placental toxicity will be discussed in much greater detail in Chapter 15.

## Normal embryonic and fetal development

### *Blastocyst formation and differentiation of the germ cell layers*

In order for a zygote to develop into a viable offspring, multiple steps involving cellular division, migration, differentiation and organization must take place. Embryonic and fetal survival requires that these various steps take place in a precise order and at set times during the gestation of each species. Within 24 h following fertilization, the zygote located in the oviduct begins to divide, within the confines of the zona pellucida, into multiple blastomeres, which ultimately form a ball of cells referred to as the morula (Ginther, 1992; Senger, 2003). A fluid-filled cavity (blastocoele) develops, and the newly formed blastocyst, which is divided into cells forming either the inner cell mass (future embryo proper) or the trophoblast (future chorion), enters the uterus (Senger, 2003). The blastocyst undergoes rapid growth and "hatches" from the zona pellucida. The subsequent cellular division and differentiation results in the formation of the three germ layers (i.e. endoderm, mesoderm and ectoderm), which are destined to develop into the embryonic tissues forming the various organs and body systems, as well as the extraembryonic membranes involved in placental formation and attachment (Ginther, 1992; Senger, 2003). Germ layer differentiation leads to organogenesis and the transformation of an embryo into the fetus which continues to grow and develop for the remainder of pregnancy. With respect to reproductive toxicity in non-rodent mammals, the organogenic and other developmental processes occurring during the first trimester of pregnancy are especially susceptible to the teratogenic effects of xenobiotics. The abnormalities induced by a teratogen are dependent on the specific developmental processes or signaling pathways targeted by that toxicant and the timing of the exposure.

### *Sex determination and sexual differentiation of reproductive function*

*Genotypic sex and development of the primitive sex cords*

The genotypic sex of a mammalian conceptus is determined at fertilization by the sex chromosome (X or Y) contributed by the sperm, which, in combination with the X chromosome in the ovum, denotes either a genotypically female (XX) or a male (XY) zygote. During early gestation in most species, the primordial germ cells arise from the epithelium of the embryonic yolk sac and migrate through the developing mesentery to the gonadal (genital) ridge (testicular or ovarian anlage) in its position contiguous with the mesonephros (Senger, 2003; Evans *et al.*, 2007). Germ cells and stimulated somatic cells proliferate and organize into primitive sex cords within undifferentiated (bipotential) gonads, which have the potential to develop into either ovaries or testes (Senger, 2003; Basrur, 2006).

*Gonadal sex determination and phenotypic sexual differentiation*

Development of a phenotypically male or female mammalian fetus occurs during the first trimester of pregnancy in most species and consists of the determination of gonadal sex followed by the further development and differentiation of either the mesonephric or the paramesonephric ducts and regression of the other duct system. The selection of the mesonephric or paramesonephric ducts for retention and further differentiation results in the formation of genitalia (phenotypic sex) appropriate for either the male or female gonads, respectively (Genuth, 2004b). Gonadal sex determination and phenotypic sexual differentiation are dependent on complex and carefully timed signaling events and are extremely susceptible to disruption by xenobiotics. Toxicants which alter epigenetic programming or mimic or inhibit endogenous hormones can have potentially deleterious effects on sexual development (Basrur, 2006). Xenobiotic-induced abnormalities in phenotypic sexual differentiation can arise from defects in testicular formation, defects in androgen production and defects in androgenic action (Basrur, 2006; Hughes *et al.*, 2006). While some toxicant-induced abnormalities in sexual

differentiation can be very obvious [e.g. hermaphroditism (presence of ovotestes), pseudohermaphroditism (differences in gonadal and phenotypic sex), hypospadias (feminized external genitalia; failure of urethral fold fusion) and cryptorchidism (failure of testicular descent)], other, more subtle effects can be related to functional rather than structural abnormalities. In order to identify the steps in gonadal sex determination and phenotypic sexual differentiation most likely to be targeted by the effects of EDCs and other reproductive toxicants, it is important to understand how these processes are initiated within the fetus and how they impact subsequent fetal development.

For the last several decades, the model for gonadal sex determination and phenotypic sexual differentiation has been based on the premise that a "testis determining factor" (TDF) on the Y chromosome dictates that a gonad differentiates into a testis and initiates the cascade of endocrine changes (Figure 14.5) which results in a phenotypically

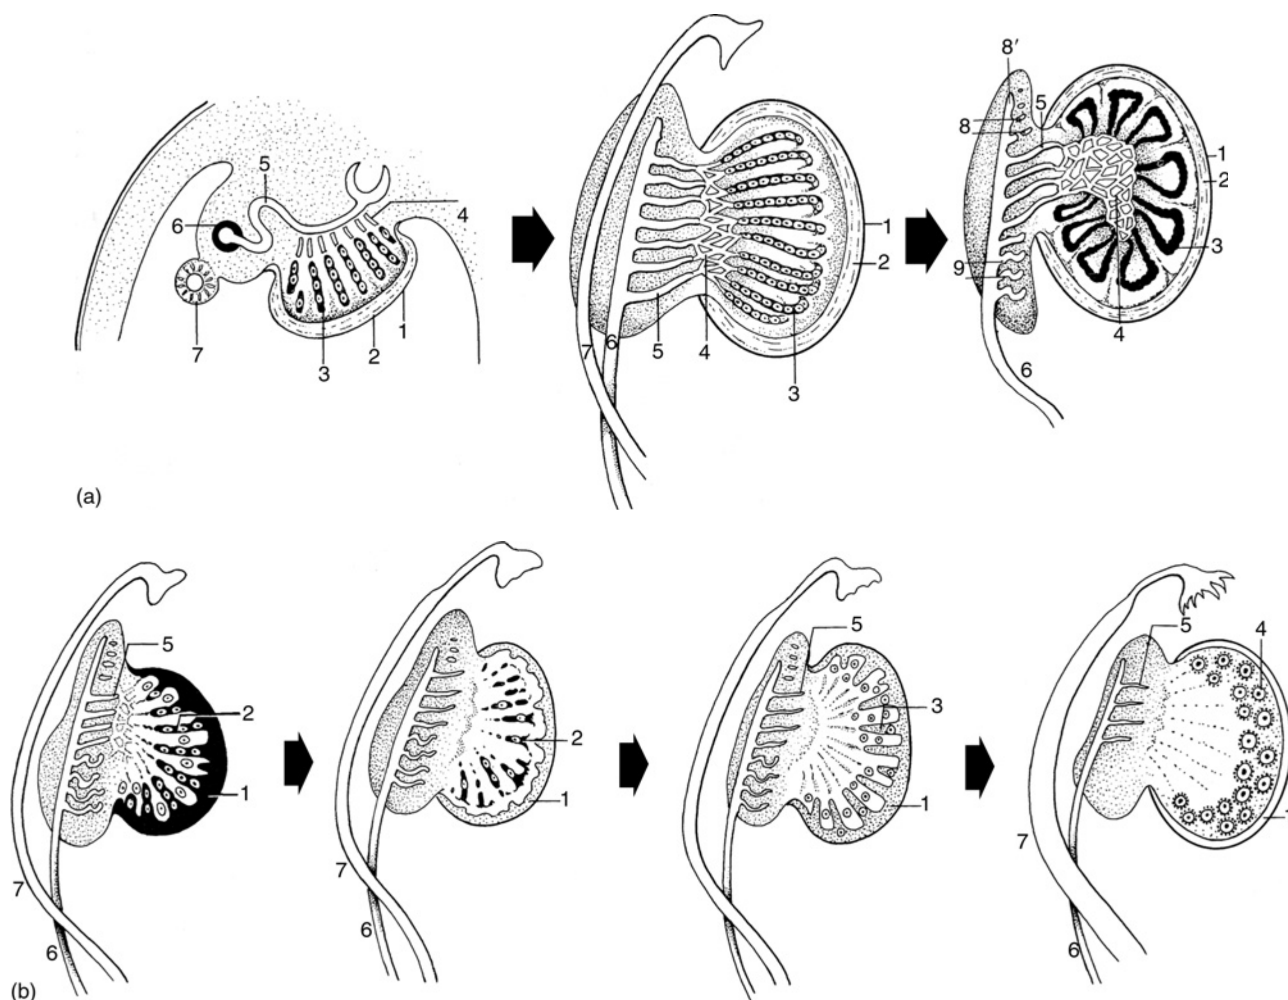

**FIGURE 14.5** The initial stages in the development of the testis and the formation of the excurrent duct system are shown in (a). The initial formation of the tunica albuginea isolates the epithelial cords from the surface epithelium, and the epithelial cords, rete testis and mesonephric tubules (also referred to as the mesonephric ductules or mesonephric duct system) subsequently interconnect. The epithelial cords (sex cords) will eventually become the seminiferous tubules, and the mesonephric ductules will be incorporated into the formation of the excurrent duct system. (1) Celomic epithelium; (2) tunica albuginea; (3) epithelial cords (future seminiferous tubules); (4) rete testis; (5) mesonephric tubules (later efferent ductules); (6) mesonephric duct (future epididymis (proximal portion contiguous with mesonephric tubules and ductus deferens (distal portion)); (7) paramesonephric duct; (8) cranial remnant of mesonephric duct system (aberrant ductules); (8′) remnant of mesonephric duct (appendix of epididymis) and (9) caudal remnant of mesonephric duct (paradidymis). The initial stages in the development of the ovary and the formation of paramesonephric ducts are shown in (b). The epithelial cords (sex cords) penetrate and then regress within the developing ovary, eventually fragmenting and organizing into cell clusters which consist of a single oocyte surrounded by a layer of granulosa cells (primordial follicles). The paramesonephric ducts undergo further development and differentiation, and the mesonephric duct system begins to regress: (1) celomic epithelium; (2) epithelial cords which initially penetrate then regress and fragment; (3) early formation of future cortical region; (4) primordial follicles; (5) regressing mesonephric tubules; (6) mesonephric duct which will eventually regress and (7) paramesonephric duct which will undergo further development and differentiation into the major female tubular genitalia. This figure was adapted, with permission, from Dyce *et al.* (2002) (modifications courtesy of Don Connor and Howard Wilson).

male fetus (developed mesonephric duct system; regressed paramesonephric ducts) (Senger, 2003; Genuth, 2004b; Basrur, 2006). Without the determination that the gonads will develop into testes, the "default" or "constitutive" pathway is followed and ovarian gonads are formed in association with a developed paramesonephric duct system and regressed mesonephric ducts (Senger, 2003; Genuth, 2004b; Basrur, 2006). While this model is useful to explain rather complex developmental processes, it should be kept in mind that other toxicant-susceptible mechanisms might also play a role in gonadal sex determination and sexual differentiation. It is apparent that very precise, sex-specific patterns of germ line epigenetic programming and interactions with somatic cells take place during the early stages of sexual differentiation (Anway and Skinner, 2006). Recent data has suggested that these signaling pathways are susceptible to epigenetic modifications induced by some antiandrogens (Anway *et al.*, 2005; Anway and Skinner, 2006). It has also been suggested that gonadal sex determination involves other genes on both sex and autosomal chromosomes that might be targeted by reproductive toxicants (Genuth, 2004b; Basrur, 2006).

*Development of the male phenotype*

Once previously undifferentiated gonads commit to testes development (TDF present), a coordinated series of endocrine-induced morphological changes take place, resulting in both a genotypically and a phenotypically male fetus (Figure 14.5a). The sequence of signaling and developmental changes, which result in male sexual differentiation, include the following: (1) Sertoli cell development and secretion of anti-Müllerian hormone (AMH) or Müllerian inhibiting substance (MIS); (2) AMH-induced regression of the paramesonephric (Müllerian) ducts and differentiation of Leydig cells capable of producing testosterone; (3) testosterone-facilitated development of the mesonephric or Wolffian ducts; (4) differentiation of the mesonephric ducts into the rete testes, efferent ductules, epididymidies and ducti deferens; (5) development of primordial accessory sex glands and the formation of external genitalia from primordia and, finally, in most species (some exceptions in wildlife species); (6) testicular descent of the intra-abdominal testes into their extra-abdominal position in the scrotum, prior to or very shortly after birth (some species) (Senger, 2003; Genuth, 2004b; Basrur, 2006; Edwards *et al.*, 2006).

*Development of the female phenotype*

If the previously undifferentiated gonads do not commit to testes development (TDF absent), ovaries are formed and a cascade of morphological changes occurs in the absence of AMH and testosterone stimulation, resulting in a genotypically and phenotypically female fetus (Figure 14.5b). This sequence of "default" or "constitutive" morphological and endocrine alterations results in the following sequence of developmental events: (1) regression of mesonephric (Wolffian ducts); (2) differentiation of the paramesonephric (Müllerian) ducts into the oviducts, uterine horns, uterine body, cervix and anterior vagina; (3) remodeling of the ovary into its typical parenchymal and cortical structure; (4) cortical development of primordial follicles, with primary oocytes arrested in meiosis and surrounded by future granulosa and theca interna cells and (5) development of the caudal vagina and vulva from the urogenital sinus (external genitalia primordia) (Senger, 2003; Genuth, 2004b; Basrur, 2006; Edwards *et al.*, 2006; Evans *et al.*, 2007).

*Sexual differentiation of the brain*

Sex-specific endocrine patterns and the resulting gender appropriate sexual behaviors in animals are necessary for fertile copulations to occur and require that the brain also undergo prenatal (postnatal in some species) sexual differentiation. Although large amounts of estradiol defeminize the brain; alpha-fetoprotein prevents most of the endogenous estrogens in the female fetus from crossing the blood–brain barrier (Senger, 2003). The brain remains inherently female under the influence of minimal amounts of estradiol, and both the GnRH tonic and surge centers are maintained within the hypothalamus of the female fetus in this low-estradiol environment (Ford and D'Occhio, 1989; Senger, 2003). Testosterone produced by the fetal testes crosses the blood–brain barrier and is converted to estradiol within the brain, and, as a result of this estradiol synthesis, the hypothalamic GnRH surge center in the male fetus is minimized (Senger, 2003).

While the differentiation of male sexual behavior in large domestic animals generally involves prenatal defeminization, especially in species having longer gestations, it should be noted that postnatal defeminization of the brain is occurs in male swine and rodents (Ford and D'Occhio, 1989). There is also evidence to suggest that the males of some species with prenatal defeminization of the brain might also require postnatal exposure to androgens for maximum masculinization of the brain (Senger, 2003). Depending on the timing of exposure, xenoestrogens and exogenously administered testosterone and, possibly, some xenoandrogens, which cross the placenta and the blood–brain barrier have the potential to have profound effects on sexual differentiation of the brain and future reproductive function.

## Parturition and lactation

### Physiology of parturition

Parturition constitutes transport of the fetus and its associated membranes from the maternal to the external

environment, and represents transition of the fetus to a neonate. Maturation of the fetal hypothalamic–pituitary–adrenal axis plays an important role in the cascade of neural and endocrine events which lead to parturition in most mammals (Senger, 2003; Evans, 2007). As most clearly demonstrated in ruminants, fetal CRF stimulates the release of ACTH from the fetal pituitary, and ACTH, in turn, stimulates fetal secretion of cortisol by the adrenal glands (Senger, 2003). Elevations in fetal cortisol (fetal LH may be involved as well) activate placental steroidogenic enzyme systems, resulting in decreased progestins and elevated estrogens prior to parturition (Ginther, 1992; Evans, 2007). The resulting increase in the estrogen:progestin ratio facilitates several important processes (e.g. cervical softening, upregulation of myometrial oxytocin receptors, uterine synthesis of $PGF_2\alpha$ and increased blood flow to the gravid uterus and placenta) which prepare the uterus for parturition (Evans *et al.*, 2007). Teratogen-induced congenital defects in the fetal pituitary gland can result in prolonged gestation (e.g. *Veratrum californicum*), and any xenobiotic exposure causing maternal and/or fetal stress can be associated with abortion or premature parturition (e.g. nitrates and pine needle abortion).

Normal parturition approaches as neural signals caused by fetal movements and myometrial contractions, along with elevated basal levels of oxytocin and increased secretion of $PGF_2\alpha$, bring about the first stage of labor. A rapid increase in oxytocin and $PGF_2\alpha$ secretion leads to rupture of the allantochorionic membrane and the commencement of the second stage of labor. Strong myometrial contractions result in the delivery of offspring, as well as the expulsion of the fetal membranes during the third stage of labor (Senger, 2003; Evans *et al.*, 2007).

#### *Physiology of lactation*

##### *Lactogenesis*

Appropriately timed lactogenesis is critical for survival of mammalian offspring. Lactogenesis is a two-stage process involving: (1) the enzymatic and cytological differentiation of the alveolar cells within the mammary gland and (2) the copious secretion of milk, which is distinct from the colostral sequestration of antibodies (Tucker, 1994). Growth hormone, aldosterone, prostaglandins, insulin, estrogens, progestins and prolactin are required for the first stage of lactogenesis, which generally occurs during the last trimester of pregnancy (McCue, 1993; Tucker, 1994). Large increases in pulsatile prolactin secretion by lactotropes in the anterior pituitary are necessary for the initiation of the second stage of lactogenesis, which generally occurs in close temporal association with the endocrine milieu of parturition (Evans, 1996). In many species, circulating concentrations of prolactin are elevated above basal levels for a month or two after parturition (McCue, 1993). In some species of animals, a placental lactogen performs many of the same endocrine functions as prolactin.

##### *Control of prolactin secretion*

Lactotropic prolactin secretion is tonically inhibited by dopamine secreted by hypothalamic neurons belonging to either the tuberoinfundibular or tuberohypophysial dopaminergic systems (TIDA and THDA, respectively) (Neill and Nagy, 1994; Evans *et al.*, 2007). Vasoactive intestinal peptide (VIP) and TRH are thought to act as prolactin releasing factors and can interfere with the dopamine-associated tonic inhibition of prolactin release (Evans, 1996). Oxytocin, in conjunction with the suckling reflex, will increase pituitary lactotropic production and secretion of prolactin (Neill and Nagy, 1994). In species strictly dependent on prolactin for lactogenesis, toxicants which mimic dopamine and tonically inhibit prolactin secretion (e.g. ergopeptine alkaloids) pose a risk to fetal survival.

## THE MECHANISMS AND EFFECTS OF REPRODUCTIVE TOXICANTS

### The effects of EDCs on wildlife species, humans and domestic animals

It should be evident from the previous discussion that maximum reproductive efficiency, including normal embryonic and fetal development, is dependent on the structural and functional integrity of multiple organs and tissues, as well as various signaling pathways (Figure 14.6). There is increasing concern within the scientific and regulatory communities regarding the effects of prenatal exposures to EDCs on wildlife species and humans. Domestic animals have been shown to be susceptible to the effects of several naturally occurring reproductive toxicants in clinical settings, and it is possible that low-level environmental exposures to EDCs can also hinder reproductive function.

#### *Endocrine disruption in wildlife species*

There have been many, well-documented instances of reproductive abnormalities in species of wildlife living in environments contaminated by industrial and/or agricultural chemicals (McLachlan, 2001; Hess and Iguchi, 2002; Jobling and Tyler, 2006; McLachlan *et al.*, 2006). The deleterious reproductive effects of DDT on birds reported in Rachel Carson's *Silent Spring* have been shown to be result of eggshell thinning related to abnormalities in prostaglandins synthesis induced by the *p,p*-DDE metabolite of DDT (Lundholm, 1997; Guillette, 2006). Wildlife populations are very likely sentinels for endocrine disruption because of the contamination of the aquatic habitats in which many of them live and the likelihood that predatory

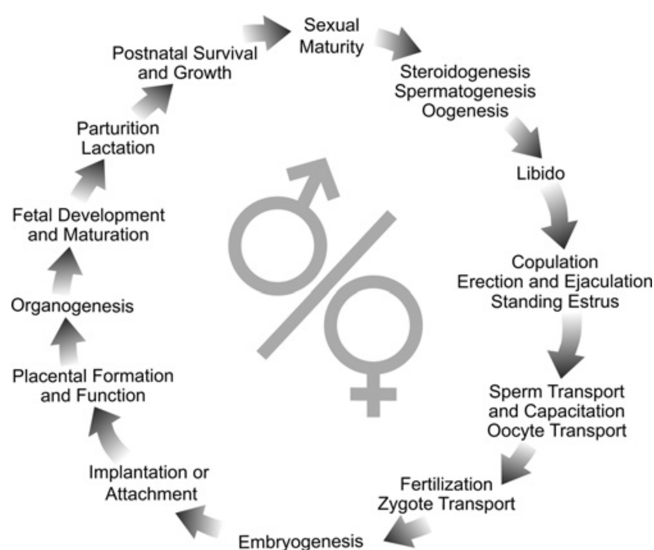

**FIGURE 14.6** The multiple steps involved in reproductive development and function in both males and females are shown schematically to illustrate the complexity of reproduction in mammalian species and to demonstrate the various stages in the reproductive process which can be targeted for toxic insult. With respect to embryonic, fetal and placental development, it should be understood that these events are species-dependent and interrelated, with many of them taking place concurrently. This figure was adapted, with permission, from Ellington and Wilker (2006) (modifications and artwork courtesy of Don Connor and Howard Wilson).

animals will have relatively high exposures to chemicals which bioaccumulate within the environment (Hess and Iguchi, 2002). Lessons learned from instances of endocrine disruption in wildlife species can be applied to EDC exposures involving humans and domestic animals.

### *"Androgenic" and "estrogenic" effects of EDCs on wildlife species*

Prenatal and postnatal exposures to androgenic and estrogenic environmental contaminants, as well as chemicals classified as having the opposite phenotypic effects, have been associated with various reproductive abnormalities in wildlife. Effluents from pulp and paper mills, as well as runoff from cattle feedlots where the synthetic androgen, trenbolone, was used for growth promotion, have been shown to be androgenic and capable of masculinizing female fish (Orlando *et al.*, 2004; Gray *et al.*, 2006). "Androgynization" or a state of indeterminate sexual development encompassing both feminization and demasculinization in males has been observed in populations of fish, amphibians, reptiles, birds and mammals and is thought to be similar to the testicular dysgenesis syndrome described in humans (Edwards *et al.*, 2006). Adult and immature amphibians exposed to the herbicide, atrazine, which has been associated with increased aromatase activity in a number of species, have been reported to exhibit various manifestations of feminization (Hayes *et al.*, 2006). Hatchling, juvenile and adult male alligators (*Alligator mississippiensis*), originating from a Florida lake previously contaminated with DDT and other persistent, bioaccumulated pesticides, as well as ethylene dibromide and DBCP, have demonstrated varying patterns of androgynization, including phallic malformations, which are thought to result from ovo exposure of maternal origin, as well as post-embryonic modifications and/or continuing environmental exposures to EDCs (Milnes *et al.*, 2006).

### *Endocrine disruption in humans*

Based, in part, on the observations of endocrine disruption in wildlife and ongoing concerns about reproductive dysgenesis, as well as the effects of embryonic and/or fetal exposure to diethylstilbestrol (DES), the emphasis with respect to endocrine disruption in humans and one of the bases for the "Theory of Hormone Disrupting Chemicals" (THDC) or the "Environmental Endocrine Hypothesis" (Krimsky, 2000, 2001) has been the enhanced effects of prenatal, as compared to postnatal, exposures to suspected endocrine disruptors. The embryo and fetus, without a developed blood–brain barrier and with only rudimentary DNA repair mechanisms and hepatic detoxifying and metabolizing capabilities, are especially susceptible, as compared to adults, to the adverse effects of low-level exposures to xenobiotics (Newbold *et al.*, 2006). In addition, previous discussions in this chapter have described the important organizational events taking place during gonadal and phenotypic sexual differentiation, which are potentially very sensitive to alterations in the normal endocrine milieu.

Although still extremely controversial, there is a growing body of evidence to support the observation that sperm counts in men within some industrialized regions of the world have been decreasing over the last several decades (Swan *et al.*, 2000; Skakkebæk *et al.*, 2006; Jørgensen *et al.*, 2006a). In conjunction with these alterations in sperm numbers within ejaculates, there appears to have been a concurrent increase in developmental abnormalities within the male reproductive tract consistent with TDS (Skekkebæk *et al.*, 2001). Similar to what has been observed in xenobiotic-exposed wildlife, reproductive dysgenesis in human males (i.e. TDS) is associated with a suite of clinical abnormalities which include reduced semen quality, cryptorchidism, hypospadias, decreased anogenital distance and testicular cancer (Skakkebæk *et al.*, 2001; Edwards *et al.*, 2006). Failure of Sertoli cell proliferation and functional maturation within the seminiferous tubules has been one mechanism proposed for the pathogenesis of TDS (Sharpe *et al.*, 2003). The findings of a recently completely epidemiological study have suggested a relationship between decreased anogenital distance and prenatal phthalate exposure in male infants (Swan *et al.*, 2005), and a possible rodent model for human TDS has been developed using prenatal exposure to dibutyl phthalate [di (*n*-butyl) phthalate] (Fisher *et al.*, 2003; Mahood *et al.*, 2005, 2006).

In addition to phthalates, which are used as plasticizers, a number of other widely used agricultural and industrial chemicals have been associated with adverse reproductive effects in humans and/or rodent models. In epidemiological studies a correlation has been shown between reduced semen quality in men within certain regions of the United States and the metabolites of several economically important herbicides (Swan *et al.*, 2003a, b). Metabolites of the commercially available fungicide, vinclozolin, have been demonstrated to interfere with interactions between androgens and their nuclear receptor, resulting in antiandrogenic effects on exposed rodents (Wong *et al.*, 1995; Monosson *et al.*, 1999; O'Connor *et al.*, 2002; Kubota *et al.*, 2003; Gray *et al.*, 2006). At concentrations well below those routinely found in humans, bisphenol A, which is widely used in the plastics industry and other manufacturing processes, can initiate nongenomic estrogenic responses with plasma membrane receptors and interact with the nuclear estrogen receptor as an SERM (Welshons *et al.*, 2006). With the increased societal awareness of the possible effects of hormonally active xenobiotics on human reproduction, further research is required to make educated decisions, based on "good science", with respect to the continued use and/or regulation of economically important chemicals associated with the potential for reproductive abnormalities in humans and/or documented impairment of reproductive function in laboratory animals.

### *The effects of reproductive toxicants on domestic animals*

#### *Abortion, teratogenesis and impaired fertility in domestic animals*

Animal-based agriculture is dependent on the efficient production of viable and reproductively functional offspring. Toxicant-induced abortions, congenital defects and male or female infertility can have devastating effects on livestock production. Cattle are commonly at increased risk, especially under drought conditions, for adult mortality and abortions in pregnant cows related to the consumption of nitrate-accumulating forages [e.g. *Sorghum* spp., oat hay (*Avena sativa*), cornstalks (*Zea mays*), and many others], which cause nitrite-induced fetal methemoglobinemia, hypoxia and, consequently, fetal stress and, potentially, even death (Casteel and Evans, 2004). Multiple congenital contractures (MCC) ("crooked calf disease") associated with the ingestion of lupines (*Lupinus* spp.) have resulted in the loss of large numbers of calves in the western United States (Panter, 2002), and multiple species of livestock exposed to swainsonine-containing plants (e.g. species of *Astragalus* and *Oxytropis* in North America species of *Swainsona* in Australia) have experienced congenital defects, abortions and/or ovarian and testicular abnormalities (Cheeke, 1998). Cleft palate, cyclops lambs, prolonged gestation and various tracheal and limb deformities have resulted from different periods of exposure of pregnant ewes to *Veratrum californicum* (false hellebore) (Burrows and Tyrl, 2001). Ergot alkaloids produced by the tall fescue endophyte, *Neotyphodium coenophialum*, are responsible for suboptimal reproductive performance in large numbers of cattle and horses, with late-gestational mares being particularly susceptible to endophyte-related prolonged gestation and agalactia (Evans *et al.*, 2004).

#### *Endocrine disruption in domestic animals*

With respect to the adverse reproductive effects of endocrine disruption on domestic animals, there have been many instances of impaired reproductive function involving naturally occurring EDCs of plant and fungal origin. However, there is still much to be learned about the potential adverse effects of pre- as well as postnatal environmental exposures to EDCs in these species where selection of breeding animals is often based on reproductive soundness. Postnatal exposures to phytoestrogens in some leguminous plants, including soybeans, have resulted in reproductive abnormalities and subfertility in multiple species (Cheeke, 1998; Ford *et al.*, 2006). The adverse effects of postnatal exposures to the estrogenic mycotoxin, zearalenone, on swine fertility have also been well documented (Cheeke, 1998). In experimental studies, female swine appear to be more sensitive than rodents to the effects of atrazine on the hypothalamic–pituitary–gonadal axis (Gojmerac *et al.*, 2004), and it is possible that companion and agricultural animals are also more susceptible than laboratory species to other EDCs. As many hormonally active xenobiotics also have important agricultural and industrial uses, it is important to continue research which attempts to accurately predict the effects of environmental exposures to EDCs, as well as other reproductive toxicants, on domestic animals.

## Toxicants affecting the male reproductive function

There have been relatively few documented reports regarding the adverse effects of reproductive toxicants on male fertility in the major animal species of veterinary interest. Realistically the lack of examples is more likely a reflection of the limited number of controlled studies performed using non-rodent mammalian species and/or the number of toxicant-associated reproductive abnormalities which remain undiagnosed, rather than an accurate indication of the scope of the problem (Schrader, 2002). A large number of chemicals are currently thought to have the potential for causing abnormalities in male reproductive function in domestic animals. Based on extrapolations from effects observed in a various mammalian species and the limited scientific and anecdotal reports, a partial listing of these

**TABLE 14.1 Xenobiotics/environmental and physiological factors that affect male fertility**

| Xenobiotic | Observed effect(s) on male |
|---|---|
| *Antimicrobials* | |
| Metronidazole | High doses: ↓ sperm number; ↑ abnormal morphology |
| Nitrofurantoin | High doses: ↓ sperm number |
| Tetracycline | Very high doses: ↓ sperm number; ↓ sperm capacitation; testis atrophy |
| Trimethoprim | 1-month course: ↓ sperm number by 7–88% |
| *Antifungals* | |
| Ketaconazole | Decreased testosterone and libido; ↓ sperm number and motility |
| Miconazole | Interferes with testosterone in male fetus |
| *Immunosuppressants* | |
| Cyclophosphamide | Decreased sperm number; birth defects in offspring |
| *Hormones* | |
| Testosterone | Decreased sperm number; testicular degeneration |
| Anabolic steroids | Decreased sperm number, motility and morphology |
| Trenbolone | Increased sperm abnormalities |
| Estrogens | Decreased sperm number; behavioral feminization |
| Phytoestrogens | Bioaccumulation in cats on soy diets can cause poor fertility |
| Zearanol | Decreased spermatogenesis |
| *Antivirals* | |
| Acyclovir | Dose- and age-dependent testicular degeneration |
| Ganciclovir | Decreased sperm number and quality |
| *Carbonic anhydrase inhibitors* | |
| Acetazolamide | Decreased libido and impotence |
| *Psychoactive drugs* | |
| Buspirone | Decreased libido and impotence |
| Benzodiazepine tranquilizers | Impotence and possible ejaculatory dysfunction |
| Phenothiazine tranquilizers | Priapism and impotence |
| Tricyclic antidepressants | Decreased libido and erectile dysfunction |
| *Antihistamines* | |
| Chlorpheniramine | *In vitro* experiments: ↓ sperm motility |
| *Antineoplastics* | |
| Adrimycin | Dose- and age-dependent testicular toxicity |
| Cisplatin | Decreased sperm number; ↓growth in offspring; pregnancy loss |
| Vincristine | Decreased sperm number; possible reversibility |
| *Antimetabolite* | |
| Cytarabine | Decreased sperm number |
| *Gastrointestinal tract drugs* | |
| Cimetidine | Decreased sperm number |
| Metaclopramide | Impotence |
| *Non-steroidal antiinflammatories* | |
| Naproxen | Decreased seminal prostaglandins; ↓ sperm motility |
| Phenylbutazone | Inhibition of sperm acrosome reaction; unknown effect on fertility |
| Sulfasalazine | Decreased sperm number and motility |
| *Glucocorticoids* | |
| Prednisone | Decreased sperm number and motility; ↓ testosterone |
| *Herbicides* | |
| 2,4-D (dichlorophenoxyacetic acid) | Abnormal sperm quality; testicular degeneration; ↓ fertility |
| Diquat and paraquat | Altered sexual differentiation in the male |
| *Solvents* | |
| Nitrobenzene | Decreased sperm number and motility; testicular degeneration |
| Napptha | Decreased fertility |
| *Phthalic acid esters* | |
| Diethylhexaphthalate (DEHP) | Testicular atrophy |
| *Gasoline additives* | |
| Ethylene dibromide | Testicular degeneration and poor sperm quality |

(*Continued*)

**TABLE 14.1 (Continued)**

| Xenobiotic | Observed effect(s) on male |
|---|---|
| *Insecticides* | |
| Carbamates | Decreased sperm quality |
| Chlorinated hydrocarbons | Testicular degeneration and atrophy |
| Methoxychlor | Testicular degeneration associated with estrogenic activity |
| Kepone | Decreased sperm number |
| Lindane | High doses: testicular toxicant<br>In utero exposure: ↓ sperm number and ↓ testosterone in offspring |
| Organophosphates | No information |
| Pyrethrins | *In vitro*: 40–60% ↓ in testosterone binding to androgen receptor |
| *Fungicides/nematocides* | |
| DBCP (dibromochloropropane) | Decreased sperm number; testicular toxicant |
| *Fungicide* | |
| Vinclozolin | Antiandrogen: disruption of male phenotypic sexual differentiation |
| *Heavy metals* | |
| Cadmium | High doses: ischemic necrosis of the testis |
| Chromium | Decreased testosterone; ↓ sperm number |
| Lead | Decreased testosterone; ↓ sperm number; ↓ fertilization rates |
| Mercury | Decreased sperm quality |
| *Miscellaneous xenobiotics* | |
| Dioxin | Decreased libido; abnormal sperm morphology; ↓ response to GnRH |
| DBP (dibutyl phthalate) | Altered sexual differentiation |
| PCBs | Decreased sperm number; altered hypothalamic–pituitary–adrenal axis |
| Gossypol | Decreased sperm number |
| Ethylene glycol | Decreased sperm number and motility |
| *Environmental factors* | *Observed effect(s) on male* |
| Heat | Damaged sperm chromatin and quality |
| Microwaves | Decreased sperm number |
| Radiation | High doses: death of stem cells and permanent azoospermia |
| Stray voltage (AC and DC) | Decreased sperm number |
| *Physiological factors* | *Observed effect(s) on male* |
| Stress | Decreased sperm motility |
| Fever (hyperthermia) | Damaged sperm chromatin and quality |

This table was adapted, with permission, from Ellington and Wilker (2006).

compounds is presented in Table 14.1 (Ellington and Wilker, 2006). In the following section a few selected male reproductive toxicants and their proposed mechanisms of action will be briefly described in order to familiarize the reader with the various different ways that male fertility can be affected by reproductive toxicants.

### *Selected male reproductive toxicants and mechanisms of action*

#### *Cell-specific reproductive toxicants*

Some reproductive toxicants adversely affect specific cells within the testes. Ethane dimethane sulfonate is specifically cytotoxic to the Leydig cells, and excessive exposure to this compound results in complete loss of this population of cells within the interstitium, and, consequently, the ability of the testes to synthesize testosterone and, in some species, estrogens (Creasy and Foster, 2002). Tri-*o*-cresyl phosphate (TOCP) is an industrial chemical used in lacquers and varnishes, which inhibits LH-induced steroidogenesis in the Leydig cells and, after Leydig cell-mediated conversion to its active metabolite, morphological abnormalities in Sertoli cells (Thomas and Thomas, 2001; Creasy and Foster, 2002).

Sertoli cells are specifically targeted by several toxicants, including diethylhexyl phthalate (DEHP), 1,3-dinitrobenzene (DNB) and 2,5-hexanedione (metabolite of *n*-hexane) (Creasy and Foster, 2002) and the effects of these xenobiotics are age- and species specific (Thomas and Thomas, 2001). With respect to DNB, the parent compound is converted to its toxic metabolites, nitosonitrobenzene and nitroaniline, within the target Sertoli cells, and, similar to other Sertoli cell-specific toxicants, germ cell death and exfoliation occur secondary to toxic insult to the Sertoli cells (Creasy and Foster, 2002). Sertoli cell microtubules

appear to be the intracellular targets of 2,5-hexanedione (Thomas and Thomas, 2001; Creasy and Foster, 2002). The fungicide dibromochloropropane (DBCP) appears to affect the Sertoli cell (Thomas and Thomas, 2001), but its metabolites epichlorhydrin and $\alpha$-chlorhydrin induce capillary permeability and vascular damage within the epididymis (Creasy and Foster, 2002).

There are a number of reproductive toxicants which target-specific populations of germ cells. Spermatogonia, spermatocytes, round spermatids and elongate spermatids are specifically targeted by busulfan, 2-methoxyethanol, ethylmethane sulfonate and dibromacetic acid, respectively (Creasy and Foster, 2002). Ionizing radiation and a variety of chemotherapeutic agents, including cyclophophamide, nitrogen mustard, vincristine and vinblastine, generally target rapidly dividing mitotic or meiotic germ cells in the testes, and TCDD appears to adversely affect several populations of spermatozoal precursors (Thomas and Thomas, 2001). The compound 7,12-dimethylbenz[*a*] anthracene (DMBA) is toxic to spermatogonia but must undergo a stepwise biotransformation in the Leydig cell and, subsequently, the Sertoli cell to produce the ultimately toxic metabolite (Creasy and Foster, 2002).

### *Heavy metals*

Lead and cadmium are ubiquitous heavy metals and have both been associated with testicular toxicity and impaired fertility in a number of species. Excessive cobalt can potentially interfere with normal spermatogenesis, and severe cobalt intoxications have actually resulted in generalized hypoxia related to increased blood viscosity or which affects the testes (Thomas, 1995). Chromium and vanadium have also been associated with adverse reproductive effects (Thomas and Thomas, 2001), and cis-platinum exposure has been associated with the death of spermatocytes and spermatids, as well as disruption of Sertoli cell tight junctions (Thomas, 1995). Although testicular toxicity is generally not observed with excessive parenteral exposure to zinc (other than possibly secondary to hemolytic anemia-related hypoxia) (Thomas, 1995), intratesticular injections with zinc gluconate have been successfully used for chemical castration in several species.

Divalent lead is known to interact with physiological processes involving calcium and generally has an affinity for sulfhydryl groups. Lead is reported to be directly toxic to germ cells and Leydig cells and can suppress anterior pituitary secretion of LH and FSH (Thomas and Thomas, 2001). Lead also appears to be able to adversely affect the ability of spermatozoa to fertilize ova, but, this effect, like others associated with lead exposure, appears to be dependent on age and individual variations in susceptibility, adaptation and reversibility (Sokol, 2006).

Like lead, cadmium is thought to adversely affect male reproduction by several different mechanisms. With respect to spermatogenesis, the stage of the seminiferous epithelium associated with spermiation appears to be specifically inhibited by cadmium (Thomas, 1995). Cadmium has also been shown to have possible interactions with the hypothalamic–pituitary–gonadal axis (Akinloye *et al.*, 2006). The endothelium of the testicular and epididymal vasculature is extremely susceptible to toxic insult by cadmium, potentially resulting in reduced vascular perfusion and testicular necrosis (Creasy and Foster, 2002). Cadmium can also alter the actin filaments in the junctional complexes between adjacent Sertoli cells, thereby disrupting the integrity of the blood–testis barrier (Thomas and Thomas, 2001). Cadmium can interfere with the cellular metabolism of zinc, an essential trace element necessary for normal reproductive function, and diets deficient in zinc can predispose individuals the toxic effects of cadmium (Akinloye *et al.*, 2006). Pretreatment with zinc has been reported to reduce the incidence of cadmium-induced Leydig cell cytotoxicity and neoplasia (Thomas, 1995).

### *Gossypol*

Gossypol is a yellow, polyphenolic pigment, which is contained in most of the parts of plants belonging to the *Gossypium* genus and is concentrated in pigment glands within the seeds (Morgan, 2004; Casteel, 2007). Gossypol exists as two isomers within plants (+and the more toxic −), and these isomeric forms can be non-toxic and bound to plant proteins or toxic and "free" or unbound (Cheeke, 1998). The concentrations of the toxic free form of gossypol vary widely in whole seeds and meals, with the gossypol in direct solvent-extracted cottonseed meal being much more readily bioavailable than the gossypol contained in whole seeds (Cheeke, 1998; Casteel, 2007).

Gossypol can cause systemic and reproductive disease syndromes, depending on the species of exposed animal and the dosage of free gossypol consumed (Randel *et al.*, 1992). The toxic effects of gossypol are cumulative, and systemic disease, characterized by hepatic, renal, cardiovascular and pulmonary abnormalities, is generally observed in monogastric animals (Cheeke, 1998). Mature ruminants are considered to be relatively resistant to the severe systemic effects of free gossypol because of the propensity of this form of the pigment to become bound to proteins in ruminal fluid and, therefore, "detoxified" (Casteel, 2007). Gossypol-induced male subfertility has been observed in monogastrics and, especially, ruminant species and is dependent on the dosage of free gossypol and the duration of gossypol exposure (Randel *et al.*, 1992; Cheeke, 1998).

Exposure of peri-pubertal or sexually mature males, to sufficient dosages of free gossypol, adversely affects the seminiferous epithelium and disrupts normal spermiogenesis, resulting in spermatozoa with aplastic midpieces (i.e. segmental aplasia of the mitochondrial sheath) (Randel *et al.*, 1992; Chenoweth *et al.*, 2000).

Additional sperm abnormalities, possibly associated with gossypol-induced oxidative damage (Velasquez-Pereira *et al.*, 1998), can potentially develop as stressors, related to the acquisition of motility in the epididymidis, alter the structural integrity of already weakened spermatozoa (Chenoweth *et al.*, 2000). The spermatozoal abnormalities induced by exposure of immature bulls to free gossypol are most likely reversible (Hassan *et al.*, 2004) and can be ameliorated by concurrent treatment with vitamin E (Velasquez-Pereira *et al.*, 1998). Total dietary concentrations of free gossypol supplied as cottonseed meal or whole cottonseed should not exceed 150 and 600 ppm, respectively, in young developing bulls, or, similarly, 200 and 900 ppm in sexually mature animals (Morgan, 2004).

*Xenoestrogens and antiestrogens*

Reproductive function in sexually mature males can potentially be adversely affected by exposures to nuclear ER agonists or antagonists, as well as by estrogenic or antiestrogenic EDCs acting independently of receptor-mediated interactions. However, it is clear from the feminizing effects of prenatal exposures to DES (McLachlan, 2001; Newbold *et al.*, 2006) and observations of androgynization in wildlife species (Edwards *et al.*, 2006), that the male fetus is much more sensitive to the adverse effects of endocrine disruptors than male animals during postnatal period (Hess and Iguchi, 2002). It is also important to remember that, even in males, xenobiotics which interfere with estrogenic signaling pathways can adversely affect normal reproductive development and function (O'Donnell *et al.*, 2001; Hess, 2003).

*Xenoandrogens and antiandrogens*

Normal phenotypic sexual differentiation of the male fetus, as well as all of the postnatal events which result in the delivery of fertile spermatozoa to the female reproductive tract, is dependent on appropriately timed androgenic stimulation of the male. It has been well-recognized for quite some time that xenoandrogens (e.g., anabolic steroids and exogenous testosterone and DHT) can interfere with hypothalamic–pituitary–gonadal feedback mechanisms (Figure 14.2), resulting in decreased LH release, sperm abnormalities and testicular atrophy (Ellington and Wilker, 2006). In recent years, there has been increasing interest in xenobiotics which can interfere with interactions between androgens and their receptors or, in some other way, disrupt androgen-dependent signaling pathways. The dicarboximide fungicides, vinclozolin and procymidone and/or their metabolites inhibit the binding of androgens to nuclear androgen receptors and can demasculinize and feminize the prenatally exposed male fetus or induce important alterations in pre- or peri-pubertally exposed offspring (Monosson *et al.*, 1999; Gray *et al.*, 2006). Vinclozolin has also recently been shown to be capable of inducing epigenetic modifications which facilitate the occurrence of transgenerational or vertically transmitted reproductive abnormalities (Anway *et al.*, 2005; Anway and Skinner, 2006). Other EDCs, including linuron, *p,p′*-DDE (another metabolite of DDT) and prochloraz, can also function as androgen receptor antagonists, and PBDEs can act as competitive inhibitors of the androgen receptor as well as androgen-induced gene expression (Gray *et al.*, 2006). The AhR-mediated effects of TCDD can interfere with the biosynthesis of testosterone and disrupt testosterone signal transduction pathways (Jana *et al.*, 1999; Sikka *et al.*, 2005).

*Phthalates*

It is recognized that phthalates, which are used as plasticizers and which are abundant within the environment, share a unique antiandrogenic mechanism, which can result in reproductive dysgenesis in male offspring. Unlike vinclozolin, phthalates are not androgen receptor antagonists, but it is also clear that they are not uterotropic nor are they capable of inducing a persistent estrus, as would be expected with estrogenic EDCs (Gray *et al.*, 2006). Phthalates actually alter fetal Leydig cell function, resulting in decreased testosterone synthesis and downregulated expression of insulin-like peptide-3, which is required for gubernacular cords formation (Foster, 2006; Gray *et al.*, 2006). Appropriately timed fetal exposure to di (*n*-butyl) phthalate can result in an abnormal aggregation of Leydig cells in the fetal rat testis, resulting in a failure of Sertoli cell proliferation and functional maturation, similar to what has been proposed as a possible mechanism the development of TDS in humans (Sharpe *et al.*, 2003; Mahood *et al.*, 2005, 2006).

## Toxicants affecting the female reproductive function

There have been many documented reports of female reproductive abnormalities associated with exposures of domestic animal species to naturally occurring EDCs (i.e. phytoestrogens and zearalenone). Likewise, the reproductive effects of the ergot alkaloids produced by the tall fescue endophyte *Neotyphodium coenophialum* are also very well understood (Evans *et al.*, 2004). Unfortunately, however, there are still instances of toxicant-induced subfertility which very likely go unrecognized. An effort will be made to the review some of the major mechanisms of action for toxic insult to the female reproductive tract in domestic animals, in the hope that the reader might better understand the potential scope of xenobiotic-induced reproductive effects.

### *Selected female reproductive toxicants and mechanisms of action*

*Cell-specific reproductive toxicants*

In general, the effects of toxicants on specific cell types within the female reproductive tract, and especially the ovaries, are not as well understood as they are in the testes (Thomas and Thomas, 2001). Many female reproductive

toxicants do not target particular cell lines, *per se*, but, rather, disrupt the endocrine milieu of the tubular genitalia or cause changes in ovarian structures secondary to alterations in the hypothalamic–pituitary–gonadal axis (Yuan and Foley, 2002). There are, however, a number of xenobiotics considered to "ovotoxic". Phthalates and TCDD can delay or decrease ovulations (Devine and Hoyer, 2005). Ionizing radiation and some of the same chemotherapeutic agents reported to adversely affect rapidly dividing germ cells within the testes (e.g. cyclophosphamide, nitrogen mustard and vinblastine) can also adversely affect primordial follicles within the ovary (Thomas and Thomas, 2001; Devine and Hoyer, 2005). Several PAHs [i.e. BaP, 3-methylcholanthrene (3-MC) and DMBA] and 1,3-butadiene appear to target oocytes in preantral follicles, and DMBA, BaP and 1- and 2-bromopropane, as well as 1,2-dibromopropane, can adversely affect antral follicular development (Devine and Hoyer, 2005). Exposure to free gossypol has been associated with increased numbers of degenerating embryos in heifers (Casteel, 2007).

Like the testes, the ovaries also have some xenobiotic biotransformation capabilities (Thomas and Thomas, 2001; Yuan and Foley, 2002). As in other organs, oxidative damage can adversely affect ovarian structure and function. In the case of 1,3-butadiene and 4-vinylcyclohexene, the adverse effects of these toxicants on small and growing follicles are due, in part, to the toxic actions of the epoxidated metabolites of these xenobiotics (Devine and Hoyer, 2005).

*Heavy metals*

The ovaries do not appear to be as sensitive to the toxic effects heavy metals as do the testes, and those adverse effects which are observed are more subject to variation between species than what was observed in the male gonads (Thomas, 1995). Anterior pituitary release of FSH and LH and ovarian steroidogenesis appear to be inhibited by cadmium in the female (Hoyer, 2006). With respect to lead, the neuroendocrine function of the hypothalamic–pituitary–gonadal axis appears to be targeted by lead in the female, as well as in the male (Thomas, 1995; Hoyer, 2006).

*Phytoestrogens*

Several genera of leguminous plants produce estrogenic compounds collectively referred to as "phytoestrogens", which can be associated with clinically relevant effects in livestock species and companion animals. Species of clover, including subterranean clover (*Trifolium subterraneum*), red clover (*Trifolium pratense*), white clover (*Trifolium repens*) and alsike clover (*Trifolium hybridum*), contain phytoestrogens classified as isoflavones (Cheeke, 1998; Burrows and Tyrl, 2001). It should also be noted that other leguminous plants, such as soybean (*Glycine max*), which is commonly used as a feed source for agricultural animals, can contain varying amounts of isoflavones. Alfalfa (*Medicago sativa*) contains another class of phytoestrogenic compounds referred to as coumestans (Cheeke, 1998).

The relatively inactive, "parent" glycosides for the most clinically relevant isoflavones in clover are formononetin, biochanin A and genestin, and the total concentration of these phytoestrogens can be as high as 2–4% (20,000–40,000 ppm) in clover (Burrows and Tyrl, 2001). Primarily within the gastrointestinal tract and, especially, the rumen, formononetin is converted into an intermediate metabolite, daidzein, and, then subsequently into the more estrogenically active phytoestrogen, equol (Cheeke, 1998; Burrows and Tyrl, 2001). Conversely, biochanin A and genestin are initially converted into genestein and then subsequently into estrogenically inactive phenolic compounds (i.e. phenolic acid and *p*-ethylphenol).

Coumestrol is the primary phytoestrogen in alfalfa. This compound has significantly greater estrogenic activity than many of the isoflavones present in other legumes, and this activity generally decreases during the drying process involved in hay production (Cheeke, 1998; Burrows and Tyrl, 2001). Coumestrol is usually only present at very low concentrations (10–20ppm) in the vegetative stages of alfalfa growth, but its estrogenic activity can vary with plant maturity and from year to year (Burrows and Tyrl, 2001).

A number of clinical syndromes have been associated with phytoestrogen exposure in domestic animals. "Clover disease" in sheep and, to a lesser extent, cattle is associated with the consumption of the isoflavones in clover, resulting in infertility associated with abnormal estrous cycles and structural and functional changes in the cervix (Cheeke, 1998; Burrows and Tyrl, 2001). Phytoestrogen-induced alterations in ovine cervical mucus interfere with the slow, sustained transport of motile spermatozoa from their cervical reservoirs (Cheeke, 1998). Genestein can induce structural changes and, possibly, irreversible organizational abnormalities in the cervix and uterus of exposed gilts (Ford *et al.*, 2006). Coumestan exposure in cattle can be associated with various and, sometimes, seemingly conflicting clinical presentations (e.g. hyperestrogenism, nymphomania, swelling of the external genitalia, estrus suppression, inhibition of ovulation and cystic ovarian disease) (Cheeke, 1998; Casteel, 2007). It is important to remember that phytoestrogens, like other xenoestrogens, can function also as antiestrogens through the inhibition of LH and FSH release from the anterior pituitary and by competing with endogenous estrogens for receptor sites within the tubular genitalia (Cheeke, 1998).

*Zearalenone*

The estrogenic mycotoxin zearalenone is produced by *Fusarium graminearum* (formerly *Fusarium roseum*), under certain environmental and storage conditions and, sometimes, in conjunction with vomitoxin or deoxynivalenol (DON). Cereal grains associated with zearalenone production include corn, wheat, barley and oats, and some grasses

in New Zealand have also been reported to have been contaminated with zearalenone (Cheeke, 1998). Swine have been shown to be particularly susceptible to the adverse effects of zearalenone, with pre-pubertal gilts being affected by concentrations of zearalenone in the feed as low as 1–3 ppm (Cheeke, 1998; Casteel, 2007). The increased sensitivity of pigs to the estrogenic effects of zearalenone is most likely related to the slow metabolism and enhanced enterohepatic recirculation of zearalenone noted in this particular species (Cheeke, 1998). Cattle and other ruminants can be affected by zearalenone but only at dietary concentrations much higher than those associated with clinical signs in swine (Casteel, 2007). Hyperestrogenism in pre-pubertal gilts is characterized swelling of the vulva and mammary glands, uterine enlargement and ovarian atrophy, and testicular atrophy and preputial swelling have been observed in immature male swine (Cheeke, 1998). As with other xenoestrogens, interference with estrogenic feedback mechanisms and various ovarian abnormalities, including follicular cysts, have been observed with excessive exposure to zearalenone. Since estrogens are luteotrophic in swine, zearalenone can be associated with prolonged luteal phases (pseudopregnancy), as well as nymphomania in cycling gilts and sows, depending on the phase of the estrous cycle at the time of exposure.

*Synthetic xenoestrogens and antiestrogens*

A wide range of agricultural and industrial chemicals, as well as pharmaceuticals used in birth control preparations, have estrogenic and/or antiestrogenic activities, depending on the endocrine environment, presence of endogenous estrogens and stage of development at the time of exposure. The type of tissue and physiological response being discussed, as well as the relative distribution of ER$\alpha$ and ER$\beta$ receptors will also affect the types of endocrine effects observed in a given circumstance. As has been emphasized previously, the developing fetus is particularly susceptible to the adverse effects of estrogenic and antiestrogenic endocrine disruptors (Hess and Iguchi, 2002).

Some of the synthetic xenobiotics most commonly discussed with respect to their estrogenic and/or, in some instances, their antiestrogenic activity include DES, DDT, PCBs, bisphenol A, nonylphenol, kepone and TCDD (MacLachlan, 2001). While the overall adverse effects of xenoestrogens have already been discussed in this chapter with respect to reproductive development and endocrine disruption, there are several unique clinical aspects of exposures to these types of xenobiotics which should be addressed for completeness. Prenatal human exposures to the synthetic, non-steroidal xenoestrogen, DES, have been associated with feminization of the male fetus, as well the increased occurrence of clear cell adenocarcinoma of the vagina in young women (McLachlan 2001; Rogers and Kavlock, 2001; McLachlan *et al.*, 2006; Newbold *et al.*, 2006). The use of DES for mismating or pregnancy prevention in dogs has been, in some instances with an increased incidence of cystic endometrial hyperplasia and pyometra. The apparent ability of the widely distributed xenoestrogen, bisphenol A, to cause adverse developmental effects at very low, environmental concentrations and in a manner characterized by a non-monotonic (inverted U) dose response remains controversial but is worthy of further, detailed discussions because of its scientific ramifications and societal relevance (Welshons *et al.*, 2006).

*Xenoandrogens*

While the emphasis in the area of endocrine disruption has traditionally been on the adverse effects of xenoestrogens reproductive development and function, there is increasing evidence that there are also instances of endocrine disruptors having androgenic activity. The effluents from pulp and paper mills have recently been shown to be able to masculinize female fish (Gray *et al.*, 2006). In addition, the runoff from cattle feedlots where the synthetic androgen, trenbolone, was used for the promotion of growth, has also been shown to have androgenic activity and is also suspected of being associated with masculinization of females in wildlife species (Orlando *et al.*, 2004).

## Teratogenesis and abortion

### *Mechanisms of actions of teratogenesis and abortion*

A large number of xenobiotics have been classified with respect to their teratogenic potential, and these are listed in Table 14.2. The ability of EDCs to interfere with phenotypic sexual differentiation in the fetus has already been extensively reviewed in this chapter. Teratogenesis can be associated with each of the following mechanisms of action: (1) excessive cell death; (2) interference with apoptosis; (3) reduced cellular proliferation rate; (4) failed interactions between cells; (5) impaired morphogenetic movements; (6) reduced synthesis of components essential for growth and development; (7) mechanical disruption; (8) and alterations in pH (Hood *et al.*, 2002; Hood, 2006). Some teratogens are capable of more than one mechanism of action. Premature parturition or abortion can be induced by any xenobiotics which cause fetal or, potentially, maternal stress and initiate the cascade of endocrine and neural signaling events which would normally lead to parturition. Any intoxication in a pregnant animal has the potential to threaten fetal survival. Toxicants which cause sudden fetal death or complete cessation of placental function or disruption of the gestational source of progestins can also induce abortion in animals.

*Heavy metals*

Several heavy metals have been identified as teratogens and possible abortifacients in humans and animals. The

**TABLE 14.2 Safety of drugs in pregnancy**

| Drug | Recommendation | Comments |
|---|---|---|
| *Antimicrobial drugs* | | |
| Amikacin | C | Aminoglycoside antibiotics easily cross the placenta and may cause 8th nerve toxicity or nephrotoxicity. |
| Ampicillin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Amoxicillin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Carbenicillin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Cephalosporins | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Chloramphenicol | C | May decrease protein synthesis in fetus, particularly in bone marrow. |
| Ciprofloxacin | D | Do not use during pregnancy; quinolones have been associated with articular cartilage defects. |
| Clavulanic acid–amoxicillin (Clavamox, Beecham) | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Clindamycin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Cloxacillin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Dicloxacillin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Doxycycline | D | Tetracyclines can cause bone and teeth malformations in fetus and may cause toxicity in mother. |
| Enrofloxacin | D | See ciprofloxacin. |
| Erythromycin | A | Appears to be safe except for erythromycin estolate, which has been shown to increase the risk of hepatotoxicity in women. |
| Gentamicin | C | Aminoglycoside antibiotics easily cross the placenta and may cause 8th nerve toxicity or nephrotoxicity. However, specific toxicities from gentamicin have not been reported, and it may be used for a serious infection in place of a suitable alternative. |
| Hetacillin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Kanamycin | C | Aminoglycoside antibiotics easily cross the placenta and may cause 8th nerve toxicity of nephrotoxicity. |
| Lincomycin | A | Crosses the placenta but has not been shown to cause problems in fetus. |
| Metronidazole | C | Teratogenic in laboratory animals, but there is no information for dogs and cats. It should be avoided during the first 3 weeks of pregnancy. |
| Neomycin | A | Not obsorbed sufficiently to cause systemic effects after oral administration. |
| Oxacillin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Oxytetracycline | D | Toxic to fetus and may increase risk of hepatitis in mother (see tetracycline). |
| Penicillin G (benzyl penicillin) | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Streptomycin | D | See gentamicin. Streptomycin is associated with higher incidence of 8th nerve toxicity than other aminoglycosides. |
| Sulfonamides | B | Sulfonamides cross the placenta and have produced congenital malformations in rats and mice, but problems have not been reported in dogs or cats; in people, they have caused neonatal icterus when administered near term. Avoid long-acting sulfonamides. |
| Tetracycline | D | Tetracyclines can cause bone and teeth malformations in fetus and may cause toxicity in mother. |
| Trimethoprim–sulfadiazine (Tribrissen, Coopers) | B | Manufacturer states that it is safe during pregnancy in dogs; see also trimethoprim and sulfonamides. |
| Trimethoprim | B | Teratogenic in rats but probably safe in other species. Folate antagonism and bone marrow depression are possible with prolonged use. |
| Ticarcillin | A | Crosses the placenta but has not been shown to be harmful to fetus. |
| Tobramycin | C | Aminoglycoside antibiotics easily cross the placenta and may cause 8th nerve toxicity or nephrotoxicity. |
| Tylosin | B | No information is available. |
| *Antifungal drugs* | | |
| Amphotericin-B | C | There are no known teratogenic effects, but amphotericin is extremely toxic. Use only if the disease is life threatening, in absence of a suitable alternative. |
| Griseofulvin | D | Teratogenic in rats; causes multiple skeletal and brain malformations in cats. |
| Ketoconazole | B | Teratogenic and embryotoxic in rats; antiandrogenic; stillbirths have been reported in dogs. |
| Miconazole | A | Apparently safe if applied topically. |

(*Continued*)

**TABLE 14.2 (Continued)**

| Drug | Recommendation | Comments |
|---|---|---|
| *Antiparasitic drugs* | | |
| Amitraz | C | Manufacturer states that reproduction studies have not been done; no information available. |
| Diethylcarbamazine | A | Manufacturer states that the drug may be given to dogs throughout gestation. |
| Dithiazanine iodide (Dizan, TechAmerica) | B | No information is available; iodide salts may cause congenital goiter if administered for prolonged periods during pregnancy. |
| Fenbendazole | A | Safe. Has been administered to pregnant bitches without producing adverse effects. |
| Dichlorvos (Task, Solvay) | B | Caution is advised when administering cholinesterase inhibitors to pregnant animals; it should not be administered to puppies or kittens, but studies in pregnant dogs and cats suggest that there are no adverse effects during pregnancy. |
| Ivermectin | A | Safe. Reproduction studies in dogs, cattle, horses and pigs have not shown adverse effects. |
| Levamisole | C | No information available. |
| Mebendazole | A | Safe. In reproduction studies in dogs, it was not teratogenic or embryotoxic. |
| Piperazine | A | Safe. No known contraindications for the use of piperazine. |
| Praziquantel | A | Safe. No adverse effects were seen when tested in pregnant dogs and cats. |
| Thiacetarsamide (Caparsolate sodium, CEVA) | C | No specific information regarding toxicity to fetus is available. It can be hepatotoxic and nephrotoxic, and heartworm adulticide should be postponed until after parturition. |
| Bunamidine | A | Has been administered to pregnant bitches without problems and is safe in pregnant cats. Slight interference with spermatogenesis has been seen in male dogs. |
| Pyrantel | A | Safe. Toxicity studies have not shown any adverse effects. |
| Thenium | A | Safe. Manufacturer states that except in young puppies, there are no known contraindications. |
| Thiabendazole | B | Thiabendazole is not teratogenic in laboratory animals, but high doses have produced toxemia in ewes. |
| Trichlorfon | C | Caution is advised when administering organophosphates to pregnant animals. Congenital toxicoses have been reported following administration to pregnant sows. Manufacturer states that trichlorfon should not be administered to pregnant mares, but there are no recommendations for dogs and cats. |
| *Anticancer drugs* | | |
| Doxorubicin hydrochloride (Adriamycin, Adria) | C | May produce malformations in newborn or embryotoxicity. |
| Azathioprine | C | May produce congenital malformations but has been used in pregnant women safely. It may be a suitable alternative to other drugs when immunosuppressive therapy is required. |
| Chlorambucil | C | May produce malformations in newborn or embryotoxicity. |
| Cisplatin | C | May produce congenital malformations, embryotoxicity or nephrotoxicity. |
| Cyclophosphamide | C | May produce malformations in newborn or embryotoxicity. |
| Methotrexate | C | May produce malformations in newborn or embryotoxicity. |
| Vincristine | C | May produce malformations in newborn or embryotoxicity. |
| *Analgesic drugs* | | |
| Acetaminophen | C | Safety not established in dogs; toxic in cats. |
| Aspirin | C | Embryotoxicity has been seen in laboratory animals but not in other species. Late in pregnancy, it may produce pulmonary hypertension and bleeding problems (see text). |
| Flunixin meglumine | C | Safety in pregnancy has not been determined. |
| Gold (aurothioglucose) | D | Laboratory animal studies clearly show increased congenital malformations. |
| Ibuprofen | C | Safety in dogs and cats not established. |
| Indomethacin administered near term. | C | Can be toxic in adult dogs; can cause premature closure of ductus arteriosus if |
| Phenylbutazone | C | Safety has not been established. Long-term use can depress bone marrow. |
| Salicylates | | Embryotoxicity has been seen in laboratory animals but not in other species. Late in pregnancy, it may produce pulmonary hypertension and bleeding disorders. |
| *Anesthetic and preanesthetic drugs* | | |
| Acepromazine | B | Phenothiazines should be avoided near term; they may produce neonatal CNS depression. |
| Atropine | B | Crosses the placenta and has been used safely but may cause fetal tachycardia. |
| Butorphanol | B | Safe for short-term use. Neonatal depression can be treated with naloxone. |
| Codeine | B | Safe for short-term use. Neonatal depression can be treated with naloxone. |
| Diazepam | C | See anticonvulsants. |
| Fentanyl | B | Safe for short-term use. Neonatal depression can be treated with naloxone. |

(*Continued*)

**TABLE 14.2 (Continued)**

| Drug | Recommendation | Comments |
|---|---|---|
| Glycopyrrolate | B | Safe. Does not cross placenta as readily as astropine. Studies in rats and rabbits have not revealed teratogenic effects. |
| Halothane | C | Decreased learning ability has been reported in rats after *in utero* exposure; depression may be seen in neonates after cesarean section; excessive uterine bleeding may be seen when administered during cesarean section. |
| Isoflurane | B | Probably safe. Depression may be seen in neonates after cesarean section. |
| Ketamine | B | Probably safe. Depression may be seen in puppies delivered by cesarean section; may increase intrauterine pressure and induce premature labor. |
| Lidocaine | A | All local anesthetics appear to be safe when used for a local nerve block or epidural anesthesia. |
| Meperidine | B | Opiates can produce neonatal sedation and respiratory depression, but the effects can be reversed with the administration of naloxone. |
| Methoxyflurane | C | Neonatal depression is seen when used for cesarean section. |
| Morphine | B | Opiates can produce neonatal sedation and respiratory depression, but the effects can be reversed with the administration of naloxone. |
| Naloxone | A | Has been shown to be safe when administered to newborns within a few minutes after birth. |
| Nitrous oxide | B | Probably safe. Used frequently for cesarean section without adverse effects. |
| Oxymorphone | B | Opiates can produce neonatal sedation and respiratory depression, but the effects can be reversed with the administration of naloxone. |
| Pentobarbital | D | Associated with high incidence of neonatal mortality. |
| Thiamylal | C | Easily crosses the placenta; all barbiturates produce respiratory depression in fetus; however, thiobarbiturates are not as toxic as pentobarbital. |
| Thiopental | C | Easily crosses the placenta. All barbiturates produce respiratory depression in fetus; however, thiobarbiturates are not as toxic as pentobarbital. |
| *Gastrointestinal drugs* | | |
| Antacids | A | Safe. Not absorbed systemically. |
| Antiemetics | B | Probably safe if administered short term. |
| Cimetidine | B | Safety has not been established, but no reports of toxicity in humans. |
| Dimenhydrinate | B | Safe if used short term. |
| Diphenhydramine | B | Safe if used short term. |
| Diphenoxylate | C | Studies have reported adverse effects in laboratory animals, but no adverse effects have been reported in pregnant dogs, cats and humans. |
| Laxatives | B | All laxatives, except castor oil (Squibb), are considered safe if they are used short term. Castor oil causes premature uterine contractions. |
| Loperamide | C | Same comment as diphenoxylate. |
| Metoclopramide | B | Safe in laboratory animals, but no studies available for cats or dogs. |
| Methscopolamine | C | Safety not established. |
| Misoprostol | D | Synthetic prostaglandin, causes a termination of pregnancy. |
| Prochlorperazine | B | No reports of toxicity when administered short term. |
| Ranitidine | B | Safety has not been established, but no reports of toxicity were reported in humans. |
| Sucralfate | A | Probably safe. Not absorbed systemically. |
| Sulfasalazine | B | Salicylate component is not absorbed enough to produce adverse effects; sulfonamide may produce neonatal icterus when used near term (see text). |
| *Cardiovascular drugs* | | |
| Atropine | B | Probably safe but may produce fetal tachycardia. |
| Captopril | C | Has been shown to be embryotoxic in laboratory animals and goats. |
| Digitalis | A | Probably safe. No adverse effects seen in humans and laboratory animals (see text). |
| Furosemide | B | No adverse effects have been reported. |
| Dopamine | B | Probably safe at therapeutic doses. |
| Heparin | B | Does not appear to cross placenta. |
| Hydralazine | B | Probably safe. There have been reports of minor toxicity in rats, but it has been administered safely to pregnant women. |
| Isoproterenol | C | May cause fetal tachycardia; beta-adrenergic drugs inhibit uterine contractions. |
| Lidocaine | B | Probably safe. May cause fetal bradycardia. |
| Nitroglycerin | C | No information available. |
| Nitroprusside | C | There is a risk of fetal cyanide toxicity with prolonged use. |
| Procainamide | B | Probably safe. May cause fetal bradycardia. |
| Propranolol | C | May cause fetal bradycardia, respiratory depression and neonatal hypoglycemia; avoid use near term. |

(*Continued*)

**TABLE 14.2 (Continued)**

| Drug | Recommendation | Comments |
|---|---|---|
| *Cardiovascular drugs* (Cont.) | | |
| Quinidine | B | Probably safe. May cause fetal bradycardia. |
| Theophylline | B | No reports of adverse effects. |
| Thiazide diuretics | C | May cause increased incidence of perinatal mortality. |
| Warfarin | D | Causes embryotoxicity and congenital malformations, neural tube defects in laboratory animals and humans. |
| *Anticonvulsant drugs* | | |
| Diazepam | C | Has been associated with congenital defects in mice, rats and people. |
| Phenobarbital | B | Has been associated with rare congenital defects and bleeding tendencies in newborn but may be safer than other anticonvulsants (see text). |
| Phenytoin | C | Teratogenic in rats, mice and people. |
| Primidone | C | Same risks as phenobarbital and has been associated with increased incidence of hepatitis in adult dogs. |
| Valproic acid | C | May cause congenital malformations. |
| *Muscle relaxants* | | |
| Dantrolene | C | Safety not established. |
| Dimethyltubocurarine | B | Quarternary base with negligible placental transfer; it does not affect the fetus unless administered in large doses. |
| Gallamine | B | Quarternary base with negligible placental transfer; it does not affect the fetus unless administered in large doses. |
| Methocarbamol | C | Safety not established; manufacturer states that it should not be administered during pregnancy. |
| Pancuronium | B | Quarternary base with negligible placental transfer; it does not affect the fetus unless administered in large doses. |
| Succinylcholine | B | Quarternary base with negligible placental transfer; it does not affect the fetus unless administered in large doses. |
| *Endocrine drugs* | | |
| Betamethasone | C | Corticosteroids have been associated with increased incidence of cleft palate and other congenital malformations, and they may induce premature labor and abortion in dogs (see text). |
| Cortisone | C | Corticosteroids have been associated with increased incidence of cleft palate and other congenital malformations, and they may induce premature labor and abortion in dogs (see text). |
| Dexamethasone | C | Corticosteroids have been associated with increased incidence of cleft palate and other congenital malformations, and they may induce premature labor (see text). Dexamethasone has caused abortion and fetal death in dogs. |
| Diethylstilberstrol (DES) | D | Malformation of male and female genitourinary systems. |
| Estradiolcypionate (ECP) | D | Malformation of male and female genital tracts and bone marrow depression. |
| Flumethasone | C | Corticosteroids have been associated with increased incidence of cleft palate and other congenital malformations, and they may induce premature labor and abortion in dogs (see text). |
| Mitotane (*o,p′*-DDD) | D | Adrenocortical necrosis. |
| Prednisolone | C | Although prednisolone has been administered to pregnant women without adverse effects, caution is advised (see dexamethasone). Prednisolone may be used in serious diseases in absence of a suitable alternative. |
| Stanozolol | D | Manufacturer states that it should not be administered to pregnant dogs and cats. |
| Testosterone | D | Causes masculinization of female fetus. |
| Thyroxine | B | Does not cross placenta easily and has not been associated with any problems. |
| *Miscellaneous drugs* | | |
| Ammonium chloride | B | May cause fetal acidosis; discontinue use during pregnancy. |
| Aspartame (Nutra Sweet) | A | No risk. |
| Dimethylsulfoxide (DMSO) | C | Teratogenic in laboratory animals; manufacturers state that it should not be applied to breeding animals. |

A: Probably safe. Although specific studies may not have proved the safety of all drugs in dogs and cats, there are no reports of adverse effects in laboratory animals or in women.
B: Safe for use if used cautiously. Studies in laboratory animals may have uncovered some risk, but these drugs appear to be safe in dogs and cats or these drugs are safe if they are not administered when the animal is near term.
C: These drugs may have potential risks. Studies in people or laboratory animals have uncovered risks, and these drugs should be used cautiously, as a last resort when the benefit of therapy clearly outweighs the risks.
D: Contraindicated. These drugs have been shown to cause congenital malformations or embryotoxicity.

adverse affects of *in utero* lead exposure, on the developing nervous systems both human and laboratory animal species, have been well documented (Evans *et al*., 2003; Rogers and Kavlock, 2001). Prenatal exposure to organotins has been associated with pregnancy loss and impaired ossification in rodents (Ema and Hirose, 2006), and organic mercury is a known developmental neurotoxicant (Golub, 2006b). Other heavy metals, including cadmium and mercury, have been associated with placental toxicity, and this topic is covered in greater detail in Chapter 15.

***Selected plant-associated teratogens and abortifacients***

Many potentially toxic plants have been found to induce teratogenesis and/or abortion in mammals. While it is not possible to extensively review all of these plants, there are several well-documented examples of plant-induced birth defects and abortion which clearly illustrate the basic principles regarding the pathogenesis of teratogenesis and abortion in domestic animals.

*Veratrum californicum*

Jervanine alkaloids (e.g. cyclopamine, cycloposine and jervine) in *Veratrum californicum* (false hellebore) and, potentially, some closely related plants have been associated with the occurrence of cyclops lambs and other developmental abnormalities in sheep (Burrows and Tyrl, 2001). The mechanism of action of the teratogenic alkaloids in species of *Veratrum* involves the inhibition of neuroepithelial cell mitosis and migration during neurulation and decreased proliferation of chondrocytes (Cheeke, 1998; Burrows and Tyrl, 2001). The specific developmental abnormalities and the precise timing of maternal exposure to *Veratrum californicum*, which results in these defects is as follows: cyclops lambs and prolonged gestation (associated with the absence of pituitary gland) from maternal exposure on days 12–14 of gestation; embryonic death from maternal exposure on gestational days 19–21; cleft palate from maternal exposure on gestational days 24–30 and metacarpal, metatarsal and tracheal cartilage defects from maternal exposure on gestational days 27–36 (Burrows and Tyrl, 2001). No abnormal effects were observed with maternal exposure to *Veratrum californicum* before day 10 or after day 36 of pregnancy, and *Veratrum*-associated birth defects can generally be prevented by avoiding exposure until at 5 weeks after breeding.

*Multiple congenital contractures*

Species of tobacco (*Nicotiana* spp.), poison hemlock (*Conium maculatum*) and lupines (*Lupinus* spp.) have all been shown to be able to induce MCC or "crooked calf disease" in cattle and, potentially, other species exposed to their toxic principles at the appropriate stage of gestation. Pyridine alkaloids (e.g. anabasine) in tobacco, piperidine alkaloids in poison hemlock (e.g. coniine and $\gamma$-coniceine) and piperidine-derived and quinolizidine alkaloids in lupines (e.g. ammodendrine and anagyrine, respectively) cause stimulation then depression (depolarizing neuromuscular blockade) of nicotinic receptors in the fetus (Cheeke, 1998; Burrows and Tyrl, 2001; Panter, 2002). This stimulation followed by neuromuscular blockade of fetal nicotinic receptors during the critical period of joint development (i.e. gestational days 40–100 in cattle; days 30–60 in sheep; days 30–60 in swine) results in decreased fetal movement and the failure of joints to form in a normal fashion (Panter, 2002).

*Pine needle abortion*

Ingestion by cattle of pine needles (*Pinus ponderosa*) containing isocupressic acid (also possibly present in the vegetation of some junipers and cypresses) results in late-term abortion (Cheeke, 1998). Inhibition of the catechol estrogen-induced blockade of potential-sensitive $Ca^{2+}$ channels, by isocupressic acid, leads to enhanced entry of divalent calcium into arterial smooth muscle cells supplying the gravid uterus and results in profound vasoconstriction (Casteel, 1997; Cheeke, 1998; Burrows and Tyrl, 2001). This isocupressic-acid-induced vasoconstriction can lead to a 50% reduction in the blood flow reaching the fetal circulation and causes fetal stress, leading to the induc-tion of premature parturition or abortion (Cheeke, 1998; Burrows and Tyrl, 2001). Late-term abortion occurs 2–14 days following heavy consumption of green or dry pine needles and results in up to 75% of exposed cows aborting or delivering dead or weak calves (Cheeke, 1998; Burrows and Tyrl, 2001; Casteel, 2007). Dams are frequently dull and depressed, with weak uterine contractions, incomplete cervical dilation, retained placenta and frequent post-partum metritis (Cheeke, 1998).

## CONCLUSIONS

Reproduction is a critical biological process, required for financially viable livestock production, as well as species survival. Toxicant-induced abortions, congenital defects, infertility can have devastating effects on both domestic animals and wildlife species. There is growing concern within the scientific and government regulatory communities about the effects of exposures to reproductive toxicants on human fertility. The information presented in this chapter was intended to familiarize the reader with terminology and concepts pertinent to reproductive toxicity and endocrine disruption, as well as to provide an overview of normal reproductive development, anatomy and physiology and the various aspects of these processes most susceptible to toxic insult by naturally occurring and synthetic xenobiotics. It is hoped that the information and references provided in this chapter will assist readers in

making informed decisions in the course of their future clinical investigations, experimental designs and interpretations of scientific literature and/or regulatory policies.

# Placental toxicity

*Ramesh C. Gupta*

## INTRODUCTION

Placental toxicology embraces the knowledge of the responses of placenta and fetus to chemical insult. It is a fascinating subject, as it deals with three components: mother, placenta, and fetus. The subject includes structural and functional changes in the placenta, placentation, implantation, embryotoxicity, fetal death, structural malformation, growth retardation, and functional deficits. Placental toxicology has blossomed and matured in the past several decades from the contributions of scientists around the world. It has received an enormous attention from the pharmacologists, toxicologists, teratologists, biologists, and regulatory agencies, since the incidence of thalidomide in the 1960s.

The placenta is a rapidly growing organ, with a limited lifespan, which interfaces two separate genomes (mother and fetus). During the pregnancy, placenta serves many functions and undergoes numerous changes, such as the production and release of hormones and enzymes, transport of nutrients and waste products, chemical information flows between mother and fetus, implantation, cellular growth and maturation, and at the terminal phase of placental life, participation in delivery (Pelkonen *et al*., 2006). In other words, the placenta plays many roles in the development of the fetus by serving as the lung, kidney, gut, and exocrine/endocrine glands. Its role in providing nutrients to the developing fetus through maternal circulation has been established for a long time. Unfortunately, some of the toxic metals, such as cadmium and lead, are also delivered to the fetus by the same mechanism as that of the nutrients. In fact, many foreign substances, including pesticides, plant alkaloids, and drugs reach the fetus with a very little or no restrictions.

The health of the placenta is a prerequisite for the health of the fetus. In the toxicant-exposed mother, the chemical encounters the placenta before it reaches the fetus. Therefore, the chemical-induced damage in the placenta is likely to reflect in the fetus. In essence, the health of the placenta seems as important as the health of the mother or the fetus. By now, it is well established that the placenta is a target organ for toxicity of a wide range of poisons. Vulnerability of this organ to toxic effects is great, since it has a considerable amount of metabolic activity, and as a result the placenta can enhance the toxicity by forming metabolites of greater toxicity than the parent compounds.

Literature abounds with ample evidence that the poisons of many classes adversely affect the mother and the fetus, however it is sparse for the placenta. Many toxicants adversely affect fetal growth or survival at doses that do not produce any toxic effects in the mother. In other words, the absence of toxic effects in the mother does not preclude toxicity in the fetus. The evidence also suggests that malformations result from specific action of chemicals, rather than as a general response to maternal illness. Another important concern that needs to be mentioned is that the mechanism involved in maternal toxicity most often differs from the mechanism involved in fetotoxicity and teratogenicity. Thus, the placenta appears to be a complex organ, as its anatomical, physiological, and metabolic characteristics vary depending on the age of the placenta. This would make it important to study placentas from different stages of pregnancy. It is beyond the scope of this chapter to discuss the placental toxicity of every single chemical, instead this chapter is focused on common poisons, such as metals, pesticides, mycotoxins, tobacco, etc. that adversely affect pregnant animals, placenta, and fetus.

## ROLE OF THE PLACENTA

The placenta serves pivotal roles in fetal nutrition, respiration, and excretion. Placenta also provides protection to the fetus. This organ has a limited lifespan, as the umbilical cord, placenta, amnion, and chorion are expelled soon after the birth of the fetus. For the decades, the view of the pharmacologists, toxicologists, teratologists, and biologists has been that the placenta is a rejected tissue and may not be suitable for bioassay or biocomparative assays of drugs and evaluation of the cellular/molecular mechanisms of actions of drugs and toxic chemicals. But, due to substantial progress in placental pharmacology/toxicology research, the view has been changed. Currently, several methods are available to use different parts of the placenta in screening drugs and chemicals and to study the molecular mechanisms for their pharmacological and toxicological effects. Use of pregnant animals is considered the preferred model to assess the toxicological actions of chemicals. In such circumstances, it is important to study placentas from different stages of pregnancy. However, obtaining material for such studies is difficult for practical reasons. Furthermore, in assessing placental toxicity of chemicals, all physiological and anatomical variables should be taken into consideration. In addition, there are several *in vitro* pharmacological/toxicological preparations from the placenta, which include: (1) perfused single placental cotyledon; (2) villus preparation; (3) segments of umbilical, chorionic plate and villus stem arteries and veins; (4) trophoblast plasma membrane; (5) isolated receptors and transporters; and (6) stem cells from umbilical blood. For further details, refer to Schneider (1995), Sastry (1997), and Pelkonen *et al*. (2006).

## TYPES OF PLACENTA

The placentas of different species vary in shape, internal architecture, and nature of the interhemal barrier. Anatomically, the placenta is a complex organ and placentas are classified into four types: (1) hemochorial (rat, rabbit, human); (2) endotheliochorial (cat, dog); (3) syndesmochorial (ruminants); and (4) epitheliochorial (pig, horse). The placenta has also been described as zonary in the dog, bidiscoid in the monkey, and multicotyledonary in the sheep. The placental thickness depends on the number of fetal and maternal cell layers. For example, the rat and rabbit have a single layer of cells, primates and humans have three layers, and pigs and horses have six layers. In addition to anatomical, there are physiological and functional differences among different types of placenta. Because of technical and practical advantages, animal placentas have been used to study placental function, and pharmacology and toxicology. However, the hemochorial placenta has been studied more extensively compared to other types. In hemochorial placenta, the membrane separating the maternal and fetal compartments are consist of three layers (syncytiotrophoblast, connective tissue, and vascular fetal endothelium). These anatomical and physiological similarities and differences in placentas of different species should be taken into consideration when studying and evaluating placental toxicity.

## METABOLISM IN PLACENTA

Both phase I reactions (oxidation, reduction, and hydrolysis) and phase II reactions (conjugation of a chemical with endogenous moiety, such as glucuronic acid or sulfate) of metabolism exist in the placenta as well as in fetus. Placenta can also be active in intermediary metabolism, such as gluconeogenesis, urea, and fatty acid synthesis. The capacity for metabolic processes appears to vary with species, gender, and gestational stage. Carbonic anhydrase activity, a marker of placental metabolism and transfer, is present much greater in pig, rat, and mink than in horse, cow, and human. Xenobiotic metabolism in the placenta seems to be similar to that in maternal tissues, but the extent of the metabolic activity is usually less. However, the metabolic activity is still enough that the placental–fetal toxicity of chemicals can be significantly modified. The placenta has an abundance of drug- and xenobiotic-metabolizing enzyme system, i.e., cytochrome P450. Cyt. P450 exists in multiple forms with distinct, but generally overlapping, substrate specificities and many of the isoforms are inducible by exposure to exogenous agents (Pasanen and Pelkonen, 1994; Juchau, 1995). In the placenta, several steroid hormones are formed and metabolized by Cyt. P450 systems, which may participate in xenobiotic metabolism (Gonzalez, 1989). In general, the metabolites produced by biotransformation are usually less toxic or inactive compared to the parent compound, and thereby the xenobiotic-metabolizing enzymes in the placenta protect the fetus from potentially fetotoxic drugs and chemical toxicants. It is noteworthy, that the same enzyme system can also form metabolites which are more toxic than their parent compounds. For example, oxon metabolites of organophosphorus insecticides and epoxides of cyclodiene chlorinated hydrocarbons have a greater potential for fetotoxicity/teratogenicity than their parental forms. In addition, placental metabolism has the capacity to form carcinogen-DNA adducts. For further details, see comprehensive reviews (Pelkonen, 1984; Pasanen and Pelkonen, 1994; Juchau, 1995). Compared to phase I, phase II reactions

in the placenta have not been studied in detail because the placenta contains very low activities of these enzymes (Juchau, 1980, 1995).

## PLACENTAL SUSCEPTIBILITY TO CHEMICAL TOXICANTS

Placenta is a unique tissue that interfaces two separate genomes, i.e., mother and fetus. Since the placenta serves as an exchanger between mother and fetus for nutrients, the health of the fetus seems to be dependent on the health of the mother and placenta. There appear to be several mechanisms by which toxicants are concentrated in the placenta and fetal tissues in greater quantities than in the maternal tissues. The large placental surface area comes in contact with a relatively large volume of maternal blood, which is required for normal placental function, and that makes the placenta vulnerable to toxicants (Eisenmann and Miller, 1996). In addition, the placenta has several biomolecules, such as proteins, lipids, carbohydrates, nucleic acids/nucleotides, and drug metabolizing and many other enzymes. The placenta, being rich in proteins, bioconcentrates chemical residues by means of protein binding and release them into the placental circulation and ultimately into the fetus. In essence, the structure and function of the placenta are so unique that its susceptibility to chemical toxicity seems far greater than that of the mother. Thus, any damage to the placenta caused by a toxic chemical is likely to reflect in the fetus.

## PLACENTAL BARRIER FOR CHEMICAL TOXICANTS

The placenta is the entry through which the fetus is exposed to most chemical poisons, and the term placental barrier appears to be a false notion. The placenta has been characterized as a lipid membrane that permits bidirectional transfer of substances between maternal and fetal compartments rather than as a barrier. In general, the placental barrier consists of the trophoblastic epithelium covering the villi, the chorionic connective tissue, and the fetal capillary endothelium. Foreign chemicals are transferred through placental membranes by passive diffusion. The two most common factors that are involved in transplacental transfer of common toxicants are: (1) physicochemical properties of the chemical and (2) type of placenta. In general, any chemical with a molecular weight $<1000$ readily crosses the placenta, and therefore the majority of the chemical toxicants are not restricted from reaching the fetus. It is important to mention that chemical properties, such as lipophilicity, polarity, and degree of ionization, can influence the placental barrier (Pacifici and Nottoli, 1995). The second factor that predominately influences the transplacental transfer of chemical toxicants is the type of placenta. For instance, the complex multilayered placenta of higher mammals can make it more difficult for chemicals to gain access to the fetus compared to the simpler choriovitelline or chorioallantoic type of placenta (Welsch, 1982; Juchau, 1995; Ala-Kokko *et al*., 2000). A number of other factors that can influence the rate and extent of transplacental transfer of chemical toxicants include: (1) maternal–fetal chemical gradient, (2) uterine and umbilical blood flow, (3) molecular weight of the chemical, (4) protein binding, and (5) lipid solubility. These factors can also determine the time required for maternal–fetal equilibrium of a toxicant. Direct or indirect evidence for placental transfer of chemical toxicants is determined based on residue analysis of these compounds and/or their metabolites in the placenta, umbilical cord, and embryo/fetus.

## FACTORS THAT MAY INFLUENCE THE PLACENTAL TOXICITY

Anatomical, physiological, and metabolic characteristics vary depending on the stage of the placenta. There are three major factors, which can modify the overall toxicity of a chemical during pregnancy: (1) maternal toxicity, (2) placental transfer of a chemical, and (3) placental–fetal metabolism.

### Maternal toxicity

Maternal toxicity can be defined as the transitory or permanent state of alteration in maternal physiology or behavior with a potential to cause adverse effect in the offspring during embryo/fetal or postnatal development. The common factors related to maternal toxicity are as follows:

1 route of drug or chemical exposure;
2 maternal drug or chemical distribution;
3 maternal drug or chemical metabolism;
4 uterine blood flow;
5 pH of the blood.

Although the precise mechanism by which maternal toxicity factors are responsible for fetal toxicity or teratogenesis has remained unexplained, alterations in placental function appear to be important. It seems that maternal

toxicity plays a major role in adverse fetal outcome by modifying placental function.

### Placental transfer of toxicants

The factors related to placental morphology, physiology, and metabolism seem to be interrelated, and with continuing change they become more complex as gestation advances. The important placental transfer factors include:

1. placental blood flow;
2. pH of the blood;
3. placental permeability (passive or active transport system);
4. placental maturity over gestation period (size, surface area, and thickness);
5. interspecies variation in placental morphology;
6. lipid–protein content of the membranes;
7. placental metabolism;
8. plasma protein binding;
9. physicochemical properties of toxicants.

Plasma protein (mainly albumin) binding appears to be the important factor that can modify placental toxicity. A chemical can cross the placenta only if the chemical is in free form, but a protein-bound form can be released into free form, since the protein binding is a reversible process. Once the chemical has reached the fetus, either it remains free to produce toxic effects, or once again it can bind to proteins of blood or fetal tissues, a phenomenon described as the "sink effect."

### Placental–fetal metabolism

Placental–fetal metabolism appears to be one of the three major factors that can alter the placental toxicity of poisonous substances. Metabolism occurs in all placental and fetal tissues, as it occurs in maternal tissues, but the capacity differs at all stages of gestation. During pregnancy, metabolism of the toxicant is complicated by two major factors: (1) the pregnancy itself, since the general metabolic activity is significantly low, which may lower the degradation of toxicants and thereby increase the toxicity and (2) pre-exposure or simultaneous exposure to other chemicals or environmental pollutants generally results in either reduced or enhanced metabolism, and consequently, alters the placental toxicity. For example, previous exposure to drug-metabolizing enzyme inducers, such as enhanced monooxygenase activity by polychlorinated biphenyls (PCBs) or similar environmental pollutants, can potentiate the toxicity of the "thioate" type of organophosphorus insecticides.

## PLACENTAL TOXICITY OF METALS

Trace minerals and heavy metals are common contaminants of the environment due to their ubiquitous presence, and thereby pose a serious threat to the environment as well as human and animal health. In excessive concentrations, these minerals and metals are known to adversely affect pregnancy and the development of the conceptus, in addition to pregnant mother. Placental toxicity of some important metals is described here in brief. It should be noted that much of the pertinent literature mentioned here is from laboratory animals.

### Aluminum

Aluminum (Al) commonly contaminates food and water, as it is one of the three most abundant metals in the earth's crust. Al can be absorbed through oral, dermal, inhalation, and parenteral routes, and concentrated in the liver, lungs, bone, kidney, spleen, heart, brain, and muscles. Al also transplacentally traverses and accumulates in the fetal tissues in amounts that adversely influence fetal development (Yokel and McNamara, 1985). Studies conducted in mice and rabbits revealed that the placenta contained 4–5 times greater Al levels than the fetal or maternal tissues (Yokel and McNamara, 1985; Cranmer *et al.*, 1986). However, the placenta of the guinea pig does not accumulate this metal. It is important to mention that the placental accumulation of Al in mice and rabbits does not preclude its accumulation in the fetal tissues.

For the detailed toxicokinetics of Al, readers are referred to the review of Yokel (1997).

Pregnancy in general enhances susceptibility to Al toxicity. Following oral administration, only a small fraction of Al is absorbed, and therefore the degree of severity of developmental toxicity is often minimized. However, based on some animal and human studies, it is likely that the oral absorption of aluminum can vary 10-fold based on chemical form alone, ranging from approximately 0.1% for relatively non-bioavailable water insoluble forms such as aluminum hydroxide to relatively bioavailable water soluble forms such as aluminum citrate. Animal studies suggest that Al accumulates in the brain and is preferentially distributed to the hippocampus, the region which is most relevant to memory and Alzheimer's disease in humans. Hippocampus can have approximately 32 times higher Al than that in the cortex and cerebellum. Animal studies also indicate that Al has the potential to cross the placenta and accumulate in the fetus.

Oral administration of Al is known to cause a developmental syndrome, which includes *in utero* death, delayed ossification of skeleton, malformations, and growth retardation, at doses that also influence maternal weight gain.

An increased incidence of resorptions occurred in female BALB/c mice treated with 41 mg/kg/day as Al chloride by gavage on GD 7–16 (Cranmer *et al.*, 1986). Gestational exposure of mice to Al lactate (83 mg/kg/day) caused increased incidences of cleft palate, dorsal hyperkyphosis, and delayed parietal ossification. Skeletal changes, such as delayed ossification and hypoplastic deformed ribs, were induced in rats exposed to 38–77 mg Al/kg/day by gavage on GD 6–14 (Patermain *et al.*, 1988). The severity of the effects is highly dependent on the form of Al administered. Studies using high Al exposures obtained by intravenous (i.v.) or intraperitoneal (i.p.) administration report a developmental toxicity syndrome consisting of death and resorptions, skeletal and soft tissue abnormalities, low birth weights, and growth retardation in rats, mice, and rabbits (Wide, 1984; Yokel, 1997). The high incidence of resorptions was found to be significantly higher in pregnant rats treated with Al chloride at dose level of 75 mg/kg on GD 9–13, 100 mg/kg on GD 14–18, and 200 mg/kg on GD 9–13 (Benett *et al.*, 1975). A high incidence of dead offspring was recovered from mothers treated with Al chloride at a dose level of 200 mg/kg on GD 9–13. These studies indicate that Al can cause delays in skeletal development in pups. Gross fetal abnormalities include abnormal digits, wavy ribs, missing ribs, absence of xiphoid, and poor ossification (particularly in the cranial bones, lower part of the vertebral column, and the long bones of the limbs). The high incidence of skeletal defects, and also poor ossification in fetuses of mothers treated with Al chloride suggest that Al has an adverse influence on fetal bone formation. This is due to the fact that Al binds with phosphate, thereby reducing the amount of phosphate available for bone formation. Depletion of phosphate can also result in fetal internal hemorrhage, due to failure of the blood clotting mechanism. Interestingly, neurotoxicity and neurobehavioral changes have been noted in offspring following Al exposure of rats, mice, and rabbits at doses of Al that did not produce maternal toxicity (Wide, 1984; Domingo, 1994; Yokel, 1997). Other forms of Al, such as Al citrate and Al nitrate, can also produce similar developmental effects. Overall, developing conceptuses are more sensitive than adults to Al toxicity.

## Arsenic

Arsenic (As) occurs in many forms and commonly found in high concentrations in water and food. Both animal and human studies have shown that As crosses the placenta. Inorganic As crosses the placental barrier and selectively accumulates in the neuroepithelium of the developing animal embryo. Uptake, distribution, and metabolism of sodium arsenite (2.5 μg/kg, po) and sodium arsenate (40 μg/kg, po) were determined in pregnant mice on GD 18 (Hood *et al.*, 1987). Maximum concentrations of As in the placenta were found at 4 and 2 h after administration of arsenite and arsenate, respectively. Corresponding concentrations in the fetal tissues appeared at 24 and 6 h. In the fetal tissues, inorganic As is converted to the organic form and methylation appears to be the major detoxification mechanism. As is completely eliminated from the placental/fetal tissues within 24 h of exposure. Unlike inorganic As, organic As does not cross the placenta, instead it is stored in the placenta. In other studies conducted on hamsters, rats, and mice, As ingested at higher doses has been found to be fetotoxic and teratogenic. There is evidence that sodium arsenate and sodium arsenite are embryotoxic (Chaineau *et al.*, 1990). Common deformities include hypoplasia of the prosencephalon, somite abnormalities, and failure of development of limb buds and sensory placodes. In hamsters, a single i.v. injection of sodium arsenate (20 mg/kg) given on GD 8 resulted in 49% malformed and 84% either malformed or resorbed embryos on GD 13 (Holmberg and Ferm, 1969). Common malformations included exencephaly, encephalocele, cleft lip/palate, micro/anophthalmia, and ear malformations. In rats, the spectrum of malformations induced by As is similar to that described for hamsters. Placental/fetal toxic effects of As have been more extensively described in mice than in rats and hamsters. Exposure of female mice with arsenite/arsenate on GD 9 produces the highest incidence of malformed live fetuses, whereas exposure on GD 11 or 12 produces the highest rate of resorptions. The common external malformations include exencephaly, micrognathia, exophthalmia, anophthalmia, cleft lip, hydrocephalus, micromelia, ectrodactyly, open eyes, rib defects, and vertebral defects. Rats treated with a single gavage dose of 23 mg As/kg as As trioxide on day 9 of gestation had a significant increase in post-implantation loss and a decrease in viable fetuses per litter, while those treated with 15 mg/kg showed no effects (Stump *et al.*, 1999). Rats and mice are much more sensitive than hamsters to organoarsenicals, in terms of placental toxicity. But the most sensitive species is the rabbit, in which 1.5 mg As/kg/day can increase resorptions and decrease viable fetus.

Although the exact mechanism involved in placental toxicity of As is not yet explained, As is known to interact with protein sulfhydryl groups, thereby adversely affecting the activity of many enzymes, including glutamic–oxaloacetic transaminase, pyruvate oxidase, monoamine oxidase, choline oxidase, glucose oxidase, urease, oxidoreductases, and kinases. As has also been shown to adversely affect a number of enzymes that are involved in mitochondrial respiration (Rogers, 1996). In addition, As inhibits succinic dehydrogenase activity and thereby uncouples oxidative phosphorylation and causes fall of ATP levels affecting virtually all cellular functions ($Na^+/K^+$ balance, protein synthesis, etc.). Since As is known to affect vasculature and altered placental and/or embryonal vasculature has been suggested as a mechanism leading to

neural tube defects, the embryo may be sensitive to this manifestation of As toxicity. At high dose, As impairs assembly and disassembly of microtubules, thus interfering with mitotic spindle formation and embryonal cell division. As compounds also cause chromosomal aberrations, which may disrupt cell cycling. The direct toxic effects of high levels of As in the developing embryo result not from a difference in the mechanism of toxicity during development, but rather from the existence of a unique target tissue, the neuroepithelium (ATSDR, 2005). Induction of stress proteins or heat shock proteins synthesis in the embryo has been explained as a common mechanism of teratogenesis. Animal studies have also presented evidence that inorganic As may be a transplacental carcinogen.

In essence, inorganic arsenicals are much more toxic than organic arsenicals. Trivalent As is developmentally more toxic than pentavalent As. In fact, pentavalent As compounds exert their toxic actions only after their conversion to the trivalent form. Placental/fetal toxicity of As is of serious concern, especially at the levels that are maternotoxic.

## Cadmium

Cadmium (Cd) is a naturally occurring metal found in the earth's crust. Most of the Cd is produced as a byproduct during the production of other metals, such as copper, lead, and zinc. The major source of Cd exposure to animals can be from industrial pollution and environmental contamination, especially water. Much of the information obtained on developmental toxicity of Cd is from laboratory animals. By now, it is well established that the placenta itself is a target organ for Cd toxicity. In low to moderate doses, Cd is sufficiently sequestered in the placenta, whereas in high doses, Cd accumulates in the placenta, which perturbs the placental transport of essential elements (such as calcium and zinc), and causes placental necrosis and fetal toxicity. Maternal exposure to Cd is known to cause ultrastructural changes in the placenta, especially trophoblast cell layer II (DiSaint' Agnese *et al.*, 1983). Common changes include lysosomal vesiculation, nuclear chromatin clumping, nucleolar alterations, and apparent mitochondrial calcification. Cd-induced placental necrosis occurs initially in trophoblast cell layer II, and that follows rapidly in the remaining trophoblasts. Subcutaneous administration of Cd chloride, Cd acetate, or Cd lactate to pregnant rats at a dosage of 0.04 mmol/kg between the 17th and 21st day of gestation resulted in rapid, progressive placental damage, especially in the pars fetalis (Parizek, 1964). Cd-induced necrotic changes could occur as early as within 6 h.

Maternal exposure to Cd during pregnancy can result in a variety of adverse reproductive outcomes, such as maternal toxicity, placental damage/hemorrhage, impaired implantation, increased resorptions, reduced litter size, fetal growth retardation, congenital malformation in the fetuses, and embryonic/fetal death. Exposure to Cd during mid-to-late gestation can result in both placental toxicity (reduced blood flow and necrosis) and diminished nutrient transport across the placenta. Exposure during the late gestation can also result in fetal death, despite low levels of Cd entering the fetus (Levin and Miller, 1980; Rogers, 1996). Many studies conducted on rats and mice indicate that Cd can be fetotoxic from oral exposures prior and during gestation. The fetotoxicity is most often manifested as reduced fetal or pup weight, but malformations, primarily of the skeleton, have been reported in some studies. Common malformations or skeletal effects include sirenomelia (fused lower limbs), amelia (absence of one or more limbs), and delayed ossification of the sternum and ribs, dysplasia of facial bones and rear limbs, edema, exenteration, cryptorchism, and palatoschisis.

Cd has also been shown to induce teratogenesis in rats, mice, and hamsters. Cd sulfate administered to pregnant hamsters (2 mg/kg, i.v.) caused high incidence of resorptions. Live fetuses showed a high rate of malformations, including facial clefts, exencephaly, anophthalmia, limb defects, and rib fusions (Ferm and Carpenter, 1967). In rats and mice, the common malformations are club foot, dysplasia of facial bones and rear limbs, cleft palate, micrognathia, sirenomelia/amelia, delayed ossification of the sternum and ribs, microphthalmia/anophthalmia, cryptorchism, gastroschisis, and palatoschisis.

The placenta serves as a remarkable barrier to Cd, and thereby it minimizes fetal toxicity. Cd is known to induce the synthesis of metallothionein (MT), which is a small protein rich in sulfur-containing amino acids and commonly synthesized in maternal tissues and the placenta. MTs retain Cd in maternal tissues and the placenta, and thereby reduce Cd transport to the conceptus. The mechanism involved in developmental toxicity of Cd can be explained based on the interaction between Cd and Zn. In brief, Cd substitutes for Zn in metalloenzymes, thereby Cd interferes with Zn transfer across the placenta. Because of the high affinity of MT for Zn, MT sequesters Zn in the placenta, impeding transfer to the conceptus. Reduced uteroplacental blood flow, reduced nutrient transport, and placental toxicity by Cd seem to be the major contributing factors for low fetal birth weight, fetal toxicity, malformations, and death. Cd-induced impaired fetal growth is partly due to Zn deprivation, since maternal tissue and the placenta retain Zn. In addition, Cd accumulates in the fetus and produces a variety of adverse effects directly on the fetus. These adverse effects include: (1) embryotoxicity (Fein *et al.*, 1997); (2) inhibition of embryonic DNA and protein synthesis (Holt and Webb, 1987); and (3) reduced calcium handling ability of trophoblasts, which is a consequence of alterations in subcellular cytosolic calcium binding properties.

## Lead

The common sources of lead (Pb) exposure include Pb-based paints, batteries, crank-case oil, ceramics, shots and sinkers, calking and roofing materials, and ammunition. Plants and animals appear to bioconcentrate lead, but lead is not biomagnified in the aquatic or terrestrial food chain. Pb exposure in the pregnant animals usually occurs through oral route. It is also known that absorption of Pb increases during pregnancy. After oral absorption, Pb is distributed to most of the tissues, but it deposits mainly in the skeleton, kidney, and brain (primarily gray matter). Pb is known to cross the placenta and it accumulates in the fetus. Accumulation of Pb occurs in the fetal brain owing to lack of blood–brain barrier. Lead also accumulates in the placenta in times of fetal stress. In fact, a large maternal–fetal concentration gradient exists and the placenta poses a limited transplacental barrier. In addition, a number of adverse maternal health conditions can affect the transfer of lead to the fetus and/or the retention of Pb by the mother or the fetus.

Lead produces toxicity in general by interfering with protein/hemoprotein biosynthesis and by inhibiting membrane and mitochondrial enzymes (Eisenmann and Miller, 1996). Pb is also known to cause deficits in cholinergic, dopaminergic, and glutamatergic functions, although the exact mechanism involved in placental toxicity of Pb is yet to be elucidated. Following *in utero* exposure Pb can have direct effects on the developing conceptus. In fact, developing nervous system is the most sensitive target of lead toxicity. Developmental toxic effects of Pb have been determined in experimental animals, including rats, mice, hamsters, and chicks. *In utero* exposure to Pb can cause reduction in fertility and growth retardation. Embryotoxic and fetotoxic effects of Pb seem to be dependent on the exposure occurs on GD 9, teratogenic effects are observed with few resorptions, compared with exposure on GD 16, with hydrocephalus and CNS hemorrhage (McClain and Becker, 1975). At maternotoxic doses, Pb can cause retarded skeletal development. In mice, Pb can cause post-implantation mortality and skeletal malformations in fetuses. The common skeletal anomaly observed is the fusion of two or more cervical vertebrae (Jacquet and Gerber, 1979). Malformations in hamsters due to Pb exposure occur in the tail, ranging from stunting to complete absence of the tail (Ferm and Carpenter, 1967). In experimental animals, common malformations include brain defects, neural tube defects, urogenital system, and tail defects. It is important to mention that Pb has a greater potential for neurotoxicity than for placental and developmental toxicity.

## Mercury

Mercury (Hg) occurs naturally in the environment and exists in several forms. Common sources of Hg include mining, industrial, adhesives, inc, fungicides, and interior/exterior paints.

As a result, Hg is a widespread environmental contaminant that threatens the health of animals in general, and aquatic life and wildlife in particular. It is noteworthy that Hg is toxic in all forms. In most foodstuffs, Hg is found in the inorganic form. Fish, marine animals, and some microorganisms have capability to convert elemental Hg to organic Hg, which accumulates in the food chain. In most of the poisoning incidents, MeHg was involved because of its popular use as a fungicide. During the outbreak of MeHg poisoning in Japan and Iraq, it was proven that there was placental transfer of MeHg through the placenta into the fetus. Following *in utero* exposure to MeHg, the target organ is the fetal brain. This is partly due to accumulation of Hg in the fetal brain because of its high requirement for protein synthesis. MeHg is readily absorbed and distributed throughout the body with various concentrations in different tissues. In humans, brain MeHg levels can be as high as 6-fold, compared with blood levels. This is in contrast to rats, which have a brain to blood ratio of 0.06, and mice with a ratio of 1.20. There is evidence that the placenta presents some barrier to Hg. By using the Gray PBPK model for MeHg, the placenta is modeled as four compartments with separate transfer constants for placental barrier and placental tissue transport. Generally, organic and metallic Hg crosses the placenta more readily than inorganic Hg. As a result, MeHg and metallic Hg accumulate in the fetus, whereas inorganic Hg concentrates in the placenta. Metallic Hg, after crossing the placenta, can be oxidized to $Hg^{2+}$ in fetal tissues. $Hg^{2+}$ accumulates in the placenta, where it inhibits the fetal uptake of certain essential metabolites or analogs of these metabolites.

MeHg has been found to produce embryotoxicity, fetotoxicity, and teratogenicity in rats, mice, cats, guinea pigs, and hamsters. In general, resorptions, dead fetuses, and cleft palate are the most common findings. Some other common developmental effects include generalized edema, brain lesions, wavy ribs, asymmetric sternebrae, and decreased ossification of parietal and occipital bones (Domingo, 1994). In essence, prenatal exposure to sufficient amounts of Hg results in developmental toxicity. In addition, Hg has a strong potential for neurotoxicity and neurobehavioral toxicity.

# PLACENTAL TOXICITY OF INSECTICIDES

Depending on the duration, frequency, and level of exposure, the insecticides of various classes (organophosphates (OPs), carbamates (CMs), organochlorines, and pyrethroids) can adversely affect one or all three

components of the maternal–placental–fetal unit. Numerous studies demonstrate that the insecticide residue is present in the exposed mother, placenta, cord blood, embryo, and fetus, thus suggesting that the placenta and fetus are potentially exposed to these compounds. In this chapter, OPs and CMs are discussed together because their effects are quite similar (Gupta, 1995; Gupta and Sastry, 2000; Pelkonen *et al*., 2006).

## OPs and CMs

In general, both OPs and CMs exert their overt toxicity by inhibiting the activity of acetylcholinesterase (AChE). Inactivation of AChE occurs owing to phosphorylation by OPs and carbamylation by CMs. Inhibition of AChE results in accumulation of acetylcholine (ACh), which overstimulates the muscarinic and nicotinic ACh receptors. There is evidence from a rat study that placenta may be a target of direct toxic effect by OP pesticides (Levario-Carrillo *et al*., 2004). By having active metabolic activity, the placenta can modulate the potency of OPs and CMs. The placenta can probably convert certain OPs of the "thioate" or "dithioate" group to their "oxon" analogs, which are many times more potent AChE inhibitors and thus more toxic than their parent compounds. In such circumstances, the placenta can be one of the several determining factors for fetal toxicity.

It is well established that an active cholinergic system exists in the placenta of some species and not in others, and there is evidence that a cholinergic system may have more than one function in placenta. In the placenta, ACh-like activity is highest in membranes, medium in the cotyledons, and minimal in the cord, and it varies in the placenta as a function of gestational stage. The concentration of ACh in the placenta (a non-innervated tissue) is found to be greater than in various regions of the brain, and a marked decline occurs soon after parturition and expulsion of the placenta. The existence of cholinergic system (using choline acetyltransferase activity, ChAT) has been studied in the term placenta of several species (monkey, mongoose, lemur, horse, cow, sheep, goat, pig, hamster, cat, rabbit, guinea pig, and rat) (Hebb and Ratkovic, 1962). Literature abounds showing that the two species in which the placental cholinergic system has definitely been found are the two higher primates, man and monkey. In general, ACh has many functions in the placenta: (1) acts as a local hormone related to uterine contractions and mechanisms associated with birth; (2) the control of permeability and transport; (3) regulation of blood flow and fluid volume in placental vessels; (4) involvement in the mechanism of parturition; and (5) acts as a local messenger molecule. ACh also seems to play a vital role in the maturation of the placenta. In addition, ACh may regulate trophoblastic channels, fluid balance, and osmotic pressure, and therefore may influence contractile properties of myofibroblasts in the placenta. For further details on the roles of ACh, refer to King *et al*. (1991), and Sastry (2000).

The placenta and fetus, by having AChE and other cholinergic elements (muscarinic and nicotinic ACh receptors), remain susceptible to OPs and CMs (Koshakji *et al*., 1974; Cambon *et al*., 1979; Simone *et al*., 1994; Sastry, 2000). Inhibition of AChE and BuChE activities can be used as a marker of exposure to an OP or CM, while AChE can also be used as a marker of effects. OPs and CMs readily cross the placental barrier and can act on the cholinergic and non-cholinergic components of the developing nervous system and other vital organs (Gupta *et al*., 1984, 1985; Gupta and Sastry, 2000; Pelkonen *et al*., 2006). Significant inhibition of AChE and/or BuChE activities in maternal, placental, and fetal tissues of rats and mice following prenatal exposure to several OPs (quinalphos, dicrotophos, methyl parathion, diazinon, etc.) has been demonstrated (Bus and Gibson, 1974; Srivastava *et al*., 1992; Gupta, 1995; Gupta and Sastry, 2000; Abu-Qare and Abou-Donia, 2001). Similar findings have been reported for CMs, including aldicarb, carbaryl, carbofuran, and pirimicarb (Declume and Derache, 1977; Cambon *et al*., 1979, 1980). From all these studies, AChE inhibition appears to be the major mechanism of toxicity. With either type of insecticides, the developing organism is much more susceptible to the induction of functional neural deficits. Furthermore, subchronic prenatal exposure to methyl parathion in rats resulted in altered postnatal development of brain AChE and ChAT activities, in addition to selected subtle alterations in behavior (Gupta *et al*., 1985).

Anticholinesterase compounds have strong potential for embryotoxicity, embryolethality, fetotoxicity, and teratogenesis. These effects vary depending on the particular OP and CM involved. With these compounds, embryolethality is encountered so often that the expression of teratogenesis is rarely seen. In some experimental studies conducted in rats, mice, rabbits, and hamsters, OPs at maternotoxic doses have been shown to produce developmental alterations, including growth retardation and embryotoxicity. Khera (1979) discovered polydactyly in fetuses of cats treated with dimethoate (12 mg/kg/day) during the 14th to 22nd day of pregnancy (Figure 15.1). Methamidophos administration at a no-maternal toxicity dose (1 mg/kg, po) to female rats during GD 6–15 produced neither lethal effect on embryos nor caused congenital malformations at term, however the embryo–fetal maturation process was significantly altered (De Castro *et al*., 2000).

Wide species variability exists in sensitivity to OP-induced placental toxicity. It needs to be mentioned that the mechanisms involved in embryonic/fetal developmental malformation appear to be different from those involved in general toxicity. Alkylation of nicotinamide adenine dinucleotide ($NAD^+$) coenzymes by OPs is the

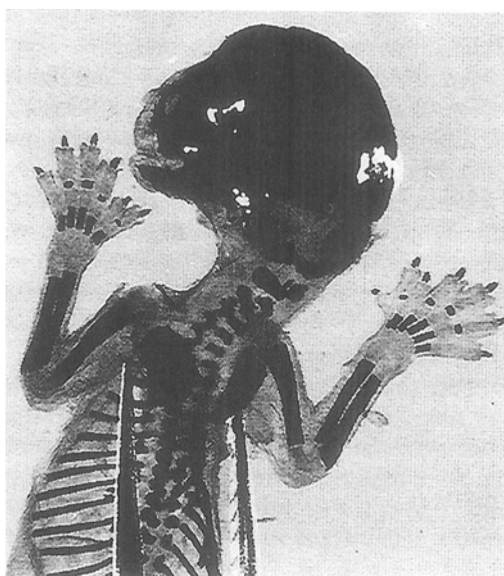

**FIGURE 15.1** Fetal cat showing heptadactyly (right forepaw) and hexadactyly (left forepaw), from a cat exposed to dimethoate (Khera KS (1979) *J Environ Pathol Toxicol* **2**: 1283–8).

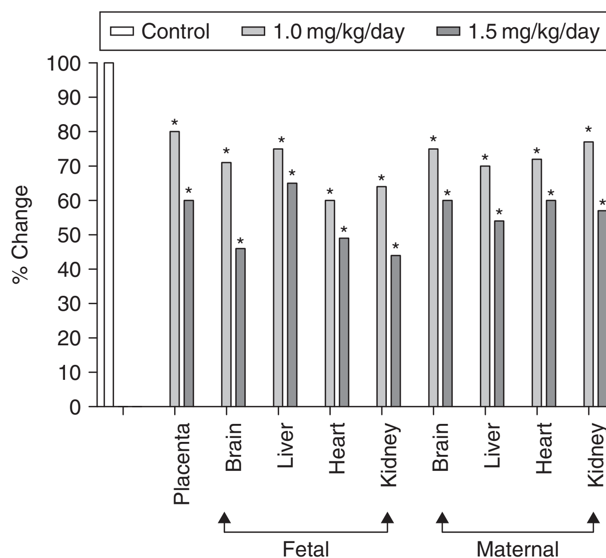

**FIGURE 15.2** Methyl parathion-induced inhibition of *in vivo* protein synthesis in placental, fetal, and maternal tissues. An asterisk indicates a significant difference between methyl parathion-treated and control rats.

major mechanism involved in the induction of teratogenesis (Schoental, 1977). In recent studies, diisopropyl fluorophosphate (DFP) and carbofuran have been shown to cause marked depletion of $NAD^+$ in rats (Gupta *et al.*, 2001a, b). OPs are also known to cause alterations in the levels of RNA, glycogen, sulfated mucopolysaccharides, and calcium in the developing tibiotarsus bones (Ho and Gibson, 1972). Prenatal exposure to OPs has been shown to affect protein synthesis both *in vivo* (Clouet and Waelsch, 1963; Gupta *et al.*, 1984) and *in vitro* (Welsch and Dettbarn, 1971; Marinovich *et al.*, 1996). The inhibitory effect on *in vivo* protein synthesis of methyl parathion (daily oral exposure throughout the period of organogenesis) was shown to be dose-dependent, greater on day 19 than day 15 of gestation, and more pronounced in fetal than in placental or maternal tissues of rats (Gupta *et al.*, 1984). The inhibitory effect on protein synthesis was more pronounced at a dose causing overt maternal toxicity (Figure 15.2). A mixture of OPs, including diazinon, dimethoate, and azinphos, has been found to be more toxic to protein synthesis than any of the single OP compound alone (Marinovich *et al.*, 1996).

Many placental toxicity studies conducted in mice, rats, hamsters, and rabbits revealed no teratogenic responses to OPs. Among CMs, carbaryl is the only insecticide that has been studied in detail for placental toxicity. Like OPs, CMs have a greater potential for embryolethality and fetotoxicity and that precludes an expression of teratogenicity. Beagle dogs receiving carbaryl gave birth of fetuses with terata in 21 of a total of 181 pups. Fetal abnormalities included abdominal–thoracic fissures with varying degrees of intestinal agenesis and displacement, brachygnathia, ecaudate pups, failure of skeletal formation, and superfluous phalanges (Smalley *et al.*, 1968). Carbaryl exposure during organogenesis produced terata in guinea pigs, but not in hamsters and rabbits (Robens, 1969). Other CMs, such as carbofuran and propoxur, have not been found to be teratogenic.

## Organochlorines

Organochlorine insecticides are classified into three groups: (1) dichlorodiphenylethanes (DDTs) (dichlorodiphenyltrichloroethane, dicofol, methoxychlor, and perthane); (2) hexachlorocyclohexanes (benzene hexachloride, chlordane, lindane, mirex, and toxaphene); and (3) chlorinated cyclodienes (aldrin, dieldrin, endrin, chlordane, endosulfan, and heptachlor).

The mechanism of action of organochlorines is not yet fully explained. The DDT-type compounds alter the transport of sodium and potassium ions across axonal membranes, resulting in an increased negative after-potential and followed by prolonged action potentials. As a result, repetitive firing and a spontaneous train of action potentials occur. Specifically, DDT inhibits the activation of sodium channels and the activation of potassium conductance. The mechanism involved in cyclodienes induced hyperactivity of the CNS and convulsions can be explained based on their structural resemblance to the cyclic $\gamma$-aminobutyric acid (GABA) receptor antagonist picrotoxin. The mammalian GABA receptor is coupled to an intrinsic chloride ion channel and is the primary mediator of neuronal inhibition in

the brain. Like picrotoxin, cyclodienes block the inhibitory action of GABA. Similar to other organochlorines, mirex and kepone cause stimulation of the CNS, hepatotoxicity, and induction of the mixed-function oxidase system. In the CNS, symptoms observed in animals by cyclodiene organochlorines include tremors, convulsions, ataxia, and changes in EEG patterns. The CNS symptoms could be due either to (1) inhibition of the $Na^+/K^+$ − ATPase or the $Ca^{2+}/Mg^{2+}$ − ATPase activity, which can then interfere with nerve action or release of neurotransmitters, and/or (2) inhibition of the GABA receptor function.

The acute toxic signs associated with DDT and chlorinated benzene types of insecticides include paresthesia of the tongue, lips and face, apprehension, tremors, and convulsions. Stimulation of the CNS is the most prominent effect. The acute signs and symptoms produced by cyclodienes include dizziness, nausea, vomiting, myoclonic jerking, motor hyperexcitability, and convulsive seizures. Usually, epoxide metabolites of cyclodiene type of insecticides are much more toxic than their parent compounds. It is important to mention that the developing nervous system is the most sensitive target of organochlorines toxicity.

There are only few placental toxicity studies have been conducted with organochlorine compounds. In experimental studies, organochlorines, including DDT, DDE, DDD, dieldrin, endosulfan, methoxychlor, and toxaphene, have been associated with estrogen-like effects in the reproductive system of laboratory animals. Exposure of female rats to methoxychlor before and during pregnancy can cause blockade of implantation, suppression of uterine decasualization, lack of corpora lutea, and atresia of ovarian follicles. Exposure during the preimplantation blocks implantation, whereas exposure during the post-implantation causes fetal resorptions. Interference in the requisite hormonal milieu seems to be the major effect. Other effects of methoxychlor include estrogenic effect on uterine preimplantation differentiation, ovum transport rate, luteal regression, and post-implantation decidual growth. In an experimental study, exposure of Swiss mice to lindane at different stages of pregnancy produced various toxicological effects, such as fetotoxicity and reproductive failure (Sircar and Lahiri, 1989). Lindane exposure during early pregnancy (days 1–4) caused total absence of any implantation; during mid-pregnancy (days 6–12) caused total resorptions of fetuses; and during late-pregnancy (days 14–19) caused the death of all pups within 12 h to 5 days after parturition. Lindane can also cause reproductive failure by inducing a deficiency of steroid hormones (estrogen and progesterone).

Some studies in animals suggest that young animals exposed during gestation and infancy may be very sensitive to heptachlor and heptachlor epoxide. Changes in nervous system and immune function were found in these animals. Exposure to higher doses of heptachlor in animals can also result in decreases in body weight and death in animal newborn babies. A decrease in fertility and an increase in resorptions were observed in female rats acutely exposed to 1.8 mg/kg/day. Reduced fertility has also been observed in mice exposed to 8.4 mg/kg/day. A number of animal studies have demonstrated that exposure to heptachlor can result in decreased fertility and pregnancy losses. Impaired fertility was reported in female rats administered via gavage of 0.6 mg/kg/day heptachlor in groundnut oil for 14 days prior to mating (Amita Rani and Krishnakumari, 1995). In essence, though the exact mechanism in the placental toxicity has yet to be elucidated, impaired fertility and pregnancy losses, in addition to the impaired development of the nervous system and immune system have been found with organochlorine.

There are reports that dieldrin produced teratogenic effects, such as supernumerary ribs, with concomitant decrease in ossification centers in fetal hamsters (Chernoff *et al.*, 1975, 1979). In rats, exposure to mirex during pregnancy has been associated with perinatal deaths due to persistent cardiovascular problems, such as first- to third-degree fetal heart blockade (Grabowski, 1983). In addition, mirex causes altered lens growth and cataracts, along with other biochemical, physiological, and histological changes (Rogers and Grabowski, 1983).

## Pyrethrins and pyrethroids

In recent years, the use of synthetic pyrethroids over the other classes of insecticides has increased tremendously because of their selectively high toxicity to insects and low toxicity to mammals. Still, the risks to animal health exist because the products containing pyrethrins and pyrethroids are commonly used as ectoparasiticides. Exceeding the recommended levels of these insecticides or time of exposure often results in poisoning and deaths, especially in cats and dogs. Pyrethroids are of two types. Type I pyrethroids are those which lack $\alpha$-cyano moiety and give rise to the tremor syndrome (T syndrome). The syndrome includes the signs of whole body tremors, incoordination, prostration, tonic–clonic convulsions, and death. Few common examples of type I are pyrethrin I, allethrin, tetramethrin, resmethrin, and permethrin. Type II pyrethroids are those which contain $\alpha$-cyano moiety and cause the choreoathetosis/salivation (CS) syndrome. The CS syndrome is characterized by hyperactive behavior, profuse salivation, tremors, motor incoordination, and hunch-backed posture. Few common examples of type II pyrethroids include cyphenothrin, cypermethrin, deltamethrin, and fenvalerate.

Intoxication by pyrethroids results primarily from hyperexcitation of the nervous system. Type II syndrome involves primarily an action in the CNS, whereas with type I syndrome, peripheral nerves are also involved. Hyperexcitation of the nervous system is caused by repetitive firing and

depolarization in nerve axons and synapses. Pyrethroids act directly through interaction with the sodium channel gating mechanism, thereby interfering with the generation and conduction of nerve impulses and inducing marked repetitive activity in various parts of the brain. Type I pyrethroids affect sodium channels in nerve membranes, causing repetitive neuronal discharge and a prolonged negative after-potential, the effect being similar to those produced by DDT type of insecticides. Type II pyrethroids produce an even longer delay in sodium channel inactivation, leading to a persistent depolarization of the nerve membrane without repetitive discharge, a reduction in the amplitude of the action potential and eventually failure of axonal conduction and a blockade of impulses.

Prenatal or early postnatal exposure to pyrethroids (cypermethrin, fenvalerate, and others) has been linked with significant neurochemical alterations in neonatal rats (Husain *et al.*, 1991, 1992; Malaviya *et al.*, 1993). Delayed maturation of the cerebral cortex occurs due to alterations in key enzymes of the neurotransmission process (e.g., monoamine oxidase, acetylcholinesterase, and $Na^+/K^+ -$ ATPase). Prenatal exposure to these insecticides significantly delays differential responses in the levels of brain regional polyamines and ontogeny of sensory and motor reflexes in offspring. Other biochemical and neurochemical effects of these insecticides include impairment at the neurotransmitter receptors, including dopaminergic, cholinergic, and catecholaminergic.

Compared to other classes of insecticides, pyrethroids are not well studied for placental toxicity because they are relatively less toxic to mammalian species. For example, permethrin at concentrations of 2000–4000 ppm showed only a week to moderate influence on *in utero* fetal development. Female rats dermally exposed to cyhalothrin throughout gestation period had offspring with delayed fur development, delayed ear and eye opening, and delayed descent of the testes, but with no change in the age of vaginal opening. In adulthood, however, the sexual behavior of both male and female rats exposed to cyhalothrin prenatally is no different from that of control animals (Gomes *et al.*, 1991a, b). Prenatal exposure of rats to deltamethrin caused increase in early embryonic deaths and fetuses with retarded growth, hyperplasia of the lungs, dilatation of the renal pelvis, and increase in placental weight (Abdel-Khalik *et al.*, 1993).

## MYCOTOXINS

Mycotoxins are secondary metabolites of fungi and several of them are found to be toxic *in utero* in both man and animals. In general, mycotoxins can produce placental toxicity by one or more of three common mechanisms. In brief, mycotoxins can interfere with hormonal activity, which can damage parental gametes, producing infertility or abnormal offspring if successful fertilization occurs. Mycotoxins can cause fetal malformations, especially during organogenesis, by interfering with fetal nucleic acid and protein biosynthesis. This interrupts normal cell differentiation and organogenesis, resulting in fetal malformations. Mycotoxins can also affect the fetus indirectly by affecting vital maternal organs, such as the liver, reducing nutrient transfer to the fetus, or increasing transfer of toxicants (Hayes, 1981; Lebepe-Mazur *et al.*, 1995). Some of the common mycotoxins that cause placental toxicity are briefly discussed below.

### Aflatoxins

Aflatoxins ($B_1$, $B_2$, $G_1$, and $G_2$) are mainly produced by *Aspergillus flavus and Aspergillus parasiticus*, which commonly contaminate a variety of animal food. Aflatoxins are proven to be mutagens, carcinogens, and teratogens. From a limited studies conducted on laboratory animals, aflatoxin $B_1$ and $G_1$ appears to have strong potential for embryocidal, fetotoxic, and teratogenic effects. Aflatoxin $B_1$, and $G_1$, with varying doses administered orally or i.p. in mice on gestation day (GD) 12 and 13, produced moderate retardation in fetal development, cleft palate, and changes in diaphragm. Aflatoxin $G_1$ also produced malformations in the kidneys (Roll *et al.*, 1990). Pregnant rats exposed to aflatoxin $B_1$ via the oral route has been shown to result in significant anti-implantational activity and loss of viability among the litters (Choudhary *et al.*, 1992).

### Fumonisins

Fumonisins ($FB_1$, $FB_2$, $FB_3$, $FB_4$, $FA_1$, $FA_2$, and $C_1$) are produced by *Fusarium* fungi, primarily *Fusarium moniliforme* and *Fusarium proliferatum*. These mycotoxins are found in the corn and therefore contaminate corn-based food/feed worldwide. It is well established that $FB_1$, and $FB_2$ are most abundant and most toxic mycotoxins of this group. Fumonisins-induced toxic effects appear to be species specific. Consumption of fumonisins-contaminated food/feed has been associated with many organ-specific diseases. For example, esophageal cancer in man in the Transkie region in South Africa and Linxian County in China, hepatopathy and hepatocarcinoma in laboratory rats, porcine pulmonary edema (PPE) in swine, and equine leukoencephalomalacia (ELEM) or moldy corn poisoning in equidae. In addition, fumonisins produce mild to fatal toxicity in the liver, kidney, and heart of rats and horses. Among all species, equidae is the most sensitive because fumonisins affect the brain of this species.

Experimental animal studies and anecdotal field-case findings revealed that fumonisins have a strong potential for developmental toxicity and teratogenicity. Purified $FB_1$ and *F. proliferatum* culture extract have been shown to be embryotoxic when inoculated into incubated eggs (Javed *et al.*, 1993a, b). In addition to mortality, which was dependent on the dose and time of administration (i.e., day 1 or 10), embryonic changes occurred, including hydrocephalus, enlarged beaks, and elongated necks. In hamsters, $FB_1$ caused increased incidence of prenatal losses, including deaths and resorptions. At a dose of 12 mg/kg, all litters were affected and all the fetuses were dead and resorbed, without any clinicopathological evidence of maternal toxicity. Fetal resorptions were associated with a greater severity of placental necrosis. Placental tissues showed signs of degeneration and involution, focal distortion, and necrosis of the trophoblastic layer, especially at the periphery, and hemorrhage and necrosis at the base of the placenta. Placentas had extensive necrosis and fetal capillaries in the hemochorial portion, with concomitant collapse of the stroma. Such changes were consistent with the embryolethal effects of $FB_1$. External malformations include hooked or curled tail, ectrodactyly of the front/rear limbs, and cleft palate. Developmental effects of aqueous culture extract of *F. moniliforme* in CD1 mice are reported to be due to $FB_1$. The effects include maternal deaths, reduced maternal body weight gain, increased embryonic resorptions, reduced pup weights, and fetal malformations, such as cleft palate, hydrocephalus, and ossification deficits (Gross *et al.*, 1994; Reddy *et al.*, 1995).

$FB_1$ is found to be fetotoxic in F344/N rats. Pregnant rats receiving $FB_1$ at a dose of 30 or 60 mg/kg, po (GD 8–12) developed significant impairment of ossification of the sternebrae and vertebral bodies in their fetuses (Lebepe-Mazur *et al.*, 1995). It appears that $FB_1$ produces fetotoxicity in rats by suppressing growth and fetal bone development (Figure 15.3). However, in Sprague–Dawley rats, there is little or no evidence of embryotoxicity or fetotoxicity by $FB_1$, especially in the absence of maternal toxicity (Ferguson *et al.*, 1997). Pregnant New Zealand white rabbits receiving $FB_1$ showed no evidence of embryotoxicity or teratogenicity, despite the fact that the pregnant rabbits were very sensitive to $FB_1$ (LaBorde *et al.*, 1997).

In pregnant mares, late-term abortions have been observed by consuming fumonisins contaminated corn/corn-based feed. The surviving colts are usually slow learners and behaviorally abnormal. Suppressed growth, bone development, and immune system appeared to be the major contributing factors. Abortions have also been observed in pregnant sows by consuming fumonisins contaminated corn that caused hypoxia resulting from maternal respiratory distress (Harrison *et al.*, 1990).

Although the exact mechanism of action involved in fumonisins toxicity is yet to be established, it has been demonstrated that fumonisins inhibit sphinganine-sphingosine *N*-acetyl transferase (ceramide synthase) activity, and consequently increase the concentrations of sphinganine to sphingosine in target organs of many species (Wang *et al.*, 1992; Riley *et al.*, 1993). Accumulation of sphinganine may be responsible for cell death because long-chain bases such as sphinganine and sphingosine are known protein kinase C inhibitors and can be cytotoxic. It is suggested that an abnormal sphinganine/sphingosine ratio in the fetus, while normal ration in the dam, may attest to the unique sensitivity of the conceptus to fumonisins (Riley *et al.*, 1993; Floss *et al.*, 1994a, b).

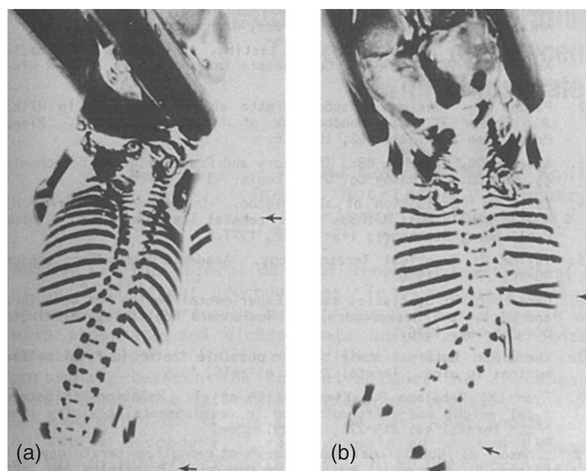

**FIGURE 15.3** Skeletal development of control (a) and fumonisin (b) treated rat pup. (a) Pup from a control dam, with normally shaped ribs and normal ossification of the phalanges and vertebrae bodies. (b) Pup from a dam treated with 60 mg/kg fumonisin $B_1$, having under-ossification of the vertebral bodies of the cervical and lumbar regions as well as the phalanges (Lebepe-Mazur *et al.* (1995) *Vet Hum Toxicol* **37**: 126–30).

## Ochratoxin A

Ochratoxin A (OTA) is produced by several *Aspergillus* and *Penicillium* species. This mycotoxin is known to contaminate food/feed and thereby cause a variety of adverse health effects (nephrotoxicity, carcinogenicity, teratogenicity, and immunotoxicity), nephrocarcinogenicity being the most prominent. OTA has been demonstrated to cause carcinogenesis, immunotoxicity, and teratogenesis in rats and rabbits (Mayura *et al.*, 1982a; Wangikar *et al.*, 2004). In general, the underlying mechanisms involved in the toxicity of OTA include: (1) inhibition of protein synthesis, (2) increased lipid peroxidation, and (3) partial inhibition of ATP-dependent calcium uptake and inhibition of the cell-mediated immune response. In addition, OTA inhibits the phosphorylase enzyme system, possibly by competing with 3′, 5′-cyclic AMP for phosphorylase b kinase activity.

In the kidney, OTA specifically affects organic anion transport, but not organic cation transport, in both the brush border and basolateral membranes, which explains its entry into the renal cells and the development of toxicity. Gene expression study indicates that OTA-induced renal toxicity involves the impairment of defense potential causing oxidative damage that eventually lead to cell proliferation and cancer. Epigenetic mechanism appears to be highly probable (Marin-Kuan *et al.*, 2006).

It has been established that OTA transplacentally traverses in rodents and other species (Galtier, 1991), and causes fetal death in laboratory and domestic animals (Still *et al.*, 1971). Pregnant rats receiving a culture of *Aspergillus ochraceus* on GD 10 showed embryo resorptions and fetal deaths. Subsequent studies in rats further demonstrated that a high dose of purified OTA administered on GD 10 also caused a large number of fetal deaths and embryo resorptions. However in sheep, placental transfer of OTA was found to be in trace amounts resulting in very little or no evidence of fetal toxicity or teratogenesis. Rabbits receiving a combination of OTA and aflatoxin $B_1$ showed antagonistic interaction, yet revealed a characteristic cardiac anomaly with a valvular defect at auriculo-ventricular junction (Wangikar *et al.*, 2005).

## Rubratoxins

Both rubratoxin A and B are produced by *Penicillium rubrum* and *Penicillium perpurogenum*. Rubratoxin B is the primary mycotoxin that causes hepatotoxicity, nephrotoxicity, and splenotoxicity in several animal species. In both laboratory and domestic animals, typical signs of poisoning are hepatic failure, coagulopathy, hemorrhage of the gut mucosa, bloody feces, and death. Rubratoxin $B_1$ has been demonstrated to be a potent mutagen and teratogen in laboratory animals (Wilson and Harbison, 1973). Although, the underlying mechanism in rubratoxin-induced placental toxicity is yet to be explained, rubratoxin B is known to produce gross malformations, internal anomalies, skeletal malformations, embryo lethality, intrauterine growth retardation, increased skeletal variations, and delayed ossification in the mouse fetuses. The teratogenic effects in near-term fetuses include exophthalmos, missing ears, spina bifida, microphthalmia, anophthalmia, short tail, exencephaly, and hydramnion.

## Secalonic acid D

Secalonic acid D (SAD) is produced by *Penicillium oxalicum*. In rats and mice, SAD is known to cause embryotoxicity, embryolethality, fetotoxicity, and teratogenicity. Pregnant CD1 mice receiving SAD (>5 mg/kg/day, ip, GD 7–15) showed a reduction in maternal body weight gain, and an increase in resorptions of implanted embryos (Reddy *et al.*, 1981). The resorptions rate was found to be 100% at 15 mg/kg dose. Multiple gross, skeletal, and visceral anomalies were noted in fetuses born to mothers receiving 10 mg/kg or more. Major malformations included cleft palate, cleft lip, open eyelids, missing phalangeal ossification centers, and shortened mandibles. In CD1 mice, SAD is proved to be an embryocidal, fetotoxic, and teratogenic. Pregnant rats receiving SAD as a single sc dose (25 mg/kg) on one of GD 6–10, 12, 14; or 15 mg/kg on GD 10, produced fetotoxic and teratogenic effects, although the effects were less marked with the lower dose (Mayura *et al.*, 1982b). The highest number of resorptions, greatest depression of fetal body weight, and largest number of malformations occurred when SAD was injected on GD 10. The major gross malformations were anophthalmia (GD 9 and 10), exencephaly (GD 9), and defects in limbs, digits, and tail (GD 10). The major skeletal defects involved the vertebrae and ribs. The major internal soft tissue defects were hydronephrosis (GD 9 and 10), tracheo-esophageal fistula, and renal agenesis (GD 10). Thus, it can be concluded that pregnant rats are most sensitive to SAD exposure on GD 10 for fetotoxicity and teratogenicity.

## Trichothecenes

The trichothecenes are a group of structurally related mycotoxins with varying degrees of cytotoxic potency. Diacetoxyscirpenol (DAS), T-2 toxin, and deoxynivalenol (DON or vomitoxin) are the three major mycotoxins of this group that are commonly encountered in animal poisonings. T-2 and DAS are produced by *Fusarium sporotrichiodes* and vomitoxin is produced by *Fusarium roseum*. There is strong evidence that trichothecenes cross the placental barrier and can cause both embryonic death and structural malformations when administered to laboratory animals during pregnancy (Francis, 1989). Since domestic and avian species are exposed to trichothecenes through consumption of contaminated feed, and trichothecenes in general cause feed refusal, it is expected that the induced maternal/fetal toxicity to be minimal. Furthermore, *in vivo* studies with different animal species indicate that orally or parenterally administered trichothecenes do not bioaccumulate due to their short elimination half-lives: <30 min for T-2 toxin in swine, cattle, and dogs (Yagen and Bialer, 1993); and 3–5 h for DON in swine and cattle (Rotter *et al.*, 1996).

## DON

Feeding of a DON (vomitoxin)-contaminated diet at 5 ppm to rats throughout gestation does not adversely affect pregnancy or increase birth defects (Morrissey, 1984). Vomitoxin

does not produce teratogenesis even at a 20-ppm level. However, at this dose it can decrease the rate of pregnancy. Mice intubated with vomitoxin (2.5 and 5 mg/kg) on GD 8–11 produced embryolethality, and at doses of 5 mg/kg or greater produced embryolethality (Khera *et al.*, 1982). In mice, vomitoxin at a dose of 10 mg/kg caused maternal mortality. Fetal mortality by vomitoxin is dose-dependent (100% at 10 mg/kg, 80% at 5 mg/kg, and 72% at 2.5 mg/kg). However, none of the dose of vomitoxin induced damage to the placenta or teratogenesis in mice.

## DAS

There is very little known about placental toxicity of DAS. In rats, DAS at a dose rate of 2, 3, or 6 mg/kg i.p. given on one of GD 7–11 caused no maternal toxicity (Mayura *et al.*, 1985). The highest dose of DAS caused 100% resorptions, while with the lowest dose, the surviving pups showed a variety of malformations, including hydrocephaly and exencephaly.

## T-2 toxin

T-2 toxin is the most potent mycotoxin of the trichothecenes group, and has been involved in mass poisoning in animals (Hsu *et al.*, 1972). It has been well established that T-2 toxin crosses the placenta (Hayes, 1981). In rats, T-2 toxin produced behavioral teratogenesis, when the toxin was given prenatally (Francis, 1989). Mice exposed to a single dose of T-2 toxin (3 mg/kg) on GD 7, 8, 10, 11, or 12, showed maternal toxicity with 17% mortality and whole litter resorptions (Roussoux *et al.*, 1985). Maternal death was typically due to placental hemorrhage, and surviving pups showed retardation defects of the skeletal system, exencephaly, abdominal defects, and cleft palate. Findings of a comprehensive study in mice treated with T-2 toxin (0.5, 1.0, or 1.5 mg/kg i.p.) on GD 7, 9, 10, or 11 are briefly described here (Stanford *et al.*, 1975). Treatment on GD 9 reduced the survival rate to 85% at 1 mg/kg and to 8% at 1.5 mg/kg, without any evidence of teratogenesis in surviving pups. Among the surviving pups of dams treated at 1.0 or 1.5 mg/kg on GD 10, 37% grossly malformed and 42% had skeletal malformations. Commonly observed malformations were exencephaly, congenitally open eyelids, and retarded jaws. Treatment on GD 11 resulted in greater embryotoxicity (75% deaths at 1 mg/kg and 100% deaths at 1.5 mg/kg), but the malformation rate among surviving pups was not greater than 13% at any dosage. In another study, mice given T-2 toxin in feed at 5 and 10 ppm throughout gestation resulted in whole litter abortions in 67% and 100% of the dams, respectively (Francis, 1989). Delayed ossifications of the coccyx and growth retardation were the prominent effects. Overall, the observed effects were cumulative and dose-dependent.

It appears that the trichothecenes induce embryotoxicity at maternotoxic doses in laboratory animals. Death of embryo/fetus is the most common finding. The surviving pups rarely show frank malformations of nervous system and skeletal system.

## Zearalenone

Zearalenone is produced by the fungi *Fusarium graminearum* and *Fusarium culmorum*, and other *Fusarium* species. It is important to study the placental toxicity of zearalenone and its two major metabolites ($\alpha$- and $\beta$-zearalenol) as they bind to estrogen receptor and produce a variety of reproductive problems. Zearalenone has been found to cross the placenta and reach fetus of mice and rats (Appelgren *et al.*, 1982; Bernhoft *et al.*, 2001). In maternal tissues, zearalenone and its metabolites accumulate in the liver, but in fetal tissues it is yet to be established. Due to its estrogenic activity, zearalenone is known to perturb the ovulation cycle and reduce litter size in domestic animals, particularly swine. Similar findings have been noted in experimental studies conducted in swine, mice, and rats, where exposure to zearalenone during pregnancy reduces fetal survival (Kuiper-Goodman *et al.*, 1987). The structurally related compound $\alpha$ -zearalanol, which is used for growth promotion in cattle, has been shown to accelerate testicular development and exert alterations in Leydig cells in mice after *in utero* exposure (Perez-Martinez *et al.*, 1997).

# TOBACCO

Tobacco plants and their products contain many toxic alkaloids, but nicotine is believed to be the major component causing alterations in embryo and fetal development that leads to teratogenesis. Pets are exposed to tobacco by ingesting commercial products (e.g., cigarettes, chewing tobacco, etc.), whereas livestock by consuming discarded tobacco stalks or contaminated hay with tobacco plant dripping in the barn. Most often, poisoning encountered in animals with tobacco is of acute in nature exhibiting the signs of neurologic and muscular disturbances.

The pharmacological and toxicological effects of nicotine are dose-dependent and primarily occur in the CNS, cardiovascular system, skeletal muscles, and gastrointestinal (GI) tract. Nicotine is a rapidly acting sympathetic and parasympathetic ganglionic depolarizer. In small doses, nicotine stimulates the autonomic ganglia, while in larger doses it blocks the ganglia. Similarly, in skeletal

muscles small doses of nicotine initially stimulate the nicotinic receptors of the motor end plate, while larger doses block these receptors. Cardiovascular signs, such as tachycardia and hypertension, result from stimulation of sympathetic ganglia and the adrenal medulla. Death occurs from paralysis of respiratory muscles and cardiac arrest.

Some tobacco alkaloids, especially nicotine, have been studied for their distribution, metabolism, and elimination in animals. It is also established that some of these alkaloids cross the placenta and produce the teratogenic effects (Suzuki *et al.*, 1974; Sastry and Janson, 1995; Panter *et al.*, 1999; Czekaj *et al.*, 2002). In some studies, tobacco components have been shown to produce deleterious effects on embryonic development in the early stages of pregnancy, before the placenta is fully formed. In mice, nicotine increases $[Ca^{2+}]_i$ and reactive oxygen species levels, which play a role in nicotine-induced embryonic apoptosis and malformations, and that eventually leads to teratogenesis (Zhao and Reece, 2005). Swine appears to be the most sensitive species in the context of teratogenesis. The fetal arthrogryposis occurs without signs of intoxication in the dams and without fetal deaths or abortions, but the deformed piglets usually die shortly after birth. With *Nicotiana glauca* fetal deformities are preceded by the appearance of signs of acute toxicity in the dam (Keeler *et al.*, 1981). Deformities in the newborn following *in utero* exposure include severe flexure and lateral rotation of the carpal joints, moderate rotation of the fetlocks, and less commonly spinal malformations resulting in lordosis or scoliosis, and cleft palate (Burrows and Tyrl, 2001). Exactly, which component(s) of the tobacco is involved in inducing teratogenesis is yet to be confirmed.

## CONCLUSIONS AND FUTURE DIRECTIONS

Until recently, placental toxicity has received very little attention compared to fetal or maternal toxicity. This is due to the fact, that placenta is discarded at the termination of pregnancy. However, healthy placenta with normal structure and function is required for proper supplies of nutrition to the fetus and its protection from adverse conditions. It is important to mention that the placenta is also a source of several growth factors that are required by the fetus. Placenta by having active metabolism appears to influence fetal toxicity of chemicals. Many chemicals cross the placenta and produce deleterious effects on fetus, while other chemicals cause damage to the placenta and thereby adversely affect the fetus. Detailed studies need to be done to understand exactly how the toxicants from various classes interfere with the structure, function, and development of the placenta. Special emphasis should be given to explore the molecular mechanism(s) involved in deleterious effects of chemicals in placenta, as much as given to the fetus or mother.

## ACKNOWLEDGEMENTS

The author would like to thank Mrs. Debra A. Britton for her assistance in preparation of this chapter.

CHAPTER

# 16

# Dermal toxicity

*Faqir Muhammad and Jim E. Riviere*

## INTRODUCTION

Skin is an essential and dynamic organ. In addition to performing important functions including thermoregulation and preventing insensible water loss, it also has important metabolic, immunological and neurosensory properties. However, the predominant function of skin is to protect the body against a variety of toxicological insults. Animals are relatively less protective against such insults as compared to humans due to lack of clothing, inferior housing and different social interactions. In most instances, the skin of animals directly contacts environmental, chemical and other pollutant exposure without the benefit of manmade protection. Although the largest organ of the body can often face these insults to a certain threshold, animals exhibit symptoms of dermal toxicity when this limit is passed.

Knowledge of the basic structure of skin is necessary to understand the mechanisms of dermal absorption and toxicity of topically applied toxicants. Skin is composed of three distinct layers namely, epidermis, dermis and hypodermis. Out of these layers, the epidermis (consists of kerationocytes and non-keratinocytes) is considered the most important barrier to dermal penetration of most chemicals. The epidermal layers can further be classified from external surface inward as stratum corneum, stratum lucidum, stratum granulosum, stratum spinosum and stratum basale. The stratum basale consists of single layer of cuboidal or columnar cells resting on basal lamina and is the viable layer of cells in the epidermis. These cells are mitotically active, thus keeping the epidermis replenished as the stratum corneum (SC) cells are sloughed from the surface epidermis (Lavker and Sun, 1983; Monteiro-Riviere, 2006). The approximate cell turnover and self-replacement time in normal human skin is 28 days. This differs widely across species. Mechanical or chemical injuries can increase the mitotic rate of basal cells. Stratum spinosum consists of several layers of irregular polyhedral cells. The cells of this layer have numerous tonofilaments and small membrane bound organelles (lamellar granules). Stratum granulosum consists of several layers of flattened cells containing irregularly shaped, non-membrane bound and electron-dense keratohyalin granules. These granules have a role in keratinization and maintaining the barrier functions of the skin. The lamellar granules contain several types of lipids (ceramides, cholesterol, fatty acids) and hydrolytic enzymes including proteases, acid phosphatases, lipases and glycosidases (Downing, 1992; Monteiro-Riviere, 2006). Stratum lucidum is a thin layer only present in very thick areas of skin such as palmer and plantar surfaces.

The outermost layer of epidermis is the SC that consists of several layers of completely keratinized dead cells (corneocytes) embedded in an extracellular lipid matrix. This has been depicted as the "brick and mortar model" where keratinized cells, the bricks, are embedded in the lipid mortar. The dead keratinized cells are highly water absorbent and keep the skin moist and soft. The water holding capacity of the epidermis is further maintained by sebum (natural oil covering the skin) secretion from glandular structures of the skin. A number of non-keratinocyte cell types are found in skin. The melanocytes are involved in skin pigmentation; Merkel cells act as mechanoreceptors for touch, while Langerhans cells play a major role in the skin immune response. These specialized cells are not involved in barrier functions of skin (Monteiro-Riviere, 2006).

Other specialized regions of the epidermis are the skin appendages which include hair, sweat and sebaceous glands, hoof, claw, nail, feathers and horn. The dermis consists of dense irregular connective tissue with collagen, elastic and reticular fibers in a mucopolysaccharides ground

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*
*Copyright © 2007, Elsevier Inc. All rights reserved.*

substance. Fibroblasts, mast cells and macrophages are the predominant cells of this layer. In addition, sweat glands, sebaceous glands, hair follicles and erector pili muscles are located in the dermis. The hypodermis is a layer of loose connective tissues beneath the dermis. This layer helps to anchor the dermis to the underlying tissues such as muscle or bone (Monteiro-Riviere, 2006).

SC is considered the primary barrier of skin against the penetration of foreign substances as this layer provides up to 1000 times the resistance to exogenous compounds as compared to the layers beneath it. Disruption of this layer either by physical (tape striping) or by chemical means will adversely affect the barrier properties. Extraction of these epidermal lipids with organic solvents (Monteiro-Riviere *et al.*, 2001) and jet fuel hydrocarbons (Muhammad *et al.*, 2005b) can reduce the barrier functions of the skin. The other two deeper layers of skin (dermis and hypodermis) offer no resistance to penetration of most compounds. Once a substance has penetrated the epidermis, it will easily traverse the other layers. The potential exceptions are very lipophilic compounds (log lipid to water partition coefficient, greater than four) that may tend to stay in the lipid environment of skin.

## ABSORPTION

Toxicants traverse biological membranes either by passive diffusion or by active transport. A passive diffusion process implies that the solute flux is linearly dependent on the solute concentration gradient; while, active transport processes typically involve a saturable mechanism (Friedman, 1986). Dermal absorption is a passive process. Generally, topical absorption involves a sequence of events that include partitioning of the molecule into the SC from the applied vehicle phase, diffusion through the SC, partitioning from the SC into the viable epidermis, diffusion through the epidermis and upper dermis and finally capillary uptake and systemic exposure. Hence, the movement of toxic molecules across the skin involves transport through a series of resistances. In general, for polar toxicants, the diffusional resistance of the SC is large compared to that presented by the viable epidermis and dermis. For more lipophilic molecules, the resistance of the SC is smaller. However, the SC maintains a rate-controlling role since a highly lipophilic molecule does not favorably partition out of the SC into the more aqueous viable epidermis. From the description of SC components and structure, one can envisage that a diffusing molecule can adopt one or more of the following penetration pathways:

1 The intercellular/para-cellular path, via the tortuous but continuous intercellular lipids.
2 The transcellular path, indicating that the toxicants transfer sequentially and repeatedly through the "bricks" and "mortar".
3 The transappendageal path via hair follicles, sweat pores, etc.

Most molecules follow the first penetration pathway, yet the absorption of certain compounds can take place via transfollicular path or sweat pores, often resulting in skin penetration (residing within skin) rather than true absorption (systemic exposure). Both absorption and penetration are important determinants of direct chemical toxicity to the skin. Diffusion occurs through the intercellular lipids hence partitioning into these lipids is often the primary determinant of absorption. Species differences in lipid makeup thus also translate into species differences in absorption.

Percutaneous absorption through the intercellular pathway of the SC is driven by passive diffusion down a concentration gradient described at steady state by Fick's law of diffusion (Riviere, 1999):

$$\text{Flux} = [(D \bullet PC \bullet SA)/H](\Delta x)$$

where $D$ is the diffusion coefficient and $PC$ is the partition coefficient, $SA$ is the applied surface area, $H$ is membrane thickness (or more precisely the intercellular path length) and $\Delta x$ is the concentration gradient across the membrane. Since *in vivo* blood concentrations after absorption are negligible compared to applied surface concentration, $\Delta x$ reduces to the concentration ($C$). It is this relationship that allows the prediction of compound flux across the skin to be correlated to factors predictive of $D$ and $PC$ (e.g. octanol/water partition coefficients reflecting chemical partitioning into the SC lipids). Flux is expressed in terms if applied surface area, often normalized to $cm^2$.

The term ($D \bullet \mathrm{PC/H}$) is compound dependent and is termed the permeability coefficient ($K_p$), reducing the determination of flux to $K_p \bullet \Delta X$ or $K_p \bullet C$, a first-order pharmacokinetic equation ($dx/dt = kX$). Rearrangement of this equation yields the primary method used to experimentally determine $K_p$:

$$K_p = \text{steady state flux/concentration}$$

It must be stressed that both transdermal flux and $K_p$ are not only chemical dependent, but also tightly constrained by the membrane system studied as well as the method of topical application (neat compound, vehicle, length of experiment, etc.). The PC that is integral to $K_p$ is the PC between the surface or applied vehicle and the SC. Different vehicles will thus result in different PCs. Similarly, skin from different species may result in different PC due to differences in the SC lipids and intercellular path lengths.

Cutaneous biotransformation of drugs is also a barrier to absorption of certain compounds, and has been used to promote the absorption of certain chemicals (pro drugs) across the skin. This aspect is important in skin toxicology as non-toxic parent compounds may be bioactivated within the epidermis, such as benzo[*a*]pyrene to an epoxide (Riviere, 1999).

There are numerous factors that can affect the dermal toxicity in animals. These include the species, breed, age, health status, skin condition (dryness, hairiness or thickness) and local environment (weather, humidity, temperature). Some of these factors including epidermal thickness, epidermal cell size, number of cell layers and blood flow patterns can vary between species as well as within the species (Monteiro-Riviere *et al*., 1990). As a general rule, young and emaciated animals are more prone to dermal intoxication than are adults or healthy animals. In this chapter, the agents involved in dermal toxicity directly or indirectly are described. There are a variety of compounds including pesticides, polycyclic aromatic hydrocarbons (PAHs), volatile organic compounds (VOCs), heavy metals, photosensitizing agents and toxic plants that can affect the skin of animals by multiple mechanisms.

## PLANTS CAUSING DERMAL TOXICITY IN ANIMALS

Exposure to plant toxins may be the most common cause of dermal toxicity in animals, since the majority of production animals are reared on pastures where they come in contact with various types of vegetation. Some plants have compounds that directly affect the skin after contact, while others have thorns/spines that can cause mechanical injury to the skin. Many compounds may induce allergic dermatitis, similar to poison ivy in humans. A discussion of contact sensitization is beyond the scope of the present chapter. A text in immunology or allergy medicine should be consulted. Many plants have pigments or compounds that once absorbed from the gastrointestinal tract, induce a direct effect on non-pigmented skin when exposed to light. Other plants can result in a secondary photosensitization by virtue of toxic alkaloids that cause irreversible liver disease.

### Photosensitization

Photosensitization is a severe dermatitis resulting from a complex reaction induced by plant pigments exposed to ultraviolet (UV) sunlight in the skin of animals that have eaten certain plants (Rowe, 1989). UV radiation can induce acute or chronic photobiologic reactions in the absence of exogenous chromophores such as nuclear DNA (Horio *et al*., 2005). Non-pigmented skin gives the most severe reaction where these reactive compounds are directly exposed to UV light, most likely secondary to light-enhanced photooxidation. The amino acids susceptible to oxidation (histidine, tyrosine and tryptophan) once oxidized evoke an intense inflammatory response in the blood vessels and surrounding cells resulting in tissue necrosis. In addition to plant pigments, fungal toxins and certain chemicals can induce photosensitization. Quite frequently horses and cattle develop photosensitization during grazing on pasture may be due to oxidative damage in photodynamic therapy (Clare, 1955; Babilas *et al*., 2005). Similarly outbreaks of facial eczema (pithomycotoxicosis), a hepatogenous photosensitization caused by the mycotoxin sporidesmin, have been reported in ruminants in the Azores Islands of Portugal (Pinto *et al*., 2005).

Photosensitization may be classified into primary and secondary types (Table 16.1). Primary photosensitization is associated with photodynamic compounds in certain plants, which react in the non-pigmented skin with UV light to cause a severe dermatitis. Secondary photosensitization, results when an animal's liver is sufficiently diseased to be unable to remove plant by-products that can react with UV light to cause photosensitization. Phylloerythrin, a bacterial breakdown product of chlorophyll, is a potent photosensitizing compound. Normally phylloerythrin is removed by the liver and is excreted in the bile, but if the liver is severely diseased, it accumulates in the blood to cause photosensitization if a white skinned animal is exposed to UV light. Secondary photosensitization is much more common in livestock than primary photosensitization.

Primary photosensitization develops when animals eat plants having polyphenolic pigments. Historically, two plants buckwheat (Kingsbury, 1964) and St. John's wort (Marsh, 1930; Araya and Ford, 1981) are associated with primary photosensitization. Bishop's weed (*Ammi majus*), Rain lily (*Cooperia pedunculata*), Spring parsley (*Cymopterus watsonii*), Buckwheat (*Fagopyrum esculentum*), Giant hogweed (*Heracleum mantegazzianum*), St. John's wort (*Hypericum perforatum*) and Dutchman's britches (*Thamnosma texana*) are reported as primary photosensitizing plants (Knight and Walter, 2003). These plant species (Table 16.1) contain photodynamic furanocoumarin compounds that have been associated with photosensitivity through ingestion and direct contact with the skin (Dollahite *et al*., 1978; Oertli *et al*., 1983). A seasonal photosensitivity of cattle, associated with the consumption of the dead leaves of rain lily has been reported in southeast Texas (Rowe *et al*., 1987; Casteel *et al*., 1988). Similarly, giant hogweed (*Heracleum mantegazzianum*) and Cow parsnip (*Heracleum* spp.) are also known to cause photosensitivity in Europe and North America, respectively (Knight and Walter, 2003).

**TABLE 16.1 Important plants causing photosensitization in animals**

| Common name | Botanical name | Type of photo-sensitivity |
|---|---|---|
| St. John's wort | *Hypericum perforatum* | Primary |
| Spring parsley | *Cymopterus watsonii* | Primary |
| Bishop's weed | *Ammi majus* | Primary |
| Dutchman's britches | *Thamnosma texana* | Primary |
| Rain lily | *Cooperia pedunculata* | Primary |
| Groundsels, Senecio | *Senecio* spp. | Secondary |
| Fiddle neck | *Amsinckia* spp. | Secondary |
| Rattle box | *Crotolaria* spp. | Secondary |
| Hound's tongue | *Cynoglossum officinale* | Secondary |
| Blue weed | *Echium vulgare* | Secondary |
| Lantana | *Lantana camara* | Secondary |
| Panic grasses | *Panicum* spp. | Secondary |
| Horse brush | *Tetradymia* spp. | Secondary |
| Alsike clover | *Trifolium hybridum* | Secondary |
| Black sage | *Artemisia nigra* | Secondary |
| Puncture vine | *Tribulus terrestris* | Secondary |

Secondary photosensitization is primarily caused by a variety of compounds toxic to the liver that are found in plants, the most important of which are the pyrrolizidine alkaloids (PAs). There are four important plant genera namely, *Senecio*, *Crotolaria*, *Cynoglossum* and *Amsinckia* that cause liver disease and secondary photosensitization in North America (Table 16.1). Most PA poisoning of livestock in the Western United States is attributable to three species of *Senecio*: tansy ragwort (*S. jacobaea*), threadleaf or wooly groundsel (*S. douglasii* var. *longilobus*), (Johnson and Molyneux, 1984; Johnson *et al*., 1989) and Riddell's groundsel (*S. riddellii*) (Johnson *et al*., 1985; Molyneux *et al*., 1991). *Senecio* species are also the most common cause of PA poisoning throughout the world (Lombardo de Barros *et al*., 1992; Odriozola *et al*., 1994). Fiddleneck (*Amsinckia intermedia*), and hound's tongue (*Cynoglossum officinale*), members of the Boraginaceae, have significant quantities of PA capable of producing secondary photosensitization in cattle and horses (John *et al*., 1974; Stegelmeier *et al*., 1994). The PA content of plants varies considerably, generally increasing with maturation of the plant and reaching a maximum just before the flower buds open (Candrian *et al*., 1984). Flowers have the greatest amount of the alkaloid, while seeds of *Crotolaria* and *Amsinckia* concentrate high levels of PA (Johnson and Smart, 1983; Nobre *et al*., 1994). Pigs are the most susceptible to PA poisoning, followed by poultry, cattle, horses, goats and sheep (Mattocks, 1968; Craig *et al*., 1992).

A variety of plant toxins other than PAs are also involved in secondary photosensitization. Amongst these, horse brush (*Tetradymia glabrata* and *T. canescens*) has been attributed to cause secondary photosensitivity in sheep in North America (Johnson, 1974; Flemming *et al*., 1922). However, sheep are much more susceptible to horse brush photosensitivity if they concurrently browse on black sage (*Artemisia nigra*), big sage (*A. tridentata*) or both (Flemming *et al*., 1922; Johnson, 1974). These plants frequently grow in the same locations in western rangelands, and when eaten together have a synergistic effect in causing photosensitivity. Certain plant species like *Lantana camara*, *Agave lecheguilla*, *Tribulus terrestris* and *Panicum* grass species cause secondary photosensitization through inflammation and obstruction of the biliary system (Knight and Walter, 2003). These photosensitizing plants contain saponins that cause inflammation and obstruction of the bile ducts. When the liver cannot excrete bile normally, photosensitizing compounds will accumulate in the blood of animals and will result in photosensitization (Radostits *et al*., 1994). Sheep eating puncture vine (*Tribulus terrestris*) develop photosensitivity secondary to biliary obstruction that was initially thought to be caused by a mycotoxin, but later found to be the result of steroidal saponins in the plant (Glasonbury and Doughty, 1984; Kellerman *et al*., 1994). An outbreak of photosensitization in sheep in Great Britain and Western Europe due to bog asphodel (*Narthecium ossifragum*) was caused by plant saponin that occluded the biliary system (Pass, 1987; Burrows, 1990). Alsike clover (*Trifolium hybridum*) is a perennial legume that is commonly grown for livestock consumption in northern parts of North America. This plant can cause secondary photosensitivity in horses that can be attributed to the accumulation of phylloerythrin in the horse's circulation as a result of liver failure (Nation, 1991; Colon *et al*., 1996).

Animals can also develop photosensitivity while eating moldy grains containing hepatotoxic mycotoxins (aflatoxins) produced by fungi belonging to the genera of *Aspergillus* and *Penicillium*. Moldy straw and water-damaged alfalfa hay may also cause photosensitivity in cattle as a result of mycotoxins that induce hepatitis and cholangitis (Richard, 1973; Putnam *et al*., 1986; Scruggs and Blue, 1994). Feeding moldy alfalfa hay and silage to cattle has been associated with a secondary photosensitivity due to liver toxins produced by a variety of fungi cultured from the hay (House *et al*., 1996). However, cattle appear to be more susceptible to these unidentified toxins as compared to sheep, goats and horses (Casteel *et al*., 1994).

Blue-green algae or cyanobacteria is reported to cause poisoning in North America include members of the genera *Microcystis*, *Anabaena* and *Aphanizomenon*. These organisms release potent toxins into the water that can cause severe poisoning in animals drinking the contaminated water. Some of these toxins can act on the liver to cause liver failure and photosensitization (Beasley *et al*., 1989a, b; Osweiler *et al*., 1985a; Hoover and Smith, 1995). Southdown sheep may also develop photosensitivity due to a congenital defect in the liver's ability to excrete the photoreactive compound phylloerythrin (Hancock, 1950). In addition to plants, certain drugs and chemicals such as phenothiazine sulfoxide, some tetracycline antibiotics and psoralen, which

employs this toxic property as a mechanism of its therapeutic effect to treat conditions such as psoriasis, also produce photosensitivity in animals.

Some molds are not only photosensitizing, but may be toxic to the skin of animals directly or indirectly by other mechanisms. Ergot alkaloids can induce gangrene in all species of animals if ingested over a period of several days or weeks. The most commonly involved fungus is *Claviceps purpurea.* The distal extremities, tail, ears and nose may slough away during this disease. Other mold toxins like serotoxins (trichothecene toxin T-2) have the ability to irritate the skin and mucous membranes of animals on contact. Stomatitis, oral ulcers and necrosis of areas of skin that are in direct contact to moldy plant may be seen in the affected animals. Another trichothecene toxin produced by *Fusarium tricinctum* is diacetoxyscirpenol. It may cause dermal necrosis and gangrene in cattle fed on moldy corn. Acute fescue (a common pasture grass in United States) toxicosis in cattle resembles gangrenous ergotism. In this condition, animals can develop dry gangrene of the extremities. The clavicipetaceous fungi are mostly present in fescue pasture. Fescue hay and seed infected with this mold are reported to be toxic to cattle (Jackson *et al.*, 1984).

## TOPICAL CHEMICALS CAUSING DERMAL TOXICITY IN ANIMALS

Skin is the second most frequent route by which chemicals enter the body of animals. Liquid chemicals are generally absorbed well through the skin if they can partition into the SC lipids. Chemicals in the forms of solids, gases and vapors are only absorbed through the skin if they are first dissolved in the moist layer at the surface of the skin. The skin is a major target for gaseous and liquid pollutants. Various allergic or inflammatory conditions of skin including eczema, atopic dermatitis or acne are often observed on exposure to various chemicals (Baudouin *et al.*, 2002). The topical chemicals that react most specifically with the skin are PAHs, VOCs, pesticides and heavy metals. A great deal of research has been conducted on experimental exposures to the common laboratory animals as components of mechanistic carcinogenesis studies or as a component of human risk assessments. Unfortunately, less is known about mechanisms of actions of compounds of veterinary importance.

### PAHs

PAHs including benz[*a*]anthracene, benzo[*b*]fluoran-thene, benzo[*j*]fluoranthene, benzo[*k*]fluoranthene, benzo-[*a*]-pyrene, dibenz[*a,j*]acridine, dibenz[*a,h*]acridine, dibenz[*a,h*]-anthracene, -dibenzo[*c,g*]carbazole, dibenzo[*a,e*]pyrene, dibenzo[*a,h*]pyrene, dibenzo[*a,i*]pyrene, dibenzo[*a,l*]pyrene, indeno[1,2,3-*cd*]pyrene and 5-methylchrysene are reported to cause toxicity in experimental animals (IARC, 1987). Most of these PAHs have been studied in biomedical, biochemical and other laboratory-based experiments. Out of these 15 PAHs, at least 8 are present in coal tar that is used as a fuel in the steel industry and blast furnaces. Coal tar is also used in the treatment of skin diseases like dermatitis, psoriasis and eczema. Coal tar can cause allergic or irritant contact dermatitis, erythema, stinging, precipitation of exfoliative dermatitis or generalized pustular psoriasis, tar folliculitis, atrophy, telangiectasia, pigmentation, cutaneous horns, keratoacanthomas and tar warts (Andrew and Moses, 1985; Burden *et al.*, 1994). Coal tar pitch is used for roofing, surface coatings and a variety of other applications (IARC, 1983); 3 out of these 15 PAHs are found in bitumen and asphalt that are used for paving roads, water proofing and coating pipes. Therefore, considerable risk exists for the animals to come in contact with these toxic PAHs in these localities/applications. Animals are exposed to PAHs through inhalation, eating fodders grown on contaminated soils or through skin when in contact with PAH contaminated soil or products such as heavy oils, coal tar and roofing tar or creosote (a wood preservative). The toxic levels of PAH has been measured in various tissues of fish that are supposed to be absorbed through the skin (Oliveira-Ribeiro *et al.*, 2005).

When administered topically, benz[*a*]anthracene and benzo[*j*]fluoranthene induced-skin papillomas in mice while benzo[*k*]fluoranthene was active as an initiator of skin tumors in female mice (IARC, 1983). Benzo[*a*]pyrene-induced skin papillomas and carcinomas in mice, rats, guinea pigs and rabbits. Dibenz[*a,j*]acridine has also been reported to cause skin tumors in mice. Whereas dibenzo-[*a,e*]pyrene, dibenzo[*a,h*]pyrene, dibenzo[*a,i*]pyrene and 5-methylchrysene produced skin tumors in mice when applied topically (IARC, 1973). To date, dibenzo[*a,i*]pyrene has been found to be the strongest tumor-initiating PAH ever tested in rodent skin and mammary tumor-models (Mahadevan *et al.*, 2005). However, the tumor promoting potential of benzopyrene can be increased many folds in combination with other toxic chemicals. For example the combinations of benzo[*a*]pyrene and UV-A light (Wang *et al.*, 2005), or benzo[*a*]pyrene and arsenic (Fischer *et al.*, 2005) treatment synergistically increased tumor incidence and multiplicity in hairless mouse skin. It has been reported that cytochrome P450 1B1 determines susceptibility to dibenzo[*a*]pyrene-induced tumor formation (Buters *et al.*, 2002). However, the organic extracts of black raspberries can inhibit benzo[a]pyrene-induced cell transformation *in vitro* possibly by inhibiting the transactivation of activated protein-1 and nuclear factor kappa-B (Huang *et al.*, 2002).

Chlorinated PAHs such as polychlorodibenzodioxines and polychlorofuranes are found in impurities in certain pesticides or as secondary residues in industrial processes.

These halogenated PAHs are very toxic for the skin and can cause chloride acne (Baudouin *et al*., 2002). In a recent incident, former Ukraine Prime Minister and Presidential Candidate Victor Yushchenko developed chloracne from dioxin poisoning. This mysterious poisoning had left his face pockmarked and ashen.

Skin can act as a storage organ for certain halogenated PAHs like hexachlorobiphenyl (Di Francesco *et al*., 1988). The halogenated PAHs are oily compounds, which can obstruct the pores of the skin, thus resulting in accumulation of sebum and keratin, leading to the formation of cysts. This hypothesis was supported with hyperkeratinization observed around the follicles along with involution of the sebaceous glands by topically applied 2,3,7,8-tetrachlorodibenzo-*p*-dioxin to mouse skin (Panteleyev *et al*., 1997).

The skin is particularly active in the metabolism of PAHs. Some PAHs are activated by epidermal cytochrome P450 and hydrolases to generate epoxides and diols, active metabolites able to bind to DNA and initiate the processes of carcinogenesis. Other PAHs cause the skin toxicity by different mechanisms. For example, topical application of 7H-dibenzo[*c,g*]carbazole caused the appearance of DNA adducts in mouse skin (Schurdak and Randerath, 1989). Another study exhibited the potentiating effect of iron on 7, 12-dimethylbenz[*a*]anthracene in the mouse skin. In addition to genotoxic effects of this PAH, the resulting oxidative stress makes this association tumorigenic in the skin tissue (Rezazadeh and Athar, 1997). The photoactivation of certain PAHs like 2-nitrofluorene by UV radiations in rats, can generate intermediates that can bind covalently to RNA and to the skin proteins. This association of 2-nitrofluorene and UV-A is mutagenic and could cause skin cancers (Wierckx *et al*., 1992).

## VOCs

VOCs such as hydrocarbons, ketones, aldehydes, solvents (benzene, fluorocarbons) and gases (methane) are generated from automobiles and industries. Certain VOCs such as benzene are highly genotoxic, inducing cancers in various tissues. Other VOCs can cause precancerous lesions in the lungs and in the skin (Michielsen *et al*., 1999). Some VOCs can produce inflammatory mediators in cultured epidermal keratinocytes. These mediators such as interleukin-8 and -1β are significantly increased that could favor the allergic/inflammatory reactions as in atopic dermatitis or eczema (Ushio *et al*., 1999).

Certain VOCs present in jet fuel like ethyl benzene, o-xylene and naphthalene did not produce direct skin irritation in pigskin (Muhammad *et al*., 2005a). Interestingly, these three hydrocarbons had higher absorption through pigskin compared to other aromatic and aliphatic hydrocarbons studied. Transmission electron microscope and Fourier

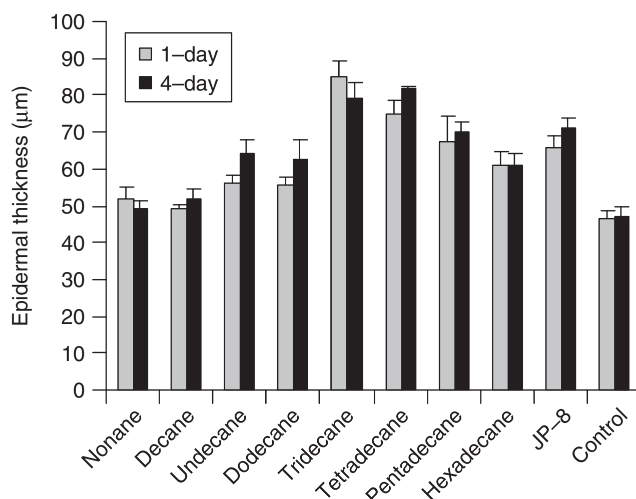

**FIGURE 16.1** Epidermal thickness (mean + SEM) after 1 and 4 days of exposure to *in vivo* JP-8 or constituent aliphatic hydrocarbons in pigs. Note the maximum toxic *in vivo* response with tridecane (C-13) and tetradecane (C-14) hydrocarbons.

transform infrared spectroscopy indicated that these PAHs have the potential to extract the lipids out of the SC of skin thus affecting the skin's permeability barrier and increasing the absorption of exogenous substances (Muhammad *et al*., 2005b). On the other hand, less volatile hydrocarbons of jet fuels such as tridecane, tetradecane and pentadecane produced significant direct dermal irritation and microscopic changes in pigskin (Figure 16.1).

Polychlorinated naphthalenes are present in lubrication greases, oils, fuels and in wood preservatives. Chlorinated naphthalenes can cause severe hyperkeratosis in cattle. The most prominent lesions were observed on the neck and wither but may affect the entire integument. This dermal toxicity in cattle needs to be differentiated from avitaminosis A. Chlorinated naphthalenes did not produce hyperkeratosis in sheep and swine (Clarke and Clarke, 1975). Ethylene glycol monomethyl ether (EGME) and its acetate ester (EGMEA) are moderately volatile liquids with very good solubility properties. They are used in paints, lacquers, stains, inks and surface coatings and as an antiicing additive in hydraulic fluids and jet fuel. EGME and EGMEA are efficiently absorbed via dermal penetration. Skin absorption in animals may contribute substantially to the total uptake following skin contact with liquids or vapors containing EGME or EGMEA (Johanson, 2000).

## Pesticides

The word "pesticide" in this chapter will encompass various relevant chemicals including insecticide for controlling termites or fleas, herbicides for ridding the crops/lawn of dandelions or fungicides that protect plants during fungal

diseases. Despite oral ingestion, dermal absorption is the major source of pesticide exposure in occupational, agricultural and veterinary settings, a topic recently reviewed (Riviere, 2006). Since most of the pesticides are highly lipophilic, their penetration and accumulation in skin with resulting local dermal irritation, and/or mild to severe systemic toxic effects in the exposed animals cannot be overlooked.

Livestock and pet animal exposure to pesticides is usually accidental. The most common source of dermal toxicity induced with insecticides in both large and small animals is the miscalculation of concentrations for spraying and dipping procedures. A misplaced decimal point can result in hundred-or thousand-fold increase in exposure. A common source of non-recommended exposure to animals is the inadvertent mixing of powdered pesticides, mistaken for salt or mineral preparations, into animal feeds. A low level contamination of animals by insecticides can also occur with the use of persistent chlorinated hydrocarbons such as dichlorodiphenyltrichloroethane (DDT), aldrin, dieldrin and heptachlor, etc. on crops which may be used for animal feeds. These insecticides may persist in soil for several years. Thus, forage crops grown on such soils could be sufficiently contaminated to produce toxic effects in animals. Other sources of insecticide exposure in animals includes carelessness in leaving insecticides accessible to animals, leaving insecticide preparations on sills of sheds or barns, inadequate covers on back rubbers containing insecticide concentrates, or using pesticide containers to water and feed animals without proper decontamination (Osweiler *et al*., 1985b). Thus, animals can exhibit signs of dermal toxicity after oral or systemic exposure to pesticides. On the other hand, washing the skin of humans or animals after exposure to a pesticide or other chemical may leave a major portion of the dose on/in the washed skin. This skin residue can contribute to the toxicity of a pesticide by continued post-wash absorption (Zendzian, 2003). According to a recent statistics on occupational dermatosis among private farmers, pesticides accounts for 18% as the causative factor for various skin disorders (Spiewak, 2003). The other most frequently identified causative factors for occupational dermatosis were plant dusts (38%), animal allergens (36%), metals (29%) and rubber chemicals (15%).

Certain organophosphorus insecticides such as chlorpyriphos have been shown to exert its systemic effects in the form of cholinesterase inhibition after dermal application to rats (Abu-Qure *et al*., 2001). The topical application of chlorpyriphos and cypermethrin to rats showed an inhibition of acetylcholinesterase and butyrylcholinesterase activity in the brain (Latuszynska *et al*., 2001). Another study suggested that skin could act as a reservoir and may release chlorpyriphos over a prolonged period (Griffin *et al*., 2000). Pyrethrins are insecticides that are derived from the extract of chrysanthemum flowers. The synthetic forms of pyrethrins are called pyrethroids. The initial plant extract (crude pyrethrum) contains about 30–35% pyrethrins. Allergic contact dermatitis has been observed in sensitized and non-sensitized guinea pigs by topical exposure to various extracts from pyrethrum flowers (Rickett *et al*., 1972). Occupationally, skin is the main route of pyrethroid absorption. The major toxic effect of dermal exposure is paraesthesiae, presumably due to hyperactivity of cutaneous sensory nerve fibers (Bradberry *et al*., 2005). The face is most commonly affected and the paraesthesiae are exacerbated by sensory stimulation such as sunlight, scratching, heat, sweating or water application. The specific treatment is not generally required, as paraesthesiae usually resolve in 12–24 h. Topical application of dl-$\alpha$ tocopherol acetate (vitamin E) may reduce the severity (Bradberry *et al*., 2005). Similarly, cypermethrin (a pyrethroid) can penetrate through the skin of animals and can exert its systemic effects (Latuszynska *et al*., 2001). Dermal exposure to permethrin (another pyrethroid) has often been considered a mitigating factor in Gulf War Syndrome (Riviere *et al*., 2002). Studies have shown that systemic exposure of certain chemicals such as diisopropyl fluorophosphate (DFP) or pyridostigmine bromide and topical application of DFP or *N*,*N*-diethyl-*m*-toluamide (DEET) can alter the disposition of [14C]permethrin in skin and possibly its bioavailability in soldiers simultaneously exposed to these chemicals (Baynes *et al*., 2002a).

A number of chemicals are used as fumigants for control of insects, nematodes, fungi and weeds in soils, stored grains, feedstuffs, storage spaces in mills and common carrier vehicles. Most of the toxicology of such chemicals is studied in laboratory animals and need to be extrapolated for the domestic animals. One such chemical (ethylene dichloride) is reported as irritating to the skin and mucous membranes. It can be absorbed through the skin although large doses are required to cause toxicosis in animals. Ethylene dibromide and metham-sodium are other skin irritants that also have the potential to absorb through the skin. Fluoroacetate was developed for insecticide and rodent control applications in early 1940s. This chemical has been reported to absorb through the abraded skin but not through the intact skin (Osweiler *et al*., 1985b). Paraquat is a non-volatile bipyridyl herbicide and is insoluble in water. Low-to-moderate amounts of bipyridyl herbicides are absorbed from the skin of animals. Direct contact of animals with paraquat results in irritation to skin (Longstaffe *et al*., 1981). Experimental studies in pigskin demonstrated epidermal toxicity in the absence of appreciable transdermal absorption (Srikrishna *et al*., 1992).

Many chemicals and solvents are dermal penetration enhancers. Such chemicals may increase dermal penetration by damaging the skin's barrier, by modifying the SC, or by promoting the partitioning of co-penetrating chemicals (Moser *et al*., 2001; Medi *et al*., 2006). This scenario may serve useful purposes in transdermal drug delivery but at

the same time, penetration enhancers may also increase skin penetration of harmful chemicals (Baynes *et al.*, 2002a). The percutaneous penetration of five pesticides having different solubilities was studied through a slightly damaged skin. It was observed that the percutaneous penetration of the most hydrophilic compounds will be affected most, and may significantly affect the rate, lag-time as well as total penetration of chemicals (Nielsen, 2005). A combination of two solvents (pyridostigmine bromide and DFP) increased the dermal absorption of DEET through isolated perfused porcine skin (Riviere *et al.*, 2003). Earlier studies by Baynes *et al.* (1997) reported that the extent of DEET absorption was greater with dimethyl sulfoxide (DMSO) and acetone than with ethanol in rat and mouse skin. These studies support that DEET can have sufficient systemic exposure to potentially cause signs of toxicity when simultaneously applied with pesticides such as permethrin or carbaryl. Thus, penetration enhancement can have undesirable consequences. In this context, commercial sunscreen formulations are found to significantly increase the transdermal penetration of a herbicide 2,4-dichlorophenoxyacetic acid in *in vitro* rat skin (Pont *et al.*, 2004). In addition to the active ingredients, "inert" ingredients in sunscreen or pesticide formulations may also be responsible for controlling the transdermal penetration of herbicide 2,4-dichlorophenoxyacetic acid (Pont *et al.*, 2003) and carbamate insecticide carbaryl (Baynes and Riviere, 1998), respectively.

Pentachlorophenol (PCP) has been widely used as a pesticide. The persistence of PCP in soil and water and apparent widespread use has resulted in significant exposure to animals. Young swine have died following dermal exposure to freshly PCP treated wood used in farrowing crates or farrowing houses. *In vivo* studies in swine demonstrated that exposure to PCP-contaminated soil can result in significant dermal absorption of the pesticide (Wester *et al.*, 1993; Qiao *et al.*, 1997). It has been demonstrated that the presence of solvent and/or surfactant mixtures can influence PCP absorption in the isolated, perfused porcine skin flap (IPPSF) (Riviere *et al.*, 2001). Baynes *et al.* (2002b) demonstrated that PCP is fairly well absorbed across porcine skin. PCP absorption in skin was greater in water or water-based mixtures than in 100% ethanol. PCP is barely soluble in water, but this pesticide is more likely to partition from water than an organic solvent vehicle such as ethanol into the SC. This situation warrants the dermal uptake of lipophilic pesticides through the skin of animals as the later have free access to water all the times. Both PCP and its major metabolite tetrachlorohydroquinone (TCHQ) could induce mice skin epidermal hyperplasia and proliferating cell nuclear antigen (PCNA) labeling index in the epidermis. However, TCHQ caused a more significant induction of epidermal hyperplasia and PCNA positive cells than PCP. Furthermore, topical application of PCP-induced significant organ enlargement and lymphoma in mice (Chang *et al.*, 2003).

The insecticide D-limonene toxicosis has been rarely described in canine species. One study has reported skin lesions consisted of coalescing erythematous patches in the cat groomed previously with a D-limonene-based insecticidal shampoo. Dermatohistopathologic changes included multifocal areas of acute coagulative epidermal necrosis (Lee *et al.*, 2002). Epichlorohydrin (ECH) is one of the more commercially important aliphatic epoxides used extensively as an insecticide, an industrial intermediate and as a laboratory reagent. It is a volatile, colorless liquid and behaves as an alkylating agent. Reports have shown that it causes the dermal toxicity in animals (Giri, 1997). Dodecen-1-ol (an insect attractant) acted as a primary skin irritant, since it caused superficial chemical burns (Beroza *et al.*, 1975). Ortho-phenylphenol (OPP) and its sodium (SOPP) and potassium (POPP) salts are used as fungicides and disinfectants. OPP has been reported as irritating, and SOPP and POPP as corrosive for the skin and mucous membranes (Bomhard *et al.*, 2002).

White phosphorus had been used to prepare rodenticides that are generally mixed with a greasy or oily base. Skin irritation or burning may occur from dermal exposure to high concentrations of such rodenticides but absorption is not observed with dermal exposure. Thallium is another rodenticide that is primarily used by government agencies. In subacute thallium poisoning in dogs and cats, reddening and pustule formation in the skin starting from the ears and nose and progressing to the axilla, abdomen and the rest of the body; associated with loss of hair was reported. In chronic thallium poisoning, skin hyperkeratosis, parakeratosis, hyperemia and vivid discoloration of skin has been observed in the cat (Osweiler *et al.*, 1985b).

## Detergents, solvents, corrosives and other household preparations

Several daily use products (soaps, detergents, drain cleaners; acids, alkalies, etc.) available in homes and other work places may cause dermal irritation. There is scarce information in literature regarding toxicosis due to these daily use products in animals. We will discuss briefly the possibilities of dermal irritation in animals based on well-known scientific principles and published reports.

The evaluation of cleansing products depends upon their cleansing properties (detergent or adsorptive), on the rinsability of the product, on the amount and nature of the additives and on the general and specifically epidermal toxicity of the components (Raab, 1990). In this context, one such preparation is denture cleaner in which the major toxic component is sodium perborate which decomposes to form hydrogen peroxide and sodium borate. These products are strongly alkaline and very irritating to the skin and mucous membranes thus can produce dermal toxicity in exposed animals. Similarly, constant or repeated exposure of skin to

anionic detergents (sulfomated or phosphorylated hydrocarbons) causes irritation with the removal of natural oils and can result in thickening of skin along with weeping, cracking, scaling and blistering (Dreisbach, 1983). This is evident that detergent substances are important components of cleansing materials. But their detergent cleansing action may also result in skin toxicity (Marks and Dykes, 1990). Non-ionic detergents such as alkyl and aryl polyether sulfates, alcohols or sulfonates are comparatively less irritating than ionic ones. The acute skin irritation potential of various detergent formulations can be assessed with patch test (Robinson *et al.*, 2005). In this test, the time of exposure required for 50% of subjects to show a positive skin reaction ($TR_{50}$ value) is calculated for each product. Using this approach, 24 detergent preparations were tested in 7 individual studies. The dermal irritation profiles could be categorized as follows (by decreasing irritancy): mold/mildew removers (average $TR_{50} = 0.37$ h) > disinfectants/sanitizers (0.64 h) > fabric softener concentrate (1.09 h) = aluminum wash (1.20 h) > 20% SDS (1.81 h) > liquid laundry detergents (3.48 h) > liquid dish detergents (4.16 h) = liquid fabric softeners (4.56 h) = liquid hand soaps (4.58 h) = shampoos (5.40 h) = hard surface cleaners (6.34 h) > powder automatic dish detergents (>16 h) = powder laundry detergents (>16 h) (Robinson *et al.*, 2005). Cleansing can also be accomplished with non-detergent containing cleaners (Marks and Dykes, 1990). Drain cleaners consisting of high concentrations (25–36%) of sodium hydroxide and sodium hypochlorite are extremely toxic and caustic to the skin. Direct skin contact to these agents causes coagulative to liquefaction necrosis by dissolving proteins and saponifying lipids. Soaps have been used for thousands of years as part of daily life. Soaps are limited by their irritancy to the skin due to their alkaline nature and their tendency to form insoluble and inactive salts when combined with either hard water or sea water (Kirsner and Froelich, 1998).

Calcium cyanide, which is a special constituent of fertilizers, may act as contact irritant causing skin ulcers. Chlorobromomethane (a fire extinguisher liquid) causes intense skin irritation from exposure to either liquid or its vapors, although this chemical has low dermal absorption. Skin contact to another chemical methyl bromide (used in fire extinguishers, refrigerants or fumigants) can result in irritation and vesiculation. Clinical poisoning may occur from its skin absorption (Osweiler *et al.*, 1985b). Liquid soldering fluxes mainly contain zinc chloride and a high proportion of hydrochloric acid. These components are caustic or corrosive and acute exposure results in direct irritation to skin. Glues and adhesives are often supplied in hydrocarbon solvents. Dermal exposure to these preparations may also produce irritation. The corrosive activity of hypochlorite (a common component of laundry bleaches) on skin is due to oxidizing potency or available chlorine. Alkalinity of some preparations may contribute to tissue injury. Metal cleaners and oven cleaners contain components like soda/potash and KOH/NaOH in high concentrations, respectively, in addition to petroleum-based solvents. All these components would be expected to cause dermal irritation. Ethylene glycol and propylene glycol (PG) are used in most of the topical pharmaceutical and cosmetic preparations as solvents. The localized dermal effects from both solvents are mild, while the published data suggested that PG might have a skin contact sensitization potential (Lakind *et al.*, 1999).

The alkalies present in oven cleaners may cause severe necrotic lesions similar to drain cleaners. Domestic animals, especially pets, may be exposed dermally to paints and varnish removers containing mixtures of benzene, methanol, acetone and toluene. These solvents can absorb through the skin in considerable amounts. Certain perfumes can cause local irritation of skin. This is probably due to alcohol serving as the primary vehicle. Rubbing alcohol (ethyl alcohol) may sometimes cause cutaneous hyperemia. Rust removers whose major toxic components are hydrochloric acid, phosphoric acid, hydrofluoric acid, etc. can have direct corrosive and necrotizing action like other acids. Most shampoos would not be expected to cause severe dermal irritation. Generally, skin exposures to acids, alkalies and phenols may lead to lesions that can vary from mild dermatitis to severe corrosion of the skin.

## SYSTEMIC COMPOUNDS CAUSING DERMAL TOXICITY IN ANIMALS

### Heavy metals

Metals are intrinsic in nature and are utilized by animals for many essential functions. As a rule, metals are required for life and health in small quantities but are toxic in excessive amount. The toxic heavy metals in animals include arsenic, lead, cadmium, chromium and nickel. These metals contaminate the environment from industrial, automobile and pesticide activities. The moderately toxic metals are iron, zinc, selenium, mercury and copper. Redistribution of metals in the environment is mainly responsible for access of animals to toxic metals not normally assessable. Metal toxicosis in animals results from the systemic administration of metals. The mechanisms involved in the toxicity of certain metals like cadmium, chromium and nickel have indicated that these metals act directly or indirectly on intracellular proteins in the skin (Carlisle *et al.*, 2001). Inorganic arsenic exposure in drinking water is linked to skin, bladder and lung cancer. The mechanism of arsenic-induced cancer is not clear, but this is proposed that arsenic can generate reactive oxygen species, suggesting that oxidation of DNA may play a role in carcinogenesis (Fischer *et al.*, 2005).

Heavy metals can form reversible complexes with organic ligands during the chelation process. For example, lead may be concentrated as a complex in bile. Proteins such as metallothionein serve as transport molecules for metals (Hammond and Beliles, 1980). This scenario may alter the availability and delivery of metals to specific organs. On the other hand, certain toxic metals can accumulate in definite tissue locations. For instance, bone which can store high concentrations of lead, can result in distribution to plasma protein or skin and hair. Susceptibility to dermal absorption of metals may be increased when the metal is organically bound, such as methyl mercury or tetraethyl lead. One such study indicated that the dermal symptoms of inorganic, aryl and methoxy ethyl forms of mercury in cattle include skin pustules, ulcers, depilation (starting at the root of tail) and skin keratinization. Animals with severe skin damage are severely ill. The febrile response and skin color changes occurring in mercury poisoning can easily be confused with hog cholera and erysipelas. In the start of clinical syndrome, mercury poisoning in pigs also resemble the early skin reddening and abnormal gait resulted in organic arsenic poisoning (Osweiler *et al*., 1985b).

Hair of animals may be the most common site of metal depositions since hair has a chemical affinity for heavy metals like arsenic, lead, thallium, selenium, bismuth and mercury. These metals have the potential to react with sulfhydryl groups of amino acids particularly cysteine, in the follicular proteins and incorporated into the keratin. Because of the relative ease of getting hair samples, concentrations of metals in hair may be used as a biomarker for risk assessment surveys to determine the chronic heavy metal exposure in animals.

Forage crops grown on seleniferous soils contain sufficient amounts of selenium to cause poisoning in domestic animals. Selenium may cause acute and chronic poisoning in all animals, especially cattle, sheep, horses, swine, chicken and dogs. A loss of hair/wool, deformation and sloughing of the hoof is seen in cattle, sheep and horses that were poisoned chronically with selenium. This condition is commonly known as alkali disease, a misnomer (Osweiler *et al*., 1985b). Chronic selenium (Se) toxicosis has been diagnosed in pigs with loss of hair, necrotic areas in the skin, lesions of the coronary band and hooves. The cause of this intoxication was the addition of the calculated amounts of sodium selenite directly to the feedstuff instead to mineral premix (Mihailovic *et al*., 1992). In one occurrence of arsenic poisoning in cattle, arsenic in the hair of affected survivors was assayed at 0.8–3.40 ppm versus 0.09–0.10 ppm in randomly selected control samples (Riviere *et al*., 1981). Inorganic tin salts are poorly absorbed and rapidly excreted in the feces; as a result they have a low toxicity. The main results of inorganic tin toxicity are skin and eye irritation; cholangitis of the lower biliary tract, and later hepatotoxicity; and neurotoxicity (Winship, 1988). Similarly, considerable skin changes in the form of scaliness on the dorsum of the neck and sloughing of the epidermis over neck, withers, ears, briskets, shoulders, back and tail was observed in beef calves after systemic administration of iodine. A slight degree of hair loss was also reported (Osweiler *et al*., 1985b).

Chromium is an essential trace element required for normal protein, fat and carbohydrate metabolism. It also helps in energy production and increasing lean body mass. A unique form of bioavailable chromium is niacin-bound chromium (NBC) that is used to promote a healthy lipid profile. The primary skin irritation test with NBC on New Zealand Albino rabbits indicated that NBC was slightly irritating (Shara *et al*., 2005).

Compounds other than metals can also produce dermal irritation on systemic administration. Oral administration of benzo[*a*]pyrene (PAH) caused the formation of DNA adducts in the skin (Baudouin, *et al*., 2002). The ingestion of hexachlorobenzene (VOC) in the rat leads to the formation of precancerous lesions in the skin and lungs (Michielsen *et al*., 1999). The high doses of pyrethrins (insecticides) fed to rats can induce benign skin lesions (USEPA, 1995). Polybrominated biphenyls were used as fire retardant in many parts of the world. On accidental ingestion of this chemical with contaminated feed or by licking the contaminated wood, animals with alopecia and thickened skin over the thorax, neck and shoulder had been noted. Systemic exposure of ruminants and sheep to thiocarbamate (herbicide) can induce alopecia (Osweiler *et al*., 1985b). Severe dermatitis over the ventral portion of the abdomen and inner surfaces of the limbs was developed in pigs that were given adriamycin (a systemic antibiotic) intravenously (Van Vleet *et al*., 1979).

## ASSESSMENT METHODS

*In vivo* testing of certain chemicals for their irritating or sensitizing potentials and assessment of their dermal uptake are other sources of skin toxicity in experimental animals. Animal welfare regulations mandate the careful monitoring of dermal irritation and toxicity studies due to the potential for causing pain and skin damage resulting from cutaneously applied materials. In the USA, the care and use of rabbits, guinea pigs, minipigs, dogs and non-human primates are regulated by the US Department of Agriculture under the Animal Welfare Act (AWA, amended, 1985). Rats and mice are not included in this act, yet most institutions use these animals under similar internal standards for these species. According to this act skin irritancy testing is a procedure which can cause slight pain in the animal. Severe erythema, erosions, ulcers, abscesses and necrosis are the painful skin reactions produced in response to topical application of chemicals. The degree of skin toxicity in experimental animals varies with response to acute, subchronic or chronic dermal irritation studies.

Amongst assessment methods capable of causing dermal toxicity, cutaneous microdialysis, tape stripping and skin surface biopsies are the major *in vivo* models used to assess the dermal uptake of topically applied toxicants. Microdialysis is a promising technique for determination of *in vivo* dermal absorption (Simonsen *et al*., 2004). This technique consists of a semipermeable membrane forming a thin hollow tube that functionally resembles a blood vessel. The microdialysis probe is implanted in the dermis of the skin via a guide cannula. This technique is minimally invasive, and produces a minor trauma during insertion of the guide cannula for the implantation of the microdialysis probe; although this trauma is reversible (Groth and Serup, 1998) yet this can damage the skin considerably in sensitive animals. After the insertion of probe, an equilibration period of minimum 90 and 30 min in human and rat skin, respectively, is necessary to allow the effects of trauma to diminish (Groth, 1996). Tape stripping is suitable for studying the penetration of topically applied chemicals into the SC. This is composed of serial stripping of SC with the help of common adhesive tapes. This technique is invasive to the minimal extent and frequently used to study the reservoir effect of the SC for topically applied constituents and the assessment of their *in vivo* percutaneous penetration effects (Muhammad and Riviere, 2006). Another minimal invasive technique is skin surface biopsies. With the help of this technique, it is possible to track the permeation of a compound through the SC by taking consecutive biopsies in the same area (Dykes *et al*., 1997).

# Blood and bone marrow toxicity

*Shashi K. Ramaiah and Mary B. Nabity*

## INTRODUCTION

Hematotoxicology is the study of adverse effects of drugs, non-therapeutic chemicals, and other agents in our environment on blood and blood forming tissues such as bone marrow. Assessment of blood and bone marrow in veterinary toxicology is important since chemicals and drugs can significantly affect the cellular and humoral components of the blood. The hematopoietic system is unique and serves as a "cornerstone" to one's understanding of the toxicology of blood and bone marrow. Hematopoietic cells are the most dynamic, proliferative, and mitotically active cells in an animal. Over the course of a mammal's lifetime, the average basal production rate of these cells are 2.5 billion red cells, 2.5 billion platelets, and 1 billion granulocytes per kilogram per day (Gasper, 2000). Therefore, toxicity to circulating blood cells or their precursors may be very serious and can result in life-threatening anemia, hemorrhage, or profound infection.

Bone marrow is a common target for a variety of chemotherapeutic agents in animals and humans, some of which can result in total marrow aplasia (Lund, 2000). Many other drugs can also negatively impact blood components; therefore, the evaluation of blood and bone marrow in preclinical drug development is required by many regulatory agencies when assessing the safety and efficacy of test compounds (Bolliger, 2004). Because blood and bone marrow can be relatively easily assessed, sequential monitoring of blood and bone marrow has become a standard component of toxicity screening by the pharmaceutical industry as well as in the clinics. This chapter is intended to provide a basic introduction to blood and bone marrow as well as illustrate some toxicant-induced changes. Information provided in this chapter should serve as an important and accessible tool for understanding basic concepts, and for monitoring and characterizing toxic responses of the blood and bone marrow.

## ANATOMY

### Bone marrow

Hematopoiesis normally occurs in the bone marrow of both flat bones and long bones, and in mice, it can also occur normally in the spleen (Gasper, 2000). Blood supply to the marrow is mainly provided by nutrient arteries that penetrate cortical bone, particularly at the mid-shaft of long bones. These arteries extend along the longitudinal axis of the bone and send off radial branches throughout the marrow. These branches terminate at the periphery of the marrow cavity and connect with venous vessels. Venous or vascular sinuses of marrow are thin-walled vessels with abundant anastomoses, and they carry blood back to central veins. Marrow lacks lymphatic vessels and nerves in the marrow are vasomotor and found in association with the vasculature.

The hematopoietic compartment of the marrow consists of irregular and anastomosing cords that lie between vascular sinuses (Bloom, 1997). Blood cells are produced in the hematopoietic compartment of the marrow and reach the circulation by migrating through the vascular sinus endothelium. Marrow fat cells represent a mechanical buffer that occupy or release space within the medullary cavity in response to changing demands for hematopoiesis. Adventitial reticular cells provide structural support for hemopoietic colonies. The extent of marrow fat and adventitial coverage of vascular sinuses varies inversely with the degree of hematopoiesis and the rate of cell delivery to the

bloodstream. Thus, the amount of fat in the marrow increases with age (Bloom, 1997).

## HEMATOPOIETIC STEM CELLS

A pluripotent stem cell that can produce all blood cell types, including lymphocytes, is said to be totipotent. Most totipotent stem cells in adults are not in the cell cycle, but are quiescent. Totipotent stem cells account for less than 0.2% of the total hematopoietic cells in the marrow. In adult mammals, most of these cells are lodged in the bone marrow, but small numbers enter, circulate, and return from blood. Low numbers are also present in the spleen. Totipotent hematopoietic stem cells produce pluripotent myeloid and lymphoid stem cells. Pluripotent stem cells give rise to progenitor cells which are capable of forming colonies in marrow culture, like stem cells, but lack long-term self-renewal capacity and are generally more restricted in their differentiation (Meyer and Harvey, 1998). Many progenitor cells are in the active cell cycle. They are capable of producing progeny (blast cells) that can be recognized morphologically. These resultant blast cells are classified as "precursor cells."

The pluripotent myeloid stem cells give rise to a series of progressively more differentiated progenitor cells that support the production of all nonlymphoid cells. When grown in an *in vitro* cell culture assay, each colony of cells represents one progenitor cell and is referred to as a colony-forming unit (CFU). With time, few large colonies may appear in culture, originating from a more immature progenitor cell and referred to as burst-forming units (BFUs) in the literature (Meyer and Harvey, 1998). Both the local marrow microenvironment and systemic humoral factors influence hematopoiesis to stimulate or suppress the proliferation and differentiation of single or multiple cell lineages. In general, multi-colony growth factors such as interleukin 3 (IL-3) stimulate early progenitor cells, whereas single colony factors such as erythropoietin (EPO) and granulocyte–macrophage colony stimulating factor (GM-CSF) act on more differentiated progenitor cells such as erythroid and granulocyte–macrophage progenitor cells, respectively.

## BLOOD COMPONENTS

Blood consists of cells and protein-rich plasma (Figure 17.1). Blood cells include erythrocytes (red blood cells), platelets (usually called thrombocytes in nonmammalian species), and leukocytes (white blood cells). The leukocytes in most vertebrates are classified as, granulocytes (neutrophils, eosinophils, and basophils) and mononuclear cells (monocytes and lymphocytes). Freshly drawn blood rapidly clots, but if clotting is prevented by the addition of an anticoagulant, the blood cells settle. This allows for separation of the plasma and cellular components into three distinct layers after centrifugation of anticoagulated blood (Andrews, 1998; Meyer and Harvey, 1998). The lowest layer is red since it consists mostly of erythrocytes, and the percent volume of this layer with respect to the total blood volume (normally approximately 35–45%) determines the packed cell volume (PCV) or hematocrit (HCT). The thin, gray–white middle layer immediately above the erythrocytes is the buffy coat, and it accounts for approximately 1% of the blood volume. The buffy coat contains platelets and leukocytes, but immature erythrocytes may also be present in this layer. The top (fluid) layer is the plasma. Plasma contains 91–92% water and 8–9% solutes such as proteins, lipids, and electrolytes (Figure 17.1). A variety of homeostatic mechanisms ensure that plasma volume, pH and constituents are tightly regulated. When clotting of blood occurs, fibrinogen and many coagulation factors are depleted, and the resulting fluid is called serum (Andrews, 1998; Meyer and Harvey, 1998).

### Erythrocyte, leukocyte, and platelet formation

Immature blood cell precursors are generally larger than mature forms, and they have a large euchromatic nucleus resulting in a high nuclear to cytoplasmic (N:C) ratio. As blood cells mature, their size and N:C ratio gradually decrease.

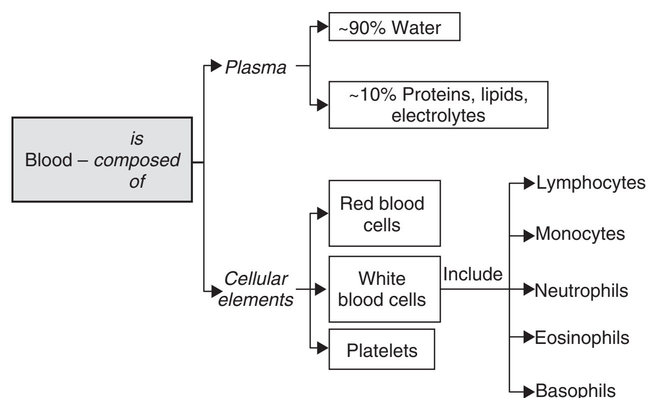

**FIGURE 17.1** Blood components. The blood consists of the fluid-rich plasma component and the cellular component consisting of red and white blood cells. The white blood cells are composed of neutrophils, basophils, eosinophils, monocytes, and lymphocytes. See text for details on morphology of these cells.

### *Erythropoiesis*

Erythropoiesis is the process by which committed hemopoietic progenitor cells develop into anucleate, hemoglobin-containing, biconcave discs called erythrocytes. EPO regulates this process. Rubriblasts, the first recognizable erythroid precursor, undergo approximately four cell divisions to generate the last nucleated stage, the metarubricyte (Figure 17.2a). However, intracellular hemoglobin concentration is an important factor in determining the number of cell divisions undergone to produce this stage (Car, 2000). With the extrusion of the nucleus, the resulting immature erythrocyte is termed a reticulocyte. The reticulocyte persists for about 2 days after release into the circulation before maturation into a mature erythrocyte. Under normal situations, few reticulocytes are seen in peripheral blood, but some strains of rodents may normally have up to 10% circulating reticulocytes (Fernandez and Grindem, 2000). The lifespan of mature erythrocytes ranges from 43 to 145 days depending on the species (Christian, 2000).

### *Granulopoiesis*

Granulopoiesis is the process by which committed hemopoietic progenitor cells develop into granulocytes under the influence of various growth factors and cytokines. Neutrophils and monocytes are derived from a common progenitor, the colony-forming unit granulocyte–macrophage (CFU-GM), whereas eosinophils and basophils are derived from different progenitor cells (CFU-Eo and CFU-Ba, respectively). The first recognizable granulocytic precursor is the myeloblast. Early granulocyte precursors (myeloblast and promyelocyte) appear similar between the various granulocytic cell lines until the myelocyte stage, which is the final stage capable of cell division. At this stage, they develop characteristic secondary lineage-specific granules (neutrophilic, eosinophilic, or basophilic). During the next stage (the metamyelocyte), the nucleus of the granulocyte indents and lobulation begins, eventually producing the characteristic polymorphonuclear appearance (Figure 17.2a, b) (Gasper, 2000; Smith, 2000).

### *Platelet formation*

The megakaryocyte is a polyploidy cell with cytoplasm that becomes increasingly granular with maturity (Figure 17.2). Platelets are derived from the megakaryocyte cytoplasm. The mechanism by which platelets are released from their parent cell is unclear, but it appears to be by cytoplasmic fragmentation. This process may take place in an extramedullary location (i.e. lung, spleen). The cytokine thrombopoietin is the major stimulus for megakaryocyte proliferation, platelet production, and differentiation from a common progenitor cell, the CFU-GEMM (Andrews, 1998). If unconsumed, the platelet lifespan ranges from 3 to 10 days depending on the species (Weiss, 2000).

## Erythrocyte, leukocyte, and platelet biology

### *Erythrocyte*

#### *Erythrocyte function*

The function of red blood cells is to transport oxygen to tissues. Decreased hemoglobin lowers oxygen delivery to tissues. This results in increased EPO secretion from the kidney and subsequent stimulation of erythrocyte production.

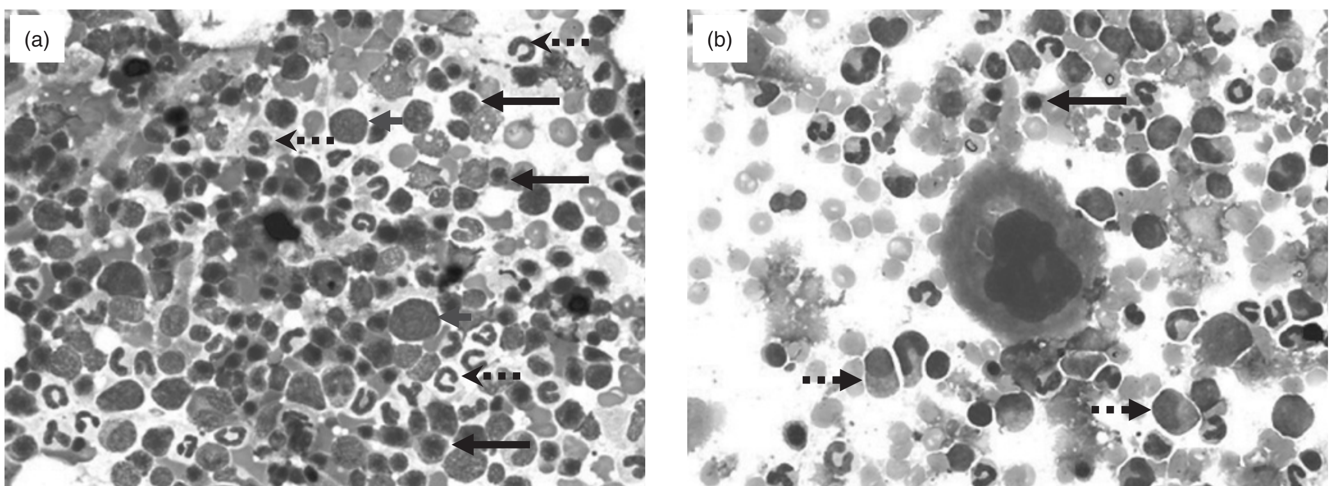

FIGURE 17.2 (a) Examples of erythroid precursors and granulocytic precursors (arrowheads) in the bone marrow of a dog. 60×, Diff-quik stain. Early erythroid precursors (arrow heads), late erythroid precursors (solid arrows) and granulocytic precursors (dotted arrows) are shown. (b) A mature megakaryocyte in the bone marrow of a dog is shown in the center of the picture. Erythroid and myeloid precursors are also noted (arrows). 60×, Modified Wrights stain. This figure is reproduced in color in the color plate section.

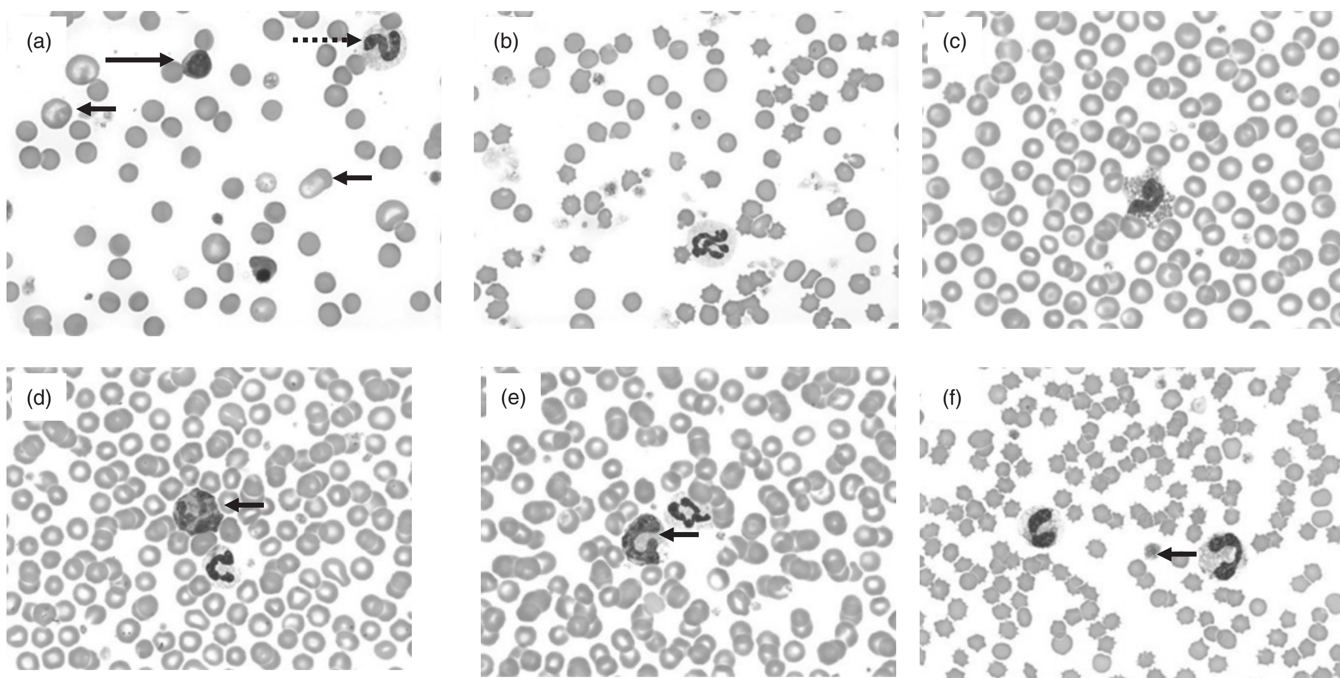

**FIGURE 17.3** Normal and few abnormal erythrocyte and leukocyte morphology. (a) Two large basophilic polychromatophilic erythrocytes or reticulocytes (small solid arrow) are present in the blood from a dog with IMHA. A normal neutrophil (dotted arrow), a metarubricyte and a lymphocyte (long arrow) are also present. 100×, Modified Wrights Stain. (b) Heinz bodies in the blood from a cat appearing as pale "spots" within erythrocytes with a modified Wrights stain, 100×. (c) Eosinophil with round granules in the blood from a dog. 100×, Modified Wrights stain. (d) Basophil (arrow) and neutrophil in the blood from a dog. 100×, Modified Wrights stain. (e) Monocyte (arrow) and neutrophil in the blood from a dog. 100×, Modified Wrights stain. (f) Toxic neutrophils in the blood from a cat demonstrating Döhle bodies, cytoplasmic vacuolation, and basophilia. A platelet (arrow) is also identified in the field 100×, Modified Wrights stain. This figure is reproduced in color in the color plate section.

*Morphology of erythrocytes*

Mature erythrocytes are anucleate biconcave discs. The degree of concavity varies among the domestic species, and typical biconcave erythrocytes, as indicated by central pallor, are present in dogs, cows, and sheep. The concavity and resulting pallor are not prominent in horses and cats. In most species, an increase in central pallor indicates decreased hemoglobin content. Slight anisocytosis (variation in size) of erythrocytes is common in most animal species, and poikilocytosis (variation in shape) is normally present on smears made from the blood of goats and deer. Erythrocytes may adhere to each other and form long chains resembling stacks of coins. This phenomenon, called rouleaux formation, is normally prominent in horses and cats, intermediate in dogs and pigs, and rare in ruminants. Rouleaux formation is often increased in inflammatory states. Reticulocytes are immature anucleate erythrocytes that appear polychromatic (pinkish blue color) and large on Wright's stained blood films (Figure 17.3a). Reticulocytes contain residual ribonucleic acid (RNA) (ribosomes and polyribosomes) and mitochondria, which aggregate into a reticular mesh when stained with vital stains (e.g. new methylene blue) but not with Romanowsky-type stains. Quantitation of reticulocytes in circulation is used as an index of bone marrow erythropoietic response since circulating reticulocytes are numerous when the marrow is responding to an increased demand for erythrocytes. Heinz bodies result from the oxidation and aggregation of hemoglobin, and they appear as pale areas within or along the edge of the cytoplasm (Figure 17.3b). They may be seen in low numbers in normal cats but are an indication of increased oxidation when present in higher numbers (Meyer and Harvey, 1998; Harvey, 2001; Figure 17.3b).

*Heme synthesis*

The synthesis of heme involves a series of reactions that starts in the cytoplasm and mitochondria of the rubriblast, the earliest identifiable precursor of erythrocytes. Heme synthesis begins with the vitamin $B_6$ dependent condensation of succinyl-CoA and glycine to form delta aminolevulinic acid (ALA). ALA then condenses to form a pyrrole, and this step is inhibited by lead. Porphyrin rings are then generated and a final step incorporates an iron atom. Ferrochelatase also inhibited by lead catalyzes this incorporation of the ferrous iron into the tetrapyrrole protoporphyrin IX in the mitochondria (Meyer and Harvey, 1998; Harvey, 2000; Kaneko, 2000).

*Iron metabolism*

Iron is primarily obtained from dietary sources where it is absorbed from the gut and transported as a complex with

transferrin to the marrow. Iron is transferred to red blood cell precursors by receptor-mediated endocytosis. Iron stores are usually assessed by staining the marrow with Prussian blue or by measuring serum ferritin (Jain, 1993; Harvey, 1997). Cats normally lack stainable iron in their marrow (Nadrew *et al*., 1994).

*Red blood cell energy requirements and hemoglobin breakdown*

The energy required by erythrocytes is especially important for the maintenance of a reduction potential to prevent hemoglobin oxidation. In mature red blood cells there are no mitochondria, therefore, the glycolytic pathway and pentose phosphate pathway are the main sources of ATP and NADPH that provide energy to prevent oxidative damage, e.g. via reduced glutathione (GSH). Aged or damaged red blood cells are removed from circulation by macrophages of the reticuloendothelial system in the spleen, liver, and marrow. In the macrophage, hemoglobin is catabolized to globin and heme. The amino acids from globin reenter the protein synthesis pool. Heme is degraded to biliverdin then to bilirubin and excreted in the urine and bile (Jain, 1993).

### Leukocyte

*Leukocyte biology*

Neutrophils primarily function in inflammatory responses and bacterial killing. With an increased demand for neutrophils, neutrophil production is upregulated by growth factors and proinflammatory cytokines. Mature circulating neutrophils are either present in the circulating pool or the marginal pool. Neutrophils in the marginal neutrophil pool are loosely bound to capillary endothelial cells. Several physiological factors such as epinephrine and corticosteroids due to excitement and stress cause demargination of neutrophils and result in neutrophilia (Babior and Golde, 1995).

*Morphology of leukocytes*

Total leukocyte count refers to the total absolute count of circulating neutrophils, eosinophils, basophils, monocytes, and lymphocytes, and this number varies among different animal species. The differential leukocyte count refers to the percentage of each leukocyte population in peripheral blood and should be performed by counting and differentiating a minimum of 200 cells on a stained blood film. Granulocytes are classified according to the staining characteristics of their specific (or secondary) cytoplasmic granules. Eosinophils have pronounced acidophilic granules, basophils possess distinct basophilic granules, and neutrophils have neutral, usually indistinct granules. The proportion of different populations of leukocytes also varies among animal species. For example, neutrophils predominate in dogs and cats, whereas they only slightly outnumber lymphocytes in horses. In ruminants and laboratory animals (rats and mice), lymphocytes predominate. The morphology of the various populations of leukocytes is fairly similar among animal species (Duncan *et al*., 1994).

*Neutrophils*

Once released from the bone marrow into the peripheral blood, neutrophils circulate for 6–14 h before migrating into tissues, where they survive for 1–4 days (Smith, 2000). Neutrophils account for approximately 40–70% of the total leukocyte count in most animal species. Mature neutrophils have a segmented nucleus with three to five lobes joined by thin strands, and they contain heterochromatic (clumped) chromatin (Figure 17.3). Occasionally a nuclear appendage, an extra chromatin lobe resembling a drumstick, is present in neutrophils of female animals. This nuclear appendage is commonly known as the Barr body. The neutrophil cytoplasm is pale and contains a moderate number of fine pink or pale granules, depending on the animal species. Neutrophils contain two types of cytoplasmic granules: azurophilic (primary) and specific (secondary) granules. In birds, reptiles, and fish, the equivalent of a neutrophil is called a heterophil, and it contains large, reddish cytoplasmic granules. The neutrophils in rabbits, guinea pigs, and hamsters also contain similar-appearing granules and are therefore often referred to as heterophils. Rat and mouse granulocytes are unique in that their granulocytic precursors can develop "ring forms" which appear as a small "hole" in the center of the nucleus. These ring forms are also called "stab cells." Ring forms are seen in neutrophil and eosinophil precursors but not in basophil precursors (Bolliger, 2004).

In health, only mature neutrophils are present in circulation. Immature neutrophils, as indicated by a decrease in nuclear segmentation, are normally restricted to the bone marrow but may be released into the blood during a granulocytic response to a disease process. Neutrophil toxicity is seen secondary to a toxic environment in the blood or bone marrow, resulting in maturational defects. Neutrophil toxicity is characterized by increased cytoplasmic basophilia, foamy vacuolation, and Döhle bodies (amorphous blue-grey cytoplasmic inclusions) (Figure 17.3f) (Jain, 1993; Meyer and Harvey, 1998).

*Eosinophils*

Eosinophils are seen in low numbers, and they contain a polymorphic nucleus that is less condensed and less segmented than that of neutrophils. As eosinophils mature in the bone marrow, most primary azurophilic granules disappear or transform into specific granules. In mature cells, the pale blue cytoplasm contains mostly specific eosinophilic granules that are loosely packed in the cell (Figure 17.3c). The size, shape, number, and staining characteristics of eosinophils vary among different animal species (Young, 2000).

*Basophils*

Few basophils are present in normal blood. They have a segmented or irregularly shaped, often string-like, heterochromatic nucleus. The nuclear segmentation, as in eosinophils, is less pronounced in basophils. Cytoplasmic granules are metachromatic and prominent, and they stain reddish violet (Figure 17.3d). The size, number, and staining reaction of granules vary among animal species. Basophils have some morphologic resemblance to mast cells, which are widely distributed in connective tissues and only rarely observed in blood. Compared to basophils, mast cells are bigger with a round nucleus and more abundant cytoplasmic granules (Scott and Stockham, 2000).

*Monocytes*

The monocyte is generally the largest blood leukocyte and accounts for 3–8% of the total leukocyte count. Monocytes are precursors of tissue macrophages, and their nucleus can vary from bean shaped to convoluted. Their cytoplasm is abundant, blue-gray, and often appears foamy or vacuolated with a few large vacuoles (Figure 17.3e). Monocytes often have many fine or indistinct azurophilic cytoplasmic granules (Bienzle, 2000).

*Lymphocytes*

Lymphocytes account for 20–40% of the total leukocyte count in dogs, cats, and horses; 60–70% in ruminants, mice, and rats; and 50–60% in pigs. Morphologically, lymphocytes are classified as small, medium, and large depending on their size. The size, shape, and staining characteristics of lymphocytes vary among and within animal species. Dogs and cats have mostly small circulating lymphocytes (Figure 17.3a). Both small and large lymphocytes are present in cows, sheep, goats, and rodents. In cows, large lymphocytes occasionally may have vacuolated cytoplasm and a few large azurophilic granules (Meyer and Harvey, 1998).

### *Platelet biology*

*Platelet function*

Platelets function largely in primary hemostasis. Initially, platelets adhere to the endothelium of damaged blood vessels, undergo shape changes, and release proteins that cause the aggregation of more platelets to form a platelet plug and help stimulate the coagulation pathway (Figure 17.4). Platelets play a major role in secondary hemostasis as well. For example, platelets provide a surface for the assembly of several enzyme complexes that form during the process of coagulation, provide coagulation factor V, and participate in the activation of factor X. Collagen stimulates platelet aggregation and platelet adhesion. Adhesion occurs between the platelet membrane and subendothelial components (collagen and fibronectin) via von Willebrand factor and glycoprotein receptors. ADP and thromboxane A2 are secreted by adherent platelets and released from damaged tissue and erythrocytes, and these contribute to early platelet aggregation. Fibrinogen plays a major role in the coagulation cascade as well as in platelet aggregation (Bauer and Rosenberg, 1995).

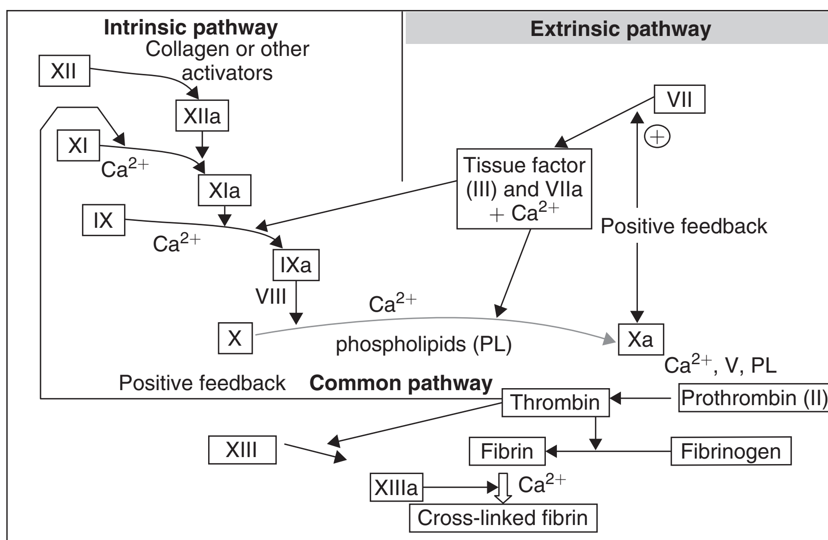

FIGURE 17.4 A diagram of the coagulation cascade consisting of intrinsic, extrinsic, and common pathways. Coagulation is an enzymatic process involving the conversion of inactive enzymes to active forms resulting in amplification of the process. The final product of these pathways is the formation of cross-linked fibrin. PL is phospholipid of platelets. Roman numerals refer to the coagulation factors with these numbers. "a" following a Roman numeral indicates "active enzyme." For details, see section on platelet biology.

*Morphology of platelets*

Platelets generally vary in size and shape and are smaller than red blood cells. In stained blood films, platelets are discoid, spherical, or elongated and may appear individually (Figure 17.3f) or in small to large aggregates. A direct platelet count is performed on blood samples using a hematology analyzer. A subjective screening of platelet numbers (normal, increased, or decreased) can also be made from their relative number on stained blood films. The terms platelet and thrombocyte are used interchangeably, although the term thrombocyte is preferentially used to describe nucleated platelets in fish, reptiles, amphibians, and birds (Boudreaux, 1996; Meyer and Harvey, 1998).

*Hemostasis*

Hemostasis occurs when there is a balance between continuous activation of the coagulation cascade and removal of the end product of coagulation, fibrin, by fibrinolysis. As mentioned previously, hemostasis can be categorized into primary hemostasis, with the formation of a platelet plug, and secondary hemostasis, culminating in a fibrin clot. There are three major pathways involved in secondary hemostasis: the extrinsic, intrinsic, and common pathways (Figure 17.4). In the extrinsic pathway, the initiating stimulus is the release of tissue factor from damaged endothelium and other tissues. The intrinsic pathway can be initiated by either the extrinsic pathway or by contact with negatively charged surfaces such as damaged endothelium. Both the extrinsic and intrinsic pathways stimulate a series of steps, many of which are shared in the common pathway, resulting in the production of thrombin and eventually a stable fibrin clot. Calcium is a requirement in many of these steps, and phospholipids (provided by platelets) are also required for enzyme complex activity. The majority of the coagulation factors are produced by the liver. Some factors such as Factors II, VII, IX, and X are dependent on vitamin K, which is obtained from the diet and produced by intestinal bacteria. Breakdown of the fibrin clot is achieved by activating plasminogen to plasmin, which degrades fibrin. Tests commonly used to measure secondary hemostasis include prothrombin time (PT), partial thromboplastic time (PTT), and activated coagulation time (ACT) (Table 17.1) (Bauer and Rosenberg, 1995; Boudreaux *et al.*, 1996).

## BIOCHEMICAL BASIS OF HEMATOPOIETIC TOXICITY

In toxicology, it is a well-known fact that both the parent compound and its metabolites may mediate toxicity. Although there are several reports of drug-mediated hematopoietic toxicity in clinical cases, the precise mechanisms for such toxicity are not established in the majority

**TABLE 17.1 Commonly used tests to detect toxic effects on blood and bone marrow in clinical and preclinical toxicology**

| Name of test | Usefulness | Comments |
|---|---|---|
| *Complete blood count* (CBC): PCV, MCV, MCHC, WBC count, Differential leukocyte count, platelet count | Routine blood analysis for screening effect of toxic chemicals | Modern blood analyzers report these erythrocyte indices as part of a full blood count, and manual evaluation may be necessary to confirm findings and detect unusual red cell abnormalities |
| *Hemolysis testing* (e.g. osmotic fragility test and Heinz bodies) | To confirm if hemolysis is responsible for lowered red blood cell count | Look for Heinz bodies, methemoglobinemia, and eccentrocytes to detect oxidant-induced changes |
| *Hemostatic tests* (e.g. platelet numbers, PT, PTT, ACT, bleeding time) | To detect abnormalities of coagulation in the extrinsic (PT) and intrinsic (PTT, ACT) path ways and platelet function (bleeding time) | Special tests like D-dimer assay, antithrombin, platelet function tests and individual factor assays are available in some commercial research laboratories |
| *Special blood tests* Reticulocyte count, Coombs, Platelet associated immunoglobulin G (PAIgG) | These tests are based on the routine CBC findings and are considered "problem driven" tests | Reticulocyte evaluation will determine bone marrow response to anemia; Coombs and PAIgG tests determine the immune mediated component in anemia and thrombocytopenia |
| *Bone marrow cytology (evaluate myeloid: erythroid ratio)* | Confirm blood findings and to evaluate marrow function | This is an elaborate and time-consuming procedure. Cytochemical staining can be performed to differentiate abnormal cells in cases of leukemia |
| *In vitro* stem cell assays using clonogenic (CFU-E, CFU-GM, CFU-GEMM) assays | Possible to examine effects on the myeloid, erythroid and megakaryocytic lineages in a fashion where concentration of the chemical and duration of exposure are tightly controlled | *In vitro* clonogenic assays have proven useful in understanding mechanisms of toxicity and in formulating strategies for treatment |

of cases. However, *in vitro* studies have investigated the effect of compounds on the direct lysis of erythrocytes and the inhibition of growth of hemopoietic colonies in culture systems. Although mechanistically important, these results may only be extrapolated to the *in vivo* situation where the compound under test is not modified by host metabolic processes. Classic examples of discrepancy between *in vitro* and *in vivo* studies include chloramphenicol-induced myelosuppression and 2-butoxyethanol-induced hemolysis (Turton *et al*., 2002a, b; Corley *et al*., 2005). The myelosuppressive activity of chloramphenicol is usually ascribed to the parent compound, but the nitroso metabolite of chloramphenicol shows a far greater inhibitory effect in mouse hematopoietic culture assays. In addition, there is considerable variation in the susceptibility of cells from different mouse strains to the nitroso metabolite. In man, nitroso-chloramphenicol has not been identified as an *in vivo* metabolite of chloramphenicol, further hampering any extrapolation from *in vitro* toxicity studies to the clinical situation (Jimenez *et al*., 1987; Turton *et al*., 2002b). The cleaning agent 2-butoxyethanol (2-BE) is reported to be inactive in the *in vitro* hemolysis test in rats, while oral administration in this species produces a hemolytic anemia. However, the major metabolite of 2-BE, butoxyacetic acid, produces marked swelling and lysis of erythrocytes *in vitro* (Corley *et al*., 2005).

Another major mechanism of toxicity seen with many compounds involves the formation of reactive oxygen species (ROS), including superoxide anion, hydrogen peroxide, and hydroxyl radical. ROS are capable of reacting with cellular proteins, lipids, and other molecules leading to changes in their structure and cellular damage. Despite numerous cellular defense mechanisms such as antioxidant enzymes and low molecular weight antioxidants such as GSH, hemolysis may result if these mechanisms are overwhelmed in red blood cells. Many oxidants cause hemolysis by this mechanism (e.g. acetanilide, naphthalene, phenol; Table 17.2). One such compound that has been extensively tested is microcystin-LR, which significantly increases oxidative stress causing lipid peroxidation, changes in membrane fluidity, transformations of cell shape, and hemolysis. A significant dose-and time-dependent increase in lipid peroxidation products was found in red blood cells treated with microcystin-LR when compared with untreated controls (Sicinska *et al*., 2006). Recently, we reported a clinical case in a horse with massive intravascular hemolysis associated with likely pyrrolizidine alkaloid toxicity. In this study, the red blood cell GSH was significantly decreased during the hemolytic crisis and returned to normal when the hemolytic episode subsided, further confirming the probable role of oxidative stress during hemolysis (Ramaiah *et al*., 2003).

The mechanism of leukemia induced by toxic agents, particularly alkylating agents, is likely linked to cytogenetic abnormalities, especially with the loss of part or all of a chromosome. The frequency of cytogenetic abnormalities in human patients who develop dysplastic syndrome or acute leukemia after treatment with alkylating or other antineoplastic agents ranges from 67% to 95%. However, there are other forms of leukemia that have weak correlations with exposure to alkylating agents (Bloom and Brandt, 1997).

## TOXICITY-INDUCED ALTERATIONS OF HEMATOPOIETIC ELEMENTS

An incomplete list of drugs/chemicals shown to have toxic effects on blood and bone marrow is included in Table 17.2.

**TABLE 17.2 Few examples of drugs and chemicals associated with a variety of toxic effects and their likely mechanism of action**

| Drug/chemical | Effect | Mechanism of action |
|---|---|---|
| Chloramphenicol, benzene, sulfonamide, diclofenac | Bone marrow aplasia | Unknown |
| Trimethoprim-sulfadiazine, cephalosporin, phenobarbital | Pancytopenia | Possibly immune-mediated destruction of stem cells |
| Benzene | Idiosyncratic marrow aplasia | Stem cell defect |
| Estrogen | Anemia; bone marrow suppression | Stem cell damage and decreased EPO |
| Amphotericin B, insulin, isoniazid, cisplatin, rifampicin, naproxen, sulfonamide | Immune-mediated hemolytic anemia (IMHA) | Antibody-mediated destruction of erythrocytes |
| Aniline, acetanilide, napthalene, phenol, nitrobenzene, sulfanilamide | Oxidative stress-induced anemia | Oxidative damage to erythrocytes |
| Nitrites, nitrobenzenes, phenacetin, methylene blue | Toxic methemoglobinemia | Oxidation of red blood cell hemoglobin |
| Warfarin, cephalosporins | Bleeding | Inhibition of the carboxylation of vitamin K dependent coagulation factors |
| Heparin, gentamycin, aspirin, acetazolamide, cephalexin, gold salts | Thrombocytopenia | Immune-mediated platelet destruction |

## Myelosuppression

Bone marrow suppression is a widely recognized side effect of chemotherapeutic/antineoplastic agents, primarily due to the high mitotic rate of this tissue. All cell lines may be affected resulting in granulocytopenia, thrombocytopenia and/or anemia. The changes are usually dose related and reversible after withdrawal of the drug/test compound (Turton *et al.*, 2006). The mechanisms involved in such dose-dependent myelosuppression are related to inhibitory effects on primitive cells in the marrow such as BFU-E and CFU-GM (Deldar, 1994). The inhibition of these primitive cells will manifest as erythroid hypoplasia and neutropenia, respectively, and may be due to direct cytotoxicity, inhibition or blockage of specific growth factors, or interference with some fundamental process such as DNA replication. For example, EPO production has reportedly been suppressed by excess estrogen either due to exogenous administration or endogenous release as occurs with estrogen-secreting tumors (Thrall *et al.*, 2004). Other known bone marrow suppressants whose actions are dose dependent and reversible include aminopterin, a folic acid antagonist, and benzene (Table 17.2). Azidothymidine (AZT) used in the treatment of feline immunodeficiency virus and feline leukemia virus is another example of a drug that causes anemia primarily by bone marrow suppression. Ingestion of trichloroethylene is known to cause aplastic anemia in cattle. Other chemicals/drugs known to cause bone marrow suppression include, chloramphenicol, meclofenamic acid, phenylbutazone, quinidine, trimethoprim-sulfadiazine, albendazole, and fenbendazole (Manyan *et al.*, 1972). Chronic treatment with recombinant human erythropoietin (rhEPO) has also been shown to cause erythroid hypoplasia and nonregenerative anemia due to the production of anti-EPO antibodies. This effect is reversible over the course of 2–12 months after discontinuation of the drug (Langston *et al.*, 2003).

## Anemia

A mild anemia is a common feature in preclinical toxicology studies in which high doses of a drug or a chemical are administered. The anemia is usually secondary to toxicity affecting other organ systems and is thought to be similar to anemia of inflammatory disease often seen in clinical cases. This finding is usually nonspecific and insignificant. The other common reason for mild anemia in toxicology studies is attributed to the combination of frequent blood sampling for toxicokinetic studies and the stress of repeated handling, especially in primates (Hall, 1992; Gossett, 2000).

### *Immune-mediated hemolytic anemia*

Drug-induced immune-mediated hemolytic anemia (IMHA) in humans is thought to occur as a result of the following three mechanisms: formation of antibodies (IgG, IgM, or IgA) to drug adhered to red cell membranes (hapten or neoantigen formation), binding of preformed drug-antibody complexes to the red cell membrane, or autoantibody formation. However, documented cases of drug-induced IMHA in animals are infrequent and most are probably related to hapten formation. Examples of IMHA caused by drugs in animals include penicillins and cephalosporins, which are known to cause anemia by a combination of immune-mediated hemolysis and bone marrow suppression. Levamisole is another drug suspected of inducing IMHA in dogs that are being treated for heartworm disease. Vaccination has also been implicated in cases who present with IMHA within short periods of time after vaccination. However, the precise mechanism for such a response due to vaccination is not known at present (Andrews, 1998; Bloom *et al.*, 1988; Gossett, 2000).

### *Oxidative or nonimmune hemolysis*

Exposure to oxidants results in the production of large aggregates of oxidized, precipitated hemoglobin that are attached to the internal surface of erythrocyte membranes (Heinz bodies). Eccentrocytes are also often formed with oxidative damage resulting from altered cytoplasmic-membrane adhesions. The attachment of Heinz bodies to the plasma membrane causes membrane rigidity with subsequent red blood cell lysis and anemia. Several oxidants are implicated in oxidative hemolysis caused by Heinz bodies. Few examples include methylene blue, phenazopyridine, acetaminophen, and propylene glycol in cats, and phenothiazine in horses. Several reports of zinc-induced hemolytic anemia occurred due to ingestion of metallic hardware items, pennies, and topical formulations containing zinc oxide. Sudden release of copper from accumulations in the liver of several species has been reported to cause Heinz bodies and an acute hemolytic crisis. Vitamin K and DL-methionine induce methemoglobinemia in multiple species although Heinz bodies and anemia are not frequent (Houston and Myers, 1993; Schlesinger, 1995).

### *Basophilic stippling*

Basophilic stippling is usually seen in mature erythrocytes and is thought to be due to the presence of rough endoplasmic reticulum aggregates. This condition is seen in lead poisoning and is due to the failure of RNA degradation. Basophilic stippling usually represents a regenerative response to anemia in ruminants and less commonly in other species. Siderotic inclusions (Pappenheimer bodies) in the red blood cells resemble basophilic stippling. Siderotic inclusions contain iron and may be seen after isoniazid therapy, lead toxicity, chloramphenicol, and zinc toxicity.

### *Neutrophilia*

An elevated neutrophil count is often present in cases of bacterial infection and many inflammatory conditions. In addition, chemicals such as lead, mercury, phenacetin, and pyridine may induce neutrophilia as a secondary response to tissue damage or hypersensitivity reactions. Neutrophilia is often seen in laboratory animals as a secondary event in neoplastic conditions or following hemorrhage. Increased neutrophil production and delivery to the circulation in response to inflammation may be the result of multiple signals including endotoxin, interleukins, interferons, and cytokines (Anderson, 1993). Approximately 3–5 days are required for a significant increase in neutrophils to be observed peripherally due to increased bone marrow production (Duncan *et al.*, 1994).

### *Eosinophilia, monocytosis, and lymphoctyosis*

Eosinophilia is seen in parasitic infections, dermatitis, and occasionally in allergic reactions to drugs such as salicylates. Increased eosinophils may be seen in the peripheral blood and wall of the rat gut following the use of dietary expanders such as modified starches and sugars (sorbital, mannitol, lactose, and polyethylene glycol). Eosinophilia has also been reported with excessive fluoride ingestion in rats (Andrews, 1998).

Monocytosis is often seen concomitant with neutrophilia and is usually a nonspecific finding of inflammation or stress. It is also seen acutely after trauma such as accidental gavage of the lung in rodents. Monocytosis has been described resulting from the administration of the antipsychotic drug chlorpromazine (Andrews, 1998).

Increased lymphocyte numbers may be present peripherally following immunization and with physiological excitement due to epinephrine (Meyer and Harvey, 1998).

### *Erythrocytosis and thrombocytosis*

Increased numbers of erythrocytes (erythrocytosis) seen in peripheral blood is usually a relative versus absolute increase, and it is frequently associated with food intake as well as hemoconcentration/dehydration due to fluid loss such as diarrhea and vomiting. The increased erythrocyte counts in these situations may therefore only reflect the change in the plasma compartment rather than alterations in the production or fate of red blood cells. A sudden release of erythrocytes due to splenic contraction is another cause of a relative increase in erythrocytosis (Duncan *et al.*, 1994).

Increased platelets may be seen following acute blood loss or following trauma. The cytotoxic drug 5-fluorouracil causes an immediate fall and then a sustained increase in platelet numbers. Other compounds causing thrombocytosis are the drugs AZT and vincristine and the food additive butylated hydroxytoluene. The mechanisms involved in drug-related thrombocytosis are unclear, although cytokines including stem cell factor and interleukin-6 have been implicated. Thrombocytosis is often synchronous with reticulocytosis, supporting the hypothesis that EPO has a stimulatory effect on megakaryocytes (Boudreaux, 1996).

### *Thrombocytopenia/blood loss/coagulation inhibition*

Thrombocytopenia caused by drugs and chemicals may be directly caused by their cytotoxic effect on bone marrow progenitor cells, as noted with chemotherapeutics agents, or by peripheral destruction due to immune-mediated mechanisms. Other than chemotherapeutic agents, chloramphenicol has been associated with thrombocytopenia in dogs and cats. Similarly, estrogen and interferons can cause destruction of stem cells resulting in marrow suppression and thrombocytopenia. Agents that can specifically destroy megakaryocytes include, anagrelide, ethanol, estrogens, interferons, and thiazide diuretics (Anthony *et al.*, 1994; Okamura *et al.*, 1994; Rodman *et al.*, 1997). Drugs associated with peripheral destruction of platelets include, methyldopa, levadopa, and gold therapy. Toxins that induce thrombocytopenia include, aflatoxin B1, brackenfern, and trichloroethylene (Weiss, 2000). Xenobiotic-induced platelet destruction is due to either immune- mediated or nonimmunologic destruction (Bloom *et al.*, 1988; Shebuski, 1993). Hapten (neoantigen/compound epitope formation), induction of antibodies, and immune complex formation are all possible mechanisms of immune-mediated platelet destruction.

The two main toxicologic consequences of platelet modulation are predisposition to hemorrhage and thrombosis. Nonsteroidal anti-inflammatory drugs have been known to cause blood loss anemia, which is thought to be due to gastrointestinal damage or ulceration secondary to the local inhibition of prostaglandin synthesis (George and Shattil, 1991). Aspirin decreases platelet function and aggregation and can also cause gastrointestinal ulceration resulting in hematemesis and melena in humans and animals.

Coumarin-like compounds, such as warfarin, inhibit the carboxylation of vitamin K dependent coagulation factors II, VII, IX, and X resulting in prolonged clotting times (Bloom, 1997; Bloom and Brandt, 1997). Cephalosporins are also responsible for prolonged clotting times by the same mechanism. Several antibiotics that cause eradication of gut microflora and thus lower the levels of available vitamin K can prolong coagulation and cause bleeding. Any toxic compound that results in liver failure (such as acetaminophen) will cause decreased synthesis of the coagulation factors needed for clotting and may result in bleeding.

### *Toxic leukemogenesis*

A few examples of leukemogenic agents include aromatic hydrocarbons (benzene), alkylating chemotherapeutic agents, and ionizing radiation. The development of

leukemia is not highly predictable or dose related in humans (Irons, 1997). Exposure to chemical clastogens that cause chromosomal damage (benzene and its metabolites) results in genetic damage. In many cases the damage is reversible by DNA repair mechanisms. For example the folic acid antagonist methotrexate causes transient *in vitro* DNA damage, but therapeutic use of the drug is not associated with the development of leukemia. However, a secondary insult may overcome natural DNA repair capability resulting in permanent chromosomal damage. Acute myeloid leukemia can be induced in rats by very small quantities of dimethylbenzanthracene or with ionizing radiation (Levine and Bloomfield, 1992; Andrews, 1998).

## PERSPECTIVES

The hematopoietic system is very susceptible to a variety of toxic chemicals and drugs, and such toxic effects may result in financial liability in cases of preclinical drug development and mortality in clinical practice. Because of this, systematic examination of blood and bone marrow is a major requirement of clinical and preclinical toxicity studies, and it has become a routine part of diagnostic evaluation in the clinics when screening for toxic effects of drugs, especially chemotherapeutic agents. In most cases, bone marrow toxicity can be assessed by evaluating complete blood cell counts and peripheral blood smears. Finding toxic effects of a test compound in a dose-related fashion typically halts further development of the drug.

Similar to other areas of toxicology, there has been significant advancement in an understanding of the growth and differentiation of hematopoietic stem cells as well as early diagnosis of leukemia. The recent "functional genomics" and "proteomics" approaches have not only led to understanding of the molecular basis of toxicity of a variety of test compounds, but they also have revolutionized bone marrow disease classification and treatment strategy.

In conclusion, it is possible for a toxicologist to systematically evaluate blood and bone marrow toxicity in laboratory settings and to devise a hypothesis for development of such toxicity. Because of this, it is imperative for toxicologists to understand the basic concepts of the hematopoietic system in order to interpret the results of toxicological studies.

# Immunotoxicity

*Raghubir P. Sharma*

## INTRODUCTION

### Definition

Immunotoxicology is defined as the study of toxic effects of chemicals (or in some cases physical agents such as radiation) on the immune system. The concern about the undesirable effects of chemicals on the immune system or the immune system as a mediator of systemic toxic responses is relatively new; much of the advances have followed our understanding of the molecular events involved in immune mechanisms and discoveries in molecular biology. Immunotoxicity in veterinary practice is almost non-described even though interest in this area has emerged (Kende *et al*., 1984). In public health the interest in immunotoxicity increased after awareness of the unwanted effects of environmental chemicals, including air and water pollutants, food additives or contaminants. Even at present there is limited information on the harmful effects of chemicals on the immune system of domestic animals; much of the information is derived from experimental studies in laboratory models or the information is restricted to poultry or fish.

### Historical

Although the modern discipline of immunotoxicology is relatively new and immunology itself is nearly a century old, concern with infections and its possible prevention dates back to nearly one thousand years. It was realized long ago that survivors of smallpox or plagues were relatively resistant to the disease they have acquired earlier and people were inhaling dried smallpox scabs to prevent infection in China as early as in 11th century. It was not until late 19th century that boosting immunity with vaccination for specific infections was possible. The cellular basis of immune responses was recognized in the middle of 20th century. The same period also saw the realization that inadvertent exposure to chemicals and even the therapeutic use of drugs may influence the optimal mounting of immune responses against invading organisms. There were occasional published reports of immunotoxic effects against environmental chemicals, especially pesticides, prior to 1970; a systematic study of immunotoxicity of various chemicals followed that period.

The search for drugs that modulate immune functions predates the experimental approach in immunotoxicity and has also provided valuable information about immune mechanisms. It was also known sometime ago that environmental factors are important for development of cancer or certain autoimmune diseases; this information has led to screening of various chemicals for their untoward effects on the immune system. Yet, the information regarding the immunotoxicity of chemicals is often incomplete, controversial, and has little relevance to doses or concentrations which are encountered in normal environmental exposures.

### Importance of studying immunotoxicity

1 *Infectious diseases.* The immune response is an important defense mechanism for the host. In many cases a chemical or physical stress leads to immunosuppression that compromises the host defense mechanisms against invading organisms. Higher mortality or prolonged and serious illness may result as a consequence of such immune deficiency. If the immune responses are delayed or decreased even a mild infection may provide discomfort or serious disease. In some cases it leads to decreased growth or productivity in livestock.

*Veterinary Toxicology, Edited by Ramesh C. Gupta*
*ISBN: 978-0-12-370467-2*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

2 *Interference with effectiveness of vaccination.* Since the start of vaccinating animals against prevalent infectious diseases the general health of livestock has notably improved. Routine prophylactic immunization has prevented a number of epizootic problems and has nearly wiped out a variety of lethal diseases, resulting in reduced mortality and improved life expectancy. As a result of chemically elicited immunosuppression the effectiveness of immunization is likely to be compromised. The measure of the efficiency of immunization, either an antibody titer or lethal response to a controlled infection, is usually evaluated as a measure of immunotoxicity of chemicals; it is not known if this effect has relevance at low levels of exposure to which animals generally come in contact with chemicals.

3 *Cancer surveillance.* The concept of immune surveillance in tumor survival and growth is now widely accepted. A higher incidence of tumors has been observed in transplant patients receiving immunosuppressive therapy. Dietary supplements or therapeutic agents that enhance the immune effectiveness are generally used in conjunction with chemotherapy. It is also believed that stress-induced interference with immune mechanisms may lead to a number of health problems including neoplasia. Yet nude mice that are inherently immunodeficient do not show an increased frequency of spontaneous tumors. Such conflicting evidence leads to arguments whether the immune system has an important role in the development of incipient tumors. It is unlikely that immune responses are involved in the initiation of neoplasms but may ultimately influence their growth and propagation. Exposure to chemicals that are potent immunosuppressants may lead to higher incidence of tumors and resulting mortality.

4 *Allergy and autoimmunity*. The immune response against undesirable invaders is highly beneficial to general health; however, more of this is not necessarily good. There are a number of disorders that involve enhanced immune responses. Increased immunity may lead to allergic responses. Many chemicals being small molecules are not immunogenic in themselves but after entering the body they can combine with natural proteins and mount immune responses against either the normal proteins or the chemical moiety itself. Some chemicals are allergenic either because of their reactivity to biological molecules or may be metabolized to reactive products in the body. An activated immune system will increase the probability of such reactions. Production of immune response against tissue components is a step in the development of autoimmunity. There are a number of autoimmune disorders that occur in people or animals; the frequency of these diseases is genetically determined in most cases, however, exposure to environmental chemicals has been implicated as a trigger in some repressed conditions. It is not coincidental that allergic or autoimmune disorders are effectively treated with immunosuppressant therapy.

## THE IMMUNE SYSTEM

A brief description of the immune system is desirable here to review basic concepts of immunology. The following is not meant to be a complete description of the highly complex system that is activated after immunologic challenge and produces responses that are highly specific, cooperative, redundant, and interactive with each other or with other bodily functions, and in addition have properties such as immunologic memory and self-tolerance. For a comprehensive discussion of the immune responses it is desirable to consult textbooks on this topic (Mak and Saunders, 2006). The complexity and multiple stages involved in the immune responses provide a large number of target sites for toxicants to act upon and influence the immune system.

### Immune system is diffuse throughout the body

One of the characteristics of the immune system is that it is not confined to a body compartment but is present throughout the body. The immune system consists of many interdependent cell types that protect the body from various infections (bacterial, viral, fungal, parasitic) and from the development of tumor cells. The principal cellular components of the immune system, the lymphocytes, are found in nearly all tissues; sometimes they are modified to specialized cells. In addition to lymphocytes, the macrophages are an integral component of this system. Other leukocytes (particularly granular leukocytes) in circulation or in tissues help a variety of immune responses, particularly during inflammation. The immune cells are concentrated in some organs (indicated below) but may travel throughout the body via lymphatic and blood circulation. Many of these cell types have specialized functions, however, they work in concert by helping each other.

### Innate versus acquired immunity

Different parts of the body contain natural or innate immunity that is relatively non-specific. Components of innate immunity are principally localized at the sites of entry of invading organisms, such as skin and mucous membranes of digestive and respiratory systems. Lymph nodes underlying the mucous membranes of the digestive and respiratory tracts are integral part of this natural immunity; these can also partake in the adaptive immune

responses. These reactions are not specific to an antigen type and are produced without a prior challenge of the invading organism. Circulating and resident macrophages assist in phagocytosis and remove foreign material in addition to their important role in other aspects of immune responses.

Acquired immunity on the other hand is mounted in response to an antigenic challenge and is specific to the antigen type. It can be either cell mediated (that involves principally T lymphocytes) or humoral (also known as antibody mediated, involving specific antibodies produced by B lymphocytes). Antigens are initially engulfed by macrophages that process them and display parts of them on their surface together with some of their own proteins. This sensitizes T cells to recognize these antigens. All body cells are coated with various protein complexes called CD (cluster of differentiation); more than 160 clusters have been defined, each of which is a different chemical molecule that coats the surface.

## Functional units of the immune system

1 *Primary and secondary organs.* The primary organs of the immune system are bone marrow and thymus. In avian species the bursa is also a primary organ. Different cells of the immune system are derived initially from the bone marrow. During hemopoiesis, stem cells in bone marrow differentiate into either cells of the immune system or into precursors of cells that leave the bone marrow to continue their differentiation elsewhere.

   The other primary immune organ, thymus, differentiates lymphocyte precursors into T cells. Immature precursor lymphocytes leave bone marrow and migrate to the thymus. During the maturation in this organ T cells that are beneficial to the immune system are spared while those cells that might provoke autoimmune response are eliminated. The mature T cells are then released into the bloodstream. In birds the lymphocytes that migrate to bursa are differentiated into B cells. In most mammalian organisms differentiation of precursor cells to B lymphocytes is believed to occur either in the bone marrow or fetal liver.

   The secondary immune organs are spleen and lymph nodes. The spleen is the organ that eliminates both red and white unneeded blood cells. The cell types in spleen are T cells, B cells, natural killer (NK) cells, macrophages, dendritic cells, and red blood cells. Migratory macrophages and dendritic cells bring antigens to the spleen via the bloodstream where foreign antigens are captured from the blood that passes through the spleen. The lymph nodes, which function as a filter for lymph, are found throughout the body and drain interstitial fluid from most of tissues. The lymph nodes consist of T cells, B cells, dendritic cells, and macrophages. Lymph nodes are the organs where B cells are activated to produce large amounts of antibody.

2 *Cellular components.* Immune system comprises a variety of cells that communicate with each other or even other organs in the body to mount effective immune response against foreign invaders. Different types of cellular components of the immune system along with their characteristic CD markers are listed in Table 18.1. One of the major types of the immune cells consists of lymphocytes that are further classified in several subpopulations. Two major classes of lymphocytes are T cells (matured in the thymus) and B cells (termed after the bursa of Fabricius in birds, where these were first discovered). T lymphocytes are usually divided into two major subsets that are functionally and phenotypically different. The T and B cells each have about 100,000 molecules on their surfaces. T cells have CD2, CD3, CD4, CD28, CD45R, and other non-CD molecules on their surfaces. The T helper cell, also called the CD4+, is a pertinent coordinator of immune regulation. The main function of the T helper cell is to augment immune responses by the secretion of specialized factors or cytokines that activate other white blood cells to fight infection. Two further subsets of T helper cells, Th1 and Th2, have been identified based on the type of cytokines produced by them.

   Another important type of T cell is called the T killer/suppressor subset or CD8+ T cell. These cells are important in directly killing certain tumor cells, viral-infected cells, and sometimes parasites. The CD8+ T cells are important in down-regulation of immune responses. Both types of T cells can be found throughout the body, the distribution often depends on the secondary lymphoid organs where activation occurs, but they are also found in liver, lung, blood, and intestinal and reproductive tracts.

   Natural killer cells, often referred to as NK cells, are similar to the killer T cell subset (CD8+ T cells). These cells directly kill certain tumors such as melanomas, lymphomas, and viral-infected cells, including herpes and cytomegalovirus-infected cells. NK cells, unlike the CD8+ (killer) T cells, kill their targets without being primed in lymphoid organs. However, NK cells activated by secretions from CD4+ T cells kill their tumor or viral-infected targets more effectively.

   The major function of B cells is the production of antibodies in response to foreign proteins of bacteria, viruses, and tumor cells. Antibodies are specialized proteins that specifically recognize and bind to one particular protein. Antibody production and binding to a foreign substance or antigen, is critical as a means of signaling other cells to engulf, kill, or remove that substance from the body. B cells are coated with CD21, CD35, CD40, and CD45 in addition to other non-CD molecules.

TABLE 18.1 Cellular components of the immune system and their functions in mammals

| Cell types | Specific surface markers | Functions |
|---|---|---|
| Stem/progenitor cells | CD34, CD90, CD110, CD111, CD117, CD133, CD202, CD243 | Differentiate into hematopoietic cells, including erythrocytes and leukocytes |
| T lymphocytes | CD3, CD4, CD5, CD7, CD8, CD25, CD28, CD45R, CD52L, CD69, CD134, CD152, CD154 | Matured in thymus T cells are differentiated into subsets; cytokine production |
| T helper lymphocytes (Th1 and Th2) | CD2, CD3, CD4, CD28, CD45R (plus T cell markers) | Help maturation of T and B cells |
| Cytotoxic T lymphocytes (CTL) | Most lymphocytic markers + CD8 | Cause lysis of antigen-bearing cells; regulate Th cell action |
| NK T lymphocytes | CD11b, CD16a, CD56, CD69, CD94, CD152, CD158a, CD161 | Cytotoxicity of invading organisms and tumor cells |
| Null T cells | SWC6 (swine workshop cluster 6) cell surface antigen; devoid of other T cell markers | Not defined; may be involved in immunologic memory |
| B cells | Lymphocyte markers + CD21, CD35, CD40, CD45 | Differentiated into specific antibody producing cells |
| Plasma cells | CD38 | Production of antibodies |
| Monocytes, macrophages | CD11b, CD13, CD14, CD64, CD80, CD86, CD115, MHC class II | Monocytes are circulating cells whereas macrophages are both circulating and tissue residents; cytokine production; antigen presentation; phagocytosis |
| Dendritic cells | CD1a, CD11c, CD80, CD83, CD86, CD123, CD205, CD207, CD209 | Both circulating and tissue-specific; attract antigens and present to T cells |
| Mast cells | CD33, CD117, CD203c | Release of vasoactive products |
| Granulocytes (leukocytes, e.g. neutrophils, etc.) | CD15, CD16b, CD31, CD88, CD156a | Phagocytosis; help in inflammatory process |

Phenotypes indicated refer to human cells; only human and mouse cells are extensively analyzed. Only differentiating markers are indicated. Information on most domestic animals is limited. *Source*: eBioscience, San Diego, CA.

Macrophages are very important in the regulation of immune responses. They are often referred to as scavengers or antigen-presenting cells (APC) because they ingest foreign materials, process and present these antigens to other cells of the immune system such as T cells and B cells. This is the first step in the initiation of an immune response. Stimulated macrophages produce cytokines and exhibit increased levels of phagocytosis.

Another cell type in the immune system, only recently characterized, is the dendritic cell. Dendritic cells, originate in the bone marrow, and function as APC; these cells are more efficient APCs than macrophages. The dendritic cells are primarily found in the structural compartment of the lymphoid organs such as the thymus, lymph nodes, and spleen; they are also present in the bloodstream and other tissues. The dendritic cells are hard to isolate, which is often a prerequisite for the study of the functional qualities of specific cell types.

Other leukocytes or white blood cells also participate in the immune system, particularly via their contribution in inflammatory responses. These cells are granulocytes or polymorphonuclear leukocytes (PMNs), composed of three cell types, that is neutrophils, eosinophils, and basophils, so named for their staining characteristics with certain dyes. Eosinophils that are also found in certain tissues like lungs or beneath the skin are termed as mast cells. All granulocytes are especially important in the removal of bacteria and parasites from the body as they engulf these foreign bodies and degrade them using their enzymes.

3 *Cell–cell interactions*. A characteristic of the complex and diverse immune functions is the ability of cells to communicate with each other and with cells of other systems. These communications are made possible either by direct contact involving the cell surface receptors or by the soluble mediators termed as lymphokines or cytokines. The cytokines (see Table 18.2 for major cytokines and their functions) are usually small proteins that act on receptors either in the same cell or on other cells and carry out a variety of functions, including maintaining their homeostasis. Various cytokines possess properties that include redundancy and cascade effects, and have synergistic or antagonistic activity with other cytokines. Major cytokines stimulate cell proliferation and differentiation, or activate cells to mount an effective immune response.

## Cellular versus humoral immunity

The two major types of immune responses are mediated by T and B lymphocytes, respectively. These types of immune responses are distinct but not totally independent of each other. For example, T cells regulate the T dependent antibody formation whereas the antibody-dependent cell-mediated cytotoxicity (ADCC) has also

**TABLE 18.2 Major cytokines involved in immune responses***

| Cytokine | Source (s) | Function |
|---|---|---|
| TNFα | Macrophages, mast cells, NK cells | Regulation of cytokine expression and cell adhesion molecules; tumor cell death |
| TNFβ | Th1 and cytotoxic T cells | Phagocytosis, cell death; NO production |
| IFNγ | Macrophages, Th2 cells, activated B cells | Elimination of pathogens; switching of Ig classes; inhibits viral replication and cell proliferation |
| TGFβ | Monocytes, T cells | Chemotaxis of macrophages; IL-1 activation; IgA synthesis |
| MIF | Macrophages, lymphocytes | Chemotaxis of monocytes and T cells |
| IL-1α and β | Monocytes, macrophages, dendritic cells, B cells | Activation of Th and NK cells; B cell amplification; inflammation |
| IL-1Ra | Macrophages, monocytes | Inhibits IL-1 and IL-2 action |
| IL-2 | Th1 cells | Activation of T, B and NK cells |
| IL-3 | Th cells, NK cells, monocytes | Growth and differentiation of stem cells and mast cells; degranulation of mast cells |
| IL-4 | Th2 cells | T cell and B cell proliferation and differentiation; MHC II expression on macrophages |
| IL-5 | Th2 cells | Proliferation and differentiation of activated B cells; IgA synthesis; eosinophil growth |
| IL-6 | Macrophages, monocytes, Th2 cells, stromal cells | Maturation of B cells into plasma cells; antibody secretion; differentiation of stem cells; acute phase response; inflammation |
| IL-7 | Bone marrow and thymus stromal cells | Differentiates stem cells into progenitor T and B cells |
| IL-8 | Macrophages, endothelial cells | Attracts neutrophils |
| IL-10 | Th2 cells | Cytokine production by macrophages; activates B cells |
| IL-12 (p70 and p40) | B cells, monocytes, dendritic cells | Differentiation and activation of cytotoxic T cells and NK cells; induction of IFNγ |

*Abbreviations are defined in text. Only selected cytokines are listed; nearly three dozen interleukins (IL) and other cytokines have been described. Many cytokines are species-specific; others show cross reactivity.

been described. Maturation and differentiation of T cells may require cellular interactions or soluble messengers. B cells can be primed by antigen-presenting T cells or macrophages to produce a vast repertoire of antibodies specific to each antigen. The diversity of antibody production by B cells is accomplished by antigen recognition (depending on variation in antigen binding sequence, a characteristic of the variable region of antibody protein) and by antibody effector function (antibody isotype variability based on the constant region of antibodies). By using combinations from a multiple source of gene segments in the germ line DNA and hypermutations based on activation-induced deamination (Petersen-Mahrt *et al.*, 2002) an extremely large variety of specific antibodies can be created. Various isotypes of antibodies produced by B cells have been named as IgA, IgD, IgE, IgG, or IgM, with specific functions.

## Cooperation and interactions between immune and other systems

1 *Immune mechanisms subsequent to pathologic damage*. The purpose of the immune functions is to ward off undesirable organisms or materials from the body, its relationship with inflammatory processes and pathologic damage is implied. Many of the cellular components of the immune system are also primary components in the inflammation. Therefore it is natural that various components of this system are activated after damage to other tissue or organs of the body. The immune system responds to altered proteins or to other biological molecules formed by binding with reactive intermediates, which may be produced in the body subsequent to metabolic activation of a number of exogenous chemicals or due to tissue damage.
2 *Control of the immune system by nervous system*. The immune system interacts with other systems and is profoundly influenced by the central nervous system, both directly via innervations of lymphatic organs and indirectly via neuroendocrine mechanisms. The autonomic nervous system directly innervates thymus, spleen, lymph node, bone marrow, and other lymphoid tissues. Pharmacological manipulation of post-ganglionic noradrenergic nerve fibers affects immune functions. Increased levels of cyclic nucleotides, which respond to neurotransmitters, also alter the immune response. The cells of the immune system produce factors that influence the nervous system.
3 *Endocrine mechanisms.* Hormones, such as somatotrophin (growth hormone) and thymosin (thymic maturation factor), stimulate the immune responses, whereas steroids,

including sex hormones, generally suppress the immune responses. Role of stress on immune functions has been shown; it is presumed that exposure to exogenous chemicals may induce stress. Stress-like effects after stimulation of hypothalamic–pituitary–adrenal axis lead to cortisol production; the latter is a well-known immunomodulatory agent.

4 *The complement system*. A complex system that consists of a cascade of serum proteins, mostly of β-class globulins, is present in most vertebrates. The function of this system is to enhance the action of antibodies by causing cell membrane alterations, often cytolysis. The complement combines with the Fc receptors of an antibody molecule and is enzymatically activated to a cytotoxic membrane attack complex. Immunotoxic chemicals may modify the complement function and may alter the inflammatory processes.

## POSSIBLE MECHANISMS FOR IMMUNOTOXICITY

Exposure of animals to toxicants may have effects on their immune system by a variety of mechanisms. Not only is the immune system profoundly influenced by other organs or systems of the body, but the complexity of immune responses also provides multiple targets for effects of chemicals. A generalized scheme of how chemicals may influence the immune system is illustrated in Figure 18.1. Both immunosuppression and immunostimulation are undesirable for the general health of animals. Chemicals may affect protein synthesis required for cell proliferation as well as antibodies. Chemicals that have potential for alkylating nucleic acids or proteins are immunotoxic because they interfere with the function of various proteins in the immune responses. Some mycotoxins or their metabolites are highly reactive in mammals and may bind to or destroy tissues. The acquired immunity depends largely on cellular proliferation and any substance that interferes with cell production will cause immunosuppression.

Chemicals may interfere with the function of enzymes directly that are required in the immune processes. Activated esterases may degranulate mast cells, releasing histamine, and may be involved in the process of chemotaxis by polymorphonuclear cells. Protease inhibitors will interrupt the post-translational processing of various cytokines and can interrupt their release. Chemicals likely to modify cell membrane functions will have a similar effect. By altering cytokine signaling chemicals may profoundly alter differentiation of immune cells, such as lymphocyte subtypes, and since various cellular components have synergistic or antagonistic function, the homeostasis of the immune system is likely to be disrupted. Some chemicals, particularly biologically reactive immunogens, can selectively eliminate specific cells of this system. For example chemicals that can destroy macrophages will interrupt antigen processing and presentation to other cells for mounting an effective immune response.

Immune responses may cause tissue damage or can be mediators for causing health problems in animals. Allergy or hypersensitivity is a good example where the well being of the animal can be compromised. The allergic reactions

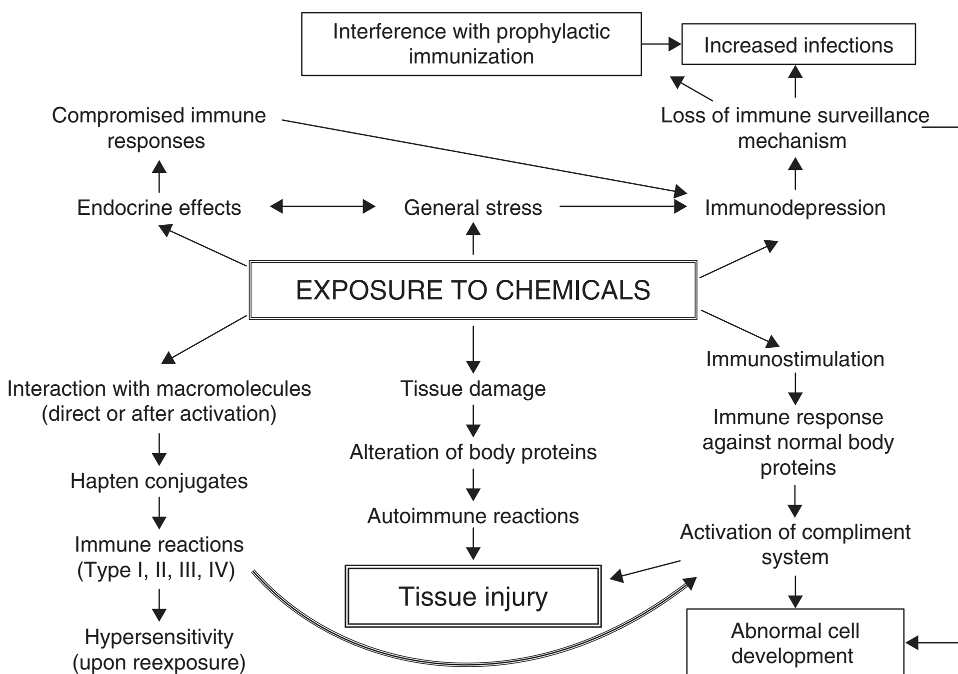

**FIGURE 18.1** A hypothetical scheme depicting various pathways indicating steps by which a chemical may produce immunotoxic effect and ultimately a disease or immune-mediated tissue damage (adapted from Sharma, RP (1984) Chemical interactions and compromised immune system. *Fundam Appl Toxicol* **4**: 345–51. Copyright 1984, with permission from Elsevier.

require initial sensitization and later a challenge exposure to a chemical to mount the response. Four distinct types of allergic mechanisms have been described (Gell and Coombs, 1975), all of which lead to inflammatory processes. Type I hypersensitivity is IgE mediated where specific IgE link on mast cells, a subsequent challenge to either the same or an antigenically similar chemical causes degranulation releasing bioactive substances. This type of reaction is exemplified by asthma, hay fever, food allergy, or anaphylactic reactions. Type II allergy is also antibody mediated; in this case the antigen may be cell bound and reacts to specific IgG or IgM type antibodies. The cell may be destroyed by either complement activation or phagocytosis. Drug-induced hemolytic anemia is a good example of such a reaction. Type III hypersensitivity requires a complex formation of the antigen with IgG or IgM antibodies, the immune complex may trigger complement activation leading to inflammatory changes, such as in Arthus reaction (localized edema or infiltration resulting in abscess or gangrene). The type IV hypersensitivity is cell mediated, where sensitized T helper lymphocytes react with the antigen, resulting in activation of macrophages and release of inflammatory mediators.

## IMMUNOTOXIC AGENTS

There is limited information on immunotoxic potential of different chemicals directly in animals of economic importance. Much of the available data relates to either laboratory animals or obtained from epidemiological studies in people. However, since there are common pathways of immune mechanisms in various higher mammals and also in birds, the conclusions of laboratory studies are applicable to domestic animals. In a few studies the target animal species have been employed but it is not always definite if the alterations of immune functions were primary or subsequent to damage to other organs or systems.

### Mycotoxins

Mycotoxins are of particular importance in animal management as these are common contaminants in animal feeds (Sharma, 1985, 1993). Feeds are contaminated in field with various molds or these can develop during storage. Some mycotoxins can indirectly influence the immunologic functions. Others can be neurotoxic or cause other organ pathology, and these compounds may activate the endocrine mechanisms. The stress-induced release of corticosteroids inhibits immune functions. Mycotoxins such as aflatoxin $B_1$ and fusarium T-2 toxin inhibit protein synthesis and cell proliferation, some may have selective effects on various subpopulations of lymphocytes. Several mycotoxins are cytotoxic to lymphocytes *in vitro*, perhaps because of their effects on membranes (including lymphocytic receptors) or interference with macromolecular synthesis and function. For example, cytochalasins (mycotoxins isolated from moldy rice) are highly cytotoxic and act on cytokinesis by binding to the filamentous actin; their immunotoxic potential has not been ascertained. Selected effects of immunotoxic mycotoxins that have been studied in domestic animals are listed in Table 18.3.

Immunomodulation by aflatoxin $B_1$ has been investigated in detail (Bondy and Pestka, 2000). In most species, resistance to infection is reduced by simultaneous exposure to aflatoxin $B_1$. Effects of aflatoxin $B_1$ are primarily on the cell-mediated immune functions; however, T cell-dependent humoral responses are also adversely affected. Often the humoral responses that are independent of T cells are not affected by low doses of aflatoxins. The immunosuppressive effects of aflatoxin $B_1$ can be explained on the basis of DNA binding of resulting epoxide derivative of aflatoxin $B_1$, thereby interfering with cell proliferation and protein synthesis. Limited studies suggest that aflatoxin $B_1$ alters cytokine production. The expression of macrophage derived cytokines, namely interleukin (IL)-1$\alpha$, IL-6, and tumor necrosis factor $\alpha$ (TNF$\alpha$), was suppressed in mitogen-stimulated macrophages derived from aflatoxin $B_1$ exposed mice; the effect of aflatoxin $B_1$ was greater on macrophages than on other types of immune cells (Dugyala and Sharma, 1996). Macrophages engulf large amounts of aflatoxin-bound macromolecules and thereby may be selectively sensitive to the toxin.

There have been a number of investigations involving fumonisin $B_1$ and immune responses (Bondy and Pestka, 2000). Fumonisin $B_1$ generally inhibited lymphocyte blastogenesis in cells obtained from exposed mammals; the poultry was relatively resistant. Inconsistent effects of fumonisin on immune functions have been reported. Decreased antibody formation to injected antigens has been reported in turkeys, pigs, calves, or even rodents; however, the levels of fumonisins used in these studies have been fairly large. Fumonisin-induced immunomodulation has been suggested in some studies; however, the results depend on the protocol of testing and sequence of exposure to toxin and the antigens. Fumonisin $B_1$ causes accumulation of free sphingoid bases, sphinganine, and sphingosine, by interfering with their conversion to ceramide and interrupts cell cycle (Johnson *et al*., 2003). The free sphingoid bases and their phosphates are important signaling agents in cells, the bases and their phosphates having opposite outcomes for cell survival. Cellular signaling is critical in mounting immune responses; fumonisin $B_1$ has been used as a tool to define the role of ceramide in signaling in lymphocytes. The exposure to fumonisin $B_1$ caused localized activation of the cytokine network, implying that innate immune responses are important in the hepatotoxic outcome (Bhandari and Sharma, 2002).

**TABLE 18.3 Selected examples of immunotoxic effects of mycotoxins in domestic or food animals**

| Mycotoxin | Species | Observed effects | Reference |
|---|---|---|---|
| Aflatoxin $B_1$ | Bovine | Decreased lymphocyte proliferation *in vitro* | Paul *et al*. (1977) |
| | Swine | Decreased lymphocyte proliferation, macrophage migration, DTH and titers to SRBC | Hoerr and D'Andrea (1983) |
| | | Increased sensitivity to *Salmonella* | Miller *et al*. (1978) |
| | Chicken | Decreased CMI and titers | Verma *et al*. (2004) |
| | | Decreased antibody titer | Thaxton *et al*. (1974) |
| | | Increased mortality against *Salmonella* | Boonchuvit and Hamilton (1975) |
| | | Reduced phagocytosis by reticuloendothelial cells | Chang and Hamilton (1979) |
| | Turkey | Thymic atrophy | Pier *et al*. (1972) |
| | | Reduced resistance to *Pasteurella* | Pier and Heddleston (1970) |
| Deoxynivalenol | Swine | Activation of immune responses at low doses | Zielonka *et al*. (2003) |
| | | Increase in serum IgA concentration | Drochner *et al*. (2004) |
| Fumonisin $B_1$ | Chicken | Depression in phagocytosis of peritoneal macrophages after *in vitro* exposure | Qureshi and Hagler (1992) |
| Ochratoxin | Dog | Necrotic mesenteric lymph nodes | Szczech *et al*. (1973b) |
| | Swine | Necrosis of gut-associated lymph nodes | Szczech *et al*. (1973a) |
| | Chicken | Lymphopenia and decreased phagocytosis by heterophils | Chang and Hamilton (1980) |
| | Turkey | Thymic atrophy, leukocytopenia, and heterocyclopenia | Chang *et al*. (1981) |
| Patulin | Rabbit | Reduced lymphocyte proliferation and serum immunoglobulins | Escoula *et al*. (1988a, b) |
| T-2 toxin | Cattle | Reduced lymphocyte proliferation and neutrophil function | Mann *et al*. (1984) |
| Zearalenone | Chicken | Decreased serum titers to Newcastle disease virus | Danicke *et al*. (2002) |

Ochratoxin A, a nephrotoxicant and widely encountered food and feed contaminant, has been investigated for its immunologic effects. Ochratoxin poisoning interferes with macromolecular synthesis, increases lipid peroxidation, and diminishes mitochondrial respiration. This mycotoxin is fairly cytotoxic and causes atrophy of gastrointestinal lymph nodes after oral ingestion (Bondy and Pestka, 2000). Systemic investigations suggest that exposure to ochratoxin A results in the inhibition of cellular, humoral, or innate immune responses; however, many of these effects are produced at exposure levels that are also nephrotoxic. Its immunotoxic effects were demonstrated in poultry and pigs.

Patulin has been investigated with regard to the immune system only to a limited extent. This toxin is less toxic; however, effects such as altered number of splenic T lymphocytes, diminished serum immunoglobulin concentrations, decreased delayed hypersensitivity responses, and increased neutrophil numbers have been reported. The observed changes in cellular phenotype distribution of immune cells may or may not indicate ultimate effects on immune functions.

T-2 toxin and deoxynivalenol cause severe depletion of T cells. In routine immunotoxicologic testing in rodents, both increase and decrease of immunologic functions have been reported depending on the protocol employed. T-2 toxin was immunosuppressive in murine *in vivo* and *in vitro* models. Effects of deoxynivalenol and T-2 toxin on cytokine production were not consistent. T-2 toxin caused increased expression and production of IL-2, IL-3 and interferon $\gamma$ in splenocytes from T-2 treated mice, but a decrease in IL-1$\alpha$, TNF$\alpha$, and IL-6 was noticed (Dugyala and Sharma, 1997). Deoxynivalenol, however, caused an increase in TNF$\alpha$ production by macrophages (Yang and Pestka, 2002).

Other mycotoxins occur in certain circumstances as food or feed contaminant. Many of these are toxic and influence immunologic functions. Rubratoxins that cause liver and kidney toxicity and diffuse hemorrhage, macrocyclic trichothecenes that include a large family of mycotoxins with varied toxicity, cytochalasins that bind to actin and also inhibit hexose transport in cells, ergotoxins with potent vasoconstrictor action, penicillic acid, etc. all produce inconsistent effects on immune functions.

## Metals

Different heavy metals, both in their inorganic and organic forms, elicit toxic responses on the immune system. Toxic metals such as lead, cadmium, and mercury possess immunotoxic properties at exposure levels that may not produce effects on other systems. The heavy metal lead is of particular concern in veterinary practice as exposure and poisoning of domestic animals with this metal has been encountered. Selected few studies with metals involving domestic animals are listed in Table 18.4. Lead, mercury, and nickel were reported to be immunosuppressive in different reports, whereas low doses of selenium, zinc, and manganese are immunostimulant. Organic tin compounds

**TABLE 18.4 Selected metals evaluated in domestic or food animals for immunotoxic potential**

| Metal | Reported or possible effects | Reference |
|---|---|---|
| Lead | Immunosuppression in cattle | Black *et al*. (1992) |
| | Decreased spleen plaque-forming cells in mallards | Rocke and Samuel (1991) |
| | Decreased peripheral lymphocyte counts and depressed interferon $\gamma$-like cytokine production by splenocytes of chicken | Lee *et al*. (2002) |
| | In Japanese quail, primary and total antibody response to immunization suppressed; secondary total antibody and IgG responses also reduced | Grasman and Scanlon (1995) |
| Mercury | Suppressed immunocompetence in fish | Sweet and Zelikoff (2001) |
| Molybdenum | Decreased antibodies to swine erythrocytes in calves | Gengelbach and Spears (1998) |
| Copper | Higher titers to ovalbumin in heifers | Salyer *et al*. (2004) |
| Zinc | Decreased antibody response at day 7 but increased phagocytosis by peritoneal exudates cells in pigs | van Heugten *et al*. (2003) |
| | Potentiation of immunity against *Salmonella* in chicken | Barbour *et al*. (2001) |
| | Higher antibody titers to ovalbumin in heifers | Salyer *et al*. (2004) |
| Chromium | Enhanced antibody response to ovalbumin in calves | Chang *et al*. (1996) |
| | Decreased lymphocyte proliferation and phagocytosis in carps | Steinhagen *et al*. (2004) |
| | Lower antibody titers and splenic and kidney plaque-forming cells in catfish | Khangarot *et al*. (1999) |
| Selenium | Enhanced cell mediated immune response in eiders | Wayland *et al*. (2002) |
| Vanadium | Increased IL-6 activity in macrophage supernatants | Qureshi *et al*. (1999) |

are highly thymotoxic. Cadmium has mixed effects, showing suppressive effects in certain test situations but either no effect or stimulation of the immune system in others. Large animals may consume selenium containing plants in locations with high soil contents for this metal; however, laboratory studies suggest that while inorganic selenium is immunotoxic the organic forms of this metal present in plants are not (Johnson *et al*., 2000).

The immunotoxic effects of metals are believed to be mediated by a variety of mechanisms. Metals form complexes with biological macromolecules, forming chelates and may replace essential metals. Protein synthesis, membrane integrity, and/or nucleic acid replication are often affected by metals. The *in vitro* and *in vivo* effects of the same metal are sometimes opposite. For example, lead produces immunosuppression when administered internally, whereas it acts as a mitogen in lymphocyte cultures. *In vitro* studies have promise for discerning cellular and molecular mechanisms involved; however, they offer little value in predicting the *in vivo* immunotoxic potential of a chemical.

## Pesticides

In spite of a vast amount of information dealing with the immunotoxic effects of organophosphorus and carbamate insecticides, there is little consensus that anticholinesterase pesticides are immunotoxic (Sharma, 2006). Rabbits fed low doses of methylparathion were reported to have atrophy of the thymus cortex and fewer antibody-forming cells in the lymph node; splenic morphology was considerably altered. Delayed hypersensitivity response was not altered in a consistent manner. There was no significant influence on circulating antibody levels against sheep erythrocytes. Diets containing carbaryl or carbofuran fed to rabbits reduced the numbers of activated lymphocytes in lymph nodes, decreased the number of splenic germinal centers, and produced atrophy of the thymic cortex.

Humoral immune response in rabbits exposed to malathion or dichlorvos was decreased against *Salmonella typhimurium.* A single high dose of malathion, parathion, or dichlorvos reduced primary IgM response to sheep erythrocytes at levels producing cholinergic symptoms. Dichlorvos inhibited the lysis of antibody-sensitized sheep erythrocytes in a dose-dependent manner. The organophosphates had no effect when given in multiple lower doses. A cholinomimetic agent arecoline reduced IgM antibody response only when given in a form that would sustain prolonged cholinergic symptoms.

Dimethoate caused a decrease in delayed type hypersensitivity reaction measured as foot-pad swelling in mice. Mitogen response of female mice splenic cells to phytohemagglutinin and lipopolysaccharide was reduced by this insecticide. Diazinon caused pathologic changes in spleen, thymus, and lymph nodes; however, these effects were dependent on dietary protein or lipid content. Organophosphates triphenylphosphate and triphenylphosphine oxide were reported to be immunomodulatory primarily to the innate immune functions.

Several impurities often present in organophosphates are potent cholinesterase inhibitors and may potentiate organophosphate toxicity. For example, of many impurities in malathion, *O*,*O*,*S*-trimethyl phosphorothioate (OOS-TMP) and *O*,*S*,*S*-trimethyl phosphorothioate (OSS-TMP) are potent cholinesterase inhibitors but they inhibit

immune responses at doses that produce no cholinergic symptoms.

Various chlorinated hydrocarbon insecticides such as dieldrin, *p′p′*-dichlorodiphenyl-trichloroethane (DDT), lindane, etc. have been tested for immunotoxic effects (Street, 1981). In most cases a reduced production of antibody to test antigen was noted; however, effects varied with the dose, species, and the protocol employed (Sharma and Zeeman, 1980).

## Industrial and environmental chemicals

Domestic animals may be accidentally exposed to industrial or environmental chemicals. Some of the investigations in domestic animals are summarized in Table 18.5. Contamination of cattle feed by a fire-retardant Firemaster, a polybrominated biphenyl (PBB) mixture, in Michigan in 1973 prompted several investigations on the immunotoxic potential of this compound. In cattle, small amounts of PBB did not induce alteration of immune functions (Kateley *et al*., 1982). In swine a decreased responsiveness of peripheral lymphocytes to mitogenic stimulation was observed when animals were given relatively large doses (200 ppm) of PBB. Chlorinated phenols, found in a variety of foods, were evaluated for their immunotoxic potential. Prompted by an episode of suspected poisoning in dairy cattle by pentachlorophenol, Forsell *et al*. (1981) investigated the immunologic profile of cattle given a commercial grade of this chemical and indicated no effect in treated animals; it appears that the immunotoxic effects are caused by tetrachlorodibenzo-*p*-dioxin (TCDD) impurity in the technical grade. The sensitive immune responses are likely T-cell mechanisms and are species-dependent; the effects are known to be reversible. TCDD and its analog 2,3,7,8-tetrachlorodibenzofuran (TCDF) produce immunotoxic effects discernible only at levels that induce other pathologic lesions.

A number of other industrial chemicals, primarily those used in the manufacture of plastics, have been studied for their effects on parameters of immune system. Toluene diisocyanate stimulated lymphocytes *in vitro*; vinyl chloride and styrene produced a similar effect. Dioxin depressed T-cell while stimulating B-cell responses. Benzene, vinylidene chloride, ethylenimine, and epichlorohydrin do not produce consistent *in vitro* effects on the immunocompetent cells, although many of these chemicals were cytotoxic in high concentrations.

## Miscellaneous chemicals and drugs

A number of drugs have the capability of altering the function of the immune system and for that reason are used therapeutically. Several drugs on the other hand have side effects involving the immune system or its functions. Diethylstilbestrol (DES) is a synthetic estrogen used in therapy. The immunosuppressive potential of this drug is of concern since the chemical has been used as a growth promoter in animals. DES is a suppressor of both cell mediated and humoral immunity, and a potent stimulant of macrophage function. DES increased tumor susceptibility and increased mortality against parasitic infection.

Cyclophosphamide, a potent immunosuppressive and an inhibitor of protein synthesis, impairs both T-cell and humoral functions. The effect of cyclophosphamide is selective for B-cell responses. In mammals, cyclophosphamide suppressed systemic and local graft versus host

**TABLE 18.5 Selected examples of contaminants in feed that may influence immune responses in domestic or food animals**

| Chemical | Species and effects | Reference |
|---|---|---|
| Organochlorine insecticide mixture | In swine elevated lymphocyte proliferation and CD4+/CD8+ ratio and leukocyte phagocytic activity after gestational and lactational exposure | Bilrha *et al*. (2004) |
| Organochlorine insecticides | Suppression of NK cell activity and T cell responses in harbor seals | de Swart *et al*. (1996) |
| Polyaromatic hydrocarbon mixture | Decreased lymphocyte response to T cell mitogens but increase to B cell mitogens in fish, aberration in NK cell activity in fish | Faisal *et al*. (1991a, b) |
| Polychlorinated biphenyls | Decreased T cell mediated immunity related to amount of pollutants in eggs of herring gull and Caspian tern | Grasman *et al*. (1996) |
| Polychlorinated biphenyls | Decreased antibody titers and delayed type hypersensitivity in fish-eating birds and reduced T cell proliferation and NK cell activity in seals | Luebke *et al*. (1997) |
| Polychlorinated biphenyls and other contaminants | Decreased NK cell activity, T cell mitogen response, antigen specific proliferation, mixed lymphocyte response and delayed hypersensitivity in harbor seals | van Loveren *et al*. (2000) |
| Tributyltin and polychlorinated biphenyls mixture | Suppressed antibody response and phagocyte oxidative burst activity in catfish | Regala *et al*. (2001) |
| Bleached kraft pulp mill effluent | Impairment of delayed type hypersensitivity but no effect on antibody response in minks | Smits *et al*. (1996) |

reaction, caused depletion of various leukocyte elements, and interfered with the mitogen-induced lymphocyte transformation, in addition to having a marked inhibitory effect on antibody synthesis.

Other drugs that have also been reported to have immunosuppressive properties include dexamethasone, azathiopurine, chlorpromazine, and chloral hydrate. Several other drugs may indeed have similar properties, but it does not appear that therapeutic doses of these in most instances will cause alteration of immunologic functions to any appreciable extent.

## TESTING FOR IMMUNOTOXIC POTENTIAL OF CHEMICALS

There is no single or simple test that can be used for the evaluation of immunotoxic effects of chemicals. A listing of selected tests usually employed for this purpose is provided in Table 18.6. The National Toxicology Program recommended a 2-tier approach for immunotoxicity testing; the first suggestive of immunotoxic potential, the second involving comprehensive testing if immunotoxic potential is apparent in preliminary testing (Luster *et al.*, 1988). Specific tests include testing of humoral and cell-mediated immunity and also interacting cells in various immune functions (i.e. macrophages). *In vitro* tests using heterogeneous mixtures of cells or their isolated subpopulations are useful. In many cases the reactivity of specific cells to surface-acting agents can be readily evaluated *in vitro* by using the mitogens. A number of chemicals decrease the response of lymphocytes to blastogenic agents by virtue of being cytotoxic. Direct effects of chemicals can be evaluated by their addition to cultures but should be viewed with caution. Some chemicals may have non-specific mitogenic properties themselves. Interaction of chemicals with mitogens in the medium may modify their function.

Lymphocyte cultures *in vitro* are useful when carried out after administering the test chemicals to the animals and then evaluating the mitogenic responsiveness of cells harvested from major lymphatic organs. In this case the test chemical can be transformed in the body if its action is dependent on the formation of reactive metabolite. Addition of metabolizing systems can be of value but their presence may modify lymphocyte transformation *in vitro*. Chemicals that modify the immunologic mechanisms indirectly (i.e. through alteration of other systems like steroid levels) can be suitably evaluated after *in vivo* administration.

## FUTURE TRENDS

Available information on the role of immune mechanisms in the manifestation of toxicity by various chemicals is inadequate. Immune suppression is sufficiently important in toxicology and more studies relating dose and effect need to be conducted. Immunosuppressive potentials of chemicals are of little importance if the effects occur only with exposure levels that equal or exceed those that directly affect other systems. Defining the mechanisms of action

**TABLE 18.6 Clinical or toxicological tests indicative of compromised immunologic responses**

| Tests | General principle |
|---|---|
| Hematology and lymphatic organ weights and pathology | Initial estimate of immunotoxic potential may be derived on general toxicity studies, both short and long term, by total and differential leukocyte counts, and when thymus, spleen and lymph nodes are examined. |
| Resistance to various pathogens | Bacterial, viral, or parasitic infections and tumor cell inoculations that have known effects on immune parameters can be used. In early stages mortality to sublethal infections can be used. |
| Lymphocyte typing | Phenotyping of cells bearing different markers can be employed in routine epidemiologic studies. |
| Lymphocyte proliferation | Responses to B and T cell mitogens, either on cells derived from exposed animals or cells treated *in vitro*, have been employed. |
| Antibody production | In domestic animals antibody titers to commonly used vaccinations are useful. In laboratory animals or small species (chicken, fish, etc.) antibodies against T dependent responses (sheep erythrocytes) or T independent responses (heterologous albumin) can be employed. Both antibody titers and enumeration of peripheral plaque-forming cells have been used. |
| Delayed hypersensitivity responses | These T cell dependent effects are common in smaller species; however, they can be used in large animals as well. |
| Cytokine levels | Measuring levels of various cytokines in serum or in tissues is useful after toxicant exposure. Production of cytokine after stimulation of target immunocytes *in vitro*, either from toxicant exposed animals or after *in vitro* treatment of cells with the toxicant, is useful. |
| Phagocytosis and/or cell migration | Leukocytes and macrophages can be evaluated for phagocytosis and/or chemotaxis; production of signaling agents can be measured. |

and the structure–activity relationships are needed for evaluating immunotoxic potential of chemicals.

Immunotoxicity in domestic animals should be considered as a part of their management. Housing and nutrition are of importance as they contribute substantially to the well being of animals. In particular, feed contaminants should be avoided and health surveillance to detect immunotoxic potential should be monitored. More studies involving target species are necessary to fully understand the toxicity potential; chicken are ideal and have been used when effects of chemicals on avian species are suspected. Veterinary diagnostic laboratories should realize the importance of potential immunotoxicity as it may effect productivity even when no other clinical symptoms are observed. Many of the analytical tests involving immune principals (such as for detection of infectious agents) are already available and can be modified to analyze immune functions; lymphocyte proliferation tests can easily be added to the available tools (Sharma *et al*., 1984).

## INTRODUCTION

By some estimates, growth of nanotechnologies and nanomaterials (NMs) far exceed the impact of the Industrial Revolution; they are predicted to become a $1-trillion market by 2015 (Nel *et al.*, 2006). Investigators continue to discover unique properties of conventional materials at the submicrometer scale (Hoet *et al.*, 2004). Nanoparticles (NPs) are a diverse class of small-scale substances with one or more dimensions <100 nanometers (nm). They may be formed in nature, or by carbon combustion or by being released from power plants or from automobile exhausts. Alternatively, NP can be engineered from NM by molecular-level engineering to achieve unique mechanical, optical, electrical, and magnetic properties (Hoet *et al.*, 2004; Tsuji *et al.*, 2006).

NMs are expected to improve virtually all types of products; commercialization of products that exploit these unique properties is increasing. However, these same properties present new challenges to understanding, predicting, and managing potential adverse health effects following exposure. NMs have already found commercial application as sporting goods, tires, sunscreens, sanitary ware coatings, stain resistant textiles and clothing, food products and electronics (Hoet *et al.*, 2004; Nel *et al.*, 2006; Tsuji *et al.*, 2006).

Widespread application of NM confers potential for environmental release and subsequent human exposure. While the benefits of nanotechnology are widely publicized, the discussion of risks conferred by using consumer and industrial products are only beginning to emerge. Technological development and applications are outpacing research for safe use and a documentation of health and environmental risk (Hoet *et al.*, 2004; Tsuji *et al.*, 2006).

The future of nanotechnology will depend on public acceptance of the risks of inhaled NP relative to their benefits. Assuming public acceptance, toxicologist's experience with past "miracle" materials (e.g. asbestos) advises us that caution in using novel substances without fully evaluating potential health risks may be ill advised (Hoet *et al.*, 2004; Tsuji *et al.*, 2006). The purpose of this chapter is to describe the risks conferred on animals, especially companion animals from the use of NM.

As with conventional chemicals, risk assessment will be the basis of assessing and regulating releases from NMs to protect health and the environment. Many applications will likely have limited or manageable exposures and thus potential for effects; however, nanoscale compounds are not the same as their larger counterparts, and risks are expected to be product specific (Hoet *et al.*, 2004; Tsuji *et al.*, 2006). Some studies suggest that NMs are not inherently benign and that they may travel to organs throughout the body. In fact, preliminary studies suggest that pulmonary exposure to NMs induces inflammation, oxidative stress, and distant organ involvement. These factors are most likely related to small size of the particles and their ability to generate oxidative stress. They raise the question, "Do NM properties necessitate a new toxicological science?" (Nel *et al.*, 2006).

## BASIC NP CONCEPTS

### Particle size and agglomeration

The unusual physicochemical properties of NM are attributable to their small size (more than 1 dimension is

*Veterinary Toxicology, Edited by Ramesh C. Gupta*

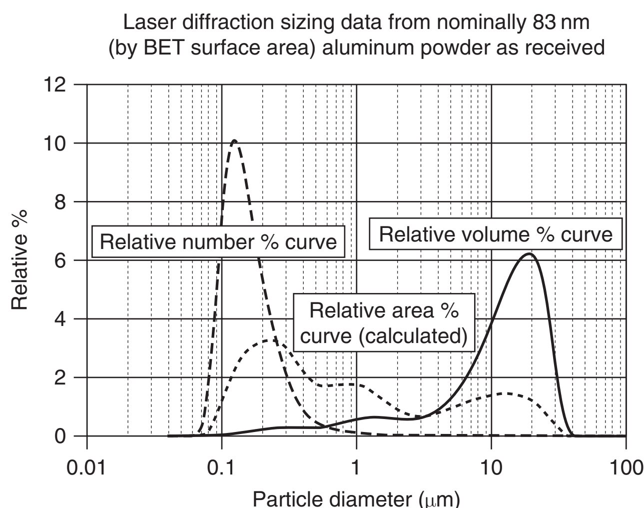

**FIGURE 19.1** Laser diffraction size data for "nanoscale" aluminum powder used for *in vitro* toxicity experiments. Note the apparent difference in size when depicted as a number distribution versus an area or volume distribution. This occurs because volume scales as the cube of the particle diameter and calculated area scales as the square. Each curve, if presented alone, would give an incomplete picture of the particle size distribution/state of agglomeration of the sample. The three curves will overlay only for an ideal spherical, monodisperse, and unagglomerated system. By comparing changes in particle size distribution to that of an "ideal" dispersion, a qualitative assessment of the degree of agglomeration can be made (reproduced with permission of Powers *et al.*, 2006).

less than 100 nm); *surface structure* – surface reactivity, groups, and coatings; *chemical composition* – purity, crystallinity, and electronic properties; *solubility* – surface morphology; and the effect of adsorbed chemicals; shape and aggregation (Nel *et al.*, 2006). The relationships between these factors are only beginning to be worked out.

Particles or particle agglomerates are usually not perfect spheres and are almost never singly dispersed. However, particle size is most often defined as the diameter of a sphere that is equivalent in the selected property to the particle measured; this makes it possible to conveniently plot size distributions of irregularly shaped particles or particle agglomerates using a single value (diameter) along a single axis. The property most often described is volume or mass; i.e. the diameter of a sphere of equal volume to the particle(s) in question (volume or mass diameter). In Figure 19.1, particle diameter is expressed as that which was the median (120 nm), surface area (250 nm), or volume (20 μm (20,000 nm)). Peak distributions in this figure contain some agglomerates of smaller particles.

## Cluster size

The average agglomeration number (AAN) is derived from the ratio of the volume-based median particle size to the average equivalent spherical volume derived from Brunauer Emmett Teller (BET) gas adsorption. An approximate AAN would be ~15,000/160$^3$ ~825,000 equivalent volumes.

## Solubility

Dissolution is affected by surface morphology and agglomeration. Larger more densely aggregated particles will dissolve more slowly. Adsorbed organic chemicals will slow solvation (Powers *et al.*, 2006).

Both particle size and solubility are important determinants of biological response after lung exposure. Particles must be small enough to be inhaled into deep lung, usually taken to be ≤4μm (4000 nm). Particles between 4000 and 500 nm will be phagocytized and cleared rapidly. Particles <500 nm aggregate size will be inefficiently phagocytized or ignored by phagocytes and translocate to the pulmonary interstitium and remain there as a potential toxin. If cleared rapidly they will not be injurious; if not they will remain as a chronic irritating source (Pickrell *et al.*, 2004, 2006).

Solubility of nano-sized particles (NSPs) can be considered to be a lack of biopersistence. Solubility and chemical reactivity are thought to be a function of environment; they should be measured in an environment as near to that of the biological environment as possible. This can sometimes be accomplished with *in vitro* conditions closely simulating biological solutions (Powers *et al.*, 2006). Solubility is thought to be a function of chemical activity, specific surface area, radius and curvature, agglomeration, and specific chemicals that are adsorbed to the NSP (Borm *et al.*, 2006). It is important to consider not just solubility in water, but in fluids that bear significant resemblance to that of the epithelial lining fluid (ELF). ELF is the fluid than lines the epithelial cells in the respiratory tract. A minimal volume is predicted –40–100 ml for mature humans. The pH varies from 6.9 at the end of inspiration to 7.5 at the end of expiration. Bicarbonate is a major buffer; the change is caused by removing $CO_2$ of expiration (Langmuir, 1965). Bicarbonate concentration in lung stimulant fluid increases the solubility of MgO (Pickrell *et al.*, 2006). Surprisingly, macrocrystalline (bulk) MgO is dissolved as extensively as microcrystalline NSP MgO in lung stimulant fluids in about 10–20 min (Pickrell *et al.*, 2006). This paradoxical result suggests that bicarbonate chemical activity may have a direct relation to the rapid dissolution of MgO in lung stimulant fluid related to its modest solubility in distilled water. Stoichiometry of the likely chemical species suggests a conversion of MgO to $Mg(OH)_2$ in aqueous media and a subsequent conversion to the hydrated carbonate (nesquehonite; Langmuir 1965; Pickrell *et al.*, 2006).

# ANIMAL OR TISSUE EXPOSURES

## *In vitro* exposures to NMs

Early indicators for NP-derived adverse health effects were needed for an adequate assessment cytotoxicity of different types of well-characterized NP; cytotoxicity was used to infer relative risk (Brunner *et al.*, 2006). For this purpose, the authors chose a mesothelioma and a fibroblast cell line. Two assays were performed. The first was mean culture activity, indicated by mitochondrial activity in converting a formazan type of dye from its leukoform to an active dye. In addition, DNA content, indicating cell number was measured (Brunner *et al.*, 2006).

The particles were ultrafine (UF) or NPs (Brunner *et al.*, 2006). Other than the positive asbestos control, none had >20% of the particles larger than 200 nm. Specific surface area was also higher than the asbestos positive control (90–190 $m^2/g$ versus the 8.5 $m^2/g$ of the asbestos). Mass median sizes were 20–50 nm and surface area median sizes were 6–21 nm, although they differed in terms of the shape and degree of agglomeration (Brunner *et al.*, 2006). Soluble amorphous silicate, a negative control caused minimal response in either cell line, consistent with its anticipated lack of toxicity (Brunner *et al.*, 2006). Crocidolite asbestos had a significant reduction in both cell activity and cell number (DNA) in both cell lines. The mesothelioma cell line was more severely affected, perhaps reflecting its metabolic activity. This toxicity was consistent with expectations from a positive control (Brunner *et al.*, 2006). Calcium phosphate had no significant cytotoxicity at 3 days; these data are consistent with it having no toxicity like the negative control particle – amorphous silica (Brunner *et al.*, 2006).

Insoluble metal oxides ($TiO_2$, $ZrO_2$, and $CeO_2$) had modest toxicity at 3 days of exposure that was most prominent in mesothelioma cells. By 6 days of exposure, these cells had returned to normal (Brunner *et al.*, 2006). Morphologically, the high dose of zirconium oxide caused the appearance of decreased cell number and function, even after 6 days incubation. These data are consistent with only a modest health effect relative to the positive control (Brunner *et al.*, 2006).

Zinc and ferric oxide were slightly soluble and quite toxic to both cell lines after 3 days incubation (Brunner *et al.*, 2006). The authors advance no explanation for zinc, beyond chemical toxicity. For iron, the toxicity resulted from free-radical production from the Haber–Weiss reaction. Because this reaction occurred at 40-fold less than the chemical toxicity of iron, it is said to be specific for the NP (Brunner *et al.*, 2006).

*In vitro* analysis of particulate matter (PM) effects on alveolar macrophages, epithelial cells, and neutrophils, demonstrates PM- and oxidant-dependent responses. These effects were observed after *in vitro* exposure to concentrated PM(2.5) ((concentrated ambient particles), CAPs) collected in real time. Oxidative stress mediated by reactive oxygen species (ROS) is an important mechanism of PM-induced lung inflammation (Tao *et al.*, 2003).

## Intratracheal instillation and pharyngeal aspiration

### *UF particles*

Exposure to ambient air pollution particles (PM) caused increased cardiopulmonary morbidity and mortality, particularly with pre-existing disease (Tao *et al.*, 2003). Exacerbation of pulmonary inflammation in susceptible people (e.g. asthmatics, chronic obstructive pulmonary disease (COPD) patients) is a central mechanism by which PM cause lung disease.

After intratracheal instillation, UF colloidal silica (UFCS) particles had greater ability to induce tissue damage and inflammation that did fine colloidal silica (FCS) particles. Electron microscopy demonstrated UFCS and FCS particles on both bronchiolar and alveolar wall surfaces; type I epithelial cell necrosis and basement membrane damage was greater in UFCS than FCS particles (Kaewamatawong *et al.*, 2005). A similar trend with $TiO_2$ required repeated exposure (Oberdorster *et al.*, 1995).

### *Carbon nanotubes*

Pharyngeal aspiration of single-walled carbon nanotubes (SWCNT) elicited an acute pulmonary inflammation in C57BL/6 mice that progressed to fibrosis and granulomas (Shvedova *et al.*, 2005). SWCNT caused a dose-dependent release of protein, lactate dehydrogenase (LDH), and gamma-glutamyl transferase activities into bronchoalveolar lung washings (lavage). In addition, accumulation of 4-hydroxynonenal (oxidative biomarker), depletion of glutathione in lungs, leukocyte accumulations, and cytokines were present in bronchoalveolar lavage fluid (BALF) at days 1–7. This was followed by fibrogenic transforming growth factor (TGF)-beta 1 that peaked on day 7. The progressive fibrosis found in mice exhibited two distinct morphologies – SWCNT-induced granulomas and diffuse interstitial fibrosis and alveolar wall thickening. Functional respiratory deficiencies and decreased bacterial clearance (*Listeria monocytogenes*) were found in mice treated with SWCNT (Shvedova *et al.*, 2005). *In vitro* exposures of multiwalled carbon nanotubes to fibroblasts at high doses induces a similar inflammation (Ding *et al.*, 2005).

Equal doses of UF carbon black particles or fine crystalline silica ($SiO_2$) did not cause either granulomas or alveolar wall thickening. Instead they caused weaker pulmonary inflammation and damage (Shvedova *et al.*, 2005).

## Intranasal exposure

### *Carbon black*

High doses of carbon black, given intranasally, showed adjuvant activity as indicated by enlargement of peribronchial lymph nodes and ovalbumin specific production of thymocyte (Th) 2 specific interleukin (IL) 4, IL5, and IL10; local cytokine production after carbon black exposure is predictive of allergic airway inflammation. This particle may predict adjuvant potential (de Haar *et al.*, 2005).

## Inhalation exposure

### *Polytetrafluoroethylene*

Inhalation of highly insoluble UF (nano) particles (diameter 20 nm) of low intrinsic toxicity ($TiO_2$), resulted in pulmonary inflammatory responses. However, these effects were not acute and occurred only after prolonged inhalation exposure of the aggregated UF particles at high levels $>1\,mg/m^3$ (Oberdorster *et al.*, 1995).

By way of comparison, recent studies with thermodegradation products of polytetrafluoroethylene (PTFE) we found that freshly generated PTFE fumes contained singlet UF particles (median diameter 26 nm); the fumes were toxic to rats at inhaled concentrations of $0.7–1.0 \times 10^6$ particles/$cm^3$. Exposure caused an acute hemorrhagic pulmonary inflammation and death after 10–30 min of exposure. Rat performance on a treadmill wheel was reduced by PTFE fume exposure (Oberdorster *et al.*, 1995).

These results confirm reports from other laboratories that the toxic nature of PTFE fumes cannot be attributed to gas-phase components of these fumes, HF, or to reactive compounds. Mass concentrations of the inhaled UF PTFE particles were low, $<60\,\mu g/m^3$. Aging of the fumes with concomitant aggregation of the UF particles significantly decreases their toxicity (Oberdorster *et al.*, 1995). Inhalation studies with UF particles ($\leqslant$100 nm; NP) in rats suggest that particles $\leqslant$50 nm in diameter, may contribute to increased mortality and morbidity.

# ENVIRONMENTAL EPIDEMIOLOGY

Recent epidemiological studies show an association between particulate air pollution and acute mortality and morbidity down to ambient particle concentrations below $100\,\mu g/m^3$. Whether this association also indicates causality between acute health effects and particle exposure at these low levels is unclear at this time; no mechanism is known that would explain such dramatic effects of low ambient particle concentrations.

## Sulfur dioxide (oxides of sulfur particles)

Sulfur dioxide (oxide of sulfur particles) comes mainly from burning sulfur containing fuels (Sullivan *et al.*, 2006), causing both indoor and outdoor pollution. For example, frequent or prolonged use of kerosene space heaters, especially poorly ventilated ones is a source of indoor sulfur dioxide. Sulfur dioxide particles are hygroscopic and tend to grow with increasing hydration of the atmosphere (Sullivan *et al.*, 2006).

Nasal breathing filters out much of the inhaled sulfur dioxide; it is very soluble and is often absorbed in the upper portion of the respiratory tract (Sullivan *et al.*, 2006). Sulfur dioxide is so irritating to the eyes, nose, and airways that its odor is detected as low as 0.5 ppm. At >6 ppm, companion animals often show acute clinical signs – tearing, runny nose, cough, bronchospasm, and shortness of breath. Additional chronic signs that come from prolonged exposure at lower exposure concentrations include cough, mucus hypersecretion, and clearing of the throat; these reflect airway inflammation and chronic bronchitis. Massive exposure is capable of inducing severe permanent pulmonary damage (Sullivan *et al.*, 2006). Low level prolonged human exposures correlate well with bronchial asthma. Future work will need to confirm this correlation in companion animals.

## Swine barn dust exposure

Healthy human volunteers weighing pigs for 3 h developed a neutrophilic pneumonitis; they had an increased bronchial responsiveness to methacholine. Wearing a mask reduced but did not abolish the inflammatory response. Gases and/or UF particles in this environment could be important factors in the development of increased bronchial responsiveness both in animals and their human caretakers (Larsson *et al.*, 2002). *In vitro* data suggest that airway epithelial cell swine dust extract exposure enhances subsequent lymphocyte adhesion to epithelial cells by a modulation of expression of intracellular adhesion molecule 1 and protein kinase C alpha (Mathisen *et al.*, 2004). Exposure caused inflammation characterized by increased numbers of neutrophils, macrophages, and to a lesser degree, lymphocytes in animals and swine barn caretakers. Interestingly, this inflammation is most pronounced in caretakers with no prior exposure to this environment. These findings suggested a tolerance to endotoxin or other substances in this environment was induced by repeated exposures. Interventions have been devised to reduce the risk of symptomatic respiratory disease (Von Essen and Romberger, 2003).

## NP exposure in the home

Use of engineered NM in sunscreens – zinc oxide or titanium dioxide or as bio-imaging probes, as cosmetics, or as

imaging probes of supra-magnetic iron oxides – has not led to reports of toxicities in humans (Nel *et al.*, 2006) or animals; however, ferric oxide NP are cytotoxic to mesothelioma cells and fibroblasts *in vitro* (Brunner *et al.*, 2006). As a point of comparison zinc oxide fumes at high doses (500 μg/m$^3$), in an occupational setting, caused fume fever (fatigue, chills, fever, myalgia, cough, and leukocytosis) (Nel *et al.*, 2006). Several factors may differ between the two situations. In occupational settings, exposures tend to be more persistent, have higher exposure levels and have more complex composition. Thus, they may confer more risks than in single inhalation exposure situations. None of these factors were evaluated in these situations.

Environmental tobacco smoke (ETS) from the burning of tobacco indoors can cause a health hazard for companion animals; because its aerosol can contain more than 4000 toxicants into the airway (Sullivan *et al.*, 2006). Some of them are carcinogens; the Environmental Protection Agency (EPA) has classified ETS a group A carcinogen, meaning that there is sufficient evidence to indicate that it will produce cancer in humans (Sullivan *et al.*, 2006).

Inhaled cigarette smoke often did not cause significant increases in numbers of malignant respiratory tumors in rats, mice, hamsters, dogs, or non-human primates even when exposed for long periods of time to very high concentrations of mainstream cigarette smoke. The results are different from the epidemiological evidence in human smokers. It is difficult to reconcile this major difference between observational studies in humans and controlled laboratory studies. Mice exposed to ETS experimentally and at high doses developed increased incidences of cancer (Hecht, 2005). Most investigators continue to compare the experimental dose pattern with that in humans, animals appear to be less sensitive than man (Coggins, 2002).

Beta-carotene supplementation attenuated cardiac remodeling induced by 1-month tobacco-smoke exposure in rats (Zornoff *et al.*, 2006). After 1-month exposure to ETS cardiac remodeling was present as indicated by disorganization or loss of myofilaments, infolding of plasma membrane, dilation of the sarcoplasmic reticulum, and polymorphic mitochondria with swollen or decreases cristae. Rats given beta-carotene during cigarette-smoke exposure had minimal or no significant cardiac remodeling. These data suggest beta-carotene attenuates, reduces or minimizes cardiac remodeling induced by cigarette smoke (Zornoff *et al.*, 2006). These data are probably most relevant to obese cardiac-compromised companion animals.

While smoke inhalation may have most of its clinical signs and health effects caused by toxic gases (e.g. carbon monoxide), airborne releases include gases, fumes, aerosols, and vapors. Irritant particles such as acrolein are capable of producing pulmonary damage and debris (Fitzgerald and Vera, 2006). Signs indicating increased risk from inhalation injury of smoke particles include confinement in a close space, alteration in breathing pattern, respiratory compromise, stridor, and singed hair. For example, wheezing, chronic cough, chronic hyper-reactive airways, and chronic bronchitis are frequently noted. Water-soluble toxins are absorbed and injure mostly the upper respiratory tract, while less soluble materials, organic materials, go deeper into the lungs and injure pulmonary parenchyma (Fitzgerald and Vera, 2006).

Differential diagnoses or conditions which must be adequately distinguished from smoke inhalation include asthma, heart disease, allergic pulmonary disease, inhalation of toxic solvents or sprays, pneumonia, neoplasia, trauma, COPD, and pneumothorax (Fitzgerald and Vera, 2006).

Overheated frying pans release only small amounts of Teflon™ (PTFE) which causes a fatal hemorrhagic pneumonitis in cockatiels directly adjacent in both time and space to the overheating (Anonymous, 2006; Blandford *et al.*, 1975). Within a short period of time, and in an adjacent room, there is only a minimal reaction. Current understanding implies that the small particles are capable of causing pulmonary injury directly after the overheating, but rapidly condense into larger and less biologically potent particles. As a point of comparison, the owner developed fume fever from which he recovered within 24 h (Blandford *et al.*, 1975; Lee and Seidel, 1991).

Aged particles collected as agglomerates were not toxic when given intratracheally to the rats. The particles became toxic when rats were given inhalation exposure to fumes evolved from the reheated agglomerate. The fumes contained numerous toxic submicron particles evolved from thermal decomposition of agglomerates by reheating. Rats died with pulmonary edema and hemorrhage reflecting type I pneumocyte damage. The edematous lungs revealed some agglomerated particles. However, small PTFE pyrolysis particles were difficult to differentiate from contaminating dust or cellular debris (Lee and Seidel, 1991).

Birds appear to be more sensitive than rats and humans to direct inhalation of Teflon™ fumes from overheated skillets; this sensitivity probably reflects their physiologically more efficient respiratory system. Oxygen is taken up more efficiently than in mammals. In addition, many birds are sufficiently small to have high metabolic rates.

## Stray dog exposures to automobile exhaust aerosols

The UF PM are seen in alveolar type I and II cells. Bronchoalveolar lavage show significant numbers of activated alveolar macrophages. Exposure to complex pollutant mixtures is causing lung structural changes induced by the sustained inflammatory process and resulting in airway and vascular remodeling and altered repair. Cytokines released from both, circulating inflammatory and resident lung cells in response to endothelial and

epithelial injury may be central to the pathology (Calderon-Garciduenas *et al.*, 2001a, b). Myocardial findings, lung epithelial and endothelial pathology, and chronic inflammatory lung changes were closely related (Calderon-Garciduenas *et al.*, 2001a, b).

UF particle exposures delivered at environmental levels, over long times relative to animal lifetimes to stray dogs in Mexico (City), UF were reported by Calderon-Garciduenas (2001a, b). These exposures are complicated by a heavy load of oxidant gases. The investigators report only a modest pulmonary fibrosis, approximately the amount which we see from our 1 ppm $O_3$ ozone exposure (Pickrell *et al.*, 1987; Calderon-Garciduenas *et al.*, 2001a, b). Although difficult to quantitate, the fibrosis is no more than we expected from the oxidant exposure alone in Mexico (City), DF. Thus, we must consider the possibility that UF particles cause so small a lesion, and disrupt so little architecture that healing is favored. Thus, the induction of procollagen and deposition of increased tissue collagen would be beneficial. Similar changes were seen in humans exposed to the same atmosphere (Churg *et al.*, 2003).

## RISK FROM PRODUCTION OF MANUFACTURED NPs

Risks from manufactured NP come from their preparation and subsequent use. For example, to assess risk of preparation, five representative NMs were selected for an analysis (Robichaud *et al.*, 2005). Their selection was based on their current or near-term potential for large-scale production and commercialization. The NMs were SWCNT, bucky balls ($C_{60}$), one variety of quantum dots (Q-dots), alumoxane NPs, and nano-titanium dioxide NPs. The assessment focused on the activities surrounding the fabrication of NM, exclusive of any impacts or risks with the NM themselves. A representative synthesis method was selected for each NM based on its potential for commercial production (Robichaud *et al.*, 2005).

A list of input materials, output materials, and waste streams for each step of fabrication was developed and entered into a database that included key process characteristics such as temperature and pressure (Robichaud *et al.*, 2005). The physical–chemical properties and quantities of the inventoried materials were used to assess relative risk based on factors such as volatility, carcinogenicity, flammability, toxicity, and persistence. These factors were first used to qualitatively rank risk. Then they were combined using an actuarial protocol developed by the insurance industry for the purpose of calculating insurance premiums for chemical manufacturers. This protocol ranks three categories of risk relative to incident risk, normal operations risk, and latent contamination risk (Robichaud *et al.*, 2005).

Results from this analysis determined that relative environmental risk from manufacturing each of these five materials was comparatively low in relation to other common industrial manufacturing processes (Robichaud *et al.*, 2005). Of these Q-dots, metal oxides, and SWCNT were especially low, in the range of silicon wafers, aspirin, and wine production. Only carbon black carried as high a risk as high density plastics and automotive lead batteries. All of these were lower than petroleum refining (Robichaud *et al.*, 2005).

A second study that examined health and safety funding for NM, showed that funding is expected to increase so that $85,000,000 is projected for environmental and health safety research globally (Dunphy-Guzman *et al.*, 2006). Nanotechnology exposure, environmental fate, and transport are considered fundamental to air pollution and possibilities for animal and human exposure. Cerium oxide particles have recently been shown to decarboxylate and polymerize small organic molecules. These molecules are considered to have potential as a gasoline additive. Thus, they have potential for exposure and impact on the ecosphere. Transportation studies to date have been limited (Dunphy-Guzman *et al.*, 2006).

Some smaller NPs show increased animal experimental toxicity due to their increased surface area. Certain carbon-based materials are of concern, because they may partition into cells. In addition, fullerenes can induce photodamage to lipids proteins and cells. In addition, NPs of metal oxides have been shown to induce DNA damage. Finally, hydroxyapatite, a material much like bone matrix has been shown to induce cell death (Oberdorster *et al.*, 2000; Dunphy-Guzman *et al.*, 2006).

Small particles have been shown to have atmospheric impact that is they band together in clouds (Dunphy-Guzman *et al.*, 2006). Titanium dioxide NPs have been shown to disinfect and degrade pollutants. There is a distinct possibility that they may have other activities that are photodegrative or induce biochemical transformations. In addition, NPs are key players in biochemical and geological processes. Global-scale impact should be considered; only life-cycle analyses will provide the information needed to directly predict the impact of NPs on the future of animals and the people who care for them (Dunphy-Guzman *et al.*, 2006).

## CONCLUSIONS

Swine barn dust inhaled in confined animal feeding operations is small enough to deposit in the deep lung; it is mostly allergenic and elicits low-grade allergenic lung disease that probably affects only their feed efficiency (feed required/pound of gain) and rate of growth (average

daily gain). Stray dogs exposed to the Mexico City polluted atmosphere sustain mild-to-moderate lung inflammation and scarring which probably does not affect them greatly. Whatever effect they sustain relates to both the toxic gases and the UF atmospheric particle co-exposure.

Much higher exposure levels of manufactured NP are required to cause health effects than are usually found. Although welder atmospheres may appear similar, they can only be compared to a limited extent, because they are occupational with persistently high levels and often complex containing several airborne toxins. ETS causes less lung cancer in animals than in man, although increased cancer rates compared to smoke free-environmental controls have been observed. Dogs with short- or medium-length noses are more likely to get lung cancer than longer nosed dogs that filter the toxic aerosols out in the nose and get nasal cancer.

Toxicity from overheated non-stick Teflon cookware is most likely to be seen in companion birds with more efficient respiratory systems. Only the particles that are the most recently after thermal decomposition are the smallest and have the most active surface elicit an acute adverse reaction.

## ACKNOWLEDGMENTS

The author would like to thank Dr. Larry Erickson, Chemical Engineering, Kansas State University for his support in this effort and Dr. Frederick W. Oehme Comparative Toxicology Laboratories, Department of Diagnostic Medicine/Pathobiology, Kansas State University for his support, and for critically reading the manuscript.

CHAPTER

# 20

# Oxidative stress and neurodegeneration

*Manashi Bagchi, Shirley Zafra-Stone, Debasis Bagchi, and Sangeeta Patel*

## INTRODUCTION

Oxidative stress is characterized by the presence of an excess of oxidants caused by an imbalance between the formation and neutralization of reactive oxygen species (ROS) (Behl, 1999). Oxidative stress can lead to the formation of chain reaction by-products, which create a potentially unstable cellular environment by causing massive cellular injury and extensive damage to the lipids, proteins, and biological macromolecules. Oxidative stress has also been linked to tissue damage, advancing age associated dysfunctions, and a broad spectrum of degenerative diseases including neurodegeneration (Barone *et al.*, 2000).

Free radicals or oxidants are highly reactive, unstable molecules that have an unpaired electron in their outermost electron orbit which react with or oxidize various cellular components and biological macromolecules including proteins, DNA, RNA, lipids, fatty acids, and advanced glycation end products, i.e. carbonyls (Stohs and Bagchi, 1995). These reactions between cellular components and free radicals lead to DNA-single-strand break (DNA-SSB) and DNA-double-strand break, DNA fragmentation, lipid peroxidation, protein oxidation products, mitochondrial malfunction, cell membrane damage, lactate dehydrogenase (LDH) leakage, and eventually programmed cell death (apoptosis) and unprogrammed cell death (necrosis). Examples of free radicals or oxidizing molecules are hydrogen peroxide, singlet oxygen, superoxide anion, hydroxyl radical, peroxyl radical, reactive nitrogen oxides, and peroxynitrite. Superoxide is produced deleteriously by a one-electron transfer in the mitochondrial-electron transfer chain. Hydrogen peroxide is also produced by a wide variety of enzymes including monoxygenases and oxidases. Peroxynitrite is a potent free radical which is 1000 times more potent as an oxidizing compound than hydrogen peroxide (Stohs, 1995; Stohs and Bagchi, 1995). Specific markers of free-radical peroxynitrite formation, such as nitrotyrosines or isoprostanes, have been linked to chronic heart disease, liver disease, areas of inflammation, and as well as neurodegenerative diseases including Parkinson's disease, Alzheimer's disease, amyotrophic lateral sclerosis, and Huntington's disease (Stohs, 1995; Stohs and Bagchi, 1995).

The steady-state formation of free radicals is normally balanced by a similar rate of consumption of antioxidants. Various pathological processes disrupt this balance by increasing the formation of free radicals in proportion to the available antioxidants and antioxidant enzymes. Enhanced formation of free radicals induces a compromised effect on the body's immune system leading to inflammation, ischemia–reperfusion injury of different organs, apoptosis, necrosis, and altered gene expression. Enhanced formation of free radicals and oxidative stress, and inadequate antioxidant activity are associated with a broad spectrum of disease states such as cardiovascular dysfunctions, chronic fatigue syndrome, hepatitis, cancer, autoimmune disorders, HIV and AIDS, cancer, and diverse neurodegenerative diseases (Stohs, 1995; Stohs and Bagchi, 1995).

## OXIDATIVE STRESS AND NEURONAL INJURY

Numerous studies confirmed the damaging effects of oxidative stress on the nervous system. In a study conducted by Urano *et al.* (1997) rats were exposed to 100% oxygen in a chamber, in which many morphological changes,

*Veterinary Toxicology, Edited by Ramesh C. Gupta*

*Copyright © 2007, Elsevier Inc. All rights reserved.*

e.g. swollen astrocytes around vessels, deformed nuclei in nerve cells, pigmentation, swollen mitochondria, and abnormal accumulation of synaptic vesicles in swollen nerve terminals, were observed by electron microscopy. When synaptosomes isolated from oxygen-exposed rats were stimulated by KCl, acetylcholine release from the terminal decreased more significantly than in synaptosomes from control rats ($p < 0.01$). Synaptic plasma membrane fluidity decreased in response to oxygen exposure, while plasma membrane permeability to sucrose increased significantly ($p < 0.05$). Cholesterol: phospholipids ratio of the plasma membranes was increased by oxidative stress and the content of unsaturated fatty acids, especially arachidonic acid and docosahexaenoic acid, decreased. The levels of lipid peroxidation (as determined by the amount of thiobarbituric-acid-reactive substances (TBARS)) in the plasma membranes of oxygen-exposed rats were significantly higher than in control rats ($p < 0.01$). Results suggested that free radicals derived from oxygen may attack nerve terminals and peroxidize the plasma membrane (Davies, 1990; Urano *et al.*, 1997).

## OXIDATIVE STRESSORS: HEAVY METALS, ENVIRONMENTAL TOXICANTS, AND TOBACCO

Numerous evidence suggests that exposure to structurally diverse environmental toxicants, including heavy metals, polyhalogenated or polycyclic aromatic hydrocarbons, and tobacco and its carcinogenic counterparts, may involve a common cascade of events which includes the production of ROS and oxidative stress leading to lipid peroxidation (Bagchi *et al.*, 1998a, 2002), DNA-SSB and fragmentation (Stohs *et al.*, 1997), membrane damage with decreased membrane fluidity (Bagchi *et al.*, 1992), apoptosis (Stohs, 1995), glutathione depletion (Bagchi *et al.*, 1996a), altered calcium homeostasis (Bagchi *et al.*, 1997, 1998a, b), enhanced release of tumor necrosis factor alpha (TNF-$\alpha$), induction of stress/heat shock protein (HSP) 90 (Von Burg and Lui, 1993), stimulation of oncogene expression, and inhibition of tumor suppressor genes (Schwarz *et al.*, 1995).

### Chromium, lead, cadmium, and other heavy metals

#### *Chromium*

Chromium exists predominantly in two valence states: Cr(III) and Cr(VI). Cr(III) is an essential micronutrient, while Cr(VI) is carcinogenic. Cr(VI) is a highly reactive transition metal widely known to cause allergic dermatitis as well as toxic and carcinogenic effects (Von Burg and Lui, 1993; Goyer, 1996). Chromate, $(CrO_4)^{2-}$, is the most dominant form of Cr(VI) in neutral aqueous solutions and can readily cross cellular membranes via non-specific anion carriers (Danielsson *et al.*, 1982).

The ability of Cr(VI) to induce an oxidative stress is well known. Von Burg and Lui (1993) and Barceloux (1999) summarized the acute and chronic toxicity, neurotoxicity, dermotoxicity, genotoxicity, carcinogenicity, immunotoxicity, and general environmental toxicity of chromium. Chromium (VI)-induced internucleosomal DNA fragmentation, inhibition of macromolecular synthesis, and apoptosis have been demonstrated in cultured Chinese hamster ovary cells, and low-dose exposure to chromium has been shown to potentiate cell proliferation and apoptosis (Von Burg and Lui, 1993; Manning *et al.*, 1994; Barceloux, 1999). Vitamin E, glutathione, and oxygen scavengers can decrease chromate-induced cytotoxicity, lipid peroxidation, and DNA damage, with vitamin E exhibiting the greatest protective effect (Sugiyama, 1991). Both forms of chromium undergo redox cycling (Stohs and Bagchi, 1995). Various investigators have examined the mechanism of DNA cleavage by Cr(VI). The results indicate that Cr(VI) complexes are produced in the reduction of Cr(VI) by cellular reductants such as NADPH that react with hydrogen peroxide to generate hydroxyl radicals (Shi and Dalal, 1989). The hydroxyl radicals are believed to be the initiators of the primary events in Cr(VI) cytotoxicity and are responsible for causing DNA-strand breaks. The reactions involved in the redox cycling of Cr(III) and Cr(VI) are:

$$Cr(III) + O_2^{-\bullet} \rightarrow Cr(III) + O_2$$

$$Cr(II) + H_2O_2 \rightarrow Cr(III) + OH^{\bullet} + OH^-$$

$$Cr(VI) + O_2^{-\bullet} \rightarrow Cr(V) + O_2$$

$$Cr(V) + H_2O_2 \rightarrow Cr(VI) + OH^{\bullet} + OH^-$$

Although Cr(III) is much less non-toxic compared with Cr(VI), Cr(III) can be reduced to Cr(II) by biological reductants such as NADH and L-cytenine (Ozawa *et al.*, 1993). The newly formed Cr(II) reacts with hydrogen peroxide to produce hydroxyl radical, which is presumably responsible for tissue-damaging effects including the production of DNA damage. In summary, both Cr(VI) and Cr(III) are biologically active oxidation states of chromium, although Cr(VI) is much more toxic and produces greater oxidative stress and carcinogenesis. Both oxidation states of chromium are involved in redox cycling with the production of ROS.

Investigations have shown that sodium dichromate [Cr(VI)] more effectively induces the formation of ROS and causes oxidative tissue and DNA damage compared with Cr(III) (Manning *et al.*, 1994; Bagchi *et al.*, 1995a). The effect of an oral low dose (0.05 median lethal dose ($LD_{50}$))

of Cr(VI) (2.5 mg/kg/day) on brain mitochondrial and microsomal lipid peroxidation, excretion of urinary lipid metabolites, and brain nuclear DNA-SSB in Sprague–Dawley rats has shown that maximum increases in these parameters occur between 60 and 75 days of treatment. The results of these experiments clearly indicate that low-dose subchronic administration of Cr(VI) induces oxidative stress, resulting in tissue-damaging effects that may contribute to the toxicity and carcinogenicity of Cr(VI) (Bagchi *et al*., 2002).

The *p53* tumor suppressor gene plays a major role in the regulation of cellular stress response including oxidative stress, in part, through the transcriptional activation of genes involved in cell cycle control, DNA repair, and apoptosis (Amundon *et al*., 1998). Many factors have been shown to contribute to control the activation of *p53*, and the downstream response to *p53* activation may vary depending on the cellular environment or other modifying factors in the cell, including exposure to diverse xenobiotics. Because *p53* is activated in response to DNA damage and different signaling mechanisms, the role of the *p53* gene was assessed to unveil the mechanism of structurally diverse xenobiotics-induced oxidative stress and toxicity in the brain tissues (Bagchi *et al*., 2000). Measured biomarkers included superoxide anion production (cytochrome *c* reduction), DNA fragmentation, and lipid peroxidation (TBARS). The levels of these parameters were not significantly different in the brains of untreated C57BL/6NTac- and C57BL/6TSG p53-deficient mice. A comparative study was conducted using different types of environmental stressors including 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD), endrin, naphthalene, and Cr(VI) in p53-deficient mice. Treatment of C57BL/6NTac mice with a 0.01 $LD_{50}$ dose of TCDD, endrin, naphthalene, and Cr(VI) increased cytochrome *c* reduction by 1.5- to 1.6-fold in brain tissues as compared to the control animals, although under the same conditions, approximately 1.7- to 2.4-fold increases in cytochrome *c* reduction were observed in brain tissues of *p53*-deficient mice (Table 20.1). Similar results were obtained in brain lipid peroxidation (Table 20.2) and DNA fragmentation (Table 20.3) (Bagchi *et al*., 2000).

Approximately 2.5-, 3.0-, 3.4-, and 2.5-fold increases in cytochrome *c* reduction were observed in brain tissues of C57BL/6NTac mice after treatment with 0.10 $LD_{50}$ doses of TCDD, endrin, naphthalene, and Cr(VI) compared to corresponding values in untreated control animals. Under the same conditions, approximately 4.0-, 6.9-, 5.1-, and 3.7-fold increases in cytochrome *c* reduction were observed in brain tissues of TSG-p53 mice compared to control animals. In comparison, at a 0.10 $LD_{50}$ dose, TCDD, endrin, naphthalene, and Cr(VI) induced 1.6-, 2.3-, 1.5-, and 1.5-fold greater increases in cytochrome *c* reduction in brain tissues of p53-deficient mice than in C57BL/6NTac animals (Table 20.1). Similar results were obtained in brain

| Naphthalene | $5.34 \pm 0.71^{c}$ | $10.46 \pm 0.88^{c}$ | $3.00 \pm 0.22^{a}$ | $8.26 \pm 1.04^{c}$ | $3.03 \pm 0.47^{a}$ | $4.63 \pm 0.48^{b}$ |
| Cr(VI) | $6.20 \pm 0.51^{b,c}$ | $12.55 \pm 1.22^{b}$ | $3.90 \pm 0.41^{b}$ | $5.81 \pm 0.66^{b}$ | $3.74 \pm 0.31^{b}$ | $4.30 \pm 0.61^{b}$ |

DNA fragmentation was determined in brain tissues of C57Bl/6NTac and p53-deficient mice 24 h after treatment with a 0, 0.01, 0.10, or 0.50 $LD_{50}$ dose of the four xenobiotics. Each value is the mean ±SD of four experiments.

[a–c] Values within a column with non-identical superscripts are significantly different ($p < 0.05$) from each other.

lipid peroxidation and DNA fragmentation (Tables 20.2 and 20.3) (Bagchi *et al.*, 2000).

Treatment of C57BL/6NTac mice with 0.50 $LD_{50}$ dose of TCDD, endrin, naphthalene, and Cr(VI) increased cytochrome *c* reduction by 5.7-, 5.4-, 5.3-, and 4.1-fold in brain tissues compared to corresponding values in untreated control animals, although under the same conditions, approximately 8.1-, 10.1-, 9.6-, and 7.7-fold increases in cytochrome *c* reduction were observed in brain tissues of p53-deficient mice. In comparison, at a 0.50 $LD_{50}$ dose, TCDD, endrin, naphthalene, and Cr(VI) induced 1.4-, 1.9-, 1.8-, and 1.9-fold higher increases in cytochrome *c* reduction in brain tissue of p53-deficient animals than in C57BL/6NTac mice (Table 20.1) (Bagchi *et al.*, 2000). These results demonstrate the massive production of ROS and oxidative DNA damage by Cr(VI) and other xenobiotics. Similar results were obtained in brain lipid peroxidation and DNA fragmentation (Tables 20.2 and 20.3) (Bagchi *et al.*, 2000).

### *Lead*

Lead is another major environmental toxicant that causes neurological, hematological, and gastrointestinal dysfunction. Prolonged exposure to lead may also cause reproductive impairment, hypertension, and nephropathy. Furthermore, lead slows nerve conduction, alters calcium homeostasis, inhibits enzymes, and stimulates synthesis of binding proteins (Stohs and Bagchi, 1995; Goyer, 1996). Although lead is not considered a transition metal, the catalysis of peroxidative reactions by lead may be a major contributor to the toxic effects of this metal. Various studies have shown that administration of lead to experimental animals results in the production of lipid peroxidation in the brain tissues (Stohs and Bagchi, 1995). Administration of vitamin E prevents enhanced lipid peroxidation and toxicity of lead (Ramstoeck *et al.*, 1980), providing additional evidence for the role of oxidative stress in lead toxicity. As observed with cadmium and nickel, lead produces a compensatory increase in tissue glutathione levels. Results involving the role of ROS and oxidative stress in the toxicity of lead are consistent with the results for other heavy metals (Stohs and Bagchi, 1995).

### *Iron, copper, manganese, and zinc*

The brain, particularly the gray matter, is rich in metal ions such as iron (Fe), copper (Cu), manganese (Mn), and zinc (Zn) which may consist of significant concentrations within the range 0.1–0.5 mM (Hamai *et al.*, 2001). Experimental data has shown these metal ions are key neurochemical factors in both the generation and defense against ROS and neurological diseases. In neurological diseases, an abnormal reaction occurs between a protein and a redox-active metal ion promoting the formation of ROS, which can be detrimental to the nervous system (Jenner, 1996). ROS and oxidative stress significantly contribute to the pathophysiology of Alzheimer's disease, and the amyloid precursor protein (APP) has been shown to alter expression in response to selected metal supplementation and chelation (Cheng and Trombetta, 2004). Other studies have shown that rabbits fed a high-cholesterol diet in the presence of copper ions developed amyloid brain lesions and cognitive deficiencies (Bush *et al.*, 2003; Sparks and Schreurs, 2003). Currently, several independent research groups are conducting investigation to unveil the mechanism of action.

## Oxidative stress by organophosphate and carbamate pesticides

Residential and industrial use of organophosphate and carbamate pesticides is widespread in the United States. According to the 1997 findings of the US Environmental Protection Agency, over 40 organophosphate pesticides and 22 carbamate pesticides are the among 900 pesticides registered for use in the United States which pose the highest risks to human health (Bagchi *et al.*, 2006). organophosphates have been used extensively to control wide range of

(sucking and chewing) pests of field crops, fruits, and vegetables. The widespread use of well-known organophosphate pesticide chlorpyrifos has raised major concerns about its potential to cause fetal or neonatal neurobehavioral damage, even at doses that do not evoke acute toxicity. Chlorpyrifos has been shown to inhibit replication of brain cells, to elicit alterations in neurotrophic signaling, governing cell differentiation, and apoptosis, as well as to evoke oxidative stress (Bagchi *et al.*, 2006). Both organophosphate and carbamate pesticides primarily target of action in the nervous system of insects. Exhibiting many structural similarities with naturally occurring compounds, organophosphate and carbamate interfere with the conduction of signals and cholinergic reactions in the nervous system of insects via inhibiting the release of the enzyme acetylcholinesterase at the synaptic junction. Eserine, parathion, and malathion are further examples of cholinesterase inhibitors responsible for the hydrolysis of body choline esters, including acetylcholine at cholinergic synapses (Bagchi *et al.*, 2006).

Experimental exposure of animals to these pesticides elicits potential of neurotoxicity and DNA damage as well as development of birth defects, abnormal spermocytes and oocytes, and even fetal death (Kaplan *et al.*, 1993). Present case reports of residential exposure to chlorpyrifos resulting in such symptoms as cognitive slowing, cognitive problems, and sensory neuropathy may arise weeks to months after application.

Recent studies indicate that toxic manifestations induce by these pesticides are associated with the enhanced production of ROS which provides an explanation for the multiple types of toxic responses as well as a characteristic wasting syndrome. Most of these pesticides may also serve as common mediators in the activation of protein kinase C (PKC), oncogene expression, apoptosis, and tumor formation. The ability to produce ROS *in vivo* with successive tissue damage was examined by brain lipid peroxidation and DNA-SSB. Chemiluminescence, LDH leakage, and DNA-SSB were assessed to determine the *in vitro* production of ROS. Organophosphates have also shown the mechanism involved in the induction of oxidative-tissue-damaging effects, including lipid peroxidation and nuclear DNA-SSB in *in vivo* models.

A comparative *in vitro* and *in vivo* effect of organophosphates such as chlorpyrifos and fenthion were assessed in cultured neuroactive PC-12 cells and in treated animals (Bagchi *et al.*, 1995b). Dissimilar polyhalogenated cyclic hydrocarbons, such as endrin and chlordane, and chlorinated acetamide herbicides, such as alachlor were also compared to these organophosphates insecticides.

The ability to produce ROS *in vivo* with successive tissue damage was examined by hepatic and brain lipid peroxidation and DNA-SSB. Chemiluminescence, LDH leakage, and DNA-SSB were assessed to determine the *in vitro* production of ROS. These results clearly demonstrated that administration of organophosphates result in the *in vitro* and *in vivo* induction of brain lipid peroxidation, chemiluminescence response, LDH leakage, and DNA-SSB suggesting that the ROS and/or free radicals may be involved in the toxic manifestations of organophosphates and other structurally dissimilar pesticides. Furthermore, results indicate the tissue specificity of organophosphates with respect to the responses.

#### In vitro *and* in vivo *generation of ROS and lipid peroxidation in the brain tissue by structurally dissimilar pesticides*

Organophosphate- and other xenobiotics-induced *in vivo* production of ROS and membrane damage in the brain tissue were assessed by brain lipid peroxidation and DNA damage. Endrin, chlordane, alachlor, chlorpyrifos, and fenthion were administered orally to female Sprague–Dawley rats in two 0.25 $LD_{50}$ doses at 0 and 21 h and killed at 24 h. Lipid peroxidation assays were determined on the brain whole homogenates from control and treated animals according to the method of Buege and Aust (1972), based on the formation of TBARS. Following treatment of the rats with chlorpyrifos, fenthion, endrin, chlordane, and alachlor approximately 4.6- to 5.3-fold increases in brain lipid peroxidation were observed in brain homogenates. Similar results were obtained in cultured PC-12 cells using these pesticides. The effects of these pesticides on lipid peroxidation and DNA damage in brain homogenates are summarized in Table 20.4 (Bagchi *et al.*, 1995a, b).

The effect of dichlorvos exposure on lipid peroxidation and antioxidant defense system in different regions of the rat central nervous system was investigated. An inhibition of acetylcholinesterase activity was used as an index of dichlorvos neurotoxicity. Dichlorvos exposure resulted in a significant decrease in glutathione peroxidase (GSHPx) activity. The decreased levels of both reduced and oxidized glutathione as observed following dichlorvos exposure affected the GSH/GSSG ratio. The results also supported that the enzymes superoxide dismutase (SOD) and catalase may enhance the disposal of potentially toxic free radicals. Furthermore, the decrease in GSH levels may be a mechanism for the detoxification of dichlorvos in the brain (Julka *et al.*, 1992).

#### *Chemiluminescence response by chlorpyrifos, fenthion, and other structurally diverse pesticides for generation of ROS*

The chemiluminescence assay is a non-specific test for the identification of ROS. The sustained chemiluminescence produced by brain tissues following treatment with chlorpyrifos, fenthion, and other pesticides including alachlor, chlordane, and endrin is presumably due to the continued production of ROS. The chemiluminescence responses produced following *in vitro* administration of these

**TABLE 20.4 Effects of pesticides on nuclear DNA-SSB in brain tissue and cultured PC-12 cells and lipid peroxidation (TBARS content) in Sprague–Dawley rats**

| | DNA-SSB (elution constant $\times 10^{-3}$) | | |
|---|---|---|---|
| Treatment | Brain tissue | Cultured PC-12 cells | TBARS (nmol/mg protein) |
| Control | 7.9 ± 2.1[a] | 3.4 ± 0.4[a] | 5.4 ± 0.6[a] |
| Endrin | 15.0 ± 2.3[b] | 8.5 ± 0.9[b] | 12.7 ± 0.9[b] |
| Chlordane | 13.0 ± 1.0[b,c] | 7.6 ± 0.7[b] | 11.4 ± 1.1[b] |
| Alachlor | 17.0 ± 1.7[b] | 7.2 ± 0.6[b] | 19.6 ± 1.3[c] |
| Fenthion | 11.0 ± 0.8[c] | 8.6 ± 0.3[b] | 28.6 ± 2.0[d] |
| Chlorpyrifos | 11.0 ± 1.6[c] | 8.3 ± 0.5[b] | 25.0 ± 2.1[d] |

Female Sprague–Dawley rats received two 0.25 $LD_{50}$ doses of the pesticides in corn oil at 0 and 21 h and killed at 24 h. Control animals received the vehicle. Effects of 100 nM concentrations of the pesticides on DNA-SSB of cultured PC-12 cells at 24-h post-treatment were determined. DNA-SSB were determined by the alkaline elution method and are expressed as DNA elution constants. Lipid peroxidation was determined as the content of TBARS, using MDA as the standard. Each value is the mean ±SD of at least four to six animals in each group. Values with non-identical superscripts are significantly different ($p < 0.05$).

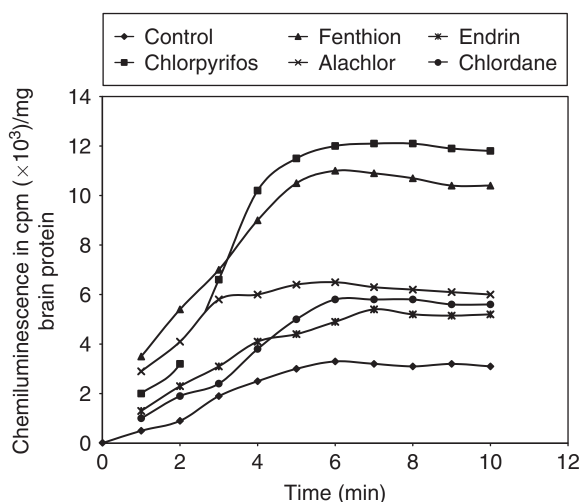

**FIGURE 20.1** Chemiluminescence production by brain homogenates *in vitro* following exposure to structure diverse pesticides.

pesticides in brain tissues are shown in Figure 20.1. The chemiluminescence response produced by brain homogenates from pesticide(s)-treated rats rapidly increases, reaching a maximum between 6 and 8 min of incubation, while brain homogenates from control animals reach a peak chemiluminescence at 6 min. The chemiluminescence persisted for over 10 min. Increases of 2.9- and 2.4-fold were observed in the chemiluminescence responses in the brain homogenates of the animals treated with chlorpyrifos and fenthion. The greatest chemiluminescence responses in brain tissues were induced by chlorpyrifos (Bagchi *et al.*, 1995b, 2002).

### *LDH leakage by chlorpyrifos, fenthion, and other pesticides*

Organophosphates produce toxicological problems due to their high environmental persistence and ability to accumulate in the adipose tissue. Organophosphates exhibit similar abilities as inducers of hepatic drug metabolizing enzymes (Viviani *et al.*, 1978), and act as potent competitive and stereospecific inhibitors of ligand binding to specific types of brain receptors (Botham, 1990).

As an index of membrane and cellular damage, the release of LDH from cultured PC-12 cells was measured as a function of concentration of the pesticides. Increased release of LDH into the media of cultured cells is an indicative of cellular and membrane damage. Cultured PC-12 cells were incubated in the presence of 0, 50, 100, or 200 nM of chlorpyrifos, fenthion, and other pesticides, and the release of LDH by the cells was measured after 24 h of incubation as an index of cytotoxicity. The amount of LDH released by these pesticides was concentration dependent. However, the differences in the release of LDH into the media were not significantly different at concentrations of 100 and 200 nM. Maximal release of LDH from cultured PC-12 cells was observed at 100 nM concentrations of the pesticides. Increases of 2.3-, 2.5-, 2.8-, 3.1-, and 3.4-fold were observed in LDH leakage following incubation of the PC-12 cells with endrin, chlordane, alachlor, chlorpyrifos, and fenthion, respectively (Table 20.5) (Bagchi *et al.*, 1995b, 2002).

A sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis study demonstrated the overexpression of 60 and 90 kDa protein in hepatic, brain, and lung tissues following treatment with structurally dissimilar pesticides (Figure 20.2). Enhanced expression of 90 kDa protein was also observed in cultured PC-12 cells following treatment with these pesticides (Figure 20.2) (Bagchi *et al.*, 1996b, 2002). Table 20.6 depicts the radioactivity ($P^{32}$ counts/min) associated with Hsp89$\alpha$ and Hsp89$\beta$ mRNA expression in control and pesticide-treated cultured PC-12 cells. The cultured PC-12 cells were incubated with 50, 100, or 200 nM concentrations of the pesticides and the concentration-dependent effects of the pesticides were determined. At various concentrations of alachlor, endrin, chlorpyrifos, and fenthion, the expression of Hsp89$\alpha$ and Hsp89$\beta$ significantly increased as compared to the control values.

**TABLE 20.5 Concentration-dependent effects of pesticides on the release of LDH from cultured PC-12 cells**

| Treatment | Concentration of LDH in the media (U LDH/l) | | |
|---|---|---|---|
| | 50 nM | 100 nM | 200 nM |
| Control | 77.4 ± 9.2[a] | 76.9 ± 10.3[a] | 79.2 ± 8.6[a] |
| Endrin | 123.8 ± 16.5[b,c] | 178.1 ± 11.6[b] | 183.6 ± 20.2[b] |
| Chlordane | 100.6 ± 9.8[b] | 193.5 ± 20.4[b,c] | 212.4 ± 19.5[b,c] |
| Alachlor | 131.7 ± 11.4[c] | 216.7 ± 19.3[c] | 230.3 ± 22.6[c] |
| Chlorpyrifos | 147.1 ± 15.3[c,d] | 239.9 ± 20.8[c,d] | 241.0 ± 25.7[c,d] |
| Fenthion | 162.5 ± 13.7[d] | 263.2 ± 24.6[d] | 266.5 ± 20.4[d] |

PC-12 cells ($25 \times 10^4$ cells/35-mm Petri-dish) in 2 ml of RPMI 1640 were incubated for at least 3 h to allow cell adherence and 50, 100, or 200 nM concentrations of pesticides were added to the cultures in two equally divided portions at 0 and 24 h. The incubation was continued at 37 °C in an atmosphere of 5% $CO_2$ for 24 h. Media were collected from the cultures and assayed for LDH activity. Data are expressed as the mean value of six experiments ±SD. Values with non-identical superscripts are significantly different ($p < 0.05$).

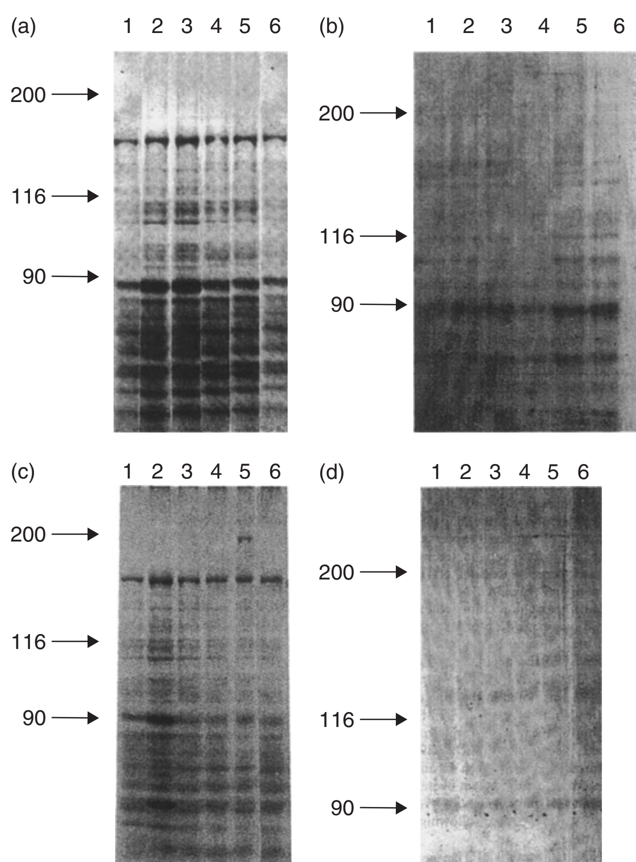

**FIGURE 20.2** SDS polyacrylamide gel electrophoresis of the hepatic (a), brain (b), and lung (c) tissues from control and pesticide-treated rats, and cell lysates (d) from control and pesticide-treated cultured PC-12 cells. Lanes as follows: 1, control sample; 2, alachlor-treated sample; 3, endrin-treated sample; 4, chlordane-treated sample; 5, chlorpyrifos-treated sample; and 6, fenthion-treated sample.

### *Genotoxicity of organophosphate*

The detection of genotoxicity caused by organophosphate pesticides has also been determined using the single-cell gel electrophoresis assay or comet assay. Chlorpyrifos and acephate were tested for their ability to induce *in vivo* genotoxic effect in leukocytes of Swiss albino mice (Rahman *et al.*, 2002). The mice were administered orally with doses ranging from 0.28 to 8.96 mg/kg body weight of chlorpyrifos, or 12.25 to 392.00 mg/kg body weight of acephate. A comet assay was performed on whole blood at 24, 48, 72, and 96 h. A significant increase in mean comet tail length indicating DNA damage was observed at 24-h post-treatment ($p < 0.05$) with both pesticides in comparison to cyclophosphamide (positive control) demonstrating the DNA damage was dose related. The mean comet tail length revealed a clear dose-dependent increase. A gradual decrease in mean tail length was noted from 48-h post-treatment. By 96 h of post-treatment the mean comet tail length reached control levels indicating repair of the damaged DNA.

Organophosphate-induced oxidative stress at the tubular level has been hypothesized as playing a role in the pathogenesis of acute tubular necrosis. Bidrin®, an organophosphate insecticide formulation with dicrotophos as the active ingredient, has been associated with renal tubular epithelial cell (LLC-PK1) toxicity. A study conducted by Poovala *et al.* (1999) assessed LDH release, $H_2O_2$ levels (μmol/mg protein per h), and malondialdehyde (MDA) formation (nmol/mg protein). Results showed LDH which significantly increased with concentration and time, after exposure of the cells to 1000, 1250, 1500, 1750, and 2000 ppm of Bidrin® for 6, 12, 24, and 48 h. Antioxidants 2-methylaminochroman (2-MAC) and desferrioxamine reduced cell damage induced by 1250 ppm of Bidrin® over a 24-h incubation. The greatest reductions in the percentage of LDH were produced by desferrioxamine 2 mM and 2-MAC 2.5 μM, both significantly lower than Bidrin® alone. $H_2O_2$ levels were significantly elevated after exposure to 1250 ppm of Bidrin®. Significantly increased MDA formation compared with control was also found in Bidrin®-exposed cells indicating enhanced lipid peroxidation. MDA generation was significantly

Cultured PC-12 ($1 \times 10^7$) cells were incubated individually with either 50, 100, or 200 nM of alachlor, chlordane, chlorpyrifos, or fenthion, and total RNA was isolated after 24 h using the guanidium isothiocyanate method. The RNAs were run on 1% agarose gels, transferred to nylon membranes, and Northern blot analyses were performed by using $^{32}P$-labeled HSP89$\alpha$ and HSP89$\beta$ probes. Values are expressed as mean counts/min ±SD of four to six animals. Values within each column with non-identical superscripts are significantly different ($p < 0.05$).

suppressed by 2-MAC and desferrioxamine. These results demonstrated that Bidrin® can cause direct tubular cytotoxicity, and implicate, at least in part, a role for ROS and accompanying lipid peroxidation in cytotoxicity.

### In vitro *and* in vivo *PKC activation by structurally diverse pesticides and chromium (VI) and cadmium (II)*

Various pesticides and transition metals induce oxidative deterioration of biological macromolecules in which PKC may play a major regulatory role. PKC is a family of isoenzymes with distinct roles in normal and pathogenic activities within cells. PKC is involved in signaling pathways mediating the regulation of many cell processes including cell differentiation, cell survival, gene expression, secretion, cytoskeletal function, and cell–cell interactions (Lord and Pongracz, 1995). Thus, PKC is involved in a cascade of events associated with cell regulation which is subject to both internal and external factors. A growing body of evidence indicates that free radicals and ROS may be involved in mediating signal transduction through interaction with PKC (Brawn *et al.*, 1995; Lander *et al.*, 1995). Recent studies have demonstrated that PKC is rapidly activated in cells following oxidative exposure (Brawn *et al.*, 1995). For example, the modulation of PKC activity by oxidant tumor promoters and the phorbol esters is well known (Prasad and Jones, 1992; Lord and Pongracz, 1995). The modulation of PKC by carbon tetrachloride has been shown to depend on the degree of oxidative unbalance provoked by various concentrations of this haloalkane.

The comparative *in vitro* and *in vivo* abilities of structurally diverse pesticides including TCDD, endrin, chlordane, lindane, dichlorodiphenyltrichloroethane (DDT), alachlor, chlorpyrifos, and fenthion, and chromium (VI) and cadmium (II) to modulate PKC activity were assessed in both cultured neuroactive PC-12 cells *in vitro* and in the brain tissues of these xenobiotics-treated animals (Bagchi *et al.*, 1996a, b, 1997).

**TABLE 20.7 Comparative PKC activity in female Sprague–Dawley rats following treatment with pesticides, cadmium chloride (Cd(II)), and sodium dichromate (Cr(VI)) in brain**

| Treatment | PKC activity/μg of protein/min |
|---|---|
| Control | 10.7 ± 1.1[a] |
| TCDD | 25.2 ± 2.9[b] |
| Endrin | 24.4 ± 3.7[b,c] |
| Chlordane | 20.8 ± 1.7[c] |
| Lindane | 22.0 ± 2.5[c] |
| DDT | 21.1 ± 1.6[c] |
| Alachlor | 19.1 ± 1.4[c,e] |
| Chlorpyrifos | 37.4 ± 4.2[d] |
| Fenthion | 35.4 ± 2.9[d] |
| Chromium (VI) | 16.7 ± 1.9[e] |
| Cadmium (II) | 26.4 ± 3.6[b] |

Female Sprague–Dawley rats were treated orally with two 0.25 $LD_{50}$ doses at 0 and 21 h with pesticides, cadmium chloride (Cd(II)), or sodium dichromate (Cr(VI)), and killed at the 24-h time point. PKC activity was monitored using a kit from Upstate Biotechnology, NY. Values with non-identical superscripts are significantly different ($p < 0.05$).

Approximately 2.0- to 3.5-fold increases in PKC activities in the brain tissues were observed as compared to the control tissues (Table 20.7). Concentration-dependent effect of these xenobiotics was observed on enhanced PKC activities (2.9- to 4.3-fold) in neuroactive pheochromocytoma PC-12 cells (Table 20.8). In these *in vitro* experiments, maximum activation of PKC was also observed primarily with 100 nM concentrations of these xenobiotics. No further increases in PKC activity were observed following treatment with 200 nM concentrations of these xenobiotics. Thus, organophosphates pesticides as well as these xenobiotics can modulate a vital component in the cell signaling pathway (Tables 20.7 and 20.8) (Bagchi *et al.*, 1997).

### *Developmental neurotoxicity of chlorpyrifos on cultured PC-12 and gliotypic C6 cells*

Studies have demonstrated that glial-type cells have been targeted by chlorpyrifos through the same multiple

**TABLE 20.8 Comparative PKC activity in cultured neuroactive PC-12 cells following treatment with pesticides, cadmium chloride (Cd(II)), and sodium dichromate (Cr(VI))**

| Treatment | PKC activity/μg of protein/min | | |
|---|---|---|---|
| | 50 nM | 100 nM | 200 nM |
| Control (DMSO) | 0.78 ± 0.08[a] | 0.77 ± 0.10[a] | 0.95 ± 0.13[a] |
| TCDD | 2.28 ± 0.16[b] | 2.31 ± 0.26[b] | 2.02 ± 0.15[b] |
| Endrin | 2.10 ± 0.12[b,c] | 2.45 ± 0.32[b] | 2.28 ± 0.32[b] |
| Chlordane | 1.87 ± 0.20[c] | 2.41 ± 0.16[b] | 2.12 ± 0.14[b] |
| Lindane | 1.37 ± 0.09[d] | 2.09 ± 0.24[b] | 2.21 ± 0.18[b] |
| DDT | 1.59 ± 0.22[d] | 2.44 ± 0.27[b] | 2.45 ± 0.21[b] |
| Chlorpyrifos | 2.26 ± 0.20[b] | 3.31 ± 0.38[c] | 3.22 ± 0.40[c] |
| Fenthion | 1.88 ± 0.14[c] | 3.26 ± 0.43[c] | 3.12 ± 0.35[c] |
| Alachlor | 1.86 ± 0.24[c] | 2.37 ± 0.28[b] | 2.33 ± 0.17[b] |
| | 0.2 μM | 0.4 μM | 0.6 μM |
| Chromium (VI) | 1.95 ± 0.22[c] | 3.17 ± 0.37[c] | 3.21 ± 0.32[c] |
| Cadmium (II) | 1.21 ± 0.14[d] | 2.95 ± 0.32[c] | 2.88 ± 0.30[c] |

Cultured cells were treated individually with 50, 100, or 200 nM concentrations of pesticides, or 0.2, 0.4, or 0.6 μM concentration of cadmium chloride (Cd(II)) or sodium dichromate (Cr(VI)) in two equally divided concentrations at 0 and 21 h and incubated at 37°C. PKC activity was monitored using a kit from Upstate Biotechnology, NY at the 24-h time point. Values with non-identical superscripts are significantly different ($p < 0.05$).

mechanisms that have been demonstrated for the effects of chlorpyrifos on brain development *in vivo* (Garcia *et al.*, 2001). Post-neurogenesis, glial development continues and given that chlorpyrifos targets events in both glial cell replication and the later stages of differentiation, the vulnerable period for developmental neurotoxicity of chlorpyrifos is likely to extend well into childhood or even early adolescence. Early *in vitro* studies have also demonstrated the methods causing neurotoxicity by chlorpyrifos, by means of assessment of cultures of immature brain tissue (Roy *et al.*, 1998; Monnet-Tschudi *et al.*, 2000) or transformed neural cell lines, such as neuronotypic PC-12 cell lines. PC-12 cell lines are less receptive to neurotoxins and have shown to effectively establish cell replication as a major target because they maintain a fixed pattern of mitosis until differentiation is triggered by addition of trophic factors and deletion of serum (Crumpton *et al.*, 2000). To demonstrate the antimitotic effects of chlorpyrifos, a study in two *in vitro* models, PC-12 cells and gliotypic C6 cells were compared (Qiao *et al.*, 2001). In the first set of experiments, PC-12 and gliotypic C6 cells were exposed to chlorpyrifos or chlorpyrifos metabolites for 1 h in the absence of serum, to obviate any potential protective effect of serum proteins (Garcia *et al.*, 2001) selecting a chlorpyrifos concentration (30 μM) which was previously found to cause robust but submaximal inhibition of DNA synthesis *in vitro*. Equimolar concentrations of chlorpyrifos oxon also produced significant inhibition of DNA synthesis, again with gliotypic C6 cells showing a greater effect than PC-12 cells; however, chlorpyrifos oxon was also significantly less effective than was chlorpyrifos itself (Monnet-Tschudi *et al.*, 2000).

The effects of chlorpyrifos were also compared to those of other cholinesterase inhibitors, using equivalent concentrations (30 μM) of each compound demonstrated that both diazinon, an organophosphate, and physostigmine, a competitive cholinesterase inhibitor, caused significant inhibition of DNA synthesis in gliotypic C6 cells. For PC-12 cells, diazinon caused a significant decrement, though smaller than the effect of chlorpyrifos, and physostigmine was ineffective. The current results are consistent with previous concepts where it was demonstrated that chlorpyrifos exerts antimitotic actions on developing neural cells independently of cholinesterase inhibition (Pope, 1999; Slotkin, 1999). It was also observed that chlorpyrifos was more effective than chlorpyrifos oxon, despite the fact that the latter is a far more potent cholinesterase inhibitor.

The effects of chlorpyrifos and its major metabolites in two *in vitro* models, PC-12 cells and gliotypic C6 cells showed chlorpyrifos inhibited DNA synthesis in both cell lines but had a greater effect on gliotypic cells. Chlorpyrifos oxon, the active metabolite that inhibits cholinesterase, also decreased DNA synthesis in PC-12 and gliotypic C6 cells with a preferential effect on the latter. However, diazinon, another organophosphate pesticide, also inhibited DNA synthesis with predilection toward gliotypic C6 cells, was less effective than was chlorpyrifos. It was also found that the addition of sera protected the cells from the adverse effects of chlorpyrifos and that the effect could be reproduced by addition of albumin. These results indicate that chlorpyrifos and other organophosphates such as diazinon have immediate, direct effects on neural cell replication, preferentially for gliotypic cells. In light of the protective effect of serum proteins, the fact that the fetus and newborn possess lower concentrations of these proteins suggests that greater neurotoxic effects on them and may occur at blood levels of chlorpyrifos that are non-toxic to adults (Aschner, 1999; Monnet-Tschudi *et al.*, 2000; Garcia *et al.*, 2001).

Adverse effects of chlorpyrifos on glial cell replication are of critical importance in defining the sensitive period for effects on central nervous system development. Glia cells provide nutritional, structural, and homeostatic support essential to architectural modeling of the brain (Morita *et al.*, 1999; Barone *et al.*, 2000) and because glial development continues well into the postnatal period, glial targeting implies a prolonged vulnerability, extending into childhood. Chlorpyrifos administration *in vivo* inhibits DNA synthesis and causes loss of brain cells during gliogenesis (Dam *et al.*, 1998) with maximal effects on neural functions appearing during peaks of glial development (Monnet-Tschudi *et al.*, 2000). In aggregating brain-cell cultures, chlorpyrifos affects glial markers, again unrelated to cholinesterase inhibition (Monnet-Tschudi *et al.*, 2000). The above results thus confirm conclusively that chlorpyrifos, rather than its active metabolite, chlorpyrifos oxon, is the primary agent in these effects (Bagchi *et al.*, 2006).

Taking together, TCDD, endrin, chlordane, lindane, alachlor, naphthalene, Cr(VI), and Cd(II) are environmental as well as industrial pollutants, and extensive research has provided evidence that ROS and oxidative stress are involved in the toxicity of these xenobiotics in the brain tissues.

## Naphthalene: a bicycylic aromatic hydrocarbon

Naphthalene is widely used in various commercial and industrial applications including lavatory scent disks, soil fumigants, and moth balls. Exposure to naphthalene is associated with the development of hemolytic anemia in humans and laboratory animals (Germansky and Jamall, 1988). The toxic manifestations induced by naphthalene appear to involve the conversion of naphthalene to the naphthoquinones as 1,2-naphthoquinone and 1,4-naphthoquinone (Lubek *et al.*, 1989) as well as hydroxylated products including 1-naphthol, 2-naphthol, and 1,2-dihydro-1,2-dihydroxynaphthalene (Seaton and Tjeerdema, 1995). In general, quinones are believed to be toxic by a mechanism involving redox cycling and oxidative stress. The role of ROS in the cytotoxicity of various quinine derivatives has been reviewed extensively. Menadione (2-methyl-1,4-naphthoquinone) has been the most extensively studied model compound with respect to the toxicity of quinones and naphthoquinones (Stohs, 1995).

### *Naphthalene-induced membrane microviscosity*

In a study by Vuchetich *et al.* (1996), membrane fluidity studies were performed on mitochondrial and microsomal membranes of brain tissues by steady-state fluorescence spectroscopy. The membranes were treated with 0.5 mM diphenyl-hexatriene (DPH) in tetrahydrofuran as the fluorescent probe and incubated for 2 h at 37°C. The membranes were kept at 4°C for 3–5 h for complete incorporation of DPH. Fluorescence polarization, a measure of membrane fluidity, was determined at 25°C with a Perkin-Elmer spectrofluorometer equipped with perpendicular and parallel polarizers, using an excitation wavelength of 365 nm and an emission wavelength of 430°nm. Fluorescence polarization and the apparent microviscosity were calculated as described by Shintzky and Barrenholz (1978) and Bagchi *et al.* (1992) (Table 20.9).

| NAP + VES | 0.208 ± 0.009[c] | 114 | 0.220 ± 0.005[d] | 123 |
| *48 h* | | | | |
| Control | 0.182 ± 0.005[a] | – | 0.160 ± 0.011[a] | |
| VES | 0.073 ± 0.290[a] | 95 | 0.121 ± 0.019[b] | 76 |
| NAP | 0.259 ± 0.022[d] | 142 | 0.210 ± 0.012[c] | 131 |
| NAP + VES | 0.211 ± 0.065[c,d] | 116 | 0.170 ± 0.035[d] | 106 |

Female Sprague–Dawley rats were individually treated with vitamin E succinate (VES) 100 mg/kg for 3 consecutive days and 40 mg/kg on days 4, 5, 6, and 7. Naphthalene (NAP) (1100 mg/kg) in corn oil was administered on day 4, 2 h after VES, and the animals were killed 12, 24, 48, and 72 h after NAP administration. Control animals received the corresponding vehicle. Each value represents the mean ±SD of four to six animals. Values within each column with non-identical superscripts are significantly different ($p < 0.05$).

The ability of naphthalene to induce an oxidative stress was determined by measuring lipid peroxidation (TBARS), DNA-SSB, glutathione depletion, and membrane microviscosities of the brain tissues. The effects of administering naphthalene (1100 mg/kg) and/or vitamin E succinate to rats were assessed on lipid peroxidation in brain mitochondria and microsomes. Following naphthalene administration, maximum increases in lipid peroxidation in brain subcellular fractions were observed at the 12-h time point. Increases in lipid peroxidation of 2.4- and 2.0-fold occurred at 12-h post-treatment were observed in the brain mitochondria and microsomes, respectively, as compared to control values (Bagchi *et al.*, 1998a).

The results indicate that naphthalene induces the production of ROS. The ROS produced may lead to enhanced lipid peroxidation, as well as other cell-damaging effects, including membrane and DNA damage and glutathione depletion, contributing to the toxic manifestations of naphthalene. The administration of vitamin E succinate significantly attenuates these effects following an acute dose of naphthalene in rats (Table 20.10).

In another study, low-dose (0.05 $LD_{50}$) chronic effects of naphthalene (110 mg/kg/day p.o. in corn oil) were investigated for 120 consecutive days on increased lipid peroxidation and DNA fragmentation in brain tissues of female Sprague–Dawley rats. The results of this study demonstrated the low dose, chronic administration of naphthalene may induce an oxidative stress leading to brain lipid peroxidation and DNA fragmentation (Bagchi *et al.*, 1998a, b).

## Tobacco and neurotoxicity

The use of tobacco products constitutes the most significant cause of morbidity and mortality in the world causing respiratory disease, cancer, and cardiovascular diseases related to atherosclerosis and stroke leading to neuronal injury (Euler *et al.*, 1996). Tobacco smoke is a complex mixture of more than 3800 known components including a variety of trace elements, many of which are implicated in free-radical-producing reactions, and subsequently lead to the formation of highly reactive secondary radicals and toxic organic products (Deliconstantinos *et al.*, 1994a). Nitric oxide may be the most important free radical in the gas phase of tobacco smoke, and may participate in the formation of other free radicals (Deliconstantinos *et al.*, 1994b). Other free radicals present in tobacco smoke include carbon-centered radicals as isoprene radicals, alkoxyl radicals, peroxyl radicals,

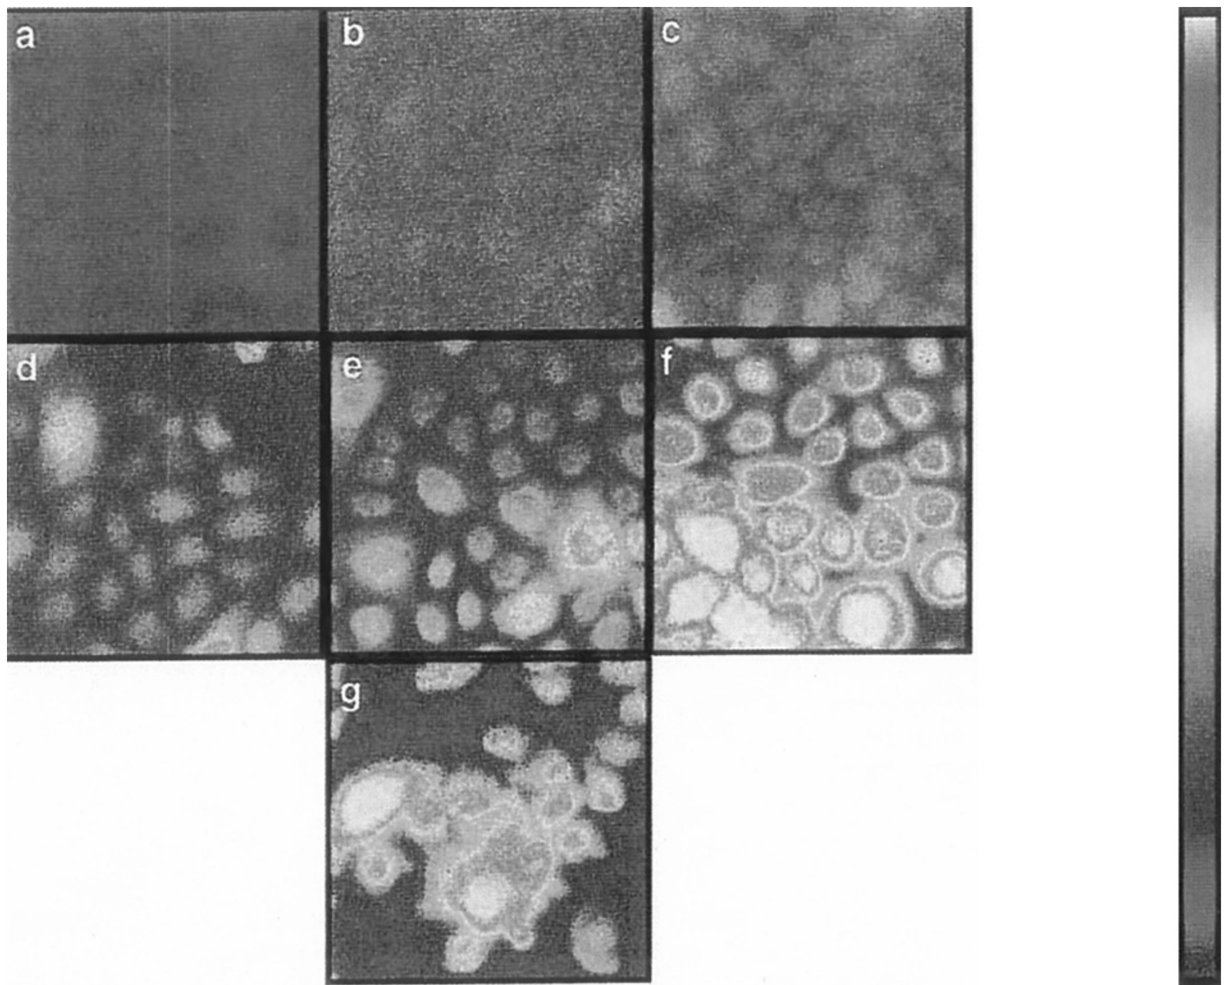

**FIGURE 20.3** Changes in intracellular redox states of human cells after treatment with a tobacco extract. Cells (70% confluent) were treated with the tobacco extract for 24 h. After 24 h, medium was replaced with fresh medium containing 5 μm 2,7-dichlorofluorescein diacetate and fluorescence intensity was measured 5 m later at 513 nm with a confocal laser scanning microscope. a, Control; b, 100 μg/ml; c, 150 μg/ml; d, 200 μg/ml; e, 250 μg/ml; f, 300 μg/ml; and g, 3 mM hydrogen peroxide (positive control). This figure is reproduced in color in the color plate section.

superoxide anion, hydrogen peroxide, nitrogen dioxide, and peroxynitrite radical (Pryor and Stone, 1993). The peroxynitrite radical is formed from the condensation of superoxide anion and nitric oxide.

The ability of tobacco to induce the production of ROS and an oxidative stress is demonstrated in Figure 20.3 (Bagchi *et al.*, 1999). Human oral keratinocytes were incubated with an aqueous extract of tobacco for 24 h, and the cells were treated with 2,7-dichlorofluoroscein diacetate as the fluorescent probe. The cells were then examined by scanning laser confocal microscopy. The cells had been incubated with the following concentrations of the tobacco extract: a, control; b, 100 μg/ml; c, 150 μg/ml; d, 200 μg/ml; e, 250 μg/ml; f, 300 μg/ml; and g, 3 mM hydrogen peroxide (positive control). The hydrogen peroxide was used as a positive control. A concentration-dependent increase in fluorescence intensity occurred was demonstrated, indicating an increase in the intracellular oxidized states of the cells (data not shown). The relative intensities of the fluorescence were quantitated, and a concentration-dependent increase in oxidative states was observed in the cells. Results indicated that tobacco products can initiate the formation of ROS and produce an increase in the intracellular oxidized state of exposed cells. ROS may also be produced in smokers by phagocytic and neuronal cells that are activated in response to enhanced ROS production as a result of exposure to various constituents in tobacco smoke (Anderson, 1991; Becker *et al.*, 1996; Bagchi *et al.*, 1999).

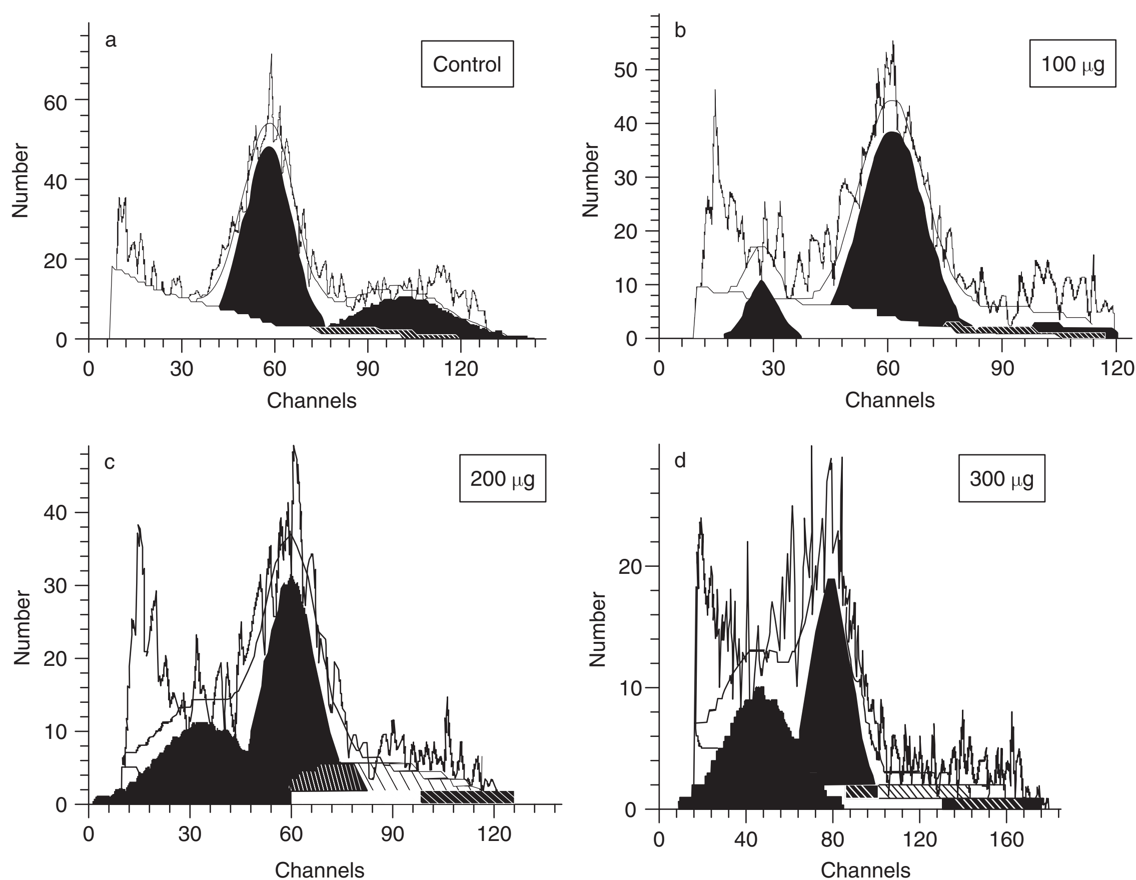

**FIGURE 20.4** Flow cytometric analysis of cell cycle distribution and apoptosis in human cells in response to increasing concentrations of tobacco extract. Primary keratinocytes were grown approximately 70% confluence and then treated with various concentrations of tobacco extract for 24 h. Following incubation, the cells were removed from culture surfaces by trypsinization and DNA content and apoptosis were determined using the method of Bagchi *et al.* (1999). a, control; b, tobacco extract (100 μg/ml); c, tobacco extract (200 μg/ml); and d, tobacco (300 μg/ml).

### *DNA cell cycle modulation and apoptotic cell death*

Concentration-dependent effects of tobacco extract on apoptotic cell death of human cells were determined using flow cytometry (Figure 20.4). The cells were incubated with tobacco extract for 24 h prior to labeling with propidium iodide. The percentages of the apoptopic peak (cell death) increased with increasing concentrations tobacco extract. The percentages of the cells exhibiting apoptotic cell death as analyzed by ModFit cell cycle analysis were approximately 0%, 9%, 29%, and 35% when cells were treated with 0, 100, 200, and 300 μg/ml of tobacco extract, respectively. A distinct loss of cells in the G2-M phase coincides with the appearance of the apoptotic cell population. The results indicate that tobacco treatment to human cells enhanced the production of free radicals which may initiate destructive pathways via indirect mechanism (Bagchi *et al.*, 1999).

## ROLES OF OXIDATIVE STRESS, GLUTATHIONE DEPLETION, HSP AND MITOCHONDRIAL DYSFUNCTION IN NEURODEGENERATIVE DISEASES

Oxidative stress has been extensively studied in neurological diseases including Alzheimer's disease, Parkinson's disease, multiple sclerosis, amyotrophic lateral sclerosis, and Huntington's disease. Compared with other organs, the brain is believed to be particularly susceptible to the damaging affects of ROS due to its high metabolic rate and relatively reduced capacity for cellular regeneration. Neuronal cells are especially susceptible to oxidative stress and subsequent damage including cell death. In a study conducted by Urano *et al.* (1997) active oxygen species have been shown to induce oxidative damage to the nervous system. Results suggested that free radicals derived from oxygen may attack nerve terminals and peroxidize the

plasma membrane. However, in response to the oxidative stress, the status of the defense system in synapse, i.e. the concentration of vitamin E, activities of SOD, and GSHPx changed, and that many of the changes observed were reduced remarkably by the intraperitoneal administration of vitamin E prior to stress. Therefore, results also supports the idea that vitamin E contributes to the protection against nerve dysfunction caused by oxidative stress (Urano *et al*., 1997).

In cases of Parkinson's disease, Alzheimer's disease, and amyotrophic lateral sclerosis, various indices of ROS damage have been reported within the specific brain region that undergoes selective neurodegeneration. For example, markers for lipid peroxidation, such as 4-hydroxynonenal (4-HNE) and MDA, have been identified in the cortex and hippocampus of patients with Alzheimer's disease, the substantia nigra of patients with Parkinson's disease and in spinal fluid from patients with amyotrophic lateral sclerosis (Butterfield *et al*., 2002). Protein nitration, a marker of protein oxidation, has also been demonstrated to be elevated in the hippocampus and neocortex of individuals with Alzheimer's disease, in lewy bodies in cases of Parkinson's disease and within motor neurons in amyotrophic lateral sclerosis (Smith *et al*., 1997).

Alternative explanations for the pathogenesis of neurodegenerative diseases include subsequent depletion or reduced function of necessary antioxidant enzymes. Antioxidant enzymes such as SOD, catalase, GSHPx, and glutathione reductase (GSHRd) display reduced activities in affected brain regions in Alzheimer's disease (Behl, 1999). Glutathione and oxidized glutathione depletion is the earliest known biochemical indicator of substantia nigral degeneration (Behl, 1999).

## Depletion of glutathione

Oxidative stress may be initiated by a decline in the antioxidative defense system or oxidative stress caused by other factors may decrease the concentrations of antioxidants. Alterations of antioxidant defenses support the hypothesis that oxidative stress may play an important role in the pathophysiology of Parkinson's disease. The most robust and significant alteration in the antioxidant defense is a decrease in GSH concentration. Initially, a complete absence of GSH in the presence of high GSSG concentrations was reported (Perry and Yong, 1986; Perry *et al*., 1988).

## Glutathione transferases

Glutathione transferase is a group of detoxification enzymes involved in the metabolism of pesticides and other toxins. Glutathione transferases have direct antioxidant activity and are involved in the metabolism of dopamine. The activity of glutathione transferase has been reported to be normal in the brains of Parkinson's disease patients. Although there is no association between idiopathic Parkinson's disease and glutathione transferase polymorphism, the distribution of the glutathione transferase 1 genotype differed significantly between patients and controls that had been exposed to pesticides (Menegon *et al*., 1998). Therefore, glutathione transferase 1, which is expressed in the blood–brain barrier, may influence response to neurotoxins and may explain the susceptibility of some people to the parkinsonism-inducing effects of pesticides.

## Roles of ROS, HSP, and neurodegenerative diseases

The concept that oxidative stress occurs in Parkinson's disease derives primarily from the fact that the metabolism of dopamine, by chemical or enzymatic means, can generate free radicals and other ROS. Auto-oxidation of dopamine leads to the formation of neuromelanin and can generate quinone and semiquinone species and other ROS. Perhaps more importantly, enzymatic oxidation of dopamine catalyzed by monoamine oxidase leads to the formation of hydrogen peroxide ($H_2O_2$) as well as its deaminated metabolites 3,4-dihydroxybenzoic acid (DOPAC) and homovanillic acid (HVA). Normally, $H_2O_2$ is inactivated by catalase or by GSHPx in a reaction in which GSH is used as a cosubstrate. Because catalase is compartmentalized into peroxisomes the detoxification of cytosolic and mitochondrial peroxides depends predominantly on GSHPx. $H_2O_2$ can react with $Fe^{2+}$ and forms the highly reactive and cytotoxic hydroxyl radical ($^{\bullet}OH$) via the Fenton reaction. The situation is likely to be self-perpetuating because dopamine depletion caused by a decrease in dopamine neurons leads to a compensatory increase in dopamine turnover, with increased formation of $H_2O_2$ and increased demands on the glutathione system in the remaining neurons. This hypothesis is supported by experimental studies demonstrating that enhanced dopamine turnover is associated with increased formation of oxidized glutathione (GSSG) which, in turn, can be prevented by inhibitors of dopamine metabolism (Spina and Cohen, 1989). A variety of critical biomolecules, including lipids, proteins, and DNA, can be damaged by ROS, thereby potentially leading to neurodegeneration.

Increased oxidative alterations to proteins such as $\alpha$-synuclein in Parkinson's disease, $\beta$-amyloid (A$\beta$) in Alzheimer's disease, and SOD1 in amyotrophic lateral sclerosis might result in increased protein misfolding and impaired degradation. This, in turn, might cause the toxic accumulation of soluble protofibrils or insoluble aggregates within the diseased brain that can contribute to neurodegeneration. Oxidative stress increases with age in the brain, and neurons might be particularly affected because they are postmitotic. The ability of cells to respond to

oxidative protein damage also seems to decline with age and might contribute to protein buildup. A decline in induction of HSPs, for instance, can result in an increase in oxidatively damaged proteins that might be resistant to ubiquitinylation and degradation by the 26S proteasome. Depletion of soluble HSPs has been proposed to be an important influence in the cellular neurodegeneration that is associated with amyotrophic lateral sclerosis. Indeed, pharmacological induction of HSPs by the agent arimoclomol has recently been demonstrated to slow disease progression in amyotrophic lateral sclerosis – SOD1 transgenic mouse models (Kieran *et al*., 2004). Increased expression of HSP70 has been suggested to protect against the toxic effects associated with human Parkinson's disease mutations in both the $\alpha$-synuclein and parkin genes, including oxidative damage that results in protein misfolding (Takeuchi *et al*., 2002; Winklhofer *et al*., 2003).

### Roles of oxidative stress and mitochondrial dysfunction in neurodegenerative diseases

Epidemiological studies have identified certain environmental agents, including pesticides and herbicides, as being risk factors for Parkinson's disease. Animals that are treated with the insecticide rotenone display selective neuropathology that is extremely reminiscent of the disease state (Betarbet *et al*., 2006). Both 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) and rotenone are selective complex I inhibitors. Complex I inhibition by MPTP can directly result in increased oxidative stress, particularly through the production of $O_2^{-\bullet}$. It also results in reduced mitochondrial function, including decreased ATP generation. ATP depletion can result in increased cytoplasmic dopamine levels, which might in turn result in indirect production of oxidative stress through the generation of dopamine oxidation by-products (German *et al*., 2000).

## PATHOPHYSIOLOGY OF NEURODEGENERATIVE DISEASES

Substantial evidence that oxidative stress is either a causative or an ancillary factor in the pathogenesis of major neurodegenerative diseases, including Parkinson's disease (Ebadi *et al*., 1996), Alzheimer's disease (Behl, 1999), and amyotrophic lateral sclerosis (Hall *et al*., 1998), as well as in cases of stroke, trauma, and seizures (Facchinetti *et al*., 1998). Important new data showing the role of free-radical damage in transmissible spongiform encephalopathies has also come to light. In Parkinson's diseased patients, decreased levels of antioxidant enzyme activities have been found (Fahn and Cohen, 1992) and evidence of oxidative stress in the form of increased lipid peroxidation and oxidation of DNA bases is seen in the substantia nigra, the area of the brain affected by Parkinson's disease (Jenner, 1996). Similar increased lipid peroxidation and oxidation of DNA and proteins are seen in Alzheimer's disease (Retz *et al*., 1998).

### Alzheimer's disease

Alzheimer's disease is the most common neurodegenerative disorder worldwide. In the United States alone, approximately 4.5 million people suffer from this devastating condition and affect almost half of all patients with dementia. The 2–3% of persons aged 65 years show signs of the disease; while 25–50% of persons aged 85 years have symptoms. Alzheimer's disease is characterized clinically by progressive cognitive deterioration together with declining activities of daily living and neuropsychiatric symptoms or behavioral changes. Early symptom is amnesia that becomes steadily more pronounced with illness progression, with relative preservation of older memories. As the disorder progresses, extensive cognitive impairment includes aphasia, apraxia, agnosia, and frontal lobe functions such as decision-making and planning.

Alzheimer's disease consists principally of neuronal loss or atrophy of the hippocampus and cerebral cortex together with the deposition of an abnormal protein or A$\beta$ in the form of extracellular amyloid (or senile) plaques and intracellular neurofibrillary tangles of abnormally hyperphosphorylated tau protein (Selkoe, 2003). Amyloid plaques contain small, toxic cleavage products, denoted as A$\beta$40 and A$\beta$42 of the APP. The apoE4 (apolipoprotein E4) genotype is a powerful risk factor for developing Alzheimer's disease, and it may possibly affect A$\beta$ deposition and neurofibrillary tangle formation (Roses, 1996).

#### *Glutathione in Alzheimer's disease*

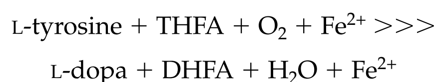
Strong evidence that oxidative stress is involved in the pathogenesis of Alzheimer's disease comes from a clinical study showing that oral vitamin E intake delayed progression in patients with moderately severe impairment from Alzheimer's disease (Sano *et al*., 1997). A role of oxidative stress in Alzheimer's disease is further supported by increased levels of TBARS, a measure of lipid peroxidation (Lovell *et al*., 1995; Marcus *et al*., 1998). However, studies reporting a disturbance of glutathione homeostasis are less clear. The total brain levels of glutathione appeared to be unaffected in Alzheimer's disease (Perry *et al*., 1987), whereas GSHPx and GSSG reductase were found to be elevated in different brain regions (Lovell *et al*., 1995) or unchanged (Marcus *et al*., 1998). Transcription of GSH peroxidase and GSSG reductase was elevated in hippocampus and inferior parietal lobule, but not in cerebellum of

Alzheimer's disease patients, which may reflect the protective gene response to the increased peroxidation in the brain regions showing severe Alzheimer's disease pathology (Aksenov *et al*., 1998). 4-HNE, one marker of lipid peroxidation, is neurotoxic in neuronal culture and *in vivo* and is elevated in Alzheimer's disease brain and cerebrospinal fluid (CSF). The levels of glutathione transferase, a protective enzyme against aldehydes and especially 4-HNE were decreased in the brain and ventricular CSF of autopsied Alzheimer's disease and normal control subjects (Lovell *et al*., 1998). Together these data imply that oxidative stress plays an important role in the pathogenic process but that alterations in the glutathione system are secondary to other events leading to neurodegeneration.

## Parkinson's disease

Parkinson's disease also known as paralysis agitans is the most common neurodegenerative movement disorder. According to the CDC's National Center for Health Statistics (NCHS), approximately 1% of the United States population older than 65 years suffers from this slowly progressive neurodegenerative disease. Although uncommon, cases of Parkinson's disease have been reported at all ages, even as low as 11. It occurs in all parts of the world, but appears to be more common in people of European ancestry than in those of African ancestry. Those of East Asian ancestry have an intermediate risk. It is more common in rural than urban areas and men are affected slightly more often than women. About 2% of the population develops the disease some time during life.

Parkinson's disease is primarily due to the insufficient formation and action of dopamine, a substance produced in the dopaminergic neurons in the brain. The disease was first formally recognized and documented in 1817 in *An Essay on the Shaking Palsy* by the British physician Dr. James Parkinson. The biochemical changes in the brain of Parkinson's disease patients were identified in the 1960s. Parkinson's disease or "shaking palsy" is a brain disorder that causes muscle tremor, stiffness, and weakness. Early symptoms of Parkinson's disease include muscular stiffness, fatigue, and trembling that usually begins with a slight tremor in the hand, arm, or leg. As the disease progresses, muscle dysfunctions occur such as stiffness, weakness, trembling, and rigidity. In the later stages of Parkinson's disease the affected person loses the ability to control their movements, making everyday activities hard to manage, and the intellect begins to be affected by the disease. About one-third of Parkinson's disease sufferers eventually show signs of dementia. The disease runs an average 10-year course and ultimately results in death usually by an infection or aspiration pneumonia. Selective and progressive degeneration of pigmented dopaminergic neurons in the substantia nigra pars compacta is the principal pathology that underlies Parkinson's disease. Pathological changes to the dopamine neurons of the substantia nigra pars compacta are also thought to be involved in schizophrenia and psychomotor retardation sometimes seen in clinical depression. Several reasons for the death of dopamine neurons include age-related liver deficiency, genetic influences, viral infections such as encelphalitis, or environmental toxins. Some studies have suggested free-radical damage may also play a part in Parkinson's disease by allowing dopamine to be lost via oxidation and may lead to further neuronal damage (Xu *et al*., 2002). Cellular damage occurs due to the lack of L-dopa formation, the metabolic precursor of dopamine. Normal L-dopa formation occurs as a result of the following reaction from L-tyrosine and tetrahydrofolate (THFA) (product of vitamin folic acid and nicotinamide; DHFA, dihydrofolate):



$$\text{L-tyrosine} + \text{THFA} + O_2 + Fe^{2+} >>> \text{L-dopa} + \text{DHFA} + H_2O + Fe^{2+}$$

However, lack of L-tyrosine or THFA will result in the unsuccessful formation of L-dopa. In a THFA-deficient reaction, superoxide anion formation occurs in the following reaction:

$$\text{L-tyrosine} + Fe^{2+} + O_2 >>> \text{L-tyrosine} + Fe^{3+} + O_{-2}$$

### *Glutathione and oxidative phosphorylation in Parkinson's disease*

The mutual effects of glutathione homeostasis and inhibition of oxidative phosphorylation in the pathogenesis of Parkinson's disease were also studied. However, whether a decrease in glutathione precedes the defect of oxidative phosphorylation or conversely remains controversial. Past research in Parkinson's disease patients demonstrated a defect in oxidative phosphorylation via decrease in complex I activity of the electron transport chain in the substantia nigra (Schulz and Beal, 1994). However, in a contrasting study, depletion of glutathione by buthionine sulphoximine (BSO) produces enlargement and degeneration of mitochondria in neonatal rats (Jain *et al*., 1991) and a decrease in the activity of complexes I and IV in weaning rats (Heales *et al*., 1995); therefore, disputing that pathogenesis of Parkinson's disease results from the primary dysfunction of glutathione homeostasis and secondary inhibition of oxidative phosphorylation.

A recent study in the intersecting pathways to neurodegeneration in Parkinson's disease was studied in the relationship of mitochondrial impairment at complex I, oxidative stress, as well as the aggregation of Parkinson's-disease-related gene $\alpha$-synuclein, and dysfunctional protein degradation. Betarbet *et al*. (2006) evaluated the pathogenesis Parkinson's disease in *in vivo* and *in vitro* models of chronic low-grade complex I inhibition with the pesticide

rotenone. Chronic rotenone exposure *in vivo* caused oxidative modification of DJ-1, a gene linked to Parkinson's disease, accumulation of $\alpha$-synuclein, and proteasomal impairment. The effects became more regionally restricted such that systemic complex I inhibition eventually resulted in highly selective degeneration of the nigrostriatal pathway, one of the major dopamine pathways in the brain. DJ-1 modifications, $\alpha$-synuclein accumulation, and proteasomal dysfunction were also seen *in vitro* and these effects could be prevented with $\alpha$-tocopherol. Thus, chronic exposure to a pesticide and mitochondrial toxin brings into play three systems, DJ-1, $\alpha$-synuclein, and the ubiquitin–proteasome system, and thus implies that mitochondrial dysfunction and oxidative stress link environmental and genetic forms of the disease (Betarbet *et al*., 2006).

## Huntington's disease

Huntington's disease or Huntington's chorea is an autosomal-dominant inherited neurodegenerative disorder characterized by abnormal body movements and a reduction of various mental abilities. Huntington's disease was discovered by the Ohio physician George Huntington who first described it in 1872. Afflicted individuals lose their ability to walk, talk, think, and reason and may become depressed, and lose their short-term memory capacity. Huntington's disease affects males and females equally and crosses all ethnic and racial boundaries. It typically begins in mid-life, between the ages of 30 and 45 years, though onset may occur as early as the age of 2 years. Children who develop the juvenile form of the disease rarely live to adulthood. In the United States alone, about 30,000 people have Huntington's disease and at least 150,000 others have a 50 percent risk of developing the disease (National Institute of Neurological Disorders and Stroke, 2006).

Clinical cases of Huntington's disease illustrate selective neuronal dysfunction and subsequent loss of neurons in the striatum, cerebral cortex, and other parts of the brain. Several mechanisms of neuronal cell death have been proposed for Huntington's disease, including excitotoxicity, oxidative stress, impaired energy metabolism, and apoptosis. Excitotoxicity refers to the neurotoxic effect of excitatory amino acids in the presence of excessive activation of postsynaptic receptors. Oxidative stress in Huntington's disease is caused by the presence of large amounts of free radicals or highly reactive oxygen derivatives and may occur as a consequence of mitochondrial malfunction or excitotoxic cell death. Striatal damage induced by quinolinic acid can be ameliorated by the administration of spin-trap agents, which reduce oxidative stress, providing indirect evidence for the involvement of free radicals in excitotoxic apoptosis.

Candidate treatments to slow the progression of the disease are under study, yet have been slow to reach Huntington's disease patients. According to recent research, eicosapenaenoic acid (EPA) an omega-III fatty acid has shown to slow and possibly reverse the progression of the disease. In the United States, it is available over the counter in lower concentrations in omega-III and fish oil supplements. Other agents and measures such as creatine, CoQ10, the antibiotic minocycline, trehalose, exercise, antioxidant-containing foods and nutrients, and select dopamine antagonists, such as tetrabenazine might also slow the progress of Huntington's disease.

## Amyotrophic lateral sclerosis

Amyotrophic lateral sclerosis also known as Lou Gehrig's disease or Maladie de Charcot, is a progressive, and perpetually fatal motor neuron disease. Amyotrophic lateral sclerosis involves degeneration of both the upper and lower motor neurons resulting in progressive muscle, weakness, fasciculation, and atrophy. Eventually, all muscles under voluntary control are affected resulting in paralysis and respiratory failure. Most people with amyotrophic lateral sclerosis die from respiratory failure within 3–5 years from the onset of symptoms. Amyotrophic lateral sclerosis is one of the most common neuromuscular diseases worldwide which affects people of all races and ethnic backgrounds. As many as 30,000 Americans have amyotrophic lateral sclerosis, and an estimated 5000 people in the United States are diagnosed with the disease each year.

Amyotrophic lateral sclerosis is associated with mutations in the gene that produces the SOD1 enzyme. SOD1 is a powerful antioxidant that protects the body from damage caused by free radicals. Although it is not yet clear how the SOD1 gene mutation leads to motor neuron degeneration, researchers have theorized that an accumulation of free radicals may result from the faulty functioning of this gene. Animal studies have shown that motor neuron degeneration and deficits in motor function accompany the presence of the SOD1 mutation. However, studies involving transgenic mice have yielded a different theory about the role of SOD1 in amyotrophic lateral sclerosis. Mice lacking the SOD1 gene entirely do not develop amyotrophic lateral sclerosis, or exhibit any adverse reactions to the missing gene. This and the presence of SOD1 mutant proteins in amyloid-like neurofilaments indicate that SOD1 may act as an amyloid protein. Amyloid proteins exhibit a mutant conformation that can associate with other amyloids to form higher-order structures which may block cellular transport and other machinery necessary to the cell's proper function. Recent structural evidence suggests that some copper and zinc SOD1 mutations result in destabilization of normal dimers of the enzyme and promote aggregation, forming amyloid or pores (Koo *et al*., 1999; Hough *et al*., 2004). Therefore, stabilization of dimers has been proposed as a therapeutic intervention (Ray and Lansbury, 2004).

Autoimmune responses, which occur when the body's immune system attacks normal cells, have been suggested as one possible cause for motor neuron degeneration in amyotrophic lateral sclerosis. Some scientists theorize that antibodies may directly or indirectly impair the function of motor neurons, interfering with the transmission of signals between the brain and muscles. In searching for the cause of amyotrophic lateral sclerosis, researchers have also studied environmental factors such as exposure to toxic or infectious agents. Studies have also focused on the role of glutamate in motor neuron degeneration. Scientists have found that, compared to healthy people, amyotrophic lateral sclerosis patients have higher levels of glutamate in the serum and spinal fluid. Studies have demonstrated that neurons begin to die off when they are exposed over long periods to excessive amounts of glutamate. Scientists are trying to understand what mechanisms lead to a buildup of unneeded glutamate in the spinal fluid and how this imbalance could contribute to the development of amyotrophic lateral sclerosis. Some scientists also theorize that antibodies may directly or indirectly impair the function of motor neurons, interfering with the transmission of signals between the brain and muscles. Researchers have also studied environmental factors such as exposure to toxic or infectious agents.

### *SOD in amyotrophic lateral sclerosis*

Numerous studies on autosomal-dominant amyotrophic lateral sclerosis have provided evidence that oxidative stress may play an important role in the pathogenesis of amyotrophic lateral sclerosis. Transgenic expression of mutated CuZn SOD gene may lead to an amyotrophic lateral sclerosis phenotype despite normal or increased SOD activity. Although mutations in the SOD gene may not lead directly to the generation of ROS by a failure to detoxify superoxide, the gain of function mutations are likely to cause oxidative stress, e.g. by the formation of peroxynitrite. 3-Nitrotyrosine, a marker of peroxynitrite formation, is increased in cortex, spinal cord, and CSF of patients with autosomal-dominant or sporadic amyotrophic lateral sclerosis, as well as in transgenic animals (Ferrante *et al*., 1997; Tohgi *et al*., 1999). In addition, other markers of oxidative damage such as protein carbonyl and nuclear DNA 8OH20dG levels are increased in the motor cortex of sporadic amyotrophic lateral sclerosis patients (Ferrante *et al*., 1997).

Although the evidence for oxidative stress is strong in amyotrophic lateral sclerosis, the role of altered glutathione metabolism is less clear. Although changes in glutathione metabolism suggest enhanced generation of ROS and implicate increased concentrations of glutamate, insufficient research demonstrates glutathione concentrations in the cortex or spinal cord of amyotrophic lateral sclerosis patients. An increase of glutathione-binding sites in the spinal cord of amyotrophic lateral sclerosis patients may be construed as an upregulation caused by a deficiency of glutathione. (Lanius *et al*., 1993; Bains and Shaw, 1997).

## PROTECTION AGAINST NEURODEGENERATIVE DISEASES: TOCOPHEROL, ASCORBIC ACID, AND OTHER ANTIOXIDANTS

Nutrients have been used in clinical studies and are widely used by people with neurodegenerative diseases in order to partially treat the disease or slow down its deterioration. It has been suggested that following diets high in antioxidants may reduce the chances of developing neurodegenerative diseases (Grant, 1997). A number of *in vitro* studies have shown that antioxidants, both endogenous and dietary, can protect the nervous tissue from damage by oxidative stress (Urano *et al*., 1997). In an animal study by Tagami *et al*. (1998), tocopherol was shown to prevent cell death in rat neurons subjected to hypoxia followed by oxygen reperfusion and prevent neuronal damage from reactive nitrogen species. Tocopherol and $\beta$-carotene was also shown to protect rat neurons from oxidative stress caused by exposure to ethanol (Mitchell *et al*., 1999).

Most *in vivo* and clinical studies of the effects of lipid-soluble antioxidant supplementation on neurological diseases have focused on tocopherol or vitamin E and $\beta$-carotene. Vitamin C and tocopherol in large doses are commonly used by patients in order to lessen the cell damage that occurs in Parkinson's disease. The enzymes SOD and catalase require these vitamins in order to nullify the superoxide anion, a toxin commonly produced in damaged cells. Coenzyme Q10 has more recently been used for similar reasons.A report in 1991 demonstrated that ascorbic acid and synthetic tocopherol slowed the rate at which Parkinson's disease progressed in patient by 2.5 years (Fahn, 1991). In a Dutch study, it was found that the risk of Parkinson's disease was lower in subjects who had higher dietary intakes of antioxidants, particularly tocopherol (de Rijk *et al*., 1997). In another study, it was found that patients suffering from Parkinson's disease had consumed less of the small-molecule antioxidants $\beta$-carotene and ascorbic acid than did non-sufferers of the disease, implying that dietary antioxidants do play a protective role in this disease (Hellenbrand *et al*., 1996).

The L-dopa precursor L-tyrosine was also shown to relieve an average of 70% of neurological disease symptoms (Jankovic, 2001). Ferrous iron, the essential cofactor for L-dopa biosynthesis was shown to relieve between 10% and 60% of symptoms in 110 out of 110 patients (Birkmayer and Birkmayer, 1986).

## CONCLUSIONS

Neurodegenerative disorders constitute one of the major challenges of modern medicine and health professionals. Although these diseases are relatively common and often highly debilitating, the mechanisms responsible for their pathologies are poorly understood, and there are currently no effective preventative or therapeutic strategies. As demonstrated earlier, common themes occur in several neurodegenerative disorders. Slowly progressive neurodegenerative diseases are probably not the result of a single event, but rather a multi-cascade event/process involving environmental, epigenetic and genetic events. ROS may serve as common mediators in programmed cell death (apoptosis) or unprogrammed cell death (necrosis) in response to many different toxicants and pathological conditions. Recent studies demonstrated that oxidative stress and oxidative DNA damage may be involved in the cytotoxicity of chlorpyrifos, fenthion, and other pesticides, as well as heavy metals. Neurotransmitter systems play a key role in behavioral function and disturbances, and structurally dissimilar pesticides and heavy metal significant disrupt the system. Figure 20.5 exhibits a schematic diagram of the mechanistic pathways involved in the disease pathophysiology. Finally, much experimental evidence demonstrates that structurally diverse and dissimilar environmental pollutants including pesticides, tobacco, and heavy metals have adverse effects on dopamine, neurotransmitters, and brain functions. These cascade of events lead to altered gene expression and downregulation of antioxidant defense system and cause neurodegeneration.

Thus, the next generation of drug treatment will focus on combined therapies selective for several decisive events that characterize these disorders. Lowering the burden of protein aggregation, oxidative and nitrosative stress, mitochondrial injury, inflammatory response, and heavy metal accumulation in the brain so as to re-establish neurotransmission and block excitotoxicity may prove beneficial in the treatment of several neurodegenerative diseases.

# Radiation and radioactive materials

*John A. Pickrell*

## INTRODUCTION

Although radiation cannot be seen, its interaction with matter is understood at a theoretical and partially at an experimental level. Its effects in humans have been extensively explored in large studies (Harley, 2001). Studies include the radium dial painters, survivors of the atomic bomb, patients with ankylosing spondylitis, children treated for ringworm (*Tinea captis*) and uranium miners exposed to radon soil gas, and to the short-lived radon daughter isotopes (Harley, 2001).

Models of radiation damage have been developed. For many years, inadvertent releases of ionizing radiation have been universally feared. Alternatively it has been used in controlled, defined amounts as radiation therapy for certain tumors in both companion animals and man. All studies provide the same picture of radiation toxicity. There are sufficient details of radiation effects to make credible estimates of risk from radiation exposure (Harley, 2001).

Since acute radiation toxicity becomes apparent shortly after exposure, history is an important criterion in determining whether the radiation is related to the cause of a particular complication or adverse effect. In contrast, late radiation toxicity in organs such as the kidneys, liver or central nervous system (CNS) will not be seen until months or perhaps even years after radiation exposure (Center for Drug Evaluation, 2005).

## BASIC RADIATION CONCEPTS

The four main types of irradiation are X-rays, gamma rays, electrons (negatively charged beta particles or positively charged positrons) and alpha particles. An atom can decay by the loss of mass (helium – loss of two protons and neutrons), the loss of a positively or negatively charged electron (beta particle or positron). Gamma irradiation occurs when excess energy is released from the nucleus (alpha, beta or positron transition) (Harley, 2001).

### Energy

$$\text{Energy} = \frac{1}{2}(\text{particle mass}) \times (\text{particle velocity})^2$$

Both high amounts of mass and high velocity can be used experimentally (artificially) to contrive releases of large amounts of energy (neutron activation (bombarding) of an atom).

Alpha particles have sufficiently low velocity relative to the speed of light that no correction is required. Thus, alpha particle energy = 0.511 (1 − velocity of particle$^2$/velocity of light$^2$) + 0.511. Gamma rays are pure electromagnetic radiation with energy = ($6.626 \times 10^{-34}$ J/s − Planck's constant) × (frequency of the radiation). Conventional units of radiation to be considered are one electron volt (1 eV) = $1.6 \times 10^{-19}$ J and one million electron volts (1 MeV) (Harley, 2001).

### Alpha particles

Alpha particles are a helium nucleus (two protons and two neutrons) ejected from the nucleus of a radioactive element $^{226}$Radium$_{86}$ decomposes to $^{222}$Radon$_{84}$ and an alpha particle ($^{2}He^{2++}$) + energy (5.2 MeV, range 4–8 MeV). There are several, discrete monoenergetic alphas emitted from an alpha emitter, not a continuous spectrum of emissions (Harley, 2001).

*Copyright © 2007, Elsevier Inc. All rights reserved.*

### Beta particles, positron and electron capture

Beta particles are emitted when a neutron is converted to a proton plus an electron and the electron is lost. Positrons are emitted when a proton becomes a neutron and decays by beta emission or an electron is captured. These are competing processes, and both occur with about the same frequency (Harley, 2001).

### Gamma ray (photon) emission

Gamma ray emission is mostly secondary to an alpha, beta or positron emission or electron capture. When all of the energy is not used by the emission, the nucleus is in an excited state with energy available for emission. This excitation energy is emitted as a photon when the particle is emitted. In many cases the photon will not be emitted, but bind to an electron which is ejected as a monoenergetic particle equal to the photon energy minus the binding energy (Harley, 2001).

## INTERACTION OF RADIATION WITH MATTER

Ionizing radiation loses energy by producing ion pairs (an electron and a positively charged atom). About 33.85 eV is needed to produce an ion pair. This is ~2 times the energy needed for ionization, which is lost in the ion pair formation. Alpha and beta particles and gamma rays lose energy in somewhat different ways (Harley, 2001).

### Alpha particles

An alpha particle is heavily charged with a mass equal to 7300 times that of an electron. Yet energy can be transferred to particles going only twice as fast as the alpha particle. Since it requires 33.85 eV to produce an electron pair, a 5 MeV can produce ~7400 pairs within 1 μm of the decay. One micrometer (1/1,000,000 m; 1/1000 mm; 15% of the diameter of a human red blood cell) is much thinner than a sheet of paper. This linear energy transfer (LET) is said to be much greater than is needed to have deoxyribonucleic acid (DNA) strand breakage. Thus, it is said to have a high LET.

### Beta particles

Energy loss in matter cannot be simplified as it can in alpha particles because:

1 Even low energy beta emitters are traveling near the speed of light and must be corrected for mass increase.
2 Electrons are interacting with particles of the same mass; large energy losses are possible.
3 Radioactive (Bremstrahlung) energy loss from slowing down is appreciable (Harley, 2001) (with alpha particles they were not).

### Gamma rays

$$E\ (\mathrm{MeV\,m^2/kg}) = \text{mass energy absorption coefficients } (\mathrm{m^2/g^2})\ (\text{initial photon energy})$$

Mass energy absorption coefficients in air and in muscle are somewhat similar between 0.01 and 3.0 MeV. Energy loss/unit length is obtained by multiplying absorption coefficients by density ($kg/m^3$). Density is usually between 1 and 2.6 for most tissues. Thus, relative biological effectiveness (RBE) is not too different from 1. Rad (dose in air) is ~ roentgen equivalent in man (rem). This LET particle can penetrate much farther into tissue. Thus, radiation dose is distributed over much greater areas, tending toward diffuse as opposed to focal (Harley, 2001).

If lead shielding were used, density would be much greater, and penetration would be much less. If energy emitted is sufficiently low penetration can be taken to be negligible. A lead shield is often used when obtaining diagnostic X-rays as a safety feature. Some fraction of energetic gamma emitters (e.g. $^{60}$Cobalt) irradiation can penetrate even lead and added earth shielding. This radiation leakage may be as high as 1–10% of the source strength depending on the amount of shielding used if therapeutic gamma instead of X-irradiation is used.

## ABSORBED DOSE

### Total dose and dose rate

Total dose is the total energy absorbed per unit of mass; this measurement is independent of the time taken to deliver it (the dose rate) (Harley, 2001). If the dose is delivered quickly in a single exposure (high dose rate), there is almost no time to repair radiation damage and damage/unit of dose absorbed is high. Alternatively if the total dose is delivered quite slowly, say over the lifespan of the animal, there is more time to repair radiation damage and damage/unit of dose is much lower.

Very little time is required to initiate repair. For example, if multiple fractionated doses are delivered per hour, the damage/unit of total dose decreases significantly. Fractionated radiotherapy leads to the emergence of a more homogeneous population from cell repopulation

and by the high degree of radiosensitivity of the G2 cells that is a decrease in the percentage of G2 cells. Variations in the chromatin pattern of the cells may be explained by DNA repair processes (El-Khattabi *et al.*, 1997; Murata *et al.*, 1998; Harley, 2001). While these data may be relevant to higher radiation doses required for therapy where present tolerable doses are merely palliative, protraction does lengthen the time and therefore the cost required to deliver that dose.

Absorbed dose = mean energy deposited in mass divided by the mass of the target organ (Harley, 2001). Sometimes absorbed dose is called kerma (kinetic energy released in matter). Dose is delivered to target organs. Because exposure and dose are often used interchangeably, dose is often confused with exposure level. For comparison, exposure level is radiation in air = total radiation ions (one sign) per unit mass divided by mass.

## Equivalent dose and cancer risk

For alpha particles, with large mass produce intense ionization tracks per unit distance relative to beta particles. Beta particles produce more intense ionization than gamma rays. LET measures this transfer of energy per unit distance. If dose is considered to be proportional to response, that dose must be normalized for LET. For a particular endpoint (e.g. cell death in mouse fibroblasts), frequently one calculates relative biological effectiveness (RBE). RBE = dose of radiation under study/dose of gamma rays to achieve the same effect.

We calculate equivalent dose as equivalent dose = (dose) (weighting factor (RBE)).

Weighting factors recommended are ~1 for X-rays, gamma rays, beta particles and electrons and 20 for conventional neutrons (>>>0.1–2 MeV), protons, alpha particles and charged particles of unknown energy.

For example, the weighting factor and RBE of plutonium-238 ($^{238}Pu$) is about 10–30. Thus, the rem is 10–30 roentgen dose in air (rad s). This radiation dose pattern following alpha emission is confined to an immensely small area and is said to be focal as opposed to being diffuse if LET were operating. It is not uncommon to focal dose corresponding to focal response in alpha particle exposure (Harley, 2001). Thus, one might see millions of *burned out zones* or indicators of cell death following alpha emission if microscopic resolution was sufficiently good.

The term effective dose allows comparison of cancer and genetic risks from different partial body and whole body doses, to be integrated for the purposes of estimating a whole body response. Some tissues (gonads weighting factor = 0.2) are more sensitive than others (red bone marrow, colon, stomach and lung weighting factors = 0.12; bladder, breast, liver, esophagus and thyroid weighting factors = 0.05). Skin and bone surface are the least sensitive (weighting factors = 0.01). Other tissues not specified are taken to have a weighting factor of 0.05 as a conservative estimate (cited in Harley, 2001).

It is useful to calculate doses using the tissue weighting factor in protracted exposures (exposures over significant periods of time). Most non-experimental companion or domestic animals do not receive protracted exposures. A major exception to this is the animal receiving repeated fractionated doses as radiation therapy, or the relatively rare animals in which radiation has been implanted so that it acts as an internal emitter of radioactivity (Harley, 2001).

## Committed equivalent dose

Once radioactivity is placed internally it becomes an internal emitter. Internal emitters are used infrequently either therapeutically or with accidental exposure via ingestion or inhalation; internal emitters may be removed only with varying degrees of difficulty (Harley, 2001). Usually they cannot be removed simply or easily and irreversible committed equivalent dose is said to exist. For radionuclides with half-lives 0–3 months the equivalent dose is equal to the annual dose of the year of intake (Harley, 2001). For a radionuclide with a half-life of 3 months, a years exposure would allow the passage of four half-lives so that fraction of dose delivered was $(1-\frac{1}{2}^{4})$ ~94% of the total dose for all time. Those with shorter half-lives would approach 100% more closely (half-life of 1 month $(1-\frac{1}{2}^{12})$ ~99.98% of the total dose for all time).

## Negligible individual risk level (negligible dose)

Radiation is feared because its delivery cannot be seen, and is often not measured, because it is only in retrospect that one realizes that radiation exposure has occurred. We accept the concept of linear, non-threshold cancer induction from ionizing radiation (Harley, 2001); this allows calculation of cancer risk regardless of how small (or large) the dose may be. Calculating very low risks leads us to calculating a risk that one would consider acceptably low, that is below the ability to detect a response (Harley, 2001).

The National Council for Radiation Protection (NCRP) has identified a negligible individual risk level (NIRL) as a level of annual excess risk fatal risks of health effects attributable to irradiation below which further effort to reduce radiation to the individual is unwarranted. The NCRP emphasized that this level should not be confused with an acceptable risk level, a level of significance or a

standard. The NCRP recommended a level ~½ the natural background radiation level; the final recommended NIRL level is 1 mrem; this level is now called negligible individual dose (NID) level (Harley, 2001).

Effective dose was a parameter used to assess biological risk related to radiation exposure, from dual-energy X-ray absorptiometry (DXA). Children are a worst-case estimate because they absorb higher doses than adults. With the exception of the hip scans in 1- and 5-year-old children, the effective doses were below the NID limit of 1 mrem/year (Thomas *et al.*, 2005).

By way of comparison, NCRP has set the allowable human exposure to avoid cancer at 2000 mrem/year (2 rem/year). Total lifetime exposure was taken to be 1000 mrem/year (1 rem/year) × the person's age. This level is more than 1000 times the level defined as NIRL (NID) (Harley, 2001).

### Radiation safety for diagnostic imaging

Diagnostic imaging with radiation must be performed with proper protection (Kahn and Line, 2005). Although exposure factors are substantially lower than with past diagnostic imaging, considerable radiation dose may be delivered over time if proper protection is not worn. Lead gloves will lower external radiation dose ~1000-fold from scatter radiation, not in the direct radiation beam, but only 10-fold from radiation when directly in the beam of irradiation. Thyroid and eye shields are recommended. For example, upper limb and skull studies are especially likely to result in substantial exposure to anyone holding the film or horse (Kahn and Line, 2005).

## MECHANISMS OF DNA DAMAGE AND MUTAGENESIS

### Energy deposition in the cell nucleus

Radiation is released and slows down by forming ion pairs (Harley, 2001). Different ion densities result in formation of alpha particles, beta particles or gamma rays. Tract structure is roughly characterized into sparsely populated (low LET) and densely populated (high LET) tracts. Each tract from X-irradiation of gamma rays results in a 70 events across the width of the nucleus for ~0.5 rad s. Alternatively, an alpha track may produce many 30,000 of events across the same nucleus for ~300 rad s.

Within a cell indirect effects occur within nanometers of the direct effects. Bigger tracts are caused by radiation that is high LET. Low doses of high LET result in a few cells being hit by a single track. Low LET radiation tends to be spread out over the cells more evenly. One gray of radiation will produce 1000 single strands and less double strand breaks (~40); intermediate levels of damage were seen in base damage (500 breaks) and DNA protein crosslinks (150 breaks). About 30% of the double strand breaks are complex because of additional breaks (Harley, 2001).

### *In vitro* irradiation studies

Small lymphocytes from horses were transformed into larger radioresistant lymphoblast-like cells following stimulation by phytohemagglutinin, *in vitro*; 100 rad s X-irradiation killed all the small lymphocytes, but only ~1/3 of the lymphoblast-like cells (Dewey and Brannon, 1976). Horse lymphocytes were more radiosensitive than human lymphocytes. The ratios between doses inducing the same effect are 1.3, 1.7 and 9.4 for the number of binucleated cells with micronuclei, micronucleus frequency in binucleated cells and DNA synthesis inhibition, respectively (Catena *et al.*, 1997).

In cattle, at any LET value, repair is much slower after heavy ion exposure than after X-irradiation. For ions with an LET of <10,000 keV/μm more than 90% of the strand breaks induced are repaired within 24 h. At the highest LET value (16,300 keV/μm) no significant repair is observed (Baumstark-Khan *et al.*, 2003). Thus, a steep dose–response effect is seen at higher doses.

The base-line frequency of sister chromatic exchange (SCEs) was similar in the three species and no significant variation in man, cattle or muntjac (deer) cells was not different even after administration of 400 rad of X-rays (Das and Sharma, 1983). Pre-irradiation of artificial vessel walls substantially decreased the wall's capabilities to resist fibrosarcoma-induced lysis and abilities of blood vessels to limit extravasation and perhaps invasion (Heisel *et al.*, 1984).

X-rays induce DNA damage including strand breaks that lead to formation of micronuclei and chromosomal aberrations; X-irradiation was associated with an increased number of apoptotic cells (Konopacka and Rzeszowska-Wolny, 2006). This phenomenon was termed "bystander effect". A number of studies suggest that bystander effect appears to be associated with up-regulation of oxidative metabolism. The factors causing micronucleation by X-irradiation, oxidative DNA damage and incomplete repair may be regulated by apoptosis-independent pathways (Konopacka and Rzeszowska-Wolny, 2006).

Immature B lymphocytes in the chicken bursa of fabricius have previously been reported to undergo apoptosis by low doses of ionizing radiation. Increase of the pyknotic cells in number was observed at a dose of as little as 1 Gy. The chicken bursal cells are hypersensitive to X-irradiation with regard to induction of apoptosis, and that the apoptotic bursal cells exhibit most of the ultrastructural features known to be typical of apoptosis (Arai *et al.*, 1996).

# ANIMAL EXPOSURES AND RADIATION TOXICITY

## Introduction

Animals may show acute irradiation-induced changes from high single doses of radiation either from external or internal emitters. Alternatively, irradiation regimens may be devised which have high radiation dose rates. Irradiation of cells likely to be most sensitive to high doses of irradiation may be used to model the changes expected to be seen from these radiation doses. High external doses are most commonly accumulated from either an X-irradiation source or a $^{60}$Cobalt gamma ray source. Usually diagnostic X-irradiation will not be sufficiently high to produce acute symptoms. However, if therapeutic irradiation is given as a single dose, high doses of external irradiation may be sustained. Most often very high doses of external irradiation given for therapeutic purposes are fractionated over several to many doses, allowing more total radiation dose to be sustained without causing clinical signs of radiation toxicity to appear, because of the lower radiation dose rate. Mammary tumors are sometimes treated with external irradiation. The radiation field commonly includes the areas occupied by the intestines and lungs. Less commonly, fugitive releases (reactor accidents) may release radioactive iodine which localizes to irradiate the thyroid glands.

The highest levels of this type of radiation produce CNS changes. It is unlikely that anything but a gross miscalculation of radiation dose and dose rate would lead to this high level of radiation. At ultra high external irradiation doses, people and animals die quickly with associated CNS nervous signs and death at <1 week. Disruption of the blood–brain barrier (BBB) occurs after radiation injury; it is detectable by magnetic resonance imaging or horseradish peroxidase studies. For example, rats, irradiated at 60 Gy, were serially sacrificed at 2–24 weeks showed a detectable disruption of the BBB at 2 weeks post-irradiation; disruption of BBB preceded white matter necrosis (Rubin *et al*., 1994). In humans, one pilot study administered 55–60 Gy which as a single exposure would have been fatal; however, they hyperfractionated this dose in 110 cGy fractions. The hyperfractionation allowed completion of the course of radiotherapy. Tumor regression was noted, with minimal reoccurrence of tumors and no overt radiation toxicity (Fontanesi *et al*., 1995). Thus, hyperfractionation allows delivery of high doses that were therapeutic to tumors.

At high levels of this type of irradiation, but below the levels capable of inducing CNS signs, the short-lived intestinal epithelial cells die in massive amounts and gastrointestinal (GI) mucosal changes are said to occur. Death usually occurs in 1–2 weeks. Again, only the worst radiation accident or miscalculation of dose would lead to exposures of this level. For example, Chernobyl had fatalities in 30 of ~3000 staff members, but no record of GI changes being the predominant cause of death (Harley, 2001).

At lower levels there can still be appreciable clinical contributions from GI mucosal changes; great effort is made to minimize the importance of these to people or animal survival. One such way of improving chances of survival from radiation therapy is directing the radiation toward the field of the tumor; we call this involved field radiation therapy (IFRT) (Albuquerque *et al*., 2005). This is relatively simple to effect in large animals such as humans; it is more difficult to sufficiently focus the beam sufficiently for the same advantages in smaller dogs. Twenty ovarian cancer patients treated with 50.4 Gy of directed radiation were 66% 5-year recurrence free and 33% disease free. Thus, directed beam radiation therapy that would have been fatal if not directed minimized the consequences of human ovarian cancer (Albuquerque *et al*., 2005). After radiation treatment for gynecological cancer, patients gained more body fat than expected in Chilean women around menopause; the loss of fat-free mass observed during radiation treatment was probably associated with infrequent physical activity (Pia de la Maza *et al*., 2004). The extent to which this effect occurs older dogs has not been determined.

At still lower doses failure renewal of blood cells from bone marrow aplasia or hypoplasia may occur. These occur at low enough doses that radiotherapy may induce them clinically. Hyperfractionation of radiation dose helps minimize the consequences of these changes, by lowering the overall dose rate. When human external beam irradiation 50–70 Gy was combined with cisplatin chemotherapy to treat head and neck cancer 6% of the patients had groin hematomas requiring no treatment. In addition, 6% of the patients had mucosal events; hematologic changes were less frequent at 2% (Gemmette, 2003). Intensive induction chemotherapy combined with external beam irradiation therapy of children with brain stem gliomas produced objective improvements in 50% of the cases; this treatment course also produced severe but manageable hematologic toxicities. The data suggest that future radiation therapy regimens may require hematologic toxicities to be managed (Benesch *et al*., 2001). IL-17A is a T-cell-derived proinflammatory cytokine required for microbial host defense (Tan *et al*., 2006). *In vivo* expression profoundly stimulates granulopoiesis. Knockout mice establish IL-17A as an inducible mechanism that is required for recovery of granulopoiesis after radiation injury (Tan *et al*., 2006).

Depending on dose, external irradiation may lead to different types of reproductive toxicity in the male companion animal (Scialli *et al*., 1995 and De Celis *et al*., 1996 cited in Ellington and Wilker, 2006). At very high doses, it may lead to permanent aspermia. At intermediate doses it may lead to reduction in sperm numbers. Finally, at lower doses

external irradiation may lead to DNA alterations in sperm cells (Scialli *et al.*, 1995; and De Celis *et al.*, 1996 cited in Ellington and Wilker, 2006).

Finally, at lower levels, but with continuing irradiation, degenerative changes, for example cancer, are of the greatest concern. Usually, these changes are caused by fugitive releases of radiation (reactor accidents). The Chernobyl Reactor Accident released massive quantities of $^{131}$Iodine causing increased thyroid cancer in Belarus (>100 thyroid cancers/year). Less than 1/3 of this increase was seen in the Ukraine and the Russian Federation (Harley, 2001). No such tumors are reported for companion dogs, but they were similarly exposed and some tumors may have occurred. Widespread radioactivity was released across much of Europe and has been recorded >10,000 miles around the world at Fiji Atoll. Increased $^{90}$Strontium was observed in European cow's milk near the time of Chernobyl.

Thirteen dogs with invasive thyroid carcinoma were treated by four once-weekly fractions of 9 Gy of 4 MeV X-rays of external beam irradiation (Brearley *et al.*, 1999). Four of the dogs died from primary thyroid carcinoma and four from metastatic spread. Of the remaining five dogs, three died of unrelated problems, and two were still alive at the time of the census. Median survival time from first dose to death from either primary or metastatic disease was 96 weeks; with a range was 6–247 weeks. Radiation therapy should be considered an important modality for the control of invasive canine thyroid carcinoma (Brearley *et al.*, 1999).

Animals receiving fractionated external radiation therapy for mammary tumors may develop chronic pulmonary degenerative disease because the thorax is irradiated. To achieve the desired therapeutic effect, the dose may be too high to heal by primary intent; thus, they will heal by secondary intent – fibrosis. Type II cell proliferation is a common early event in radiation toxicity to the lungs. Following 10–15 Gy of X-irradiation, first wave of type II cell proliferation correlated with an increase in surfactant in alveolar fluids (Coggle, 1987). The second wave follows an additional delay allowing the alveolar epithelial continuity to be sufficiently compromised by the low rates of type I alveolar pneumocyte loss; type I cell loss triggered a compensatory wave of type II cell divisions that contrasted with the dramatic and immediate hyperplastic responses which many toxic irritants produce in type II epithelial cells (Coggle, 1987). At later times, fractionated external thoracic irradiation 1–2 times weekly to achieve 4000–6000 rad s modestly increased total lung collagen (Pickrell *et al.*, 1975; Pickrell *et al.*, 1983). Collagen production was initially increased, leading to the increase in total lung collagen; collagen metabolism returned to a more normal level at later times (Pickrell *et al.*, 1978; Pickrell *et al.*, 1983).

The relation of static compliance of excised lungs to collagen accumulation and histologic fibrosis was examined in Syrian hamsters inhaling sufficient high LET $^{238}PuO_2$ particles to achieve initial lung burdens of 50 or 100 nCi (Pickrell *et al.*, 1983). Hamsters exposed to 50 nCi $^{238}PuO_2$ showed normal collagen content and static lung compliance with minimal histologic fibrosis 288 days after exposure. In contrast, hamsters exposed to 100 nCi had significant pulmonary fibrosis at that time and the highest incidence of dense scars at any time period. Such findings are consistent with a stiffening of lung parenchyma. Hamsters had increased total lung collagen, reduced lung compliance and histologic evidence of diffuse interstitial fibrosis. The diffuse interstitial fibrosis developed by this injury resolves spontaneously as indicated by total lung collagen, compliance and histology; dense fibrous scars, however, do not resolve (Pickrell *et al.*, 1983; Pickrell and Abdel-Mageed, 1995).

Total body irradiation-induced changes in expression of CD25 and CD71 activation markers on the surface of lymphocytes, suggesting that radiation may alter tumor surveillance. Taken together, the relative percentages and activation status of immune cell compartments support the conclusion that these total body irradiation-induced changes function to slow tumor progression.

## Consequences of radiation therapy

When X-ray therapy (XRT) has been given, radiation injury is often limited to organs within the radiation beams. The risk of radiation injury to an organ is determined by the organ's radiosensitivity and by the concentration time–activity curve of the agents in that organ or at a specific anatomical target. For example, late radiation effects can occur if the kidneys receive a significant radiation absorbed dose. The kidneys are known to have a relatively low radiation tolerance dose (23 Gy for conventionally fractionated XRT); therefore, late radiation nephritis may be a dose-limiting toxicity. Radiation fibrosis is a common sequelae to XRT for lung cancer (Pickrell *et al.*, 1975; Pickrell *et al.*, 1978; Pickrell and Pickrell-Mageed, 1995; Center for Drug Evaluation, 2005).

It is possible to predict the effect of treatment in cancer in a non-invasive manner by apoptosis imaging *in vivo* after radiotherapy, by using $^{125}$I-annexin V. Brain tumors were implanted in susceptible (nude) mice. By 6 h after receiving levels of X-irradiation as low as 2 Gy both autoradiography and immunohistochemical staining showed more apoptosis in the tumors of irradiated groups than in the control group (Watanabe *et al.*, 2006).

Therapeutic brain irradiation can cause progressive decline in cognitive function, particularly in children, but the reason for this effect is unclear. Neocortical neurons of very young mice are more susceptible to radiation-induced apoptosis than are older mice. However, this sensitivity decreases rapidly after birth. By 14 days after parturition, acute cell loss due to radiation occurs primarily in non-neuronal populations (Nakaya *et al.*, 2005).

Poly (ADP-ribose) polymerase-1 (PARP-1) facilitates the repair of DNA strand breaks (Calabrese *et al*., 2004). Inhibiting PARP-1 increases the cytotoxicity of DNA-damaging chemotherapy and radiation therapy *in vitro*. But classical PARP-1 inhibitors have limited clinical utility. AG14361 is, to our knowledge, the first high-potency PARP-1 inhibitor with the specificity and *in vivo* activity to enhance chemotherapy and radiation therapy of human cancer (Calabrese *et al*., 2004). GR205171 has the most potent anti-emetic activity of any tachykinin NK1 receptor antagonist described to date. The compound is orally active in the ferret and dog, long-lasting, and warrants further investigation as a potential broad-spectrum anti-emetic agent (Gardner *et al*., 1996).

Three-dimensional dose-rate/time/response surfaces for chronic exposure to carcinogens and ionizing radiation clarify the interactive roles of competing risks (Raabe, 1987). The three dimensions are average dose rate, exposure time and risk. The improved conceptualization afforded by them contributes to the planning and evaluation of epidemiological analyses and experimental studies involving chronic exposure to radiation toxicants (Raabe, 1987).

## Conclusions

Radiation is of concern because it cannot be seen, exposure is frequently not painful, but it can cause significant biological effects. Alpha and neutron particles are the largest radiation particles, they penetrate the least and deliver the highest radiation energy per unit distance. Their dose patterns resemble multiple tiny foci of radiation damage. When irradiation interacts with matter, alpha and neutrons have 20 times the injurious cancer causing potential than beta irradiation and gamma rays have.

Cancer causing or apoptotic potentials are related to the interaction of ionizing radiation (neutron, alpha, beta or gamma) with the critical target cell nucleus. In veterinary medicine, the greatest potential for acute radiation damage lies in accidents releasing the contents of nuclear reactors such as Chernobyl in Belarus, radiation cancer therapy, most commonly for dog mammary tumors, or a gross miscalculation of irradiation dose needed for diagnostic imaging. Radiation fatalities at the highest dose can affect the CNS, perhaps by damaging the BBB. At a lower dose they can damage intestinal epithelium with rapid turnover, causing the GI syndrome, at a still lower level that can damage blood cells causing the hematologic syndrome.

Fractionating the radiation dose dramatically reduces the probability of getting an acute reaction from radiation therapy. If the dose is protracted over long time periods (months instead of hours to minutes), there is danger of chronic degenerative disease. For example, children who receive relatively low radiation doses appear to lost measurable cognitive function. The degree to which this is a lower dose manifestation of the CNS syndrome is not understood. When radiation is in the lung area, pulmonary fibrosis may develop; post-radiation nephritis is not uncommon. Dr. Raabe's 1987 model for three-dimensional dose-rate/time/response surfaces after chronic exposure to ionizing radiation by dose fractionation has helped us to understand the interactive roles of competing risks from therapeutic irradiation.

## ACKNOWLEDGMENTS

The author would like to thank Dr. Priyadarshini Gadgil for her excellent literature review on irradiation of ground beef that I was privileged to read, Dr. Larry Erickson, Chemical Engineering Kansas State University for his support in this effort and Dr. Frederick W. Oehme Comparative Toxicology Laboratories, Department of Diagnostic Medicine/Pathobiology, Kansas State University for his support, and for critically reading the chapter.

## INTRODUCTION

Animals, like humans, have always been exposed to thousands of chemical substances in their daily lives. This exposure may come from the food they eat, the water they drink, the air they breathe, etc. A high level of exposure to many of these chemicals may cause cancer in humans and animals. Cancer has become an increasingly prominent disease in recent times but incidence of cancer had been documented through writings and drawings thousands of years ago. The earliest known descriptions of cancer were found from the writings in Egyptian papyri, discovered and deciphered in the late 19th century. Two of these papyri, which were written around 1600 BC and called "Edwin Smith" and "George Ebers" papyri, contain descriptions of various cancers and Egyptian medical practice of treating cancer. Hippocrates is credited with naming cancer as "karkinoma" (carcinoma) because a tumor looked like a "crab" (karkinoma is Greek for crab). Hippocrates believed that the body contained four types of "humors" (body fluids): blood, phlegm, yellow bile, and black bile. An excess of black bile collecting in various body sites was thought to cause cancer. The black-bile theory of cancer was supported by the influential Greek physician Galen and it dominated the scientific thought for over 1300 years. The black-bile theory of cancer was eventually replaced by the lymph theory of cancer in the 17th century. The lymph theory was developed from the discovery of the lymphatic system by the Italian surgeon Gaspare Aselli, and abnormalities of lymph was viewed as the primary cause of cancer. The lymph theory gained rapid support. The Scottish surgeon John Hunter (1723–1792) lent support to the lymph theory by hypothesizing that tumors grew from lymph that is constantly thrown out by the blood. The cellular origin of cancer was propounded by Rudolph Virchow in the late 19th century when he recognized that cells, even cancerous cells, were derived from other cells.

In keeping with the theories on the possible physiological causes of cancer, an increasing number of reports from Europe and England documented the association between occupation/chemical exposure and the development of cancer. For example, Paracelsus was probably the first to identify a chemical substance, arsenic disulfide, as the causative agent of lung cancer in the miners of Schneeberg and Joachimsthal, Germany. The Italian physician Bernadrino Ramazzini reported in 1713, the absence of cervical cancer and higher incidence of breast cancer in nuns and thought this was related to their celibacy. The English physician Percival Pott observed that young men in their twenties who had been chimney sweeps, had a high rate of cancer of the scrotum. He suggested that the causative agent might be chimney soot (tar) and recommended frequent washing and changing of clothes in order to reduce exposure to the soot. In 1761, John Hill in UK implicated the use of tobacco as snuff in the development of nasal polyps. In 1795, Sammuel Thomas von Soemmering in Germany reported the occurrence of lip cancer among pipe smokers. In 1895, Ludwig Wilhelm Carl Rehn reported the occurrence of bladder

cancer among workers in German dye industry. Various epidemiological studies have since identified major environmental causes of cancer, which include both naturally occurring chemicals as well as man-made chemicals.

Experimental cancer research began in the early 20th century and has been continuing since. Recent advances in molecular genetics have provided researchers with additional tools to study the mechanisms and the molecular biology of cancer. The knowledge gained from such studies form the foundation of our understanding of the process of carcinogenesis. Today, chemical carcinogenesis is regarded as a multistep process with a long latency period. For a relatively detailed historical perspective of cancer, the reader is referred to Marquardt (1999), Pitot (2002), and the American Cancer Society website.

# TERMINOLOGY

*Cancer* is a term that is commonly used to indicate a group of diseases characterized by uncontrolled cell proliferation and usually the spread of these abnormal cells. In common parlance, the word cancer is near-synonymous with other expressions, such as *malignant tumor*, *malignant neoplasm*, *malignancy*, and *neoplasia*. Tumors or neoplasms (new growth of tissue) can thus be benign or malignant (cancerous). In this chapter, the expression "cancer" and "malignant neoplasm" will be used interchangeably. Agents causing cancer are called *carcinogens* and the process of cancer development is called *carcinogenesis*. Most neoplasms arise from the clonal expansion of a single cell that has undergone neoplastic transformation (hence monoclonal). According to Pitot (2002), *neoplasia* or the constituent lesion *neoplasm*, can be defined as a heritably altered, relatively autonomous growth of tissue. The "heritably altered" aspect reflects the abnormal genetic expression, which is either inherent in the neoplastic cells or is induced in response to environmental stimuli. Another term relevant to cancer is hyperplasia. *Hyperplasia* means an increase in cell number. Hyperplasia can be found in neoplastic as well as non-neoplastic conditions. Examples of non-neoplastic hyperplasia include callus formation, hepatomegaly (liver enlargement), etc. Hepatomegaly in response to various xenobiotic treatments usually involves both hyperplasia and hypertrophy (enlargement of cells).

In the parlance of cancer biology, the suffix "oma" means tumor, benign, or malignant. For example, *fibroma* and *lipoma* are benign neoplasms, while *melanoma*, *hepatoma*, and *seminoma* are malignant neoplasms. Sometimes even non-neoplastic lesions end with the "oma" suffix, such as *hematoma* and *granuloma*. Cancer of the embryonic tissue is denoted with the suffix "blastoma", such as *neuroblastoma* and *retinoblastoma*. Likewise, cancer of connective tissue, such as bone, cartilage, fat, muscle, and blood vessels, is denoted with the suffix "sarcoma", such as *fibrosarcoma*, *liposarcoma*, and *rhabdomyosarcoma*.

# CANCER EPIDEMIOLOGY

Cancer incidence data are available in many countries from registries that monitor the occurrence of different types of cancers in various populations. Epidemiological data show that certain cancers tend to occur more frequently among people in certain geographic locations. For example, breast and prostate cancers have lower incidence rates in Asian countries but higher incidence rates in Europe and North America (Haas and Sakr, 1997; McPherson *et al.*, 2000). In contrast, gastric cancer has lower incidence rate in economically developed Western countries including the USA, but higher incidence in Japan and Korea (Alberts *et al.*, 2003). These differences in cancer incidence reflect the role of both genetic and environmental factors. Strong evidence for the importance of environmental factors comes from studies on migrant populations. When there is a significant difference in the incidence of a specific cancer in the native country and the new host country, the migrant population acquires the cancer incidence rate of the host country. For example, Japanese populations in western countries typically acquire the higher breast and colon cancer rates of the host country within a generation or two. Incidence of cancer may also be influenced by gender. For example, gastric cancer shows about two-fold higher incidence in males than females in every region of the world studied (Alberts *et al.*, 2003). While knowledge of the genetic basis of cancer helps understand the molecular mechanism of carcinogenesis, knowledge of cancer causing environmental factors is crucial to making important health and environmental policy decisions that may have far-reaching impact on human and animal health.

# AGENTS CAUSING CARCINOGENESIS

The three main classes of agents (carcinogens) causing cancers are chemicals, radiation, and viruses. In this chapter, chemical carcinogenesis will be emphasized, while viral and radiation carcinogenesis will be discussed briefly.

## Chemical carcinogenesis

### *Chemical carcinogens*

Chemical carcinogens originate from both industrial and natural processes. In 1915, Yamagawa and Ichikawa pioneered the field of experimental cancer research when they produced tumors by repeated application of coal tars

**TABLE 22.1 Some known/suspected chemical carcinogens and their target organs**

| Chemicals/suspected carcinogens | Organs affected |
|---|---|
| Aflatoxin | Liver |
| 4-Aminobiphenyl | Bladder |
| Arsenicals | Lung, skin |
| Diesel exhaust | Lung |
| Benzene | Leukemia |
| Cigarette smoking | Lung |
| Pipe smoking | Lip |
| Soot | Scrotum |
| Dyes (aromatic amines, such as 2-naphthylamine) | Urinary bladder |
| Nickel compounds | Lung |
| Vinyl chloride | Liver |
| Radium (radioactive watch colors) | Bone |
| Formaldehyde | Nose |
| Snuff | Nose |
| Diethylstilbestrol | Genital tract |

on the skin of rabbits. Many of the chemical carcinogens identified in early research were by-products of industrial processes. Subsequent studies have revealed the carcinogenic potential of many other industrial, naturally occurring chemicals, as well as man-made chemicals. Chemical carcinogens may be synthetic ("man made") or of natural origin, they are extremely diverse in structure and belong to very different chemical classes, such as inorganic, organic, fibers, plastic, hormones, etc.

Based on their biological activities, chemical carcinogens can be classified as *genotoxic carcinogens* (DNA-reactive) and *non-genotoxic carcinogens* (non-DNA-reactive, epigenetic). Genotoxic carcinogens can be further classified as *direct carcinogens* (active without metabolic activation) and *indirect carcinogens* or *procarcinogens* (active after metabolic activation).

Table 22.1 lists some of these chemical carcinogens and the organs affected by them.

### *Biological process of chemical carcinogenesis*

Experimental cancer research with carcinogenic chemicals led to the realization that chemical carcinogenesis is a multistep process. The pathogenesis of cancer involves many individual events, such as metabolic activation (biotransformation) of a procarcinogenic chemical to a DNA-reactive compound (in the case of indirect genotoxic carcinogens), covalent binding to DNA, induction of heritable mutations, expression of the mutant phenotype at the molecular level (e.g. altered gene expression) resulting in altered cellular function, cellular transformation and neoplastic growth, and spreading of the transformed cells to other parts of the body. These events in the pathogenesis of cancer have been distilled into three distinct steps to describe the multistep nature of carcinogenesis: the steps are *initiation*, *promotion*, and *progression* (Foulds, 1954). *Tumor initiation* involves introduction of heritable genetic change in a normal cell; *tumor promotion* involves clonal expansion of the initiated cell resulting in the formation of a benign tumor; and *tumor progression* involves the conversion of a benign tumor into a malignant one.

In order for the tumors to develop *the target tissue must be exposed to an initiator first, followed by repeated exposure to promoters*. If the time gap between the exposure to initiator and promoter varies from a week to a year, tumors will still develop. However, if the exposure to promoter is first and is followed by exposure to initiator, tumors will not develop. After the promotion event, the cancer cell acquires further heritable changes that lead to malignancy and metastasis (the progression step). Figure 22.1 shows how sequential exposure to tumor initiator and tumor promoter leads to the development of cancer.

#### *Initiation*

In the initiation phase, the chemical or its reactive metabolite causes a permanent change in the DNA of the target cell(s), such as a mutation, a distortion of the DNA structure with further consequences, elimination of a component of DNA (bases or sugars), or errors in DNA repair (Pitot, 2002). Thus, initiation is a genetic process. The chemical

causing initiation is called an *initiator*. Once a target cell is initiated, initiation is irreversible. An initiated cell by itself is not a cancer cell because it has not acquired the property of uncontrolled growth. Additionally, all initiated cells do not produce tumors because many undergo programmed cell death or *apoptosis*. In order for an initiated cell to transform into a cancer cell and eventually produce a detectable tumor, promotion is necessary.

Examples of tumor initiators are benz[a]pyrene, dimethylbenz[a]anthracene, 3-methylcholanthrene, 2-acetylamino-fluorene, dimethylnitrosamine (DMN), diethylnitrosamine, etc. Exposure to the tumor initiator *N*-methyl-*N*-nitrosourea (MNU) results in the modification of guanine into $O^6$-methylguanine in the DNA of the target tissue. $O^6$-methylguanine is a major tumor-initiating lesion because if it is not repaired, it leads to G:C→A:T transition mutation. The "suicide enzyme" $O^6$-methylguanine-DNA methyltransferase (MGMT) repairs this lesion. MGMT catalyzes the transfer of a methyl group from $O^6$-methylguanine as well as $O^4$-methylthymidine to an internal cysteine residue, thereby repairing the DNA lesion in a single step but at the same time inactivating itself. Transgenic mice overexpressing MGMT are less sensitive to tumor development in the tissue overexpressing the enzyme because of the increased repair of $O^6$-methylguanine (Becker *et al.*, 1996, 2003; Liu *et al.*, 1999; Qin *et al.*, 2000). Experiments with MGMT transgenic mice have also demonstrated that the $O^6$-methylguanine lesion is possibly also involved in tumor progression (Qin *et al.*, 2000; Becker *et al.*, 2003).

*Promotion*

Tumor promoters alter the expression of genetic information of the cell, as well as, in many cases, inhibit programmed cell death (Pitot, 2002). Tumor promoters usually influence the proliferation of initiated cells, which results in the proliferation of preneoplastic cells and formation of benign focal lesions, such as enzyme-altered foci in the liver, nodules in the mammary gland, polyps in the colon, and papillomas in the skin. Therefore, tumor promotion is an epigenetic process. In addition to causing cell proliferation, tumor promoters appear to block apoptosis, thus leading to accumulation of the initiated cells as dysfunctional, non-differentiated cells within a tissue. Some of the lesions that develop due to promotion regress, but others acquire additional mutations and progress to malignant neoplasm. Tumor promotion is a reversible process up to a certain stage if the promoter is withdrawn.

Tumor promoters tend to be organ specific. For example, phenobarbital, TPA (12-*O*-tetradecanoylphorbol-13-acetate, a phorbol ester isolated from croton oil) is skin specific. Chlordane, DDT (dichlorodiphenyltrichloroethane), TCDD (2,3,7,8-tetrachlorodibenzo-*p*-dioxin), β-naphthoflavone, peroxisome proliferators, and polybrominated biphenyls are hepatic tumor promoters; mirex (an organochlorine) is a promoter in both skin and liver; saccharin is a bladder tumor promoter.

*Progression*

Tumor progression involves autonomous growth and metastasis of the malignant neoplasm. At the cellular level, chromosomal breakage and deletion, duplication, or translocation of chromosomal fragments are hallmarks of tumor progression phase. Additional mutations in the oncogenes and tumor suppressor genes also accumulate during this phase. This is why tumor initiators can also cause tumor progression (Qin *et al.*, 2000; Becker *et al.*, 2003). Karyotypic instability and accumulation of additional mutations may reflect an ongoing selection of cells suitable for neoplastic growth and metastasis (Okey *et al.*, 1998).

Some putative tumor progression agents (with no initiator activity) that cause transition from promotion to progression include benzene, benzoyl peroxide, and 2,5,2′,5′ -tetrachlorobiphenyl (Okey *et al.*, 1998).

***Mode of action of chemical carcinogens***

Both direct and indirect carcinogens (procarcinogens) interact with DNA, forming DNA adducts. Indirect carcinogens acquire carcinogenic properties after metabolic activation, forming the *ultimate carcinogen*, which is the reactive metabolite that covalently modifies DNA. The biological activity of the carcinogens depends on a balance between their activation and detoxification in the target tissue.

The majority of these compounds interact with DNA through three different types of chemical reactions (Dipple, 1995; Okey *et al.*, 1998). The reactions involve the transfer of (1) an alkyl group, (2) an arylamine group, or (3) an aralkyl group to DNA. An arylamine contains an amine-substituted aromatic ring, while an aralkyl (arylalkyl) contains an alkyl-substituted aromatic ring. An example of a reactive arylamine group is arylnitrenium ion while an example of a reactive aralkyl group is benzyl radical.

The DNA-reactive groups are generated through specific reaction chemistries, such as oxidation at carbon—carbon double bonds yielding alkylating or aralkylating agents; oxidation or reduction at nitrogen producing arylaminating agents; conjugations of hydroxy compounds producing aralkylating or arylaminating agents; and conjugation between glutathione with dihaloalkanes producing alkylating agents. There are, however, some carcinogens that do not fit these categories, such as acylating agents, α,β-unsaturated aldehydes, chloroethylene oxide, etc. (Dipple, 1995).

*Alkylation and alkylating agents*

Alkylating agents add an electrophilic alkyl group ($R\text{-}CH_2^+$) to electron-rich (nucleophilic) sites in DNA. Carcinogens that transfer alkyl residues to DNA include

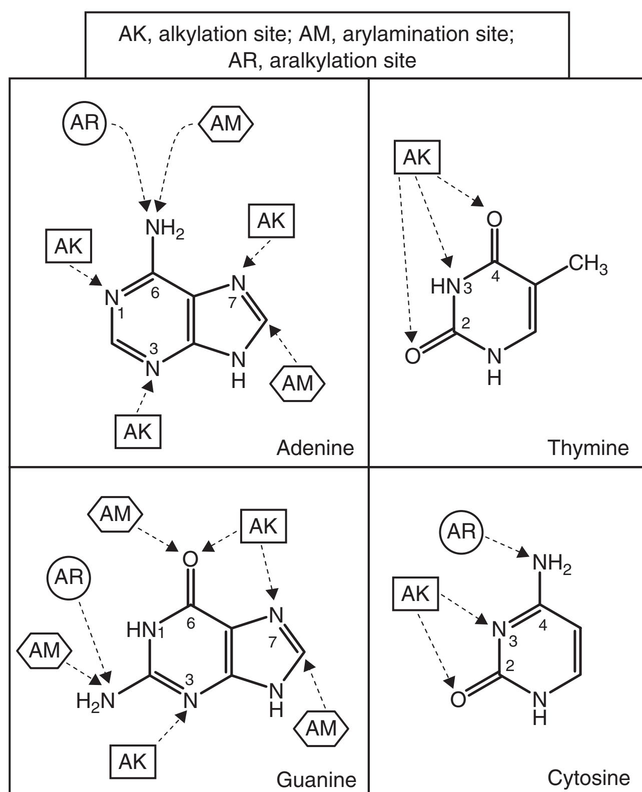

**FIGURE 22.2** DNA bases showing the sites where alkylation, arylamination, and aralkylation reactions can occur resulting in the formation of DNA adducts. N3 alkylation of guanine, although reported in the literature and shown in the figure, is less common than N7 alkylation. Adapted from Okey *et al.* 1998. In *The Basic Science of Oncology*, 3rd ed., edited by I.F. Tannock and R.P. Hill, with permissions from the McGraw-Hill Companies.

nitrosamines, aliphatic epoxides, aflatoxins, lactones, nitrosoureas, mustards, haloalkanes, aryl triazenes, and sultones (Dipple, 1995). The sites of substitution in DNA bases by alkylating agents are many and are indicated in Figure 22.2. Alkylating agents are produced by enzymatic reactions (e.g. P450 mediated). An example is cytochrome P450 2E1 (CYP2E1)-mediated metabolism of DMN (Figure 22.3). CYP2E1-mediated hydroxylation of a methyl group in DMN results in the formation of $\alpha$-hydroxynitrosamine, which undergoes spontaneous demethylation, releasing one molecule of formaldehyde and forming MMN (monomethyl nitrosamine). The MMN undergoes tautomerization to form diazonium hydroxide, which undergoes spontaneous decomposition to form the carbonium ion ($CH_3^+$). The carbonium ion is the alkylating agent. Larger *N*-nitroso compounds, such as tobacco-smoke-derived NNK ((4-methylnitrosamino)-1-(3-pyridyl)-1-butanone), are activated by cytochrome P450 1A2 (CYP1A2). Aflatoxin B1 is also bioactivated by P450. In humans, cytochromes P450 1A2 (CYP1A2) and P450 3A4 (CYP3A4) appear to be the most important in the metabolic activation of aflatoxin B1 (Van Vleet *et al.*,

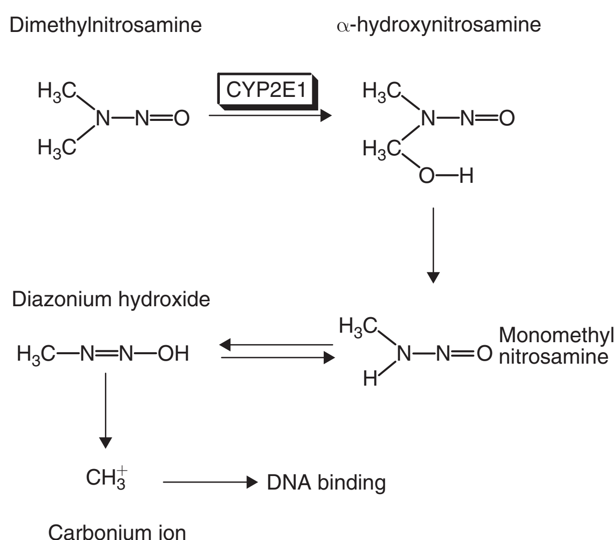

**FIGURE 22.3** Metabolic activation pathway for DMN. Adapted from Okey *et al.* 1998. In *The Basic Science of Oncology*, 3rd ed., edited by I.F. Tannock and R.P. Hill, with permissions from the McGraw-Hill Companies.

2002). Hydroxylation of the unsaturated C—C bond in aflatoxin B1 results in the formation of a reactive epoxide intermediate, the 8,9-epoxide (Figure 22.4). This aliphatic epoxide can intercalate into DNA by forming an alkyl adduct with guanine. This intercalation, resulting in a GC→TA transversion mutation at the third position of codon 249 of the p53 gene, is thought to be the major reason for aflatoxin-induced carcinogenesis (Smela *et al.*, 2001).

*Arylamination and arylaminating agents*

Aromatic amines (arylamines), amides, aminoazo dyes, heterocyclic amines, etc. all undergo metabolic activation forming highly reactive, electrophilic aryl nitrenium ions ($Ar—NH^+$). The major sites of substitution in DNA by arylaminating agents appear to be the C-8 position and the amino group of the purine nucleotides (Dipple, 1995). Potential arylamination sites in DNA bases by arylaminating agents are indicated in Figure 22.2. A prototypical example is the metabolic activation of 2-naphthylamine. *N*-oxidation by CYP1A2 forms the corresponding *N*-hydroxyarylamine (e.g. *N*-hydroxynaphthylamine), which can undergo a number of conjugation reactions forming sulfate, acetate, or glucuronide conjugates. These conjugates can be excreted in the urine. In the acidic pH of urine, the conjugate dissociates and the *N*-hydroxynaphthyl moiety is protonated to form the nitrenium ion (Figure 22.5). Formation of the nitrenium ion, which is the ultimate carcinogen, explains why 2-naphthylamine is carcinogenic in the urinary tract and urinary bladder. *N*-acetyltransferase (NAT), which catalyzes the transfer of acetyl groups from acetyl-CoA to arylamines forming acetyl

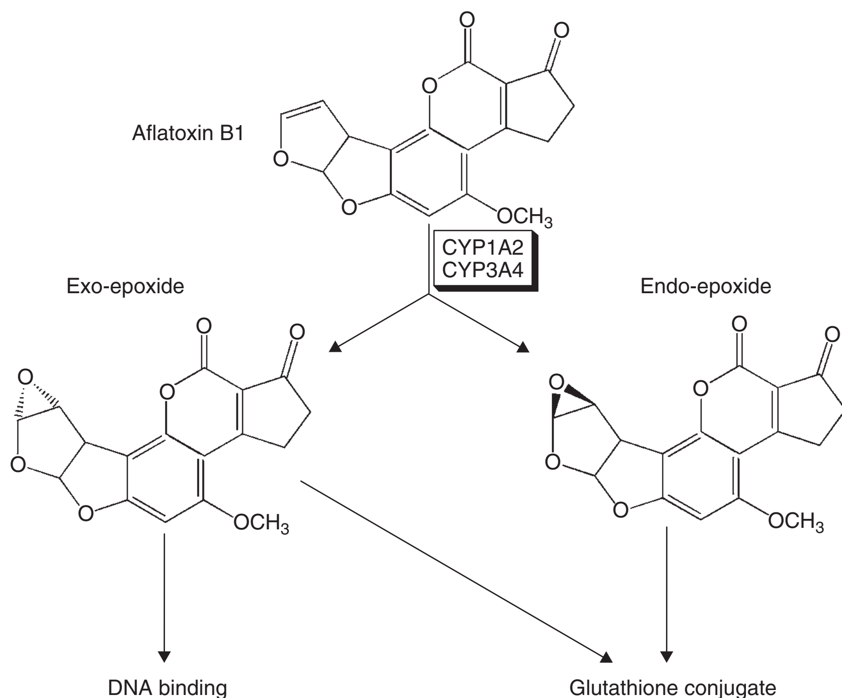

**FIGURE 22.4** Metabolic activation pathway for aflatoxin B1. Adapted from Okey *et al*. 1998. In *The Basic Science of Oncology*, 3rd ed., edited by I.F. Tannock and R.P. Hill, with permissions from the McGraw-Hill Companies.

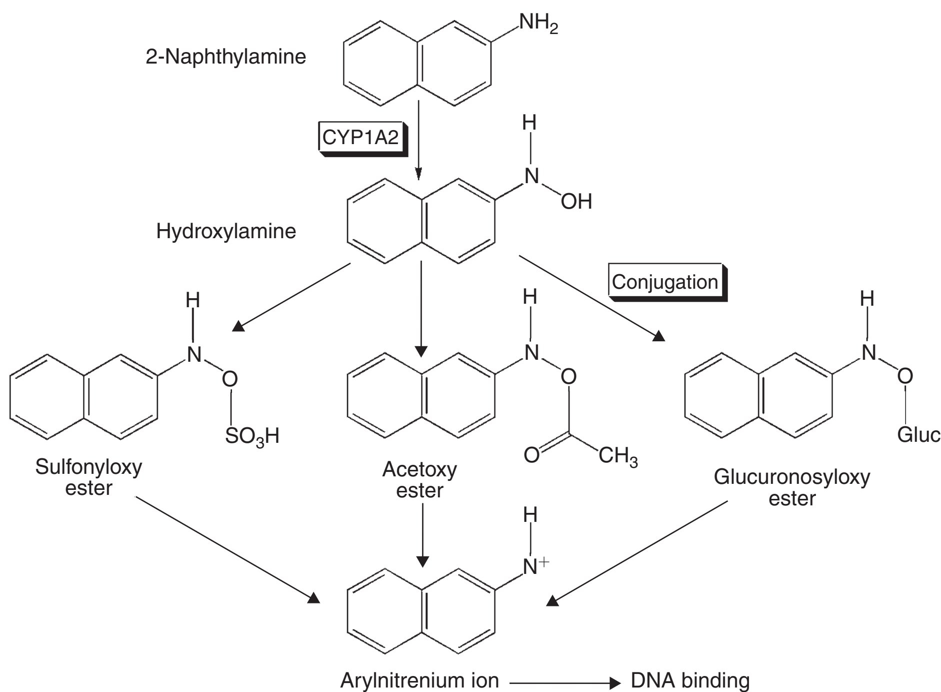

**FIGURE 22.5** Metabolic activation pathway for 2-naphthylamine. Adapted from Okey *et al*. 1998. In *The Basic Science of Oncology*, 3rd ed., edited by I.F. Tannock and R.P. Hill, with permissions from the McGraw-Hill Companies.

esters, shows a great deal of polymorphism across species. Among humans, there are slow and fast acetylators. In hamsters, acetylation is fast while in dogs and rats, acetylation is slow. These species differences in NAT activity as well as intraspecies polymorphism can greatly influence the toxicity outcome of the substances in question.

*Aralkylation and aralkylating agents*

Polycyclic aromatic hydrocarbons (PAHs) and related compounds are capable of transferring an aralkyl group to DNA. Carcinogens that transfer an aralkyl group to DNA include the PAHs, alkyl benzenes, pyrrolizidine alkaloids,

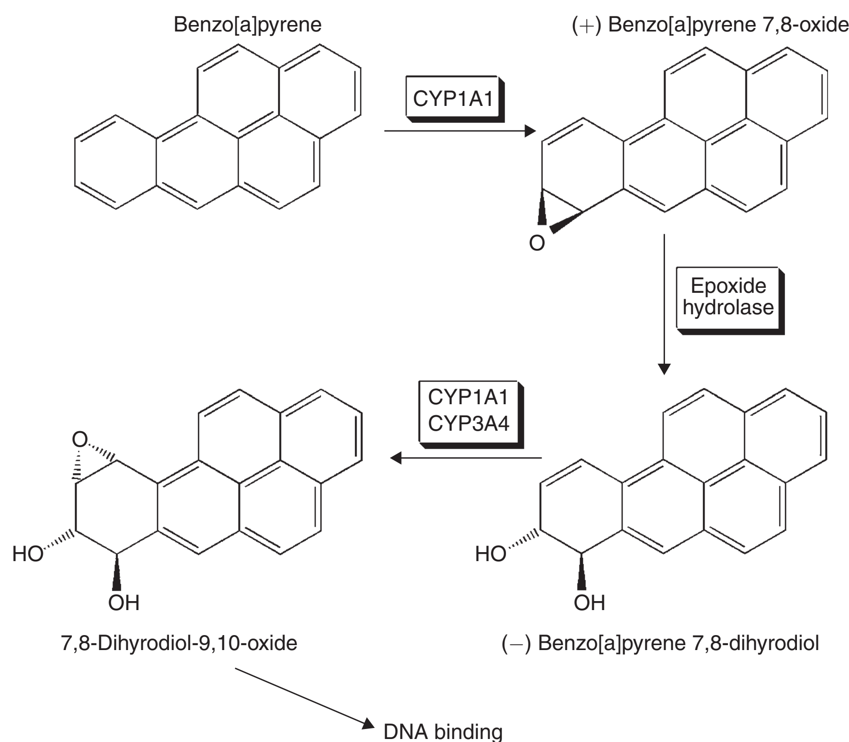

**FIGURE 22.6** Metabolic activation pathway for benzo[a]pyrene. Adapted from Okey *et al*. 1998. In *The Basic Science of Oncology*, 3rd ed., edited by I.F. Tannock and R.P. Hill, with permissions from the McGraw-Hill Companies.

and nitroaromatics that are activated through the formation of dihydrodiol epoxide (Dipple, 1995). A classic example of this class is benzo[a]pyrene, which is converted by cytochrome P450 1A1 (CYP1A1) to the 7,8-epoxide. This epoxide is hydrolyzed by epoxide hydrolase to the 7,8-dihydrodiol of benzo[a]pyrene, which again can be converted by CYP1A1 to the 7,8-dihydrodiol-9,10-epoxide of benzo[a]pyrene. This epoxide is stable, electrophilic and therefore it attacks the DNA bases (Figure 22.6). Potential aralkylation sites in DNA bases by aralkylating agents are indicated in Figure 22.2.

### *Cellular defense against DNA damage: DNA repair, and removal of DNA adducts*

DNA adducts (the chemical induced, covalently modified DNA bases) can alter the DNA structure and in turn, molecular processes, such as replication and transcription. If not repaired or repaired incorrectly, these modifications may ultimately lead to mutations and eventually cancer, particularly if the adduct is located in an oncogene or tumor suppressor gene. There are a number of mechanisms to repair DNA adducts: (1) direct repair, (2) base excision repair (BER), (3) nucleotide excision repair (NER), and (4) mismatch repair (MMR).

In *direct repair*, the bond between the nucleotide and the adduct is broken restoring the original conformation. For example, $O^6$-methylguanine ($O^6$-MeG) is repaired by MGMT (methylguanine-DNA methyltransferase) by direct demethylation of the methylguanine. If methylguanine is not repaired, it will pair with thymine instead of cytosine during replication. In the following replication cycle, this thymine will pair with adenine in the complementary strand. The net result is a G:C→A:T transition mutation in the DNA. Such G:C→A:T transition mutations are known to activate the *ras* oncogenes in nitrosourea-induced mouse lymphomas and rat mammary tumors, as well as in azoxymethane (AOM)-induced aberrant crypt foci (ACF) (Dumenco *et al.*, 1993, Zaidi *et al.*, 1995).

*BER* mechanism works mainly on non-bulky base modifications, such as those produced by methylation (in positions where it does not interfere with H-bonding, such as 3- or 7-methyladenine or 8-hydroxyguanine). These types of methylation patterns are produced by MNU. These inappropriate bases are recognized and removed by specific DNA glycosylases, which cleave the *N*-glycosidic bond between the base and the sugar. As a result, the base is removed and the sugar–phosphate backbone of the DNA remains intact. This creates a base gap in the DNA, also called an AP site (**ap**urinic or **ap**yrimidinic site). The AP site is then recognized by AP endonuclease, which introduces a nick 5′ to the AP site. A third enzyme, deoxyribophosphodiesterase (an excision endonuclease) then produces a second nick 3′ to the AP site and removes the baseless sugar–phosphate backbone. The resultant one nucleotide gap is filled in by DNA polymerase, and DNA ligase seals the nick.

*NER* is a versatile mechanism that can eliminate a wide range of structurally unrelated lesions. Bulky base modifications, such as benzo[a]pyrene–guanine adducts caused by smoking, cisplatin–guanine adducts and psoralen–thymine adducts resulting from chemotherapy,

UV-induced multiple thymine dimers, etc. are all repaired by NER. Humans do not have photolyase, so thymine dimers are corrected in humans by NER. The mechanism of NER involves generation of two nicks by an excision nuclease, one on each side of the lesion. As a result, a small portion of the affected DNA strand is removed. DNA polymerase then continues the repair synthesis and ligase seals the gap.

*MMR* mechanism repairs bases that violate Watson–Crick base pairing rules. The classic example is that of *Escherichia coli*. The sequence 5′ -GATC-3′in *E. coli* DNA is methylated at adenine, and the sequences 5′-CCAGG-3′and 5′ -CCTGG-3′are methylated at cytosine. When DNA replicates, the daughter-strand methylation is delayed. As a result, the newly synthesized daughter strand is always undermethylated compared to the parental strand. If there is a base misincorporation, the MMR machinery (MutS–MutH–MutL complex) identifies the misincorporated base by scanning the methylation status of both strands. The mismatched base is excised from the undermethylated daughter strand. The same principle applies to eukaryotic DNA MMR. Three eukaryotic protein heterodimers composed of Msh (**M**ut**S** **h**omologue) subunits recognize DNA mismatches with different but overlapping specificities: Msh2 · Msh3, Msh2 · Msh6, and (only in plants) Msh2 · Msh7. A second heterodimer, Mlh1 (**M**ut**L** **h**omologue1) · Pms2, couples mismatch recognition to excision of the error-containing nascent DNA. Deficiencies in Msh2 dramatically increase mutation rates (Hoffman *et al.*, 2004). For example, in HNPCC (hereditary non-polyposis colorectal cancer) and other human cancers, mutations in MMR genes, such as MSH2, MSH6, MLH1, PMS2, have been observed (Buermeyer *et al.*, 1999); by the same token, mice transgenic for Msh2 are tolerant to the carcinogenic effects of methylating agents (deWind *et al.*, 1995).

Apart from the above-mentioned mechanisms, two other mechanisms of DNA repair are recombination repair and strand break repair. In *recombination repair*, when DNA polymerase encounters an unrepaired lesion on the parental (template) strand during replication, it stops synthesis at that point and resumes synthesis at the next priming site. This leaves a gap in the daughter strand. This gap is filled by recombination with the other parental strand. This donor parental strand is then repaired by polymerase and ligase. *Strand break repair* may involve single- or double-strand breaks. *Single-strand breaks* do not disrupt the integrity of the DNA. The intact single strand is coated by PARP 1 (poly(ADP-ribose) polymerase-1) protein near the lesion site of the other strand. The single-strand break is then repaired as in excision repair. *Double-stranded breaks* are dangerous because they damage the integrity of the DNA. Double-stranded breaks can be repaired in two ways: either by crossing over or by synthesis-dependent strand-annealing repair. Various proteins (such as Ku) bind to the broken ends of the DNA to protect it and initiate the repair.

## Viral carcinogenesis

### *Tumor viruses, oncogenes, and tumor suppressor genes*

A number of cellular genes are now implicated in carcinogenesis. These genes are of two types: oncogenes and tumor suppressor genes. Broadly speaking, activation of oncogenes and inactivation of tumor suppressor genes may have similar consequences in terms of carcinogenesis. Oncogenes are found in cancer causing viruses which are of two types: DNA viruses with DNA genomes and RNA viruses with RNA genomes. DNA viruses with oncogenic potential are from six distinct viral families: hepatitis B viruses, simian virus 40 (SV40) and polyomavirus, papillomaviruses, adenoviruses, herpesviruses, and poxviruses. In contrast, members of only one family of RNA viruses, the retroviruses, are capable of inducing oncogenic potential (Cooper, 1995).

#### *Retroviral oncogenes and their evolution*

The discovery of retroviral oncogenes significantly advanced our understanding about the function of genes specifically responsible for the induction of abnormal cell proliferation. They replicate inside the cell through a DNA intermediate, called *provirus*, which is integrated into the chromosomal DNA of the infected cell. Transforming viruses (viruses capable of inducing malignant transformation of animal cells) do not need the oncogene for their replication. Viral oncogenes (*v-onc*) are derived from cellular proto-oncogenes (*c-onc*). Cellular proto-oncogenes contain introns while the corresponding viral oncogenes generally lack the introns. Thus, viral oncogenes originated in the host through recombination between the genome of a non-transforming retrovirus and a cellular oncogene. This has been demonstrated in studies on the *v-src* oncogene by Hanafusa and colleagues in the early 1980s.

Figure 22.7 shows how a cellular proto-oncogene (*c-onc*) could be acquired by the viral genome. Transforming viruses preferentially integrate at the fragile sites on the host genome. These fragile sites correspond to the hot spots of recombination. Integration of the provirus in the genome next to the *c-onc* produces a transcription unit under the control of the viral LTR (long terminal repeats). Transcription of this unit produces a viral/cellular hybrid RNA. Intact viral RNAs are also produced from other integrated proviruses. These intact viral RNAs and hybrid RNAs, through reverse transcription and recombination, captures the processed cellular proto-oncogene as part of the viral genome. The captured processed cellular proto-oncogene now becomes a retroviral oncogene (*v-onc*).

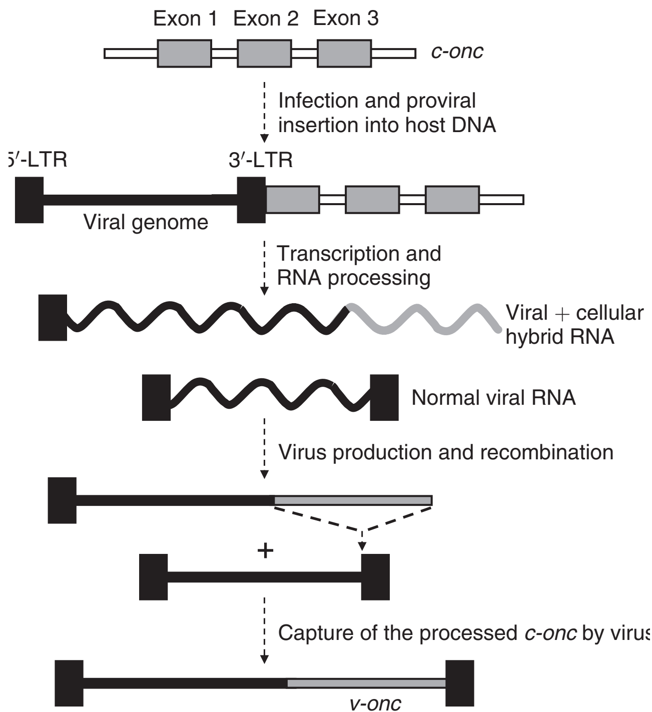

**FIGURE 22.7** Mechanism by which a cellular proto-oncogene (*c-onc*) is captured by retrovirus to give rise to a viral oncogene (*v-onc*).

*Activation of oncogenes*

Retroviral oncogenes (*v-onc*) are altered versions of normal cellular genes called proto-oncogenes. The function of the *v-onc* product is similar or identical to that of the proto-oncogene (*c-onc*) product, but its expression is generally unregulated. Proto-oncogenes may be activated by mutation, chromosomal re-arrangement, or gene amplification. Chromosomal re-arrangements that include translocations and inversions can activate proto-oncogenes by dysregulation of their transcription (e.g. transcriptional activation) or by gene fusion. For example, the product of the *ras* oncogene differs from that of the normal proto-oncogene by one base which is caused by a point mutation in the 12th codon (GGC→GTC) resulting in one amino acid change (Gly→Val). An example of oncogene activation through gene amplification is *myc*, which codes for a transcription factor that plays a role in cell division. One-third of all neuroblastomas shows *myc* oncogene amplification that inversely correlates with the prognosis. Such amplification of the *myc* oncogene results in the generation of a very high amount of its product. Generation of a high amount of *myc* oncogene product can also be due to high levels of transcription. This has been reported in Burkitt's lymphoma where translocation of the *myc* proto-oncogene from its normal location (chromosome 8) to chromosome 14 brings it close to the immunoglobulin heavy chain gene promoter. As a result, c-*myc* now finds itself in a region of vigorous gene transcription, with a consequent overproduction of its product. Another example of chromosomal translocation and dysregulation of proto-oncogene is found in chronic myelogenous leukemia (CML). In CML, a reciprocal translocation occurs between chromosomes 9 and 22 [t(9;22)]. A portion on the long arm of chromosome 9 (9q) containing the *abl* gene is translocated next to the *bcr* (breakpoint cluster region) gene on the long arm of chromosome 22 (22q). The altered chromosome 22 is called the Philadelphia chromosome (Ph′ ). The *bcr–abl* produces higher levels of a fusion protein Bcr–Abl that has protein kinase activity. Some other oncogenes associated with cancers of various organs are *hst* (stomach cancer), *met* (osteosarcoma), *bcl-1* (B-cell leukemia), etc.

*Inactivation of tumor suppressor genes*

Tumor suppressor genes, which also participate in the regulation of normal cell growth, are usually inactivated by point mutations or truncation of their protein sequence coupled with the loss of the normal allele. The first mutation may be inherited or somatic. The second mutation will often be a gross event leading to loss of heterozygosity and tumor suppressor function. This mechanism provides support to the two-hit hypothesis. In 1971, Alfred Knudson proposed the *two-hit hypothesis* in which he applied statistical analysis to compare patients with hereditary and non-hereditary forms of retinoblastoma. Knudson hypothesized that one germline copy of the damaged gene that is inherited in the hereditary form of retinoblastoma was not sufficient to trigger the development of this cancer. A second hit to or loss of the good copy in the gene pair was necessary to produce retinoblastoma. Frequent loss of heterozygosity in the tumor cells provides support to Knudson's hypothesis. Analysis of linkage markers in retinoblastoma cells and normal cells from the same individual shows that the markers that are heterozygous in normal cells are hemizygous in tumor cells, indicating the loss of the normal allele in the tumor cells (second hit).

*Functions of oncogene products (oncoproteins)*

Proto-oncogenes encode proteins that are mostly involved in the regulation of cell growth, division, and differentiation. Consequently, proto-oncogenes encode products that can act as growth factors, growth-factor-receptor-associated tyrosine kinases, membrane-associated non-receptor tyrosine kinases, G-protein-coupled receptors, membrane-associated G-proteins, serine–threonine kinases, transcription factors, and regulators of programmed cell death.

Growth factors play important roles in cell cycle control, and they signal a cell to either enter the G1 phase or bypass it. The right amount of growth factors should be produced at the right time, or else cell cycle control may be dysregulated. Examples of oncogene-encoded growth factors are *sis* oncogene-encoded platelet-derived growth factor (PDGF) B chain and *int*-2 oncogene-encoded

fibroblast growth factor (FGF)-related growth factor. Receptor-associated and non-receptor tyrosine kinases as well as G-proteins, G-protein-coupled receptors, and serine–threonine kinases all encode products that are important in regulating the transduction of mitogenic signals in the cell, thereby regulating normal cell division. In most cases, these oncogenes encode mutant forms of the proteins so that they are not subject to the on–off regulation in response to mitogenic signals. In other words, the mitogenic signal is perpetually "on", resulting in uncontrolled cell proliferation.

Oncogenes, such as *src* and *abl*, encode tyrosine kinases that are membrane associated, while *erb*B, *neu*, and *fms* encode transmembrane kinases. An example of an oncogene encoding a GTP-binding GTPase is *ras*. Normal GTP-binding proteins (G-proteins), including *ras*, are important signal transducers. The active form binds GTP and transduces the mitogenic signal; hydrolysis of GTP to GDP inactivates the protein and terminates the signal. Further activation involves exchange of GDP for GTP. Mutant forms of *ras* exist in an inactive GDP-bound form, resulting in a perpetual "on" mode of the mitogenic signal. Oncogenes encoding transcription factors also act by the same principle. The proto-oncogene products of *fos* (Fos) and *jun* (Jun) form a heterodimer to produce the transcription factor *activator protein-1* (AP-1). Mutant AP-1 may act in a constitutive manner without activation by agents, such as phorbol esters. Other oncogenes, such as *myc* and *myb*, also code for transcription factors that, when mutated, can cause aberrant transcriptional dysregulation.

The cell growth and division suppressor effects are also lost in mutant *p53* which is a tumor suppressor gene and whose product (p53 protein) is a transcription factor. The three dimensional structure of p53 protein with its target DNA molecule defined the core domain and the amino acids involved in DNA binding (Cho *et al.*, 1994). These amino acids that are involved in DNA binding show the highest mutation rate in various cancers. This demonstrates how mutations in tumor suppressor genes can abrogate their tumor suppressor function by disrupting the transcriptional regulation of their target genes. Another role of p53 is to regulate apoptosis or programmed cell death by upregulating the pro-apoptotic gene *Bax*. Mutant p53 cannot mediate apoptosis; thus cells with unrepaired DNA damage are prevented from undergoing apoptosis. Survival of these cells and their subsequent division may lead to the development of cancer cells.

Mutagenic chemicals that can disrupt the structure and/or expression of these proto-oncogenes can cause their oncogenic activation. For example, phorbol ester is a known activator of AP-1-mediated transcription. The procarcinogen 1,2-dimethylhydrazine has been reported to induce mutation in *ras* which was detectable in preneoplastic and neoplastic rat colonic mucosa (Jacoby *et al.*, 1991).

## Radiation carcinogenesis

### *Radiation dose and risk*

In the following discussion, radiation will refer to only ionizing radiation. A radiation dose to tissue is expressed as *absorbed energy per unit tissue mass*. *Gray* (Gy) is the unit of radiation dose and is quantified as 1 J/kg. The older unit *rad* is still used and 1 rad = 0.01 Gy. Carcinogenic potential depends on the absorbed dose (energy).

LET (linear energy transfer, $L$) is a measure of the rate at which energy ($E$) is deposited to the absorbing medium per unit distance ($l$) traversed by the radiation ($L = dE/dl$; if the distance traversed is measured in mm, then $L = \text{keV/mm}$). Consequently, high-LET radiations (e.g. $\alpha$-particles, neutrons, heavy ions, pions, also known pi mesons) will loose, i.e. deposit in the absorbing medium, greater amounts of energy than low-LET radiations (e.g. $\gamma$-rays, X-rays, electrons). In the case of tissue exposure, the energy deposited by the radiation causes ionizations and the generation of free radicals, which cause macromolecular damage. Thus, high-LET radiations are more destructive to biological materials than low-LET radiations because at the same dose, low-LET radiations induce the same number of radicals more sparsely within a cell, whereas high-LET radiations transfer most of their energy to a small region of the cell. The localized DNA damage caused by dense ionizations from high-LET radiations is more difficult to repair than the diffuse DNA damage caused by the sparse ionizations from low-LET radiations.

Experimental studies with animals as well as epidemiological studies and data indicate that higher or continual radiation exposure increases the incidence of specific cancers. Increased incidence of lung cancer has been observed among uranium miners, fluorspar miners, zinc and iron ore miners (Adams and Cox, 1997). Gottlieb and Husen (1982) studied the incidence of lung cancer among American Indians. According to the authors, lung cancer has been a rare disease among the Indians of the southwestern United States, but the advent of uranium mining in the area has been associated with an increased incidence of lung cancer among Navajo uranium miners. The study centered on Navajo men with lung cancer who were admitted to the hospital from February 1965 to May 1979. Of a total of 17 patients with lung cancer, 16 were uranium miners. The cause of the lung cancers are the $\alpha$-particle radiation from the inhaled radon gas emanating from the radium present in the ore. Another well-documented example of radiation-induced cancer is the occurrence of osteosarcoma among workers in luminous dial watch factories. Workers used to lick the paint brush to maintain sharp edges and in the process consumed radium-226 and radium-228. The ingested radium deposited in the bone and was the source of short-range $\alpha$-particles. A recent example of radiation-induced increases in thyroid cancer comes from the Chernobyl incident.

The nuclear reactor explosion at Chernobyl in 1986 resulted in substantial contamination of some parts of Belarus, Ukraine, and Bryasnk. Immediately after the accident, these regions were contaminated with cesium-137 as well as various isotopes of iodine, including iodine-131 (Stsjazhko *et al.*, 1995). Cesium-137 is a very dangerous radioisotope to the environment because of its long-term effects. Its half-life of about 30 years ensures that it stays in the environment for a very long time. The authors reported that those who continued to live in the contaminated region and to consume locally produced milk for the 3 months after the accident, most (about 85%) of the radiation dose to the thyroid was derived from iodine-131, while the remainder was from short-lived isotopes of iodine. The incidence of thyroid cancer among children under 15 years was 30.6 per million during 1991–1994 as compared to 0.3 during 1981–1985. Another source of human data on carcinogenesis by ionizing radiation is from the A-bomb survivors from Hiroshima and Nagasaki. Data showed that in the first 5–10 years after the exposure, the risk of leukemia increased rapidly but declined thereafter. The risk of solid tumors in many organs also increased significantly (Okey *et al.*, 1998).

#### *Mechanism of radiation-induced carcinogenesis*

An absorbed dose of 1 Gy generates about $2 \times 10^5$ ionizations within the mammalian cell. Approximately 1% of these ionizations occur in the DNA itself (Adams and Cox, 1997). Consequent DNA damage involves both single- and double-strand breaks, most of which are repaired within a few hours. Single-strand breaks, which are more frequently caused by low-LET radiations, are more readily repaired than double-strand breaks. UV radiation is known to distort the DNA strands by causing thymine dimers. In animals that have photolyase, thymine dimers are repaired by the direct repair mechanism that involves breaking of the bond causing the lesion. Humans do not have photolyase, so thymine dimers in humans are corrected by the NER mechanism.

Ionizing radiation and oxidative stress are closely associated. Irradiated cells produce damaging reactive oxygen species (ROS), which can cause severe damage to cellular macromolecules including nuclear DNA (Wu *et al.*, 1999; Spitz *et al.*, 2004). A cell's oxidative status plays an important role not only at the time of radiation exposure, but also long after exposure. Irradiation may produce ROS for several minutes or even hours after exposure (Spitz *et al.*, 2004).

At the cytological level, an extension of radiation-induced DNA damage is chromosome breakage. Radiation can induce aberrant intra-chromosomal crossing over that involves one or both chromatids. Radiation can also induce non-disjunction of homologous chromosomes resulting in trisomy in the $F_1$ offsprings, as well as other chromosomal aberrations, such as translocations and deletions (Adams and Cox, 1997). Chromosomal breaks have been shown to occur at a higher frequency in certain fragile sites. In other words, depending on the energy, radiation can cause increased genomic instability.

Unrepaired DNA-strand/chromosomal breaks can lead to deletion or scrambling of gene sequences. The hypoxanthine–guanine phosphoribosyltransferase (HPRT) locus on X-chromosome is known to undergo such aberrations following high radiation exposure (Thacker, 1986). If the target gene is an oncogene or a tumor suppressor gene, then radiation-induced mutations in oncogenes or inactivation of tumor suppressor genes may have serious consequences.

It should be emphasized that most of the molecular data on radiation-induced carcinogenesis have been obtained from laboratory studies, including *in vitro* studies. For humans, epidemiological studies from accidents and disasters involving ionizing radiation also demonstrate increased risk of cancer owing to high exposure to radiation. Nevertheless, little reliable information is currently available on the increased risk factors for high-LET radiations or about dose-rate effects of low-LET radiations (Okey *et al.*, 1998).

## CLASSIFICATION OF CARCINOGENS

The most widely used systems for classifying carcinogens comes from the International Agency for Research on Cancer (IARC). The US Environmental Protection Agency (EPA) has also developed a very similar classification scheme. In the past 30 years, the IARC has evaluated about 900 likely candidates for their cancer causing potential in humans. Most of the agents are of probable, possible, or unknown risk. Only about 90 are classified as carcinogenic to humans. The IARC classification scheme is described below:

- *Known human carcinogen*

*Group 1*: There is sufficient evidence of carcinogenicity in humans.

- *Probable human carcinogen*

*Group 2A*: There is limited evidence of carcinogenicity in humans, but sufficient evidence of carcinogenicity in experimental animals, and a strong evidence that the carcinogenesis in experimental animal is mediated by a mechanism that also operates in humans.

- *Possible human carcinogen*

*Group 2B*: There is limited evidence of carcinogenicity in humans, and less than sufficient evidence of carcinogenicity in experimental animals.

- *Not classifiable for human carcinogenicity*

*Group 3*: The evidence of carcinogenicity is inadequate or limited in experimental animals.

- *Not likely to be a human carcinogen*

*Group 4*: Not carcinogenic to humans.

## ASSAYS FOR CARCINOGENS

Tests most frequently used to determine the carcinogenic activity include (1) long-term bioassays and (2) short-term assays. Recently, building of databases of known/suspected carcinogenic compounds has helped in the development of computer programs that can predict the carcinogenic potential of new compounds, using quantitative structure–activity relationships (QSAR). These programs provide additional tools when there is ambiguous data or insufficient data to infer safety. Some of the common tests under each category are discussed below.

### Long-term bioassays

The National Toxicology Program (NTP) rodent cancer bioassay evolved out of the National Cancer Institute (NCI) cancer bioassay protocol in the 1970s. Groups of 50 or more rodents are assigned to control or treatment groups. Test substances are given by intubation, dietary or drinking water consumption, or dermal or inhalation exposure. Dosing starts at age 5–6 weeks and lasts for 2 years, at which point surviving animals receive a complete histopathological examination (Bucher, 2002). In a classic lifetime tumor bioassay, the maximum tolerated dose (MTD) for a particular chemical is determined in a dose-range finding study, then doses close to the MTD are administered to male and female rats and mice for 2 years. A statistically significant, chemical-associated increase in tumor count is taken as evidence of carcinogenicity (Parsons and McKinzie, 2001). These assays are expensive and time consuming. Additionally, the use of MTD is debatable since the high doses of chemical used to develop tumors often lead to cytotoxic effects in animal tissues. This cytotoxicity may lead to cell proliferation and other promoter-like events. Nevertheless, the rodent tumor bioassay has been used for carcinogenicity testing for many years, primarily for four reasons. First, the rodent tumor bioassay fulfills an obvious need for an experimental system. Second, *in vivo* exposure and tumor development are considered more relevant endpoints for assessing human cancer risk than *in vitro* tests with bacterial or mammalian cells or non-tumor endpoints. Third, the rodent tumor bioassay has been used for many years without disastrous human health consequences, and finally, at the present time there is no other "ideal" assay with which to replace the rodent tumor bioassay (Parsons and McKinzie, 2001).

### Short-term assays

These assays may be used to determine a chemical's ability to cause *mutational events*, *chromosomal aberrations* or *DNA damage*, *in vitro* or *in vivo*.

Two major assays used to detect *mutational events* are the *Ames test* for bacterial mutagenesis, and the *mammalian cell gene mutation assays*. The Ames test was developed in the early seventies by Bruce Ames at The University of California, Berkeley. The Ames method is based on inducing growth in genetically altered strains of *Salmonella typhimurium*. These strains need histidine in order to grow. If the chemical agent under investigation is a mutagen, it should cause some of the bacteria to undergo mutations so that some of these bacteria (revertants) can grow without histidine, just like the wild-type bacteria. To evaluate the effect of metabolism on the chemical, such tests are performed in the presence and absence of S9 fraction (post-mitochondrial supernatant fraction). The S9 fraction contains liver enzymes, generally from a rat treated with a broad-spectrum xenobiotic-metabolizing enzyme inducer, such as Arochlor 1254. There are several altered *Salmonella* strains used in the Ames test, such as TA97, TA98, TA100, TA1535, and TA1537; each varies in sensitivity to specific mutagens. The Ames test yields a number, such as the number of revertants (could be as high as several hundred thousands) per microgram of a pure chemical (mutagen) or per gram of food containing that mutagen. The mammalian cell gene mutation assays measure forward mutations at a specific locus. Two of the well-studied loci are the thymidine kinase (TK) locus in mouse lymphoma cells and the HPRT locus in Chinese hamster ovary (CHO) cells. To evaluate the effect of metabolism on the chemical, such tests are performed in the presence and absence of S9 fraction.

Cytogenetic analysis for *chromosomal aberrations* enables direct observation of various chromosomal aberrations. Cells are arrested in metaphase, examined microscopically, and the chromosomal aberrations are enumerated. The cells used could be CHO cells, human peripheral blood lymphocytes, or rat lymphocytes. An alternate cytogenetic approach is the observation of *micronuclei*. A micronucleus is formed during the metaphase/anaphase transition. It may arise from a lagging chromosome (*aneugenic* event resulting in chromosome loss) or an acentric chromosome fragment detaching from a chromosome after breakage (*clastogenic* event). Micronuclei are easily scored. Another assay for measuring chromosomal aberrations is the *sister chromatid exchange* (SCE) assay, which detects the ability of a chemical to enhance the exchange of DNA between two sister chromatids of a duplicating chromosome. SCE means a reciprocal interchange of the two chromatid arms within a single chromosome. This exchange is visualized during metaphase. Detection of SCEs requires some means of differentially labeling sister chromatids, such as by the incorporation of bromodeoxyuridine (BrdU) into chromosomal DNA for two cell cycles. The most commonly used assays employ mammalian bone marrow cells or peripheral blood lymphocytes,

often from rodent species. All these assays could be performed in the presence and absence of metabolic activation systems (S9).

Detection of *DNA damage* can be determined using the *comet assay*. It is also known as the *single-cell gel electrophoresis assay* and it is a very useful and sensitive technique for detecting DNA damage at the level of a single cell. The technique acquired its name from the comet-like shape of the DNA of the cells which can be seen under the microscope after the procedure. This technique was developed by Swedish researchers Östling and Johansson in 1984, and was later modified by Singh and coworkers in 1988 as the alkaline comet assay. The alkaline comet assay is much more sensitive than the original comet assay. Briefly, the single suspension of the cells of interest are suspended in low-melting agarose and layered onto slides pre-coated with agarose. Cells are lysed under high salt concentration to release the damaged DNA. The DNA is subjected to unwinding under alkaline/neutral conditions to allow DNA supercoils to relax. Electrophoresis of this DNA under neutral or highly alkaline (pH > 13) conditions allows the broken ends to migrate forming the "comets". After neutralization, staining is done using fluorescent DNA dyes (e.g. ethidium bromide, propidium iodide, Hoescht 33258, acridine orange, etc.) and the DNA is visualized under a fluorescent microscope. The slides are then scored. About 50–100 cells are counted per sample, by manual counting or using specific software. Both qualitative and quantitative assessment of DNA damage is carried out. The alkaline comet assay enables the detection of single-strand DNA breaks in individual cells. Therefore, the alkaline comet assay can measure low levels of DNA-strand breaks. The ability of a genotoxic agent to induce DNA lesions can also be investigated by measuring the *unscheduled DNA synthesis* (UDS). The assay measures DNA repair synthesis after excision and removal of a stretch of DNA containing the lesion induced by chemical and physical agents. The assay is based on the incorporation of tritium-labeled thymidine into the DNA of mammalian cells which are not in the S phase (DNA synthesis phase) of the cell cycle. The uptake of tritium-labeled thymidine can be determined by autoradiography or by liquid scintillation counting of DNA from the treated cells.

## Structure–activity relationships and carcinogenicity

Over 70,000 chemicals are used commercially and more than 100,000 naturally occurring chemicals have been identified (Cramer *et al.*, 1978). It would be virtually impossible, impractical, economically unfeasible, and not sensible to test all these compounds for potential carcinogenicity. This then begs the question – how do scientists (toxicologists, food technologists, drug developers, regulatory scientists, etc.) make decisions as to the safety of chemicals for addition to food, as drugs, for industrial use and/or for prioritizing those that do require additional, extensive toxicity testing?

One of the ways toxicologists have prioritized the study of chemicals is through the use of structure–activity relationship (SAR) analysis. SAR can be divided into two classes: (1) qualitative relationships and (2) quantitative relationships.

### *Qualitative structure–activity relationships*

A qualitative structure–activity relationship is an association between a molecular (sub)structure and the presence or absence of a biological activity, or the capacity to modulate a biological activity imparted by another substructure. A substructure associated with the presence of a biological activity is sometimes called a structural alert. Therefore, chemicals with similar chemical structures and physicochemical properties should exhibit similar biological activity whether it is a specific toxic effect or a pharmacological activity.

Qualitative SAR analyses rely upon a finite knowledge base of compounds that have been previously tested and the researcher's ability to identify key structural similarities between the compound of interest and compounds in the previously established knowledge bases. A variety of classification schemes, such as those detailed in Cramer *et al.* (1978), Cheeseman *et al.* (1999), and FDA's Red-book (Rulis *et al.*, 1984), have been developed that exploit these relationships, most of which are based on classifying either mutagens or carcinogens into broad categories. The Ashby and Tennant classification scheme (Ashby *et al.*, 1989) for structural alerts (Figure 22.8) is probably one of the simplest approaches to identifying potential carcinogenic activity of a compound that has unknown toxicity. This classification scheme correlates a structural alert (a fragment of a chemical's structure that may participate in an electrophilic attack on DNA) with a compound's carcinogenic potential. These alerts can be used in the evaluation of a chemical to give a qualitative sense of the compound's likelihood of being carcinogenic. A list of structural alerts proposed by Ashby *et al.* (1991) and functional groups cited by Munro *et al.* (1996) are summarized in Table 22.2.

In addition to using classification schemes to identify compounds for potential concerns, there are a number of structurally searchable database that allow one to identify close structural analogs of the compound in question. Publicly available examples are the National Library of Medicine's (NLM) ChemIDPlus (NLM, 2005) and EPA's Distributed Structure-Searchable Toxicity (DSSTox) Public Database Network (EPA, 2005). The data from these analogs may be used to extrapolate a numerical risk value for a potential toxic effect.

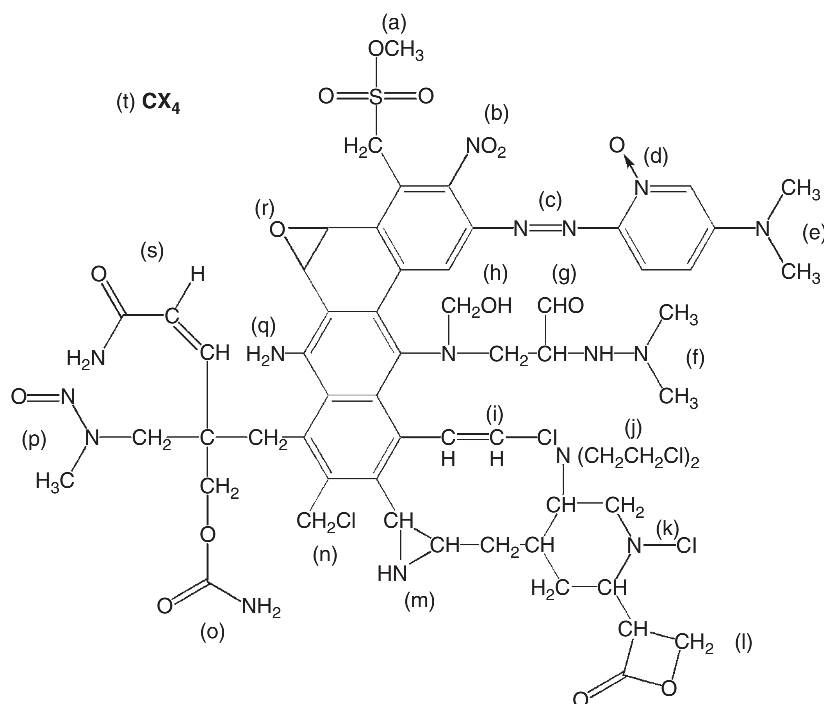

**FIGURE 22.8** Hypothetical chemical structure highlighting (in black) the Ashby and Tennant structural alerts for carcinogenicity. Adapted from Ashby *et al*. 1989. Classification according to chemical structure, mutagenicity to Salmonella and level of carcinogenicity of a further 42 chemicals tested for carcinogenicity by the U.S. National Toxicology Program. *Mut Res* **223**: 73–103, with permission from Elsevier. (a) alkyl ester of either phosphonic or sulfonic acids; (b) aromatic nitro groups; (c) aromatic azo groups, by virtue of their reduction to an aromatic amine; (d) aromatic ring *N*-oxides; (e) aromatic mono- and di-alkylamino groups; (f) alkyl hydrazines; (g) alkyl aldehydes; (h) *N*-methylol derivatives; (i) monohaloalkenes; (j) a large family of *N* and *S* mustards (*β -haloethyl*); (k) *N*-chloramines (substructure has not been associated with carcinogenicity, but potent genotoxic activity has been reported); (l) propiolactones and propiosultones; (m) aromatic and aliphatic aziridinyl derivatives; (n) both aromatic- and aliphatic-substituted primary alkyl halides; (o) derivatives of urethane (carbamates); (p) alkyl *N*-nitrosamines; (q) aromatic amines, their *N*-hydroxy derivatives and the derived esters; (r) aliphatic epoxides and aromatic oxides; (s) $\alpha,\beta$-unsaturated carbonyls; and (t) halogenated methanes (X = H, Cl, Br, I in any combination).

### *Quantitative structure–activity relationships*

QSAR is a quantitative relationship between a biological activity (e.g. toxicity) and one or more descriptors that are used to predict the activity. In other words, QSAR utilizes the existing scientific data to make decisions about the potential carcinogenicity of new and/or untested chemicals using predictive models based on some type of algorithm (e.g. relating structural topology, chemical bond types, bioavailability, solubility, etc. to some toxic endpoint – genotoxicity, carcinogenicity, etc.) powered by computer software.

There are several commercially available predictive toxicity programs currently available. These programs can be divided into two general categories: (1) human expert/ruled-based programs such as OncoLogic and DEREK and (2) human expert/statistical/correlative programs such as MDL QSAR, TOPKAT, and MCASE-MC4PC.

An example of a human expert/rule-based program is OncoLogic, which predicts carcinogenicity based on the chemical structure of a substance (Woo *et al.*, 1995). Analysis is done by applying a decision tree approach that incorporates the knowledge of mechanisms of action and human epidemiological studies. OncoLogic contains four carcinogenicity modules focused on fibers, metals or organometallics, polymers, and organics. The output consists of a justification of the potential carcinogenicity, or lack thereof, using a tiered level of concern (low, marginal, low moderate, moderate, high moderate, or high) with identification of the chemicals used in the decision tree analysis that led to the conclusions.

An example of a statistical/correlative program is MCASE-MC4PC (MultiCase, 2005), which has several predictive modules, including mutagenicity, carcinogenicity, and teratogenicity. MultiCASE uses an algorithm to identify all possible 2–10-atom fragments for each discrete chemical structure within a diverse training set of substances. The program then identifies fragments (structural alerts or biophores) that are primarily associated with the biological activity (e.g. carcinogenicity) of the training set and modulators of the activity, such as bioavailability and conformational comparisons. New substances with unknown toxicity are screened by entering the structure of the untested substance using a structural drawing program. The molecule in question is reduced to all possible 2–10-atom fragments and these fragments are compared to the list of structural alerts (biophores) and modulators

**TABLE 22.2 A list of Ashby and Tennant structural alerts and functional-group list compiled by Munro (Me = —$CH_3$, Et = —$CH_2CH_3$)**

| |
|---|
| *Aryl and heterocyclic ring-substituted amino- and nitro- derivatives (Ashby AA class)* |
| Bioactivation to nitrenium ions (Ar—$N^+$—H) by *N*-hydroxylation to arylhydroxylamines (Ar—N(OH)R) |
| 1°- and 2°-amines [Ar—NHR, where R may be —H, —Me, —Et, or activated Me or Et] (examples mostly 1°-amines and include hydrochloride salts) |
| 3°-amines [Ar—$NR^1R^2$, where $R^1$ and $R^2$ = —Me, —Et] (few examples mostly di-Me) |
| 2°-acetamides and -formamides [Ar — NHCOR, where R = —H, —Me, or activated Me] (examples mostly R═NHCOMe) |
| Nitroarenes [Ar— $NO_2$] (reduction to nitroarene; many examples) |
| Nitrosoarenes [Ar—N═O] (reduction to arylhydroxylamine) |
| Arylhydroxylamines [Ar—N(OH)R] |
| *Nitroso compounds (Ashby NO class)* |
| Bioactivation to carbonium ($R_2CH^+$) or diazonium ions ($RN^+$≡N) by oxygenation at α-C to diazohydroxides (R-N═N—OH); substrate must possess —H, —OH on α-C or α-C═O relative to nitrogen |
| *N*-nitroso-*N*-dialkylamines [$R^1R^2$N—N═O, most examples are from this class] |
| *N*-nitroso-*N*-alkylamides [$R^1R^2$N—N═O, where $R^2$ = $COR^3$, $R^3$ = alkyl or aryl] |
| *N*-nitroso-*N*-alkylureas [$R^1R^2$N—N═O, where $R^2$ = $CONR^3R^4$, $R^3$ = H, $R^4$ = alkyl or aryl] |
| *N*-nitroso-*N*-alkylcarbamates (a.k.a. urethanes) [$R^1R^2$N—N═O, where $R^2$ = $CO_2R^3$, $R^3$ =alkyl or aryl] |
| *N*-nitroso-*N*-alkylnitriles [$R^1R^2$N—N═O, $R^2$ = CN] |
| *N*-nitroso-*N*-hydroxylamines [R-N(OH)NO] |
| *Hydrazo derivatives (Ashby NZN class)* |
| Bioactivation to carbonium ($R_2CH^+$) or diazonium ions ($RN^+$≡N) by oxygenation at α-C; R groups may be alkyl or aryl, but one must possess —H, —OH on α-C or α-C═O relative to nitrogen |
| Hydrazines [$R^1R^2$N—$NR^3R^4$] (oxidation to azo then azoxy derivative; examples mostly terminal $R_2$N—$NH_2$) |
| Azoxy alkane [$R^1$-$N^+$($O^-$)═N-$R^2$, R is $C_4$ or less] |
| *Natural electrophiles (Ashby ALK class)* |
| Aliphatic halides [R-$CH_2$X, where R is ⩽$C_4$ and contains activating groups; not more than one —X per C] |
| Benzylic halides [Ar—$CH_2$X, where X = Cl, Br, I] |
| Oxiranes and aziridines [3-membered *O*- and *N*-containing rings] |
| Propiolactones [4-membered ring-containing —$CO_2^-$] |
| Alkyl esters of sulfonic [$RSO_2OR^1$] and sulfuric [$ROSO_2OR^1$] acids (where $R^1$ =Me or Et) |
| Alkyl esters of phosphonic [RP(═O)$(OR^1)_2$] and phosphoric [$(RO)_2$P(═O)$OR^1$] acids (where $R^1$ = Me or Et) |
| Mixed alkyl esters of phosphoric acid [$(RO)_2$P(═S)$OR^1$, where $R^1$ = Me or Et] |
| Haloethylamines [—$NCH_2CH_2X$] |
| Haloalkylethers [ethyl (—$OCH_2CH_2X$) and methyl (—$OCH_2X$)] |

identified within the training set. The output consists of scalar units, referred to as CASE units, in increasing activity values ranging from 10 to 80. A CASE rating of 10–19 is considered non-toxic, 20–29 are marginal (equivocal, weak, or inconsistent findings), 30–49 are moderately potent toxins (*trans*-gender, single site tumors), and 50–80 are potent toxins (*trans*-species, *trans*-gender, multiple site tumors in rodents). The biophores identified by the program are subjected to a set of human expert rules that take into account specificity, positive predictivity, false positives, and coverage to arrive at a decision as to whether the test molecule is carcinogenic, level of confidence with the prediction, and whether the program-generated CASE-unit score is appropriate.

These types of predictive software continue to be refined and their concordance, specificity, and predictivity are approaching the 90+ percent range. As long-term testing becomes increasingly expensive and controversial (animal rights activism, etc.), look for these QSAR software packages to play an increasing and more prominent role in the safety assessment of new chemical substances.

The accumulated knowledge of the metabolism, chemical reactivity, exposure, SAR, and other relevant information on chemicals, when scientifically and systematically

woven together, can allow us to make expert judgments as to the potential risks due to exposure to chemicals in food, air, and water. These judgments can be used to identify those compounds that merit further toxicity testing and those not worth pursuing. All schemes used to make these decisions must be thoroughly tested, be transparent, and evoke public confidence that such decisions now require.

## CONCLUSION

After more than three decades since President Nixon declared the "War on Cancer" with the enactment of the National Cancer Act, the war still continues. Routine checkup has been effective in the early diagnosis and cure of certain forms of cancer, such as colon cancer and breast cancer. Inventions in modern medicine have further added to better prognosis. Nevertheless, cancer largely remains an incurable disease unless it is detected pretty early.

In spite of significant advances in our knowledge on the molecular mechanisms of carcinogenesis, scientists seem to have a long way to go before all these advances in knowledge could be translated into effective and curative therapy. In the meantime, more work is needed to understand certain aspects of carcinogenesis, such as the mechanisms of action of non-genotoxic carcinogens. However, the accumulated knowledge on various aspects of carcinogenesis has definitely helped scientists make appropriate risk assessment and health policy recommendations. Finally, recent progress in the science of genomics has provided scientists with renewed hope that further breakthroughs in cancer detection and therapy are not far away, allowing us to effectively control the disease.

## Drugs of Use and Abuse

CHAPTER

# 23

# Toxicity of over-the-counter drugs

*Karyn Bischoff*

## INTRODUCTION

The topic of over-the-counter (OTC) drugs is complicated. It encompasses a large number of products. Many contain more than one active ingredient. Products are available for oral, topical, intraocular, intranasal, and intrarectal administration. Most veterinary exposures are through ingestion. These products are readily available in many homes. Toxicosis may result when animals are medicated by well-intentioned animal owners or even veterinarians, or exposure may be accidental, in which case the amount of medication ingested may not be known. Response to a given drug may be species specific or different between individuals of the same species. Idiosyncratic reactions to drugs must also be considered, though reports in domestic animals are rare (Papich, 1990; Brumbaugh, 2001)

Approximately one-quarter of the calls to human poison control centers in 1990 dealt with OTC drugs, and similar reports are common with the American Society for the Prevention of Cruelty to Animals' National Animal Poison Control Center (Murphy, 1994; Villar *et al.*, 1998). It has been estimated that there are over 300,000 OTC drug formulations available. Approximately 700 active ingredients in various combinations may be present in these formulations (Papich, 1990). Only a small fraction can be addressed in this chapter.

Important classes of drugs that will be addressed include analgesics, cold, flu, and allergy medications, and drugs used to treat gastrointestinal symptoms. Nutritional supplements, for the most part, will not be addressed here. A few herbal preparations, notably ma juang and guarana, are discussed in this chapter. Toxicologically important minerals such as iron, and important vitamins such as vitamin D, are addressed elsewhere in the text. Stimulants and diet pills may contain methylxanthines such as caffeine, addressed elsewhere in the text, as well as sympathomimetic amines, discussed below with decongestants.

Though this chapter deals mostly with drugs intended for per os (PO) dosing, a few topical preparations are discussed below.

### Suspected OTC drug reactions

Obtaining a thorough history is of great importance when dealing with suspect OTC drug-related problems (Talcott, 2006). Animal owners may not volunteer critical information. Well meaning pet owners may administer OTC drugs to treat perceived symptoms in their pets (Papich, 1990; Jones *et al.*, 1992; Villar *et al.*, 1998; Roder, 2005a; Sellon, 2006). Veterinarians may share the blame for inappropriate dosing (Papich, 1990). Chronic analgesic administration to treat orthopedic problems is a particular hazard affecting all classes of animals that may present to the veterinary practice (Roder, 2005a). Accidental ingestions may occur if drugs are improperly stored (Papich, 1990; Jones *et al.*, 1992; Villar *et al.*, 1998). Unexpected circumstances may arise, making it difficult to properly assess the history. One such example concerns severe clinical signs prompting euthanasia in a kitten. It was later discovered that the feline in question had been allowed to play with an empty acetaminophen container (Allen, 2003).

If an adverse reaction to an OTC drug is suspected, administration of this drug should be immediately discontinued. The owner should be instructed to bring the drug container to the veterinarian as a source of information on the active ingredients, indications for use, and manufacturer identification and telephone number or address. The manufacturer may have information on treatment

and prognosis and, in the United States, will use the information you provide for adverse events reporting to the US Food and Drug Administration (FDA), and thus should be contacted. More information on adverse event reporting can be found at the FDA website: http://www.fda.gov/cvm/adetoc.htm. Any material remaining in the container may be analyzed to verify that the contents are as expected (Brumbaugh, 2001).

Early gastrointestinal decontamination may be helpful in the asymptomatic animal and may involve emetics, gastric lavage, and instillation of activated charcoal and cathartics. If drugs are used topically, removal with a mild detergent bath is usually beneficial (Brumbaugh, 2001). Careful monitoring and maintenance of body temperature is required after bathing, and bath towels may be warmed by tumbling in heated clothes drier to help prevent hypothermia.

# ANALGESICS

According to Jones *et al.* (1992), about 5% of dog- and cat-related calls to one poison control center were in response to analgesic ingestion, and nearly 80% involved dogs. Commonly used OTC analgesics include acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), such as aspirin, ibuprofen, naproxen, and ketaprofen. Aspirin shares many properties with other NSAIDs, but will be addressed separately due to some of its unique features.

## Acetaminophen

Acetaminophen does not have the anti-inflammatory properties of NSAIDs, though it is an analgesic and antipyretic (Hjelle and Grauer, 1986). Acetaminophen is found in a variety of OTC pain relievers and may be combined with other drugs in cold, flu, and allergy medications (Roder, 2005a). Common brand names in the United States include Tylenol® and Anacin-3®. Acetaminophen is sold under the name Paracetamol® in Australia and Great Britain, and is a metabolite of the analgesic phenacetin.

Acetaminophen toxicosis is most commonly reported in cats (Rumbeiha *et al.*, 1995). Clinical acetaminophen toxicosis is usually associated with a single exposure, though adverse effects as a result of multiple dosing have been reported (Hjelle and Grauer, 1986; Villar *et al.*, 1998). The most common clinical situation results from the owner medicating their animal without a veterinarian's advice or supervision (Hjelle and Grauer, 1986; Aronson and Drobatz, 1996). One report documents severe poisoning in a kitten that had played with an empty acetaminophen container (Allen, 2003).

### *Toxicity*

Individual differences in sensitivity to acetaminophen are reported within species (Webb *et al.*, 2003), but the use of acetaminophen is always contraindicated in cats due to their sensitivity to this drug (Jones *et al.*, 1992; Villar *et al.*, 1998; Wallace *et al.*, 2002; Roder, 2005a). Clinical signs of acetaminophen toxicosis in cats, including death, have been reported at doses of 10 mg/kg (Aronson and Drobatz, 1996). Most poisonings have been associated with doses of 50 mg/kg and greater (Murphy, 1994; Aronson and Drobatz, 1996; Allen, 2003; MacNaughton, 2003; Roder, 2005a; Sellon, 2006). Villar *et al.* (1998) reported 50% methemoglobinemia within 4 h in cats dosed with 120–140 mg/kg acetaminophen, and one of four cats dosed with 143 mg/kg died. One regular acetaminophen tablet contains 352 mg of the active ingredient, and an extra-strength tablet contains 500 mg.

The recommended dose for acetaminophen in dogs is 15 mg/kg PO every 8 h of 10 mg/kg PO every 12 h (Plumb, 2002). Toxicosis has been reported at a dose of 46 mg/kg (Sellon, 2006), though doses of 100 mg/kg or greater are more likely to be associated with clinical signs (Jones *et al.*, 1992; Boothe, 2001a; Roder, 2005a). Most dogs recover if dosed with less than 500 mg/kg (Villar *et al.*, 1998). Doses over 460 mg/kg have been associated with methemoglobinemia in dogs and deaths have occurred (Schlesinger, 1995; Villar *et al.*, 1998; Wallace *et al.*, 2002). A dose of 900 mg/kg caused "fulminant liver failure" (Boothe, 2001a). Doses greater than 1000 mg/kg (1g /kg) are reported to cause unconsciousness and cyanosis within hours and death within 12 h (Villar *et al.*, 1998).

### *Toxicokinetics*

After ingestion, acetaminophen is rapidly absorbed in the stomach and small intestine (Schlesinger, 1995; Wallace *et al.*, 2002). Peak plasma concentrations occur 4 h after ingestion in cats (Rumbeiha *et al.*, 1995).

Circulating acetaminophen is minimally bound to plasma protein and distributed widely (Wallace *et al.*, 2002). The therapeutic plasma concentration of acetaminophen in a dog is about 30 μg/ml, and toxicosis is associated with levels of 300 μg/ml and greater (Court and Greenblatt, 1997).

Metabolism of acetaminophen occurs primarily in the liver. There are three major pathways: direct glucuronide conjugation, direct sulfate conjugation, and oxidation mediated by cytochrome P450 enzymes (Hjelle and Grauer, 1986; Wallace *et al.*, 2002).

Acetaminophen has an available hydroxyl group. Immediate phase II conjugation is the primary route of metabolism in most species and involves glucuronide and sulfate (Dahm and Jones, 1996). Due to limitations of cat physiology, they have only about one-tenth the acetaminophen biotransformation ability of dogs (Hjelle and

Grauer, 1986; Sellon, 2006). Glucuronide conjugation is the fate of 50–60% of a dose of acetaminophen given to either a human or dog (Aronson and Drobatz, 1996). This pathway is deficient in cats due to decreased microsomal UDP-glucuronyltransferase 1,6 enzyme activity (Court and Greenblatt, 1997; Wallace *et al.*, 2002). The amount of acetaminophen that is conjugated to glucuronide in cats is dependent on dose, but is always a relatively small proportion. After an oral dose of 20 mg/kg acetaminophen, 1% undergoes glucuronidation. Five percent of a 60 mg/kg dose is conjugated to glucuronide, and 16% of a 120 mg/kg dose enters this pathway (Hjelle and Grauer, 1986).

Sulfate conjugation is less important than glucuronide conjugation in the disposition of acetaminophen in most species (Aronson and Drobatz, 1996; Boothe, 2001; Allen, 2003). Dogs metabolize about 10–20% of a given dose of acetaminophen via sulfation. However, this is the more important, though still limited, pathway in cats. Again, use of this pathway is dependent on dose of acetaminophen. After dosing with 20 mg/kg, 92% of the acetaminophen underwent sulfation, but after a dose of 60 mg/kg acetaminophen, 78% was sulfated, and if the dose was 120 mg/kg, only 57% was sulfated. The sulfation pathway may be saturated due to the limited availability of inorganic sulfates (Hjelle and Grauer, 1986).

Metabolism of acetaminophen by phase I processes is relatively minimal in most species, but is very important to the mechanism of action of this drug, as will be described below. Cytochrome P450 oxidation increases as phase II pathways become saturated (MacNaughton, 2003; Sellon, 2006). Approximately 5% of a dose of acetaminophen undergoes oxidation by cytochrome P450s in the dog. When cats are dosed with 20 mg/kg acetaminophen, 5% undergoes oxidation, but this number increased to 10% at doses of 60–120 mg/kg (Hjelle and Grauer, 1986). The product of the oxidation pathway is *N*-acetyl-*p*-benzoquinoneimine (NAPQI). NAPQI is conjugated to reduced glutathione (GSH), forming an inactive product (Savides and Oehme, 1985; Schlesinger, 1995; Jones *et al.*, 1992; Aronson and Drobatz, 1996; Sturgill and Lambert, 1997; Wallace *et al.*, 2002; Allen, 2003; MacNaughton, 2003; Roder, 2005a; Sellon, 2006).

The by-products of acetaminophen metabolism are excreted predominantly through the urine (Sturgill and Lambert, 1997; MacNaughton, 2003; Sellon, 2006). Less than 5% of a dose is excreted as the parent compound in humans (Wallace *et al.*, 2002). Some conjugates are eliminated in the bile (Sturgill and Lambert, 1997). Rate of elimination is dependent on the species and the dose. The elimination half-life of a 100–200 mg/kg dose of acetaminophen is 72 min in dogs and increases to 210 min when the dose is increased to 500 mg/kg. The elimination half-life in cats for a 20 mg/kg dose is 36 min, but the half-life for a 60 mg/kg dose is 144 min, and that for a 120 mg/kg dose is 288 min (Hjelle and Grauer, 1986). The half-life is prolonged in male cats compared to females (Rumbeiha *et al.*, 1995).

#### *Mechanism of action*

Unlike NSAIDs, the therapeutic effects of acetaminophen are independent of cyclooxygenase (COX) but based on its interference with endoperoxidase (Boothe, 2001a). Toxic effects of acetaminophen are due to the formation of the metabolite NAPQI. Large doses of acetaminophen overwhelm the sulfide and glucuronide conjugation pathways and lead to increased formation of the active metabolite (Hjelle and Grauer, 1986; Dahm and Jones, 1996; Sturgill and Lambert, 1997; MacNaughton, 2003; Roder 2005a). NAPQI is usually conjugated with GSH, as noted above. GSH stores become depleted 16–24 h after exposure to acetaminophen (Rumbeiha *et al.*, 1995). This is due to oxidation and decreased production of GSH (Hjelle and Grauer, 1986; Allen, 2003; Webb *et al.*, 2003; Sellon, 2006). GSH was 28% depleted in one dog 48 h after acetaminophen dosing (Wallace *et al.*, 2002).

Erythrocyte injury is the predominant problem associated with acetaminophen ingestion in cats. Oxidative injury to erythrocytes may take the form of methemoglobin production or Heinz body production (Rumbeiha *et al.*, 1995; Webb *et al.*, 2003). GSH becomes depleted in erythrocytes and hemoglobin is oxidized to methemoglobin, which cannot carry oxygen (Hjelle and Grauer, 1986; Aronson and Drobatz, 1996). Animals with 30% of their hemoglobin converted to methemoglobin show clinical signs and cyanotic mucous membranes (Rumbeiha *et al.*, 1995; Aronson and Drobatz, 1996). Methemoglobinemia is reversible (Schlesinger, 1995). Methemoglobin reductase is the enzyme responsible for converting methemoglobin to hemoglobin. Cats have less methemoglobin reductase activity than other domestic species (MacNaughton, 2003). Acetaminophen may produce methemoglobinemia in dogs, but this change is not seen in humans, rats, or hamsters (Hjelle and Grauer, 1986).

Heinz body formation is an irreversible change caused by the precipitation of hemoglobin (Schlesinger, 1995; Aronson and Drobatz, 1997). Heinz bodies increase red cell fragility and decrease survival time of erythrocytes, and thus may cause hemolysis and anemia (Schlesinger, 1995; Aronson and Drobatz, 1997; Allen, 2003). NAPQI binds to the sulfhydryl groups on hemoglobin (Allen, 2003). There are eight such groups on feline hemoglobin, but only four on the hemoglobin of other domestic species and two on the human molecule (Hjelle and Grauer, 1986; Rumbeiha *et al.*, 1995; Aronson and Drobatz, 1996; Allen, 2003; Sellon, 2006).

Hepatic effects predominate in dogs, mice, rats, and humans (Wallace *et al.*, 2002; Sellon, 2006). Oxidative damage to hepatocytes leads to zone 3 (centrilobular) hepatocyte degeneration and necrosis (Hjelle and Grauer, 1986;

Dahm and Jones, 1996; Treinen-Moslen, 2001; Wallace *et al.*, 2002). NAPQI acts as an electrophile. It causes tissue damage by forming covalent adducts with biological macromolecules (Savides and Oehme, 1985; Hjelle and Grauer, 1986; Jones *et al.*, 1992; Dahm and Jones, 1996; Sturgill and Lambert, 1997; Villar *et al.*, 1998; Zimmerman, 1999; Treinen-Moslen, 2001). Mitochondria may be a primary target for NAPQI, which may alter their functional integrity and bind to adenine nucleotides (Dahm and Jones, 1996; Treinen-Moslen, 2001). NAPQI may bind to membrane proteins that regulate calcium homeostasis, leading to increased intracellular calcium ions (Dahm and Jones, 1996; Sturgill and Lambert, 1997). Cytoskeletal damage or activation of endonucleases with DNA fragmentation has been proposed in the mechanism of cell death (Dahm and Jones, 1996). Production of superoxide anions and peroxidative injury occur during phase I metabolism of acetaminophen and cause oxidative stress to the cell, particularly after GSH depletion (Hjelle and Grauer, 1986; Dahm and Jones, 1996; Zimmerman, 1999; Sellon, 2006). Endothelial damage may cause some of the clinical signs reported, such as edema of the face and extremities and hemorrhage (Wallace *et al.*, 2002).

Factors that enhance the toxic effects of acetaminophen include GSH depletion due to fasting (Treinen-Moslen, 2001) and induction of P4502E1, as occurs with exposure to barbiturates (Sturgill and Lambert, 1997). Cimetidine inhibits cytochrome P450s and has been used therapeutically (Murphy, 1994; Schlesinger, 1995; Sellon, 1996; Aronson and Drobatz, 1997; Zimmerman, 1999; MacNaughton, 2003). Young animals may be less sensitive to acetaminophen toxicosis than mature animals. This is the case in children and neonatal mice, and is believed to be due to the immaturity of the mixed-function oxidase system and more rapid GSH synthesis in young animals (MacNaughton, 2003).

### *Clinical signs*

Clinical signs of acetaminophen toxicosis are attributable to its toxic effects on erythrocytes and hepatocytes. Clinical methemoglobinemia is the most common problem in cats and occurs in dogs. Centrilobular hepatic necrosis is more common in dogs and also occurs in other species, including cats, humans, rats, and hamsters (Hjelle and Grauer, 1986).

Clinical signs in cats usually occur within an hour or two of exposure. Anorexia is reported in 35% of cats presenting for acetaminophen exposure, as is vomiting. Hypersalivation is reported in 24% (Aronson and Drobatz, 1996), and commonly occurs within 2 h of exposure (Savides and Oehme, 1985). Diarrhea occurred in 18% of cats. Mental depression was reported in 76% (Aronson and Drobatz, 1996) and usually takes place within 3 h (Savides and Oehme, 1985).

Methemoglobinemia usually occurs within the first 4 h after acetaminophen ingestion and is dose dependent. Cats given a dose of 60 mg/kg acetaminophen had 21.7% of their hemoglobin converted to methemoglobin, and the methemoglobin concentration in cats dosed with 120 mg/kg acetaminophen was 45.5% (Hjelle and Grauer, 1986). Clinically evident cyanosis may occur at 30% methemoglobinemia (Rumbeiha, 1995; Aronson and Drobatz, 1996). Fifty-nine percent of the cats in Aronson and Drobatz (1996) study had pale or dark mucous membranes. An equal percent had evident respiratory distress, and blood was noted to be brown in 12%. Animals may appear weak and depressed (Hjelle and Grauer, 1986; Jones *et al.*, 1992; Allen, 2003) and 12% presented comatose (Aronson and Drobatz, 1997). Tachycardia was seen in 18%. Hemolysis, anemia, icterus, and pigmenturia have been described and may be seen for up to 48 h after acetaminophen ingestion (Savides and Oehme, 1985; Rubin and Papich, 1990; Rumbeiha, 1995; Allen, 2003; Villar *et al.*, 1998; Sellon, 2006).

Edema of the face and forelimbs or front paws is commonly described in affected cats (Savides and Oehme, 1985; Hjelle and Grauer, 1986; Papich, 1990; Murphy, 1994; Rumbeiha, 1995; Aronson and Drobatz, 1996; Villar *et al.*, 1998; Roder, 2005a). Aronson and Drobatz (1996) reported an incidence of 29%. Death is usually due to methemoglobinemia, but fatal liver failure (Rumbeiha *et al.*, 1995). Evidence of hepatic necrosis is unusual in cats, but has been reported with high-dose exposures, particularly in males (Roder, 2005a; Sellon, 2006).

Dogs may vomit soon after ingesting a high dose of acetaminophen (Schlesinger, 1995). More severe clinical signs in dogs are usually attributable to hepatic necrosis (Hjelle and Grauer, 1986; Schlesinger, 1995; Sellon, 2006). Signs may commence about 36 h after ingestion and include nausea and vomiting, anorexia, abdominal pain, and depression (Hjelle and Grauer, 1986; Murphy, 1994; Villar *et al.*, 1998; Boothe, 2001; Roder, 2005a). Tachycardia and tachypnea have also been noted (Roder, 2005a; Sellon, 2006). Mild cases may recover in another 2–3 days, but severe cases progress to icterus and death, usually within 4 days (Murphy, 1994; Sellon, 2006).

Methemoglobinemia also occurs in dogs, is often associated with high doses of acetaminophen, and may be more likely to cause death than liver failure (Schlesinger, 1995; Villar *et al.*, 1998; Wallace *et al.*, 2002; Roder, 2005a; Sellon, 2006). Methemoglobinemia usually occurs 4–12 h after ingestion but dogs may not present for 48 h (Wallace *et al.*, 2002; MacNaughton, 2003). Doses of 200 mg/kg acetaminophen PO converted 18.8% of hemoglobin to methemoglobin in dogs, and 500 mg/kg produced 51.5% methemoglobinemia (Hjelle and Grauer, 1986). Signs reported included cyanosis, brown color to blood, lethargy and recumbence (Schlesinger, 1995; Wallace *et al.*, 2002; MacNaughton, 2003). Hemolysis, anemia, icterus, and

shock have been described (Schlesinger, 1995). Several authors report pigmenturia. Occasionally, signs of methemoglobinemia occur in acetaminophen intoxicated dogs in the absence of clinically evident liver damage (Schlesinger, 1995; Wallace *et al.*, 2002).

Facial edema, edema of conjunctiva and nictitating membrane and edema of the forelimbs or paws have been reported in dogs (Hjelle and Grauer, 1986; Schlesinger, 1995; Villar *et al.*, 1998; MacNaughton, 2003; Sellon, 2006).

### *Clinical chemistry*

Methemoglobinemia and hemolysis may be noted on blood work. Whole blood exposed to air may have a brown tinge (Schlesinger, 1995; MacNaughton, 2003; Sellon, 2006). Heinz bodies in cats and dogs may be evident on a blood smear stained with new methylene blue (Murphy, 1994; Schlesinger, 1995). Heinz bodies are reported to occur 3 days after dosing (Webb *et al.*, 2003) and were evident in 12% of accidentally intoxicated cats (Aronson and Drobatz, 1997). Anemia occurred in 75% of cats (Aronson and Drobatz, 1997) and has been reported in dogs (Schlesinger, 1995; Wallace *et al.*, 2002; MacNaughton, 2003). Hyperbilirubinemia may occur within 48 h of acetaminophen ingestion in cats and has been reported in dogs with hemolysis (Schlesinger, 1995; Sellon, 2006). Regeneration was apparent in one dog 11 days after acetaminophen ingestion (Schlesinger, 1995).

Alanine transaminase (ALT) may be elevated in both cats and dogs. This change was reported by Aronson and Drobatz (1996) in 35% of cats exposed to acetaminophen. It has been reported to occur 3 days after dosing and may represent hepatic injury due to hypoxia or toxic insult in cats (Rumbeiha *et al.*, 1995; Webb *et al.*, 2003; Sellon, 2006). Increased ALT is usually believed to be due to toxic hepatic injury in dogs and occurs within 24 h of dosing (Roder, 2005a; Sellon, 2006). Hypoxic injury may contribute to increases in ALT in dogs (Schlesinger, 1995). Increases in aspartate transaminase (AST) and alkaline phosphatase (ALP) have been recorded (Schlesinger, 1995; Wallace *et al.*, 2002; Roder, 2005a). Prothrombin time (PT) and partial thromboplastin time (PTT) may be elevated if liver damage is severe (Sellon, 2006). Progressive decreases in serum cholesterol and serum albumin have been described (Sellon, 2006). Forty-one percent of cats presenting for acetaminophen toxicosis had hypocholesterolemia and 12% had hypoalbuminemia (Aronson and Drobatz, 1996).

Hemoglobinuria and hematuria may be noted in dogs and cats with acetaminophen toxicosis (Hjelle and Grauer, 1986; Murphy, 1994; Villar *et al.*, 1998; Wallace *et al.*, 2002; Sellon, 2006).

### *Diagnosis and management*

Diagnosis of acetaminophen poisoning is usually based on a history of clinical exposure and appropriate clinical signs. Plasma, serum, and urine are commonly tested for acetaminophen at human hospitals and some veterinary laboratories (Murphy, 1994; Allen, 2003; Sellon, 2006). Test results are not be available until hours or days after the sample is submitted, but acetaminophen toxicosis often presents as an emergency and treatment should be initiated immediately.

If the animal presents within 6 h of ingestion, decontamination measures should be instituted to prevent further absorption (Sellon, 2006). Emetics may be used in the alert animal (Wallace *et al.*, 2002; Roder, 2005a; Sellon, 2006). If large doses are ingested, gastric lavage of the anesthetized, intubated animal is appropriate (Roder, 2005a; Sellon, 2006). After gastric emptying, the patient is given activated charcoal and a cathartic such as sorbitol (Wallace *et al.*, 2002; Roder, 2005a; Sellon, 2006).

Antidotal therapy should be initiated as soon as possible in animals suspected of ingesting toxic doses of acetaminophen (Hjelle and Grauer, 1986; Villar *et al.*, 1998; Roder, 2005a). Antidotal therapy involves use of sulfate sources to bind NAPQI and enhance GSH production. Several compounds are available that act as sulfur donors, and include *N*-acetylcysteine, *S*-adenosylmethionine (SAMe), and sodium sulfate. *N*-acetylcysteine therapy is the most commonly recommended treatment for acetaminophen toxicosis. Additionally, antioxidants may be used to reduce methemoglobin.

*N*-acetylcysteine is a source of sulfhydryl groups that may be used for phase II sulfation or for production of GSH (Savides and Oehme, 1985; Hjelle and Grauer, 1986; Villar *et al.*, 1998). *N*-acetylcysteine is hydrolyzed to L-cysteine by deacetylation and may be oxidized in the liver to inorganic sulfate (Hjelle and Grauer, 1986). Use of *N*-acetylcysteine promotes sulfation of acetaminophen in cats. Rumbeiha *et al.* (1995) report a 50% decrease in the plasma half-life of acetaminophen in cats treated with *N*-acetylcysteine and Savides and Oehme (1985) reported an increase in the total fraction excreted as a sulfate conjugate. Cats treated with *N*-acetylcysteine have a more rapid recovery of blood GSH levels than untreated cats (Savides and Oehme, 1985). *N*-acetylcysteine decreased the half-life of methemoglobin in the blood of cats from more than 10–5 h (Rumbeiha *et al.*, 1995). *N*-acetylcysteine is reported to prevent anemia in acetaminophen intoxicated cats (Webb *et al.*, 2003).

*N*-acetylcysteine therapy should be initiated to any suspected case of acetaminophen toxicosis, even if exposure cannot be confirmed or time until treatment is delayed (Hjelle and Grauer, 1986; Villar *et al.*, 1998). Treatment is most effective if given within 8 h of exposure (Aronson and Drobatz, 1996; Roder, 2005a). Treatment within 24 h decreases mortality, but liver damage may occur (Roder, 2005a). *N*-acetylcysteine is sold in 10% and 20% solutions. Twenty percent solutions may be diluted 1:1 in normal saline or 5–10% dextrose solution (Plumb, 2002;

MacNaughton, 2003; Sellon, 2006). An initial dose of 140 mg/kg may be given intravenously (IV) slowly (Hjelle and Grauer, 1986; Murphy, 1994; Schlesinger, 1995; Aronson and Drobatz, 1996; MacNaughton, 2003; Roder, 2005a; Sellon, 2006). This dose may be given orally if no vomiting is evident and activated charcoal was not recently administered (Schlesinger, 1995; Sellon, 2006). Doses of 70 mg/kg should be given IV or PO every 6h thereafter for 42–48 h (Hjelle and Grauer, 1986; Schlesinger, 1995; Aronson and Drobatz, 1997; MacNaughton, 2003; Roder, 2005a).

SAMe is another possible sulfate source that has been used to treat acetaminophen toxicosis in dogs and cats. Decreased hemolysis and overall improvement was reported in treated dogs (Wallace *et al.*, 2002). SAMe may prevent methemoglobin production in cats, though this was not evident in one study. The number of Heinz bodies was lower and the packed cell volume (PCV) did remain higher in treated versus untreated cats (Webb *et al.*, 2003; Sellon, 2006). Dogs are given 40 mg/kg PO as their first dose and 20 mg/kg daily for 7–9 days (Wallace *et al.*, 2002; Sellon, 2006). Protocols that have been used experimentally in cats include doses of 180 mg/kg PO every 12 h for 3 days, and 90 mg/kg PO every 12 h for 14 days (Webb *et al.*, 2003; Sellon, 2006).

There are reports of sodium sulfate use to treat acetaminophen toxicosis. This protocol decreased the plasma half-life of acetaminophen and increased the amount excreted as a sulfate conjugate, similar to *N*-acetylcysteine (Savides and Oehme, 1985). Severity and duration of clinical signs were decreased in treated animals, methemoglobin levels were decreased, and GSH concentrations rebounded faster than in untreated animals (Villar *et al.*, 1998). Sodium sulfate was given as a 1.6% solution at a dose of 50 mg/kg IV every 4 h for six treatments (Savides and Oehme, 1985; Villar *et al.*, 1998).

Ascorbic acid and methylene blue are the most common compounds used to reduce methemoglobin to hemoglobin. Ascorbic acid causes nonenzymatic reduction of methemoglobin, but is slow acting (Hjelle and Grauer, 1986; Rumbeiha *et al.*, 1995; Aronson and Drobatz, 1997). Ascorbic acid may be given at a dose of 30 mg/kg PO every 6 h for six or seven treatments (Hjelle and Grauer, 1986; Aronson and Drobatz, 1996; MacNaughton, 2003; Sellon, 2006). Methylene blue has a more rapid onset of action than ascorbic acid, but is known to induce hemolytic anemia in cats, thus its use may be risky. Still, methylene blue has been used successfully for short-term management of methemoglobinemia in felines (Rumbeiha *et al.*, 1995; Aronson and Drobatz, 1996; Sellon, 2006). Use of methylene blue concurrently with *N*-acetylcysteine in cats should probably be avoided, at least in males. Rumbeiha *et al.* (1995) reported that this combined therapy caused severe depletion of blood GSH and actually increased the half-life of methemoglobin in the male cats in his study.

Supportive and symptomatic therapy for acetaminophen toxicosis may include oxygen therapy for animals with methemoglobinemia (Aronson and Drobatz, 1997; Villar *et al.*, 1998; Sellon, 2006). Transfusions or hemoglobin replacements should be administered to animals with severe anemia if needed (Murphy, 1994; Sellon, 2006). Fluid therapy is aimed at improving hydration, electrolyte balance, and pH (MacNaughton, 2003).

Cimetidine has been recommended for use in dogs and cats to inhibit acetaminophen metabolism by inhibiting cytochrome P450 enzymes (Murphy, 1994; Schlesinger, 1995; Aronson and Drobatz, 1996; Wallace *et al.*, 2002; Sellon, 2006). However, the doses required for enzyme inhibition may be higher than doses used routinely (Sellon, 2006).

The time that elapses between exposure and treatment may be the most important factor when determining the prognosis for survival, according to Aronson and Drobatz (1996). The median dose of acetaminophen ingested by cats that died or were euthanized was 100 mg/kg with a range for 10–170 mg/kg, whereas the median dose for survivors was 170 mg/kg with a range of 10–400 mg/kg. Most cats that survived were treated within 14 h of exposure, though one was not treated for 24 h. Most of the cats that were treated 17 or more hours post exposure died. Cats with underlying disease may have a worse outcome than otherwise healthy cats. The survival rate in dogs is decreased if they are not treated within 72 h (Sellon, 2006). Animals that were treated and survived usually recovered within 48 h and were hospitalized for 3 days (Aronson and Drobatz, 1996).

#### *Postmortem findings*

Icterus is a common finding secondary to acute hemolysis in cats or chronic cholestasis in dogs (Sellon, 2006). Centrilobular necrosis occurs commonly in intoxicated dogs and has been described in cats, though necrosis is often more diffuse in cats (Hjelle and Grauer, 1986; Wallace *et al.*, 2002; Webb *et al.*, 2003; Roder, 2005a; Sellon, 2006). Bile duct proliferation, vacuolar degeneration of hepatocytes, and mononuclear cholangitis are all reported in dogs with chronic liver injury (Sellon, 2006). Subcutaneous (SC) edema may extend from the head along the fascial planes of the neck and thorax, and may affect the conjunctiva (Allen, 2003).

## Nonsteroidal anti-inflammatory drugs

NSAIDs are defined straightforwardly as "compounds that are not steroidal and that suppress inflammation" (Boothe, 2001a). These drugs have antithrombic actions when taken at low doses, relieve minor pain and pyrexia at higher doses, and have anti-inflammatory effects at

higher doses (Rubin and Papich, 1990; Boothe, 2001a). NSAIDs are the drugs most commonly prescribed by physicians and it is estimated that 30 million people worldwide take NSAIDs, including aspirin, each day (Verbeeck, 1990). NSAIDs are commonly used to treat orthopedic problems in dogs (Roder, 2005a). About 8% of all human- and veterinary-related calls to the Illinois Poison Control Center were reported to involve NSAIDs, most commonly aspirin, ibuprofen, naproxen, piroxicam, indomethacin, and phenylbutazone. Seventy percent of the nonhuman animal calls were for dogs and 25% for cats (Kore, 1990). NSAID toxicosis may be related to a single large dose or multiple smaller doses (Albretsen, 2002).

There are more than 30 commercially available NSAIDs (Mazué *et al.*, 1982). They are classified based on their structure into the carboxylic acid group, which includes salicylic acid derivatives, acetic acid derivatives, fenamates or anthranilic acid derivatives, and the proprionic acid derivatives, as well as the enolic acid groups. An incomplete list of NSAIDs may be found in Table 23.1.

**TABLE 23.1 An incomplete list of NSAIDs**

| Carboxylic acid group | Enolic group |
|---|---|
| *Salicylic acid derivatives* | *Pyrazolone derivatives* |
| Aspirin | Azapropazone |
| Diflunisal | Dipyrone |
| Salicylates | Isopyrin |
| *Indolacetic acids* | Oxyphenbutazone |
| Etodolac | Phenylbutazone |
| Indomethacin | *Oxicam derivatives* |
| Sulindac | Meloxicam |
| Tolmetin | Peroxicam |
| Zomepirac | Tenoxicam |
| *Fenamates/anthranilic acid derivatives* | |
| Alclofenac | |
| Diclofenac | |
| Ibufenac | |
| Meclofenamic acid | |
| Mefanamic Acid | |
| Niflumic | |
| Tolfenamic acid | |
| *Propionic acid derivatives* | |
| Benoxaprofen | |
| Carprofen | |
| Ibuprofen | |
| Fenbufren | |
| Fenoprofen | |
| Flurbiprofen | |
| Ketoprofen | |
| Suprofen | |
| Tiaprofenic acid | |
| *Aminonicotinic acid derivatives* | |
| Flunixin meglamine | |
| Clonixin | |
| *Quinolone derivatives* | |
| Cinchopen | |

A relative few of these drugs are available OTC, the most common being aspirin, which is discussed separately below, in addition to ibuprofen, ketoprofen, and naproxen. These drugs will be addressed in more detail here, and a few other important veterinary drugs such as phenylbutazone will be mentioned. The mechanism of action is similar for all drugs in this classification. However, toxicity and pharmacokinetic data vary significantly between different compounds and different species. Cats, for example, are more susceptible to salicylate toxicosis than other species (Roder, 2005a), and dogs are very sensitive to ibuprofen (Rubin and Papich, 1990). Attempts should not be made to extrapolate the therapeutic dose from one species to another (Lees *et al.*, 1991).

Individual factors also affect susceptibility to NSAIDs. Young and aged animals may not metabolize these drugs in the same way as older animals (Roder, 2005a). Drug excretion may be delayed in animals with poor hepatic or renal function (Lees *et al.*, 1991; Isaacs, 1996; Roder, 2005a). Dehydration or cardiac disease may decrease renal circulation, slowing drug excretion, and promoting renal damage (Isaacs, 1996; Roder, 2005a). Gastrointestinal disease may predispose to ulceration when NSAIDs are used (Isaacs, 1996).

Various drugs may interact with NSAIDs. Changes of bioavailability may be caused by inhibition of absorption, displacement from binding proteins in plasma and tissues, or interference with elimination through competition for active renal secretion. Drugs may enhance or diminish metabolism of other drugs by hepatic cytochrome P450 enzymes (Verbeeck, 1990). An incomplete list of possible interactions may be found in Table 23.2. NSAIDs may affect the bioavailability of other drugs. There have been reports of deaths in people using NSAIDs with methotrexate, and ibuprofen decreases renal clearance of digoxin and lithium (Verbeeck, 1990). The diuretic affects of furosemide and bumetanide are mediated by prostaglandins (PGs) and may be inhibited by NSAIDs (Verbeeck, 1990; Isaac, 1996; Talcott, 2006). NSAIDs do not influence response to thiazide diuretics in this way, but may decrease the hypotensive response to thiazides (Verbeeck, 1990). NSAIDs may decrease the effectiveness of angiotensin converting enzyme (ACE) inhibitors such as captopril (Verbeeck, 1990; Talcott, 2006). NSAIDs may decrease the hypotensive response to $\beta$-blockers, though naproxen does not interfere with the effects of propranolol in humans (Verbeeck, 1990). NSAIDs have additive effects when used together, with decreased rates of metabolism and clearance for each (Verbeeck, 1990; Lees *et al.*, 1991). NSAIDs also have additive effects when used with corticosteroids, and such mixing should be avoided (Lees *et al.*, 1991; Talcott, 2006).

### *Toxicity*

There are significant species difference in NSAID tolerance, as noted above. Dogs are more susceptible to ibuprofen

**TABLE 23.2 Some NSAID–drug interactions; consult Verbeeck (1990) for more detailed information**

| Methotrexate |

and naproxen toxicosis than many other species (Kore, 1990; McKellar *et al.*, 1991; Isaacs, 1996;). Use of these drugs in dogs should be avoided.

Ibuprofen doses greater than 5 mg/kg have been associated with adverse reactions in dogs (Villar *et al.*, 1998). Gastric lesions occurred in dogs when 8 mg/kg ibuprofen per day is given over a 30-day period, either PO or parenterally, though clinical signs were not evident (McKellar *et al.*, 1991; Godshalk *et al.*, 1992; Boothe, 2001a; Talcott, 2006). Clinical signs were evident in dogs dosed with 16 mg/kg/day for 8 weeks (Villar *et al.*, 1998). A single dose of 50–125 mg/kg may be associated with gastrointestinal disease (Jackson *et al.*, 1991, Murphy, 1994; Talcott, 2006) and a perforating gastric ulcer was reported in a dog dosed with 110 mg/kg ibuprofen over a period of 48 h (Godshalk *et al.*, 1992). Doses of 175–250 mg/kg ibuprofen may be associated with acute renal failure (Kore, 1990; Godshalk *et al.*, 1992; Villar *et al.*, 1998; Talcott, 2006). Serum ibuprofen concentrations less than 31 μg/ml have not been associated with clinical signs in dogs. Melena was noted with serum concentrations of 138 μg/ml. Serum ibuprofen concentrations of 10–50 μg/ml are considered therapeutic in humans (Jackson *et al.*, 1991).

Cats dosed with 50 mg/kg ibuprofen had gastrointestinal hemorrhage and irritation (Kore, 1990; Talcott, 2006). Doses of 200 mg/kg were associated with renal failure and over 600 mg/kg caused death (Kore, 1990). A ferret that had ingested at least 347 mg/kg ibuprofen died from respiratory failure and asystole approximately 12 h post exposure (Cathers *et al.*, 2000).

Naproxen induced toxicosis in dogs given 5 mg/kg/day (Daehler, 1986; Rubin and Papich, 1990; Boothe, 2001a). Plasma naproxen concentrations were greater than 50 μg/ml (Boothe, 2001a). Severe toxic effects were seen in a Samoyed given 5.6 mg naproxen per kg for 1 week, including anemia, melena, and renal and hepatic dysfunction (Kore, 1990). A perforating ulcer was described in a dog given 10–20 mg/kg naproxen per day sporadically over several weeks (Daehler, 1986). Doses of 15 mg/kg/day were lethal in some dogs (Daehler, 1986; Gfeller and Sandors, 1991).

Horses do not appear to be sensitive to naproxen toxicosis. Horses given 3 times the recommended dose of naproxen for 6 weeks did not have clinical signs (Boothe, 2001). More than a quarter of humans given therapeutic doses of naproxen, on the other hand, had gastric lesions on endoscopy and fatalities from gastrointestinal hemorrhage have been reported (Daehler *et al.*, 1986; Carson and Strom, 1988).

Phenylbutazone is commonly used in horses. The recommended oral dose is 4 mg/kg/day (Plumb, 2002). A dose of 4.4 mg/kg every 12 h over a 2-week period was associated with changes of mineralization patterns in cortical bone in growing horses from 18 to 30 months of age. This effect was reversible (Brumbaugh, 2001). Doses of 4.4 mg/kg twice per day have been associated with clinical signs including central nervous system (CNS) depression and protein losing enteropathy. Shock was reported in one of nine horses after 5 days of dosing (Collins and Tyler, 1985). Therapeutic plasma concentrations for phenylbutazone in a horse range from 10–30 μg/ml. The therapeutic range in humans, 100–150 μg/ml, would be lethal in a horse (Lees *et al.*, 1991). Phenylbutazone doses of 100 mg/kg/day did not cause gastrointestinal ulcers in dogs (Mazué *et al.*, 1982).

### *Toxicokinetics*

NSAIDs are small, weakly acidic molecules with p$K_a$ values less than 4.5 and thus are well absorbed in the stomach (Mazué *et al.*, 1982; Kore, 1990; Rubin and Papich, 1990; Verbeeck, 1990; Isaac, 1996; Boothe, 2001a). Peak plasma concentrations for most NSAIDs occur within 3 h of oral dosing (Verbeeck, 1990). Some absorption may occur in the proximal small intestine (Roder, 2005a).

Ibuprofen is 60–80% bioavailable in dogs (McKellar *et al.*, 1991; Boothe, 2001a). Naproxen is 68–100% bioavailable in dogs (McKellar *et al.*, 1991; Boothe, 2001a) and blood levels are almost identical whether dosing is PO or IV (Runkel *et al.*, 1972). Naproxen is 50% bioavailable in

horses (Boothe, 2001a) and nearly 100% bioavailable in pigs (Runkel *et al.*, 1972).

NSAID distribution is variable between individual drugs and species (Boothe, 2001a; Talcott, 2006). Because they are highly protein bound in the circulation, mostly to albumin, NSAIDs generally have a low volume of distribution (Brater, 1988; Verbeeck, 1990; Boothe, 2001a; Talcott, 2006). Protein binding in humans is 99% for ibuprofen (Brater, 1988), greater than 99% for naproxen (Runkel *et al.*, 1972; Rubin and Papich, 1990), and 98.7% for ketoprofen (Brater, 1988). The remaining unbound fraction becomes distributed in the extracellular fluid and is responsible for the clinical effects (Brater, 1988; Kore, 1990; Boothe, 2001a; Talcott, 2006). Hypoalbuminemia or displacement from binding sites on albumen by other drugs leads to a transient increase in the unbound fraction. Though this unbound drug will be excreted rapidly in most cases, clinical effects may be evident (Boothe, 2001a). Age effects protein binding in humans, and the unbound fraction of a drug in an elderly patient is approximately twice that expected in a younger individual (Brater, 1988). NSAIDs can partition into lipid, allowing them to cross cell membranes (Boothe, 2001a; Talcott 2006).

Metabolism of NSAIDs takes place primarily in the liver (Kore, 1990; Verbeeck, 1990; Boothe, 2001a). They often undergo cytochrome P450 mediated oxidation to increase water solubility (Verbeeck, 1990; Talcott, 2006). Phenylbutazone is converted to oxyphenbutazone, which is similarly potent, via phase I hepatic metabolism (Lees *et al.*, 1991). Phase I metabolites and, in the case of carboxylic acid group NSAIDs, the parent compound can undergo phase II reactions such as glucuronide conjugation, sulfate conjugation, and GSH conjugation, which further increases water solubility and usually inactivate the drug (Talcott, 2006). Acyl-glucuronidation of propionic acid NSAIDs such as ibuprofen and naproxen is reversible. Drugs may deconjugate if excretion is delayed (Brater, 1988; Verbeeck, 1990).

Drug elimination is dependent on compound and species (Lees *et al.*, 1991; Boothe, 2001a). This may be the basis for many adverse reactions (Boothe, 2001a). Animals less than 6 weeks old and aged animals may metabolize drugs more slowly, and hepatic or renal failure may delay elimination (Mazué *et al.*, 1982; Boothe, 2001a; Talcott, 2006). High plasma protein binding slows excretion (Runkel *et al.*, 1972; Talcott 2006).

Plasma clearance is biphasic, with a rapid initial decline as the drug is distributed to the tissues and a slower decline as it is metabolized and excreted, terminating drug activity (Lees *et al.*, 1991). Urinary excretion is the most important rout of elimination for metabolites of NSAIDs in humans (Verbeeck, 1990). Less than 1% of a dose of naproxen or ketoprofen is eliminated unchanged, and approximately 1% of a given dose of ibuprofen is excreted in the urine as the parent compound (Brater, 1988). Urinary excretion is pH dependent and tends to be more rapid in alkali urine due to ion trapping (Kore, 1990; Talcott, 2006).

Fecal elimination through biliary excretion is important for ibuprofen and naproxen in dogs (Runkel *et al.*, 1972; Gfeller and Sandors, 1991; Daehler, 1996; Isaacs, 1996; Talcott, 2006). Half of a given dose of naproxen is eliminated in the bile of dogs. Only 1–2% is eliminated in the bile in humans and 94% is found in the urine within 5 days of administration (Runkel *et al.*, 1972). Drugs eliminated in the bile, such as ibuprofen and naproxen, as well as indomethacin, piroxicam, flunixin, tolfenamic acid, meclofenamic acid, and diclofenac, undergo enterohepatic circulation in dogs (Lees *et al.*, 1991; Isaacs, 1996; Talcott, 2006). This may increase the susceptibility of dogs to these compounds by prolonging their plasma half-life.

The plasma half-life of ibuprofen is 2.5–6 h in dogs and cats, 1 h in rats, and 2–3 h in humans (Mazué *et al.*, 1982; Lees *et al.*, 1991; Boothe, 2001a). The half-life for naproxen in plasma is 35 h in beagles (Runkel *et al.*, 1972) and 74 h in mixed-breed dogs (Isaacs, 1996), 5 h in horses (Lees *et al.*, 1991; Isaacs, 1996), 4.8 h in cows (Lees *et al.*, 1991), 4.8 h in minipigs, 1.9 h in Rhesus monkeys, 8.7 h in guinea pigs, and about 14 h in humans (Runkel *et al.*, 1972; Lees *et al.*, 1991; Isaacs, 1996). Elimination of phenylbutazone in dogs may follow zero-order kinetics (Lees *et al.*, 1991). The plasma half-life is between 5 and 8 h in horses, 37 h in cattle, 4 h in swine, and 72 h in humans (Lees *et al.*, 1991).

### *Mechanism of action*

The basic mechanism of action of NSAIDs is through inhibition of COX enzymes. These enzymes are found in all cells except mature erythrocytes (Kore, 1990; Boothe, 2001a). Arachidonic acid, a 20-carbon unsaturated fatty acid, is released from the cell membrane by phospholipase $A_2$ and phospholipase C when a cell is damaged (Mazué *et al.*, 1982; Kore, 1990; Lees *et al.*, 1991; Boynton *et al.*, 1988; Boothe, 2001a). Carprofen causes moderate inhibition of phospholipases (Lees *et al.*, 1991; McKellar *et al.*, 1991). Though arachidonic acid itself has little activity, it can enter two pathways, the COX pathway which produces eicosanoids, or the lipoxygenase pathway which produces leukotrienes (LTs) (Lees *et al.*, 1991).

Oxidation of arachidonic acid by COX and further metabolism by other enzymes leads to the production of various PGs and release of oxygen free radicals (Boynton *et al.*, 1988; Lees *et al.*, 1991). These PGs include $PGH_2$, $PGE_2$, and $PGI_2$. With the addition of prostacycline synthase $PGF_{2\alpha}$ is formed, and thromboxane synthase is needed for production of thromboxane $A_2$ (Kore, 1990; Lees *et al.*, 1991; Boynton *et al.*, 1988).

$PGE_2$ and $PGI_2$ have similar actions, though the effects of $PGI_2$ tend to be of shorter duration (Lees *et al.*, 1991). $PGE_2$, which is secreted by the gastrointestinal mucosa and at other sites, causes smooth muscle relaxation, vasodilation

which enhances blood flow to the kidneys and gastric mucosa, and increased vascular permeability. It inhibits gastric acid production and pepsin production, increases gastric mucus synthesis, and is believed to mediate repair and turnover of gastric epithelium (Collins and Tyler, 1985; Boynton *et al.*, 1988; Kore, 1990; Rubin and Papich, 1990; Wallace *et al.*, 1990; Lees *et al.*, 1991). $PGE_2$ is also found in inflammatory exudate and enhances pain response due to bradykinin and histamine (Kore, 1990; Lees *et al.*, 1991). $PGI_2$ also inhibits platelet aggregation (Lees *et al.*, 1991). $TXA_2$ is produced in platelets, where it stimulates aggregation and promotes vasoconstriction through its action on vascular smooth muscle. $PGF_{2\alpha}$ causes smooth muscle constriction (Boynton *et al.*, 1988; Kore, 1990; Rubin and Papich, 1990).

NSAIDs bind the active site of COX, usually through competitive inhibition, though aspirin binds platelet COX irreversibly (Rubin and Papich, 1990; Talcott, 2006). There are two isoforms of COX, conveniently designated $COX_1$ and $COX_2$. $COX_1$ is found in almost all tissues, including the gastrointestinal tract, platelets, endothelium, and kidneys, is continuously produced, and functions in tissue homeostasis. Most of the adverse affects associated with NSAID use are due to inhibition of $COX_1$ (Boothe, 2001a; Roder, 2005a; Talcott, 2006). Inhibition of $PGE_2$ promotes production of gastric acid and pepsin, decreases the ability of the mucosa to secrete mucus glycoproteins and bicarbonate, and to respond to injury (Mazué *et al.*, 1982; Collins and Tyler, 1985; Kore, 1990; Rubin and Papich, 1990; Isaacs, 1996; Talcott, 2006). Impairments to mucosal circulation due to loss of PG activity may cause mucosal hypoxia and thrombosis (Mazué *et al.*, 1982; Talcott, 2006).

Loss of the vasodilative actions of $PGE_2$ and $PGI_2$ produced by the kidneys may lead to hypoxic renal injury (Rubin and Papich, 1990; Isaacs, 1996; Talcott, 2006). Production of PGs by the kidneys is relatively low, and the renal effects of acute NSAID toxicosis are seldom reported in the veterinary literature (Rubin and Papich, 1990; Talcott 2006). Renal pathology is more often associated with chronic NSAID use (Boothe, 2001a; Talcott, 2006). Renal papillary necrosis has been described frequently in horses, and is often associated with chronic phenylbutazone use (Gunson, 1983; Rubin and Papich, 1990). This condition has also been reported in cats, dogs, mice, rats, gerbils, hamsters, rabbits, desert mice, primates, and pigs (Brix, 2002). The traditional theory for pathogenesis of this lesion holds that decreased PG production leads to redistribution of blood away from the renal medulla, causing endothelial cell necrosis (Kore, 1990; Roder, 2005a). $COX_1$ is present in high concentrations within renal collecting ducts and vasculature. Recent evidence suggests that low doses of NSAIDs cause degeneration of medullary interstitial cells and later damage to vascular endothelium, leading to microvascular thrombosis and hypoxia. Higher doses cause early endothelial damage (Brix, 2002). Dehydration is a major predisposing factor for renal papillary necrosis (Gunson, 1983; Rubin and Papich, 1990; Villar *et al.*, 1998; Isaacs, 1996; Boothe, 2001a; Talcott, 2006). Dehydration may be secondary to gastrointestinal disease, diuretic use, anesthesia, surgical stress, hemorrhagic shock, or sepsis (Kore, 1990; Isaacs, 1996; Talcott, 2006). Other risk factors described for dogs include advancing age, congestive heart failure, hepatic cirrhosis, preexisting renal problems, hypotension, and concurrent administration of nephrotoxic drugs such as gentamicin or amphotericin (Boynton *et al.*, 1988; Kore, 1990; Rubin and Papich, 1990; Isaac, 1996; Boothe, 2001a; Talcott, 2006).

Inhibition of platelet $COX_1$ activity leads to decreased $TXA_2$ production and prolonged bleeding times (Kore, 1990; Rubin and Papich, 1990; Talcott, 2006). Predisposing factors in dogs include concurrent use of anticoagulants and preexisting bleeding disorders such as von Willebrands' disease (Kore, 1990; Rubin and Papich, 1990; Talcott, 2006).

$COX_2$ is produced by macrophages, fibroblasts, chondrocytes, endothelial cells, and some other cell types (Roder, 2005a). This isoform only functions intermittently and is induced by cytokines in areas of inflammation (Isaacs, 1996; Roder, 2005a; Talcott, 2006). Inhibition of this enzyme produces antipyretic, analgesic, and anti-inflammatory effects of NSAIDs (Roder, 2005a; Talcott, 2006).

Most NSAIDs inhibit both isoforms of COX, but some new drugs have been developed that are specific for human $COX_2$ enzymes. These drugs include nimesulide, meloxicam, flosulid, and etodolac. Selectivity is species specific, and thus these new drugs are likely to cause $COX_1$ inhibition in domestic species (Talcott, 2006). $COX_2$ selective drugs will cause $COX_1$ inhibition in humans if given in very high doses (Albretsen, 2002; Talcott, 2006). Interestingly, caprofen is $COX_2$ specific in dogs, though not in humans (Talcott, 2006).

LTs are also produced from arachidonic acid via the lipoxygenase pathway; 5-lipoxygenase produces LTA4 which is converted to LTB4, LTC4, LTD4, LTE4, and others. LTB4 is an important chemoattractant for neutrophils. Various LTs cause vasoconstriction, bronchospasm, and increased vascular permeability (Boynton *et al.*, 1988; Strøm and Krogsgaard-Thomsen, 1990; Lees *et al.*, 1991). Some NSAIDs inhibit lipoxygenase. It has been found that in dogs, flunixin is a more potent inhibitor of LTB4 mediated neutrophil migration than phenylbutazone, which is more potent than indomethacin (Strøm and Krogsgaard-Thomsen, 1990). Alternately, some NSAIDs may increase LT production due to increased availability of arachidonic acid not entering the COX pathway (Boothe, 2001a).

NSAIDs may inhibit phosphodiesterase. Phosphodiesterase breaks down cyclic AMP (cAMP). Increased intracellular cAMP levels may stabilize lysosomal membranes in polymorphonuclear leukocyte, inhibiting release of inflammatory products (Kore, 1990).

NSAIDs may have topical irritant properties. They are weak acids and may partition to the gastric mucosa. This leads to decreased hydrophobicity of mucus and thinning of the mucus barrier, allowing gastric acid to penetrate to the epithelial layer (Mazué *et al.*, 1982; Gfeller and Sandors, 1991; Roder, 2005a; Talcott, 2006). Enterohepatic recycling may enhance these toxic effects (Mazué *et al.*, 1982; Isaacs, 1996; Boothe, 2001a; Talcott, 2006).

NSAIDs frequently cause mild and transient liver damage, which may lead to cholestasis and increased liver enzymes (Boynton *et al.*, 1988; Isaacs, 1996; Roder, 2005a). More severe problems, such as hepatic necrosis, are rare (Boynton *et al.*, 1988). Four percent of people with ibuprofen toxicosis have hepatotoxicosis, but lethal hepatic effects have not been reported and hepatic toxicosis is uncommon in dogs (Talcott, 2006).

Cartilage degeneration has been reported in mice given aspirin, phenylbutazone, indomethacin, ibuprofen, and naproxen (Isaac, 1996). Anaphylactic reactions have been reported, but hypersensitivity to NSAIDs is rare (Kore, 1990; Isaacs, 1996). Agranulocytosis and aplastic anemia, though rare, is a major cause of NSAID-related death in humans (Boynton *et al.*, 1988). This problem is even less common in domestic animals, but has been documented in dogs due to phenylbutazone administration (Rubin and Papich, 1990; Lees *et al.*, 1991; Isaacs, 1996;). More commonly reported in dogs is idiosyncratic hepatotoxicosis due to carprofen (Albretsen, 2002; Roder, 2005a; Talcott, 2006). Approximately one-third of these cases were in Labrador retrievers (Talcott, 2006).

### *Clinical signs*

The most common clinical signs of NSAID overdose in all species are due to gastric mucosal irritation and ulceration. All NSAIDs tested have produced peptic ulcers in animal models (Carson and Strom, 1988). Clinical signs do not always correlate well with the severity of the lesion, possibly due to the analgesic effect of NSAIDs. The asymptomatic ulcer rate among NSAID users is estimated at 50% (Isaacs, 1996). Emesis is frequently reported and the vomitus may contain blood (Wallace *et al.*, 1990; Gfeller and Sandors, 1991; Lees *et al.*, 1991; Jones *et al.*, 1992; Murphy, 1994; Villar *et al.*, 1998; Boothe, 2001a; Roder, 2005a). Anorexia, diarrhea, melena, and abdominal pain or colic may be noted (Wallace *et al.*, 1990; Gfeller and Sandors, 1991; Daehler, 1986; Isaacs, 1996; Roder, 2005a). Animals with gastric perforations will often present with a distended abdomen due to effusion, dehydration, pyrexia, collapse, pallor, and abdominal pain (Godshalk *et al.*, 1992; Talcott, 2006).

The lower gastrointestinal tract may be affected, leading to protein losing enteropathy, most common in horses, or stricture formation (Collins and Tyler, 1984, 1985; Isaacs, 1996). Horses with hypoproteinemia may show secondary edema (Collins and Tyler, 1984, 1985). Endotoxemia and shock have been noted in horses secondary to gastrointestinal ulceration (Collins and Tyler, 1984, 1985).

Analgesic nephropathy occurs in humans but is uncommon in domestic animals, though it has been reported in dogs given naproxen (Isaacs, 1996; Boothe, 2001a). Chronic use of NSAIDs and high doses may be predisposing factors (Lees *et al.*, 1991; Boothe, 2001a). Clinical signs may be evident after 2 weeks or many months of chronic dosing (Kore, 1990) or after single very high doses (Mazué *et al.*, 1982; Murphy, 1994). Acute onset of oliguric renal failure has been described (Kore, 1990; Villar *et al.*, 1998; Roder, 2005a). Animals may present with polyuria and polydipsia, dehydration, oral ulceration, and uremic coma (Mazué *et al.*, 1982).

People in early stages of renal papillary necrosis may have headaches. Later clinical signs include nocutria, dysuria, polyuria with the presence of bacteria, ureteral colic, and lower back pain. Later in the disease process, they may experience hypertension, cardiovascular disease, urolithiasis, and pyelonephritis (Brix, 2002).

Hepatotoxicosis is not common in NSAID intoxicated small animals, though it has been reported in a dog given naproxen (Kore, 1990; Lees *et al.*, 1991; Isaacs, 1996). Clinical signs may include anorexia and weight loss, vomiting, lethargy, icterus, ascites, and coagulopathy (Albretsen, 2002; Roder, 2005a). Increased bleeding times are rarely reported in domestic animals (Murphy, 1994). Prolonged gestation and teratogenesis have been seen experimentally (Lees *et al.*, 1991).

### *Clinical chemistries*

Approximately one-quarter of gastroduodenal ulceration cases in dogs present with microcytic, hypochromic anemia due to chronic blood loss (Stanton and Bright, 1989). Acute blood loss is uncommon. Individuals with acute blood loss present with rapid deterioration, normocytic and normochromic anemia, a normal albumin to globulin ratio, and evidence of regeneration (Stanton and Bright, 1989; Wallace *et al.*, 1990). Peracute hemorrhage is rare and may occur if a mesenteric blood vessel is eroded in the area of ulceration. Such a complication would be rapidly lethal and no regenerative response would occur (Stanton and Bright, 1989; Wallace *et al.*, 1990). Increased PCV may be seen in horses with diarrhea due to dehydration (Collins and Tyler, 1985).

Fecal occult blood is unreliable. It may be negative for low-level blood loss or positive if red meat was fed within 72 h of testing (Talcott, 2006). Hypoalbuminemia has been seen with gastrointestinal ulcers and protein loosing eneteropathy secondary to NSAID use (Collins and Tyler, 1984; Roder 2005a; Talcott, 2006). Both albumin and globulin concentrations will be decreased (Collins and Tyler, 1984; Talcott, 2006). Coagulation profiles may reveal poor

platelet aggregation, thrombocytopenia, and increased bleeding times (Talcott, 2006).

Serum chemistry may reveal increased ALT, AST, ALP, and bilirubin (Albretsen, 2001; Roder, 2005a). A mild, transient rise in liver enzymes frequently occurs during the 1st week of NSAID administration (Boynton *et al.*, 1988; Isaacs, 1996). Elevated blood urea nitrogen (BUN) may indicate nephropathy (Roder, 2005a; Talcott, 2006). Phosphorus, calcium, and potassium may also be elevated (Kore, 1990; Villar *et al.*, 1998; Talcott, 2006).

Animals with renal damage due to NSAIDs may present with isosthenuria, hematuria, and proteinuriea (Kore, 1990; Talcott, 2006). Ketonuria and polyuria have also been reported (Mazué *et al.*, 1982; Kore, 1990).

Horses on chronic high-dose phenylbutazone therapy had normal lymphocyte counts with a left shift due to neutrophil loss into the gastrointestinal tract. Increased serum glucose levels were attributed to endotoxemia. Hypokalemia and hyponatremia may be seen in horses with diarrhea (Collins and Tyler, 1985).

### *Diagnosis and management*

Diagnosis of NSAID toxicosis is often based on history and clinical signs. Serum or plasma testing is available at many veterinary laboratories and human hospitals (Roder, 2005a; Talcott, 2006). Serum drug concentrations are unlikely to be useful in management, but some reference values are listed in the toxicokinetics portion of this section.

Endoscopy is the most sensitive test for gastric ulceration, though occasionally the ulcer will not be visible. Anesthesia is required, thus the patient must be stabilized (Wallace *et al.*, 1990; Talcott, 2006). Survey radiographs are not usually useful (Stanton and Bright, 1989; Wallace *et al.*, 1990). If there is gastrointestinal perforation, then poor visualization of serosal surfaces, peritoneal effusion, free gas in the peritoneal cavity, and intestinal ileus may be noted (Godshalk *et al.*, 1992; Talcott, 2006). Large ulcerations may be identified on contrast radiographs (Wallace *et al.*, 1990). However, if perforation is present, barium sulfate will complicate peritonitis, thus a water-soluble agent is preferred (Talcott, 2006). Ulcers may be detected using ultrasound in an animal given water by stomach tube. The gastric wall is thickened with a loss of the normal five-layer structure, disruption of the mucosa, and gas bubble formation. Increased fluid in the abdomen will be seen in the case of perforation due to peritonitis (Talcott, 2006).

Renal papillary damage can be diagnosed in humans, horses, and foals using ultrasound (Brix, 2002; Roder, 2005a). Computed tomography has been used to diagnose renal papillary necrosis in humans, and magnetic resonance microscopy has been used experimentally (Brix, 2002).

Animals on NSAID therapy should be closely monitored for adverse effects. Attitude and appetite, hydration, electrolyte status, urine concentrating ability, urine protein concentrations, BUN, creatinine, and liver enzymes should be examined (Villar *et al.*, 1998; Roder, 2005a).

When animals present with adverse effects attributable to an NSAID, administration of the drug should be discontinued (Wallace *et al.*, 1990; Albretsen, 2001; Talcott, 2006). Gastric emptying is appropriate for animals that have ingested large quantities of NSAIDs but are not yet showing clinical signs (Kore, 1990). Emetics may be used in some species, though they are contraindicated in animals with severe CNS suppression (Albretsen, 2001; Roder 2005a; Talcott, 2006). Gastric lavage may be used in the anesthetized, intubated animal (Cathers *et al.*, 2000). Activated charcoal and cathartics should be given after gastric emptying or if the animal presents late (Kore, 1990; Cathers *et al.*, 2000; Albretsen, 2001; Roder, 2005a; Talcott, 2006). Repeated activated charcoal administration is recommended for various reasons. Some tablets are sustained release. Regular tablets may form concretions in the stomach and have delayed absorption. Furthermore, enterohepatic recycling is believed to cause the prolonged half-life of ibuprofen and other NSAIDs in dogs (Kore, 1990; Cathers *et al.*, 2000). Animals should be monitored for hydration, electrolyte imbalances, acid–base imbalances, blood glucose, liver enzymes, BUN and creatinine, body temperature, and blood pressure. Deviations from expected values should be corrected as needed (Cathers *et al.*, 2000; Albretsen, 2001). Fluid therapy may be needed to correct dehydration, hypotension, electrolyte imbalances, and improve renal perfusion (Kore, 1990; Villar *et al.*, 1998; Talcott, 2006). It has been suggested that fluids be given at twice maintenance rates. Villar *et al.* (1998) recommend 0.9% saline, or 0.45% saline plus 2.5% dextrose in hypoglycemic animals, given at a rate of 120 ml/kg/day plus estimated fluid losses over a 48–72 h period. Lactated ringers solution or 0.9% saline may contribute to hypernatremia (Albretsen, 2001). Dopamine at a dose of 2.5 μg/kg/min or dubutamine at 2.5 μg/kg/min may be given to increase renal perfusion (Kore, 1990). Diuretics may predispose animals to dehydration and subsequent renal hypoperfusion, thus should be avoided (Albretsen, 2001). Sodium bicarbonate may be used to treat acidosis (Murphy, 1994; Roder, 2005a). Urine alkalinization for ion trapping may be useful with salicylates, aspirin, and ibuprofen, but urinary pH must exceed 7.5–8 to increase naproxen secretion (Runkel *et al.*, 1972; Villar *et al.*, 1998; Roder, 2005a). Urine alkalinization must be used with caution to prevent metabolic alkalosis. Forced diuresis and dialysis are of limited use to enhance elimination of NSAIDs due to the high level of protein binding (Kore, 1990; Cathers *et al.*, 2000). If perforation has occurred, parenteral fluids can become sequestered into the abdomen (Talcott, 2006).

Gastric lavage with iced saline or water has been recommended for severe and continued gastric bleeding, but the efficacy of this treatment is questionable and surgical

correction may be required in cases of refractory bleeding (Wallace *et al.*, 1990). Transfusions or use of blood substitutes may be needed to treat severe anemia (Murphy, 1994; Sellon, 2006). Acute loss of greater than 30% of the blood volume, a PCV less than 20%, plasma protein less than 3.5 g/dl, or continued blood loss are possible indications for transfusion (Talcott, 2006). Vitamin $K_1$ may be given to aid in coagulation (Kore, 1990). Perforating ulcers must be managed surgically (Godshalk *et al.*, 1992; Talcott, 2006).

Gastrointestinal protectants are typically used in NSAID overdose cases to prevent or heal gastric ulcerations. Healing of gastric ulcers is highly correlated with gastric pH in humans. Gastric pH must be maintained above 3 for 18–20 h a day for effective healing, and above 4 in critically ill patients. Gastric pH above 4 inhibits fibrinolysis and the activity of pepsin. Gastric pH must be above 6 to promote platelet aggregation and prevent clot dissolution, therefore allowing hemostasis. Gastric secretion is variable in beagles, with a median pH of 4.44 in fasted dogs and of 1.30 in dogs with fixed feeding times (Bersenas *et al.*, 2005). Therefore, simply withholding food has the benefit of decreasing gastric acid secretion as well as minimizing emesis (Wallace *et al*. 1990; Talcott, 2006).

Treatment with antacids such as magnesium hydroxide (milk of magnesia) or aluminum hydroxide may be adequate for animals exposed to low NSAID doses (Kore, 1990; Jackson *et al.*, 1991; Isaacs, 1996; Villar *et al.*, 1998; Cathers *et al.*, 2000). Antacids require dosing every 2–4 h and may cause changes in fecal consistency (Wallace *et al.*, 1990). Products containing bismuth subsalicylate (Pepto Bismol and Kaopectate) should be avoided because salicylate is an NSAID (Kore, 1990).

Misoprostol is a long-lasting synthetic analog of $PGE_1$. It is the only agent that consistently prevents and treats NSAID-induced gastric and duodenal ulcers (Isaac, 1996). When given concurrently with aspirin, misoprostol prevented gastric ulcers in dogs (Villar *et al.*, 1998). Dogs given NSAIDs and misoprostol had less gastrointestinal hemorrhage, less vomiting, and less mucosal ulceration on endoscopy than dogs given NSAIDs only (Talcott, 2006). Misoprostol may protect renal function in domestic animals and may be chondroprotective in pigs (Isaacs, 1996). This drug has been used safely for up to a year in humans (Talcott, 2006). However, at high doses misoprostol may cause diarrhea (Villar *et al.*, 1998) and use of this synthetic PG is contraindicated in pregnant animals (Villar *et al.*, 1998; Talcott, 2006). Dogs may be given 1–5 μg/kg misoprostol PO every 8 h (Plumb, 2002).

Proton pump inhibitors suppress gastric acid secretion by inhibiting the $Na^+/K^+$ ATPase pump in gastric parietal cells (Walan *et al.*, 1989; Villar *et al.*, 1998). Omeprazole and pantoprazole are proton pump inhibitors (Bersenas *et al.*, 2005). Omeprazole has been used successfully in humans and dogs to treat gastric ulcer (Walan *et al.*, 1989; Villar *et al.*, 1998; Roder, 2005a; Talcott, 2006). Eighty percent of people treated with omeprazole at a dose of 40 mg for 4 weeks had gastric ulcer healing compared to 69% given a dose of 20 mg and 59% given ranitidine. After 8 weeks, 96% of the 40 mg dose group had ulcer healing, compared to 89% of the 20 mg group and 85% of the ranitidine group. Healing rates were also higher for duodenal ulcers in patients treated with omeprazole versus ranitidine (Walan *et al.*, 1989). Bersenas *et al.* (2005) found 2 mg/kg omeprazole PO given to dogs twice per day kept their gastric pH from going below 3 for 90.9% of the day, and kept the gastric pH above 4 for 78.3% of the day, though one in six dogs vomited. Omeprazole remains biologically active for nearly 24 h and only need be given once per day. Plumb (2002) lists the canine daily dose as 0.5–1.0 mg/kg PO, and the feline dose as 0.7 mg/kg. Villar *et al.* (1998) recommend a 3–4-week treatment protocol. Rebound acid secretion has been reported at discontinuation of omeprazole therapy (Driman *et al.*, 1995).

Sucralfate is an aluminum salt of sucrose sulfate. This drug complexes with exposed proteins on the surface of gastric ulcers, specifically fibrinogen and albumin, and acts as a direct mucosal protectant (Kore, 1990; Wallace *et al.*, 1990; Talcott, 2006). Sucralfate has 5 times as much affinity for damaged mucosa as it does for normal mucosa (Villar *et al.*, 1998). Sucralfate also adsorbs pepsin and bile acids (Kore, 1990; Wallace *et al.*, 1990; Talcott, 2006). This drug may promote bicarbonate and mucus secretion by the gastric mucosa (Kore, 1990). Sucralfate is equally as effective as cimetidine at reducing discomfort and promoting ulcer healing (Villar *et al.*, 1998). Dogs given sucralfate to treat gastric ulcers, with and without concurrent cimetidine treatment, had complete healing of the gastric mucosa within 9 days of treatment (Talcott, 2006). Sucralfate may be used alone if gastric hyperacidity is not suspected (Wallace *et al.*, 1990). If used with cimetidine, dosing should be staggered or cimetidine should be given by a parenteral route. Sucralfate may interfere with absorption of cimetidine from the gastrointestinal tract (Wallace *et al.*, 1990). Cimetidine should be given 1 h before a meal (Murphy, 1994; Villar *et al.*, 1998). Dogs are dosed with sucralfate every 8 h. Dogs weighing more than 20 kg can be given 1 g per dose, and smaller dogs can be dosed with 0.5 g (Murphy, 1994; Albretsen, 2002; Plumb, 2002). Cats may be given a total of 0.25–0.5 g every 8–12 h and ferrets may be given 75 mg/kg 4–6 times a day, preferably 10 min before feeding. Foals may be given 1–2 g PO 2–3 times daily (Plumb, 2002).

$H_2$ histamine receptor inhibitors, including cimetidine, ranitidine, and famotidine, are routinely used to treat NSAID-induced gastric ulcers. Histamine stimulates gastric parietal cells to secrete hydrogen ions through an $H^+/K^+$ ATPase pump. Acetylcholine, gastrin, and histamine stimulate this proton pump. $H_2$ inhibitors only block the histaminic effect on parietal cells, but cause significant inhibition of gastric acid secretion nonetheless

(Bersenas *et al.*, 2005). Human studies showed healing of 40–88% of NSAID-induced ulcers with 4 weeks of $H_2$ inhibitor treatment, and 90% healing after 3 months. There was 67–100% healing of duodenal ulcers, despite continued NSAID therapy. $H_2$ inhibitors may suppress clinical signs associated with unhealed ulcers (Talcott, 2006).

Cimetidine has been commonly used to treat and prevent NSAID-induced ulcers, though research on its efficacy has had conflicting results (Verbeeck, 1990). Cimetidine may decrease gastrointestinal discomfort and does decrease gastric acid secretion (Boulay *et al.*, 1986; Isaacs, 1996). Cimetidine has not been proven to be effective with continued NSAID use and did not prevent gastric ulcer formation when used concurrently with aspirin (Kore, 1990; Wallace *et al.*, 1990; Isaac, 1996; Talcott, 2006). Cimetidine is more useful when NSAID administration has ended and may be helpful with single large doses (Kore, 1990). Gastric acid production is dependent on local circulation, which provides oxygen and energy. Cimetidine decreases gastric blood flow, which contributes to decreased mucosal alkalinity (Cheung and Sonnenschein, 1983). Reduced circulation may contribute to tissue hypoxia. Cimetidine is known to inhibit hepatic cytochrome P450 enzymes and may decrease the rate of metabolism of NSAIDs (Wallace *et al.*, 1990; Verbeeck, 1990; Talcott, 2006). Cimetidine given at a dose of 6 mg/kg every 6 h caused decrease basal acid output in dogs by 30–50% and food-induced output by 63–71%. When 12 mg/kg was used every 6 h, there was a 70–80% decrease in basal acid output and complete suppression of food-induced output (Boulay *et al.*, 1986). Cimetidine can be given to dogs at a dose of 5–10 mg/kg PO, SC, or slow IV every 6–8 h (Villar *et al.*, 1999; Plumb, 2002). Similar dosing protocols are used in cats and ferrets (Plumb, 2002).

Ranitidine does not inhibit microsomal enzymes like cimetidine (Wallace *et al.*, 1990; Talcott, 2006). However, Bersenas *et al.* (2005) found no significant effect on gastric acid secretion in dogs dosed with ranitidine. Ranitidine also decreases gastric blood flow (Wallace *et al.*, 1990; Talcott, 2006). Ranitidine is given at a dose of 0.5–2.0 mg/kg PO, IV, or IM every 8–12 h in dogs, and 2.5 mg/kg IV or 3.5 mg/kg PO in cats every 12 h (Plumb, 2002). Villar *et al.* (1998) recommend continuous treatment for 3–6 weeks.

Famotidine increases intragastric pH in dogs better than ranitidine. Famotidine given at high doses prevents gastric lesion formation in human patients when given concurrently with NSAIDs. Gastric pH must remain above 3 for 18 out of every 24 h for optimal ulcer healing in humans. A 0.5 mg/kg IV dose of famotidine given 2–3 times a day was not able to accomplish this prolonged pH increase in dogs (Bersenas *et al.*, 2005). Famotidine was found protective against reduced gastric perfusion when used at a dose of 0.5 mg/kg IV in dogs given diclofenac (Hata *et al.*, 2005). Dogs may be given 0.5–1 mg/kg famotidine PO or slow IV every 12 h. The dose for cats is 0.5 mg/kg and 0.25–0.5 mg/kg may be given to ferrets. Horses are given 0.23 mg/kg IV or 1.88 mg/kg PO every 8 h, 0.35 mg/kg IV or 2.8 mg/kg PO every 12 h. Rapid IV infusion has been associated with bradycardia (Plumb, 2002).

The prognosis for NSAID toxicosis is dependent on chronicity, dose, and clinical signs (Talcott, 2006). A study by Wallace *et al.* (1990) found that seven of seven dogs treated for chronic NSAID toxicosis recovered after 2–9 days of hospitalization. The mean hospital stay was 6 days. Gastrointestinal irritation and ulceration are reversible, but perforation and peritonitis require intensive surgical and medical management and have a guarded prognosis (Roder, 2005a; Talcott, 2006). Renal effects such as nephropathy are often reversible, but papillary necrosis is a permanent change (Kore, 1990; Roder, 2005a). Loss of the long loops of Henle decreases urine concentrating ability, but horses with renal papillary necrosis may appear clinically normal (Gunson, 1983; Roder, 2005a). Severe acute cortical necrosis is associated with irreversible renal failure (Jones *et al.*, 1992). NSAID-induced coagulopathies are reversible once the NSAID has been eliminated (Talcott, 2006). However, with aspirin and salicylates, coagulopathy is prolonged as discussed below. Dogs with idiosyncratic hepatic injury usually recover within 4 weeks (Albretsen, 2002).

#### *Postmortem findings*

Gastrointestinal lesions are most commonly associated with NSAID toxicosis. Mild lesions may include mucosal edema, irritation, and petechiation. Erosive lesions, which do not extend through the mucosa, may progress to ulcerations through the mucosal layer (Collins and Tyler, 1985; Murphy, 1994; Isaacs, 1996; Roder, 2005a; Talcott, 2006). The location for gastric ulceration in the canine stomach is variable according to the literature. Lesions may be near the pylorus, lesser curvature of the fundus, or diffuse (Daehler, 1986; Stanton and Bright, 1989; Wallace *et al.*, 1990; Godshalk *et al.*, 1992; Talcott, 2006). Duodenal ulcers and perforations have been reported in dogs, but other predisposing factors may have been present (Stanton and Bright, 1989; Gfeller and Sandors, 1991). Perforations may occur in the stomach, small intestine, or colon (Roder, 2005a). Ulcers that erode mesenteric vasculature are rapidly lethal (Stanton and Bright, 1989).

Gastric ulcerations in the horse usually occur in the glandular mucosa and may be adjacent to the margo plicatus (Collins and Tyler, 1984, 1985; Roder, 2005a). Linear circular erosions were reported in the duodenum of horses dosed with phenylbutazone, and ulcers and erosions were found throughout the small intestine (Collins and Tyler, 1985). Ulcerative colitis of the right dorsal colon is commonly seen in horses with NSAID toxicosis (Roder, 2005a). Fibrinonecrotic typhlocolitis was seen in the Collins and Tyler study (1985).

Papillary necrosis occurs with long-term NSAID administration (Mazué *et al.*, 1982). The lesion is bilateral and the papillae are cavitated, yellow-green to orange, and demarcated from the medulla by hemorrhage. The lesion is most severe at the poles. Histologically, the papilla has undergone coagulative necrosis with dilation of the collecting ducts and loops of Henle. Interstitial fibrosis may extend through the medulla and cortex in chronic cases (Gunson, 1983). This lesion has been reported in horses, dogs, cats, mice, rats, gerbils, hamsters, rabbits, desert mice, primates, and pigs (Brix, 2002). The lesion is common in horses given phenylbutazone, but has also been reported with flunixin, aspirin, and dipyrone (Gunson, 1983). Papillary necrosis occurred in two of five dogs dosed with peroxicam (Talcott, 2006).

Interstitial nephritis, with multifocal or diffuse infiltrates of lymphocytes, has been reported. There may be vacuolar degeneration of proximal and distal convoluted tubules (Kore, 1990). Tubular nephritis with epithelial necrosis and regeneration, in addition to interstitial inflammation and fibrosis, has been described (Mazué *et al.*, 1982). Acute cortical necrosis due to NSAID toxicosis has been documented (Jones *et al.*, 1982).

Lymphoid necrosis has been noted in dogs and a ferret. Mild necrosis in the white pulp of the spleen was described in the ferret (Cathers *et al.*, 2000). Depletion and necrosis of germinal centers was discovered in a dog, though circulating lymphocytes were within the reference range (Collins and Tyler, 1985).

## Aspirin and salicylates

This group, which constitutes the most extensively used OTC drugs (Kore, 1990), includes acetylsalicylic acid or aspirin, sodium salicylate, bismuth subsalicylate, and diflunisal. Aspirin and salicylates are NSAIDs with many characteristics similar to those of other NSAIDs, as described above. Aspirin and salicylate also have certain unique properties. Clinical toxicosis of products containing bismuth subsalicylate, an OTC drug commonly used for gastrointestinal distress, are similar to those associated with other sources of salicylate, thus these products will be further discussed in this section.

Salicylates have been used since ancient times by Greek and Roman physicians Hippocrates and Galen, by South African tribes, and by North American Indians (Boynton *et al.*, 1988; Lees *et al.*, 1991). Reverand Edmund Stone wrote of the use of *Salix alba* bark in the journal of the Royal Philosophical Society in London in 1763. Salicylic acid was first isolated from the bark of willows (*Salix* spp.) and beech trees (*Fagus* spp.) in the early 19th century (Lees *et al.*, 1991). Bayer Pharmaceutical Company synthesized acetylsalicylic acid in 1893 and aspirin has been marketed since 1899 (Boynton *et al.*, 1988; Lees *et al.*, 1991).

Contraindications for aspirin use include coagulation disorders, recent (within 1 week) surgery, and concurrent use with certain drugs (Brater, 1988; Verbeeck, 1990; Talcott, 2006). See Table 23.2 for a list of drugs that may interact with aspirin and other NSAIDs. Aspirin inhibits the diuretic effects of spironolactone (Verbeeck, 1990).

### *Toxicity*

The efficacy of aspirin is dose dependent. Circulating aspirin concentrations of 20–60 μg/ml are associated with analgesic and antipyretic effects in humans (Papich *et al.*, 1987; Boothe, 2001). Plasma levels in excess of 50 μg/ml are associated with anti-inflammatory effects and concentrations of 200 μg/ml occur in the treatment of rheumatic disorders (Lees *et al.*, 1991; Boothe, 2001a). Fecal blood loss is reported at concentrations between 120 and 350 μg/ml (Papich *et al.*, 1987). However, toxic changes are most commonly associated with levels greater than 300 μg/ml (Papich *et al.*, 1987; Boothe, 2001a). About half of people receiving therapeutic doses of aspirin that were tested had gastric lesions visible on endoscopy (Carson and Strom, 1988). Neonates less than 1 month old may be more susceptible to the adverse effects of aspirin because of the prolonged plasma half-life in this group (Davis, 1980).

Aspirin is used in dogs at doses of 10–25 mg/kg every 8–12 h for analgesia (Kore, 1990; Rubin and Papich, 1990; Plumb, 2002). Dogs dosed with 25 mg/kg aspirin every 8 h for up to 3 weeks had no severe adverse effects (Lees *et al.*, 1991). Dogs dosed in this way have peak plasma concentrations were greater than 50 μg/ml but peak concentrations were lower in pups 12–16 weeks old. The half-life may be increased in pups less than 30 days old, who have a decreased metabolic capability (Waters *et al.*, 1993). A study of dogs dosed with 25–35 mg/kg aspirin every 8 h found increased fecal hemoglobin and gastric ulceration on endoscopy (McKellar *et al.*, 1991). Seizures were reported on a dog given 37 mg/kg aspirin every 12 h for 2 weeks (Schubert, 1984); 50 mg/kg aspirin given to dogs every 12 h was associated with emesis (McKellar *et al.*, 1991). Similar daily doses were associated with perforating gastric ulcers within 4 weeks (Kore, 1990). One dose of 400 mg/kg will cause hemorrhage, and daily dosing caused pyloric ulcers within 2 weeks (Mazué *et al.*, 1982).

Cats are more susceptible to the toxic effects of aspirin than dogs and humans (Papich, 1990; Roder, 2005a). Doses of 25 mg/kg every 2–3 days are recommended to control thromboembolic disease and 10 mg/kg every other day may be used for analgesia and antipyresis (Plumb, 2002). A dose of 10.5 mg/kg aspirin every 52 h produced plasma concentrations ranging from 50 to 20 μg/ml. No clinical signs were seen in cats dosed with 25 mg/kg aspirin every 48 h (Boothe, 2001a). No severe signs were seen in cats dosed with 25 mg/kg aspirin every 24 h for 2–3 weeks (Lees *et al.*, 1991). Aspirin doses between 100 and 110 mg/kg daily

may cause death in cats within 7 days (McKellar *et al.*, 1991). Young cats, old cats, or cats with renal or hepatic disease may be particularly sensitive to the effects of aspirin (Kore, 1990).

Aspirin may be used in cattle and goats, but they require larger oral doses to reach appropriate plasma concentrations. A dose of 100 mg/kg PO given every 12 h in cattle maintains a therapeutic concentration of 30 μg/ml (Davis, 1980; Boothe, 2001a). IV dosing with 6.5 mg/kg hourly is associated with plasma concentrations of 50–20 μg/ml, 26 mg every 1.6 h yields plasma concentrations of 200–50 μg/ml, and 39 mg every 2 h yields levels of 300–50 μg/ml in the plasma (Davis, 1980).

Horses may be given 35 mg/kg aspirin IV according to Davis (1980). A single oral dose of 20 mg/kg was associated with prolonged bleeding times (Boothe, 2001a).

Liquid bismuth subsalicylate preparations contain 8.77 mg salicylate per ml (Papich *et al.*, 1987). Ingestion of greater than 7 ml/kg daily has been associated with toxicosis in humans (Papich *et al.*, 1987; Papich, 1990). Tablets contain 102 mg available salicylate (Sainsbury, 1991).

### *Toxicokinetics*

Aspirin is lipophilic at acid pH, thus it is readily absorbed from the stomach and duodenum in dogs and cats (Rubin and Papich, 1990; Talcott, 2006). Aspirin is 68–76% bioavailable in dogs, with some variation based on formulation (Boothe, 2001a). Enteric-coated and buffered products are used in humans and dogs (McKellar *et al.*, 1991; Murtaugh *et al.*, 1993; Boothe, 2001a). Acid-resistant forms are more readily absorbed at the relatively alkaline pH range of the duodenum and absorption may be delayed up to 12 h (Verbeeck, 1990). Buffered aspirin is more soluble and less ionized, thus slowing absorption and decreasing gastric irritation (Rubin and Papich, 1990; Boothe, 2001a). Ingestion of a fatty meal can reduce aspirin bioavailability by 30% (Mazué *et al.*, 1982). Aspirin is 70% bioavailable in cattle, but absorption is relatively slow (Boothe, 2001a). When humans were given bismuth subsalicylate, 95% of the salicylate was recovered in the urine. Salicylates in bismuth subsalicylate are 97.5% absorbed in dogs and 85.4% absorbed in cats (Papich *et al.*, 1987).

Peak serum concentrations occur 4 h after oral dosing with buffered aspirin. Peak serum concentrations are lower in immature dogs than in mature dogs after PO or IV dosing (Waters *et al.*, 1993). Circulating salicylate is 72% protein bound in humans and 45% protein bound in dogs (Waters *et al.*, 1993). There is more free, and therefore bioavailable, salicylate in the hypoalbuminemic animal, but the excess is rapidly eliminated (Boothe, 2001a). Aspirin is rapidly distributed to most tissues, including synovial fluid, peritoneal fluid, saliva, and milk (Boothe, 2001a; Talcott, 2006). Aspirin has a lower volume of distribution in cattle compared to other domestic species (Davis, 1980).

Aspirin is rapidly hydrolyzed to salicylate by esterases in the gastrointestinal tract, liver, and erythrocytes. These enzymes are less efficient in immature dogs (Waters *et al.*, 1993). Most of the metabolism takes place in the liver (Talcott, 2006). Salicylate is bioactive and responsible for most of the clinical effects of aspirin (Lees *et al.*, 1991; Talcott, 2006). Salicylate may be conjugated to glucuronide or glycine. The glucuronide pathway is deficient in cats, limiting their ability to eliminate salicylate (Rubin and Papich, 1990; Jones *et al.*, 1992; Isaac, 1996; Boothe, 2001a; Talcott, 2006). Bismuth subsalicylate is metabolized to bismuth and salicylate in the gastrointestinal tract (Boothe, 2001a).

The kidneys eliminate salicylate and its glycine conjugate (Boothe, 2001a). Two to 30% of a dose of aspirin is excreted as unconjugated salicylate (Verbeeck, 1990). The rate of elimination for aspirin varies with species and age (McKellar *et al.*, 1991). The elimination half-life in dogs is dependent on the dose form. The half-life for enteric-coated products ranges from 7.5 to 12.2 h. The elimination half-life for aspirin given IV is 2.2–8.7 h (Boothe, 2001a). The elimination half-life in cats is long and increases with dose. If low doses of 5–12 mg/kg are given, the elimination half-life is 22–27 h, but the half-life for the much higher dose of 25 mg/kg is 45 h (Boothe, 2001a). Salicylate may have zero-order kinetics in cats (Lees *et al.*, 1991). The elimination half-life in horses is about an hour due to ion trapping in alkaline urine. Salicylates are a normally component equine urine (Boothe, 2001a). The elimination half-life in cattle is about half an hour (Lees *et al.*, 1991; Boothe, 2001a). The half-life in humans is 3 h (Lees *et al.*, 1991; Isaacs, 1996). Young animals metabolize aspirin more slowly, and the elimination half-life may be prolonged in puppies less than 30 days old, piglets, kids, and foals (McKellar *et al.*, 1991).

### *Mechanism of action*

The effects attributed to aspirin are mostly caused by the active metabolite salicylate (McKellar *et al.*, 1991). Salicylate inhibits COX to block PG synthesis, as described for NSAIDs (Boulay *et al.*, 1986; Carson and Strom, 1988; Jones *et al.*, 1992; Murtaugh *et al.*, 1993). Other NSAIDs competitively inhibit COX, but salicylates can permanently inactivate the enzyme by acetylating a serine residue (Kore, 1990; Rubin and Papich, 1990; Boothe, 2001a; Talcott, 2006). Platelets are unable to synthesize COX (Rubin and Papich, 1990; Lees *et al.*, 1991; McKellar *et al.*, 1991). Unlike other NSAIDs, where coagulopathy resolves once the drug is eliminated, it takes about a week to resolve aspirin-induced coagulopathy (Boothe, 2001a).

Aspirin has a direct irritant effect on the gastric mucosa. Aspirin is an acidic drug and is taken up by the mucosal epithelium, where it becomes concentrated (Carson and Strom, 1988; Rubin and Papich, 1990; Isaacs, 1996). Aspirin inhibits oxidative phosphorylation of the gastric mucosal

epithelium, thus decreasing ATP production and $Na^+/K^+$ movement across the cell membrane, leading to cell swelling and necrosis (Rubin and Papich, 1990). Disruption of ion transport allows increased $H^+$ ion back-diffusion into the mucosa (Boulay *et al.*, 1986; Carson and Strom, 1988; Rubin and Papich, 1990). Injury may extend into submucosal capillaries, leading to hemorrhage, inflammation, and ulceration (Boulay *et al.*, 1986; Rubin and Papich, 1990). IV dosing of cats produced gastric erosions and ulcers, confirming that there is also a role for COX inhibition and reduced PG synthesis in the pathophysiology of gastric mucosal damage (Villar *et al.*, 1998).

Aspirin uncouples oxidative phosphorylation, as noted above. Aspirin allows penetration of $H^+$ across the mitochondrial membrane, thus disrupting the proton gradient. The result is inhibition of the enzyme ATP synthetase. Energy that would go into ATP production is dissipated as heat. When oxidative phosphorylation is inhibited systemically, the result is elevated body temperature (Roder, 2005a).

Salicylates may produce acidosis and increase the anion gap. Salicylate and its metabolites increase the anion gap directly (Schubert, 1984; Kore, 1990). Anaerobic metabolism compensates for reduced ATP production due to inhibition of oxidative phosphorylation. Metabolites of anaerobic metabolism include lactic acid, pyruvic acid, and ketones. These substances cause acidemia (Kore, 1990; Roder, 2005a). Aspirin may also directly stimulate respiratory centers in the CNS, causing hyperventilation and respiratory alkalosis, which promotes renal secretion of bicarbonate (Kore, 1990; Boothe, 2001a). Later in the progression of the toxicosis, CNS suppression may decrease the respiratory rate, resulting in acidosis (Schubert, 1984; Kore, 1990).

### Clinical signs

Similar to other NSAIDs, gastric irritation is the most common side effect of aspirin (Talcott, 2006). Vomiting, gastric ulceration, and hemorrhage are often reported (Davis, 1980; Papich, 1990; McKellar *et al.*, 1991).

Depression is often seen in aspirin toxicosis in dogs and cats (Kore, 1990; Jones *et al.*, 1992). Profound depression has been reported in dogs given high doses of aspirin (McKellar *et al.*, 1991). Dogs collapse or appear too weak to stand (Wallace *et al.*, 1990). Restlessness progressing to tremors, seizures, and eventually coma have been reported in dogs (Schubert, 1984; Kore, 1990). One dog had a progressive increase in seizure duration from 5 to 45 min (Schubert, 1984). Seizures and coma have also been reported in cats (Jones *et al.*, 1992; Isaacs, 1996; Talcott, 2006). Seizures have been attributed to hypoventilation, acidosis, and hypoglycemia (Schubert, 1984; Talcott, 2006). Anemia due to bone marrow suppression has also been reported in cats (Kore, 1990; McKellar *et al.*, 1991).

Aspirin toxicosis may cause hyperthermia in children and cats. Hyperthermia is uncommon in adults and carries a poor prognosis (Talcott, 2006). There may be an initial hyperpnea in acute aspirin toxicosis due to stimulation of respiratory centers (Kore, 1990; Boothe, 2001a; Talcott, 2006). Fatal acidosis may occur within 4 h of aspirin overdose in humans (Talcott, 2006).

Bismuth subsalicylate toxicosis has not been described in the veterinary literature (Papich *et al.*, 1987). Overdose described in humans is similar to aspirin toxicosis. One lethally affected patient presented with dehydration, progressive CNS depression, coagulopathy and anemia, and pulmonary edema (Sainsbury, 1991).

### Clinical chemistries and postmortem findings

Metabolic acidosis and increased anion gap have been noted in acute aspirin toxicosis (Roder, 2005a). Other changes are similar to those described with other NSAIDs.

Lesions similar to other NSAIDs are expected on necropsy. Gastric mucosal lesions have been documented in the pyloric antrum, body, and cardiac region of the stomach of dogs (Boulay *et al.*, 1986). Pulmonary edema has been found in humans that died from acute aspirin toxicosis (Talcott, 2006).

### Management

Diagnosis and treatment is similar to that described above for NSAIDs. Urine and plasma testing is available at many veterinary and hospital laboratories. There is a poor correlation between plasma salicylate levels and with clinical signs (Talcott, 2006). The presence of salicylate in horse urine is expected, even in horses not given aspirin, and not a significant finding (Boothe, 2001a).

Salicylates may inhibit gastric emptying and gastrointestinal absorption is prolonged with enteric-coated tablets, therefore gastric lavage may be useful up to 12 h after exposure. Activated charcoal should be administered, and is most useful within 2 h of aspirin ingestion. Cathartic use has not been shown to decrease absorption (Talcott, 2006).

Forced alkaline diuresis is more useful with aspirin than with other NSAIDs, and is frequently used by physicians. Low urinary pH promotes salicylate elimination by trapping the ionic form in the urine (Kore, 1990; Roder, 2005a; Talcott, 2006). Alkaline peritoneal dialysis has been recommended for severe overdose (Davis, 1980; Kore, 1990). Acetazolamide, a carbonic anhydrase inhibitor, has been used to alkalize urine, but may exacerbate metabolic acidosis (Talcott, 2006). Acid–base status must be closely monitored in any animal undergoing alkaline diuresis.

Monitoring and supportive care for changes in hydration, electrolyte balance, and body temperature are warranted. Use of NSAIDs to treat hyperthermia is to be avoided (Kore, 1990). Diazepam may be used for seizure management (Schubert, 1984). Gastric protectants should be used, as described with NSAIDs.

## COLD, COUGH, AND ALLERGY MEDICATIONS

Medications for the symptomatic relief of cold, flu, and allergies are common and often contain multiple active ingredients. Preparations frequently contain analgesics, decongestants, antihistamines, expectorants, and antitussives. Other ingredients may include ethanol and caffeine (Papich, 1990).

Detailed information on analgesic toxicosis can be found in the previous section of this chapter. Toxic effects of decongestants and antihistamines will be discussed below. Toxic effects of alcohol and caffeine are addressed elsewhere in this book.

Dextromethorphan is a centrally active antitussive. Structurally similar to opioids, it acts on receptors in medullary cough centers. Toxic effects are rare in small animals. Sedation is the most common side effect, but respiratory suppression is unlikely. If an animal is overdosed with dextromethorphan, activated charcoal may be given early. Treatment consists of observation and supportive and symptomatic care as needed (Papich, 1990).

Guafenasin or glyceryl guaicolate, is the most common expectorant. It is used as a sedative and muscle relaxant at high doses and may cause gastritis and vomiting, but is present in relatively small concentrations in OTC products. Treatment for guafenasin overdose would include routine detoxification early, observation, and symptomatic and supportive care (Papich, 1990).

### Decongestants

Sympathomimetic amines are used as decongestants because of their vasoconstricting effects. Common decongestants include pseudoephedrine, ephedrine, phenylephrine, and phenylpropanolamine. Pseudoephedrine is the most common decongestant associated with toxicosis in small animals, more commonly dogs than cats (Papich, 1990). Pseudoephedrine has been commonly used in cold and allergy preparations (Means, 2005). Due to its illicit use in the manufacture of methamphetamine, some US states now regulate its sale. Pseudoephedrine is a steroisomer of the plant alkaloid ephedrine. Ephedrine is found in *Ephedra* sp. and *Sida cordifolia*. *Ephedra* sp. is used to produce ma huang, an herbal drug used in asthma, allergy, and cold formulations, diet pills, and in other supplements (Means, 1999; Ooms and Khan, 2001; Means, 2005). Phenylephrine is found in nasal sprays and hemorrhoid creams (Means, 2005). Oxymetazolin is found in ophthalmic drugs (Papich, 1990). Phenylpropanolamine was used in cold and allergy products and diet pills (Papich, 1990; Means, 2005). It is no longer sold OTC in the United States (Crandell and Ware, 2005).

Sympathomimetic amines may interact with digoxin, monoamine oxidase (MAO) inhibitors, halothane, and methylxanthines (Means, 1999; Ooms and Khan, 2001; Means, 2005). Certain conditions may predispose animals to adverse reactions when given sympathomimetic amines. These include diabetes, hypothyroidism, hyperthyroidism, cardiac disease, hypertension, seizure disorders, renal disease, and glaucoma (Means, 2005).

#### *Toxicity*

Pseudoephedrine is used to improve urethral sphincter tone as a treatment for urinary incontinence in dogs, and is given at a dose of 1–2 mg every 12 h (Means, 2005). Clinical toxicosis has been reported in dogs given 5–6 mg/kg, and death was documented in dogs given 10–12 mg/kg (Means, 1999; Ooms and Khan, 2001; Means, 2005).

Drugs containing ephedrine, in the form of ma huang, are often combined with caffeine, in the form of guarana, and this combination of drugs may act synergistically and enhance the toxicity of this product. Doses of 1.3–88.9 mg/kg ma huang given concurrently with 4.4–296.2 mg/kg guarana have been associated with clinical toxicosis in dogs. One dog given a dose of 5.8 mg/kg ma huang and 19.1 mg/kg guarana died. There seems to be great individual difference in sensitivity to this combination of drugs, and prognosis may be dependent on the time that elapses between exposure and treatment (Ooms and Khan, 2001).

The therapeutic dose of phenylpropanolamine in dogs is 1.1 mg/kg (Crandell and Ware, 2005; Means, 2005). Elevated blood pressure was seen in beagles given 3.1 mg/kg PO every 8 h, and myocardial damage was noted in a dog given 48 mg/kg (Crandell and Ware, 2005).

#### *Pharmacokinetics*

Decongestants are rapidly absorbed by the gastrointestinal tract (Papich, 1990; Means, 2005). Ephedrine is absorbed within 2 h of ingestion (Ooms and Khan, 2001). The onset of action is usually within 30 min, though it may be delayed up to 8 h with extended release products. Sympathomimetic amines are believed to cross the blood–brain barrier and the placenta, and are secreted into milk. Metabolism occurs primarily in the liver (Means, 2005). Most of the dose of ephedrine is excreted unchanged in the urine, and other decongestants may be excreted 55–75% as the parent compound. The elimination half-life of pseudoephedrine is 2–21 h and that for phenylpropanolamine is 2–4 h (Means, 2005). Urinary excretion is accelerated at low urine pH (Ooms and Khan, 2001; Means, 2005).

#### *Mechanism of action*

The effects produced by decongestants are from stimulation of adrenergic receptors (Papich, 1990; Means, 1999;

Ooms and Khan, 2001; Crandell and Ware, 2005; Means, 2005). Stimulation of α-1 receptors causes vasoconstriction and subsequent drying of the mucous membranes of the nasal mucosa and sinuses. Ophthalmic solutions decrease eye redness by constriction of conjunctival and scleral vasculature (Papich, 1990). Peripheral vasoconstriction leads to increased systemic vascular resistance and hypertension (Papich, 1990; Means, 1999; Ooms and Khan, 2001; Means, 2005). α-1 receptor stimulation may cause vasospasm of the coronary artery and myocardial necrosis (Crandell and Ware, 2005). Other α-adrenergic effects may include appetite suppression, CNS stimulation, and mydriasis (Papich, 1990; Means, 1999; Ooms and Khan, 2001; Means, 2005). The effects of phenylephrine and oxymetazole are α-receptor specific (Papich, 1990). Stimulation of α-receptors by phenylpropanolamine is known to cause release of endogenous catecholamines in the brain and heart, and may inhibit MAO at high doses (Means, 1999; Crandell and Ware, 2005).

Stimulation of β-receptors is the cause of the cardiac effects attributed to decongestants, which include increased contractility and output, increased heart rate and tachyarrhythmia (Papich, 1990; Means, 1999; Means, 2005). Reflex bradycardia may occur. Bronchodilation is also mediated β-receptors (Papich, 1990).

### *Clinical signs*

Stimulation of the CNS is common in decongestant overdose. Hyperactivity, restlessness, agitation, pacing, and vocalization may be observed (Papich, 1990; Means, 1999; Means, 2005). Hallucinatory behaviors in dogs may include staring into a corner or at unseen objects, perhaps even biting at them. Tremors, seizures, and head bobbing have been reported (Means, 1999; Means, 2005). Hyperthermia may be secondary to increased activity, and disseminated intravascular coagulation (DIC) or rhabdomyolysis with associated renal failure are possible outcomes (Papich, 1990; Means, 2005). Cardiovascular changes include tachycardia, reflex bradycardia, and hypertension (Means, 1999; Papich, 1990; Means, 2005). Hypertension was described in beagles 30–60 min after dosing. Blood pressure in some dogs remained elevated for 6 h (Crandell and Ware, 2005). Animals may die from cardiovascular collapse (Means, 1999; Means, 2005). Postmortem lesions are nonspecific (Means, 2005).

Vomiting, diarrhea, dehydration, and anorexia were reported in a dog with phenylpropanolamine toxicosis. This dog was ataxic, lethargic, tachycardic, and tachypneic. Eyes were bilaterally dilated with vertical nystagmus and loss of pupillary light reflex. This dog was not hypertensive, possibly because it did not present to the veterinarian until 12 h after ingestion (Crandell and Ware, 2005).

Ooms and Khan (2001) studied dogs accidentally overdosed with a combination of ma huang and guarana herbal preparations. They found that the onset of clinical signs could be as early as 30 min after ingestion, but was usually within 8 h. Duration of signs ranged from 10 to 48 h. Vomiting was seen in 47% of dogs and 5% were anorexic. Tachycardia occurred in 30%, tachypnea in 6%. Mydriasis was reported in 21% of dogs, tremors in 27%, and behavioral changes such as snapping, pacing, and head shaking in 6%, and seizures in 6%. Incidence of depression, weakness, and apprehension were each 5%. Hyperthermia was reported in 28% of these dogs.

### *Clinical chemistries*

Hypokalemia, hyperglycemia, and hyperinsulinemia are usually reported in dogs with decongestant toxicosis (Means, 1999; Means, 2005). Hypoglycemia was seen in a dog that had ingested phenylpropanolamine. Other findings with phenylpropanolamine overdose included elevated ALT and ALP, mild hyperbilirubinemia, elevated BUN and creatinine, and increased CK. Blood pH and calcium levels were elevated. Polycythemia and thrombocytopenia were noted. A urine sample contained blood, hemoglobin or myoglobin, and protein. Serum troponin was elevated, indicating myocardial damage (Crandell and Ware, 2005).

### *Management*

Diagnosis of decongestant toxicosis is usually based on history and clinical signs (Ooms and Khan, 2001; Means, 2005). Some laboratories are able to test for pseudoephedrine, ephedrine, and phenylpropanolamine in plasma or urine.

Treatment consists of detoxification, symptomatic, and supportive care. Emetics should only be used in the asymptomatic animal due to the risk of aspiration (Papich, 1990; Means, 1999; Means, 2005). Onset of signs is often rapid (Means, 2005). Gastric lavage may be performed in the stabilized, anesthetized, and intubated patient after a large ingestion (Ooms and Khan, 2001). Activated charcoal and cathartic should be given (Papich, 1990; Means, 1999; Ooms and Khan, 2001; Means, 2005). Blood pressure, ECG, and body temperature should be monitored closely. Complete blood count (CBC), serum chemistry, and acid–base status should be monitored every 1–3 days.

Tachycardia is treated with β-blockers. Propranolol may be administered at a dose of 0.02–0.06 mg/kg slowly by IV (Means, 1999; Ooms and Khan, 2001; Means, 2005). Propranolol therapy may stabilize hypokalemia (Means, 2005). Lidocaine has been used at a dose of 2 mg/kg IV by intermittent bolus or by continuous infusion at a rate of 80 μg/kg/min in dogs (Crandell and Ware, 2005). Crandell and Ware (2005) recommended atenolol at 0.2 mg/kg every 12 h and enalapril 0.5 mg/kg every 12 h, both given orally, to support myocardial function for phenylpropanolamine toxicosis. Papich (1990) recommended atropine at a dose of 0.04 mg/kg SC or IV. High peripheral

vascular resistance and hypertension may be treated with α-adrenergic receptor blocking agents. Prazocin may be given at 1–2 mg PO every 8 h. Phentolamine may be given at 0.1 mg/kg IV as needed (Papich, 1990; Ooms and 2001).

Severe CNS stimulation may require treatment with more than one anticonvulsant. Though acepromazine and chlorpromazine are known to decrease the seizure threshold, they can be used to treat pseudoephedrine or ephedrine toxicosis, which induce seizures by a different mechanism (Means, 1999; Ooms and Khan, 2001). Acepromazine is given at a dose of 0.05–1.0 mg/kg IM, IV, or SC in dogs, starting with a low dose and adding more as needed. Chlorpromazine is given IM or IV at a dose of 0.5–1.0 mg/kg, starting with a low dose and increasing as needed. Phenobarbital may be given at a starting dose of 3 mg/kg to effect (Means, 1999; Means, 2005). Isofluorane anesthesia may be used for severe clinical signs. Use of diazepam or other benzodiazepines may be contraindicated because the dissociative effects of this drug class may exacerbate clinical signs of sympathomimetic amines (Means, 1999; Ooms and Khan, 2001; Means, 2005).

Fluid therapy and urinary acidification may promote excretion. Glucose is added to IV fluids to treat hypoglycemia. Overhydration must be avoided to prevent pulmonary edema of the hypertensive patient (Means, 1999, 2005). Urinary acidifiers enhance excretion of pseudoephedrine in humans and may be used in dogs. Acid–base status must be monitored closely when acidifiers are used. The dose for ascorbic acid is 20–30 mg/kg IM or IV every 8 h. Ammonium chloride is given 50 mg/kg PO every 6 h (Means, 2005).

Adverse clinical signs associated with decongestants may last for 24–72 h (Means, 2005). One dog with severe clinical signs after phenylpropanolamine ingestion recovered after 6 days of hospitalization (Crandell and Ware, 2005). Most animals respond to treatment. Clinical signs that have been associated with an unfavorable outcome include uncontrollable seizures, DIC, myoglobinuria, and head bobbing (Means, 2005). Ooms and Khan (2001) reported that 26 of 34 dogs recovered, usually within 10–48 h, with treatment for toxicosis after ingestion of a ma huang and guarana combination drug. The remaining 8 dogs died or were euthanized.

## Antihistamines

Antihistamines act by competitive inhibition of histamine at histamine receptors. Compounds referred to as antihistamines in this section are the $H_1$ histamine receptor inhibitors. $H_2$ receptor antagonists are also sold OTC and are covered later, with drugs affecting the gastrointestinal system. They will be referred to as $H_2$ antagonists.

Many antihistamines, including brompheniramine, chlorpheniramine, clemastine, diphenhydramine, loratidine, and triprolidine, are found in allergy, cold, and flu formulations. Others are used as antiemetics in drugs to treat motion sickness. Examples of these include dimenhydrinate and meclizine. Doxylamine is used as a sedative in sleep aids. Hydroxyzine is used by veterinarians to treat canine atopy (Tegzes *et al.*, 2002). Amitriptyline is a prescription tricyclic antidepressant.

There were 23,000 human antihistamine overdoses reported to poison control centers in 2002. Drugs that were implicated in these reports included diphenhydramine, brompheniramine, chlorpheniramine, doxylamine, hydroxyzine, carbinoxamine, promethazine, and meclizine (Nine and Rund, 2006). An incomplete list of antihistamines can be found in Table 23.3.

**TABLE 23.3 Antihistamines ($H_1$ histamine receptor inhibitors); see Gwaltney-Brant (2006) for more detailed information**

| First generation | Second generation |
|---|---|
| *Alkylamines* | *Piperadines* |
| Brompheniramine | Terfenadine |
| Chlorpheniramine | Astemizole |
| Dexbrompheniramine | Levocabastine |
| Dexchlorpheniramine | Loratidine |
| Dimethindene | *Piperazines* |
| Pheniramine | Cetirizine |
| Pyrrobutamine | |
| Triprolidine | **Third generation** |
| *Ethanolamines* | Desloratidine |
| Clemastine | Fexofenadine |
| Dimenhydrinate | Levocetirizine |
| Diphenhydramine | |

| Buclizine | |
| Chlorcyclizine | |
| Niaprazine | |
| *Tricyclics* | |
| Amitriptyline | |
| Promethazine | |

### *Toxicity*

Chlorpheniramine is the antihistamine most commonly associated with adverse effects in dogs (Papich, 1990; Gwaltney-Brant, 2006). The oral $LD_{50}$ for clemastine in dogs is 175 mg/kg (Gwaltney-Brant, 2006). The therapeutic dose for hydroxyzine is 2.2 mg/kg, and 111 mg/kg is reported as toxic in dogs (Tegzes *et al.*, 2002). Terfenidine, which is no longer sold in the United States, caused clinical signs of toxicosis in a dog at a dose of 6.6 mg/kg, but there is considerable individual difference in sensitivity to this drug (Otto and Greentree, 1994; Gwaltney-Brant, 2006). Electroencephalogram changes were noted in dogs dosed with 30 mg/kg. Clinical signs were noted in dogs given in 100 mg/kg/day for 2–3 weeks. Vomiting was a consistent finding in dogs dosed with 150 mg/kg (Otto and Greentree, 1994).

### *Pharmacokinetics*

Antihistamines are well absorbed by the monogastric gastrointestinal tract, but oral doses are poorly absorbed in ruminants (Adams, 2001; Gwaltney-Brant, 2005). The anticholinergic effects of antihistamines may slow absorption by delaying gastric emptying (Tegzes *et al.*, 2002; Gwaltney-Brant, 2005). Peak plasma concentrations usually occur within 2–4 h of ingestion and the onset of clinical effects tends to be 20–45 min after ingestion. Therapeutic effects may last from 3 to 12 h (Adams, 2001; Gwaltney-Brant, 2005). Antihistamines are highly protein bound (Gwaltney-Brant, 2005). First-generation antihistamines are able to freely cross the blood–brain barrier and are more likely to cause CNS effects than second-generation products, which do not normally enter the CNS (Table 23.3). Second-generation antihistamines may cross the blood–brain barrier if given at very high doses. Terfenidine is known to cross into the cerebrospinal fluid in overdose situations (Otto and Greentree, 1994).

Metabolism of antihistamines takes place predominantly in the liver (Gwaltney-Brant, 2005). Hydroxyzine is metabolized to the active product cetirizine, which does not cross the blood–brain barrier (Tegzes *et al.*, 2002). The elimination half-life of antihistamines is dependent on the individual compound. Most metabolites are excreted in the urine, though there is some biliary excretion of terfenadine (Otto and Greentree, 1994; Gwaltney-Brant, 2006). Antihistamines excreted into the bile may undergo enterohepatic recycling.

### *Mechanism of action*

Antihistamines act by competitive inhibition of histamine at $H_1$ receptors (Papich, 1990; Gwaltney-Brant, 2005). Binding is reversible, but may become irreversible or slow to dissociate at high doses, as with terfenadine (Otto and Greentree, 1994; Gwaltney-Brant, 2005).

$H_1$ receptors are found on mast cells in the skin, smooth muscle myocytes, capillary endothelium, and in the CNS. Histamine produces dermal itching and allergic responses in the skin (Gwaltney-Brant, 2005). Histamine causes contraction of smooth muscle in the bronchial tree and intestine (Adams, 2001; Gwaltney-Brant, 2005). Low doses of histamine produce a rapid onset of vascular dilation. Histamine causes a wheal-and-flair reaction due to increased vascular permeability (Gwaltney-Brant, 2005). Histamine in the CNS modulates sleep–wake cycles (Tegzes *et al.*, 2002).

Antahistamines block allergic response and reduce itching (Adams, 2001; Gwaltney-Brant, 2005). Antihistamines block smooth muscle contraction, reducing bronchoconstriction, and affecting vascular and uterine smooth muscle. Effects on intestinal smooth muscle may cause gastrointestinal disturbances (Adams, 2001). Antihistamines prevent increases in vascular permeability associated with histamine release. CNS effects produced by antihistamines include both sedation and excitement (Adams, 2001; Gwaltney-Brant, 2005).

Muscarinic stimulation is believed to be involved in motion-sickness-induced vomiting. The antimuscarinic actions of antihistamines decrease nausea and vomiting (Papich, 1990). Gastrointestinal motility is decreased, and there may be respiratory suppression (Tegzes *et al.*, 2002). Phenothiazine type antihistamines also block $\alpha$-adrenergic receptors (Gwaltney-Brant, 2005). Allergic reactions to antihistamines have been documented (Adams, 2001).

### *Clinical signs*

Clinical signs of antihistamine overdose are usually evident within half an hour of dosing. Signs of CNS depression may occur with therapeutic doses of first-generation antihistamines and include sedation, ataxia, and drowsiness (Papich, 1990; Adams, 2001; Gwaltney-Brant, 2005). More severe clinical signs such as profound depression, coma, and respiratory suppression incompatible with life have been described (Gwaltney-Brant, 2005). A dog with hydroxyzine toxicosis presented with tachycardia and weakness progressing to stupor, coma, loss of gag reflex, and apnea (Tegzes *et al.*, 2002).

Higher doses of antihistamines may have a stimulatory effect on the CNS, particularly in children and young animals. These effects are less commonly reported in adults (Otto and Greentree, 1994; Gwaltney-Brant, 2005). Overdosed individuals may appear to experience hallucinations, lack of coordination, disorientation, irritability, anxiety, aggression, seizures, and pyrexia.

Vomiting and diarrhea have been associated with first-generation antihistamines (Gwaltney-Brant, 2005). Anticholinergic effects include dry mucous membranes, fixed and dilated pupils, tachycardia and arrhythmia, and animals may be hypertensive or hypotensive (Adams,

2001; Gwaltney-Brant, 2005). Cardiac abnormalities were documented in humans and dogs that ingested terfenadine (Otto and Greentree, 1994; Gwaltney-Brant, 2005).

Diphenhydramine has been associated with 75 human fatalities in the literature. Cardiac arrhythmias are commonly reported and may include bradycardia, tachycardia, ventricular fibrillation, and asystole. Hyperexcitability, seizures, respiratory suppression, apnea, and cyanosis also contributed to deaths (Nine and Rund, 2006).

Animals may have allergic reactions to topical or oral antihistamines. A list of associated clinical signs would include dermatitis, pyrexia, and photosensitization (Gwaltney-Brant, 2005). Teratogenic effects have been detected in experimental animals treated with piperazine (Gwaltney-Brant, 2005).

Metabolic acidosis and electrolyte abnormalities may be documented based on serum chemistries of animals overdosed with antihistamines, but overall changes are nonspecific. Changes reported on postmortem examination also tend to be nonspecific. Rhabdomyolysis and associated renal lesions or DIC may be complications of antihistamine toxicosis (Gwaltney-Brant, 2005). Pulmonary congestion has been reported with diphenhydramine toxicosis in humans (Nine and Rund, 2006).

#### *Management*

Diagnosis of antihistamine toxicosis may be based on history and clinical signs. Laboratory testing of urine or plasma may be helpful to confirm exposure, but quantitation is unlikely to be of value (Gwaltney-Brant, 2005).

Emetics are appropriate to promote gastric emptying in asymptomatic animals that recently ingested large doses of antihistamines, but onset of clinical signs may be rapid (Papich, 1990; Gwaltney-Brant, 2005). Gastric lavage of the anesthetized, intubated animal is more appropriate in the treatment of symptomatic animals (Otto and Greentree, 1994). Activated charcoal and a cathartic are instilled after lavage or given to the stable patient. Multiple doses of activated charcoal may interrupt enterohepatic circulation (Otto and Greentree, 1994; Staley and Staley, 1995; Tegzes *et al.*, 2002; Gwaltney-Brant, 2005).

Drugs such as penicillin G and NSAIDs have been recommended to reduce protein binding and enhance excretion (Tegzes *et al.*, 2002). However, this may worsen clinical signs in the short term by making the antihistamine more bioavailable.

Serum chemistries should be assessed and monitored for hydration, electrolyte balance, acid–base status, and liver and kidney function. Animals with poor hepatic or renal function may have a decreased rate of antihistamine elimination (Gwaltney-Brant, 2005). Cardiac function, blood pressure, and body temperature should be monitored as well (Otto and Greentree, 1994; Gwaltney-Brant, 2005). Respiratory function should be closely monitored, as intubation may be required to support the comatose patient (Tegzes *et al.*, 2002; Gwaltney-Brant, 2005).

Fluid therapy is useful to maintain hydration and for cardiac support and diuresis (Staley and Staley, 1995; Tegzes *et al.*, 2002; Gwaltney-Brant, 2005). Imbalances in electrolytes and pH are corrected as needed. Animals rarely require treatment for hypotension and mild to moderate cardiac arrhythmias, which often respond to fluid therapy. Epinephrine should not be used to treat promethazine overdose. Promethazine inhibits adrenergic receptors and addition of epinephrine may lead to further decrease in blood pressure (Staley and Staley, 1995). Atropine should not be used, as it may potentiate the anticholinergic effects of antihistamines (Gwaltney-Brant, 2005).

Seizures may be treated cautiously with benzodiazepines or short-acting barbiturates (Otto and Greentree, 1994; Adams, 2001; Gwaltney-Brant, 2005). The depressive effects of antihistamines may be additive with the effects of sedatives, causing "rebound depression" (Gwaltney-Brant, 2005).

Though cholinergic signs may be present, treatment with physostigmine is contraindicated as it may potentiate cardiovascular dysfunction and seizures (Gwaltney-Brant, 2005).

Animals overdosed with antihistamines usually improve within 24 h, though signs sometimes persist for 3 days. Prognosis is dependent on the severity of signs and is guarded in animals presenting with seizures or coma (Gwaltney-Brant, 2005). Tegzes *et al.*, (2002) reported recovery of a comatose dog that had been overdosed with hydroxyzine, though the authors noted that 1 or 2 weeks of supportive care are required in such cases.

## DRUGS USED TO TREAT GASTROINTESTINAL SYMPTOMS

This classification includes antacids, laxatives, and antidiarrheal drugs.

### Antacids

$H_2$ histamine receptor inhibitors and mineral antacids are used to increase gastric pH and associated discomfort. Use of these products to aide in healing of gastroduodenal ulcers secondary to NSAID use was discussed noted in a previous section. Few adverse effects have been reported with these drugs.

#### *$H_2$ histamine receptor inhibitors*

$H_2$ histamine receptor inhibitors include burimamide, cimetidine, famotidine, metamide, nizatidine, and

ranitidine. Cimetidine may impair gastrointestinal absorption of some drugs and may prolong the effects of others by inhibiting their metabolism by microsomal enzymes (Boothe, 2001).

*Pharmacokinetics*

Cimetidine is rapidly absorbed and 70% of a given dose is bioavailable. Absorption may be slowed by the presence of food in the stomach. The mean absorption time for ranitidine was approximately 1 h and absorption was not impaired by the presence of food in the stomach. Ranitidine is 73% bioavailable in dogs and 27% available in horses after oral dosing. Famotidine is poorly absorbed and only 37% bioavailable. Nizatidine is rapidly and almost completely absorbed (Boothe, 2001b). $H_2$ receptor inhibitors are less lipid soluble than $H_1$ receptor inhibitors and are less likely to cross the blood–brain barrier well (Adams, 2001). Ranitidine is about 15% protein bound (Boothe, 2001b).

Cimetidine and ranitidine are metabolized predominantly in the liver. Seventy-three percent of an oral dose of ranitidine undergoes hepatic metabolism in people, compared to 40% in dogs. Cimetidine is mostly eliminated as the parent compound. Unchanged cimetidine, famotidine, and nizatidine are excreted in the urine. The plasma half-life for cimetidine is about an hour, but may be prolonged in individuals with renal or hepatic insufficiency. The elimination half-life of ranitidine is 2.5 h in humans and 4 h in beagles (Boothe, 2001b).

*Mechanism of action*

Histamine inhibitors block histamine receptors by competitive inhibition. $H_2$ receptor inhibitors act specifically at $H_2$ receptors. $H_2$ receptors are present in the enterochromaffin cells of the gastric mucosa and histamine stimulates acid secretion and, to a limited extent, pepsin secretion (Adams, 2001; Tegzes *et al.*, 2002). High doses of histamine produce a slow onset, prolonged vasodilatory response (Adams, 2001). $H_2$ receptor inhibitors decrease acid and pepsin secretion (Boothe, 2001b). They also block some of the cardiovascular effects of histamine. Famotidine is 9 times more potent as a $H_2$ receptor inhibitor than ranitidine, which is 5–12 times more potent than cimetidine. Famotidine also has the longest duration of clinical effects (Boothe, 2001b).

Cimetidine reduces hepatic blood flow by around 20% and inhibits microsomal cytochrome P450 enzymes, thus it may interfere with metabolism of other drugs (Boothe, 2001b).

*Clinical signs*

Minor side effects have been reported with cimetidine, but Krenzelock *et al*. (1987) reported that 79% of large ingestions in humans did not produce adverse effects. Signs that were reported included CNS depression and dizziness within 90 min of ingestion, slurred speech, mental confusion, xerostomia, epigastric pain, sinus tachycardia, and mydriasis. None of the signs were deemed life threatening (Krenzelock *et al*., 1987). When $H_2$ receptor inhibitor drugs are discontinued, “rebound gastric acid hypersecretion” may occur. This is more common with cimetidine than famotidine or nazitidine (Boothe, 2001b).

Idiosyncratic effects have been reported with $H_2$ receptor inhibitors. Idiosyncratic hepatitis has been reported in humans, and is often asymptomatic. The incidence of this response in people dosed with ranitidine is 1/100,000, it is 1/600,000 in patients on cimetidine, and rarely reported with famotidine (Jiménez-Sáenz *et al*., 2000). Idiosyncratic dermatosis has also been reported with famotidine (Scheinfeld *et al*., 2000). Muscle spasms of the face and neck have been reported in people given therapeutic doses of cimetidine (Peiris and Peckler, 2001). Thrombocytopenia has been associated with $H_2$ receptor inhibitors in people (Wade *et al*., 2002).

### Mineral antacids

A list of common active ingredients in mineral antacids can be found in Table 23.4. Products may contain more than one active ingredient (Papich, 1990; Boothe, 2001b). Sodium bicarbonate is present in baking soda and in effervescent antacid products. These products are common in many households, and may be accidentally ingested by pets or administered by pet owners (Papich, 1990). They are used in veterinary medicine to decrease gastric hyperacidity and treat peptic ulcers, uremic ulcers, reflux esophagitis, and rumen acidosis secondary to grain overload (Boothe, 2001b). Few adverse effects are associated with mineral antacids (Papich, 1990), but severe clinical signs have been reported due to sodium bicarbonate and calcium carbonate use in humans (Gonzalez and Hogg, 1981; Okada *et al*., 1996; Fitzgibbons and Snoey, 1999).

Sodium bicarbonate and calcium carbonate are absorbed after ingestion. Transcutaneous absorption of sodium

| Sodium bicarbonate |

bicarbonate across damaged skin may occur (Gonzalez and Hogg, 1981). Some of the magnesium in magnesium salt-containing antacids is absorbed, and hypermagnesemia has been reported with repeated dosing (Boothe, 2001b).

Mineral antacids increase gastric pH. Rebound acid secretion may occur when dosing is discontinued. Some mineral antacids inactivate pepsin and some bind bile salts. Magnesium-containing salts have a laxative effect, and aluminum-containing salts have a constipating effect, thus these active ingredients are often used in combination. Aluminum complexes phosphate in the intestine and aluminum hydroxide has been used to decrease phosphate absorption in patients with renal disease (Boothe, 2001b).

Carbon dioxide is produced rapidly when sodium bicarbonate is introduced to an acid, and this reaction may cause gastric distension (Boothe, 2001b). Metabolic acidosis and secondary hypokalemia have been reported in humans after sodium bicarbonate ingestion (Okada *et al.*, 1996). Renal dysfunction may predispose to the adverse effects associated with bicarbonate ingestion. Clinical signs that have been documented in human patients with bicarbonate overdose include weakness, fatigue, dizziness, syncope, seizures, muscle pain, tachycardia and arrhythmia, volume depletion, and hypoxia (Fitzgibbons and Snoey, 1999). Patients have systemic alkalosis, hypokalemia, and hypernatremia (Gonzalez and Hogg, 1981; Papich, 1990; Okada *et al.*, 1996). Treatment consists of fluid and electrolyte therapy, and produces rapid resolution of symptoms. Electrolyte and pH abnormalities resolve over a few days (Gonzalez and Hogg, 1981; Okada *et al.*, 1996).

Adverse effects attributed to calcium carbonate in humans include nausea and vomiting, dehydration, and progressive renal insufficiency. Chronic use of calcium carbonate antacids may produce metabolic acidosis, hypercalcemia, hypophosphatemia, and calciuria with urolithiasis and metastatic calcification (Fitzgibbons and Snoey, 1999; Boothe, 2001b).

Antacids may interfere with absorption of other drugs, including digoxin, prednisolone, ranitidine, and cimetidine (Papich, 1990).

## Laxatives, cathartics, and enemas

Drugs in this category may be designated as bulk forming laxatives, lubricant laxatives, irritant laxatives, hyperosmotic cathartics, and enemas.

### *Bulk forming laxatives*

Nonabsorbable polysaccharide cellulose derivatives are used as bulk forming laxatives (Papich, 1990). Natural sources include psyllium or plantago seed, wheat bran, and fruits such as prunes. Synthetic forms include methylcellulose and carboxymethylcellulose. These products act by absorbing water in the gastrointestinal tract and swelling the softened fecal mass. This causes intestinal distension and reflex peristaltic contractions. Intestinal bacteria act on cellulose and hemicellulose, and produce volatile fatty acids, enhancing the osmotic effect. Fluid feces and tympany may result (Boothe, 2001b). No serious adverse effects have been reported in companion animals, though these products may cause fluid and electrolyte loss secondary to diarrhea. Papich (1990) suggested that subsequent dehydration may lead to intestinal impaction.

Animals treated with bulk forming laxatives should have fresh water available. If diarrhea occurs, monitor hydration and electrolyte status and correct as needed.

### *Lubricant laxatives*

Lubricant laxatives, including mineral oil and white petrolatum, are hydrocarbon mixtures derived from petroleum. Mineral oil is frequently used in large animals and white petrolatum products are often used to treat trichobezoars in cats (Papich, 1990). These large hydrocarbons are minimally absorbed and act by coating feces with a film that entraps moisture and lubricates passage. Hydrocarbon laxatives reduce absorption of fat-soluble vitamins and possibly other nutrients, thus chronic use may be associated with deficiencies. Intestinal irritability may decrease over time with repeated use, leading to chronic constipation. The small amount of absorbed hydrocarbons may provide a nidus for granuloma formation in the intestinal mucosa, mesenteric lymph nodes, or liver (Papich, 1990; Boothe, 2001b). Adverse effects, however, are rarely reported with lubricant laxatives (Papich, 1990).

### *Irritant laxatives*

This group accounts for most of the common OTC laxatives. Table 23.5 lists common types of irritant laxative. Phenophthalein laxatives may be chocolate flavored, increasing palatability, but are only effective in primates and swine (Papich, 1990; Boothe, 2001b). Vegetable oil

**TABLE 23.5 Irritant cathartics**

| |
|---|
| *Diphenylmethanes* |
| Phenophthalein |
| Biscodyl |
| *Vegetable oils* |
| Castor oil |
| Raw linseed oil |
| Olive oil |
| *Anthraquinones* |
| Danthron |
| Cascara sagrada |
| Senna |
| Aloin |

products contain irritant fatty acids such as ricinoleic acid in castor oil, linoleates in linseed oil, and oliveates in olive oil. Common anthraquinone type cathartics are derived from plants: cascara sagrada from *Rhamnus* spp., senna from *Cassia* spp., and aloins from *Aloe* spp. Danthron (1,8-dihydroxyanthroquinone) is synthetic, but is considered the prototype for the anthraquinone laxative group.

Five percent of an oral dose of bisacodyl is absorbed. There is some absorption of anthraquinone glycosides, and delayed transit through the small intestine decreases effectiveness. Anthraquinones may be secreted in the milk, causing clinical effects in the nursing young (Boothe, 2001b).

As suggested by the term irritant laxative, these compounds cause contact irritation of gastrointestinal mucosa and increase fluid secretion into the lumen. Stimulation of intramural nerve plexi promotes intestinal transit (Papich, 1990; Boothe, 2001b).

Diarrhea occurs 6–8 h after diphenylmethane cathartics are administered and may be severe if large doses are given (Boothe, 2001b). Pink discoloration of alkaline urine may be seen with phenolphthalein. Acidic urine will turn pink with addition of sodium hydroxide or sodium bicarbonate (Papich, 1990).

Vegetable oil laxatives are hydrolyzed by lipase in the small intestine and form sodium and potassium salts which act as soaps, producing irritation. Ricinoleic acid is the most potent of these compounds, and initiates rapid and complete colonic emptying (Papich, 1990; Boothe, 2001b). This clinical effect is seen 4–8 h after administration of castor oil in small animals, and 12–18 h post dosing in large animals. Animals treated with castor oil should be fed moist, bulky material afterward.

Anthraquinones are hydrolyzed by bacteria in the large intestine to emodins which stimulate the myenteric plexus. Anthraquinones produce catharsis after 6–12 h in small animals and 12–36 h in large animals. Catharsis may be accompanied by reduced hydration and electrolyte loss. Abdominal pain or colic may produced by large doses (Papich, 1990; Boothe, 2001b). Changes in urine color are reported with anthraquinones. With chronic use of these laxatives, the mesenteric plexus will degenerate causing a loss in intestinal motility (Boothe, 2001b).

Animals treated with irritant cathartics should be monitored for hydration and electrolyte status with correction as needed. Some irritant cathartics may increase PG synthesis, and NSAIDs would minimize this effect (Papich, 1990).

### *Hyperosmotic cathartics*

Magnesium sulfate, or Epsom salt, is a common osmotic cathartic and is used in 6% isotonic solution. Other magnesium-containing cathartics include magnesium hydroxide (milk of magnesia), magnesium oxide, and magnesium citrate. Sodium sulfate (Glauber's salt), sodium phosphate, potassium sodium tartrate, and sodium tartrate (Rochelle salt) are used as cathartics and ingestion of large quantities of sodium chloride will produce catharsis. The sugar alcohols, mannitol and sorbitol, and synthetic disaccharides such as lactulose are also used as cathartics (Boothe, 2001b).

Osmotic cathartic use should be avoided in dehydrated animals, and water should be freely available. Other contraindications for use may include congestive heart failure, gastrointestinal stasis, and hepatic or renal impairment (Henninger and Horst, 1997; Ezri *et al.*, 2006). Hyperosmotic cathartics draw water into the intestinal tract via osmosis (Papich, 1990; Boothe, 2001b; Ezri *et al.*, 2006). Intestinal distension promotes motility. Effects of cathartics are usually evident 3–12 h after dosing in monogastrics and within 18 h in ruminants (Boothe, 2001b).

There is minimal slow absorption of most cathartics, but up to 20% of the magnesium in a dose of magnesium sulfate is absorbed in the small intestine (Henninger and Horst, 1997; Boothe, 2001b). Renal failure may enhance systemic magnesium accumulation, leading to hypermagnesemia (Papich, 1990; Boothe, 2001b). Administration of magnesium sulfate with dioctyl sodium sulfosuccinate in horses may lead to increased magnesium absorption due to mucosal damage (Henninger and Horst, 1997). Magnesium ions promote the release of cholecystokinin which enhances peristalsis (Boothe, 2001b). Systemic effects of magnesium include inhibition of calcium ion release at neuromuscular junctions, inhibition of acetylcholine release, decreased sensitivity of motor endplates, and decreased excitability of myocyte membranes, leading to paralysis (Henninger and Horst, 1997). Clinical signs of hypermagnesia secondary to magnesium sulfate administration in the horse occurred 1–6 h post administration and included perspiration, progressive tremors, recumbence, severe tachycardia, tachypnea, pale mucous membranes, prolonged capillary refill time, flaccid paralysis of the head and neck, and loss of flexor and perineal reflexes. Horses remained alert. Similar signs are reported in humans, but bradycardia is more common than tachycardia in people. Clinical signs of hypermagnesemia in humans were associated with serum magnesium concentrations greater than 3 mg/dl. Paralysis of respiratory muscles and cardiac arrest occurred at concentrations above 18 mg/dl. Severe clinical signs in horses were associated with serum magnesium levels of 14.7 and 15.8 mg/dl (Henninger and Horst, 1997).

Absorbed phosphate from phosphate-containing cathartics may deplete intracellular potassium ions and induce hypokalemia. Clinical signs reported in humans dosed with sodium phosphate include coma, hypovolemia, hypocalcemia and tetany, acute renal failure, and death. Increased serum phosphate and sodium, and decreased potassium, magnesium, and calcium, as well as lactic acidemia were reported in people given phosphate salts (Ezri *et al.*, 2006).

Lactulose reaches the colon largely intact and is degraded into lactic acid and acetic acid by large intestinal microflora. Gas may be generated, causing tympany. The associated decrease in pH has been used for ion trapping of ammonium to prevent hepatic encephalopathy in animals with liver failure (Boothe, 2001b).

Dehydration and electrolyte imbalances are the most common changes associated with cathartics. Management is aimed at correcting these imbalances. Calcium is used to treat hypermagnesemia. Calcium ions displace magnesium ions from cell membranes. Response to therapy is usually rapid, but repeated dosing with calcium gluconate may be needed. Diuresis with IV fluids and furosemide may be used to promote renal excretion. Henninger and Horst (1997) reported that horses treated for hypermagnesemia had serum magnesium concentrations within reference ranges the next day. Electrolyte changes in asymptomatic patients given oral sodium phosphate for pre-surgical catharsis returned to normal within 24 h (Ezri *et al.*, 2006).

### *Enemas*

An enema is a material given intrarectally to induce defecation. Commonly used enemas include soft anionic soap in water, isotonic or hypertonic sodium chloride, sorbitol, glycerol, sodium lauryl sulfate, sulfoacetate, mineral oil, olive oil, and phosphate salts.

Toxicosis has been reported in people and small animals administered hypertonic sodium phosphate solutions, or fleet enemas. Debilitated cats are commonly affected (Papich, 1990). Predisposing factors may include administration of a full-strength fleet enema (intended for human use) to a small animal, dehydration, preexisting electrolyte abnormalities, renal or hepatic dysfunction, colonic dilation, and colonic ulceration (Jorgensen *et al.*, 1985; Papich, 1990; Roder, 2005b). A 60 ml hypertonic phosphate enema may cause toxicosis in a cat (Roder, 2005b).

Sodium and phosphate are absorbed in the colon, and absorption may be increased with disruption of the mucosa or in animals with chronic constipation (Jorgensen *et al.*, 1985). Uptake of phosphate promotes cellular uptake of calcium and phosphate may directly bind serum calcium, both contributing to hypocalcemia. Adverse effects associated with sodium phosphate enemas usually occur within an hour of dosing (Jorgensen *et al.*, 1985; Papich, 1990). Vomiting and bloody diarrhea may be seen. Nervous signs that have been documented include depression, ataxia, anxiety, neuromuscular irritability, and convulsions. Dehydration, weak pulse, tachycardia, hypothermia, shock, and death have also been reported (Jorgensen *et al.*, 1985; Papich, 1990). Serum chemistry in these patients often reveals hyperphosphatemia, hypernatremia, hypocalcemia, metabolic acidosis, and hyperglycemia. Hyperkalemia and hypokalemia have both been documented (Jorgensen *et al.*, 1985).

Intensive fluid therapy is required in acute sodium phosphate enema overdose situations. The purpose is to correct dehydration, electrolyte imbalances, acid–base imbalances, and hypoglycemia, and treat circulatory shock. Isotonic saline solution may increase renal calcium loss and thus should be avoided. Saline solutions containing 0.45% sodium chloride and 2.5% dextrose, or 2.5–5.0% dextrose solutions have been recommended for hypoglycemic patients (Jorgensen *et al.*, 1985; Papich, 1990). Lactated ringers solution may be used in hyperglycemic patients. Fluid therapy may be needed for 4 days. Jorgensen *et al.*, (1985) suggested instillation of aluminum carbonate or aluminum hydroxide to bind phosphate in the intestine. Animals should be treated for hypothermia if needed. Prophylactic antibiotics are given for compromise of the colonic mucosa. Intoxicated cats showed improvement within 6 h of initiation of therapy, and electrolyte imbalances resolved within 2 days (Jorgensen *et al.*, 1985).

## Antidiarrheal drugs

Active ingredients in products used to treat diarrhea include bismuth subsalicylate, kaolin–pectin, and opioid receptor agonists. Most of the toxic effects associated with bismuth subsalicylate are due to the salicylate component, therefore this formulation is discussed in more detail with aspirin and salicylates. Bismuth is believed to adsorb bacterial endotoxin and may have a direct antimicrobial effect (Papich *et al.*, 1987).

Kaolin and pectin were previously the active ingredients in the popular OTC product Kaopectate®, but bismuth subsalicylate is now used. Kaolin is hydrated aluminum silicate and acts as an adsorbent. Pectin is a carbohydrate extracted from citrus fruit that acts as an adsorbed and intestinal protectant. Toxicosis attributed to kaolin–pectin preparations has not been observed, though these products may decrease absorption of other drugs.

### *Opioid receptor agonists*

The OTC drug Imodium® and the prescription drug Lomotil® contain the opioid receptor agonists loperamide and diphenoxylate, respectively. Loperamide is sold in 2 mg capsules and liquids at a concentration of 0.20 mg/ml. The effective dose for loperamide is 0.08 ml/kg PO every 12 h in small dogs and cats. These products are poorly absorbed. They function to decrease gastrointestinal secretion and motility. Side effects may include constipation, abdominal pain, vomiting, and drowsiness, but severe toxicosis is unlikely. Management consists of monitoring and supportive and symptomatic care. Activated charcoal may be given to decrease intestinal absorption if large doses were ingested. The opioid antagonist naloxone may be used to manage severe clinical signs, but this is unlikely to be necessary. Naloxone has a short half-life, requiring repeated dosing as needed (Papich, 1990).

## TOPICAL DRUGS

Toxicosis secondary to topical preparations may occur through dermal absorption or ingestion. Cats in particular are fastidious groomers and any product that is used *on* a cat may end up *in* the cat for this reason. Animals, dogs in particular, may chew through a tube containing a topical drug (Papich, 1990).

Like other OTC drugs, topical products frequently contain more than one active ingredient. Antibiotic preparations may contain bacitracin, neomycin, and polymyxin. Though rare topical hypersensitivities have been reported, these antimicrobials are poorly absorbed from the normal gastrointestinal tract, limiting their systemic effects (Papich, 1990). However, if large quantities are ingested, damage may occur to the resident gastrointestinal microflora leading to diarrhea and discomfort. Use of these products in hamsters or guinea pigs, which are predisposed to develop antibiotic-induced enterocolitis, should probably be avoided.

Benzoyle peroxide is present in some topical antiseptics and acne medications. It acts by releasing hydrogen peroxide, which has antibacterial and keratinolytic effects and promotes epithelial cell turnover. Hyperemia and blistering have been reported with overuse of products containing benzoyle peroxide. Ingestion may lead to intragastrointestinal gas production and distension. Emetics are contraindicated if this should happen. Symptomatic treatment includes gastric decompression using a stomach tube (Papich, 1990).

CHAPTER

# 24

# Toxicity of drugs of abuse

*Karyn Bischoff*

## INTRODUCTION

Potential for exposure to illegal drugs may exist for many companion animals, horses, and even livestock on occasion; 46% of Americans have used illegal drugs in one form or another (Compton *et al.*, 2005). The illegal drug trade in the United States peaked in the late 1970s, declined in the 1980s and early 1990s, and increased again through the mid- to late 1990s to stabilize in recent years (Compton *et al.*, 2005).

Marijuana is one of the most prevalent recreational drugs in the world after legal substances ethanol and nicotine (Janczyk *et al.*, 2004; Compton *et al.*, 2005; Johnson *et al.*, 2005; Vitale and van de Mheen, 2005). Cocaine may be second in popularity among illegal substances in the United States and parts of Europe (Kisseberth and Trammel, 1990; Dumonceaux, 1995; Queiroz-Neto *et al.*, 2002; Vitale and van de Mheen, 2005). Since the 1980s, the term "club drugs" has come into use, representing drugs frequently found at nightclubs and all-night "rave" parties. Club drugs are a continuing trend (Smith *et al.*, 2002; Banken, 2004). Many are stimulants, though depressants may be used to counter the effects of the stimulants or given secretly to sedate a victim for the purpose of theft or assault. Hallucinogens are also used. Some of the most common club drugs include ketamine, 3,4-methylenedioxymethamphetamine (MDMA) commonly called "ecstasy," flunitrazepam (Rohypnol®), the "date rape drug," and $\gamma$-hydroxybutanoic acid (GHB).

### Illicit drugs and small animals
